Foreword

Periodically in the evolution of an important branch of clinical medicine there develops a critical need for a textbook which combines with the clinical aspects of disease syndromes an in-depth review of the sciences basic to the disorders discussed, as well as a carefully selected but comprehensive review of pertinent literature. LABHART's *Clinical Endocrinology* revised and translated into English provides for this need in the field of endocrinology in an exemplary manner.

Prof. LABHART has selected his individual authors with great care, and they in turn have provided authoritative monographs. An interesting, useful and informative introduction to each chapter is provided by a tabulation of the dates of important or significant contributions to the field. The chapter subdivisions present in great detail a wide variety of subjects such as embryology, anatomy, biochemistry, physiology, individual hormones and their analogues, biosynthesis, metabolism and regulation of hormone release as well as a full discussion of the clinicopathological correlations. The bibliography is unusually extensive and will provide an important source book for all investigators and students in the field.

It is a tremendous accomplishment that a work of this magnitude, so broad and so extensive, could be brought up to date in its English translation with such a relatively short lag period between the author's revision and the date of publication. This volume will fill an important place in medical libraries as well as providing experts in the field with authoritative source material. Furthermore, in these days of shortened medical school curriculum in the basic sciences the sections in the book concerned with such areas as anatomy, biochemistry and physiology will provide students with an excellent background for their clinical responsibilities.

The translation of a textbook of this magnitude presents a formidable undertaking. Prof. LABHART and his co-authors are to be congratulated for making available to the English literature this updated version of their classic.

Boston, April 1974 GEORGE W. THORN

Preface to the 2nd German Edition

There has been such rapid development in the background knowledge basic to clinical endocrinology that for the second edition everything except the clinical descriptions had to be completely rewritten. Two of the authors involved in the first edition, Prof. K. G. OBER and Prof. T. ZANDER, were unable to contribute to this edition due to new commitments. Our gratitude is due to Prof. W. E. SCHREINER and Dr. P. J. KELLER, under Prof. E. HELD at the Zurich School of obstetrics and gynecology, who took over and rewrote the chapters on ovary and pregnancy.

Despite the enormous increase in the content, it has been possible to keep the number of pages about the same as in the first edition and avoid the necessity of a two-volume work by using a larger format and omitting many illustrations we had planned to include. We had intended to reproduce a large number of electron micrographs but have had to content ourselves with citing the original papers.

Where it was only possible to refer very briefly to newly discovered facts the original papers are cited. They are quoted in the text by first author and year of publication only, to save space. The lists of references for each chapter have again been divided up into subsections, and they also contain publications not referred to in the text. They can thus be used independently. The publications in the list are a personal selection; preference is given to the most recent reviews and we lay no claim to completeness or citation of first descriptions. Early papers of outstanding significance have been retained in the lists of references alongside the most recent publications on the same subjects.

Almost 20 years ago, when I asked my clinical teacher Prof. SCHÜPBACH, whether he thought I might venture to write a textbook on the total field of endocrinology, he thought for some time before answering in the affirmative, and followed up this reply with the observation that the second edition might be successful. It is not for us to judge whether this has been borne out. However, if we succeed in providing endocrinologists and other specialists with a useful survey of the whole field of clinical endocrinology and the nonclinical disciplines essential to its comprehension before it is broken down into subspecialties, we shall feel we have attained the goal of the second edition.

We are much indebted to Springer-Verlag, to Dr. H. GÖTZE for his kindly advice and unfailing help in the work of planning, and to Mrs. T. DEIGMÖLLER for her tireless help in the meticulous work involved in the production of the second edition. We should like to thank our secretaries, Mrs. WÄCHTER-BRANDENBERG, Miss L. WAGNER, Miss M. SCHITTENHELM, and Miss M. WALDVOGEL, and the librarians Miss F. BELART and Miss S. DOMEISEN for their help, our scientific assistant Dr. K. BAUMANN for the compilation of the subject index, Dr. J. ZAPF and Dr. U. KELLER for correction of the proofs, and numerous of our colleagues for constructive criticism and advice.

Zurich, April 1971 A. LABHART

Preface to the 1st German Edition

There has been substantial progress in endocrinology over the past 20 years, and the specialty's position within medicine as a whole has changed radically.

The science referred to as endocrinology 20 years ago was concerned predominantly with description and morphology; with the realization that hormones were involved in the regulation of metabolism it has become an integral element of our knowledge of metabolic disorders, and as a result of the discovery of the effects of adrenal hormones on inflammation and the involvement of the pituitary-adrenal axis in resistance mechanisms there is now hardly a single field of medicine that is not bound up with the problems of endocrinology.

During the war years and the period immediately after the war, progress was particularly rapid. Biochemically oriented medicine was undeniably more advanced in the United States than in Europe, where the tradition of medicine based on morphology and bedside observation prevailed; we have attempted to achieve a blend of both these elements in this book.

We were fortunate to have the opportunity of observing American methods of clinical medicine and research during extended stages of study at clinical endocrinology centers in the United States Peter Bent Brigham Hospital, Boston (G. W. THORN), Johns Hopkins Hospital, Baltimore (L. WILKINS), Mayo Clinic, Rochester (R. M. WILDER), University of California medical school (H. D. MOON), and we have kept in close contact and followed developments in America ever since.

Four of the authors (COURVOISIER, HEDINGER, LABHART, and WERNLY) are former students of the late Prof. SCHÜPBACH (Berne), who always kept up to date with the latest developments in endocrinology and had the ability to introduce them into bedside medicine. It was he who first aroused our interest in endocrinology. He took a lively interest in the progress of this book right up to his death.

The idea of writing a textbook on endocrinology was initially proposed by Prof. P. H. ROSSIER. His medical clinic in Zurich, as a site of both day-to-day medical activity and experimental medicine, was well suited to the blend of theory and practice we have tried to achieve. We have tried to adopt the same functional approach to medicine as Prof. ROSSIER. We would not have ventured to embark on this work without his initiative and encouragement.

The kindness of Prof. G. FRANCONI and Prof. C. KAUFMANN made it possible to include pediatric and gynecological endocrinology, without which the work would have been incomplete. We are indebted to Prof. UEHLINGER of Zurich for his valued and unstinting advice and his untiring help in the selection and acquisition of the illustrations, and no less to Springer-Verlag, Heidelberg, for their unfailing help in the planning and production of our textbook.

Zurich, December 1956 A. LABHART

I. General Aspects of Endocrinology

HANS BÜRGI

A. Introduction

Hormones are chemical messengers which are dissolved in extracellular fluid and carry information between cells*. Within any single cell, information is transmitted through chemical compounds in a similar manner. Such intracellular messengers include enzymes, allosteric ligands and proteins, certain ribonucleic acids and deoxyribonucleic acids. It is noteworthy that deoxyribonucleic acids can also store information, a feature which is lacking in the endocrine system. The function of hormones might be compared to that of nerves, which also convey information from one cell to another.

Intercellular communication cannot always be definitely assigned to either the neural or the hormonal pathway. There are certain cases where the secretion of hormones is influenced by neural stimuli, and other cases where hormones can become direct transmitters of neural information, e.g. norepinephrine, which is secreted at the nerve endings of the sympathetic nervous system. The neurosecretion of the supraoptic and paraventricular nuclei of the diencephalon is a mechanism having characteristics of both neural and hormonal communication. In this case, information flows along the axis cylinder of a nerve cell in the form of discontinuous signals. These signals are not

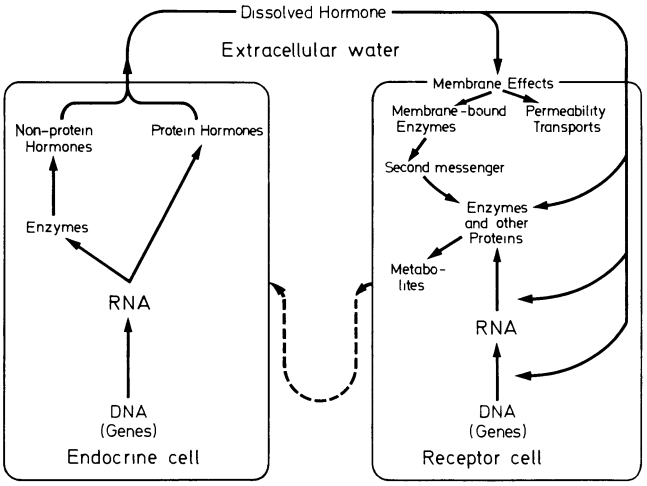

Fig. 1. Schematic representation of the flow of information within an endocrine cell and from there to the receptor cell. The dashes indicate a feedback loop. Abbreviations: RNA: ribonucleic acid; DNA: deoxyribonucleic acid

In contrast to the endocrine system but like the intracellular genetic system, the nervous system is also capable of storing information. variations in electrical potential but rather hormone-containing particles which are converted to soluble hormones in the posterior lobe of the pituitary gland. Hormone molecules are dissolved in the extracellular fluid and travel from their endocrine cell of origin to their appropriate receptor or target cells. Usually they are carried by the bloodstream and quickly reach their target cells, which may be quite

* This definition is based on physiological considerations and does not include hormones or their pharmacological derivatives as used for therapeutic or diagnostic purposes. A similar "operational" definition of hormones has recently been exhaustively discussed by VALLOTTON (1969).

distant. Hormones which diffuse only locally in the interstitial fluid surrounding an endocrine cell are called *tissue hormones*.

Hormone molecules transfer their information through contact with a receptor at the target cell. They thereby regulate certain chemical or physical processes within the receptor cell which finally result in known biochemical and clinically evident hormonal actions. In many cases the information contained in the hormone is reconverted at the cell membrane into an intracellular second messenger which in turn controls a process within the cell. In this manner information issued by the endocrine cell eventually reaches its destination. However, the flow of information in the organism does not cease at this point. Processes may be triggered in the target cell which lead to the formation of feedback loops. Under the influence of a hormone a receptor cell may release greater or smaller amounts of a chemical compound (e.g. a metabolite or another hormone) into the extracellular fluid, hereby informing the original endocrine cell that it has received and executed the instruction. Frequently, in a negative feedback, this will inhibit the endocrine cell from issuing the same information, i.e. from secreting more hormone. Fig. 1 shows a simplified representation of the flow of information from the endocrine cell to its receptor and back to the endocrine cell of origin. The individual steps in the transfer of information by hormones will now be discussed in detail and illustrated by typical examples.

B. Endocrine Genetics

Hormones are of great interest to the geneticist primarily because certain diseases are known to be caused by inherited deficiencies of specific hormones. Examples among the protein and peptide hormones are the inherited deficiencies of antidiuretic hormone and of growth hormone. Whether diabetes mellitus is due to an inherited disorder of insulin biosynthesis is still controversial. In addition, several endocrine disorders are caused by an inherited deficiency of the enzymes necessary for the biosynthesis of non-protein hormones. Examples are the various adrenogenital syndromes and certain forms of congenital hypothyroidism. Inherited failure of the target organ to respond to its corresponding hormone is the cause of pseudohypoparathyroidism and renal diabetes insipidus.

Patients with the syndrome of multiple endocrine adenomata suffer from an inherited tendency to develop tumors in various endocrine glands. Certain disorders of the thyroid gland, such as thyrotoxicosis, Hashimoto's thryoiditis, and primary myxedema, all of which appear to be associated with autoimmune processes, show a familial incidence without clear-cut genetic transmission.

Other endocrine diseases, for example, Turner's syndrome and Klinefelter's syndrome, are due to chromosomal disorders. These syndromes have provided important information regarding the function of sex chromosomes.

It may be of interest to the biochemically oriented geneticist to know that hormones were among the first proteins to have their amino acid sequences fully elucidated. Surprisingly, certain hormones with very different actions were found to be chemically closely related. Thus, large parts of the ACTH molecule are identical to the α-MSH molecule and a whole subunit of the TSH molecule is identical with a subunit of the LH molecule. Such close similarity between two proteins is probably the end result of gene duplication, an important mechanism by which new proteins are acquired in the course of evolution.

C. Biosynthesis of Hormones

Research on the biosynthesis of protein hormones has long been hampered by the lack of suitable isolated tissue preparations and, in particular, of corresponding cell-free systems. However, one may assume that protein hormones are synthesized at the ribosomes according to the "classic" concepts of molecular biochemistry. Insulin is the protein hormone whose biosynthesis has been most fully studied. The linkage of the two peptide chains of insulin by two disulfide bridges represents a particular biochemical problem. The earlier view that the two protein chains were separately synthesized and subsequently joined by the disulfide bridges no longer seems tenable. The investigations of STEINER (1967) in both man and rat demonstrated a single-chained insulin precursor – proinsulin – containing both the *A* and the *B* chains of insulin. The amino acid sequence of proinsulin has been worked out recently by CHANCE (1968). The two-chained insulin molecule arises through enzymatic removal of a peptide, the connecting or *C*-peptide, from the proinsulin molecule. The mechanism suggested by STEINER and CHANCE for the biosynthesis of insulin is shown in Fig. 2. Whether analogous "prohormones" also exist for other protein hormones remains to be investigated. Strictly speaking, thyroglobulin could be considered the prohormone of thyroxine, since thyroxine is an

amino acid which is synthesized as a component of the large protein thyroglobulin. Hormone secretion involves the splitting off of thyroxine from thyroglobulin by proteolysis. It is not known whether the low molecular weight peptide hormones of the posterior pituitary lobe are

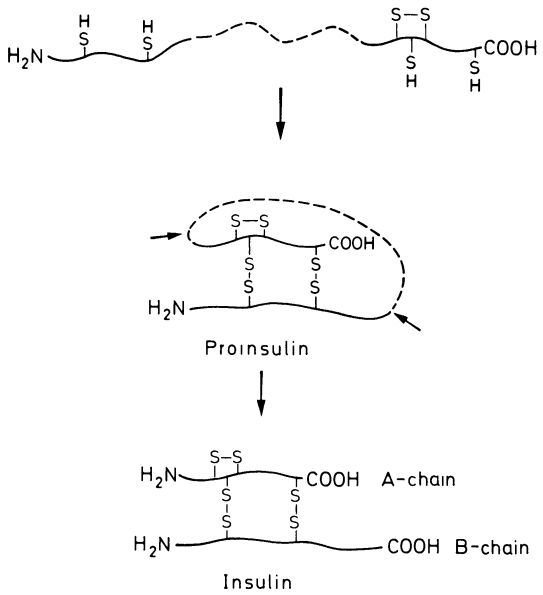

Fig. 2. Biosynthesis of insulin according to D. F. STEINER (1967). The dashed portion of pro-insulin, the so-called connecting peptide, is split off enzymatically at the points indicated by arrows

also synthesized via a prohormone at the ribosomes. It is theoretically conceivable that, like certain bacterial peptides, they are synthesized via an enzymatic non-ribosomal pathway (MACH, 1963), or they may be split off from larger prohormone molecules. The biosynthetic mechanisms for the nonprotein hormones (steroids, catecholamines) have been fully elucidated and will be discussed in the appropriate sections.

D. Storage and Release of Hormones

Hormones of the pancreatic islets, anterior and posterior pituitary gland, adrenal medulla, and thyroid gland are not only synthesized but may also be stored in considerable amounts within the endocrine organ. In contrast, steroid hormones of the adrenal cortex and gonads are not stored in any significant amount. Granules surrounded by membranes can be detected in most of the endocrine cells which do store hormones by light and electron microscopy. There is good evidence, sometimes indirect, that the granules contain stored hormone. Catecholamines can be chemically identified in the granules of the adrenal medulla (WURTMAN, 1965), and insulin has been demonstrated by immunofluorescence in the *B*-cell granules of the pancreatic islets. Few data are available on the physicochemical state of stored hormones. Adrenaline and ATP are found in a fixed molar ratio of 4 : 1 in the granules of the adrenal medulla (WURTMAN, 1965). However, the nature of a possible chemical bond between these two substances is not known. Thyroid hormones are stored in an unusual manner, namely extracellularly in the colloid as components of thyroglobulin. Thyroxine and triiodothyronine are probably bound by peptide bonds to this large glycoprotein molecule.

Release implies the expulsion of the hormone from its endocrine cell into the extracellular fluid. We have at present only limited information about the complex process by which hormones, which are often poorly fat-soluble, are transferred through the lipid-rich cell membrane. LACY (1967) was able to show by electron

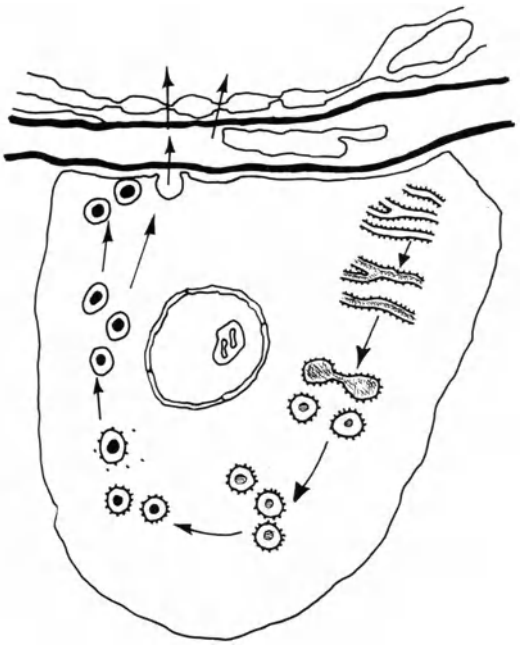

Fig. 3. Biosynthesis and release of insulin. Hormone synthesis begins in the endoplasmic reticulum. The hormone precursor, which is at first still amorphous and biologically inactive, is surrounded by a membrane and is converted into crystalline insulin or pro-insulin. The granular content is forced by emeiocytosis into the interstitial fluid where insulin is dissolved. Finally, the dissolved insulin diffuses into the capillaries. (From P. E. LACY, 1967)

microscopy that insulin granules migrate from the center of the pancreatic *B*-islet cells toward the periphery in the course of insulin secretion (Fig. 3). The granular membrane then fuses with the cell membrane and the granular content is ejected into the extracellular fluid by a process

termed emeiocytosis. According to recent investigations, the granules in the cell move along microtubular structures which may be surrounded by contractile filaments (LACY, 1968). There is now good evidence that adenosine 3′,5′-monophosphate (cyclic AMP) is involved in the mechanism for the release of insulin (MALAISSE, 1967; LAMBERT, 1967). The secretory granules of the anterior pituitary have recently been isolated by differential centrifugation and found to be rich in a protein kinase which, under certain conditions, is dependent upon cyclic AMP and phosphorylates structural proteins of the granule (LABRIE, 1971). This again suggests that cyclic AMP has a role in hormone release.

The process of hormone release must occupy a central position in the transfer of information by hormones, as underscored by the following reasoning: Most hormones have a fixed peripheral disposal rate, or half-life, once they have left the endocrine cell. Therefore, a given hormone concentration in the extracellular fluid which is crucial for the information to be conveyed can only be achieved and maintained by adjusting the rate of hormone release. Consequently, hormone release must be a delicately controlled process.

E. Hormone Transport

As stated initially, hormone molecules travel in the extracellular fluid from their endocrine cell of origin to their receptor cell. In most cases, hormones diffuse from the interstitial fluid surrounding the endocrine cell into the blood, which assures rapid transport to the receptor cell. Tissue hormones are an exception. They diffuse only locally in the interstitial fluid and thus reach only neighbouring cells. Often the concentration of a hormone is not uniform in all parts of the circulation, i.e. the circulating blood is subdivided into hormonal compartments. Such a process is probably of great importance for hypothalamic releasing factors. These factors attain an effective concentration only in the very small pituitary portal veinous system. The effects of glucagon and insulin on the liver are probably influenced by the fact that their concentration is significantly higher in the portal system than in the arterial blood.

Certain hormones are bound to specific proteins in the blood. This is true of thyroxine and cortisol, and probably also of estradiol, progesterone and testosterone. Whether insulin circulates bound to a protein is controversial. Assuming that only *one* single protein with only *one* binding site per molecule combines with the hormone, the reaction occurs according to the general formula:

$$h + p \rightleftarrows hp$$

h = free hormone, p = carrier protein, hp = hormone-carrier protein complex.

Experiments with isotopically labeled hormones have shown that the free hormone is in general fully exchangeable with the protein-bound hormone. This suggests that the hormone binds to the protein by noncovalent bonds and that the free and the bound hormone are in an equilibrium governed by the law of mass action. In the case of thyroxine, peripheral hormone action correlates better with the concentration of free hormone in the plasma than with the concentration of the protein-bound hormone. It has been generally held, therefore, that only free hormone molecules can diffuse from the blood into the interstitial fluid and reach their receptor cells (ROBBINS, 1960). It follows that appropriate clinical assessment of thyroid function would theoretically require the measurement of the free hormone concentration. Unfortunately, in the case of both cortisol and thyroxine, measurements of the free hormone in the plasma – though feasible – are still technically laborious. For both hormones the clinician must generally be satisfied with an estimate of the total hormone. Understanding of the mathematical relationship between the value of total hormone supplied by the routine chemical laboratory and the physiologically important free hormone concentrations is therefore of theoretical as well as clinical importance.

The following derivations can be made from the general formula above:

$$K = \frac{[h] \cdot [p]}{[hp]} \quad \text{(law of mass action).} \tag{1}$$

K = dissociation constant of hormone-carrier complex.

$$[P] = [p] + [hp] \tag{2}$$

= total concentration of carrier protein (free plus bound),

$$[p] = [P] - [hp], \tag{3}$$

$$K = \frac{([P] - [hp]) \cdot [h]}{[hp]} \quad \text{(by substitution of (3) into (1)),} \tag{4}$$

$$= \frac{[P] \cdot [h]}{[hp]} - [h], \tag{5}$$

$$[hp] = \frac{[P] \cdot [h]}{K + [h]}, \tag{6}$$

$$[H] = [h] + [hp], \quad \text{(by definition total amount of hormone: free plus bound),} \tag{7}$$

$$[H] = \frac{[P][h]}{K + [h]} + [h]. \quad \text{(by substitution of (7) into (6)).} \tag{8}$$

It becomes clear from Eq. (8) that the measured total hormone concentration $[H]$ is not a simple straightforward function of the physiologically important free hormone concentration $[h]$. On the other hand provided the free hormone remains constant, $[H]$ is a strict linear measure of the concentration of carrier protein $[P]$. The curves in Fig. 4 illustrate the mathematical relationships derived from Eq. (8). Although the calculations above are based on simplifying assumptions (see below), the curve shown in Fig. 4 resembles that obtained from actual measurements of total and free thyroxine (REICHLIN, 1967).

The assumption that there is only one species of carrier protein for every hormone is probably an oversimplification. Thus, Eq. (8) and the corresponding curves only approximate the actual conditions. Mathematical derivations with more general validity can be found in ROBBINS (1960) and SANDBERG (1966). In fact, thyroxine is bound to three proteins in the plasma, thyroxine-binding globulin (TBG), thyroxine-binding pre-albumin (TBPA) and albumin itself (OPPENHEIMER, 1968). TBG and TBPA have been isolated from the plasma and extensively analyzed. Cortisol is bound to cortisol-binding globulin which has also been termed transcortin. This protein has also been isolated (SANDBERG, 1966). All three hormone-binding proteins so far investigated appear to bind one hormone molecule per protein molecule.

The importance and function of hormone-binding plasma proteins are far from clear. These proteins do not appear to serve the purpose of improving solubility of hormones in the plasma, since cortisol and thyroxine

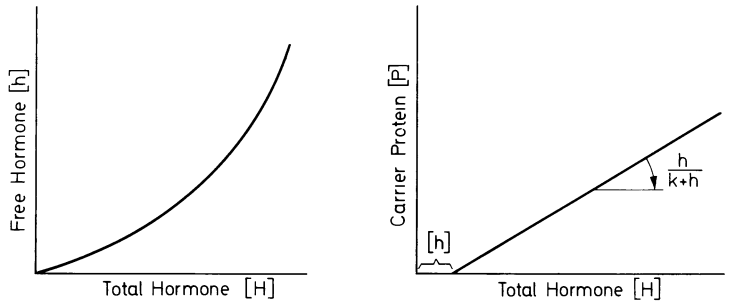

Fig. 4. Theoretic curves of $[h]$ and $[P]$ as functions of $[H]$ in Eq. (6) p. 4. In the curve on the left, $[P]$, the total carrier concentration, is taken to be constant. In the curve on the right, $[h]$, the concentration of free hormone, is taken as a constant. $[H]$ may be considered representative of the total serum hormone (e.g. cortisol or thyroxine)

From Eq. (8) it follows that, in order to calculate the level of free hormone from the measured total hormone, one must also know the concentration of carrier protein $[P]$ and the dissociation constant $[K]$. However, these two parameters are still not generally available to the clinician, and he therefore assumes that both are constant values. This simplification is only justified by the lack of suitable practical methods of measuring the free hormone concentration. One must be aware that, for example, in patients with a low plasma protein level, as in cirrhosis of the liver or the nephrotic syndrome, low plasma cortisol and serum thyroxine concentrations may be measured yet the level of free hormone can be quite normal. The reverse can, of course, be true when the proteins binding cortisol and thyroxine are elevated, a condition frequently encountered today in women taking oral contraceptives.

would be easily soluble in water in the physiologically required concentrations. The possibility that hormone-binding proteins may regulate hormone release to tissues is conjectural. For this to occur, concentrations and dissociation constants of hormone-binding proteins would have to adjust rapidly to different metabolic situations. There is no reliable evidence for such rapid adaptations so far, except perhaps in the case of TBPA, the concentration of which falls in acute inflammatory processes, resulting in a temporary rise of free hormone in the plasma (INGBAR, 1960; OPPENHEIMER, 1963). An important regulatory function of these proteins is refuted by the fact that people with an inherited deficiency of TBG are absolutely healthy and have normal thyroid function. Alternatively, the possibility has often been considered that hormone-binding proteins may prevent or slow down disposal and excre-

tion of their corresponding hormone, thus resulting in more economical hormone secretion. This view is contradicted by the observation that people with inherited TBG deficiency have a normal secretion rate of thyroxine (NICOLOFF, 1964). In conclusion, therefore, we agree with DE MOOR (1968) that the physiological significance of hormone-binding proteins in the plasma is not known.

F. Transfer of "Hormonal" Information to the Receptor Cell

"Hormonal" information in the plasma and interstitial fluid exists in the form of the hormone concentration which may be zero or any chosen positive value. In most cases the receptor cells seem to be sensitive to the hormone concentration in the surrounding extracellular fluid. In many cases the mathematical relationship between hormone concentration and hormone effect obtains according to ARIENS (1956), making the following two assumptions:

1. Hormones act by combining reversibly with cell receptors (see p. 7) according to the general formula:

$$r + h \rightleftarrows rh, \tag{9}$$

where r = receptor, h = hormone and rh = receptor-hormone complex.

In at least one system, the binding of insulin to fat-cell receptors, this assumption has been verified, since both the association and dissociation reaction followed the expected kinetics (CUATRECASAS, 1971 a).

2. Hormone effect is directly (linearly) proportional to the concentration of the hormone-receptor complex:

$$E_h = \alpha[rh], \tag{10}$$

where E_h = action of hormone h, $[rh]$ = concentration of receptor-hormone complex, α is a constant, (proportionality constant).

If $[R] = [r] + [rh]$, the total concentration of receptor (i.e. free receptors plus those bound to hormone), according to the law of mass action, the dissociation constant (K) of the hormone-receptor complex is:

$$K = \frac{[r]\cdot[h]}{[rh]} = \frac{([R] - [rh])[h]}{[rh]}. \tag{11}$$

From this, the concentration of hormone-receptor complex can be calculated as follows:

$$[rh] = \frac{[R]}{\frac{K}{[h]} + 1}. \tag{12}$$

Through substitution in Eq. (10):

$$E_h = \alpha[rh] = \frac{\alpha[R]}{\frac{K_h}{[h]} + 1}. \tag{13}$$

The maximum effect (E_h max) is achieved if all receptors are saturated with hormone, thus if

$$[rh] \rightarrow [R]$$

then

$$E_h \max = \alpha[R]. \tag{14}$$

Substitution of Eq. (14) in Eq. (13) gives:

$$E_h = \frac{E_h \max}{\frac{K_h}{[h]} + 1}. \tag{15}$$

From this equation, which is formally identical with that of MICHAELIS-MENTEN for enzyme kinetics, theoretic concentration-response curves can be drawn. Such a theoretic curve is shown in Fig. 5. It demonstrates that hormone action should be linearly proportional to the *logarithm* of hormone concentration in the middle part of the S-shaped curve.

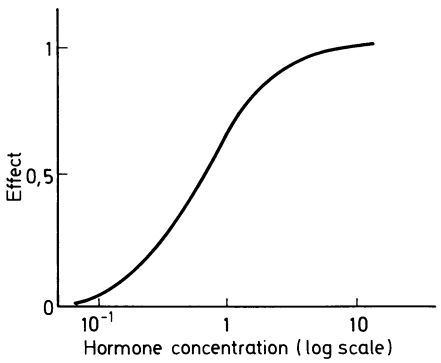

Fig. 5. Relationship between hormone concentration and hormone action. Theoretic curve calculated according to formula 15 on p. 6. (From E. J. ARIENS, 1956)

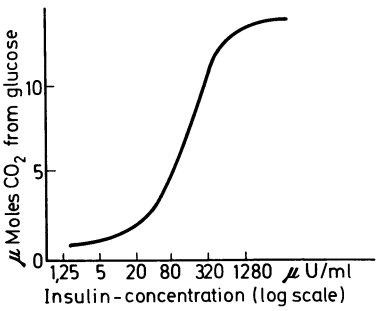

Fig. 6. CO_2 production from glucose in isolated fat cells incubated *in vitro* in the presence of different concentrations of insulin. (From J. GLIEMAN, 1965)

In practical experiments, hormonal effects often do follow curves similar in shape to those calculated theoretically, as seen in Fig. 6. The relationship between hormone concentration and effect derived from Eq. (7) may well be an oversimplification of the actual state of affairs. Recent experiments by RODBELL (1971 a, 1971 c) have shown that in the case of glucagon neither assumption (1) nor assumption (2) strictly hold. Thus, hormone-target cell interactions may be vastly more complicated than outlined above.

Occasionally, the effector cells do not seem to respond to the surrounding hormone concentration but rather to the velocity at which this hormone concentration changes. In mathematical terms, therefore, these effector cells are sensitive to the first differential of hormone concentration against time. CLYNES (1961) showed that a "differential" sensitivity of this kind existed in the pupillary reaction to light stimuli. DALLMAN (1969) found evidence of an analogous phenomenon in an endocrine system, namely the action of corticosteroids on hypothalamic centers.

G. Receptors

For a hormone molecule to produce an effect it must come into direct physical contact with the target cell. It must therefore be accepted that the target cell possesses certain structures termed receptors or discriminators which "recognize" a hormone and convert the information contained in the dissolved hormone into biochemical processes within the cell. During this process of recognition a physical or chemical reaction must take place between the hormone molecule and its receptor. It is likely that this reaction consists of the binding of the hormone molecule to its receptor. The three-dimensional shape of the receptor molecule is probably such that it is complementary to the shape of the hormone molecule or of parts of it, in which case the hormone and the receptor would fit together like pieces of a jigsaw puzzle. Since receptors transmit information from the extracellular fluid into the cell, it is logical to assume that they are located in the cell membrane facing outwards. Experimental support for this view has come from ingenious studies by CUATRECASAS (1969). He incubated isolated fat cells in the presence of insulin which was bound chemically to beads of agarose (a carbohydrate polymer), and found that insulin still exerted its biological effect on glucose transport. Since it is practically inconceivable that the agarose particles penetrated into the cells, the interaction between hormone and receptor must have taken place at the outer face of the cell membrane.

Some very relevant information about the nature of the bonds between hormones and receptors has accumulated in the past 10 years. If it is assumed that the combination is reversible (which is probable but remains to be proven for many hormone-receptor interactions), then noncovalent bonds are the most likely to be involved. On the basis of extensive comparisons of the activity of steroid hormones and their numerous chemical analogues, BUSH (1962) was able to identify certain parts of the steroid molecules which must participate in the attachment to the receptor. One conclusion he reached was that one way glucocorticoids were bound to their receptors was through a hydrogen bond involving the 11β-hydroxyl group of the hormone. Ionic and hydrophobic interactions produce other types of bonds. Hydrophobic bonds develop through the tendency of hydrophobic (uncharged, apolar) groups of molecules to associate in aqueous solution. Such apolar groups are found in abundance in the hydrocarbon side chains of certain amino acids of proteins. The bonds developed in this way are weak, but are of eminent importance, e.g. for the maintenance of the tertiary and quarternary structure of proteins, because of their large number. RODBELL (1971 d) demonstrated that a region rich in hydrophobic amino acid side chains of the glucagon molecule is involved in the binding to liver-cell membranes. The binding can be reversed by 0.4 M urea. Both observations strongly implicate hydrophobic interactions between hormone and receptor. In the case of protein and peptide hormones which contain disulfide bridges (insulin, antidiuretic hormone), the possibility has been considered that covalent bonds may occur with sulfhydryl groups of the receptors through the formation of a mixed disulfide between receptor and hormone. The *in-vitro* action of insulin upon adipose or muscle tissue can in fact be prevented by the use of sulfhydryl-blocking agents such as N-ethyl maleimide (OTT, 1963). However, the conclusion that this proves the formation of a mixed disulfide between insulin and its receptor has been seriously challenged, and excellent evidence has been produced that a disulfide-sulfhydryl exchange is *not* involved in the action of antidiuretic hormone (WALTER, 1967) or in that of insulin (CUATRECASAS, 1971).

BUTCHER (1965) and GRAHAME-SMITH (1967) observed that the maximal effects of epinephrine on adipose tissue and of ACTH on the adrenal cortex were not limited by the number of receptors, as might have been deduced from Eqs. (14) and (15) in the previous section; in

fact these tissues appeared to have an excess of hormone receptors and the maximal hormone effect is limited by secondary processes triggered in the target cell by the hormone. Usually, these secondary processes are chemical reactions where the amount of an enzyme or substrate can be rate limiting factors. ARIËNS (1966) gives a full discussion of the kinetic implications of such spare receptors.

The attachment of a hormone to the target cell can be quantitatively demonstrated by the fact that the concentration of hormone is greater in the cell than in the surrounding fluid. Such an accumulation of hormone in the target cell has been demonstrated for the non-protein hormones aldosterone (SHARP, 1966), estradiol (JENSEN, 1962), thyroxine (HOCH, 1967) and possibly also for cortisol (SEKERIS, 1967). *In vitro*, aldosterone is rapidly and completely bound to toad bladder mucosa within 30 min. It is interesting that hormonal effects become evident only after 40–120 min. The binding occurs at two different receptors with very different affinity constants of 1.4×10^{14} and 4×10^{12} Mol^{-1} (SHARP, 1966). The attachment of aldosterone to the receptors is reversible and 96% of the bound hormone can be eluted from the mucosa in chemically unaltered form. This strongly implies that the bonds between the hormone and its receptors are noncovalent.

JENSEN (1962) injected estradiol labeled with tritium into female ovarectomized rats, and found that the hormone accumulated in the uterus, vagina and anterior pituitary lobe. Fractionation of cells and autoradiographic investigations showed that estradiol was bound predominantly to the cell nuclei (STUMPF, 1966). TOFT (1966) isolated a protein from rat uterus, whose properties fulfilled the criteria of a specific estrogen receptor. JENSEN (1972) found two different estrogen receptors in rat uterus: one was a cytoplasmic protein with a sedimentation constant of 4 S, and the other, present in rate-limiting amounts, a nuclear protein with a sedimentation constant of 5 S. There is good evidence that estrogen binding converts the cytoplasmic receptor from its 4 S to a 5 S form, which then migrates to the nucleus.

Hypothyroid rats bind large amounts of injected thyroxine to their liver mitochondria. Between 1 and 5 molecules of thyroxine per respiratory chain unit are bound during this process (HOCH, 1967).

Injected cortisol is very quickly absorbed into liver cells. A part is metabolized there, whereas a smaller part remains bound to the cell nuclei as unchanged cortisol (SEKERIS, 1967). BAXTER (1972) has shown that in the cytosol of liver cells, cortisol or other steroids with glucocorticoid activity first bind reversibly to a cytoplasmic soluble receptor protein and thereby produce some change in shape (conformation) of this receptor molecule. The protein-steroid complex travels to the nucleus, and, thanks to the small conformational change produced by the binding of the steroid, it can now bind to nuclear DNA and exert control over the transcription of certain genes. The protein receptor alone without steroid hormone cannot bind to DNA because its shape is slightly different and it does not fit the DNA receptor. The details of the following reaction, the selective transcription of certain DNA strands, has not been fully worked out, but the end result appears to be the production of more of the enzyme tyrosine aminotransferase. The complex sequence of events is depicted schematically in Fig. 11 (p. 15). For a better understanding the reader is also referred to the section on protein synthesis (p. 15 and Fig. 10).

Reversible binding of peptide hormones to their target cells has been controversial until recently. Thus CROFFORD (1968) found that insulin disappeared in vitro from an incubation medium containing adipose tissue cells. He attributed this to destruction of insulin and he was unable to detect reversible binding to the fat cells. However, in the past two years excellent evidence has emerged in support of reversible binding of insulin, ACTH and glucagon. CUATRECASAS (1971c) has shown that ^{125}I-labeled insulin binds reversibly to fat cells. The insulin could be recovered unchanged from the cells by elution. One single fat cell bound up to 10000 insulin molecules and the effect on glucose oxidation was linearly proportional to the amount of insulin bound, an observation which supports assumption (2), used in the preceding section for the calculation of dose-response curves. The equilibrium (dissociation) constant of the insulin-receptor complex was 5.0×10^{-11} M. The controversy over hormone binding versus hormone destruction has recently been settled by FREYCHET (1972). He showed that liver-cell membranes actually did destroy insulin *in vitro* but that this destruction was not linked with the binding of the hormone to the receptor. The two processes, binding and destruction, were shown to be entirely independent. Analogous results were reported for the binding of ACTH to adrenal membranes (LEFKOWITZ, 1970) and for several other polypeptide hormones (see short review in CUATRECASAS, 1971b). RODBELL (1971a) reported that ^{125}I-labeled glucagon binds to isolated liver-plasma membranes. Again the binding was reversible and the biologic effect, namely the activation of the membrane-bound enzyme adenyl cyclase was

proportional to the amount of bound hormone. Some unexpected observations were made, however, in the glucagon-liver membrane system. Firstly, under certain conditions, the response of the target (the membrane-bound adenyl cyclase) is not only a function of the surrounding hormone concentration. Rather, nucleotides, in particular guanosine triphosphate (GTP), greatly influence the response to a given hormone concentration (RODBELL, 1971 b, 1971 c). Secondly, the binding of labeled hormone is not entirely reversible even by a 1000-fold excess of unlabeled hormone and the dissociation of the hormone-receptor complex does not obey simple first-order kinetics (RODBELL, 1971 a). Both findings are contrary to conventional theory about action of hormones.

Interesting compounds have been studied which specifically inhibit the response of the target organ to a number of hormones. Kinetic analysis has shown that in many cases the inhibition is of the *competitive* type. In physicochemical terms this means that the inhibitor binds to the hormone receptor, thereby blocking attachment of the hormone. Competitive antagonists usually show some chemical similarity to the corresponding hormone. Sometimes, however, competitive antagonists may be structurally quite different, which has led ARIËNS (1966) to conclude that they do not always interact with the same chemical groups of the receptors as the corresponding hormones but attach themselves to some neighbouring groups of the receptor at so-called accessory binding sites with part of their molecule extending into the region where the hormone should be bound. Thus, steric hindrance will prevent attachment of the hormone molecule. Spironolactone, which displaces aldosterone from its receptors, is a typical example of a competitive hormone antagonist (SHARP, 1966). Clomiphene and ethamoxytriphetol are hormones antagonistic to estrogens (LERNER, 1964), and cyproteron is an antagonist to androgens (NEUMANN, 1967). A glucagon derivative lacking the amino-terminal histidine has been found to act as a specific glucagon antagonist (RODBELL, 1971 d) and an ACTH-analogue may act as an ACTH antagonist (SEELIG, 1971). The antagonists mentioned so far are pharmacological substances which do not occur in nature. Naturally-occurring antagonists to insulin have been found in plasma by various authors who claim they are the cause of diabetes mellitus, but the significance of these substances is still debated. For completeness we must also mention here that immunological antibodies can arise to peptide hormones given by injection. Such antibodies can, for example, neutralize the action of insulin and may very well explain the insulin resistance found in some diabetics.

The chemical nature of receptors has been studied mainly by indirect means. RODBELL (1971 a, 1971 c) found that trypsin, phospholipase A and digitonin destroyed the glucagon-binding sites of liver membranes. He concluded that glucagon receptors were lipoproteins and the lipid and the protein moieties were both essential for proper receptor function. By contrast, insulin receptors in fat and liver cells seem resistant to the action of phospholipase, which suggests that they are chemically different compounds (CUATRECASAS, 1971 a). The receptors for both glucagon and insulin are firmly bound to particulate cell matter, most probably to the cell membrane. This has complicated the study of their chemical nature, but recently CUATRECASAS (1972) has succeeded in rendering insulin receptors of fat and liver cells soluble simply by treating the membranes with an non-ionic detergent. The soluble receptor turned out to be a protein, as had been predicted on the basis of the more indirect studies. Lipids are probably not an essential part in the function of this receptor. The estimated molecular weight was 300000.

Proteins seem particularly suited to the task of receptors since they are capable of binding a great variety of substances ranging from simple ions to large macromolecules. This property of proteins was extensively analyzed by SCATCHARD as early as 1949. MONOD (1966) discussed the possibility that hormones might be allosteric ligands, and hormone receptors allosteric proteins. Allosteric proteins are composed of two or more peptide chains (subunits) interconnected noncovalently by an incomplete fit. This incomplete fit gives rise to strain or tension in the folding of the protein chains. If a small molecular ligand now binds to a specific site of such a molecule, the strain will change, e.g. by a different electron or charge distribution, and the molecule will assume a slightly different shape (conformation). This change of shape is called an allosteric transition. Since the transition involves the whole protein molecule, sites quite distant from the original ligand-binding site may be affected, e.g. the catalytic site of an enzyme (MONOD, 1965). The concept that receptors are allosteric proteins is appealing. Thus, allosteric proteins can receive signals, transmit them along the protein-chain and translate them into another signal. According to SCHWARTZ (1966) these are exactly the properties which are required of receptors. Furthermore, allosteric proteins are also capable of greatly amplifying signals (MONOD, 1965) – they act, so to speak, as molecular amplifiers

and relay stations. BOWNESS (1966) and GRAHAME-SMITH *et al.* (1967) were actually able to demonstrate that adenyl cyclase, a possible component of the receptor for several hormones, functions as an amplifier for hormonal signals. In spite of this evidence MONOD was reluctant to support the view that hormone receptors, especially in the case of steroid hormones, are allosteric proteins. Our knowledge of the chemical nature of receptors is still so inadequate that the question must remain unsettled, but very recently BAXTER (1972) has provided good evidence that the so-called cytoplasmic receptors for glucocorticoid hormones are in fact allosteric proteins.

H. Events Following the Binding of Hormones to Receptors

Well-defined biochemical effects for practically every hormone have been described and quantitatively measured in a great variety of *in-vivo* and *in-vitro* test systems using the corresponding target organ. These well-known hormone effects are, however, not necessarily the direct consequence of the first step of hormone action, the attachment to the receptor. Thus it is not known, for example, which of the physicochemical events ultimately leading to acceleration of glucose transport occur after binding of insulin to the fat-cell membrane. The almost complete chain of events linking binding at the receptor site to the biochemically evident hormone effect has so far only been established for the action of glucagon and epinephrine on the breakdown of liver glycogen (see cyclic AMP, below). For most other hormones, virtually nothing is known of the reaction after the receptor site has been occupied, a step that has sometimes been referred to as the *primary action* of a hormone. In view of the facts now available on the glucagon-adenyl cyclase-cyclic AMP system this term is hardly appropriate, since this "primary action" may in fact be a cascade of several chemical events. Despite the gaps in our understanding of the precise chemical actions of hormones a classification according to their effects on cellular processes will be presented below. Such a classification will of course remain tentative and will have to be modified as more facts emerge.

1. Effects of Hormones on Membranes

Classically, membrane effects imply actions of hormones upon the permeability of membranes (usually the cell membrane) to small molecules or upon transport mechanisms within such membranes. Certain hormones which activate enzymes bound to the cell membrane (e.g. adenyl cyclase) without necessarily influencing permeability or transport mechanisms may also be included at this point. Insulin can be considered as the prototype of a hormone which acts on membrane properties. As was shown by LEVINE (1955), the main action of this hormone is to increase the transport of glucose from the extracellular into the intracellular fluid. This effect has been demonstrated in both muscle and adipose tissue (PARK, 1959; CROFFORD, 1965). In both tissues, glucose is transported through the cell membrane by means of a carrier (not yet identified) which is thought to bind glucose on one side of the membrane and release it into the cell on the other side. The following properties are characteristic of this type of carrier transport: 1. There is strict stereochemical specificity of the carrier to the substrate. For example, D-glucose is transported via the carrier mechanism whereas L-glucose is not. 2. Carrier transport obeys saturation kinetics and by this means differs from transport via simple diffusion. 3. Carrier transport does not require energy (so-called "facilitated diffusion") unless the substrate is transported against an energy or concentration gradient, in which case the carrier transport must be coupled to an energy-producing process. In the latter case the term "pump mechanism" has been applied. 4. Under suitable experimental conditions, counter-transport may be observed, i.e. the substrate is transported against a concentration gradient but not against an energy gradient. In erythrocytes, muscle and adipose tissue, glucose transport fulfills these criteria (WILBRANDT, 1961; PARKS, 1959; CROFFORD, 1965). In the last two tissues insulin appears to produce an increase in "carrier places" or in the affinity of the carrier for glucose (CROFFORD, 1965). For the sake of completeness it must be mentioned here that insulin has other effects which seem to be independent of glucose transport. It affects uptake of amino acids, lipolysis and protein synthesis in several tissues.

Aldosterone increases the transport of sodium ions from the tubular lumen across the renal tubular cells. SHARP (1966), using the toad bladder as an experimental model for the renal tubule, showed that aldosterone promoted the transport of sodium ions through the apical cell membrane. This effect appears only with a latent period of 45–120 min after the hormone has been added. Aldosterone has no effect if protein synthesis is blocked with puromycin or if energy production is inhibited in the toad bladder by the omission of substrate (glucose

or pyruvate). The transport of sodium ions which is induced by alosterone is thus coupled with an energy-providing process, not an unexpected finding since sodium ions are transported against a concentration gradient.

2. Cyclic AMP and the Concept of the Second Messenger

Parathormone and vasopressin are two other hormones which act upon transport mechanisms within the kidney. The former inhibits phosphate transport and the latter increases water permeability across the cells of the renal tubules. It is likely that both hormones exert their effect by increasing the conversion of adenosine triphosphate (ATP) to 3′,5′-adenylic acid (cyclic AMP), a reaction catalyzed by the membrane-bound enzyme adenyl cyclase. This fundamental mode of hormone action was discovered by SUTHERLAND in 1958 during studies on the glycogenolysis induced by glucagon and epinephrine in liver tissue. At that time it was known that glucose-1-phosphate was split off from glycogen by an enzyme, phosphorylase, and that this enzyme existed in the inactive b form and the active a form. SUTHERLAND stimulated glycogenolysis by incubating liver tissue in a medium containing glucagon. From homogenates of this stimulated tissue he recovered a heat-stable substance which was capable of activating phosphorylase in homogenates of untreated liver tissue. This small molecular substance was isolated and rapidly identified as 3′,5′-adenylic acid (cyclic adenosine monophosphate, cyclic AMP). Fig. 7 shows the structural formula of this interesting nucleotide.

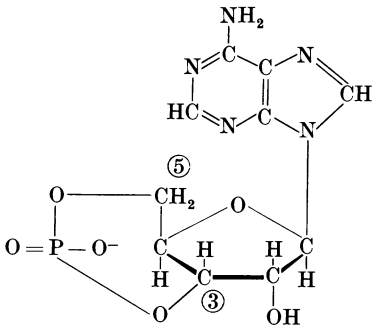

Fig. 7. Formula of 3′,5′-adenylic acid (cyclic AMP)

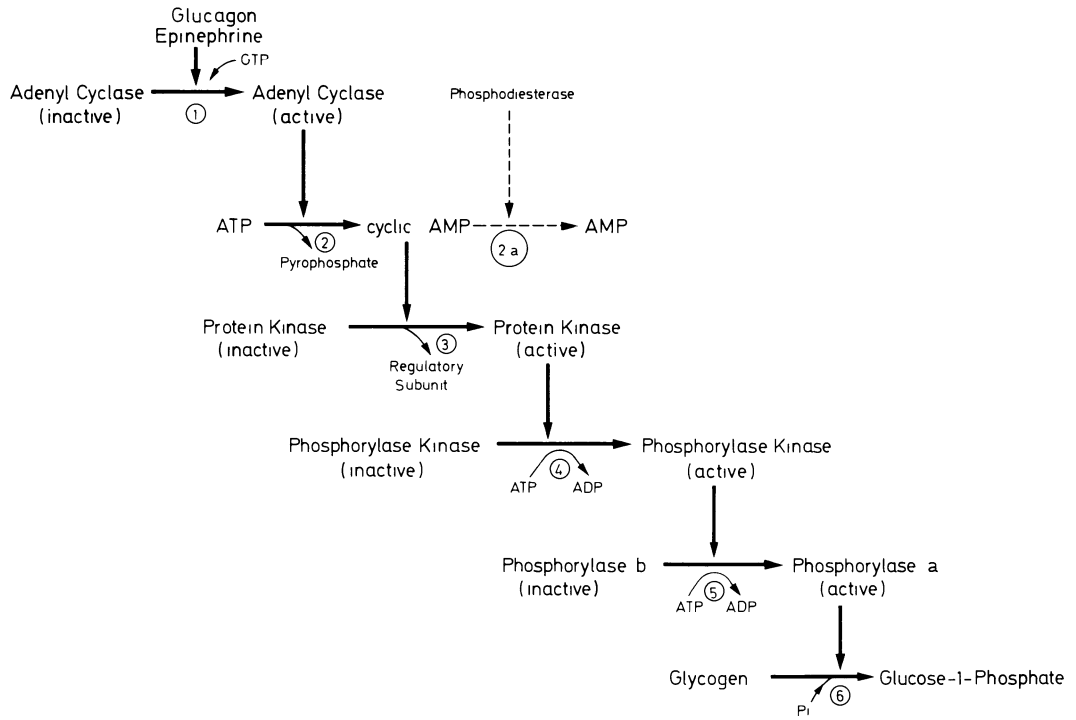

Fig. 8. Cascade of events leading to the activation of glycogen breakdown by glucagon or epinephrine in the liver. Most steps can now be exactly defined in physicochemical terms. 1. Binding of hormone to the receptor and activation of adenyl cyclase. This process is still poorly understood. Guanosine triphosphate (GTP) interferes with this process in a complex manner. 2. Formation of cyclic AMP from ATP. 2a. Enzymatic degradation of cyclic AMP. 3. Cyclic AMP binds to a regulatory subunit of the protein kinase. This leads to dissociation of the regulatory subunit from the catalytic subunit, the latter becoming active. 4. Phosphorylation of the inactive phosphorylase kinase. 5. Phosphorylation of the inactive phosphorylase. 6. Removal of glucose-1-phosphate from glycogen by phosphorolysis. Abbreviations: ATP: Adenosine triphosphate; ADP (AMP): Adenosine-di-(mono) phosphate; GTP: Guanosine triphosphate; Pi: Inorganic phosphate

Cyclic AMP is produced from adenosine triphosphate (ATP) through the enzyme adenyl cyclase. Cyclic AMP in turn is degraded into 5'-AMP by a specific enzyme termed phosphodiesterase. Phosphodiesterase is inhibited by methyl xanthines, such as caffeine and theophylline, a phenomenon which may explain some of the pharmacological effects of these substances. The exact mechanism by which cyclic AMP finally leads to the activation of the enzyme phosphorylase in muscle has been unravelled quite recently. The first step consists in the binding of cyclic AMP to a regulatory subunit of an inactive enzyme, protein kinase. This causes the dissociation of the regulatory from the catalytic subunit of this enzyme, which thereby becomes active (GILL, 1971). The active protein kinase phosphorylates (and thereby activates) the phosphorylase kinase which in turn activates phosphorylase (WALSH, 1971). The complete sequence of events is shown in Fig. 8, which shows that nearly every chemical step, from the attachment of the hormone at the receptor to the final hormonal effect, glycogenolysis, can be exactly defined. The only remaining uncertainty is how the binding of the hormone will activate adenyl cyclase, a question that seems particularly difficult to solve because both receptors and adenyl cyclase are firmly bound to the cell membrane and have not been obtained in soluble form yet. As will be discussed below, some authors have postulated that adenyl cyclase and receptor are identical.

In the few years since cyclic AMP was discovered in the liver this nucleotide has also been identified in many other tissues. The concentration of cyclic AMP in other tissues is also under hormonal control. The list of hormones whose actions may be transmitted through cyclic AMP is now long (Table 1) and several extensive reviews dealing with this subject have already been published (SUTHERLAND, 1966; ROBISON, 1968). Cyclic AMP appears to transmit the actions of so many hormones that SUTHERLAND has called it a "second messenger". According to SUTHERLAND'S concept, the hormone in extracellular fluid represents the "first messenger". The contact between hormone and adenyl cyclase leads to activation of the latter with the formation of cyclic AMP which transmits the hormone effects intracellularly by virtue of its activity as the second messenger. Fig. 9 is a schematic representation of the function of the second messenger. In this diagram adenyl cyclase is identical to the hormone receptor, an interpretation which may be an oversimplification, but has received the following indirect experimental support: 1. β-adrenergic receptor-blocking agents inhibit the catecholamine activation of adenyl cyclase in different tissues. The similarity between adenyl cyclase and β-receptors is so striking that ROBISON (1967) has postulated that β-receptors are identical to adenyl cyclase. 2. All hormones whose effects are based on an increase of cyclic AMP cause adenyl cyclase to be converted from an inactive into an active form. The *de-novo* synthesis of adenyl cyclase under the influence of hormones (which would be incompatible with a receptor function of this enzyme) has been excluded experimentally. Thyroxine may represent a possible exception to this statement, since in adipose tissue it has been reported to induce *de-novo synthesis* of adenyl cyclase (KRISHNA, 1968), whereas in myocardial tissue it appears to act like other hormones by causing the *activation* of the enzyme (LEVEY, 1969). 3. Adenyl cyclase appears to be firmly bound to membrane structures, probably the cell membrane, in all tissues investigated so far. In fact, an active hormone-sensitive enzyme has not yet been obtained in soluble form.

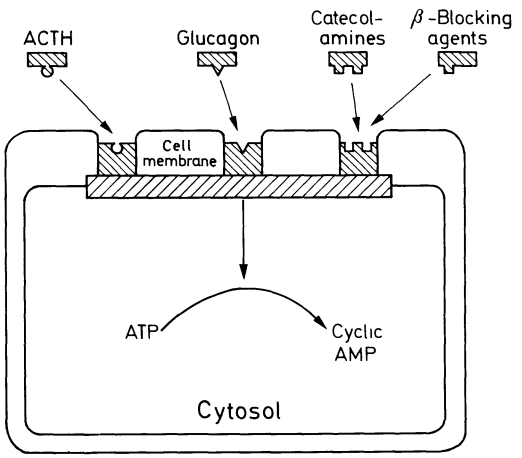

Fig. 9. Adipose-tissue cell with three different regulatory subunits that serve as hormone-specific receptors. There is a single catalytic subunit pointing toward the interior of the cell. Hormones or antagonists bind to the regulatory subunits. This simplified representation is based largely on experiments of BIRNBAUMER (1969). The exact mode whereby the binding of the hormone activates the catalytic subunit is still poorly understood.

One of the fundamentals of endocrine control is that each hormone exerts a specific action on a particular tissue. The numerous hormones listed in Table 1 which activate adenyl cyclase, and the large number of actions which are initiated by cyclic AMP appear to contradict this concept of hormone specificity. In other

Table 1. Survey of hormones whose action presumably involves 3′,5′-adenylic acid (cyclic adenosine monophosphate) as "second messenger"

Hormone	Organ or tissue	Level of cyclic AMP	Enzymes or chemical steps, influenced by cyclic AMP		End effect	
Catecholamines	Liver	+	Glycogen-Synthetase	−	Glycogen synthesis	−
			Phosphorylase	+	Glycogenolysis	+
			Pyruvate → Phosphoenolpyruvate	+	Gluconeogenesis	+
	Adipose tissue	+	Triglyceride-Lipase	+	Lipolysis	+
	Myocardium	+	Phosphorylase	+	Glycogenolysis	+
			unknown		Inotropism	+
	Skeletal muscle	+	Phosphorylase	+	Glycogenolysis	+
Glucagon	Liver	+	As for catecholamines		As for catecholamines	
	Adipose tissue	+				
	Myocardium	+				
	Pancreas (β-cell)	(+)	Unknown		Insulin-Release	
Insulin	Adipose tissue[a]	−	Triglyceride lipase	−	Lipolysis	−
	Skeletal muscle	[b]	Phosphorylase	−	Glycogenolysis	−
			Glycogen synthetase	+	Glycogen synthesis	+
	Liver[a]	−	Glycogen synthetase	+	Glycogen synthesis	+
			Phosphorylase	−	Glycogenolysis	−
			Pyruvate → Phosphoenolpyruvate	−	Gluconeogenesis	−
ACTH	Adrenal cortex	+	Cholesterol → Pregnenolone	+	Glucocorticoid synthesis	+
	Adipose tissue	+	Triglyceride lipase	+	Lipolysis	+
TSH	Thyroid gland	+	Phosphorylase	+	Glycogenolysis	+
			Unknown		Uptake and organification of iodine, hormone release	+
	Adipose tissue	+	Triglyceride lipase	+	Lipolysis	+
LH (ICSH)	Corpus luteum	+	Cholesterol → Pregnenolone	+	Progesterone synthesis	+
	Testis	(+)	Cholesterol → Pregnenolone	+	Testosterone synthesis	+
MSH	Frog skin	+	Unknown		Melanophore dispersion	+
Vasopressin	Kidney	+	Unknown		Tubular water reabsorption	+
Parathormone	Kidney	+	Unknown		Tubular reabsorption of phosphate	−
	Bone	+	Unknown		Resorption of bone	+
Thyroxine	Adipose tissue	+[c]	Neoformation of Adenyl cyclase		Sensitivity to catecholamines	
	Myocardium	+	As for catecholamines		As for catecholamines	

Key: + increase; − decrease; (?) probable increase, but not proven directly; ? unknown type of action.
[a] Action of insulin on adipose tissue and liver is only definitely measurable when adenyl cyclase is previously activated, e.g. by glucagon.
[b] Action of insulin on the level of cyclic AMP in skeletal muscle is controversial.
[c] In contrast to all other hormones, thyroxine does not seem to lead to activation of adenyl cyclase but rather to a neoformation of this enzyme (see text) in adipose tissue.
References can be found in the reviews by E. W. SUTHERLAND (1966) and G. A. ROBISON (1968).

words, if all tissues were to possess an identical adenyl cyclase then catecholamines, glucagon, ACTH and several other hormones would have exactly the same effects upon them. This, of course, is not so. ROBISON and co-workers (1967) have therefore suggested that adenyl cyclase consists of at least two subunits, one being regulatory and varying from tissue to tissue and the other being catalytic and possibly identical in all tissues. The regulatory subunit would function as the true receptor which binds only with the specific hormone, thereby activating the catalytic subunit. This interpretation is supported by several different experimental results. For example, ACTH, glucagon and catecholamines promote lipolysis in adipose tissue through the activation of adenyl cyclase. The action of catecholamines, but not that of ACTH and glucagon can be inhibited through β-receptor blocking agents. This indicates at least two different regulatory subunits (receptors) of adenyl cyclase. Furthermore, data published by BALLY (1968) suggest that there are probably two separate receptors for ACTH and glucagon. According to this concept,adipose tissue adenyl cyclase would therefore have a specific receptor for each of the three hormones considered, as is shown in Fig. 9.

Cyclic AMP has not been accepted without reservations as the almost universal second messenger of hormones and some questions remain unsolved. For example, it is disturbing that the concentration of cyclic AMP is many times higher even without hormonal stimulation in adipose tissue and in the liver than is necessary for full activation of the triglyceride lipase and phosphorylase in tissue homogenates. In order to explain this discrepancy, it has been postulated that the major part of cyclic AMP is compartmentalized within the cell segregated from the protein kinase. This speculation awaits experimental verification. Another still unexplained observation has been made in studies on the effect of insulin on glycogen synthetase of muscle. As in liver and adipose tissue insulin stimulates this enzyme; however, in muscle insulin produces a rise in cyclic AMP instead of the expected fall (GOLDBERG, 1967). Nevertheless, despite the objections that may be raised, the concept of the second messenger must be considered an important contribution to our understanding of the action of hormones.

3. Effects of Hormones on Protein Synthesis

CLEVER (1960) described that ecdyson, an insect hormone, led to swelling, so called "puff" formation, at specific locations on the giant chromosomes of the midge Chironomus tentans. In the larvae of these insects ecdyson induces enzymes that alter cuticular proteins and produce pupation. Since it was already known from other studies that chromosome "puffs" corresponded to active genes, CLEVER came to the exciting conclusion that ecdyson exerted its effect directly on the cell nucleus, where it activated a specific gene and thereby caused the induction of an enzyme protein. Since this discovery, the actions of many hormones on protein synthesis have been intensively investigated, an area of research that TATA (1968) and KORNER (1970) have briefly reviewed. For the understanding of the actions of hormones upon protein synthesis we shall first summarize the biochemical steps needed for building proteins (Fig. 10). Most of the knowledge in this field has been gained within the last 20 years from work on bacteria. However, the results can also be applied to mammalian cells with few modifications. We shall limit the discussion to those steps in protein synthesis which are essential for the understanding of the actions of hormones. For more detailed descriptions the reader is referred to standard biochemistry textbooks. The information for the production of all proteins required is stored in the form of genes within chromosomes in the nucleus of every cell. Chemically, genes are long strands of deoxyribonucleic acids (DNA) which contain the information for protein synthesis in the form of a variable sequence of four bases, adenine, thymine, cystosine and guanine. If a particular protein is to be produced, a negative copy with a complementary base sequence is first obtained from the DNA of the corresponding gene in the form of a strand of ribonucleic acid (messenger RNA = mRNA). This process is called transcription. mRNA migrates from the nucleus into the cytoplasm and comes into contact with the ribosomes. The ribosomes are small particles which move along the strands of mRNA and read the sequence of bases and put together the correct amino acids to form a peptide chain. In this process, the base sequence is translated into an amino-acid sequence (translation) according to the specific genetic code. Ribosomes themselves consist partly of ribonucleic acids, so-called rRNA. A specific transport RNA (tRNA), a third type of ribonucleic acid, combines with each of the 20 individual amino acids in the cytoplasm and facilitates their contact with and recognition by the ribosomes. rRNA and tRNA are both produced in the nucleus through transcription from DNA. It is easy to imagine from Fig. 10

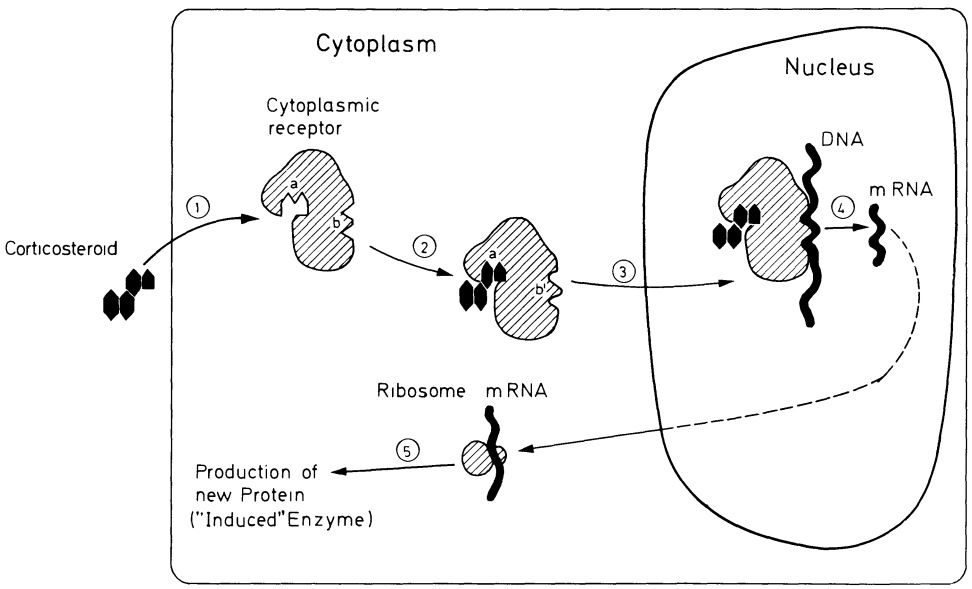

Fig. 11. Schematic representation of the mode of action of corticosteroid hormones. The stages are: 1. The steroid hormone penetrates into the cell. 2. In the cell cytoplasm it binds reversibly to the binding site (a) of a soluble receptor protein. Thereby it induces a slight change in shape of this molecule, notably in the region (b). 3. The hormone-receptor complex travels to the nucleus, and thanks to the slight alteration the region (b) fits on to nuclear DNA. 4. The binding of the complex to DNA causes the transcription of messenger RNA. 5. This ultimately leads to the production of a new protein, e.g. the enzyme tyrosine aminotransferase, on the ribosomes. This simplified representation is based on results by BAXTER *et al.* (1972). Similar mechanisms of action have been described for many other steroid hormones

that hormones may theoretically control different steps of protein synthesis, e.g. transcription from DNA into mRNA, rRNA and tRNA, or translation of mRNA into protein, not to mention the uptake of amino acids from the extracellular fluid.

So far, effects on protein synthesis have only been seen when intact cells (in vivo or in vitro) have been exposed to a hormone. Cell-free protein-synthesizing systems do not seem to be hormone-sensitive. For this reason there has been difficulty in identifying the exact mechanism of hormonal effects on protein synthesis. Nevertheless, experiments performed with chemical inhibitors of specific steps of protein biosynthesis have provided indirect evidence of the site of action. The most important conclusion to be drawn from the available data is that the mode and site of action may vary from one hormone to another, as will be seen from the following discussion and the summary in Table 2.

KORNER (1965) noted that growth hormone injections into rats produced an increase in protein synthesis in the liver. The hormone effect was demonstrable in cell-free liver homogenates, provided the hormone had been injected into the rats *in vivo*. Comparison of the activity of ribosomes from treated and untreated animals suggested that growth hormone primarily increased the concentration of mRNA in the cytoplasm. Since actinomycin D (an antibiotic which inhibits transcription of DNA in the nucleus) prevented the action of growth hormone, KORNER concluded that growth hormone promoted mRNA synthesis, i.e. transcription. It is probable that growth hormone also causes increased synthesis of rRNA. HAMILTON (1968) studied the action of a single injection of estradiol on protein synthesis in the uterus of ovarectomized rats. The results are summarized in Fig. 12. It can be seen that estradiol produces maximal stimulation of RNA synthesis in the nucleus within a few minutes. An increase in ribosomes and newly formed proteins could only be demonstrated after several hours. Analogous effects with slightly different timing are produced by testosterone on the prostate and seminal vesicles, and by corticosteroids and triiodothyronine on the liver (see TATA'S review, 1968). Matters are rather more complicated in the case of triiodothyronine than in that of the other hormones mentioned, since triiodothyronine causes stimulation of protein synthesis very rapidly, before RNA synthesis is increased. This effect is dependent upon the presence of mitochondria, for if mitochondria are absent *in vitro*, this early effect is not observed (SOKOLOF, 1968). The early triiodothyronine effect is probably related to the stimulation of mitochondrial respiration. Only in a later phase does triiodothyronine stimulate mRNA and ribosomal protein synthesis independently of mitochondria.

Abbreviations as in Fig. 10. (Simplified from T. H. HAMILTON, 1968)

In summary, growth hormone, estradiol, testosterone, glucocorticoids and thyroid hormone (with the exception of the "early" effect of the last) can be said to control protein synthesis at the stage of *transcription*. This interpretation also appears to be valid when the hormone does not stimulate but rather inhibits protein synthesis as in the action of cortisol in lymphocytes (MAKMANN, 1967).

Insulin enhances protein synthesis in muscle. This effect is independent of the well-known stimulation of glucose transport across the cell membrane. Insulin appears to increase RNA synthesis by stimulating transcription. However, it can also stimulate protein synthesis even when RNA synthesis is fully blocked with antibiotics. WOOL (1966) therefore concluded that insulin may also enhance protein synthesis at the ribosomal stage (translation). Subsequent experiments by A. G. SCHWARTZ and AMOS (1968) have confirmed the action of insulin on ribosomes and have demonstrated that ribosomes from fibroblasts cultured in a medium containing insulin synthesize more protein than ribosomes from fibroblasts cultured without insulin. In cell cultures of liver tumors cortisol does not stimulate global protein synthesis. Rather it causes a specific enzyme (tyrosine transaminase) to be synthesized. THOMPSON'S (1966) experiments have suggested that in this instance cortisol acts at the stage of translation rather than that of transcription. However, in

a different liver tumor-cell line the glucocorticoid effect has recently been located to transcription again (BARNETT, 1971). Moreover, cyclic AMP has been found to have a permissive effect on the enzyme induction (SAHIB, 1971).

Other hormonal effects on protein synthesis are summarized in Table 2. In general, the available evidence points to the fact that endocrine control of protein synthesis is not exerted at one metabolic step identical for all hormones. The site of action seems to vary from hormone to hormone and from tissue to tissue. Several hormones, e.g. insulin and cortisol, appear to act at several steps of protein synthesis. It has been said that all gonadal and adrenal steroid hormones act on the transcription of DNA into RNA in the cell nucleus. Table 2 confirms this impression, but it is wise to remember KARLSON's warning (1961) against simplifying generalizations in this field.

The exact molecular or chemical mode of action of hormones on the cell nucleus and on ribosomes remains unsolved. The opinion has been expressed that hormone receptors in the cell nucleus are identical with so-called gene *repressors*. These are proteins which combine reversibly with DNA strands and prevent transcription (BRETSCHER, 1968). Repressors can combine with derepressors at a second binding site. Attachment of the derepressor slightly distorts the shape of the repressor molecule which thereby loses its affinity for DNA. The repressor then dissociates from DNA which is cleared for transcription. Recent evidence suggests that a sequence of events roughly resembling the one postulated in this hypothesis actually takes place in the case of steroid hormones. The mechanism suggested by BAXTER (1972) has been outlined in more detail on p. 8 and in Fig. 11.

Many of the biochemical observations discussed above may be disappointing to both clinicians and physiologists, partly because they deviate widely from known clinical hormone actions and partly because they appear to contradict the concept of specificity of hormone action. For example, the observation that cortisol increases global protein synthesis instead of exerting its expected catabolic effect upon the liver is disturbing. On the other hand, it must be appreciated that the results of biochemical experiments are reasonably consistent with clinical and physiological observations in the case of the effects of testosterone on the prostate, estradiol on the uterus, and possibly growth hormone upon the liver, and agreement is excellent in the effects of cortisol on hepatoma cells in tissue culture and of prolactin on mammary tissue in organ culture. In both cases the synthesis of a single specific enzymic protein is induced without stimulation of global protein synthesis, and the enzyme induced explains some of the clinical effects of the hormone (Table 2).

4. Direct Effects of Hormones on Enzyme Activities

We shall discuss here the ability of hormones to activate or inactivate enzymes without the formation of new enzyme protein. It is important to appreciate that this process is separate from the induction of enzyme synthesis (e.g. of tyrosine transaminase under the influence of cortisol which necessitates synthesis of new enzyme protein and which has been discussed in the previous section).

A classic example of an enzyme whose activity can be increased or inhibited by different hormones is that of adenyl cyclase (see section on cyclic AMP). Despite concerted efforts to reveal other enzymes which serve as hormone receptors, few analogous hormone-enzyme interactions have been described to which one can attribute physiological significance. The earlier hypothesis that the action of insulin on glucose metabolism may be due to activation of hexokinase is no longer generally accepted. TOMKINS (1963) has surveyed the action of steroids on isolated enzymes and has distinguished two mechanisms of interaction. In one case the hormone acts as a *co-factor* on enzymatic reactions. The transhydrogenase function of estradiol may serve as an example. In the second case the steroid hormone can influence the activity of an enzyme by reversibly altering the enzyme's tertiary and quaternary structure. Glutamate dehydrogenase and pyruvate kinase are examples of two enzymes controlled by steroids in this way. Thyroxine leads to dissociation of glutamate dehydrogenase into subunits (WOLFF, 1962) and to inactivation of alcohol dehydrogenase (MCCARTHY, 1968), the latter probably through an allosteric effect. It is difficult to attribute physiological significance to these actions of steroid and thyroid hormones. The phenomena described above may well be test-tube effects unrelated to the physiological function of the hormones in the intact cells. The actions of thyroxine and triiodothyronine on the metabolism of mitochondria must be discussed in this context. In this case the thyroid hormones are assumed to influence oxygen consumption and oxidative phosphorylation in a complex multi-enzyme system involved in electron transport. For detailed discussion of these processes the reader is referred to reviews compiled by HOCH (1962) and TAPLEY (1967).

5. Effects of Hormones on Cellular Differentiation

It has long been known that certain hormones exert impressive effects on the differentiation of cells and organs. The study of organ differentiation has moved a long way in the past ten years from the classic morphologic description of embryogenesis to a biochemical understanding of the processes involved. The differentiation of a cell depends ultimately on the type and amount of enzymes it contains. The enzymes and structural proteins present in a cell will determine largely what metabolic functions the cell can perform, what substances it will take up, metabolize, store or secrete, and also what shape the cell will assume. Every nucleated cell of a given organism contains the identical full set of genes and is theoretically capable of synthesizing all the enzymes or proteins that any other cell in the same body produces. Cell differentiation therefore depends entirely on the fact that only some of the possible proteins are synthesized, while the expression of other genes is inhibited. It was therefore a safe prediction that differentiation could only be controlled by modulation of the expression of genes.

This prediction has now been largely confirmed by experiments in two interesting model systems, differentiation of the oviduct of immature chicks and metamorphosis of anurae. The former system has been extensively studied by O'MALLEY (1969). He found that the oviduct of immature chicks, which is lined with a flat undifferentiated epithelium, rapidly differentiates and starts to produce the protein ovalbumin when estrogenic hormones are injected. When progesterone is given after several days of estrogen treatment another very specific protein, avidin, is synthesized. The following facts, among others, suggest that hormones exert their control at the transcription stage (see Fig. 10): 1. The enzyme DNA-dependent RNA polymerase, which is necessary for transcription, is present in much larger quantities in the nuclei of estrogen-treated animals than in those of nontreated animals. 2. Estrogen treatment leads to the synthesis of large amounts of novel RNA which is not present in the untreated oviduct (probably mRNA). 3. Actinomycin D, a drug which selectively inhibits the process of transcription, abolishes hormonal effects on differentiation. The fact that estrogens also cause an increase in the amount of available tRNA (see Fig. 10) points to an additional control of differentiation at the stage of translation.

Biochemical studies on anuran metamorphosis have shown that the morphological changes are accompanied by numerous changes in the enzyme patterns of many organs (FRIEDEN, 1967). COHEN (1970) and GRISWOLD (1972) have focused their attention on the appearance of enzymes necessary for the production of urea. These enzymes are lacking in the tadpole, which excretes ammonia, but are present in the frog, which excretes urea. The level of some of these enzymes, e.g. carbamyl phosphate synthetase, increases 30-fold during metamor-

phosis. Injection of thyroxine greatly accelerates this change of enzyme. It has been clearly demonstrated that thyroxine does not produce *activation* of an enzyme protein already present but rather *induces* the production of new enzyme protein. As in the case of estrogen action in the chick oviduct, thyroxine produced a manifold rise in the enzyme DNA-dependent RNA polymerase. Thus the hormone affected transcription, but again additional points of control were identified at the stage of translation (COHEN, 1970).

In summary, all available data suggest that hormonal effects on differentiation must be considered in the more general context of the hormonal control of protein synthesis, which has been dealt with in the previous section. Many questions still remain unsolved in this field. For example the attentive reader will immediately point out that in the system mentioned above the chick oviduct must have undergone some differentiation before it was exposed to estrogen, since it appears to be one of the few tissues that responds to estrogens, while many other primitive epithelia, e.g. in the gut, do not change upon estrogen treatment.

I. Hormones as Components of Physiological Control Systems*

The previous sections have shown that endocrine systems are involved in the transfer of information by means of chemical signals with the ultimate goal of controlling biological processes. It is therefore possible to analyze endocrine processes with the aid of the *theory of control systems*.

In order to get acquainted with a simple control system we shall first analyze the problem of blood-sugar regulation in eviscerated rats. These rats lack both the hormones necessary for the control of the blood sugar (insulin, glucagon, adrenaline) and the organs supplying glucose (liver, kidneys, intestines). Since various tissues are in constant need of glucose, we must keep the rats alive by supplying them with external glucose in the form of an infusion. This is presented schematically in Fig. 13. We first select an infusion rate i which is equal to the consumption rate of glucose c, and the blood sugar level will remain constant. If we now double the infusion rate the blood sugar will rise. If the consumption rate c remained constant, the blood sugar would slowly rise to an infinite value. In actual fact however, after a certain

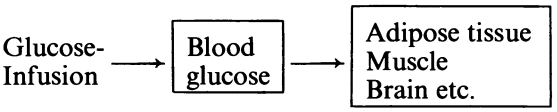

Fig. 13. Schematic representation of blood sugar control in an eviscerated rat infused with glucose

time the blood sugar adjusts itself to a new constant level (SOSKIN, 1937), because the rise in the blood-sugar level accelerates the reversible reaction

$$\begin{matrix}\text{Glucose} \\ + \\ \text{membrane} \\ \text{carrier}\end{matrix} \rightleftarrows \begin{matrix}\text{Glucose-} \\ \text{carrier} \\ \text{complex}\end{matrix} \rightarrow \begin{matrix}\text{intra-} \\ \text{cellular} \\ \text{glucose}\end{matrix}$$

from left to right, causing more glucose to be removed from the blood by the tissues. This simple control mechanism is due entirely to the law of mass action and is therefore named *passive control.* It can assure only incomplete homeostasis. To compensate for gross disturbances in a system, more sophisticated, *active* control mechanisms must be provided. These take the form of so-called feedback loops, which are of equal importance in electrical engineering and in the physiology of all living beings, including unicellular organisms. Fig. 14 shows

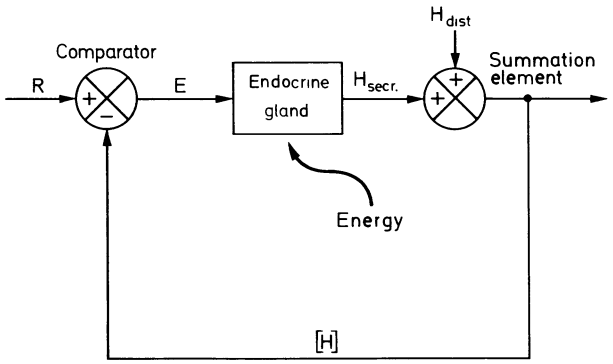

Fig. 14. Hypothetical endocrine system with negative feedback. The arrows indicate the direction of the signal flow. The symbols are explained in the text

a greatly simplified endocrine system with feedback control. Like all subsequent examples of physiological control systems, it is purely hypothetical and represents a simplification of the true conditions. This will apply in particular to the transfer functions that we shall assume to be linear, which is, however, only exceptionally true of physiological systems. The following symbols apply to Fig. 14:

H_{secr} = hormone secretion rate;
H_{dist} = external disturbance of system e.g. injection of exogenous hormone;

* I am grateful to Dr. ROLF ARNDT, Zurich, for his help in preparing this section.

$[H]$ = feedback signal, in this case hormone concentration which is a simple function of $H_{secr} + H_{dist}$;
R = reference input;
E = error signal.

We now apply the transfer functions of Fig. 15 to the control system of Fig. 14. The transfer function on the left indicates that simple subtraction of the feedback signal $[H]$ from the reference value R occurs at the comparator. The resulting signal E is converted into hormone secretion in the endocrine gland according to the transfer function on the right. Thus we have built a simple system with negative feedback and the hormone level in the blood will become stabilized at the reference value. Most endocrine systems are of course more complicated. In the control of the thyroid gland the error signal E acts on pituitary thyrotropin release. The latter process, however, is also under hypothalamic control by thyrotropin releasing hormone. We therefore have an additional transfer function in this system. Such complex systems retain negative feedback characteristics, provided the error signal abolishes or diminishes the effect of an external disturbance. Physiological feedback systems often function without apparent comparator elements and without reference values. We can cite the control of blood sugar by insulin as an example symbolized by the simple feedback loop of Fig. 16a. Despite the fact that comparator and reference values appear to be absent, the system possesses a functioning negative feedback. The desired blood levels of sugar and insulin are not determined by a reference input fed in from an external source, but derived from the equilibrium point of the entire system. This point corresponds to the point of intersection of the transfer function curves presented in a single diagram (Fig. 16b). In this example, the reference input is implicitly contained in the transfer functions.

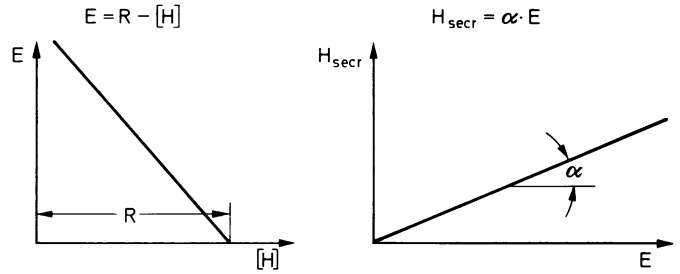

Fig. 15. Transfer functions of the system in Fig. 14. Left, transfer function of the comparator, and right, transfer function of the endocrine gland. α = constant. Meaning of remaining symbols as in Fig. 14

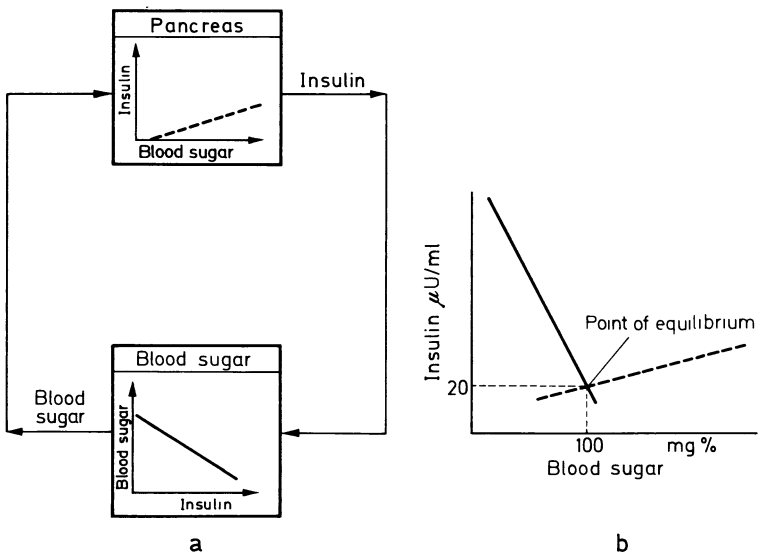

Fig. 16a and b. Control of blood-sugar level by insulin. a Diagram of a simple system with negative feedback. The transfer functions are indicated in the elements of the system. b Transfer functions of Fig. 16a drawn into a single system of coordinates. The point of intersection of the transfer functions gives the point of equilibrium of the control system. It corresponds to and replaces the reference value

Displacement of one transfer function also results in a change of the set-point of the system.

External energy must be supplied to any control system at least at one point of the feedback loop (see Fig. 14). This energy is required to amplify signals passing through the loop at one or several sites. Without this amplification of signals the feedback would be inoperative and the system would react to a disturbance like a system with passive control. To illustrate this statement we shall return to the example of blood-sugar regulation by insulin (Fig. 16), and disturb the system by infusing glucose. The blood-sugar level will change as shown in Fig. 17, where the following symbols are used:

ΔBS = theoretic elevation of blood sugar in the absence of feedback, e.g. following interruption of the feedback loop.

Δbs = actual elevation of blood sugar in the presence of functioning feedback, so-called residual disturbance.

The ratio $\frac{\Delta bs}{BS}$ is called minification. It is a good measure of the efficiency of a control system, since it indicates to what degree an external disturbance is compensated for by the feedback. The following relation is then valid:

$$\text{Minification} = \frac{\Delta bs}{BS} = \frac{1}{1 + A}\,*,$$

where A = signal amplification during passage through the whole loop;
= homeostatic index.

If $A = 0$, then the minification is 1. Any disturbance is therefore able to exert its full effect and the system behaves like a passive system without feedback.

If $A = \infty$, the minification is 0, and a disturbance is completely compensated for in the control system.

All the feedback systems mentioned so far have a *negative* feedback, i.e. the error signal works the opposite way to an external disturbance and diminishes its effects. For the sake of completeness, it must be mentioned here that systems with *positive* feedback are known to occur in electrical engineering as well as in physiology. They can be defined as unstable systems, since an external disturbance is amplified by the feedback and in theory grows infinitely. Infinite amplification of the disturbance is of course limited in fact by the amount of energy supplied externally and by other physiological factors of the system.

Systems with negative feedback can also become unstable when they begin to oscillate under certain conditions. Usually such oscillations are quickly attenuated, as is indicated for the blood-sugar curve shown in Fig. 17. Such

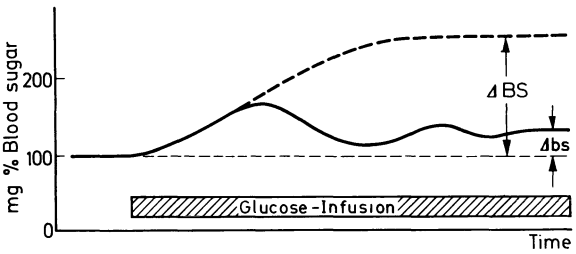

Fig. 17. Behavior of the blood-sugar level during an infusion of glucose, in the system shown in Fig. 16. The full line shows the behavior with functioning feedback, the dashed line shows the behavior with interrupted feedback, e.g. due to pancreatectomy. In the latter case the system reacts like one with passive control. See text for meaning of symbols

oscillations are due mainly to the *inertia* or time delay of a system. This delay is defined as the time needed for a signal to pass along the whole of the feedback loop. Returning to Fig. 14, we now postulate that in the endocrine gland the error signal E is converted into hormone release only after a delay of t seconds, because hormone biosynthesis requires a certain finite time. Hormone concentration $[H]$ will now always lag behind the error signal E by t seconds, as can be seen in Fig. 18 (two lower curves). Since the comparator element still executes the operation $E = R - (H)$ [or $R = E + (H)$], the system can start oscillating as shown in Fig. 18, where E and $[H]$ show a phase difference of 180°. The mathematical operation $E + [H]$ performed by the comparator always gives the required reference value R at any given time. In spite of the constant reference input our endocrine system now oscillates due to the postulated inertia of the endocrine cell*. Such oscillations arise in various physiological systems and even in unicellular organisms and in cell-free extracts. The phenomenon may be of importance in endocrinology since it may explain the female menstrual cycle. Although it is generally assumed that the periodicity of menstruation is controlled through a "clock" mechanism of the central nervous system, MILHORN (1966) put forward the idea that the menstrual cycle is the result of slow oscillations of a feedback system. ODELL's (1968)

* Refer to textbooks on control theory for the derivation of this formula.

* A more detailed analysis of conditions leading to oscillations of a system can be found in J. H. MILSUM (1966).

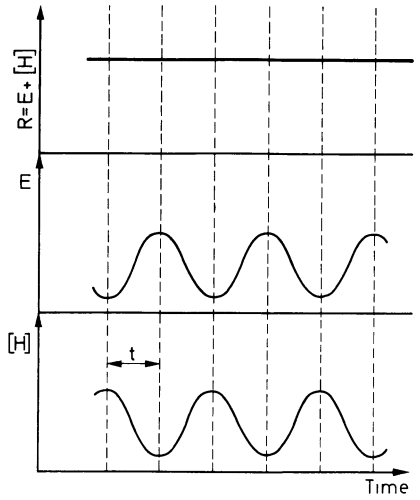

Fig. 18. Oscillations in the control system shown in Fig. 14. It has been postulated that the error signal E is converted into hormone secretion in the endocrine gland only after a latent period of t seconds. Thus, hormone release always lags behind the error signal E by t seconds, as can be seen in the two lower curves. The comparator executes the operation $E = R - [H]$ (or $R = E + [H]$), which gives the required constant reference input for any chosen time (upper curve). Meaning of symbols as in Fig. 14

experiments provide a good argument for this. He demonstrated that the periodicity of gonadotropin secretion disappears completely in castrated women. This may be taken to indicate that there is no central "clock" mechanism. Loss of the ovaries corresponds to interruption of the feedback loop. If the loop was artificially closed by administration of estradiol and progesterone in ODELL's experiments periodic release of gonadotropins recurred, indicating that the system had begun to oscillate again.

A number of endocrine control systems have now been mathematically analyzed and the corresponding model systems have been designed. The model of YATES (1968) for ACTH and corticosteroid secretion, which contains several feedback loops, has been tested in an analog computer and its performance so far has shown very good agreement to the physiologic system. Models of the control of ovulation in women (N. B. SCHWARTZ, 1969) and in rats (VAN DE WIELE, 1970) have also been published. It may be argued that these models are of no great practical value except for the amusement of the investigator. However N. B. SCHWARTZ (1969) has correctly pointed out that the mathematical formulation of the processes of endocrine feedback control has forced experimental endocrinologists to treat their data on a more exact and rational basis, instead of adopting the old semiquantitative and intuitive approach. The models have also helped in the planning of specific experiments to test assumptions made in the course of the model building. Although endocrine feedback model systems have so far had few consequences for the field of clinical endocrinology, any clinician looking at the models mentioned above will concede that endocrine feedback control is vastly more complicated than is usually thought. There is no doubt that the knowledge gained by these models will one day influence clinical endocrinology.

II. The Hypothalamus

A. LABHART

With Contributions by

CHR. HEDINGER, G. TÖNDURY, and G. KISTLER

A. Definition

The hypothalamus has a diameter of only 2.5 cm and makes up 1/300th of the weight of the brain. Nevertheless, this tiny organ coordinates and regulates most of the vital processes of life. Modulations are effected through neural and neuro-endocrine routes. The schema of HARRIS (Fig. 1) shows how the humoral substances secreted by neurons can affect the endorgans, with or without intervention of the endocrine system. The physiologic and clinical aspects of the hypothalamus will only be discussed in relation to their influence on the endocrine system, as befits a textbook of endocrinology.

The hypothalamus controls the endocrine system primarily through neurosecretions acting on the anterior pituitary. These are usually of a stimulatory nature (releasing factors), but may occasionally be of an inhibitory nature (inhibitory factors). However, in contrast to the neurohypophysis, there is only a conditioned dependence between the anterior pituitary and the hypothalamus, since the anterior pituitary can also produce hormones independently of the hypothalamus. It is probable that the anterior pituitary is also capable of certain autonomic control. On the other hand, the hypothalamo-neurohypophyseal system forms a uniform endocrine organ which is concerned with the regulation of the osmosis and volume of the body fluids. This system is discussed in a separate chapter.

B. Embryology and Gross Anatomy

G. TÖNDURY and G. KISTLER

In the human embryo, the anlagen of the forebrain (prosencephalon), midbrain (mesencephalon) and hindbrain (rhombencephalon) become distinguishable even before closure of the rostral end of the neural groove. When the brain becomes a closed tube, these three subdivisions develop into the primary brain vesicles. Early in the fourth week (when the length of the embryo is approximately 3 mm) a dorsal groove forms in the prosencephalic vesicle subdividing it into the telencephalon, with the primitive cerebral hemispheres, and the diencephalon, with the anlage of the eyes, i.e., the optic vesicles. In embryos 7–8 mm in length, the anlagen of the pineal gland (epiphysis) and the neurohypophysis appear as small outgrowths of the roof and the floor of the diencephalon, respectively.

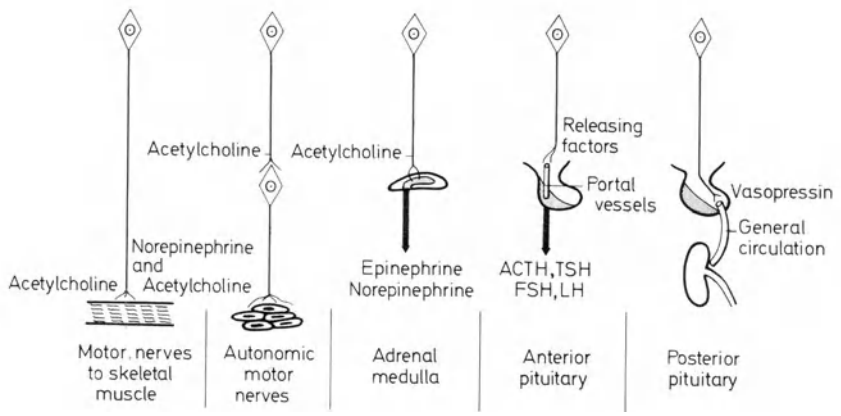

Fig. 1. Five situations in which humoral substances are secreted by neurons. The substances liberated in each case are indicated beside the nerve endings. (After HARRIS, from GANONG, in MARTINI and GANONG, 1966)

The Diencephalon can be divided into four more or less distinct major parts. The dorsally situated *epithalamus* (1) comprises the epithelial roof of the third ventricle, the striae medullares thalami, the habenular trigones and the pineal gland. The *thalamus* (2) extends basally to the sulcus hypothalamicus Monroi (sulcus diencephalicus ventralis). Its medial and lateral portions are separated from each other by the internal medullary lamina. Both contain a number of morphologically distinct nuclear masses. The *subthalamus* (3) or ventral thalamus is bounded dorsally by the thalamus, ventrally and laterally by the pars peduncularis of the internal capsule, and medially and rostrally by the hypothalamus. It includes the subthalamic nucleus, the zona incerta, the nucleus of the tegmental field of Forel, and, caudally, the rostral parts of both the substantia nigra and the red nucleus. The subthalamus is continuous with the tegmentum and the basilar portions of the mesencephalon and must therefore be considered as part of the extrapyramidal motor system. Because of its abundance of myelinated nerve fibers, the subthalamus can easily be distinguished from the *hypothalamus* (4) which contains mainly nonmyelinated nerve fibers and a much richer vascular network. The mamillary bodies, although usually considered as part of the hypothalamus, belong to the subthalamus. They receive myelinated fibers from the fornix.

The Hypothalamus comprises the lower parts of the ventral walls of the third ventricle as well as the structures of the ventricular floor (chiasma opticum, tuber cinereum and infundibulum). It is separated from the pars telencephalica of the third ventricle by a line connecting the optic chiasm with the posterior edge of the anterior commissure. Caudal and lateral to the hypothalamus is the subthalamus. An inferior view of the brain shows that the hypothalamus is bounded anteriorly by the optic chiasma, laterally by the optic tracts and posteriorly by the mamillary bodies.

The hypothalamus consists of a diffuse matrix of rather small cells which form the central gray substance. Within this matrix, a number of more or less well distinguishable nuclear masses (= nuclei) permit the hypothalamus to be divided morphologically into three regions: The *supraoptic region* (1) lies directly above the optic chiasma. It contains the supraoptic and paraventricular nuclei which are bridged by small groups of cells. Both these nuclei consist of large, often bipolar and dark-staining neurons which show cytoplasmic inclusions of colloidal material and peripherally distributed Nissl substance. The majority of their efferent nerve fibers make up the *supraoptico-hypophyseal tract*, which extends to the posterior lobe of the hypophysis. A minority of the axons, however, terminate within the nuclei themselves or within the infundibulum.

The central gray substance of the *tuberal region* (2) contains the nucleus tuberis infundibularis, the nucleus hypothalamicus ventromedialis and the so-called periventricular area. These nuclear masses consist of small, ovoid cells intermingled with some larger elements. They are the site of origin of the *tubero-hypophyseal tract*, most of whose nerve fibers terminate in close proximity to the specialized blood vessels of the hypophyseal portal system. This in turn extends to the sinusoidal capillary network of the anterior lobe of the hypophysis (see p. 81). Finally, a *lateral area* (3) of the tuber cinereum contains the tubero-mamillary nucleus and the lateral tuberal nuclei. Little is known about their nerve fiber connections.

The Blood Supply of the hypothalamus is ensured mainly by the anterior cerebral artery and the posterior communicating artery. Small branches extend from these vessels to form an intricate network within the nervous parenchyma. The supraoptic and paraventricular areas are characterized by a particularly dense capillary network which is supplied by branches of the anterior cerebral artery, more specifically the supraoptic-paraventricular arteries. The supraoptic nucleus also receives small branches from the superior hypophyseal artery.

The nuclear masses of the tuber cinereum share the general, less dense vascular network of the hypothalamus which is supplied partly by the anterior cerebral arteries and partly by the posterior communicating arteries. The blood supply of this region is therefore ensured by at least two large pairs of arteries which also supply the mamillary bodies.

The hypophysis itself receives its blood supply from the superior and inferior hypophyseal arteries which are branches of the internal carotid (see also p. 40). There are *no direct* connections between the vascular networks of the various hypothalamic nuclei and the hypophysis. The hypothalamic mechanisms controlling the activity of the hypophyseal anterior lobe are discussed on p. 81.

C. Physiology

Exogenous stimuli mediated by the sense organs, such as light and temperature, and endogenous signals from the autonomic nervous system and the psyche, are all received in the hypo-

thalamus by way of brain formations whose functions have been under investigation for the past few years. Complex connections exist between the hypothalamus and phylogenetically older parts of the brain (pyriform cortex, hippocampus, amygdala) and between the hypothalamus and phylogenetically newer parts of the brain (thalamus, mesencephalon) (NAUTA, 1963; DE GROOT, 1966). The pineal body probably also plays a part in this relationship (see p. 73f.). Intracerebral signals are transmitted neurohumorally via many carrier substances. These substances include acetylcholine (cholinesterase), noradrenaline, dopamine, serotonin, and melatonin, all of which are found in varying concentrations (see SHUTE, 1966; MARTINI, 1970; YATES, 1971). These neurotransmitter substances act on the releasing or inhibiting hormone-producing neurons, the "transducer" neurons, which reside in the "hypophysiotropic" area in the ventral hypothalamus. They extend their axons into the median eminence, where the releasing factors are secreted into the capillaries of the primary portal plexus. The neurosecreting neurotransmitters can be influenced by a variety of pharmacologic agents, such as reserpine, phenothiazines, tricyclics and amphetamines, in a complex manner which has not yet been fully explained, so that the releasing hormones and endocrine functions can be manipulated by these drugs (FROHMAN, 1972).

The blood levels of cortisone, thyroxine, triiodothyronine and the gonadal hormones also act as proprioceptive stimuli. They are perceived by the hypothalamus as a negative "feedback" mechanism, and form a connecting link in the controlling system: hypothalamus-anterior pituitary-peripheral endocrine glands.

The precise site of this registration of blood level in the brain has not yet been localized, although stereotaxic lesions and implantations of hormone crystals have been used in attempts at more exact definition. RUF and STEINER have succeeded in using a microelectrophoretic technique to place minute amounts of hormone in the immediate extracellular surroundings of single neurons in the rat's brain. Action currents were registered by microelectrodes with a diameter of 1–3 μm. Injections in the cortex, hippocampus, and thalamus had no effect. On the other hand, neurons in the upper central gray matter around the 3rd ventricle reacted immediately with cessation of activity. The neurons registering the cortisol concentration either produced CRF or functioned as collators controlling other effector neurons (RUF, 1967) (see Chap. VII, p. 299). The feedback mechanism of the individual peripheral hormones is discussed in the chapters dealing with the endocrine organs (see p. 148, 299, 452). It is possible (MARTINI, 1968), but still not certain (MCCANN, 1969), that the pituitary adenotropic hormones also exert a direct "feedback" effect ("short loop") on the hypothalamus (SZENTOGATHAI, 1961).

The hypothalamus receives the exteroceptive and proprioceptive stimuli, registers metabolic processes (osmolality, glucose concentration, the "feedback" mechanism of hormones), integrates and coordinates these factors, and controls seven vital functions via neural and endocrine routes. The functions are:

1. Energy balance,
2. Fluid balance,
3. Heat regulation,
4. Activity and sleep,
5. Circulation and breathing,
6. Growth and maturation,
7. Reproduction.

On one hand, the hypothalamus regulates homeostasis by means of these functions. On the other hand, simple neuroendocrine reflexes (stress-ACTH, suckling reflex-milk ejection, reflex ovulation in certain mammals and birds), or complex neuroendocrine responses to rhythms of long or short duration (day-night, seasonal) also take place within the hypothalamus (ROTHBALLER, 1966).

W. R. HESS has ascribed individual functions to certain areas in the hypothalamus. Thus, destruction of certain regions can cause loss of individual functions, and correspondingly, although rarely, other functions may be stimulated. However, electric, physical and chemical stimuli induce different functions and seldom inhibit them. Atlases are available giving the localization of such experimentally defined areas.

Energy balance and the nutritional intake are regulated by an appetite and satiation center. It is still not certain if these centers respond directly to the arteriovenous difference in blood sugar, to the concentration of free fatty acids, to the insulin content, or to the content of growth hormone in the blood.

Growth and maturation are closely connected with the regulation of energy exchange. Fluid intake and output are closely related to osmoregulation and volume regulation and are controlled by the thirst and osmoregulation centers (FITZSIMONS, 1972). There are areas which can influence sleep, circulation, breathing and body temperature. Finally, maturation, ovarian and testicular function and lactation. which are functions connected with reproduction, are regulated by different areas depending on the animal species. Experimentally-produced

lesions of certain areas can give rise to characteristic syndromes. A summary of these, taken from AKERT, is given in Table 1.

These experimentally definable areas coincide to some extent with morphologically demonstrable formations, but there is a great degree of overlap. HESS denies the concept of single regulation centers. It is not by chance that heat regulation, thyroid function, onset of puberty and ovulation are all controlled by the same area. Endocrine functions are controlled by zones or functional units in the sense of a syncytium rather than by individual neurons each with certain specific actions.

Table 1. Experimentally produced hypothalamic syndromes. (After AKERT, 1959)

	Syndrome	Histological localization	Nature of manifestations 1 = failure 2 = stimulation
Anterior hypothalamus	1. Diabetes insipidus	Supraoptical and paraventricular nuclei	1
	2. Failure of temperature regulation, hyperthermia	Region of the anterior hypothalamic nucleus	1 and 2
	3. Hemorrhagic pulmonary edema	Preoptical medio-ventral area	2
	4. Insomnia, hyperactivity, excitability and manic states	Suprachiasmatic area (?)	2
Tuber cinereum	1. Obesity (hyperphagia)	Region of the ventro-medial hypothalamic nucleus	2
	2. Genital dystrophy	Ventral nucleus of the tuber, infundibular nucleus (?)	1

Posterior hypothalamus	1. Hypersomnia, coma	Latero-dorsal zone	1
	2. Poikilothermia	Latero-dorsal zone	1
	3. Anorexia	Lateral hypothalamus adjacent to the cerebral peduncle	1
	4. Pubertas praecox	Infundibular-mammillary region	2 (?)
Ill-defined areas	1. Gastro-intestinal ulcers	Medial basal hypothalamus with extensive longitudinal diffusion	?

The hypothalamus exerts its control on the functions, on the one hand by neurosecretions, and on the other by way of the autonomic nervous system, which also affects the motor nervous system indirectly. Two types of hypothalamic neurosecretion can be differentiated. The paraventricular and supraoptic nuclei produce vasopressin and oxytocin together with a carrier substance, and they are released through the neurohypophysis into the blood of the greater circulation. In addition, polypeptide neurohormones formed or stored in the eminentia mediana reach the blood stream of the pituitary portal system and arrive in the anterior pituitary where they exert a limited local effect (Fig. 2). Fig. 1 (by HARRIS from GANONG, 1969) demonstrates how information from neurons can be transmitted to the endorgans with or without involvement of the endocrine system.

The neurosecretions of the hypothalamo-neurohypophyseal system have been chemically identified and synthesized, and their mode of release is largely known, but we are only beginning to understand the process of hypothalamic regulation of the anterior pituitary by means of neurohormones. It is currently assumed that eight different specifically acting neurohormones are formed within an area of nervous tissue only a few mm in diameter. The existence of other hypothalamic hormones has been suggested but is still not proven. Release of TSH, ACTH, STH, FSH, and LH is stimulated, whereas release of the melanocyte-stimulating hormones (MSH) and prolactin is inhibited. The structures of the thyrotropin-releasing hormone (TRH), luteinizing-hormone releasing hormone (LRH), growth-hormone-releasing hormone (GRH), and melanocyte-stimulating hormone release-inhibiting hormone (MIH) are already known and their synthesis has been accomplished. The existence of a prolactin-inhibiting factor (PIF) is well documented; its nature, however, is not yet known. The existence of GIF (growth-hormone in-

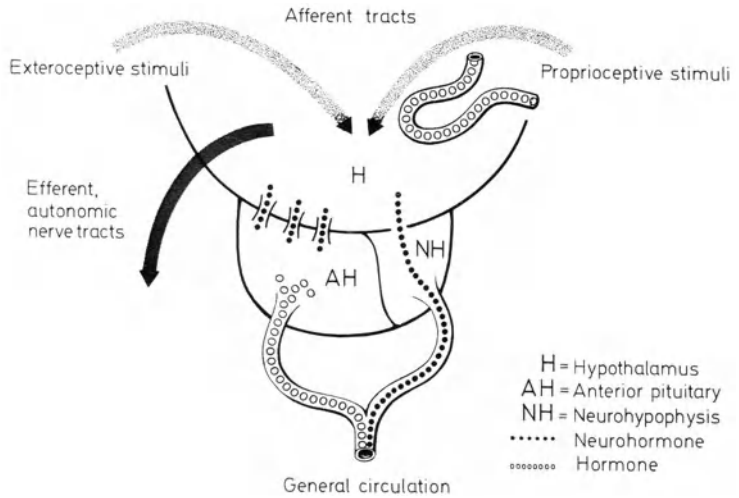

Fig. 2. The hypothalamus as a nervous and neuroendocrine coordination and regulating centre

hibiting factor)*, MRF (melanocyte-stimulating hormone-releasing factor) (McCann, 1969) and PRF (prolactin-releasing factor) has still to be confirmed (Table 2).

Table 2. Neurohormones of the hypothalamus (1973)

Circulating in the anterior pituitary portal system Local actions		Circulating in the greater circulation Distal organic effect
Structure known, compound synthesized		
TRH	Thyrotropin-releasing hormone	
LRH	Luteinizing hormone-releasing hormone	
MIH	Melanocyte-stimulating hormone release inhibiting hormone release-inhibiting hormone	Vasopressin
		Oxytocin
GRH	Growth hormone-releasing hormone	
GIF (GRIH)	Growth hormone release-inhibiting factor	
Existence proven or very probable		
CRF	Corticotropin releasing factor	
FRH	Follicle-stimulating hormone-releasing hormone	
PIF	Prolactin-inhibiting factor	
Existence to be confirmed		
MRF	Melanocyte-stimulating hormone-releasing factor	
PRF	Prolactin-releasing factor	

For more details on the biochemistry, physiology, and pathophysiology of the various hypothalamic releasing hormones see chapters dealing with the different endocrine glands. Whereas the isolation of CRF has not yet been accomplished despite a decade of research (it is still an open question whether the highly purified α_1-CRF, α_2-CRF and β-CRF isolated from neurohypophyses are identical to hypothalamic CRF) (Guillemin, 1964), in 1969 there was a breakthrough in the field of TRH. Out of hundreds of thousands of ovine and porcine hypothalami, it proved possible to extract a few mg of a substance which had a specific TRH-activity *in vivo* in the nanogram range, and *in vitro* in the picogram range. Pyroglu-his-pro-NH_2 (Gillessen, 1970) (Fig. 3) has

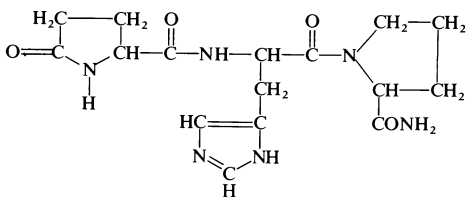

Fig. 3. The thyrotropin releasing hormone

been synthesized; it has practically the same effects and the same physicochemical properties as the purest preparations of TRH from ovine (Burgus, 1970) and porcine (Bowler, 1969) hypothalami, and is apparently identical to TRH. Pyroglutamilhistidylproline-amide is effective when given by the i.v. and i.p. routes in mice and rats, and by the oral and i.v. routes in man, causing a rapid increase in TSH (Hall, 1970). It is inactivated in human plasma at 37° C and is inhibited *in vivo* by triiodothyronine.

Besides nausea, flushing, and a desire to micturate after rapid intravenous injection, no

* In 1973 GIF (GRIH, Somatostatin) has been found to be a decapeptide and has since been synthetized (Schally, 1973; Brazeau, 1973).

serious side effects have been observed. TRH acts specifically on the release of TSH, with the exception of an occasional increase in output of luteinizing hormone and prolactin. TRH allows measurement of the TSH reserve of the pituitary (for different tests and possible therapeutic uses see Chap. VI, p. 242).

LRH is a decapeptide (BABA, 1971) causing a rapid release of LH in animal and man, and to a lesser extent, FSH. Its structure is Pyro–Glu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2. For tests and therapeutic implications see Chap. IX and X.

GRH has very recently also been shown to be a decapeptide (SCHALLY, 1972) and has already been synthesized (VEBER, 1971). Its diagnostic and therapeutic use has yet to be investigated.

Finally, the structure of MIH has been revealed as tripeptide with the identical amino acids of the C-terminal of oxytocin 1–pro–1–leu–gly–NH_2 (NAIR, 1971).

The neurosecretions controlling the anterior pituitary seem to be formed or accumulated (MARTINI, 1968) in the median eminence, which has led to the suggestion of the term "median eminence-gland" (REICHLIN, 1966).

Receptors regulating the release of pituitary hormones seem to be situated within this small tissue area (MARTINI, 1969). There is evidence that these neurohormones are not only releasing factors, but are also concerned with the formation of hormones in the hypophyseal cells and the growth of these cells. TRH and LRH do not need protein formation for their effect, and it is not blocked by inhibition of RNA or protein synthesis. They act rapidly, mainly by depolarization of the cellular membrane with subsequent Ca^{++} uptake (MCCANN, 1969). There is always a basal secretion of growth hormone, and only its additional release is controlled by the hypothalamus. In contrast, however, the gonadotropic hormones dry up completely in the absence of hypothalamic stimulation. It is assumed that prolactin is regulated through a special mechanism. After section of the hypophyseal stalk, secretion of all the pituitary hormones decreases, with the exception of prolactin which increases and results in galactorrhea. Drugs such as chlorpromazine, which exert an inhibitory effect on the brain stem can also result in the secretion of milk. It is assumed that there is a hypothalamic inhibitory factor "PIF" (prolactin inhibitory factor) (SCHALLY, 1968) whose removal results in a release of prolactin and secretion of milk. It has been stated that there is a prolactin-releasing factor in birds (SCHALLY, 1968). An interesting phylogenetic interpretation is that the hypothalamic releasing factors were originally hormones and regulated the original primitive gut from which the anterior pituitary has developed (HAMMERSCHLAG, 1966).

The hypothalamus forms part of the endocrine system. The anterior pituitary was formerly considered the conductor of the endocrine orchestra but the hypothalamus has now taken over the bâton and the anterior pituitary has been relegated to the position of first violin. The hypothalamus regulates four important endocrine organic systems – the adrenals, the thyroid gland, the gonads, and the growth hormone. This is discussed separately in the appropriate chapters. Only a survey of hypothalamic function within the endocrine system is intended here. The subject of neuroendocrinology is in a state of rapid development and has become an independent specialty beyond the scope of a textbook of endocrinology.

D. Pathology and Clinical Features of Endocrinopathies due to Hypothalamic Involvement

Lesions in the region of the hypothalamus and in neighboring areas can lead to endocrine disorders and syndromes when the hypophysis is not destroyed, as can dysfunction with no morphological substrate.

The diagnosis is difficult and can only seldom be made during life. The lesions may be small and clinically undetectable, or the destruction may be so extensive that neurological symptoms dominate the clinical picture. Furthermore, it is usually only symmetrical lesions that lead to endocrine failure. The early stages of the hypothalamic diseases are better suited to endocrine evaluation, and sometimes only the history indicates that the illness has arisen in the hypothalamus.

The neuroendocrine diseases are most often caused by tumors, such as various types of gliomas, astrocytomas, craniopharyngiomas, ectopic pinealomas, and sometimes suprasellar pituitary adenomas and meningiomas. Inflammatory changes due to basal meningitis and in particular to tuberculosis (COURVOISIER, 1960) and syphilis are now extremely rare. Chronic inflammations, such as granulomas in sarcoidosis, lymphgranulomas, leukemia or thesaurismosis, are also uncommon causes. Damage to the hypothalamus resulting from accidents or vascular aneurysms is also rare.

The symptoms are determined by the localization and the extent of the lesion.

Suprasellar lesions of the infundibulum and the stalk interrupt the hypothalamic control

of the anterior pituitary. See Chap. III, p. 50f. for the disorders of vasopressin and oxytocin secretion. Secretion of the gonadotropins fails completely with the exception of prolactin, which is secreted in increased amounts (failure of PIF, see p. 106). A basal secretion of growth hormone, ACTH, and TSH is retained but is usually uninfluenced by hypothalamic stimuli such as hypo- and hyperglycemia, stress, and variations in the hormonal "feedback" mechanism (inhibition test, methyrapone test).

The clinical picture corresponds to complete or, more frequently, to partial hypopituitarism.

If the lesions are situated high up, as in the case of an ectopic pinealoma, all the axons are interrupted, and their nuclei of origin may be destroyed [*B* in Fig. 4 (ROTHBALLER)]. All the releasing factors are lost. This leads to complete hypogonadism, partial adrenal, thyroid and growth hormone failure, and usually to diabetes insipidus, possibly associated with a simultaneous disturbance of the thirst center.

Deeper-lying lesions such as occur particularly after surgical section of the stalk or with a craniopharyngioma, and occasionally after traumatic lesion of the hypophyseal stalk lead predominantly to destruction of the portal venous system. This usually results in more or less extensive infarction of the anterior pituitary. The releasing factors are still produced, but their relay system is interrupted. The portal system is, however, capable of regeneration providing no foreign bodies are inserted. Neurosecretions continue to be produced. Diabetes insipidus is usually mild, and may be only temporary. The hypopituitarism is of varying severity, usually not very marked, and can regress. The adrenocortical reaction to fever and hypoglycemia can be retained, even when regeneration is hindered by the insertion of metal plates (VAN WYK, 1960).

Partial hypopituitarism, especially secondary hypogonadism, develops in the presence of incomplete lesions [*D* in Fig. 4 (ROTHBALLER)]. The circadian rhythm of the adrenal cortex may be retained or lost. The methyrapone test is sometimes normal and sometimes pathologic.

Galactorrhea, often associated with amenorrhea and uterine atrophy (the Chiari-Frommel syndrome, see p. 592), is characteristic of incomplete infundibular lesions. Failure of the PIF (prolactin inhibiting factor, see p. 106) leads to increased prolactin secretion. A certain basal secretion of growth hormone, ACTH, and gonadotropins must, however, be present for lactation to occur. Galactorrhea typically arises with the introduction of substitution therapy after surgical division of the stalk.

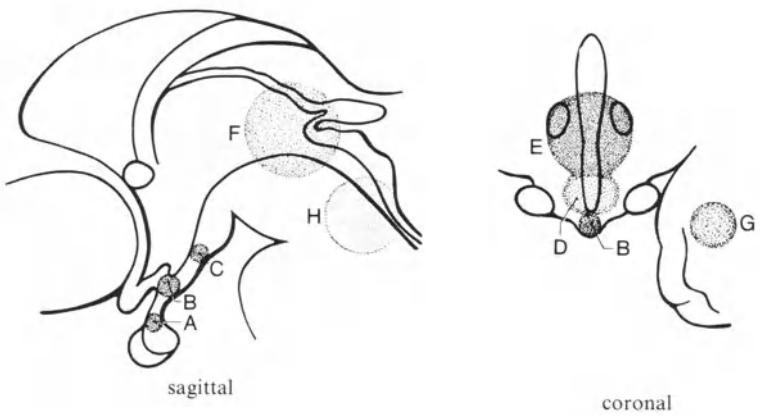

Fig. 4. Lesions of the CNS resulting in endocrinopathies. (After ROTHBALLER, Bull. N. Y. Acad. Med. **42**, 258)

Pressure effects due to the neighboring structures without interruption of the infundibular tracts result in para-infundibular lesions (ROTHBALLER, 1966) [*C* in Fig. 4 (ROTHBALLER)]. This lesion leads to failure of the "feedback" mechanism and loss of homeostasis. Pubertas praecox may then develop (Chap. XIX). These lesions are caused particularly frequently by hamartomas, but any space-occupying processes, including hydrocephalus of the third ventricle, may be causal factors.

The neuroendocrine reflex mechanisms are disturbed in intrahypothalamic lesions. Menstruation becomes disorganized in the presence of ovarian secretion. The gonadotropins are reduced to the greatest extent, TSH to a lesser extent, and ACTH least of all. There is a characteristic combination with disturbances of

emotions, consciousness, energy balance, waking-sleeping rhythm and temperature regulation [*E* in Fig. 4 (ROTHBALLER)]. Lesions outside the hypothalamus, such as lesions of the limbic system or of the brain stem and in the temporal lobes, can also inhibit the circadian rhythm of the adrenocortical secretions. These lesions are often accompanied by epileptic fits. The dexamethasone inhibition test and the methyrapone test are often pathologic. The response of the pituitary-adreno-cortical system to stress is lost in lesions of the afferent nerve tracts or of the stalk, and in particular, in lesions of the reticular formation.

But recently, endocrinopathies with none of the lesions detectable by the morphological methods currently available have become known. Most congenital cases of partial or complete hypopituitarism are probably of hypothalamic origin due to a deficiency of different releasing hormones. Growth-hormone deficiency causing dwarfism (see Chap. V, p. 98) is the most common of this group and ACTH deficiency the rarest. Hypothalamic rather than pituitary origin has to be postulated for many forms of hypgonadotropic hypogonadism (MARTIN, 1972; editorial 1972).

Conversely, as soon as sensitive assays sufficiently sensitive for releasing hormones become available, it will be possible to test the hypothesis that diseases of pituitary hyperfunction, such as certain types of Cushing's syndrome or acromegaly, may result from a primary hypothalamic disturbance.

E. Diagnosis of Hypothalamic Endocrinopathies

Endocrinopathies occurring together with certain neurological manifestations suggest a hypothalamic cause. Homonymous or temporal loss of vision occurs in a third of cases. Atrophy of the optic nerve with central scotomas and damage of the abducens and oculomotor nerves may also occur. Lesions in the anterior hypothalamic region may give rise to the Foster-Kennedy syndrome, characterized by homolateral papillary atrophy, anosmia, and contralateral papilledema. Cranial growth may give rise to impairment of thalamic sensation or even to pyramidal signs. Pleocytosis in the cerebrospinal fluid is suggestive of a pinealoma. Confirmation of the diagnosis is possible by stereotaxic tumor puncture. A series of observations of 100 patients gives an indication of the incidence of neurological disorders of this kind occurring in association with endocrinopathies due to hypothalamic lesions verified at post mortem (BAUER, 1959). Lesions of the hypothalamus are indicated particularly by the following nine symptoms or groups of symptoms: 1. Psychic disorders, especially affective disorders such as acute exogenous reaction type (outbursts of temper, compulsive laughing and crying). 2. Hypersomnia. 3. Obesity due to bulimia. 4. Loss of weight due to lack of appetite. 5. Polydipsia or adipsia. 6. Disorders in temperature regulation (fever or subnormal temperatures). Hypothalamic fever is not accompanied by leukocytosis or malaise, and it responds to sedatives which act on the brain stem. 7. Disorders of the autonomic nervous system (vegetative attacks, autonomic epilepsy). 8. Diabetes insipidus, especially if associated with hypopituitarism. 9. Pubertas praecox (Chap. XIX).

It is, however, often difficult or impossible to differentiate whether such symptoms, in particular hypersomnia, obesity, or loss of weight, are due to organic hypothalamic lesions, or whether changes in character lead to bulimia or anorexia. There are no or only isolated examples of obesity in the human due to hypothalamic lesions which have been verified at post mortem (LIPSETT, 1962).

Various tests can be of use in the differential diagnosis between hypopituitarism, partial hypopituitarism, or hypothalamic endocrinopathies.

The vasopressin test (see p. 388) should theoretically differentiate between failure of the adrenal cortex caused by hypothalamic failure and that caused by pituitary failure until purified CRF preparations are available. If the lesion lies in the hypothalamus, the plasma and urinary levels of corticoids rise under the influence of the vasopressin infusion. This rise does not occur in pituitary insufficiency. The TRH-test and the LRH-test have the same implications.

If the plasma or urinary steroid level is unaltered or not significantly reduced, certain concomitant signs indicate disturbances in the hypothalamic regulation system. These are: a pathological circadian rhythm (KRIEGER, 1966), a pathological dexamethasone inhibition test, and a pathological methyrapone test in the presence of an intact pituitary gland (HOKFELT, 1959; OPPENHEIMER, 1961). Failure of the adrenals to respond to stress, caused for example by a pyrogen injection in the presence of intact pituitary and adrenal glands, and failure of the levels of growth hormone and of the plasma corticoids to rise in response to hypoglycemia (see p. 123), are further indications of a hypothalamic disorder (BETHGE, 1967; LANDON, 1966; GREENWOOD, 1966). Whether the absence of a rise in the aldosterone level in response

to removal of salt is a sign of hypothalamic disorder (HÖKFELT, 1959; KRIEGER, 1966) has yet to be proven. The results of these tests are not only pathological in hypothalamic endocrinopathies, but also in ectopic hormone formation (paraneoplastic endocrine syndrome see Chap. XVI).

Often, however, when the tumors cannot be diagnosed by radiological and isotopic methods, the clinician can only suspect the etiology to be in the hypothalamus. Stereotactic biopsy sometimes provides evidence, otherwise the diagnosis can only be confirmed at operation or from the post-mortem findings. Irradiation and surgery can hardly be considered as therapeutic measures without positive radiological findings. However, where there is endocrine failure such as a partial or complete hypopituitarism due to hypothalamic lesions, substitution therapy must always be instituted.

F. Special Syndromes

1. The Tuberal Form of Dystopia of the Posterior Pituitary Lobe results in the interruption of the hypothalamic neurosecretion into the anterior pituitary, giving rise to hypopituitarism (see p. 104).

2. The Syndrome of Gigantism with acromegalic features occurring during childhood, accompanied by oligophrenia, macrocephaly, and coordination disorders, is assumed to be due to impaired regulation of the secretion of growth hormone resulting from brain injuries sustained at birth (SOTO, 1964). See Chap. XIX for Froehlich's syndrome.

3. The Laurence-Moon-Biedl Syndrome is a degenerative syndrome with inconstant manifestations of endocrine failure, such as diabetes insipidus. Hypogonadism can be of a primary or secondary nature. It is not consistent and is probably due to defects of the central nervous system. The disorder is hereditary, and is probably transmitted through a monohybrid simple recessive gene, though the pathogenesis of the condition is disputed. A reduction in the number of ganglion cells in the hypothalamus was thought to be found in a few of 6 cases confirmed at post mortem.

4. Albright's Syndrome was originally described as polyostotic fibrous dysplasia (Jaffe-Lichtenstein's disease) with pubertas praecox especially in females and patchy skin pigmentation. The bone lesions, often involving facial bones, tend to be unilateral as do the brown, non-elevated skin areas on the same side. Other endocrinopathies have since been observed in this syndrome: goiter and/or hyperthyroidism, acromegaly, Cushing's disease, gynecomastia and acceleration of skeletal growth without overt precocious puberty (HALL, 1972). Premature secretion of FSH and LH has been reported. The euthyroid or toxic goiters show evidence of long-standing hyperplasia without the lymphocytic infiltrations characteristic of Grave's disease but suggestive of abnormal TSH stimulation. True acromegaly has been proven in at least one case, although the facial deformities may mimic the aspect of acromegaly. The observed case of Cushing's disease was of the hypothalamic type. Pituitary histology indicated hyperplasia and no tumor formation. These observations suggest a hypothalamic origin of these endocrinopathies via increased secretion of the corresponding releasing hormones. In the few cases which have been verified at post mortem, the hypothalamus was sometimes found to be intact; however, in one case the mamillary body was smaller than normal, and an additional nucleus was present in the neighboring tissue. Originally the hypothalamic dysfunction was explained by pressure through hyperostoses on the base of the cranium, but although thickening of the cranial base can often been seen radiologically, there are endocrinopathies in cases where the base of the skull is not involved. Thus the endocrine manifestions probably result from a still undetermined hypothalamic disorder.

III. The Hypothalamo-Neurohypophyseal System

A. LABHART

With Contributions by

G. TÖNDURY and G. KISTLER

A. Historical Dates

1794 J. P. FRANK distinguished diabetes insipidus from diabetes mellitus.
1895 OLLIVER and SCHÄFER produced an extract from the pituitary which caused a rise in blood pressure.
1910 A. FRANK associated diabetes insipidus with a hypofunction of the posterior pituitary.
1913 CAMUS and ROUSSY produced diabetes insipidus in dogs by hypothalamic lesions, without injury to the pituitary.
1913 FARMI and VON DEN VELDEN established the therapeutic effect of extracts of the posterior pituitary in diabetes insipidus.
1948 VERNEY showed that the activity of the hypothalamic-neurohypophyseal system was regulated by the osmotic concentration of the blood in the hypothalamus.
1953/55 DU VIGNEAUD isolated and synthesized vasopressin and oxytocin.

B. Embryology, Gross Anatomy and Histology

G. TÖNDURY and G. KISTLER

1. The Neurohypophysis

The hypophysis has two major subdivisions which differ fundamentally in embryology, morphology, and function. The *adenohypophysis* is derived from a dorsal outpocketing of the ectodermal buccopharyngeal region. It demonstrates all the characteristics of an endocrine gland. Some aspects of its development and anatomy are discussed in Chap. V, p. 77. The *neurohypophysis* originates from the diencephalon. In the 7–8 mm-long human embryo, the neurohypophyseal anlage appears first as a thickening of the diencephalic floor. From this, a compact epithelial process grows downward behind the anlage of the adenohypophysis and develops into infundibulum and neural lobe.

Gross Anatomy. The fully developed neurohypophysis (see also p. 78) has three subdivisions: 1. The *infundibulum* (neural stalk, pars proximalis of the neurohypophysis) extends from the floor of the diencephalon down to the diaphragma sellae of the sphenoid bone. It forms the *neuro*hypophyseal portion of the hypophyseal stalk. Its boundary towards the tuber cinereum is given by the hypothalamo-hypophyseal sulcus (sulcus tuberoinfundibularis). At the root of the infundibulum, the third ventricle evaginates to form the infundibular recess (Fig. 1). The *median eminence*, a funnel-shaped extension of the tuber cinereum, must morphologically and functionally be considered as part of the infundibulum. 2. The *infundibular stalk* is the border area between infundibulum and neural (posterior) lobe. It contacts with both the pars tuberalis and the pars intermedia of the adeno-

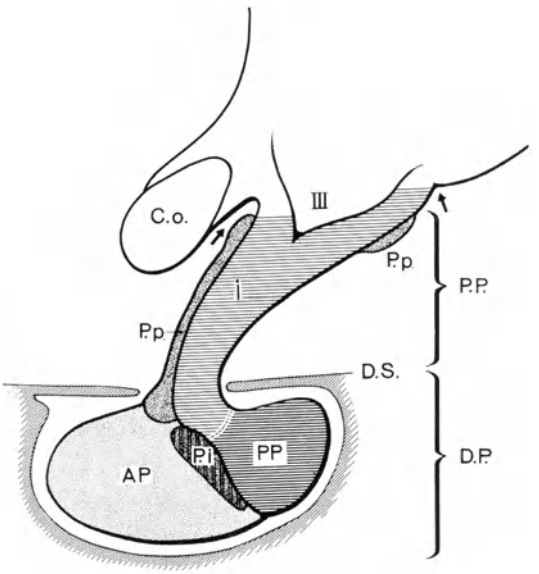

Fig. 1. Part of the pituitary of the adult man. Scheme with reference to ENGELHARDT (1968). *P.P.* proximal suprasellar pituitary; *D.P.* distal, intrasellar pituitary; *I* Infundibulum; *P.p.* pars infundibularis adenohypophysea; *D.S.* diaphragma sellae; *AP* anterior pituitary; *P.i.* pars intermedia (intermediate lobe); *PP* posterior pituitary; *C.o.* chiasma opticum; *III* third ventricle with recessus infundibuli. The darts indicate the sulcus hypothalamo-hypophyseus

hypophysis. The *infundibular process* (3) (neural lobe, pars distalis of the neurohypophysis) is lodged within the sella turcica of the sphenoid bone, adjacent to the pars intermedia of the adenohypophysis.

Blood Supply. The hypophysis is supplied by the left and right *superior* hypophyseal arteries which arise from the internal carotids near the origin of the ophthalmic arteries. Each superior hypophyseal artery divides into an anterior and a posterior branch (anterior and posterior superior hypophyseal artery, respectively). In the median eminence, the *anterior* branches form characteristic capillary loops which drain into the hypophyseal portal vessels. These in turn supply the sinusoidal capillary network in the adenohypophysis (see also p. 82). The anterior branches also supply the upper parts of the pars infundibularis of the adenohypophysis and, in addition, give rise to a small trabecular artery which passes directly into the anterior lobe where it anastomoses with the inferior hypophyseal artery. The *posterior* branches break up into a capillary network within the infundibulum. The region of the tuber cinereum receives additional blood from branches of the posterior communicating arteries. The neural lobe and the lower portions of both the infundibulum and the pars infundibularis of the adenohypophysis are supplied by the *inferior* hypophyseal arteries. These are also branches of the internal carotids and anastomose with the trabecular arteries. The *venous blood* is conveyed by capsular veins of the hypophysis into the anterior and posterior intercavernous sinuses which drain into the cavernous sinus. Thus, the hypophysis is surrounded by large blood channels anteriorly, posteriorly, and bilaterally (circular sinus).

Intra- and suprasellar portions of the hypophysis are in close proximity to vital brain structures and blood vessels. Through the foramen hypophyseale of the diaphragma sellae, the sella turcica of the sphenoid bone opens into the middle cranial fossa. The lateral wall of the dura mater lining the sella is also the middle wall of the cavernous sinus. The hypophyseal stalk, which connects the intrasellar portions of the hypophysis with the hypothalamus, is situated immediately beneath the optic chiasma. Although morphological variations of the chiasma are frequent, its close spatial relationship to the hypophyseal stalk is a constant feature. Tumors of the adenohypophysis can damage the decussating nerve fibers in the chiasma and lead to bitemporal hemianopsia. The proximal part of the infundibulum of the neurohypophysis encloses the infundibular recess of the third ventricle (Fig. 2) and thus gains close connections with the ventricular system of the brain. In the region of the perinfundibular cistern, the hypophyseal stalk is also surrounded by cerebrospinal fluid. In addition, the infundibulum lies in the center of the arterial circle of Willis and in close proximity to the small but numerous arteries of the olfactory area. This area joins the infundibulum rostrally and laterally. Finally, the tuber cinereum and the two mamillary bodies are also situated close to the infundibulum.

Histology. In routine histological sections, the neurohypophysis appears as a mass composed of innumerable ill-defined fibers, among which a rather heterogeneous population of cells is distributed. In sections stained with silver salts, a fine network of argyrophilic fibers is found to surround the blood vessels branching within the organ. Like the adenohypophysis, the neurohypophysis is enclosed by a relatively thick connective tissue capsule. From this capsule, a thin septum rises between the anterior and posterior lobe (pars intermedia) towards

the brain. This boundary may in parts be erased by a penetration of basophilic cells from the pars intermedia of the adenohypophysis into the posterior lobe.

The neurohypophysis contains two major elements. The bulk of its substance is made up of about 100000 *unmyelinated nerve fibers*, whose cell bodies are located in the hypothalamus. Distributed among these fibers are the *pituicytes*, which vary greatly in shape and size. Due to their structural relation to the axons, these cells must be considered as a special form of the neuroglia. They commonly contain various amounts of pigment granules. A broad perivascular space bounded on all sides by a basal lamina separates the nerve fiber endings and the pituicyte processes from the network of blood capillaries with fenestrated endothelia. Light microscopy reveals the characteristic strongly positive PAS-reaction of this perivascular area, which indicates the presence of large amounts of mucopolysaccharides. In the electron microscope, finger-shaped ramifications from this space can often be traced for a good distance between the axons and the pituicytes.

2. The Hypothalamo-Neurohypophyseal Connections

The axons comprising the major part of the neurohypophyseal mass collectively form the hypothalamo-neurohypophyseal tract. Its cell bodies (perikarya) are located mainly within the supraoptic and paraventricular nuclei, whereas other hypothalamic nuclear masses apparently contribute only a few nerve fibers. The axons pass via the infundibulum and the infundibular stalk to reach the posterior lobe where they terminate in intimate contact with the capillaries. When special staining methods (e.g. aldehydefuchsine) are used, variously sized, intensively staining masses can be recognized in both the cell bodies of the hypothalamic nuclei and in their axons. These are the so-called *Herring bodies*. In the electron microscope, these bodies have been found to be locally dilated portions of the axons where granules are densely packed with mitochondria and other cell organelles. The granules are thought to contain the hormones synthesized on the granular endoplasmic reticulum (Nissl substance) and bound to a carrier protein in the Golgi complex. They are carried along the entire length of the axons into the posterior lobe. In addition to these neurosecretory granules with a diameter of about 100 to 200 nm, the nerve fiber endings also contain smaller vesicles of about 40 nm diameter. Such vesicles are normally found in synapses elsewhere in the nervous system. Their function at this site is still a matter of dispute.

The two hormones formed in the supraoptic and paraventricular nuclei are oxytocin and vasopressin. Since no neurosecretory granules have been demonstrated within the extensive perivascular space separating the capillary endothelia from the pituicytes and the nerve fiber endings, it must be assumed that the granules are dissolved while still within the axon terminals and that their content is emptied in molecular form into the cytoplasmic ground substance. From there, after passing through the axonal cell membrane, the hormones reach the perivascular space rich in mucopolysaccharides and mucoproteins. One might speculate that this material acts less as a barrier and more as a distribution system ensuring unimpeded and rapid transfer of the hormones into the capillary system. The function of the pituicytes in this process has not yet been clarified. Increasing evidence indicates, however, that these cells do not only have a supportive function, but that they are largely involved in the metabolism of the neurosecretory cells and their axons.

C. Biochemistry, Transport, Inactivation, and Excretion

The hypothalamic-neurohypophyseal system of the human and of other mammals produces two hormones: vasopressin and oxytocin. They are closely related chemically and their actions overlap to a slight extent.

Both hormones are octapeptides, and both were isolated and synthesized by DU VIGNEAU. Oxytocin and vasopressin were the first hormones to be synthetically prepared. These synthesized hormones show no chemical, physical or biological differences from the naturally isolated hormones. The name vasopressin originated from the first, probably unphysiological effect of the hormone to be discovered, namely the blood pressure-raising effect. However, the terms adiuretin or antidiuretic hormone have not managed to prevail. Neurohypophyseal extracts with predominantly antidiuretic and pressor effects are termed as pitressin. Extracts with an oxytocin action are designated as pituitrin or pitocin.

In mammals there are two vasopressins. The human and most other mammals form arginine-vasopressin (LIGHT, 1958). The pig and its relations produce lysin-vasopressin. The remaining vertebrates form vasotocin instead of vasopressin, and certain osteichthyes produce

Table 1. Structural formula of the 7 neurohypophyseal hormones presently separated in nature using the usual abbreviations for the amino-acid residues (according to BERDE, 1964; HELLER, 1966; BOISSONAS, 1968)

Name	Formula	Molecular-weight
	1 2 3 4 5 6 7 8 9	
Oxytocin	H—Cys—Tyr—Ileu—Glu(NH_2)—Asp(NH_2)—Cys—Pro—Leu—Gly—NH_2	1007
Lysin-Vasopressin	H—Cys—Tyr—Phe—Glu(NH_2)—Asp(NH_2)—Cys—Pro—Lys—Gly—NH_2	1056
Arginine-Vasopressin	H—Cys—Tyr—Phe—Glu(NH_2)—Asp(NH_2)—Cys—Pro—Arg—Gly—NH_2	1084
Vasotocin	H—Cys—Tyr—Ileu—Glu(NH_2)—Asp(NH_2)—Cys—Pro—Arg—Gly—NH_2	
Ichthyotocin (Isotocin)	H—Cys—Tyr—Ileu—Ser—Asp(NH_2)—Cys—Pro—Ileu—Gly—NH_2	
Mesotocin	H—Cys—Tyr—Ileu—Glu(NH_2)—Asp(NH_2)—Cys—Pro—Ileu—Gly(NH_2)	
Glumitocin	H—Cys—Tyr—Ileu—Ser—Asp(NH_2)—Cys—Pro—Glu(NH_2)—Gly(NH_2)	

Table 2. Phylogenetic distribution and quantitative pharmacological characterization, in international units per milligram, of 5 neurohypophyseal hormones. The five pharmacological methods used here are usually employed for the characterization of the "oxytocin-like", or "vasopressin-like" properties of the substance. (After BERDE, 1964)

Neurohypophyseal hormones	Oxytocin-like activities (IU/mg)			Vasopressin-like activities (IU/mg)		Phylogenetic distribution
	Uterus (rat *in vitro*)	Blood pressure (cock)	Milk glands (rabbit)	Blood pressure (rat)	Antidiuresis (rat)	
Arginine-Vasopressin	16± 4	60± 6	65± 8	400±40	400±40	Many mammals
Lysin-Vasopressin	5± 0.5	40± 5	60±10	270±20	250	Pig, hippopotamus, pekari
Oxytocin	450±30	450±30	450±30	5± 1	5± 1	Many vertebrates
Vasotocin	115±15	285±40	210	245±15	250±35	Vertebrates with exception of mammals
Ichthyotocin, Isotocin	150±12	320±15	300±15	0.06± 0.01	0.18± 0.03	Some osseous fishes (osteichthyes)

ichthyotocin or isotocin (BERDE, 1964; SAWYER, 1966; ACHER, 1966; WALTER, 1967). See SAWYER (1967), VLIEGENTHART (1967), and ACHER (1969) for the phylogenetic relation of the hormones of the posterior lobe and their function in nonmammals (Table 1, 2).

Oxytocin and arginine-vasopression differ in only two amino-acid residues. In mammals, oxytocin predominantly causes the uterus to contract and milk to be ejected. On the other hand, vasopressin has mainly an antidiuretic effect, and in higher concentrations pressor properties. The actions overlap, and this would appear to be physiologically rational to some extent, as, for example, antidiuresis in lactation.

Vasopressin and oxytocin are stored in the neurohypophysis and bound to specific carrier proteins, neurophysin I and neurophysin II, in granules visible by electron microscopy. Neurophysin I binds more oxytocin; neurophysin II has a selective affinity for vasopressin. Vasopressin and oxytocin are usually secreted together with the neurophysins into the blood, and free hormones may also be released. Calcium ions shift during the process of release into the cells; at a certain concentration they inhibit binding to the neurophysins (GINSBURG, 1966).

It is still uncertain how much vasopressin and oxytocin circulate in the free form and to

what extent they are bound in the plasma. Neurophysins circulate in a concentration of 1.3 to 40 ng/ml in the blood, according to the state of hydration and diuresis. Neurophysins are higher in women than in men, and are elevated in pregnancy and in renal insufficiency (LEGROS, 1972; SACHS, 1969). Vasopressin is evenly distributed within the plasma volume and only a small percentage is transferred to the extracellular fluid. The half-life in the human, estimated using vasopressin labeled with tritium and ^{131}I, is extremely short, approximately 4 minutes (SILVER, 1961). However, when estimated from infusion studies, it is reported to be 16–17 min (CZACZKES, 1964). The majority of the vasopressin is inactivated in the liver and kidneys (LAUSON, 1961). A relation between receptor-effect and inactivation is under discussion (DICKER, 1961). Only 5–20% is excreted through the kidneys. The greater part of the vasopressin excreted in the urine is not dialyzable (THORN, 1959). The nature of the carrier protein in urine is unknown.

The concentration of vasopressin in human plasma lies below or just at the lower limit of biological assessment, even in blood from the internal jugular vein and during extreme dehydration. Infusion methods yield concentrations of 1–5 μU/ml = 0.01 mμg/ml (LAUSON, 1967; SCHRÖDER, 1959; SHARE, 1967). Secretion is estimated to be 7.5–50 mU/h, and the total clearance has been calculated to be 150 ml/min (LAUSON, 1967). These estimations by biological assays are roughly confirmed by the difficult radioimmunological method of determination which has recently become available and which allows measurement of concentrations of vasopressin down to 1 pg/ml. In healthy persons, the vasopressin concentration is found to be between 1 and 10 μμg/ml according to the state of hydration. The concentration can rise to 26 μμg/l in nephrogenic diabetes insipidus (ROBERTSON, 1970).

The clearence of vasopressin is elevated in central and nephrogenic diabetes insipidus. Despite the low molecular weight, many animals and also a few humans can form circulating antibodies against lysin-vasopressin or arginine-vasopressin (ROTH, 1966).

Oxytocin circulates bound to beta-globulins in a volume corresponding to approximately 40% of the body fluid. The half-life in the pregnant woman is approximately 3 min. Oxytocin is also inactivated by the liver, the kidney and the mammae during lactation. In addition, during pregnancy in primates, oxytocinase appears in the plasma which also disintegrates vasopressin. Its origin and physiological significance are, however, still unknown.

The synthesis of these polypeptide hormones permits the production of derivatives with altered activity, which can be pharmacologically useful. Over 200 analogues have been synthesized and examined (WALTER, 1967), revealing certain correlations between structure and effect (BOISSONAS, 1961). The substitutions in positions 3 and 8 are of special interest. Inhibitors can also be produced, and conclusions about the mode of action can be drawn from the molecular structure (WALTER, 1967). The synthesized hormones are sometimes more effective per unit weight than the natural hormones. Thus, the antidiuretic effect of desamino 1-arginine-vasopressin is three times greater than that of the naturally occurring hormone (BERDE, 1964). See p. 61 for information on DDVAP. 2-Phenylalanine 8-lysine-vasopressin, which has only a slight antidiuretic action but a definite pressor effect (GUHL, 1960) has been introduced into the treatment for hemorrhage of esophageal varices since it produces an arteriolar constriction in the splanchnic area with a fall in portal venous pressure (TSAKIRIS, 1964). Ornithin^{8}-vasopressin has a yet more favorable pressor/antidiuretic ratio and is used for local hemostasis (BERDE, 1964). See BERDE (1966) for the synthetic analogues and homologues. See WOOLEY (1956) for the specificity of the peptide hormones (oxytocin effect of angiotensin, vasopressin action of pepsitensin).

D. Physiology

1. Place of Formation of Vasopressin and Oxytocin

Vasopressin and oxytocin are formed in different neurons of the hypothalamic nuclei and reach the neurohypophysis by way of the nerve tracts (neurosecretion) (BARGMANN, 1954; SCHARRER, 1954; LEDERIS, 1962).

The ganglion cells of the supra-optical and paraventricular nuclei, the supra-optico-hypophyseal tract, and the neurohypophysis form a unit, which when interrupted at any point leads to functional failure of the system and thereby to diabetes insipidus. Usually the degree of the functional disturbance is proportional to the extent of the lesion. Removal of the neurohypophysis or division of the supra-optico-hypophyseal tract leads to the degeneration of a number of neurons, which increases with increasing proximity of the lesion to the ganglion cells. The neurosecretory neuron has a special place between the cells. Apart from the elements of the ordinary nerve cell, such as dendrites,

axon, neurofibrils and myelin sheath, it also contains granules of various sizes in the ganglion cell itself and along the axis cylinder. These granules can be selectively stained by GOMORI's method. This Gomori-positive or neurosecretory substance becomes more dense distally and is found in particular abundance in the neurohypophysis. Valuable support for the opinion that this substance is related to the hormonal activity of the system is obtained from the fact that the quantity of these neurosecretory granules is dependent on the functional state of the system and that the content of antidiuretic hormone of the areas surrounding the hypothalamus and neurohypophysis corresponds quantitatively to the amount of neurosecretory substance in these areas. The ganglion cells increase in size during thirst and after osmotic stress (functional nuclear edema). At the same time, there is a decrease in the neurosecretory substance as well as in the antidiuretic hormone content in the distal regions, especially in the neurohypophysis. After a water load, the neurohypophysis again becomes filled with neurosecretory substance.

This neurosecretory substance is definitely formed in the ganglion cells of the supra-optical nucleus and possibly in the paraventricular nucleus as well. Experiments show that oxytocin is formed in the paraventricular nucleus, whereas vasopressin is produced in the supra-optical nucleus (OLIVECRONA, 1957). These substances then migrate along the supra-optico-hypophyseal tract, and 80% is stored in the neurohypophysis as subcellular granular elements of 100–300 mμm diameter. When the pituitary stalk is interrupted, the neurosecretory substance stagnates in the proximal end of the stump, whereas the distal end discharges the substance. In tissue cultures of the ganglion cells of the dog's supra-optical nucleus, a movement distally of granulated elements could be demonstrated with rapid motion pictures. Finally, tests with substances labeled with ^{32}P showed migration in the direction distal to the ganglion cells. The velocity of the transport varies with the degree of the osmotic stress. The neurosecretory substance seems to move with the plasmatic flow of the axon.

No antidiuretic hormone has been demonstrated in other hypothalamic nuclei. The neurosecretory substance is not identical to the hormones of the hypothalamic-neurohypophyseal system. As far as can be determined histochemically, it appears to be a lipoglycoprotein which, like a carrier protein, combines with the hormonally active polypeptides.

In mammals, the ganglion cells of the supra-optical and paraventricular nuclei are the only cells so far known to produce a carrier substance of this kind with hormonal activity.

2. Release

The release of oxycotin and vasopressin results from numerous nervous, chemical, and physical stimuli. Pharmacological, physiological and pathological stimuli can be differentiated among the indirect stimuli.

Drugs, in particular acetylcholine, nicotine, and many analgesics, hypnotics and anesthetics, such as morphine, ether, and barbiturates, lead to the release of vasopressin. Intravenous administration of 0.5–1.0 mg nicotine (3 mg in smokers) causes the release of vasopressin when the hypothalamo-neurohypophyseal system is intact (nicotine test, see p. 59 f.). Although acetylcholine and adrenaline in small doses inhibit the release of vasopressin, adrenaline in large doses has the opposite effect.

A rise in plasma osmotic pressure is the specific physiologic stimulus causing a release of vasopressin. The act of suckling results in the release of oxytocin. Vasopressin and oxytocin can be released together, or a specific stimulus may cause one or the other to be secreted in predominance (ACHER, 1958; HELLER, 1966). However, overlapping occurs. Thus, suckling causes a simultaneous inhibition of diuresis, and the administration of hypertonic saline leads to the ejection of milk and to contraction of the uterus. In mammals, including the human, stimulation of the genital organs and coitus also result in the release of oxytocin and vasopressin. In the nursing mother milk is released, whereas in the male and other females diuresis is retarded (HARRIS, 1953; FRIBERG, 1953).

Changes of 1% in the osmolality (see p. 46 f.) of the plasma are sufficient to induce or inhibit vasopressin secretion. The chemical nature of the substances dissolved in the plasma is, however, unimportant, providing they are not prevented from exerting an effect on the end organ through excessive diffusibility (e.g. glucose, urea). VERNEY showed in his precise experiments in the dog that the electrolytes and the osmotic pressure of the total blood have little effect on the release of vasopressin. On the other hand, an 8% rise in the chloride content of the internal carotid artery, corresponding to an increase of 2% in the osmotic pressure, induces the neurohypophysis to release 1 micro unit of vasopressin per second = 3.6 mU/h), diminishing the urinary output to less than 1 $cm^3/m^2/min$. There must, therefore, be osmoreceptors in the area supplied by the internal carotid arteries. Presumably, these receptors

cause the neurosecretory cells of the hypothalamo-neurohypophyseal system to release vasopressin into the blood.

The bubbles in the supra-optical and paraventricular nuclei, considered by VERNEY to be osmo-receptors, are really vacuoles of the ganglion cells with a laterally placed signet ring-shaped nucleus. They are only found in a few species and vary in size and number according to the osmotic stress. They are, therefore, to be considered as a product and not as a controlling organ. The ganglion cells themselves must possess osmo-receptor properties since their action currents vary according to the osmotic stress. The osmo-receptors are situated in the region supplied by the internal carotid artery, but the localization has not yet been quite successfully determined (JEWELL, 1957).

On the other hand, various localizations of the release regulation have been established for the nervous, pharmacological and osmotic stimuli (DINGMAN, 1957).

The release of vasopressin is not controlled by the absolute osmotic pressure but rather by the gradient between the extra- and intracellular osmotic pressures. The difference between the two depends mainly upon the extracellular sodium concentration. On average, the release of vasopressin in man begins at an osmolality of over 285 mOsm/kg (MOSES, 1967).

The release or inhibition of vasopressin probably results immediately from perceptible variations in the osmotic pressure. Cortisol increases the stimulus threshold for the release of vasopressin, even when nicotine (DINGMAN, 1957, 1958) or osmotic stimuli are employed (AUBRY, 1965). Increase in blood volume (see beneath) also increases the osmotic stimulus threshold (MOSES, 1967).

In addition to osmoreceptors, volume receptors and baroreceptors, probably in the left atrium, the carotid sinus and in the aortic arch, are supposed to control diuresis through vasopressin secretion (GAUER, 1963; LEAF, 1952; HARE, 1967). Osmotically induced diuresis is inhibited by a slight decrease in plasma volume. Volume regulation dominates the osmoregulation (ARNDT, 1965). The "effective circulating blood volume" appears to be the critical factor rather than the extracellular fluid volume (SHARE, 1962). Vasopressin and oxytocin are liberated from the granules and pass through the cell membranes to reach the blood. Calcium ions appear to have an effect on the liberation of both vasopressin and oxytocin from their carrier substances (THORN, 1965). Only the 20% of vasopressin stored in the tissue can be released on a specific stimulus. Emotions, pain, vomiting, and loss of blood are some of the stimuli which can cause a release of vasopressin. Conversely, antidiuresis can be interrupted by hypnosis or certain reflexes (HOFER, 1963; HULET, 1963). The very variable enhancing or inhibitory stimuli must be received and integrated by a hypothalamic center. This converts them into an impulse for the release of vasopressin (PITTS, 1968).

There are only hypothetical views about the mechanism of the hormonal release from the posterior pituitary lobe into the blood. These include neural impulses, alterations in electrical potentials with electrolytic displacement, in particular the entrance of calcium ions into the cells, or permeability changes (HELLER, 1966). In addition to the immediately available portion of vasopressin, the posterior lobe contains more vasopressin which is only slowly released (SACHS, 1967, 1969). Temporal observations would make a neurohumoral transmission appear improbable, but support the concept of transmission by neural impulses (so-called stimulation-secretion-coupling, SACHS, 1967). These impulses are transmitted either by the neurofibrils of the secretory neurons or by the numerous neighboring unmyelinated nerve fibers.

3. Action of the Neurohypophyseal Hormones

a) Oxytocin

Oxytocin exerts a constricting effect on the uterine muscle. Estrogens increase the response of the uterus to oxytocin, whereas progesterone inhibits it. During pregnancy, the sensitivity of the uterus to oxytocin is greatly reduced. However, during delivery and immediately after, the uterus is particularly sensitive to oxytocin. There are many data supporting the physiological effect of oxytocin during the stages of labor (see p. 692). Further clarification will only result from the radioimmunological assay techniques recently introduced.

In addition to the effect noted above, oxytocin causes contraction of the myoepithelial elements of the excretory ducts of the mammary glands, resulting in milk ejection. In the rat and dog, oxytocin also has a diuretic effect by virtue of enhanced electrolyte excretion. This is not so in man. The effect of oxytocin on the release of prolactin is questionable, and it is not likely that oxytocin has any physiological function in the male genital system (FITZPATRICK, 1966). Finally, oxytocin and its analogues, such as vasopressin, in high doses have an insulin-like effect on glucose metabolism *in vitro* upon rat adipose tissue.

b) Vasopressin

α) Regulation of Water Intake and Diuresis

The hypothalamus, neurohypophysis and kidneys constitute a system for maintaining constant osmotic pressure or constant osmolality (see p. 46f.) of the extra- and intracellular body fluids. Like other regulatory systems, it is concerned with homeostasis. It generally succeeds in maintaining a constant internal environment, which was recognized by CLAUDE BERNARD as being essential to life.

Water intake and loss are controlled by the hypothalamus, which registers and integrates osmolality, volume of body fluids and other stimuli (Table 3).

The water intake is controlled predominantly by the thirst center. This center is situated in the ventro-medial hypothalamus, between the descending column of the fornix and the mamillo-thalamic tract, caudal to and partly overlapping the osmoreceptors controlling vasopressin secretion (ANDERSSON, 1955). Stimulation of this area with very small amounts of hypertonic saline or with an electric current results in compulsive water drinking of up to 40% of the body weight. Polyuria follows only after a latent period of several hours. Destruction of this hypothalamic area causes complete or partial adipsia. The specific stimulus inducing thirst has not been definitely identified; however, extra- and intracellular hyperosmotic dehydration appear to be predisposing conditions. An increase in the osmolality alone is not sufficient, and alterations in volume seem to be involved. It is not known whether the osmoreceptors for the release of vasopressin are also concerned with the induction of thirst, functioning through different nerve tracts, or if other receptors, partly overlapping with the osmoreceptors for vasopressin, are also present (ANDERSSON, 1957; FITZSIMMONS, 1972). A dry buccal mucosa is only an additional factor in inducing thirst. The water loss is controlled by the kidneys under the influence of the release of hypothalamic vasopressin.

The kidneys play a critical role among all organs capable of excreting water since the lungs, stomach and skin excrete water with no concern for the hydration state of the body. Apparently, these latter organs are so very much concerned with their own specialized function that they neglect the economy of the water equilibrium in preference to their own functional maintenance (lungs: CO_2 excretion; stomach: HCl production; skin: temperature regulation). In mammals, the kidney is the only secretory and excretory organ capable of delivering a hypertonic excretion, the urine. It is therefore well suited to the function of conserving water.

The body can tolerate wide ranges of variations in the amount of extracellular water. There is also a relatively wide margin of tolerance to the absolute quantities of the substances dissolved in the body fluid. The ratio of water to the dissolved substances, however, must be kept within relatively narrow limits. This is normally 300 mOsm/kg H_2O, and is dependent predominantly on the sodium concentration in the plasma. The Na concentration can vary between 120–160 mEq/l.

The unit osmol is used for measuring the number or the mass of the osmotically active molecules in an aqueous solution. It corresponds to a number or mass (according to the definition) of 6.023×10^{23} osmotically active particles, and is equal to a mol in undissociated substances. As long as the substance dissociates in solution, the number of osmotically active particles increases by a factor identical with the number of ions into which the molecule dissociates.

The osmotic pressure (as well as many other physical properties) of a solution, is a linear function of the relation between the number of osmotically active molecules and the number of molecules of the dissolving agent. This ratio or this quotient of the number of osmotically active

Table 3. Control of diuresis through the hypothalamic-neurohypophyseal-renal system (↓ decrease, ↑ increase) (TALBOT, 1952)

	Hemoconcentration	Hemodilution
Blood	Osmolality ↑	Osmolality ↓
	↓	↓
Hypothalamus	Osmoreceptors	Osmoreceptors

	↓	↓
Kidneys	Distal water reabsorption ↑	Distal water reabsorption ↓
	↓	↓
Urine	Osmolality ↑	Osmolality ↓
	Specific gravity ↑	Specific gravity ↓

molecules in osmols to the amount of solvent in kg is the osmolality. On the other hand, the osmolarity is the number of osmotically active molecules in osmols per liter of solution. It gives a poorer indication of the osmotic conditions of a solution, since in this definition, the volume of the molecule of the dissolved substance in the solution is also integrated into the formula.

This volume is very variable. The difference between osmolality and osmolarity is quite considerable for concentrated solutions of a highly molecular substance, as for example, plasma with its protein content.

For biological purposes, the osmotic pressure of solutions of different substances is measured by the fall in the freezing point. It is given in milliosmol/kg water (mOsm/kg H_2O).

When the osmolality in the extracellular space rises, intracellular fluids flow into the extracellular space. Dehydration, fever, and death may result. The limits of plasma osmolality compatible with life lie between 250 and 350 mOsm/kg H_2O. A fall in the extracellular osmolality leads to the flow of water into the intracellular space with water intoxication. Brain edema, epileptic fits and death can then occur.

When the serum osmolality rises, water excretion through the kidneys is reduced to an absolute minimum. The thirst center is stimulated and the thirst sensation secures then an adequate water intake.

β) Water Reabsorption in the Proximal and Distal Tubules of the Nephron

The plasma undergoes simple filtration in the renal glomerula. Protein and formed elements of the blood are retained in the plasma, while water and all the normally present solutes pass on into the tubule with the so-called primary urine. In the human, the primary urine formed is 100 liters/24 h/m^2 body surface, or 180 liters daily for an adult of average body weight. The amount of solutes is 31 osmol/m^2 of body surface.

About 30 osmol solutes are actively reabsorbed from the isotonic primary urine in the proximal tubule. The amount of water in the isotonic solution passively reaches the peritubular bloodstream. This occurs by means of the "osmotic suction" which exists after the active reabsorption of the solutes. The proximal tubule expends no energy for osmotic work during this process of reabsorption since the end effect of the reabsorption is an isotonic solution. Overloading with osmotically active substances such as glucose, mannitol, and urea, etc. can decrease the reabsorption so that they have a diuretic effect. Reabsorption from the proximal tubule is otherwise dependent of the tubular volume (BRUNNER, 1966). So 15 liters of water and 1 osmol or 3% of the total solutes originally contained in the primary urine reach the ascending limb of Henle's loop.

The mammalian kidneys can limit the water loss from the body to the necessary extent through vasopressin-regulated water reabsorption in the distal tubules and the collecting ducts. The mammalian kidneys employ the countercurrent multiplier system for this variable water reabsorption. This system, which is used technically and has a wide spread throughout many animal species (SCHOLANDER, 1957), permits a high osmotic effect to be achieved with relatively low energy expenditure and the urine to be concentrated in the collecting ducts (WIRZ, 1960). In animals the ability to concentrate urine is dependent on the formation of Henle's loop. Beavers have a short Henle's loop and can concentrate the urine to 600 mOsm/kg. Rabbits, with long and short loops, can concentrate up to 1400 mOsm/kg, as can the human. The sand rats in the desert, however, with an exceptionally long loop and a singular renal papilla penetrating far into the ureter can survive without water and concentrate the urine to 20 times the serum osmolality, i.e. up to 6000 mOsm/kg (O'DELL, 1960). Sodium is actively reabsorbed in the ascending limb of Henle's loop, which is impermeable to water. The sodium is then released into the extracellular fluid of the surrounding tissues, as well as into the lumen of the descending limb of the loop. A high concentration of sodium thus circulates in the portion of Henle's loop lying towards the papilla and exerts a high osmotic pressure on the surrounding tissues. This pressure increases from the renal cortex towards the medulla, and in the human it is approximately 4 times higher in the papilla. The isotonic urine from the proximal tubule thus becomes first hypertonic at the tip of Henle's loop. Since, however, urinary sodium but no water is removed from the ascending limb of the loop, hypotonic urine reaches the distal tubules. In the absence of vasopressin, the epithelium of the distal tubules and of the collecting ducts is only slightly permeable to water, and the kidneys then excrete hypotonic urine. In antidiuresis, vasopressin is released. This opens the pores of the distal tubules and the collecting ducts to water so that the urinary water is passively withdrawn through the hypertonic medullary tissue in proportion to the osmotic gradient. "Free water" which is not bound osmotically is no longer excreted with the urine. The free-water clearance becomes zero or negative. The site of action of vasopressin lies in the epithelia of the collecting ducts and distal tubules. It is not known whether vasopressin also affects the descending limb of

Henle's loop by opening the pores to sodium or whether vasopressin promotes sodium reabsorption in the ascending limb (WIRZ, 1961). Adhesion of labeled pitressin can be demonstrated by autoradiography in the distal tubule and in the collecting ducts. However, autoradiographic methods are not possible in the thin segments of Henle's loop (DARMADY, 1960). In any case, under the influence of vasopressin, more sodium is retained in the renal medulla (LEVETIN, 1962). No vasopressin is in circulation during the state of maximal hydration and maximal diuresis. The distal tubules and collecting ducts are water impermeable. Hypotonic urine is transported uninfluenced through the hypertonic medullary tissue. In the state of maximal antidiuresis, the epithelia of the distal tubules and collecting ducts are freely permeable to water. Urinary water is removed in proportion to the osmotic pressure of the extracellular fluid of the medullary tissue until the two osmotic pressures are similar (GOTTSCHALK, 1959). This osmotic pressure in man is approximately 4 times the plasma osmolarity or 1 200–1 400 mOsm/l. Some authors (JAENIKE, 1961; 1964; GARDNER, 1964) suppose that vasopressin also increases the permeability of the collecting ducts to urea, which takes part in the circulation of the countercurrent system during antidiuresis and contributes to the hypertonicity of the medullary tissue (SCHMIDT-NIELSEN, 1958). This hypothesis, however, has been rejected by others (GRANTHAM, 1966).

An average antidiuresis is necessary for the excretion of an isotonic urine. Small quantities of vasopressin open the pores of the collecting ducts and of the distal tubules to such an extent that osmotic equalization with the hypertonic medulla is not fully achieved.

A second countercurrent-exchange system exists in the vasa recta of the renal medulla. In contrast to the epithelium of Henle's loop. the walls of the vasa recta are freely permeable to both water and electrolytes, so that the osmolality of the blood in the vasa recta is always the same as that of the surrounding tissue. The vasa recta supply the medullary tissue with oxygen and nutritives and remove the reabsorbed free water. The loop-shaped arrangement of the vessels prevents the loss of the high concentration of electrolytes in the medulla through the blood flow. Blood electrolytes from the ascending limb are transferred into the hypotonic blood in the descending limb, and water from the descending limb enters the ascending limb. During maximal diuresis the blood supply to the medulla is accelerated (THURAU, 1960). It is still undecided whether the increased medullary blood circulation leads to the removal of electrolytes from the medulla with a decrease in the medullary hypertonicity (the "wash-out effect", BUCHBORN, 1964), or whether the diminished medullary hypertonicity causes an increase in circulation. Highly concentrated urine cannot be obtained when the medulla is insufficiently hypertonic, despite the presence of vasopressin and the water-permeable epithelium of the collecting ducts. A maximal but unphysiologic antidiuresis can be achieved in addition to the effect of vasopressin by reduction of the glomerular filtration by less than 30%.

Factors Influencing the Antidiuretic Effect of Vasopressin. The antidiuretic effect of vasopressin usually decreases slowly after several days of excessive water intake, and the effect steadily increases again with limited water intake. This decrease in the concentration power is related on one hand to the loss of the medullary hypertonicity (the "wash-out effect") (THURAU, 1960; KRAMER, 1960; BUCHBORN, 1964). On the other hand, the concentration power may be affected by the thickening of the basal membrane of the pars recta of the proximal tubule and the following portion of Henle's loop due to the chronic hydration (PICK, 1966).

In newborns, vasopressin has no antidiuretic effect during the first 3 days of life, although endogenously formed vasopressin not attached to neurophysin circulates freely (DICKER, 1966). In nephrogenic diabetes insipidus vasopressin exerts no or only very limited antidiuretic effects (see p. 53). Hypercalcemia also causes a diminished antidiuretic effect, but here this is most probably explained by the obstruction of individual tubules (BANK, 1965). In addition, there are morphological changes in the epithelia of the distal nephron in hypercalcemia (CARONE, 1960), and the permeability of the cells to water may be decreased. The passive absorption of water from the collecting ducts thus remains inadequate (CARONE, 1960; MANITIUS, 1960).

Hypokalemia leads to tubular nephropathy with polyuria and hyposthenuria (RELMAN, 1956). In hypokalemia, the countercurrent mechanism is probably impaired by the diminished sodium transport in the ascending limb (BANK, 1964; BRUNNER, 1966). Using the model of a toad's bladder, it was shown that a normal ionic concentration is necessary for the full effect of vasopressin (SCHWARTZ, 1967).

Maximal diuresis is not possible in adrenal insufficiency and the capacity for concentration may sometimes be limited. Diminished sodium reabsorption with insufficient medullary hypertonicity is probably responsible for the impaired concentration process. The disturbance

in diuresis is attributable to the decreased glomerular filtration, the fall in the extracellular fluid volume, and in particular, to the loss of water impermeability in the collecting ducts (KLEEMAN, 1964) (see p. 305); the increase in vasopressin secretion due to the lack of glucocorticoids may also be a contributory factor (DINGMAN, 1960).

High doses of parathormone and vitamin D result in resistance to vasopressin. This effect is not only due to the hypercalcemia, but in particular to the decrease in sodium reabsorption and an insufficient sodium-urea concentration in the renal medulla (EPSTEIN, 1959; PICKFORD, 1966).

When the amount of solute is constant, the volume of urine is inversely proportional to the release of vasopressin. If this hormone is absent, the urine volume is proportional to the quantity of the solutes. The solutes are related to the diet as well as to the amount of the body's breakdown products. The quantity of the endogenous solutes can be reduced to 200 mOsm per day with suitable carbohydrate intake. Only 135 cm^3 of urine with an osmolality of 1500 mOsm/kg H_2O is necessary to get rid of this amount. Consequently, this is the smallest possible physiological urine volume.

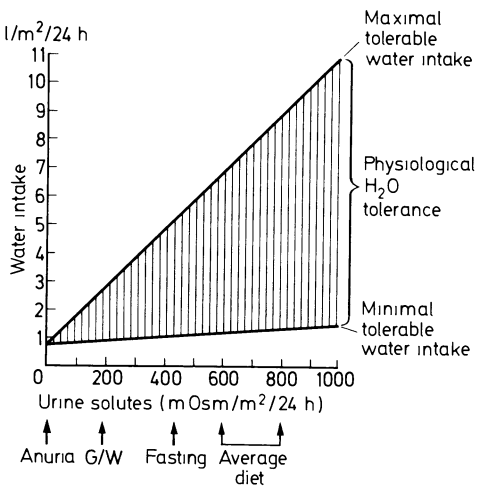

Fig. 3. Limits of the tolerable water intake related to the diet (according to KERRIGAN, 1955) (G/W: glucose-water intake)

Minimum and maximum tolerable water intake is therefore dependent on the quantity of the solutes and can be estimated from the fixed osmotic limits of the urinary volume after correction for the water loss due to insensible perspiration and water formed by oxidation (KERRIGAN, 1955).

Vasopressin exerts its antidiuretic effect on the denervated and isolated kidney. Contrary to suggestions (GINETZINSKY, 1958), the mode of action in the distal tubules and collecting ducts is not related to the liberation of hyaluronidase (BERLYNE, 1960). It is due either to a chain reaction between the disulfide links of vasopressin and the epithelial SH-radicals opening the pores (SCHWARTZ, 1964) although oxytocin derivatives without disulfide links also exert an antidiuretic effect, or to the enhanced formation of cyclic 3′,5′-AMP (ORLOFF, 1967; GRANTHAM, 1966). The action of vasopressin is independent of oxidative metabolic processes and is not related to a protein or enzyme system since puromycin and actinomycin D do not inhibit its action (RASSMUSSEN, 1960). Using the model of the toad's bladder in which the epithelium behaves like that of the collecting ducts, it has been demonstrated that vasopressin makes a dense impervious layer permeable to water and urea, whereas a second layer impermeable to dissolved substances can only be affected by amphotericin (LEAF, 1967). Vasopressin in physiological doses has no direct effect on electrolytic excretion, but in unphysiologically high doses, it has some influence through alterations in blood pressure and changed filtration conditions.

Physiological amounts of vasopressin do not directly influence glomerular filtration, the renal plasma flow or the different clearances, with the exception of the free water clearance. An extrarenal effect of vasopressin resulting in a shift of electrolytes from the extra- into the intracellular space has not been proven.

γ) Other Effects of Vasopressin

Vasopressin causes capillary and arteriolar constriction in the skin, the connective tissue, the internal organs, the smooth muscle of the gastrointestinal tract, the myocardium, and to a lesser degree in the musculature. The arterioles of the splanchnic area are particularly affected. Capillary constriction alone, however, does not explain the increase in the blood pressure. The effect on the blood pressure due to extracts of the posterior pituitary is probably of no physiological significance. It would seem more likely that vasopressin does produce a pharmacological action, since even in diabetes insipidus the blood pressure is normal. Vasopressin exerts a CRF-like effect on the anterior pituitary (see p. 300) which is probably of no physiological importance, but which can be employed diagnostically (see p. 388). Nor is the ACTH-like effect on the dog's adrenals (HILTON, 1960) of any physiological significance in man. This also applies to the other actions of vasopressin; namely, the insulin-like effect, the antilipolytic action on

adipose tissue (MIRSKY, 1963; BALASSE, 1966) and the glycogenolysis in the liver with hyperglycemia achieved by high doses of vasopressin in the dog (BERGEN, 1960). It has been suggested that in addition to its antidiuretic effect, vasopressin also influences the kidneys through the thirst center (PASQUALINI, 1959). From clinical observations, however, this appears improbable. There have recently been suggestions that vasopressin may have an effect on the transport of water and sodium in the small bowel. Either more water and sodium are secreted into the lumen of the bowel under the influence of vasopressin or the active transport of sodium from the lumen is inhibited (SOERGEL, 1968).

4. Interrelations

a) Anterior Pituitary Gland

Normal nutritional and electrolytic intake and metabolism are necessary for polyuria to become manifest. With failure of anterior pituitary function this is no longer possible. Polyuria disappears and becomes apparent again only after adequate replacement therapy.

Glucocorticoids, thyroid hormones and growth hormone promote renal blood supply and glomerular filtration. Lack of glucocorticoids causes a change in the cell permeability with a shift of the extracellular fluid into the intracellular space. The permeability of the collective ducts cannot then be reduced. Thus, polyuria disappears in diabetes insipidus subsequent to failure of the anterior pituitary gland. It is unnecessary to invoke a previously postulated anterior pituitary substance, "diuretin", which does not exist.

b) Deoxycorticosterone – "Pseudodiabetes Insipidus"

A syndrome similar to diabetes insipidus can be produced in the dog with high doses of deoxycorticosterone. Only polyuria, polydipsia, and the low specific gravity of the urine are common to "pseudodiabetes insipidus" and genuine diabetes insipidus. In contrast to the state of dehydration in diabetes insipidus, there is over-hydration in the "pseudo" syndrome, and the polyuria is uninfluenced by vasopressin but is affected by salt withdrawal. In true diabetes insipidus, polyuria can be decreased only to a limited extent by salt withdrawal. Deoxycorticosterone causes reabsorption of abnormally large amounts of sodium but also its increased filtration – the "escape phenomenon". Because of this, the extracellular fluid increases. Vasopressin secretion is insufficient and there is a simultaneous sensation of thirst which leads to polydipsia and to secondary polyuria. The low specific gravity of the urine is due to the total sodium reabsorption. In contrast with vasopressin, deoxycorticosterone has no influence on water metabolism when salt has been removed from the diet.

E. Hypofunction of the Hypothalamic-Neurohypophyseal System: Diabetes Insipidus

1. Definition

Diabetes insipidus is a disease characterized by the inability to concentrate urine and by polyuria of 5 to 20 liters daily with corresponding polydipsia. The disease is due to disorders in the formation or release of vasopressin. Nephrogenic diabetes insipidus is not due to the lack of vasopressin, but to a failure of the distal tubules to respond to vasopressin.

2. Incidence

Diabetes insipidus is an uncommon disease. It occurs somewhat more frequently in males than in females. It arises during the first decade of life in almost half the patients. In the Zurich Medical in-patient clinic (1958–1968), the disease was found 28 times in 35164 patients, with a clear preponderance of the symptomatic forms.

3. Etiology, Pathology, and Pathogenesis of Diabetes Insipidus

a) Etiology

Table 4 gives a summary of the different causes of diabetes insipidus.

The relative incidence of the different etiologies is given in Table 5.

b) Pathogenesis of the Symptomatic and Idiopathic Diabetes Insipidus

"Central" diabetes insipidus is caused by inadequate water reabsorption in the distal nephron due to the absence of vasopressin. It is still unknown to what extent the disorder is due to impaired formation or release of vasopressin. It is also unknown whether two different types of diabetes insipidus can be differentiated on this basis. It is probable that in "idiopathic" diabetes insipidus, there is a failure of the osmoreceptors. Although it has been suggested that diabetes insipidus may result from increased

Table 4. The different causes of diabetes insipidus

1. Damage to the hypothalamo-neurohypophyseal system, symptomatic diabetes insipidus	1. Nephrogenic hereditary, vasopressin-resistant diabetes insipidus
a) Tumors, in particular cysts, craniopharyngioma, gliomas, tumors of the anterior pituitary, metastases, storage granulomas (HAND-SCHÜLLER-CHRISTIAN)[a]	
b) Inflammatory diseases: encephalitis, meningitis, granulomatous processes such as TB, syphilis, sarcoidosis, lymphocytic neurohypophysitis (SAITO, 1970)	
c) Degenerative, in particular vascular destruction	
d) Traumatic damage	
e) After therapeutic hypophysectomy	
2. Hereditary diabetes insipidus, morbid anatomy mainly negative	
3. Primary "idiopathic" diabetes insipidus, unknown etiology	

[a] The Sternberg-Priesel's nodules which are typical to the posterior pituitary and pituitary stalk can occasionally form larger tumors described as tumorettes. They can, but need not give rise to endocrine disorders.

inactivation of vasopressin in the liver and kidneys (HANKISS, 1961), there has so far been no experimental support for this. The human can form antibodies to posterior pituitary extracts (ROTH, 1966); however, their clinical significance has not been evaluated. Disturbances in the regulation of diuresis become obvious when more than 85% of the neurons in the hypothalamic-neurohypophyseal system are lost. The full clinical picture does not appear until there is 95% failure.

An intact anterior pituitary and its dependent endocrine glands must be present before polyuria and the complete picture of diabetes insipidus can develop (see p. 48) since failure of these glands leads to disturbed renal function. Glomerular filtration may then decrease, and cortisol is necessary to "seal off" the collecting ducts so that maximal diuresis can occur. In addition, the responsive threshold of the osmoreceptors is raised by cortisol (AUBRY, 1965). Reduced nutritional intake may also have some effect in this regard. It has been observed that polyuria regresses when the posterior pituitary process attacks the anterior pituitary. The renal inability to concentrate continues despite the reduced polyuria, and consequently, diabetes insipidus may first become apparent when cortisone is substituted in failure of both pituitary lobes.

A concentrating power of up to 1016 may be maintained after selective loss of the pituitary without destruction to the hypothalamus such as occurs after surgical removal of the pituitary gland. From this it can be deduced that vasopressin can be further secreted under these conditions. Secretory transmitting fibers of the supra-optic and paraventricular nuclei partly terminate at the vessels of the pituitary stalk and immediately under the ependyma. Fibers of the supraoptic-neurohypophyseal tract may regenerate after division and form a sort of replaced posterior lobe with blood vessels of the proximal stump (BARGMANN, 1968). See p. 52f. for the three phases of the course of postoperative diabetes insipidus. For the rare coincidence of diabetes insipidus and SHEEHAN'S syndrome (AGUILÒ, 1969), see Chap. V, p. 93.

4. Clinical Features and Symptoms of Idiopathic and Symptomatic Diabetes Insipidus

a) History

Polyuria and subsequent polydipsia can arise overnight or may develop gradually. Polydipsia and enuresis can occasionally precede the

ability to concentrate urine and if these persist for a long time, sometimes result in children being unfairly labeled neurotics (FANCONI, 1956). According to SMITH (1951), 50% of patients with diabetes insipidus excrete a urine volume of between 4 and 8 liters; 25% of patients excrete between 8 and 12 liters. A urinary output of up to 40 liters has been described in the literature. This amount of urine is theoretically possible. Within individually set limits, however, the volume of urine is largely dependent on the serum content of the substances to be excreted in urine. Thirst caused by fluid withdrawal has a compulsive character. Patients drink everything available to them, even their own urine. If no fluid is replaced, polyuria continues leading to dehydration with dry tongue, fever, delirium, and collapse. In a baby, an unexplained fever is often the first symptom of diabetes insipidus. This thirst fever is characterized by the fact that the maximum rise is usually found in the mornings, in contrast to fever due to inflammations.

Possible causes of a lesion in the hypothalamic region must be precisely searched for while taking the case history. Inflammatory diseases and tumors must be excluded. The family history must be investigated. In contrast to the severe mental disorders due to failure of the anterior pituitary, insufficiency of the hypothalamo-neurohypophyseal system does not lead to severe psychological disturbances. Thirst is an immediate result of the excessive loss of water, and it is pointless to interpret the thirst of a patient with diabetes insipidus as a deep-seated psychological disturbance of the instinctual sphere. BLEULER (1954) clearly and decidedly objects to the psychiatric approach of diagnosis and therapy of diabetes insipidus.

b) Symptomatology

Apart from the dry skin and frequently dehydrated mucous membranes, examination of the patient does not reveal any special features.

Polyuria with great water loss which cannot be rapidly compensated through adequate intake results in a series of indirect symptoms: constipation, inadequate saliva flow, absence of sweat secretion. Sleep disturbances due to the thirst can cause the patient to be irritable and to show neurasthenic symptoms. Polyuria and polydipsia do not have any negative effects on kidneys and circulatory organs even after decades.

In the presence of a destructive process in the hypothalamus, diabetes insipidus can be associated with disturbances in the visual fields, signs of total or partial insufficiency of the adenohypophysis, pressure symptoms on the brain, and other hypothalamic syndromes (see p. 32). Even in the absence of neurological symptoms, all patients with diabetes insipidus should at least have an X-ray of the skull and a lumbar puncture and possibly a pneumoencephalography to exclude the symptomatic form.

Features due to the lack of oxytocin are not as a rule found in association with diabetes insipidus. Even pregnant women suffering from diabetes insipidus give birth normally.

c) Findings in Urine and Plasma

The most important laboratory finding is a 24-hour urinary output of over 4 liters of clear urine, devoid of sugar and protein, and with a specific gravity which seldom exceeds 1005. The urinary sodium chloride concentration is low, although the amount of NaCl in the 24-hour output is normal. The urine is almost always hypotonic and its osmolality does not exceed that of the plasma, 300 mOsm/kg H_2O (see p. 46). In the absence of vasopressin, the free water clearance which reflects the 'renal excretory power for free, as against osmotically-bound water is usually positive. Estimation of the plasma osmolality can differentiate between diabetes insipidus and polydipsia. The test is carried out in the morning in the fasting state and with free water intake, or better still, after 6–8 hours of water deprivation. The plasma osmolality in diabetes insipidus is 300 mOsm/kg H_2O or more, whereas in polydipsia, it is under 295 mOsm/kg H_2O (ROMANI, 1965). The plasma osmolality is always higher than the urine osmolality in diabetes insipidus after 8 hours of water deprivation (PRICE, 1966).

5. Special Forms of Diabetes Insipidus

a) Diabetes Insipidus after Injury, Therapeutic Hypophysectomy or after Section of the Pituitary Stalk

Experiments in animals have shown that loss of more than 85% of the neurons in the hypothalamic-neurohypophyseal system gives rise to a partial diabetes insipidus, whereas failure of more than 95% is necessary for the development of a full-blown diabetes insipidus. Similar observations were made after therapeutic hypophysectomy for treatment of carcinoma of the breast and prostate and in diabetic retinopathy. The resultant diabetes insipidus is usually mild, presents special symptoms, and runs a special course. The urinary output varies from day to day and is usually between 3–4 liters. The

average specific gravity is 1010, but the concentration power may reach 1016. The Hickey-Hare test using hypertonic saline infusion is usually pathologic but can sometimes be normal. In the majority of cases, diabetes insipidus does not develop after transsphenoidal subdiaphragmatic hypophysectomy. The risk of diabetes insipidus is not predictable in transfrontal hypophysectomic or division of the pituitary stalk. Furthermore, there is no relation between the completeness of the hypophysectomy and the severity of the diabetes insipidus that may result.

Three phases have been observed in animal experiments and after therapeutic hypophysectomy in man.

1. Immediate polyuria, arising within minutes or hours of the lesion and continuing for hours or days.

2. The intermediate phase with normal urinary output, which can last for a few hours to 3 days.

3. The permanent state with diabetes insipidus of variable severity. All combinations of the three phases are possible. The immediate polyuria can disappear, and permanent polyuria may arise days later without going through phase 1 or phases 1 and 2.

It is assumed that phase 1 is due to a release disturbance caused by the traumatic shock to the neurohypophysis. The polyuria subsequently regresses due to the mobilization of vasopressin (KOVACS, 1962). This continues until phase 3, when the increasing degeneration of the supra-optico-neurohypophyseal tract reaches the nuclei, resulting in destruction (SHARKEY, 1961).

Experience has taught us that treatment is not always indicated in the transitory first phase. The treatment of the permanent phase depends on the degree of polyuria.

Vasopressin may be produced; however, loss of the neurohypophysis, the storage organ of vasopressin, causes a disturbance in the release mechanism.

b) Hereditary Central Diabetes Insidipus

The hereditary form of diabetes insipidus it not common. At present, there are only 25 families known to be suffering from this inherited disease.

Usually no patho-anatomical changes are found in the hypothalamus. Hypoplasia of the ganglion cells of the supra-optical and paraventricular nuclei is claimed to have been found in only a few cases.

The disease is inherited by a simple dominant gene. There is a 1:1 ratio between the diseased and healthy descendants. The male sex is more prone to show manifestations of the disease, and 64% of the cases have occurred in males. The reason for the less frequent manifestation in women is not known (MARTIN, 1959). The disorder usually becomes apparent in very early adolescence.

In addition to the simple dominant inheritance, families are known which have sex-linked recessive inheritance, where only the male shows manifestations of the disease (FORSSMAN, 1955). A third mode of inheritance through an autosomal recessive gene has been described in rats (VALTIN, 1967).

In contrast to the nephrogenic diabetes insipidus, there is no vasopressin resistance.

Consequently, the disorder is due either to a disturbance in the osmoreceptors (MARTIN, 1959) or, according to limited postmortem findings, to atrophy of the supra-optical nucleus and the neurohypophysis. In the inherited diabetes insipidus described in rats, hypertrophy of the system was found (VALTIN, 1967).

c) Nephrogenic, Vasopressin-Resistant, Hereditary Diabetes Insipidus

This uncommon congenital and hereditary form of diabetes insipidus usually exhibits pronounced polyuria, polydipsia and hyposthenuria. The disease becomes apparent soon after birth, although the typical symptoms can be masked in the infant by dehydration, fever, vomiting, and convulsions (GAUTIER, 1956). Experienced mothers make these infants drink, holding them directly under the tap ("water-babies").

In the fully-developed illness, the urinary output in the adult is always more than 8 liters. It is, however, dependent upon osmotic load and especially the sodium intake. The urine osmolality lies between 50 and 100 mOsm/kg H_2O. Under osmotic stress, it should never rise above 280. The specific gravity is usually 1005 and 1010 in osmotic diuresis. All the men observed presented the full picture. In the few affected women, the full-blown disorder was present or there was only a mild form with a concentration power of up to 1019. In addition, acquired hyperuricemia and occasionally gout have been observed (GORDEN, 1971).

α) Pathogenesis

Vasopressin is produced and released normally; moreover, it is not metabolized rapidly and can be demonstrated in both plasma and urine of these patients (HOLLIDAY, 1962/63). However, there is a lack of response in the distal nephrons to endogenous and exogenous vasopressin, as well as to the synthetic lysin-vasopressin. Uri-

nary flow and urine osmolality are not influenced in any way by concentrations of vasopressin which are high enough to exert definite side effects on the vasomotor system and the gastrointestinal tract. No morphological changes are found at post mortem. The significance of a shortened proximal tubular segment, which has been observed on two occasions, is unknown (McDonald, 1955). Occasionally hydronephrosis and bladder hypertrophy have been observed, resulting from the voluntary urine retention with the polyuria. The acquired hyperuricemia occurring only in adults is due to a low endogenous uric acid clearance, probably connected to the low renal plasma flow and high filtration fraction (Gorden, 1971).

β) Differential Diagnosis

All conditions of nephrogenic polyuria come into the differential diagnosis (see Table 6, p. 56). The response to vasopressin in all the other conditions of nephrogenic hyposthenuria is merely diminished and not abolished.

γ) Genetics

Heterozygous women transmit the inheritance on the X chromosome. The expressivity of the disorder is variable. Men become clinically ill. The women are carriers but can also demonstrate abortive forms of the illness. In an investigation of a family of Ulster Scots which came to Nova Scotia in 1761 on the ship Hopewell, over 9 generations confirm this mode of inheritance. The folklore relates the illness to a curse of a gipsy (Bode, 1969). It is assumed that in certain families inheritance is autosomal. However, this has not been definitely proven.

δ) Therapy

It is most important to allow the patient to drink as much as he needs. The danger is acute for infants since brain damage can result from repeated dehydration. When the patient is inconvenienced by the frequent drinking and urinary output, it is advisable to restrict the salt in the food and to give thiazide-diuretics as well with concurrent potassium and allopurinol (Gordon, 1971) administration. The procedure is described on p. 60ff.

In acute dehydration when the patient is unable to drink, a hypotonic glucose solution should be given intravenously. A 2.5–3% glucose solution should be used, since this causes neither hemolysis nor a temporary rise in the plasma osmolality due to osmotic diuresis as would occur with a 5% glucose solution.

d) Lithium-Induced Nephrogenic Diabetes Insipidus

Lithium carbonate is widely used in the treatment and prophylaxis of manic-depressive disease. In man and in animals, chronic administration application of lithium salts can cause an insensitivity of the kidneys to vasopressin and lead to a reversible nephrogenic diabetes insipidus. Similar observations have been made with magnesium, manganese, and caesium. Whether these salts act by inhibiting activation of cyclic AMP or by a similar mechanism is not yet decided (Editorial 1972; Singer, 1972).

e) Occult Diabetes Insipidus (see also p. 55)

The inadequate fluid intake and resultant small urinary output differentiate the occult diabetes insipidus in babies and small children from the usual diabetes insipidus. In babies the thirst center is at first hyposensitive, and there is a particular tendency to become dehydrated and to develop fever and a hyperelectrolytemia. These cases often turn out to be nephrogenic diabetes insipidus. As the patient grows older, the thirst mechanism gradually or suddenly begins to function. This usually occurs after the 10th month. The occult diabetes insipidus is then converted into a manifest diabetes insipidus. Disturbances of the thirst center must be distinguished from true diabetes insipidus with inadequate fluid intake (see p. 55).

f) Transitory Diabetes Insipidus

A few cases of transitory diabetes insipidus have been observed (Kedes, 1964). The pathogenesis is unexplained. Although antibodies to lysin-vasopressin can occur in man, none have been demonstrated in this form of diabetes insipidus (Roth, 1964). It has been suggested that diabetes insipidus can arise from increased breakdown of vasopressin (Hankiss, 1961). This, however, will remain uncertain until such cases are reinvestigated with sensitive radioimmunoassays for vasopressin.

6. Primary Polydipsia

A primary irritation of the hypothalamic thirst center leads to excessive water intake of up to 20 liters with consequent polyuria. This is most often due to neurotic factors (dipsomania, potomania) and seldom to an organic lesion. Neurotic polyuria is usually connected with changes in character and psychic disorders, such as hysteria. Four-fifths of the patients are

women. The polydipsia usually develops gradually over weeks or months and may run an intermittent course. Character changes due to the illness may, however, also occur in true diabetes insipidus (ANGST, 1963). Therefore, it may be very difficult to differentiate primary polydipsia from diabetes insipidus, and this is usually only possible after several days of hospitalization or by observation of the course. It is particularly difficult to establish the diagnosis since persistent polyuria of more than three days duration, as well as over-hydration may lead to a relative renal vasopressin resistance. Estimation of the plasma osmolality in the morning in the fasting state but with free water intake reveals an important difference. Patients with diabetes insipidus are usually somewhat dehydrated after a night of unbroken sleep, and the plasma osmolality is more than 300 mOsm/kg H_2O. In polydipsic patients the plasma osmolality is slightly reduced. Therefore, the fasting plasma osmolality of patients with diabetes insipidus is generally different from that of polydipsic patients. The osmolality of both types of patients can, however, overlap with normal values. Estimation of the plasma osmolality after 6–8 hours of water restriction would permit an even more definite differentiation between diabetes insipidus and polydipsia (ROMANI, 1965). The water deprivation test alone, or the Hickey-Hare test alone, can give misleading results since in the latter test, a sufficient hypertonicity of the diluted plasma cannot be attained. In the water deprivation test lasting 24 hours or longer the overhydrated patient excretes excess water with a loss in weight. Antidiuresis cannot commence in either of these two tests. Even when the water deprivation test is continued long enough for a normal or elevated plasma osmolality to be reached, the renal response to vasopressin, in the presence of intact osmoreceptors, is only insufficient in polyuric conditions. A comparison between the concentration capacity in the water deprivation test and after intravenous vasopressin can help here. When carried out under the same osmotic conditions, a urine concentration which is higher in the water deprivation test than after intravenous vasopressin indicates polydipsia. A concentration which is higher after intravenous vasopressin than in the water deprivation test suggests diabetes insipidus (BARLOW, 1959). The depot-pitressin test usually gives a more reliable result. It is carried out as follows: fluid intake is unrestricted. On the morning of the first day of the test, a placebo, such as sesame oil, is given intramuscularly. The urinary output of patients with diabetes insipidus is uninfluenced. The fluid intake decreases in some dipsomanic patients. On the following morning, when the fluid intake and urinary volume remain unaltered, 5 units of pitressin tannate in oil are injected intramuscularly. In diabetes insipidus, the polyuria is reduced, and with suitable intake, the patient is clinically improved. The dipsomanic patient will, however, continue to drink, will feel unwell, will put on weight until the signs of water intoxication develop: nausea, headache and epileptic fits. In some polydipsic patients, however, the feeling of thirst may disappear once a certain overhydrated state has been reached. The "dipsostat", the thirst center, is set for overhydration, i.e., for a lower osmolality.

Organic polydipsia can usually only be suspected during life when it occurs together with other hypothalamic symptoms such as fever, emotional changes, and partial anterior pituitary deficiency. Polydipsia or adipsia may occur in hydrocephalus (HAGEN, 1967). Organic polydipsia can be combined with a true, or possibly a partial, diabetes insipidus. The diagnosis can then be very difficult.

7. Adipsia, Usually Associated with (Partial) Diabetes Insipidus

(Central Hyperelectrolytemia Diabetes Insipidus Occultus Hypersalemicus FANCONI*)*

In the few cases in which an organic lesion has been definitely diagnosed, polydipsia as a symptom of the irritation has preceded the later *failure* of the thirst center by years. Tumors have been described as the cause of this hypothalamic lesion, particularly often ectopic pineoloma. Traumatic hemorrhage, and inflammation are other causes. The disturbed realization of the feeling of thirst, adipsia, results in so-called central hyperelectrolytemia. The serum sodium may lie between 160–180 mEq/l, corresponding to an osmolality of 320–360 mOsm/kg. The increase of plasma electrolytes is not unlimited, but a new state of equilibrium with relative and absolute hypertonic dehydration becomes established. The plasma volume is unaltered. Intra- and extracellular fluid volumes are decreased. Normal conditions can be re-established by forced fluid intake with simultaneous vasopressin administration. The previous false adjustment is immediately resumed on the withdrawal of the vasopressin and water. Regulation of the volume is still intact, whereas osmoregulation is disturbed. An additional rise in the osmolality does not result in increased release of vasopressin so that in the majority of cases, a partial diabetes insipidus is also present. Adipsia and diabetes insipidus together

produce the occult hypersalemic diabetes insipidus (FANCONI, 1956). In the baby and small child the perception of thirst is only slight. Diabetes insipidus can therefore easily lead to dehydration and hyperelectrolytemia, that is to say, an occult diabetes insipidus can develop in the absence of an organic lesion in the thirst center. On the other hand, hemorrhage and thrombosis of the brain can produce hypernatremia, especially in infants (COOKE, 1960). The diagnosis of organic adipsia or central hyperelectrolytemia must only be made when clouding of consciousness and intellectual defects can be excluded as causes of the disturbed water intake.

8. Differential Diagnosis of Diabetes Insipidus

In a typical case, the diagnosis can be made simply from the history. However, it may be difficult to differentiate the disease from psychogenic or organic polydipsia, since they both lead to vasopressin hyposensitivity. In addition to diabetes insipidus in organic hypothalamic lesions, there may be symptoms due to stimulation and failure of the thirst center which complicate the picture. Finally, there may be partial diabetes insipidus in the presence of an insufficient vasopressin secretion.

Diabetes insipidus must be considered when the 24-hour urinary output exceeds 4 liters. The simple measurement of the urinary volume in patients who believe they excrete an enormous amount of urine can often exclude the diagnosis of diabetes insipidus. In general, the specific gravity of the urine in diabetes insipidus is under 1005 corresponding to an osmolality of < 200 mOsm/kg H_2O. The upper limit for the specific gravity is usually taken as 1008. The urine is hypotonic, its osmolality is lower than that of the plasma (300 mOsm/kg H_2O). The free water clearance is negative. It is, however, possible that slightly hypertonic urine with a correspondingly high specific gravity may be produced under particularly pathological conditions where the glomerular filtration is greatly reduced, even in the absence of vasopressin (BERLINER, 1967; KLEEMAN, 1957). Definite diagnostic border-line values for urinary outputs and concentration capacities cannot be given because of the occurrence of partial diabetes insipidus, particularly the type which develops postoperatively.

The polyuria in diabetes mellitus rarely exceeds 4 liters. The specific gravity is high and glucosuria is present. The daily urinary output in chronic nephritis and cystic kidneys is seldom more than 4 liters.

Further, nephrogenic polyuria occurs in hypokalemia with hyposthenuria (see p. 48) and also in primary aldosteronism (see p. 332). Finally, polyuria may result secondary to hyper-

Table 6. Differential diagnosis of polyuria. [Modified according to KLEEMAN *et al.*: Arch. int. Med. **101**, 1023 (1958)]

Mechanism:		
Water	Excessive water intake	Polydipsia a) Psychogenic b) Organic (seldom)
	Incapacity of tubular reabsorption	Vasopressin *deficiency* or disturbed release: Diabetes insipidus
		Disturbed *response* of the nephrons to vasopressin: Nephrogenic, hereditary diabetes insipidus Polydipsia > 3 days Hypokalemia Primary aldosteronism Nephrocalcinosis Hyperkalemia Lithium medication or intoxication Manganese, magnesium or cesium intoxication Condition after urinary tract obstructions Multiple myeloma Amyloidosis
Dissolved substances:		
Glucose		Diabetes mellitus Phlorrhizin diabetes
Mannitol		Mannitol diuresis
Salts, especially NaCl		Chronic pyelonephritis, interstitial nephritis Salidiuretics, Hg-diuretics
Urea		Chronic renal disorders

parathyroidism and hypercalcemia, in which case the urinary output seldom exceeds 4 liters.

The same amount of urine is excreted daily in nephrogenic and in true diabetes insipidus. Nephrogenic diabetes insipidus is recognized by its failure to respond to vasopressin.

Neurotic or organic polydipsia can present the greatest difficulties in differential diagnosis. Often the prognosis and treatment can only be decided upon after hospital observation or by following the course of the disease.

9. Diagnosis of Diabetes Insipidus

Tests for Investigating Polyuria and Polydipsia

The diagnostic value of all of the following tests is limited by the fact that after more than 3 days of persistent water diuresis, the concentrating ability of the kidney decreases. This means that a high specific gravity cannot be achieved regardless of whether the water deprivation test, Hickey-Hare test, the vasopressin, or the nicotine test is employed. Maximal concentrating ability can only be examined after several days of water restriction or after treatment with depot-pitressin.

The least inconvenient and most reliable tests are still the water deprivation test under osmolality control with termination after 3–5% loss in weight and the vasopressin test. The Hickey-Hare and the nicotine tests are usually dispensable.

a) Water Deprivation Test

α) Principle

The plasma osmolality rises during water deprivation. In the healthy subject, the hypothalamic osmoreceptors are stimulated and vasopressin is then released, causing the pores in the distal nephrons to open for water reabsorption. Urinary flow falls; the specific gravity and urine osmolality rise. In diabetes insipidus, because vasopressin is absent, water continues to be excreted with development of dehydration and weight loss.

β) Method

7:00 a.m. Breakfast with little fluid.

7:30 Bladder emptied. Specific gravity and, when possible, osmolality of the urine are measured. Weigh patient hourly.
Blood collection for Hb, hematocrit, Na, Cl, when possible, osmolality, perhaps K and proteins. From 7:30 stop fluid intake. Watch patient closely. Collect urine in as many portions as possible. Note amount and specific gravity. Estimate osmolality whenever possible. After 2–3 hours or when patient can no longer urinate every half hour, only the hourly output is measured.

10:30 Blood for same determinations as above. Weigh patient.
The water deprivation test should last at least 6 hours, or better still, 24 hours. When the patient has lost 3–5% of the body weight, the test must be discontinued promptly.
Before the end of the test, blood collection is repeated. Patient is weighed again.
A sedative may be used to prolong the test.

γ) Interpretation

Diabetes insipidus is probable when: the urinary volume does not decrease or decreases only slightly during the test, when the specific gravity is not more than 1008, when the urine osmolality does not rise beyond 300 mOsm/kg H_2O, and when the patient loses 3–5% of his body weight. However, a patient with polydipsia, who at the beginning of the test is very highly overhydrated, can excrete urine with a low specific gravity for a long period of time due to the water retained in the tissues.

b) Hickey-Hare Test

(Infusion of Hyperosmolar NaCl-Solution)

α) Principle

Infusion of 2.5% NaCl causes an increase in the serum osmolality, and thereby stimulation of the osmoreceptors with release of vasopressin.

β) Method

Prepare: approximately 4 liters of unsweetened tea, 1 liter sterile 2.5% NaCl solution with complete drip set.

7:00 a.m. Breakfast with 20 ml fluid per kg body weight. This corresponds to 1.4 liters fluid for a 70 kg patient. No coffee. Smoking forbidden. Fluid should be ingested between 7 and 7:30.

From 7:15 Patient should void urine every quarter hour. The amount excreted

is measured, and the same volume of tea is ingested. When patient cannot void urine regularly, catheter must be introduced. Note the amount and specific gravity of each portion of urine.

10:00 Blood collection for Na, Cl, protein, Hb, hematocrit, when possible, serum osmolality.

Immediately after blood collection, infusion is started at a rate of 0.2 ml/kg body weight per minute, i.e. a 70 kg patient receives 14 ml/min = 280 drops per minute. The infusion should be continued for 45 min so that a 70 kg patient would receive a total of 630 ml.

It is practically impossible to count the drops. The quantity of fluid which should run off in the fixed time is best measured on the infusion bottle, and the rate adjusted accordingly. It may be convenient to employ an infusion pump for this purpose. A relatively large needle must be used in order to ensure rapid flow.

10:45 Stop infusion. Blood estimation as above.

The test is discontinued as soon as the urinary output collected during the test reaches the same quarter-hour volume as before the infusion was started.

γ) Interpretation

The estimation of Na, Cl, Hb, hematocrit and proteins will indicate whether the test is being carried out correctly. During the infusion, Hb, hematocrit and protein concentration in the serum decrease, whereas Na and Cl rise. Serum osmolality may be measured directly. A patient with polydipsia can be so hypo-osmolar at the beginning of the test that the infusion causes no hyperosmolality. In this case the test must occasionally be repeated with more NaCl.

Diabetes insipidus is probable when there is no decrease in urinary output and no increase in the specific gravity during the test.

An osmotic diuresis can occasionally simulate a false pathologic result. Simultaneous measurement of the free water clearance prevents false interpretations. In patients with circulatory disturbances there is a risk of pulmonary edema due to overloading with NaCl (15 g for 70 kg body weight).

c) Vasopressin Test

α) Principle

An injection of synthetic lysin-vasopressin can show whether the kidneys react normally to this hormone. Nephrogenic diabetes insipidus can then be diagnosed or excluded.

β) Method

The vasopressin test is carried out after the Hickey-Hare test so that the patient need not be hydrated again.

If the test is done on another day, the patient must be hydrated as in the Hickey-Hare test with 20 ml fluid per kg body weight.

Thereafter, the patient must void urine every quarter hour, and the same volume of tea is given to the patient. Note the quantity, specific gravity, and when possible, the osmolality of every urine sample.

At the beginning of a quarter-hour period, 1 IU lysin-vasopressin is given rapidly intravenously.

The blood pressure should be measured before and after the injection of vasopressin. The vasopressin test is not admissible in patients with hypertension and coronary disease, since vasopressin may cause a rise of approximately 50 mm Hg in the blood pressure.

γ) Interpretation

If the patient under investigation does not react with a decrease in urinary output and a rise in the specific gravity, the same amount of vasopressin should be tested in a normal subject.

If the normal person reacts to the vasopressin, then the patient who did not react must have a nephrogenic diabetes insipidus.

Central diabetes insipidus is present when the specific gravity and the urine osmolality are higher in the vasopressin test than in the water deprivation test. A high specific gravity in the water deprivation test indicates polydipsia (BARLOW, 1959). The free water clearance is the most reliable way of assessing the effect of vasopressin.

In patients previously treated with vasopressin or posterior pituitary extracts, the presence of antibodies to vasopressin may obscure the results.

d) Depot-Pitressin Test

5 U of pitressin tannate in oil given intramuscularly leads to a decrease in the urinary output and to a rise in the urine concentration,

both with diabetes insipidus and with polydipsia. The patient with diabetes insipidus, however, feels relief at once and stops drinking. The polydipsic patient continues to drink, becomes overhydrated, gains weight, and develops headache, nausea, and confusion.

Method: 7 a.m. – after weighing the patient and measuring the hematocrit and the serum osmolality whenever possible – give 5 U depot-pitressin by i.m. injection. Fluid and food are not limited. Fluid intake, urinary output, and specific gravity are measured. Weight is measured 3 times daily. Serum osmolality and hematocrit daily. Patient is observed for at least 3 days.

e) Nicotine Test

α) Principle

Nicotine stimulates the release of vasopressin from the hypothalamic-neurohypophyseal system. According to DINGMAN, this stimulation does not occur via the osmoreceptors, but rather through direct action on the hypothalamic nuclei and the posterior pituitary. By means of an injection of nicotine, the content of vasopressin in the pituitary gland and its release can be examined. When the pituitary reacts to nicotine, urinary flow is again reduced due to the same mechanism as in the other tests.

β) Method

7:00 Empty bladder. Breakfast.

Between 7:00 and 7:30 fluid intake: 20 ml per kg body weight, i.e. 1.4 liters for a 70 kg patient. No coffee, no smoking.

Void urine quarter hourly. Drink same volume of fluid. Note the quarter hour urinary output and the specific gravity.

When urinary flow becomes constant, approximately at 10:00, at the beginning of a quarter hour period, 1 mg nicotine base is given intravenously to nonsmokers (1 mg nicotine base corresponds to 2 mg nicotine salicylate or 3 mg acidic nicotinetartrate).

Approximately 3 mg of nicotine base are injected into smokers.

The normal reaction to nicotine is the development of nausea. When this does not occur, the dose is too small and a slightly higher dose should be injected.

γ) Interpretation

It is assumed that two types of diabetes insipidus can be differentiated. If the patient does not react to nicotine, it must then be assumed that vasopressin is not formed. On the other hand, if the patient reacts to nicotine but not to osmotic stimulation, a lesion of the osmoreceptors must be assumed to be present (DINGMAN, 1957).

The stimulation threshold for the release of vasopressin by nicotine is very variable. Thus, a sufficiently high dose of nicotine cannot always be given to definitely establish a negative result (DIES, 1961).

f) Free Water Clearance

α) Principle

The urinary volume can be divided into two hypothetical portions, one with osmotically-bound water, and the other with free water. The urine volume per unit of time or the urinary flow is the sum of the osmolar clearance and the free water clearance ($V = C_{osm} + C_{H_2O}$). The latter quantity has a negative value in hypertonic urine and a positive value in hypotonic urine. The osmolar clearance is calculated from the formula:

$$C_{osm} = V \frac{\text{urine osm}}{\text{plasma osm}}$$

with V as the urinary output per minute. From this the formula for free water clearance is deduced

$$C_{H_2O} = V\left(1 - \frac{\text{urinary osm/kg } H_2O}{\text{plasma osm/kg } H_2O}\right).$$

Depending on the urinary and the plasma osmolality, the quotient will be >1 or <1, and the sum or the product will be negative or positive.

In general a negative free water clearance indicates that vasopressin is active. For convenience, the collection period for the estimation of the free water clearance is adjusted to the urinary flow. When the urinary flow is 5 ml/min, urine is collected every quarter hour. Hourly collections are made when the flow is <2 ml/min.

An exact estimation of the osmolality is essential for calculating the free water clearance. It allows exact calculation of diuresis, or antidiuresis, and it is advantageous to employ the free water clearance in the Hickey-Hare test, the nicotine test, and the vasopressin test. Thus, for example, a pathologic result may be identified as being due to simultaneous osmotic diuresis.

Where the urinary output is small, the clearance becomes inexact because of the unavoidable 5–10 ml of residual urine in the bladder.

β) Method

Patient hydrated, depending on the purpose of the investigation. When there is an average

urinary flow of 1–2 ml/min the urine is measured during 2 intervals, from 8–9 h and 9–10 h. The volume and the osmolality are measured.

Collection of blood at 9 h for estimation of the plasma osmolality. Use the formula above for the calculation.

In our experience other simplified tests such as comparison of the diuresis after drinking water or 1% saline or comparison of the urinary and plasma osmolarities during 6 to 12 h of fluid deprivation, are less reliable (JADRESIC, 1962; DECOURT, 1960; DASHE, 1963).

g) Assays of Plasma and Urinary Vasopressin

Until recently, the concentration of vasopressin in the body fluids and in tissue extracts could only be estimated from its antidiuretic and hypertensive effect in animals. Reliable results can be obtained using the unanesthetized trained dog (VAN DYKE, 1955), or by a less expensive method using the hydrated rat anesthetized with alcohol. The body fluid to be examined is injected intravenously (SAWYER, 1966). Diuresis may be registered by automatic counting of drops of urine (IRMSCHER, 1965), or a regular diuresis may be obtained by exposing the bladder and using a constant intravenous infusion (CZACZKES, 1964). It is possible to increase the sensitivity further by cannulating the abdominal aorta (SAWYER, 1966) or the jugular vein and by catheterizing the bladder (HEINTZ, 1964). 1–5 μU per ml are given as the lowest measurable values. A range of values between 0–0.05 to 22 μU/ml have been reported in the human, depending on the state of hydration (CZACZKES, 1964; LAUSON, 1967). Values of 2.5–5 μU/ml can be estimated by using brattleboro rats with hereditary diabetes insipidus which are more sensitive to vasopressin. In general, however, this sensitivity is hardly sufficient to determine the vasopressin concentration in human plasma, except in severe dehydration.

The biological estimation of vasopressin excreted in the urine has yielded values between 40–160 μU/24 h (CHAUDHURY, 1961). This method can only be conclusive in massive overproduction (see p. 63) (THORN, 1963). Radioimmunological methods for vasopressin are difficult to perform in biological fluids because of cross-reactions and interferences of unidentified substances with the hormone-antibody reaction. There are methods using antibodies produced by pure vasopressin (ROBERTSON, 1970) and others employing coupling of vasopressin to bovine serum albumin with glutaraldehyde. Previous gel filtration and acetone precipitation for elimination of the interfering substances are necessary for the determination of plasma vasopressin. Concentrations as low as 0.025 pg/ml or 0.01 μU can then be detected. In the healthy man, concentrations between 1–10 μμg/ml (= 0.1–1 μU) are found according to the state of hydration (ROBERTSON, 1970, 1971). In dehydrated diabetes insipidus patients concentrations of up to 0.6–3.2 pg/ml can be detected. In the unextracted urine rates of 1.2–6.5 mU/h arginine-vasopressin have been found in dehydration and rates of 0–0.35 mU/h during water loading. This material was dialyzable. The method is useful for the determination of secretory rates (OYAMA, 1971). The radioimmunological determination of neurophysin in plasma is easier to perform and the values parallel those of vasopressin corresponding to hydration and dehydration (CHENG, 1970; LEGROS, 1972). Further experience will show whether the determination of neurophysin can replace that of vasopressin.

10. Prognosis and Course

The course is irreversible almost without exception even when the cause of the symptomatic disturbance is successfully removed. Occasionally, diabetes insipidus can disappear after a craniopharyngeal cyst has been punctured. The prognosis of survival is good, providing a destructive process does not progress further. Spontaneous regression of symptoms is always suggestive of an additional lesion involving the anterior pituitary.

11. Therapy

In symptomatic diabetes insipidus, the underlying disorder must be treated primarily. The incidence of diabetes insipidus is high, when the etiology is unknown, and therefore irradiation of the pituitary region (in the hope

Table 7. Synopsis of investigation for diabetes insipidus

1. General examination, followed by ophthalmoscopy of the fundi, and urine examination for sugar and protein. Measurement of the urinary output and fluid intake with normal diet and unrestricted fluid intake. The specific gravity, and whenever possible, the osmolality of different urine samples are estimated.
2. Plasma and urinary osmolality in the morning in the fasting state or after 6 hours of absolute fluid deprivation.
3. Water deprivation test.
4. Intravenous vasopressin test, depot-pitressin test. Possibly test with hypertonic saline infusion and the nicotine test.
5. X-rays of the skull, antero-posterior and lateral views, possibly electroencephalography and pneumoencephalography.

of favorably influencing a possible neoplastic or granulomatous process) is not justified. Symptomatic treatment consists of vasopressin replacement, dietary measures, possibly salidiuretics and certain drugs.

Above all, the patient should be allowed to drink to satisfy his needs. The polyuria is decreased by reducing the intake of substances excreted in the urine, therefore a diet low in salt is advisable. The aqueous solution of a posterior pituitary extract and the synthetic lysin-vasopressin for i.m. administration have not proved satisfactory for replacement therapy. They are effective for only 4–6 hours, and when given in high doses produce side effects such as nausea, gastrointestinal spasms and diarrhea. On the other hand, pitressin-tannate in oil is very valuable for long-term treatment. Immediately before administration the ampoule must be warmed to body temperature and shaken well. An intramuscular injection of 1–3 units, equivalent to 0.2–0.6 ml, has a varying action lasting between 1 and 3 days. The patient is symptom-free during this period. Over-dosage easily leads to over-hydration, consequently the necessary dose must be individually adjusted. Occasionally a whole 1 ml ampoule, corresponding to 5 U, is needed. The full effect will be seen only after some days or weeks, when the high osmolality of the renal medulla is restored (HARRINGTON, 1968). Intelligent patients should be allowed to give the injection themselves as diabetics do. The use of pitressin in the form of snuff, although effective, is presently obsolete since it can give rise to the development of general or localized allergies and irritation of the nasal mucosa or even more serious complications, such as an allergic interstitial pneumonia, called "pituitary snuff-taker's lung" (PEPYS, 1966; BÜTIKOFER, 1970). On the other hand, aqueous solutions of synthetic lysin vasopressin are easily and conveniently employable in nasal sprays in a concentration of 50 μg/ml. Spraying must be undertaken every 3–6 hours, and the individually adequate dose must be determined. On an average, most patients need 50–62.5 U per day. When the duration of action does not last overnight, a cotton wool swab soaked in a vasopressin solution can be introduced. During a cold, buccal or vaginal administration is also possible. Spraying before retiring for the night can usually prevent nocturia, and urinary output usually falls to below 3 liters (DINGMAN, 1964). No effect on the uterus has been observed during pregnancy, and the blood pressure does not rise.

Synthetic vasopressin analogues such as DDAVP, 1-deamino-8-D-arginine-vasopressin, can have a higher antidiuretic potency together with a decreased pressor activity and a much longer half-life. Deamination in position 1 increases the antidiuretic effect, whereas the introduction of the D form of amino acid in position 8 is usually combined with a reduction of pressor effects. DDAVP (Desurin), administered intranasally with a simple and suitable device in doses of 15 μg, twice daily, normalizes the urine production in practically all idiopathic and symptomatic diabetes insipidus patients without any side effects. It will soon be commercially available and at present seems to be the safest and most convenient therapy (VAVRA, 1968; ANDERSON, 1972; IRMSCHER, 1972). A further indication might be Enuresis nocturna.

The paradoxical administration of thiazide diuretics is one way of decreasing the urinary volume in water diuresis (EARLEY, 1961). The effect is not satisfactorily explained, and is probably complex. Salidiuretics inhibit sodium reabsorption in the distal nephron and so decrease the formation of osmotically free water. In addition, thiazides are supposed to cause an increased proximal reabsorption of the isotonic filtrate, due to the excretion of sodium with diminished extracellular volume and restricted renal blood supply. This leads to decreased diuresis (EARLEY, 1962; CUTLER, 1962; ORLOFF, 1966). On the other hand, reduction of glomerular filtration rate with a reduced supply of isotonic solution to the distal tubule can hardly explain the beneficial effect of the salidiuretics. In patients with diabetes insipidus who respond well to depot-pitressin or the vasopressin spray, the addition of salidiuretics is of little benefit (CRAWFORD, 1960). In patients who have become resistant or over-sensitive to vasopressin, and especially in patients with nephrogenic diabetes insipidus, the complaints can be reduced and occasionally normalized through salt restriction and salidiuretics (chlorthalidone 200–400 mg daily, hydrochlorothiazide 50–75 mg), the potassium loss being compensated by daily doses of 3×1 g potassium salt. The slight antidiuretic action of aminopyrin and phenylbutazone are of no therapeutic significance now. The antidiabetic compound chlorpropamide in a dosage of 250–500 mg per day has an antidiuretic effect in patients with vasopressin-sensitive diabetes insipidus (ARDUINO, 1966; FRØYSHOV, 1968). The free water clearance becomes negative (HOCKEN, 1968; ANDREANI, 1969) by a mechanism of action which is still uncertain. Whether chlorpropamide acts by way of cyclic AMP (EARLEY, 1971) or not (INGELFINGER, 1969) is still undecided. Although a direct effect on the kidney is not entirely excluded (DANISI, 1970), most of the evidence is in favor of the view that chlorpropamide

enhances vasopressin's effect of increasing water permeability of the distal nephron (EARLEY, 1971; UHLICH, 1971). The most valid arguments are that chlorpropamide is ineffective in nephrogenic diabetes insipidus and in rats with hereditary absence of vasopressin but that it augments the effect of *small* doses of vasopressin (BERNDT, 1970). In severe cases of diabetes insipidus there is little or no effect. In a small percentage of patients with diabetes mellitus, it can lead to a reversible syndrome of inappropriate secretion of vasopressin with hyponatremia and hypo-osmolality (WEISSMANN, 1971). The hypoglycemic effect of chlorpropamide is a serious drawback for its use in patients with diabetes insipidus.

Whereas other peroral antidiabetic agents are ineffective, some other drugs, the anticonvulsant carbamazepine (Tegretol) and the anti-hypercholesteremic agent clofibrate (Atromide), have a similar antidiuretic action on patients with diabetes insipidus (BRAMHOFER, 1966; FRAHM, 1969; DECOURT, 1971). The urinary volume of patients with idiopathic or symptomatic diabetes insipidus can be reduced to half or less by peroral application of 2 or 3 doses of 200 mg carbamazepine. The side effects may be tiredness and dizziness, mainly at the beginning of the treatment. It is therefore advisable to start with small doses (100 mg 2 ×). Here again, the treatment is not or not completely effective in severe cases of diabetes insipidus. A combined treatment with smaller doses of chlorpropamide and carbamazepine (300 and 400 mg) may lessen or avoid the side-effects (STOLL, 1972). Clofibrate (Atromide), 4–6 × 0.25 can be combined with carbamazepine (PERLEMUTTER, 1971).

Not all patients want long-term replacement therapy. Many patients, especially those who developed the disorder during childhood, are accustomed to large fluid intake, have adjusted their lives accordingly, and no longer find it disturbing. They employ replacement therapy only in special situations when it is impossible to obtain the required volume of fluids.

F. Inappropriate Secretion of Antidiuretic Hormone (Schwartz-Bartter Syndrome, Oversecretion of Vasopressin)

1. Symptomatology and Pathogenesis

Hyponatremia with hypotonic hypervolemia and hypertonic urine has been observed in bronchial carcinoma and other diseases. In 1957, SCHWARTZ and BARTTER related these features to a dilution of the plasma due to hypersecretion of vasopressin. The diagnosis is made indirectly from the following findings:

1. Hyponatremia with hypo-osmolality of the serum and extracellular fluid.
2. Absence of hypovolemia and dehydration. Normal turgor, blood pressure, and serum urea.
3. Persistent natriuria despite hyponatremia. Hypertonic or not maximally diluted urine.
4. Intact renal and adrenal function.

Administration of exogenous vasopressin with simultaneous continued water intake results in increased glomerular filtration, elevated sodium excretion, hyponatremia, and dilution of the body fluids due to an increase of the plasma volume. Although the intravascular space is usually normal, the extracellular space becomes enlarged. Osmoregulation is abandoned in favor of maintenance of the volume of the body fluids. It is not clear why hypotonic hydration is well tolerated and the intracellular space does not enlarge. A shift of sodium into the intracellular space has been observed (KAYE, 1966) but it seems to be osmotically inactive. The elevated natriuresis is due to increased filtration and hypervolemia in the absence of aldosterone secretion, and also to disturbed sodium reabsorption in the presence of an enlarged extracellular volume (BARTTER, 1967); the additional effect of the hypothetic third factor (FICHMAN, 1968; BRICKER, 1967) may contribute to the natriuresis.

The syndrome has been observed:

1. in bronchial carcinoma, generally small-cell or anaplastic type. There has been only one reported case of inappropriate ADH with adenocarcinoma;
2. in cerebral diseases, primary and metastatic brain tumors, vascular diseases of the brain, trauma to the skull and malformations;
3. in certain metabolic disorders, such as porphyria with encephalopathy, and finally in an "idiopathic" group of unknown etiology (WALDVOGEL, 1967). It is not certain if this group also includes the syndrome observed in severe pulmonary tuberculosis, miliary tuberculosis, tuberculous meningitis and in the "cerebral salt-losing syndrome" (Table 8). Hyponatremia with hypovolemia usually occurs in Addison's disease, hypopituitarism and myxedema (see p. 159). There is currently some discussion as to whether hyponatremia, which occurs in postoperative conditions and in cardiac failure, is occasionally caused by excessive vasopressin secretion (BARTTER, 1967).

At first, there was only indirect support for an increased vasopressin secretion in these syndromes, as evidenced by a negative free water

Table 8. Occurrence of the vasopressin-oversecretion syndrome (inappropriate secretion of antidiuretic hormone) (BARTTER and SCHWARTZ, 1967)

1. Malignant tumors:	
	Carcinoma of the lung
	Duodenal carcinoma
	Pancreatic carcinoma
	Thymoma
2. Disorders of the central nervous system:	
	Meningitis
	Injuries to the skull
	Brain abscess
	Brain tumor
	Encephalitis
	Guillain-Barré syndrome
	Acute intermittent porphyria
	Subarachnoid hemorrhage
	Miscellaneous
3. Pulmonary diseases:	
	Pneumonias
	Tuberculosis
	Cavern formation (aspergillosis)
4. Idiopathic	

clearance. Moreover, the clearance may occasionally be positive, but it is always insufficiently high in relation to the hypotonic plasma. The kidneys are always able to retain sodium and to respond to mineralocorticoids, even with restricted renal blood supply.

Sodium administration increases natriuresis; therefore, hyponatremia can hardly be compensated by this means. On the other hand, when water deprivation restores the sodium concentration in the serum, hypernatriuria and polyuria are eliminated. Vasopression or substances with a vasopressin-like effect have been successfully demonstrated in the urine (THORN, 1963), in the plasma (BOWER, 1964), and in tumor extracts (ARMATRUDA, 1963; BOWER, 1964; BARRACLOUGH, 1966; BERDE, 1965, 1968; MARKS, 1968; ROBERTSON, 1971; UTIGER, 1966; VORHERR, 1968). However, an increased vasopressin concentration cannot be proven in all cases. It can be in the normal range, but the concentration is too high for the corresponding osmolality and is not suppressible by further hydration (BAUMANN, 1972).

Obviously there are two possible mechanisms:

1. Bronchial carcinomas or other tumors produce vasopressin or a similarly active substance. This is supported by the fact that the syndrome regresses after operation or after improvement in the pulmonary carcinoma following chemotherapy or radiation, and that such substances can be directly demonstrated in tumor extracts.

2. The pathogenesis of the syndrome in cerebral processes is probably related to a regulation disturbance in the release or production of vasopressin. The regulatory center no longer responds to the usual inhibitory stimuli (hypo-osmolality, hypervolemia, only partly to alcohol), but does, however, respond to diphenylhydantoin. This may allow a differential diagnosis between the syndrome caused by tumor and the one caused by central nervous disorders. It is not known whether and how cases of the Schwartz-Bartter syndrome occuring in pulmonary tuberculosis, are to be included here. The hyponatremia in myxedema and in pituitary insufficiency does not appear to belong to this syndrome (see p. 159, 95).

2. Differential Diagnosis and Diagnosis

The hyponatremia due to "true" salt depletion, such as occurs in ADDISON's disease, in tubular nephropathy, and during vomiting and diarrhea, lead to *hypo*volemia, hypo-osmolality, hypotension, hypotonic dehydration and azotemia. Hyponatremia and *hyper*osmolality are suggestive of mannitol abuse (AVIRAN, 1967). Hypertonic urine can also be produced when the glomerular filtration is reduced. This, however, is always associated with azotemia and an increase in plasma creatinine. Moreover, sodium excretion decreases with a fall in filtration.

The hyponatremia in terminal cardiac failure is combined with severe edema. Salt escapes into the interstitial space and into the tissue, sodium excretion is reduced, and the sodium balance is positive.

The hyponatremia in hypopituitarism (see p. 95) is not connected with hypernatriuria and does not improve with dehydration, but does respond immediately to cortisone treatment. Psychogenic or organic polydipsia can give rise to similar findings when the fluid intake is more than 25 ml/min, although the urine is always maximally diluted.

Pseudohyponatremia in hyperlipemia and in hyperproteinemia can be excluded because of the normal osmolality.

Finally, administration of mannitol can be a cause of hyponatremia with hyperosmolality of the serum (AVIRAM, 1967). The Schwartz-Bartter syndrome is present when after exclusion of dehydration and cardiac failure, hyponatremia occurs with hypertonic or insufficiently diluted urine and can be improved by limiting the fluid intake. Values of the urea in the serum are charcteristically very low, being under 20 mg%.

3. Course and Therapy

The course is determined by the primary disease. Remissions are possible, especially in porphyria. When the basic disease cannot be influenced, the hyponatremia can be improved or be avoided by limiting water intake. The general condition of the patient is thus improved.

Diphenylhydantoin which i.v. inhibits vasopressin overproduction in the central nervous system does not correct long-standing hyponatremia (FICHMAN, 1968). Although the application of mannitol counteracts the effects of vasopressin oversecretion, it has no advantage over fluid restriction alone.

IV. The Pineal Body and the Circumventricular Organs

A. LABHART

A. Pineal Body

Throughout the history of medicine, opinions on the importance and functions of the pineal body have varied more than those related to any other organ of the body. DESCARTES saw it as the seat of the functions of the soul, imagining that light impulses could be perceived by the pineal body and then transmitted as humoral signals to the musculature. From this position of eminence, theories concerning its function have relegated it to a position where it presently serves primarily as a calcified point of orientation in the middle of the skull for the neuroradiologists. At present it is receiving renewed importance as a potential fourth neuroendocrine organ, the biological clock of the organism and the rhythm initiator.

The phylogenetic history of this organ is also interesting. A million years ago, in the brontosaurians, this organ represented a third eye. It is still active as a light receptor in certain amphibians in that it contains a light-sensitive apparatus similar to the retinal cones which emit nerve impulses to light stimuli of certain wavelengths. The pineal body has become the neuroendocrine organ in mammals which need nerve impulses for the liberation of a specific hormone, melatonin. The indole alkylamine, melatonin (see Fig. 1), produced in small amounts, is the most potent pigment regulator in amphibians, causing aggregation of melanin granules in the melanophores and fading of skin pigmentation. In the mammal, melatonin has no influence on pigment regulation.

However, in the mammal the pineal body has not forgotten its past as a third eye, and although it no longer possesses any light-sensitive elements, its functions are still dependent upon light. Light impulses from the retina of the eye reach the pineal body through the sympathicus via the superior cervical ganglion where noradrenaline and serotonin are released. This is the only site where serotonin is released as a neurotransmitter. Noradrenaline and serotonin influence the synthesis of the enzyme 5-hydroxyindole O-methyl-transferase (HIOMT) which liberates melatonin from N-acetyl-serotonin. It is presently uncertain to what extent the limbic system influences the pineal body and through this means, further transmits olfactory stimuli (RELKIN, 1966).

The physiological function of melatonin in the mammal is still not clear. It is certain that it has no function in pigment regulation. It can, however, be shown to inhibit gonadal function, exerting a reducing action on the ovary, and delaying or inhibiting estrus in the rodent. Pinealectomy, darkness or division of the conveying sympathetic nervous pathway leads to loss of HIOMT, and thus also of melatonin, and to accelerated estrus. Melatonin administration reverses this acceleration. The effect of light on testicular size is also transmitted by the pineal body (REITER, 1968). The end organ of melatonin is uncertain. It acts on the brain, perhaps especially on the eminentia mediana (MARTINI, 1968), by influencing synthesis or release of one or more neurotransmitters (WURTMAN, 1971). Labeled melatonin accumulates mainly in the ovary, but also in the vagina, the brain and the pituitary gland.

In addition to the seasonal regulation of the estrus, the pineal body also appears to play an important part in the daily rhythm of the endocrine system, dependent upon light. Through the perception of light via the retina and the sympathetic system, the concentration of HIOMT and therewith the content of melatonin in the pineal body rises to its maximum at midnight. The concentration is lowest at midday. The rhythm disappears completely with continual illumination or continual darkness. A contrasting rhythm appears to be present in serotonin, the precursor, and in a certain sense possibly an antagonist. The content of serotonin in the pineal body is highest at midday and lowest at midnight. In this case, however, the rhythm is determined in the central nervous system: the light works only as a synchronizer, since the rhythm for serotonin does not disappear with light but only in the dark.

The pineal body begins to deposit calcium after puberty. This does not, however, appear

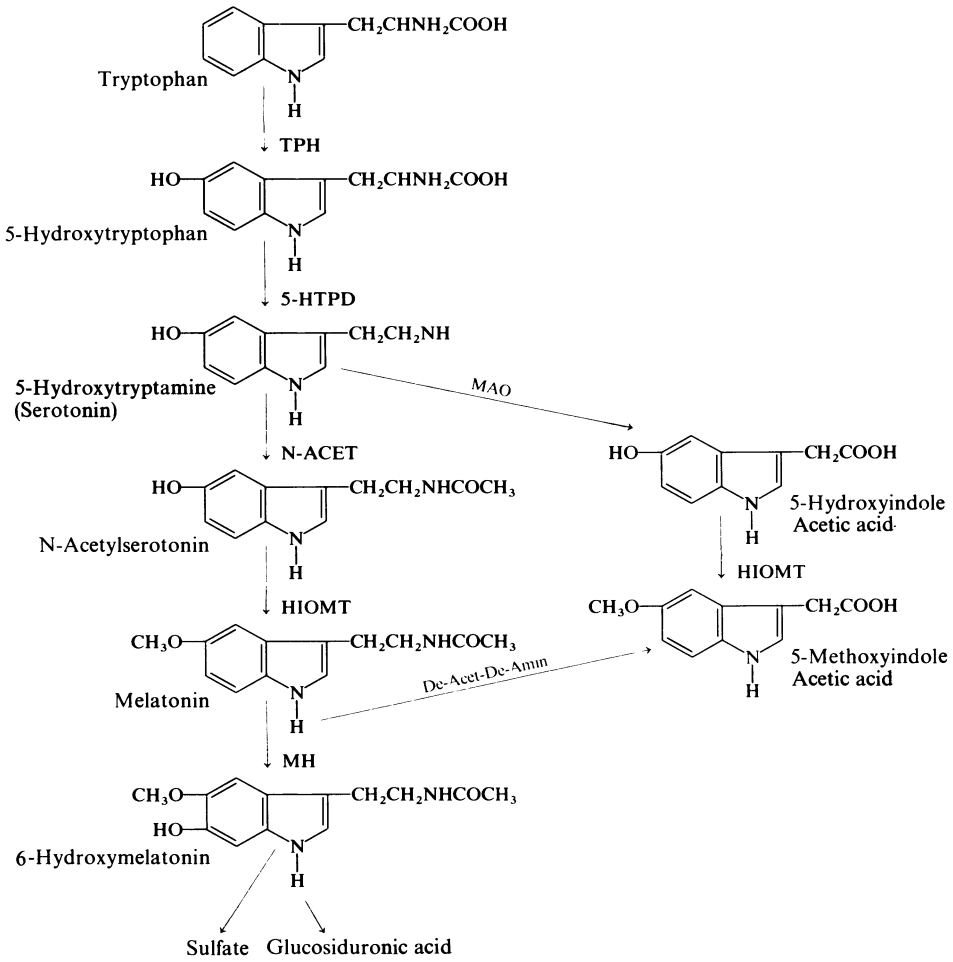

Fig. 1. Biosynthesis and metabolism of Melatonin. *TPH* tryptophan hydroxylase; 5-*HTPD* 5-hydroxytryptophan decarboxylase; *MAO* monoamine oxidase; *N-ACET.* N-acetylating enzyme; *HIOMT* hydroxyindole-O-methyltransferase- *DE-ACET.-DE-AMIN.* deacetylating and deaminating enzyme; and *MH* microsomal hydroxylase. (After RELKIN, 1966)

to influence its activity, since the activity of the decisive enzyme HIOMT remains intact from early youth to advanced age. Although the physiological significance in man is unknown, the knowledge obtained in the past few years has thrown new light on the known pathophysiological phenomena of puberty. Precocious puberty usually develops with tumors of the pineal region, although only if the tumors derive from the interstitium or a teratoma is involved. Tumors arising from the parenchyma of the pineal body lead to delayed puberty, and in at least two cases increased amounts of HIOMT have been demonstrated in these tumors. The pineal body may therefore be responsible for preventing the premature development of puberty and sexual function. It is possible that the accelerated development (Chap. XIX) observed nowadays is due to the increased light stimuli on the pineal body. There may be other antigonadotropins besides melatonin (BENSON, 1971; CHEESMAN, 1970). In addition to its influence on the pituitary-gonadal axis, the pineal body may have a role in the circadian rhythm of adrenocortical secretions. Melatonin, 5-methoxytryptophol and 5-hydroxytryptophol injected into the lateral cerebral ventricles decrease plasma corticosterone in the rat. This effect is possibly mediated via the adrenergic system (MOTTA, 1971).

As with serotonin, there are at present no known actions of melatonin on the psyche, nor is there any evidence that either of these substances is involved in the development of psychoses.

For a review of the physiology of the mammalian pineal body see REITER (1969).

Pinealomas without endocrine activity usually lead to two or more of the following symptoms: diabetes insipidus, hypopituitarism, calcifica-

tions in the region of the pineal body, deformation of the third ventricle with or without hydrocephalus. The incidence of pinealomas is highest in men before the age of twenty (PUSCHETT, 1968).

B. Subcommissural Organ

The subcommissural organ is a group of cells containing secretory granules which lie in the vicinity of the pineal body, under the pineal recess, at the caudal end of the roof of the third ventricle. In rats, it appears that these cells release a relatively insoluble substance into the cerebrospinal fluid and possibly also into the capillaries. Extracts from this region are believed to inhibit thirst and water intake. Patients with tumors in this pretectal region are supposed not to react to salt withdrawal with the normal increase of the aldosterone secretion. At present, research into the role of this organ in salt and water regulation is not sufficiently advanced for definite conclusions.

The subcommissural organ may belong to a system of "circumventricular organs" which includes the pineal body, the subfornical organ, the supraoptic crest, and certain special ependymal structures of the third ventricle. These various organs appear to possess certain morphological and functional similarities.

1543 VESAL described the hypophysis as "glandula pituitaria cerebri excipiens".
1864 VERGA and
1884 FRITZSCHE and KLEBS described the clinical and pathological features of a case of acromegaly.
1886 PIERRE MARIE named the illness "acromegaly".
1900 BENDA associated acromegaly with an eosinophil hypophyseal adenoma.
1909 ASCHNER showed that hypophysectomy in a growing animal resulted in dwarfism.
1921 EVANS and LONG, using pituitary extract, produced gigantism in rats.
1926 SMITH demonstrated pituitary control over the gonads.
1928 ASCHHEIM and ZONDEK described the gonadotropic hormones.
1928 STRICKER and GRUETER discovered prolactin.
1935 RIDDLE characterized prolactin.
1944 LI and EVANS succeeded in isolating crystallized growth hormone.
1955 KNOBIL and GREEP extracted growth hormones from monkeys which was active in man and showed the species-specificity of growth hormone.
1957 RABEN described a method for extracting human growth hormone from the hypophyses of cadavers.
1961 UTTIGER, PARKER and DAUGHADAY,
1962 HUNTER and GREENWOOD,
1963 GLICK, ROTH, YALOW and BERSON described a radioimmunological method for measuring human growth hormone.
1966–1971 LI described the complete amino-acid structure of human growth hormone and succeeded in synthesizing it.

B. Embryology and Anatomy

G. TÖNDURY and G. KISTLER

1. Embryology

In the human embryo of 6–8 somites, the primitive gut is closed at the cranial end by the pharyngeal membrane which forms the floor of an external depression, the stomadeum. At this site, ectoderm and entoderm come into direct contact. When the embryo is about 2.5 mm long (18–20 somites), the pharyngeal membrane ruptures and the stomadeum develops into the ectodermal portions of the mouth. At this stage, the stomadeal epithelium situated dorsally and just in front of the remnants of the pharyngeal membrane evaginates to form the RATHKE'S pouch, i.e., the anlage of the adenohypophysis. This outpocketing enlarges quickly towards the floor of the diencephalon. Its originally wide mouth soon becomes compressed by a proliferation of the surrounding mesenchyme. Thus, the anlage of the adenohypophysis becomes an epithelial vesicle which remains temporarily connected to the roof of the primitive oral cavity by a slender epithelial stalk.

When the embryo has reached a length of some 7–8 mm, an epithelial stalk grows downward from the anlage of the neurohypophysis in the diencephalon and contacts the upper and posterior portions of the adenohypophyseal vesicle. This leads to a marked proliferation of the front wall of the vesicle, which thickens to become the main cellular mass of the *anterior lobe*. From the rostral portions of this lobe, bilateral epithelial buds proliferate and grow upward to the floor of the third ventricle. The two buds fuse together to form the *pars infundibularis* (pars tuberalis) of the adenohypophysis. The buds often also encircle the root of the infundibulum. In contrast, the posterior wall of the adenohypophyseal vesicle remains thin. It differentiates into the *pars intermedia* of the glandular lobe. The original cavity of the vesicle becomes the *residual lumen* of the adenohypophysis. This cavity usually

disappears completely but may persist as multiple cysts filled with colloidal material throughout life. The epithelial stalk connecting the epithelium of the oral cavity with the adenohypophyseal vesicle in the early stages usually disintegrates. Sometimes, however, islets of these epithelial cells persist and form *accessory adenohypophyseal glands* which are usually situated within either the sella turcica or the sphenoid bone itself but may also be found in the pharyngeal roof. When present, the so-called *pharyngeal roof hypophysis* is usually the best developed of these accessory glands. It lies within the pharyngeal epithelium, exactly on the mid-line of the cavity, and is surrounded by small nerve fibers and blood vessels.

2. Gross Anatomy

The hypophysis of the human adult weighs about 600–700 mg and measures approximately 0.5 × 1 × 1 cm. Macroscopically, the organ can be divided not only into a neural and glandular portion, but also into a proximal and a distal subdivision separated from each other by the diaphragma sellae. The main portion is situated within the sella turcica of the sphenoid bone, where it is surrounded by a rather thick connective tissue capsule. Thus, the intrasellar portions of the hypophysis (anterior, posterior and intermediate lobe) are situated within the dura.

The diaphragma sellae separates the cavity of the sella turcica from the middle cranial fossa. This dural fold forms an opening, the foramen hypophyseale, which lies closely around the hypophyseal stalk. Above the diaphragm, the stalk passes through the peri-infundibular cistern, where it is surrounded by cerebrospinal fluid.

The hypophysis consists of two developmentally, morphologically, and functionally quite distinct parts. The neurohypophysis has already been described in Chap. III, p. 39. The *adenohypophysis* (lobus glandularis, anterior lobe) is derived from an outpocketing of the ectodermal epithelium of the primitive oral cavity (see p. 77). It shows all the characteristics of an endocrine gland. Three major subdivisions may be distinguished:

1. The *pars infundibularis* (pars proximalis or pars tuberalis of the adenohypophysis) is a subdivision of the anterior lobe. It extends from the diaphragma sellae up to the floor of the diencephalon, closely following the course of the infundibulum (pars proximalis of the neurohypophysis), from which it is incompletely separated by a thin sheet of connective tissue continuous with the organ capsule.

2. The *pars intermedia* (zona intermedia or intermediate lobe) is phylo- and ontogenetically a portion of the glandular lobe (see p. 80). It is situated in the sella turcica and is sandwiched between the secretory mass of the anterior lobe and the infundibular process (neural lobe). The intermediate zone forms the so-called distal adeno-neurohypophyseal contact which will be discussed below (see p. 82).

3. The *anterior lobe* (pars distalis of the adenohypophysis) constitutes the bulk of the glandular parenchyma. It is situated completely within the sella turcica.

3. Histology

The anterior and posterior lobes of the hypophysis are surrounded by a rather thick connective tissue capsule, the innermost layer of which is closely applied to the organ parenchyma. The next layer is rich in blood vessels and is therefore called the stratum vasculare. The outermost layer, the stratum periostale, belongs to the periosteum of the sella turcica. Even at low magnification, the deeply stained adenohypophysis stands out sharply against the less stained and more homogeneous posterior lobe. In the pars intermedia, follicles of various sizes containing colloidal material are usually observed. They are known as the Rathke's cysts.

The three subdivisions of the adenohypophysis (pars distalis, pars intermedia, and pars infundibularis) consist of irregular cords and clumps of epithelial cells which are in intimate contact with the dense network of sinusoidal capillaries. Small bundles of collagenous fibers accompany the arteries and portal venules. They are continuous with a fine network of reticular fibers which surround both the epithelial cords and the capillaries. The endothelial cells of the sinusoids are fenestrated. At these sites, the circulating blood is separated from the perivascular space and from the glandular tissue only by the extremely thin diaphragms of the fenestrae and the basal laminae of both the endothelium and the epithelial cords.

Pars Distalis. In contrast to the rather uniform cell populations of both the pars intermedia and the pars infundibularis, the various cell types of the pars distalis differ markedly in size, shape, and affinity for stains. In routine histological sections, chromophilic and chromophobic cells can easily be distinguished. According to the tinctorial reactions of their specific granules in sections stained with special dyes (e.g. alum-hematoxylin and eosin), the chromophilic cells can be further subdivided into

acidophils and basophils. As this affinity for the various stains reflects a characteristic property only of the granules and not of the cytoplasm itself, there is still some considerable controversy about the nomenclature. Identification of the cell types is perhaps best done by the PAS reaction, which is specific for the granules of the basophils and therefore allows these cells to the distinguished from the acidophils and the chromophobes. More recently, electron microscopy has permitted more accurate differentiation of the specific granules of the various cell types and their subclasses.

The *acidophils* (alpha cells) make up approximately 37–44% of the total cell population of the pars distalis (BARGMANN, 1964). They measure about 12–20 μm in diameter, are mainly rounded and contain a large number of granules, the size of which permits them to be resolved with the light microscope. Ultrastructurally, these cells display a well-developed, rough endoplasmic reticulum, a large Golgi complex and rather small, rod-shaped mitochondria. In various mammalian species, two classes of acidophils can be distinguished according to their staining reactions with azocarmine and orange-G. In the rat, the specific granules of these two cell classes also differ markedly in diameter, the one measuring approximately 3000–3500 Å and the other 6000–9000 Å. The number of cells with the smaller but more numerous granules remains fairly constant throughout life. It is believed that these elements produce growth hormone (STH). In contrast, the number of cells containing the larger but less numerous granules is obviously increased during pregnancy and lactation. It is therefore assumed that these cells synthesize prolactin (LTH, luteotropic hormone). The production of these protein hormones by the acidophilic cells, besides being confirmed by immunohistochemical methods, is also supported by pathological findings in humans. Thus, in children an acidophilic adenoma of the anterior lobe results in gigantism, whereas in the adult acromegaly results. Experimentally, removal of a litter from lactating rats leads to marked regressive changes in the prolactin-producing cells within 48–96 hours. Newly produced hormone granules no longer release their content into the perivascular space (and further into the capillaries), but enter the lysosomal cycle and are digested within the cell (SMITH and FARQUHAR, 1966).

The *basophils* (beta cells) of the anterior lobe vary considerably in size (15–25 μ) and

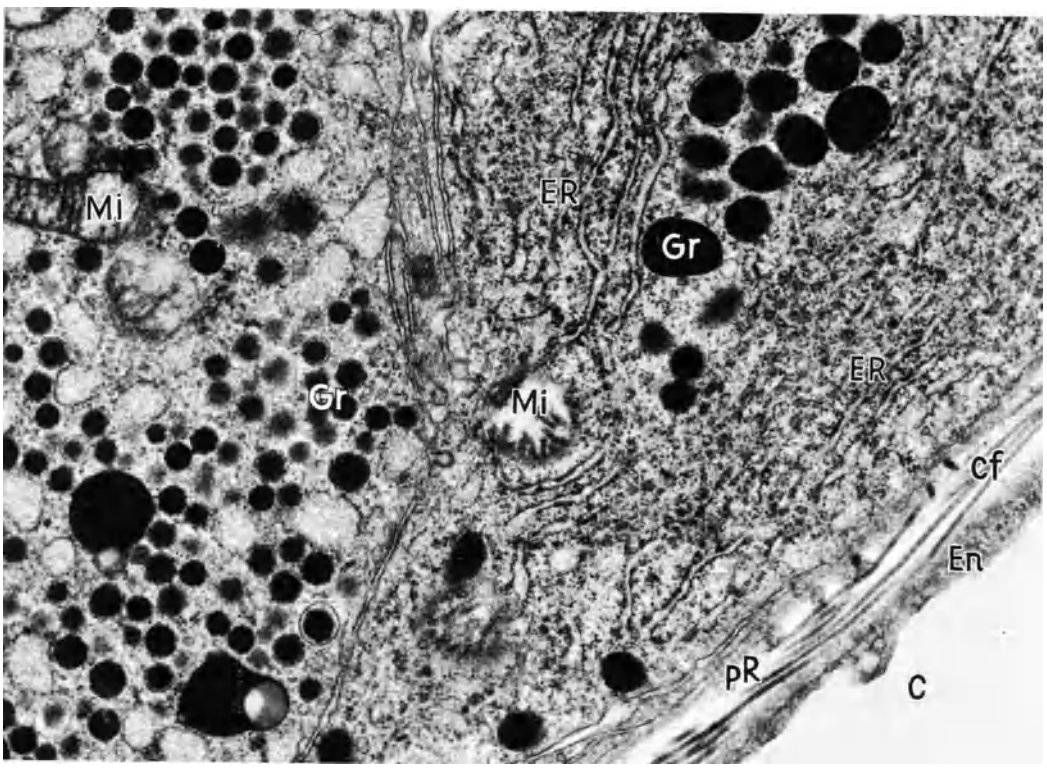

Fig. 1. Incretory cells of the anterior lobe of the rat. Note the difference in size of the hormone granules. *ER* rough endoplasmic reticulum; *C* capillary lumen; *En* endothelium; *pR* perivascular space; *cf* collagenous fibrils; *Gr* hormone granules; *Mi* mitochondria. × 20000

shape (round, oval, polygonal). Their diffusely distributed specific granules measure approximately 1000–2000 Å in diameter and are thus distinctly smaller than those of the acidophilic cells. Light microscopy barely reveals them. Since the hormones produced by the basophils are glycoproteins, the granules are best visualized by the periodic-acid-Schiff (PAS) reaction. They are, however, also stained by hematoxylin, aniline blue or resorcin-fuchsin. In most mammalian species, four types of basophils seem to be distinguishable, according to the size and the affinity of the granules for aldehyde-fuchsin. The so-called beta-basophil cell, which is presumed to produce thyrotropic hormone (TSH), stains with this dye. In the rat, its granules have a diameter of 1000–1500 Å and are situated mainly at the cell periphery. The somewhat larger delta-basophils contain an abundant endoplasmic reticulum and a well-developed Golgi apparatus. Their specific granules measure about 2000 Å in diameter and fail to stain with aldehyde-fuchsin. The delta-basophilic cells are the source of the gonadotropins, i.e., the follicle-stimulating hormone (FSH) and the luteinizing hormone (LH or ICSH). In the rat, it was possible to distinguish the cells producing the two hormones morphologically (KUROSUMI and OOTA, 1968; ROOS, 1968). It has long been known that destruction of a peripheral endocrine organ is usually followed by hypertrophy of the corresponding cells in the anterior lobe. Thus, removal of the thyroid gland leads to enlargement and apparently also to an increase in number of the betabasophilis (= thyroidectomy cells). Similarly, castration is followed by an increase in size and by vacuolization of the gonadotropin-synthesizing delta-basophils (= castration cells).

There is some evidence that the basophils are also the source of the adrenocorticotropic hormone (ACTH, corticotropin). Whether its synthesis takes place within a specific cell type or occurs in the basophils which produce gonadotropins is still an open question. Interestingly enough, in the melanocyte-stimulating hormone (MSH) produced by the basophilic cells of the pars intermedia, the amino-acid sequence is similar or even identical to that of ACTH over large parts of the molecule. Release of these two hormones often seems to occur simultaneously and ACTH is known also to have a certain melanocyte-stimulating effect. Thus the increased skin pigmentation observed in adrenal insufficiency (Addison's disease) and pregnancy is thought to be the result of an overproduction of one or both of the hormones ACTH and MSH.

The chromophobes form the third large cell group of the hypophyseal anterior lobe. They are usually smaller than the acidophils and basophils and are almost devoid of specific granules. The function of these cells has been a matter of dispute for a long time. Because mitoses in the parenchyma of the adenohypophysis are very rare, the chromophobes used to be considered as pluripotent stem cells capable of differentiating into each of the various acidophils and basophils. Ultrastructural studies have, however, shown that the chromophobes do not constitute a uniform cell population. According to their nuclear and cytoplasmic characteristics (chromatin structure, size and number of mitochondria, form of the Golgi complex, etc.), a large proportion of these cells has to be grouped with the acidophils or basophils in spite of the absence of granules. It would therefore appear that most of the chromophobes are stem cells already determined in their differentiation capability. Others, however, seem to be mature chromophils degranulated to such an extent that they fail to stain with specific dyes. It is still not known whether such a degranulation represents a reversible functional state or precedes cell death.

Pars Intermedia. In the human fetus, the borderline zone between the anterior and the posterior lobe consists of a thin sheet of connective tissue and a stratified epithelium of small basophilic cells. These cells are derived from the posterior wall of the adenohypophyseal vesicle (see p. 77) and are, in turn, separated from the main incretory mass of the anterior lobe by a distinct cleft (the remnant of the lumen of the Rathke vesicle). Postnatally, the cleft usually becomes reduced to a number of larger and smaller cysts (Rathke's cysts) lined by a ciliated epithelium and containing a yellowish, colloidal material. With age, an increasing number of basophils of the pars intermedia cross the borderline between adeno- and neurohypophysis and "invade" the posterior lobe, where they are found in close proximity to the nerve-fiber endings and the capillaries.

Light microscopy reveals only slight differences between the usually polygonal cells of the pars intermedia and the basophils of the anterior lobe. Their granules stain specifically with the periodic-acid-Schiff (PAS) reagents as well as with aldehyde-fuchsin and resorcin-fuchsin. Electron microscopy shows that these granules are characteristically accumulated close to the basal lamina. Their diameter varies between 2000 and 3000 Å. The melanocyte-stimulating hormone (MSH) produced by these basophils is a polypeptide which seems to be

bound to a glycoprotein within the granules. From the pituitaries of humans and other mammals, two different melanocyte-stimulating hormones have been isolated up to now. The sequential arrangement of the amino acids in both the strongly basic alpha-MSH and the slightly acid beta-MSH is similar to that found in the adrenocorticotropic hormone ACTH over large parts of the molecule. In the amphibian skin, MSH causes a dispersion of the melanin granules in the chromatophores and therefore a darkening of the skin. In mammals, MSH is assumed to stimulate the melanin production in the melanocytes.

The pars intermedia of the adenohypophysis and the adjacent portions of the neural lobe form the so-called distal adeno-neurohypophyseal contact zone, where blood vessels and nerve fibers are characterized by a specific arrangement (see p. 82).

Pars Infundibularis or Tuberalis. The pars infundibularis of the adenohypophysis forms a sleeve around the infundibulum, from which it is separated by a thin sheet of connective tissue continuous with the pia mater. Its thickest portion (approximately 40 to 80 μ) is on the anterior surface of the neural stalk, whereas the posterior portion is often incomplete or absent. The pars infundibularis is traversed by the major arterial vessels and the hypothalamo-adenohypophyseal portal venules, both extending to the anterior lobe. The longitudinally arranged cords of epithelial cells occupy the interstices between the blood vessels. A network of fine reticular fibers separates these two elements. Pars tuberalis, blood vessels and neural stalk together form the so-called proximal adeno-neurohypophyseal contact zone which is discussed below.

The epithelial cords of the pars tuberalis contain only a few acidophils and basophils, but predominantly undifferentiated, cuboidal cells resembling the chromophobes of the anterior lobe (pars distalis). Characteristically, these cells measure some 15 μ in diameter and contain many small, rod-shaped mitochondria. The Golgi apparatus is less developed than that of the cells of the glandular lobe. In the cytoplasm, numerous small lipid and colloid droplets are often present, as well as large amounts of glycogen. Usually, some pars infundibularis cells are found to be arranged in follicles similar to those of the pars intermedia.

4. The Hypothalamo-Adenohypophyseal Connections

In contrast to the posterior (neural) lobe, which must be regarded as a specially differentiated subdivision of the diencephalon, the anterior lobe is a true endocrine gland, i.e. it produces a number of hormones itself. The hypothalamus controls the incretory activity of the glandular lobe not through nerve fibers reaching the endocrine cells, but through the release of specific substances (neurohormones) into a unique capillary network in the hypophyseal stalk. This vascular system, which combines the diencephalon and the adenohypophysis to a functional unit, is established very early. In the human embryo 10–11 mm in length, the pars infundibularis of the adenohypophysis is already present in the form of two epithelial buds at the anterior surface of the adenohypophyseal vesicle (see p. 77). These two buds grow rapidly upward to the floor of the diencephalon and also contact the infundibulum which extends ventrally. At the same time, a dense network of blood vessels develops and surrounds the hypophysis. This network is supplied by both the meningeal plexus of the embryonic brain anlage and the hypophyseal arteries arising from the internal carotids. The two inferior hypophyseal arteries arborize within the organ capsule, branches extending to the neural and (to a lesser extent) also to the glandular lobe.

The superior hypophyseal arteries anastomose freely in the region of the root of the hypophyseal stalk. From this network, a number of capillaries form characteristic loops which extend to varying depths of the nervous substance of the median eminence. The afferent limbs of these capillaries which comprise the so-called *primary plexus* have a much smaller diameter than the efferent limbs of the loops draining into the hypophyseal *portal veins*. These veins can be recognized with the naked eye. They run downward around the hypophyseal stalk (mainly at the anterior surface of the pars infundibularis of the adenohypophysis) and supply the sinusoids of the anterior lobe.

Within the median eminence, the capillary loops of the primary plexus are found in close relation to nerve-fiber endings of the *tubero-hypophyseal tract*. On both sides of the infundibular recess, the pericarya of these axons constitute the nucleus tuberis infundibularis, the nucleus hypothalamicus dorsomedialis, and the nucleus ventromedialis. These nuclear masses are not only characterized by their proximity to the hypophyseal stalk, but also by the morphological similarity of their neurons, which are small and rather poor in cytoplasm. In contrast to the fibers of the hypothalamo-neurohypophyseal tract, the neurons of the tubero-hypophyseal tract do not react with the Gomori stain. Their secretory activity has,

however, been confirmed by numerous ultrastructural studies. The neurohormones produced by these cells are carried along the axons and released into the narrow intercellular space separating the nerve-fiber endings from the fenestrated endothelium of the primary capillary plexus. These hormones pass through the hypophyseal portal venules to reach sinusoids of the anterior lobe where they *stimulate or inhibit* the production and release of the specific adenohypophyseal hormones (see also Chap. II, p. 28). Thus, through a singular process of vascularization which in the human is fully developed only at the end of intra-uterine life, the anterior lobe becomes functionally (and indirectly) connected to the center controlling most endocrine functions of the body, the hypothalamus.

In contrast to the pars infundibularis, in which the *proximal* adenoneurohypophyseal contact zone is formed by the primary capillary plexus, the pars intermedia, as the *distal* contact zone between anterior and posterior lobe, lacks such special blood vessels. In this region, however, another kind of interaction between adeno- and neurohypophyseal elements appears to become increasingly important with advancing age, although its functional significance is by no means certain. With the disappearance of the initial cleft (see p. 80), basophilic cells of the pars intermedia frequently extend a considerable distance into the parenchyma of the posterior lobe where they are found in close spatial relation to both the axon endings of the supraoptic-neurohypophyseal tract and the sinusoidal capillaries. The nerve fibers surrounded in this way by adenohypophyseal elements appear to be particularly rich in neurosecretory material. The hypothalamo-neurohypophyseal tract thus contacts not only the vascular system of the neural lobe (as well as the ventricle system of the diencephalon) but also specific cells of the glandular lobe. Experiments have shown that prolonged thirst leads not only to depletion of the posterior lobe in neurosecretory material, but also to atrophy of the pars intermedia. On the other hand, interruption of the hypothalamo-neurohypophyseal tract was found to result in a marked hypertrophy of the pars intermedia. In spite of the morphological differences, a functional analogy between the proximal and distal adeno-neurohypophyseal contact zones might therefore be postulated.

C. Chemistry and Biochemistry

Seven different adenohypophyseal hormones have been definitely determined so far (Table 1). Five of these hormones are adenotropic (see below), i.e. hormones regulating other endocrine glands. Two of these adenotropic hormones are gonadotropins controlling gonadal function in males and females.

Gonadotropins, adrenocorticotropin and thyrotropin are discussed with reference to their target gland in the appropriate chapter. For prolaction see also Chap. XI, p. 674f. It is still unknown what physiological significance is attributable to MSH, the melanocyte-stimulating hormone, and EPS, the exophthalmos-producing substance.

1. Prolactin

Prolactin, otherwise known as mammotrophic hormone, lactogenic hormone, or LTH (luteotrophic hormone) has a wide variety of functions in the reproductive system throughout the animal kingdom from the fishes to the primates (SHERWOOD, 1971; NICOLL, 1972). In mammals, luteotrophic activity has been demonstrated in rodents but not in primates, and it is therefore no longer included in the group of gonadotropins. Its classic function in mammals, including man, is stimulation of lactation, so that the name most commonly used is prolactin. Although prolactin has been extracted and purified from the pituitaries of a large number of species and the amino-acid sequence of ovine prolactin has been determined (LI, 1969) the controversy as to whether prolactin and growth hormone are two different hormones in the human went on for some time, a problem complicated by the fact that pure human

Table 1. Hormones of the human anterior pituitary

Hormone	Chemistry	Isolated	Constitution known	Synthesis	Molecular weight
ACTH	Polypeptide	+	+	+	4540
β-MSH	Polypeptide	+	+	+	2660
Growth hormone	Polypeptide	+	+	+	21500
TSH	Glycoprotein	(+)	−	−	About 25000
FSH	Glycoprotein	Partly	−	−	About 30000
LH	Glycoprotein	Partly	−	−	About 26000
Prolactin	Polypeptide	+	+	−	23300 (ovine)

growth hormone also has some intrinsic lactogenic activity. Clinical observations of milk production in growth hormone-deficient women and a variety of biologic, immunologic, and chemical studies have now proved there is a difference between these two hormones in man. Prolactin can now be determined radioimmunologically and does not cross-react with human growth hormone. Besides its action on the mammary gland, it also has effects on the testes (BARTKE, 1970), and possibly on water and electrolyte transfer in the kidneys (MANKU, 1972) and intestine (RAMSEY, 1972). There seems to be a reciprocal mechanism controlling secretion of prolactin and gonadotropins. A potent releasing stimulus is suckling in nursing mothers. Phenothiazines, TRH stress and hypoglycemia increase prolactin secretion, whereas α-dopa, 2-α-Br-ergocryptine suppress it. Renal failure is frequently associated with high plasma prolactin, estrogens cause a rise in adults. Using a sensitive radioimmunoassay (HWANG, 1971) on the base of human prolactin, normal values for plasma in women are in the range of 10 ng/ml, for men a little bit less. Dependence of breast cancer from prolactin is discussed (SALIH, 1972; BOYNS, 1972; FRIESEN, 1973).

2. Growth Hormone

Growth hormone (somatotropin, STH) is the only pituitary hormone which exerts a direct effect without the involvement of another endocrine gland. A growth hormone-like factor has been detected which is produced, curiously enough, in a tapeworm of mice and has practically all biological effects of growth hormone except the lipolytic effect. It seems to be of high molecular weight and immunochemically different from growth hormone (Sparganum growth factor, STEELMAN, 1971), and different from the sulfation factor or somatomedin.

Apart from growth hormone, the relevance of other metabolic hormones [adipokinin, lipotropin (LEVINE, 1964; LUFT, 1966; ANSELMINO, 1965; RUDMAN, 1965)], and pancreatotropic hormones is still uncertain.

a) Chemistry

Growth hormone, (somatotropin, somatotropic hormone, STH), is a highly species-specific polypeptide hormone. The growth hormones of different mammalian species differ chemically, immunologically and in their biologic action.

Human growth hormone (HGH) consists of an unbranched chain of 188 amino acids with 2 disulfide bridges and has a molecular weight of 21,500 at an isoelectric point of pH 4.9. The complete amino-acid sequence has been successfully determined (LI, 1966) and it has recently been synthesized (LI, 1971).

Human growth hormone is extracted from human pituitaries obtained at autopsies either by using hot glacial acetic acid, purifying with oxycellulose and precipitating with ethyl alcohol (RABEN, 1959), or by using phosphate buffer precipitation with ammonium sulfate at different pH, resin, and sephadex chromatography (LI, 1966; ROOS, 1963). Growth hormone is stored in large amounts in the hypophysis and forms 3% of the acetone dry powder of the hypophysis. One human hypophysis will therefore yield 3–5 mg or even more (GEMZELL, 1958). The content of growth hormone in the hypophysis seems to be independent of the age of the individual.

Careful treatment with proteolytic ferments causes partial decomposition without affecting the biological action. Chymotrypsin can break down human growth hormone by 25%, and pepsin can break it down to 50% without affecting its potency. Therefore, the "active core" probably contains a peptide nucleus of only about 100 amino acids. Despite crystallization the human growth hormone currently extracted does not appear to be fully homogeneous. It can be dispersed into four active components by starch-gel electrophoresis and also by sephadex chromatography. It is possible that artifacts producing subtle changes occur during extraction. The immunological behavior of the hormones is similar, but they differ in biologic potency. In acromegaly, growth hormone is radioimmunologically high, and prolactin is found to be low. In the lactating woman, however, the situation is reversed, and growth hormone is found to be normal, whereas prolactin is high (ROTH, 1967).

Growth hormones of other mammalian species have other amino-acid sequences and molecular weights up to 48000. Bovine and ovine growth hormones probably consist of branched polypeptide chains. Similarities in the molecular structure exist between the growth hormones of the human and monkey, between those of pig and whale, and those of cow and sheep.

Human growth hormone produces antibodies in the rabbit which only react with human or monkey growth hormone. Bovine growth hormone forms antibodies which precipitate bovine and ovine growth hormones in agar. Bovine growth hormone is not effective in man, monkey, or guinea pig. On the other hand, growth hormone from man and from monkeys is effective in all vertebrates with the exception

of guinea pig and fish. The effect of human growth hormone in the rat, however, decreases after 10 days because of antibody formation, whereas bovine growth hormone continues to be effective.

b) Plasma Concentration, Half-Life, Turnover, Daily Production

Normal serum growth hormone values are 0–3 µg/ml (>90%) when measured by radioimmunological methods (HUNTER, 1964; UTIGER, 1964; GLICK, 1965; BODEN, 1967) under standard conditions in the adult following an overnight fast.

Age-dependence: Considerably elevated values are found in premature infants. The values estimated from the umbilical venous blood in newborns are also high. In infants and babies they lie between 0 and 10 µg/ml until the fourth year of age. These findings indicate that the notion that growth during the first year of life is not affected by growth hormone is mistaken. The values are between 0 and 5 µg/ml from the fourth year onwards, and no differences are demonstrable in the basal values from early adulthood to old age. Growth hormone secretion increases during sleep, but paradoxical sleep inhibits its secretion (HONDA, 1969). Sexual differences have been demonstrated (MERIMÉE, 1966). Oral contraceptives are thought to increase the level of growth hormone by approximately 10 µg/ml (SPELLACY, 1967).

The half-life of human growth hormone is 25 minutes. The fractional turnover rate is 2.8% or 0.5–0.8 mg/day under basal conditions. The total daily secretion under the influence of food, starvation, and muscular activity must lie between 3–5 mg, according to the therapeutic dose for pituitary dwarfism (PARKER, 1962; GLICK, 1965). The multi-exponential curve of decrease causes uncertainty in the calculation of other compartments and of the half-life (CAMERON, 1969; TAYLOR, 1969). According to more recent studies based on the determination of integrated plasma growth hormone levels (KOWARSKI, 1971), the daily secretion of growth hormone is even lower and ranges from 0.6 to 1.5 mg per day, being higher in women than in men. Breakdown is achieved partly by proteolytic enzymes not specific to growth hormone alone and partly by enzymes which disintegrate the disulfide linkage (PARKER, 1962; SIREK, 1964). A small proportion has been recently demonstrated to be excreted unchanged in the urine.

Human growth hormone does not pass into the placenta; consequently, the high concentration of growth hormone in the blood of the newborn comes from the infant. The half-life of the maternal growth hormone is reduced before birth (LARON, 1966).

3. Substances with Partial Effects of Growth Hormone

a) Lipolytic Polypeptides from the Pituitary

Apart from growth hormone there are other hormones secreted by the adenohypophysis which have a lipolytic action *in vitro*, partly species-specific. These are ACTH, TSH, and the α- and β-MSH. Arginine-vasopressin, one of the neurohypophyseal hormones, also has a lipolytic effect. The physiological significance of the lipolytic activity of these hormones is unknown.

In addition, other proteins and polypeptides with a lipolytic effect have been isolated from the pituitary gland of different types of animals (SCHWANDT, 1968; TRYGSTAD, 1967/1968; RUDMAN, 1962/1965). Although a hypophyseal hormone concerned specifically with fat metabolism was discovered over 30 years ago (ANSELMINO and HOFFMANN, 1965), it is still not known whether such substances (lipotropin, adipokinin) are involved in regulating fat metabolism, with the exception of growth hormone.

A substance of protein character can be demonstrated in the urine of fasting persons. This substance mobilizes free fatty acids *in vitro* from the adipose tissue of the rat, and *in vivo* it produces lipemia, fatty degeneration of the liver, and ketosis. The occurrence of this substance is dependent on an intact hypophysis. It is not claimed to be identical to growth hormone or ACTH (CHALMERS, 1960).

b) Chorionic Growth Hormone-Prolactin Complex (CGP, HPL, see also p. 677*)*

Pregnancy leads to changes in the facial features which can, however, vary individually and which are reminiscent of acromegaly (acromegaloidism of pregnancy). Pregnancy also causes growth of the breasts and an anabolic metabolic state. These three changes cannot be explained by an increase of the sex hormones alone during pregnancy, so that it is likely that the activity of growth hormone is also increased during pregnancy. On the other hand, hypophysectomy during pregnancy does not impair the course of the pregnancy, and the physical changes in the woman do not regress.

A protein has been extracted from placentas of the human and the monkey. In animal experiments, it shows activities similar to those

of prolactin and of growth hormone also, but only to a very slight degree. It reacts immunologically with antiserum to human growth hormone, again more weakly than human growth hormone does. The biochemistry, physiology, and clinical significance of this chorionic growth hormone-prolactin (KAPLAN, 1964) or the placental lactogen (JOSIMOWITSCH, 1962) which has been demonstrated in the serum and urine of pregnant women, as well as in the retroplacental blood, is discussed in Chap. XI, p. 677.

c) Hypoglycemic Factor

Tests are still necessary to determine whether the small molecular polypeptide obtained from bovine growth hormone with an exclusively hypoglycemic action is a hormone distinct from growth hormone (HUGGINGS, 1961).

d) Bovine Growth Hormone Digests

It has apparently been confirmed that bovine growth hormone treated carefully and briefly with trypsin can produce pronounced metabolic activities of human growth hormone in people with hypopituitarism. This suggests that there is an active core common to both molecules (SONENBERG, 1967; NADLER, 1967).

D. Physiology

1. Metabolic Effects of Growth Hormone

Growth hormone is a metabolic hormone playing a definite role in the regulation of protein, carbohydrate, and fat metabolism. It also appears to have the effect of a biological synergist which can intensify certain actions of other hormones, such as LH, testosterone, and ACTH (in relation to growth of the adrenals). Growth hormone and insulin form an important synergistic and antagonistic system.

The effect on organs such as the liver and the kidney is demonstrated by the increase of bromsulphalein-, insulin-, creatinine-, and PAH-clearances.

a) Protein Metabolism

STH has an anabolic effect. It promotes protein synthesis, and under its influence, the nitrogen balance becomes positive. The urinary excretion of urea, creatine, and nitrogen decreases, with a relative increase in the nitrogen of the amino acids. Plasma urea and nonprotein nitrogen fall, and certain amino acids (Tre, Ser, Gly, Meth) increase (ZACHMANN, 1968). A single intramuscular injection of 2 mg is sufficient to produce an effect of this nature lasting for 2–3 days in the adult.

It has been shown *in vitro* and *in vivo* that growth hormone promotes the transport of specific amino acids, particularly leucine and glycine, into the cells (KNOBIL, 1961). This transport activity is not inhibited by puromycin and is therefore independent of protein synthesis. In addition to this transport activity the mode of action of growth hormone on protein synthesis can be investigated in the cell-free system of the rat liver. In this cell-free system a growth hormone administered to the animal *in vivo* promotes the incorporation of amino acids into protein. This does not affect the amino acids activating enzymes, or the uptake, or the transmission of the soluble RNA. On the other hand, growth hormone promotes the linking together of activated amino acids into polypeptides within the microsomes (KORNER, 1965). It influences the synthesis of the Transfer-RNA, which is the limiting step in protein synthesis, and therefore increases the number of ribosomes and their aggregation to form polysomes (TALWAR, 1964; KORNER, 1968). These activities of growth hormone are not inhibited by actinomycin, and they do not, therefore, take place via DNA metabolism. Cell division may be stimulated under the influence of growth hormone (CATER, 1957; MOON, 1962), but the frequent mitoses are more likely to be due to the increased supply of substrates.

Although a direct action of growth hormone on protein synthesis has been demonstrated *in vitro*, synergism with insulin is essential to produce the maximum anabolic effect. Insulin alone also promotes the introduction of amino acids into the cells, but it has no growth-promoting effect after hypophysectomy.

In vitro, growth hormone does not promote the incorporation of sulfur into cartilagenous tissues as does the sulfation factor. This factor, however, increases in the serum under the influence of growth hormone. Therefore, growth hormone probably has an indirect effect upon growth through generation of the sulfation factor (DAUGHADAY, 1966). It has recently been shown that the sulfation factor is probably identical to NSILA-S (see Chap. XIII, p. 749f.) and it has been tremed somatomedin (see p. 88).

b) Carbohydrate and Fat Metabolism

In vitro, a lipolytic effect of relatively high doses of growth hormone can be demonstrated in isolated fat tissue due to the hydrolysis of

triglycerides in the depot fat (RABEN, 1962; WINEGRAD, 1959). Free fatty acids and glycerol are released into the medium, the latter to a greater extent, since intensive intracellular re-esterification of the free fatty acids occurs at once. The intracellular glycerol requirements are covered by increased glucose uptake by the tissue or by glycogenolysis. While glucose taken up under insulin stimulation is broken down via the pentose phosphate pathway, glucose taken up under the influence of growth hormone is metabolized by glycolysis and the KREB'S cycle. Recently, lipolysis produced by physiological concentrations of growth hormone in the presence of added glucocorticoids has been successfully demonstrated in isolated fat cells (FAIN, 1965). It is not clear how lipolysis is induced by growth hormone. It begins after a latent period of 1–2 hours and reaches a maximum after 4 hours. It is inhibited by actinomycin D (FAIN, 1965). Tissue lipase is not activated as is the case with adrenaline or ACTH. *In-vitro* experiments on the effects of growth hormone on muscular tissue have not produced consistent results (BODEL, 1962; HENDERSON, 1961).

In vivo, 3 phases can be differentiated among the metabolic effects of growth hormone. These are: an early phase lasting 0–30 minutes, an intermediate phase lasting between 30–240 minutes, and a late phase lasting some days or weeks.

In the first phase, human growth hormone promotes the intake of free fatty acids and glucose into the musculature. A brief fall in the free fatty acids and blood glucose occurs simultaneously during the first phase, particularly in the hypophysectomized or adrenalectomized animal. The hypoglycemia is difficult to explain. It is not caused by a rise in insulin, since the plasma insulin level remains low (ZAHND, 1960). Increased transport of glucose into fat tissue under the influence of lipolysis and re-esterification has been considered (WEIL, 1965), but decreased glucose uptake by the musculature and fatty tissues precedes lipolysis. Protein synthesis, which removes glucoplastic amino acids from gluconeogenesis, has also been considered as the cause of hypoglycemia, but protein synthesis commences only after several hours. The possibility that the early hypoglycemia due to growth hormone may be caused by carbohydrate retention in the liver has been discussed. Today, the role of somatomedin has to be considered.

In the second phase, growth hormone promotes lipolysis in adipose tissue, with the release of glycerol and free fatty acids into the blood and an increase in their blood level. The increased flux of free fatty acids exceeds the capacity of the liver to oxidize them completely, so that they leave the liver as ketone bodies. Peripheral tissues cannot cope with these, and thus keto-acidosis may develop under the influence of growth hormone. Glucose uptake by the musculature is inhibited, glucose tolerance decreases, and the assimilation coefficient falls to sub-normal values (IKKOS, 1962). The increased supply of free fatty acids is suspected to inhibit glucose uptake (RANDLE, 1964). However, growth hormone reduces glucose absorption before the free fatty acids in the blood rise. It is possible that inhibition of glucose absorption by the musculature and fatty tissues is the primary effect of growth hormone, and that lipolysis only results from a carbohydrate deficiency in the fatty tissue. Gluconeogenesis in the liver is increased under the influence of free fatty acids (SÖLING, 1966), which causes a further fall in the glucose tolerance. When insulin and growth hormone act at the same time, the increased glucose absorption induced by insulin is diminished, and the lipolytic effect of growth hormone is blocked.

Third phase and growth hormone-diabetes: Growth hormone promotes protein synthesis and growth only in the presence of insulin. An increased secretion of insulin, "an extra-insulin", is not necessary, as was indicated by earlier results, although growth hormone inhibits glucose absorption in the musculature and fatty tissue and reduces the sensitivity to insulin (SCOW, 1960). When growth hormone is administered for 4 days to 2 weeks, the insulin secretion diminishes in carnivores, such as dog and cat; the blood sugar rises, and reversible "idiohypophyseal" diabetes develops. The B-cells of the pancreas are irreversibly damaged if the administration of growth hormone is further continued, and permanent "metahypophyseal" diabetes indistinguishable from that produced after pancreatectomy develops. The hyperglycemia is accompanied by keto acidosis, glucosuria, and acetonuria.

Man and monkey react in a similar way to dog and cat (IKKOS, 1962). In herbivorous animals, such as rabbit, guinea pigs, and sheep, whose islet cells are more resistant and are capable of regeneration, idiohypophyseal or methahypophyseal diabetes can only be produced by concurrent forced feeding, or partial pancreatectomy, or by previous treatment with alloxan.

Growth hormone always produces growth in the rat, where the epiphyseal cartilages remain open throughout life. Puppies and cats grow under the influence of growth hormone as long as the epiphyseal cartilages remain open. In

adult animals, however, diabetes develops, since the glucose can no longer be used for building tissues. Puppies treated for long periods with growth hormone fail to grow and become diabetic. Administration of insulin abolishes the diabetes and re-establishes growth. Growth hormone only has a diabetic action when growth is impossible or when the insulin production is limited and the glucose cannot be used in other ways. Lactating or pregnant rats grow. If lactation in the goat is prevented by resection of the udder, diabetes develops (BERT, 1883).

Although 10 mg HGH i.m. reduces the glucose tolerance after 12 hours in the normal human (MITCHELL, 1970), only 25% of patients with active acromegaly are diabetic. Contrary to previous suspicions, diabetics do *not* have raised growth hormone levels in the plasma (GLICK, 1965). Growth hormone levels can, however, be relatively high in relation to the raised blood sugar in diabetics, but this is due rather to impaired intracellular carbohydrate utilization in the regulation centers (see p. 761) which may possibly be dependent upon insulin (GLICK, 1965). Whether growth hormone is or is not connected with diabetic retinopathy is still under discussion (POWELL, 1966; LUNDBAEK, 1970).

c) Effect of Growth Hormone on Energy Balance

Insulin and somatotropin regulate liberation, utilization, and regeneration of glucose, free fatty acids, and amino acids in the sequence of food intake or fasting.

The blood sugar rises immediately after intake of food and leads to the release of insulin after 1 hour and to a fall of growth hormone in the blood. Glucose absorption and glycogen synthesis are promoted. At the same time, triglyceride synthesis starts, lipolysis is blocked, and the free fatty acids in the blood fall. In the second phase, the glucose falls and growth hormone begins to rise in the presence of continuous insulin activity. This constellation promotes protein synthesis to a maximum while glucose absorption decreases with reduced glucose supply, thereby reserving the glucose for the nervous system. Finally, in the third phase, in the fasting or starving state the blood sugar falls to normal values and insulin falls while growth hormone continues to rise, inducing lipolysis. Glucose absorption is then at a minimum, protein synthesis is at a standstill without insulin, and free fatty acids are disposed of by the musculature. The glucose requirement during this phase is not only reduced by the supply of free fatty acids, but also particularly by glycerol, which is a precursor of glucose. Growth hormone fulfills different important functions for the period without any nutritional intake. In this way, it reduces the glucose requirement in the musculature, abates protein synthesis at the same time, and offers the musculature and liver free fatty acids in return, so that the remaining glucose is at the disposal of the nervous tissue which is dependent on glucose (ZIERLER, 1963).

Some authors still doubt that so many different types of actions, such as protein synthesis, fat metabolism, insulin synergism and antagonism, growth, and production of diabetes, can be due to the same hormone. Two pituitary hormones, somatotropin and adipokinin, chemically similar and with the same immunological behavior but with different biological activity, have been considered (LEVINE, 1964; LUFT, 1966). Both, however, like the purest growth hormone preparations so far known, produce protein synthesis and lipolysis. In addition, the connection of the anabolic effect with the mobilization of fuel from their depots seems to be rational. The chief effect of somatotropin is not so greatly cerned with growth (growth hormone is produced in the same amounts after growth is completed) but is concerned rather with the maintenance of homeostasis in catabolic states, such as fasting, muscular activity, and hypoglycemia. The difficulty in accepting that the same substance regulates acute metabolism and the long-term process of growth may be overcome by regarding the effect on growth as being indirect (sulfation factor) and not dependent of short-lived variations (DAUGHADAY, 1966).

d) Electrolyte and Water Metabolism

The urinary excretion of sodium, potassium, phosphorus, and chloride decreases under the influence of growth hormone, whereas the urinary calcium excretion generally rises. Aldosterone secretion is not directly influenced. Water retention is parallel to that of sodium, and the extracellular space increases (BIGLIERI, 1961). The calcium and phosphorus balance is generally positive, although a negative calcium balance has occasionally been observed (KNOBIL, 1964). Intestinal calcium absorption seems to be enhanced, and calcium may possibly be mobilized from the skeleton. This may be due to an indirect parathyroid activation (FRASER, 1960). Phosphorus and calcium are stored in proportion to the nitrogen, corresponding to the composition of muscular tissue. The excess potassium retained probably goes into

the liver. Among the serum electrolytes, only phosphorus retention is reflected in an elevated phosphate value.

e) Effects on Other Endocrine Glands

α) *Pancreas:* Contrary to previous opinions, there has been no successful demonstration that physiological amounts of growth hormone can directly induce the formation or release of insulin from the pancreas. Consequently, growth hormone leads only indirectly to increased insulin secretion and hyperplasia of the β-cells.

β) *Adrenal glands:* Enlargement of the adrenals and the thyroid gland under growth hormone is due to the effect on growth. There is no change in the excretion of 17-ketosteroids, 17-hydroxysteroids or aldosterone.

γ) *Thyroid gland:* An increase in the BMR is due to extrathyroidal factors. The protein-bound plasma iodine or thyroxine is not influenced. On the other hand, radioiodine studies have demonstrated an elevated velocity index in acromegaly (2/48 h uptake ratio) corresponding to an accelerated iodine turnover.

δ) *Parathyroids:* These glands can be activated indirectly through an elevated serum phosphate level and a fall in the calcium level.

For effects on milk secretion see p. 695. For discussion of the effects of other hormones on the secretion of growth hormone see p. 90f.

f) Influence on Growth (See also Chap. XIX)

In pituitary insufficiency in animals and man growth is interrupted in the growing phase even when nutrition remains undisturbed. Growth hormone re-establishes normal growth. It works directly on the tissues without involving other endocrine glands, since it is also effective in eviscerated animals providing that small amounts of insulin and probably "somatomedin" (see below) are present. In animals where the epiphyseal cartilages are open throughout life, STH can produce continuous growth for the rest of their lives when the dosage is adjusted to the increasing weight. Thus, in 435 days a gigantism of over 600 g could be produced in rats, with the experiment only coming to an end when the maximum life-span of the rat was reached.

Growth is presented first as an increase in weight due to synthesis of protein and water retention corresponding to the composition of the embryonic tissue. The fat content of the entire organism decreases, and growth of the liver, kidneys, heart, stomach, and gut is in proportion to body weight. Compensatory hypertrophy of the remaining kidney after unilateral nephrectomy is only possible under the effect of growth hormone (ASTARABADI, 1963).

STH promotes endochondral bone growth. Under its influence columns of cartilage and lamellae of bone with numerous osteoblasts are formed in the epiphyseal cartilages. Increased serum alkaline phosphatase reflects osteoblastic activity. The cells of the epiphyseal cartilages increase in number and size. Measurement of the width of the columnar cartilage at the transition to the bony rib has been used as a test for the activity of growth hormone (see p. 124). The incorporation of sulfate into cartilage is increased and probably occurs indirectly through the sulfation factor (see p. 89). In addition to polysaccharide synthesis, soluble collagen is also formed and its rapid turnover is apparent in the appearance of more hydroxyproline in the urine. Growth hormone promotes growth even in the absence of thyroid hormone. Thyroid hormone, however, can intensify the growth activity of STH without itself influencing growth. On the other hand, insulin is necessary for growth, even if it does not promote growth by itself. The effect on growth and that on carbohydrate and fat metabolism are probably due to the same hormone, and the connection of growth with economy of carbohydrates and amino acids at the expense of fats is reasonable.

It is not known why growth hormone can cause growth in certain phases of life and has no effect in other phases. The capacity of the tissues to respond must vary in the different phases of growth. It is possible that the effect of growth hormone on growth is only permissive.

g) Sulfation Factor, Somatomedin, NSILA-S

A peptide with a molecular weight of approximately 6000–10000 which increases the incorporation of ^{35}S and H^3-thymidine into rat and chicken cartilage has been partially purified from serum. This substance has been called "sulfation factor", and sometimes "thymidine factor". It was established that patients with acromegaly have high concentrations of sulfation factor in the serum, whereas pituitary dwarfs do not; when pituitary dwarfs are treated with growth hormone the "sulfation" activity in their serum increases. Some investigators believe that the sulfation factor is produced in the body, possibly in the liver, under the influence of growth hormone. The hypothesis has been put forward that growth hormone by itself does not stimulate growth but rather that its effects are mediated by the sulfation factor. It has therefore been suggested that the sulfation factor be called "somatomedin".

Nonsuppressible insulin-like activity (NSILA-S) has proven extremely active in stimulating the incorporation of ^{35}S into rat cartilage and the growth of fibroblasts in culture. In all likelihood NSILA-S and somatomedin are identical. However, the physiological significance of somatomedin and NSILA-S must be interpreted with caution. There are probably several substances in the blood which have some growth-promoting activity, and growth hormone is not the only hormone controlling their concentration in the serum.

2. Regulation of the Secretion of Growth Hormone

Growth hormone, as an important metabolic regulator, shows considerable variations in concentration during the course of the day. There are, however, short bursts during night sleep, whose nature has not yet been explained. It is now known that the following conditions affect the release of growth hormone:

a) Hypoglycemia and fall in blood sugar
b) Fasting
c) Muscular activity
d) Certain amino acids
e) Stress: fever, operations
f) Catecholamines
g) Other mechanisms.

a) Hypoglycemia

A fall in the blood sugar to 50% of its original value causes an approximately 5-fold increase of growth hormone. The hormone level first falls for a short interval of time, then increases to the maximum between 15–30 minutes after the nadir of the blood sugar is reached and persists at this level for several hours. The hypoglycemia can be released by insulin or tolbutamide, or by blocking liver gluconeogenesis. The increase in growth hormone can be prevented by giving glucose at the same time. On the other hand, hypoglycemia due to alcohol produces no rise in the growth hormone, probably because the hypoglycemia develops slowly. Growth hormone secretion persists at the same level throughout the hypoglycemia. Since the half-life of growth hormone is 20–30 minutes, there must be continuous secretion of the hormone to maintain a constant level. A rise in the growth hormone may even be produced by slight decreases of 10 mg/100 ml in the blood sugar which is a physiological occurrence during the day (LUFT, 1966).

The releasing stimulus is obviously a deficiency of the intracellular utilizable glucose, since administration of 2-deoxyglucose also leads to a rise in the growth hormone in spite of hyperglycemia.

A fall in blood sugar also causes release of growth hormone even if the blood sugar values are still above normal. Variable increases in growth hormone not proportional to the degree or speed of the fall in blood sugar can arise 4–6 hours after glucose overloading without necessarily producing clinical symptoms due to the fall in blood sugar.

Testosterone promotes and medroxyprogesterone inhibits the increase of growth hormone after hypoglycemia (ILLIG, 1970).

b) Fasting

A fairly long fast, i.e. deprivation of food for more than 12–15 hours, leads to a continuous rise in growth hormone in the blood. There is usually an initial high peak, after which the concentration varies around the average value during subsequent days if fasting is continued. The rise is not so pronounced or rapid as in hypoglycemia and this increase may be absent or much less pronounced in the obese. Nevertheless, overweight subjects can break down their fat depots just as well during fasting and their metabolism is not maintained at the expense of protein. The failure of growth hormone to rise is a result rather than the cause of obesity.

c) Muscular Activity

Moderate muscular activity such as walking for 30 minutes causes a pronounced rise of growth hormone levels in the blood. It has been suggested that this rise is greater in women and in men treated with estrogens (FRANTZ, 1965). It can be mitigated considerably by previous administration of glucose. Wide variations of short duration result from continuous activity (HUNTER, 1966).

d) Amino Acids

Infusion of 15–30 g of certain acids over 30 minutes leads to a considerable rise (5- to 10-fold) in the plasma growth hormone after 1–2 hours. This effect is independent of the blood sugar. There is a simultaneous release of insulin, and the two act synergistically to enhance protein synthesis. Arginine, ornithine, histidine, and lysine are effective; phenyalanine, methionine, valine, and threonine are feebly effective; leucine is not always active; and isoleucine has no effect (KNOPF, 1965; FAJANS, 1967; RABINOWITZ, 1966). It has been suggested

that the two sexes respond differently and that estrogens promote the response (MERIMÉE, 1967).

e) Operations

Serious operations involving the opening of the abdomen or the thoracic cavity lead to a considerable rise of growth hormone which cannot be inhibited by continual glucose infusions or even by hyperglycemia. Anesthesia alone or with electric shock does not produce the release of growth hormone. Minor surgical procedures, such as herniotomy, cause only a slight increase in growth hormone, which can be prevented by glucose administration.

f) Catecholamines

Adrenaline stimulates the release of growth hormone, probably via cyclic AMP (GAGLIARDINO, 1968). The α-receptors appear to promote growth hormone release by hypoglycemia, whereas the β-receptors have an inhibitory effect. Promotion and inhibition can be abolished by phentolamine (BLACKARD, 1968) respectively propranolol (IMURA, 1968).

g) Other Mechanisms

Besides the stimuli for growth hormone secretion mentioned above, other compounds such as α-MSH, L-Dopa, and metyrapone have been shown to cause a substantial increase in the plasma levels of growth hormone.

h) Stimuli Decreasing Growth Hormone

Administration of glucose causes an elevated growth hormone level to fall in healthy subjects and in diabetics. The effect of protein administration is not consistent (amino acids, see p. 89). Overloading with fat has no effect on the release of growth hormone. Glucocorticoids inhibit the release caused by hypoglycemia (PECILE, 1966) and the normal diurnal variation (STIEL, 1970).

i) Localization of the Regulation

Stress and metabolic effects are registered and co-ordinated with endogenous rhythms (sleep) in the hypothalamus which then releases GRH (growth hormone releasing hormone) to regulate the discharge of growth hormone from the adenohypophysis (see Chap. II, p. 32). Normal basal values are still found after section of the pituitary stalk. There is no rise with hypoglycemia following lesions of the ventromedial nucleus in the hypothalamus. In the monkey the hypoglycemic stimulus is ineffective. Growth hormone releasing hormone (GRH see Chap. II, p. 32), which leads to the release of growth hormone from the adenohypophysis *in vitro* and *in vivo*, has been extracted from the hypothalamus*. It is not known how the stimulus is registered in the hypothalamus. Intracellular carbohydrate deficiency seems to be a stimulus, but this does not explain the effect of fasting since the intracellular carbohydrate content of the central nervous system does not decrease and hypoglycemia does not develop.

It is not known how the hypothalamus registers muscular activity. Different factors, such as reflexes along nerve tracts, humoral stimulants from active muscle, possible metabolic products of the muscle, and finally, the drainage of the blood from the central nervous system into the active musculature have been considered. The mechanism by which surgical stress leads to the release of growth hormone is also unknown (REICHLIN, 1966).

3. Interactions of Growth Hormone with Other Hormones

Since, unlike other pituitary hormones, growth hormone exerts its multiple effects not on a target organ, but on every cell in the organism, its action might be expected to depend on the metabolic equilibrium of each cell, which in turn is modified by other hormones. Indeed, practically all known hormones have been found to have at least some direct or indirect modifying effect on the production, release and/or metabolic action of growth hormone.

The interactions between growth hormone and catecholamines and between growth hormone and insulin have already been discussed (see p. 88). In addition to the interactions with insulin, it should be mentioned that glucagon has recently also been found to stimulate the secretion of growth hormone in certain conditions (MITCHELL, 1969; WEBER, 1970). Whether this is of any physiological importance remains to be seen.

a) Growth Hormone and Other Pituitary Hormones

ACTH is capable of stimulating the secretion of growth hormone in a similar way to insulin (ZAHND, 1970). This is apparently a direct effect of ACTH, which is not mediated through the glucocorticoids. *Vasopressin* and its synthetic analogue, lysine-vasopressin, are not merely potent stimulants of ACTH secretion (GWINUP, 1967), but also stimulate the release of growth

* For GRIH see p. 32.

hormone (GAGLIARDINO, 1967). However, this effect generally occurs only if vasopressin is administered in amounts far higher than those secreted physiologically, and it is questionable whether physiologically important interactions exist.

So far, no direct interactions have been demonstrated between TSH or gonadotropins and growth hormone.

b) Growth Hormone and Thyroid Hormone

Basal growth hormone levels in hypothyroid subjects are not usually significantly different from those found in normal subjects (IWATSUBO, 1967), but in hyperthyroidism the growth hormone levels tend to be raised (VINIK, 1968). In contrast, hypothyroid patients have a blunted response to stimuli of the growth hormone secretion such as insulin (IWATSUBO, 1967) or arginine (KATZ, 1969) administration. The awareness of this interaction is clinically important, because in untreated primary hypothyroidism the results of growth hormone secretion tests may be falsely pathologic and may lead to the erroneous diagnosis of growth hormone deficiency.

c) Growth Hormone and Glucocorticoids

On the basis of experience with children requiring treatment with large doses of glucocorticoids (e.g. for bronchial asthma) whose growth became stunted, pediatricians have long suspected that glucocorticoids might inhibit the secretion of growth hormone. It is now certain that the effects of glucocorticoids on growth hormone are manifold. Although there are still many inconsistencies in the experimental evidence, it may be stated that glucocorticoids do not impair the production of growth hormone in the pituitary gland itself, but they may inhibit its release into the bloodstream (FRANTZ, 1964). In addition, glucocorticoids seem to inhibit the peripheral growth-promoting actions of growth hormone, since glucocorticoids slow the growth rate even in hypopituitary dwarfs during substitution therapy with human growth hormone (SOYKA, 1965).

d) Growth Hormone and Sex Hormones

Although *testosterone* does not influence basal growth hormone levels, it increases the maximum growth hormone-secretory capacity in response to stimuli (MARTIN, 1968; see also p. 89).

In contrast to testosterone, *estrogens* do increase the basal growth hormone levels. Adult women generally have higher fasting growth hormone levels than children, men, or postmenopausal women, and the levels in men and children can be increased by the administration of estrogens (UNGER, 1965; FRANTZ, 1965).

The influence of synthetic sexual steroids such as medroxyprogesterone and oral contraceptives on the secretion of growth hormone has already been mentioned (see p. 89).

E. Pituitary Insufficiency, Panhypopituitarism

1. Classification

Before the leading role of the hypophysis in regulating the endocrine organs was known, this illness was referred to as "pluriglandular insufficiency" (CLAUDE) or "multiple endocrine sclerosis" (FALTA). These diagnoses are only rarely justified now (see Chap. XVIII). Isolated failure of each adenotropic hormone may occur (see p. 97f.), but failure of the whole anterior lobe is much more frequent and is described as panhypopituitarism or SIMMOND's disease. The most common causes are postpartum necrosis (Sheehan's syndrome) and destruction of the anterior lobe due to a pituitary tumor usually involving the posterior lobe as well. Failure of the posterior lobe does not, however, alter the clinical picture substantially. Diabetes insipidus is due to failure of the hypothalamic nuclei.

The clinical picture of hypopituitarism in its purest form is seen after therapeutic hypophysectomy for metastasizing carcinoma of the breast. The progression of symptoms can be followed in every detail in these cases. See p. 97f. for partial pituitary insufficiency.

2. Occurrence and Incidence

Panhypopituitarism is uncommon. SHEEHAN (1968) estimates an incidence of 100 cases of the most common variation of the disease, postpartum pituitary necrosis, in 1 million women. He found hypopituitarism in 8% of patients with mild blood loss during the delivery and in 53% of patients with severe hemorrhage. While SHEEHAN expected the development of pituitary insufficiency in over half all patients with severe postpartum hemorrhage, SCHNEEBERG (1960) found pituitary failure in only 4 of 35 cases with postpartum shock, and a follow-up of 235 patients in Zurich who lost more than 1 liter of blood at delivery did not reveal a single case of Sheehan's syndrome (WIESENDANGER, 1959). The incidence is certainly low,

and it is dependent on the population under investigation.

Panhypopituitarism is found more frequently in the female (65%), and is most common in the 3rd and 4th decades of life.

The relative incidence of the processes leading to pituitary failure is seen from the review by SHEEHAN and SUMMERS. Partial pituitary insufficiency is more frequent than was previously estimated and occurs more frequently than panhypopituitarism in chromophobe pituitary adenomas.

3. Etiology and Pathogenesis

Hypopituitarism is due to hypophyseal failure which may be caused by destruction of the hypophysis itself, or its connections with the hypothalamus, or by lesions in the hypothalamus. In most cases, four-fifths of those in the table given by SHEEHAN and SUMMERS, the defect is in the hypophysis itself. As a rule, one quarter of the original parenchyma of the anterior lobe can maintain the necessary adenotropic function of the hypophysis. Therefore, only 1–2% of intact tissue is usually found in severe cases. Weeks or years may elapse between the onset of the necrosis and the clinical appearance of hypopituitarism. The patients survive for 10–15 years on average, and sometimes even for over 40 years. Hypopituitarism becomes manifest in one fifth of the patients due to processes which interrupt the connections between the brain and the hypophysis. These are usually extrasellar cysts and tumors. As indicated in the discussion of the morbid anatomy of the hypophysis below, the etiology and pathogenesis of the basic diseases leading to pituitary failure are very varied. Necrosis of the adenohypophysis can be produced experimentally in rats with intravenous hexadimethrin bromide (KOVACS, 1967).

4. Pathological Anatomy

Hypopituitarism can be caused by damaged cerebral centers. The most frequent cause of panhypopituitarism however are necrosis of the hypophysis and its residual state (KERKHOVEN, 1966). These causes are followed in frequency by tumors and cysts. In contrast, inflammatory processes are relatively seldom responsible.

Symptoms due to partial failure, however, are more frequently produced by tumors and inflammatory processes of the hypophysis than by necrosis and sequelae.

Necroses of the anterior pituitary lobe are not infrequently found during the systematic patho-anatomical examination of postmortem cases. PLAUT (1952) demonstrated this during routine examination in almost 10% of male cadavers chosen at random (13 cases among 149 sections). SHEEHAN and STANFIELD (1961) found the same in 3% of their postmortem cases. Many necroses, however, must be considered as terminal complications.

The postpartum type of pituitary necrosis due to shock is most common. Vascular spasm seems to have a decisive pathogenic effect. Vascular thrombi, which can often be demonstrated in postpartum necrosis, are only a secondary phenomenon. In addition to the shock, a further factor is still needed to cause the necroses. Hypertrophy of the anterior lobe during pregnancy in the presence of a limited blood supply, the impossibility of expansion within the sella, the increase in the hypophyseal metabolism and postpartum involution with diminished blood supply are together responsible for the necroses. Apart from necroses during pregnancy, hypophyseal necroses have also been observed after shock resulting from hemorrhage, burns, epidemic hemorrhagic fever, sickle-cell crisis, insulin-shock treatment, and pulmonary embolism. These necroses, however, are usually less extensive than the postpartum type. Necroses of the anterior pituitary also occur in diabetes and hemochromatosis.

In addition, necroses of the anterior lobe occur frequently as a concomitant symptom in *primary and metastatic tumors* of the hypophysis. As a rule, these necroses are superficial. Infarcts, however, may also be due to tumor emboli. Like tumors, inflammation, particularly granulomatous processes, can also lead to accompanying necrosis.

Surgery and massive irradiation, intensive X-ray or proton irradiation, or implantation of radioactive yttrium or gold can cause hypophyseal necroses and lead to extensive scarring as a delayed sequela. Section of the stalk results in extensive necrosis because the portal vessels are a type of "end vessel". However, about 10% of the parenchyma is still retained since these areas are supplied by other vessels.

Frequently only scars are detectable and their cause can no longer be found. If the scars are very extensive, then the "empty sella" syndrome, a phenomenon seen quite often in autopsy, results. Cystic scars are denominated as cystic degeneration. Such cysts have no epithelial layers, in contrast to proper cysts. Interstitial fibrosis generally does not lead to hypopituitarism. The empty sella, however, may also result from increased pressure of the cerebrospinal fluid in the subarachnoidal space

of the gland, flattening but not destroying the pituitary. The empty sella syndrome may have different pathogenic mechanisms. It has been suggested that the incompetent diaphragma sellae may be an anatomical variant or may be caused by repeated swelling of the stalk in multiparous women (BRISMAN, 1972). The sella may be of normal size and shape, be balloon-like, deformed, or enlarged. For clinical features see p. 103 f.

Inflammation can lead to extensive destruction of the hypophysis, and therefore cause pituitary failure. *Purulent inflammation* usually arises from inflammatory processes in the surroundings. Abscesses of the anterior lobe develop almost without exception, spreading from sphenoidal sinusitis or possibly from a necrotic chromophobe adenoma. Abscesses developing after septic infarction have been described (SHEEHAN, 1965). Meningitis, osteomyelitis of the sphenoid bone and thrombophlebitis of the cavernous sinus can all spread to the hypophysis. Finally, inflammatory vascular processes also lead to hypophyseal destruction. *Diffuse, non-purulent, chronic inflammation* reminiscent of an autoimmune process, are worth mentioning. Both GOUDIE (1962) and HUME (1967) have seen hypophysitis of this type in a female patient with Hashimoto's thyroiditis. EGLOFF (1969) has observed an isolated lympho-plasmocytic hypophysitis in a patient with panhypopituitarism.

In addition to these more diffuse processes, granulomatous inflammations also have a pronounced effect. The tuberculoid giant cell granuloma is characteristic, usually involving only the hypophysis. The cause of the inflammation is unknown. Pituitary insufficiency is a late development since the granulomas can destroy the anterior lobe to a great extent. Women around the age of 55 are most often affected. Occasionally, tuberculosis, syphilis, sarcoidosis and certain mycoses also produce granulomatous inflammations with parenchymatous destruction.

5. Symptoms and Clinical Course

a) History, Psychological Changes

The illness, due to pituitary tumors and especially to postpartum necrosis, usually develops slowly over the course of years although on rare occasions it may present itself within a few weeks due to massive postpartum necrosis. The first symptoms arise 3 weeks after total removal of the hypophysis and generally become definitely manifest after 5 weeks. As a rule, growth hormone probably fails first, followed by the gonadotropins. Thy thyrotropic hormone then fails, and the adrenocorticotropic hormone is the last to disappear. There is minimal residual thyroid function and a basal adrenocortical secretion consisting entirely of aldosterone. Complete failure of the hypophysis is therefore compatible with life, even though life is severely impaired.

A change in menstruation is the first symptom in the female. The bleeding becomes scanty, short, and irregular, and finally fails to occur. Irregular bleeding can, however, occur. Occasionally menstruation starts again after cortisone substitution. Climacteric symptoms are usually absent but may occur (PURNELL, 1964). They may arise after delivery in postpartum hypophyseal necrosis and then gradually disappear. Failure of lactation and a hypoglycemic tendency are considered early symptoms. Pubic hair, shaved before delivery, does not return. Sensitivity to cold becomes apparent later, and the patients are usually always cold and dress warmly even in summer. Increasing tiredness to the point of adynamia finally causes the patients to become bedridden. Their speech is slow, monotonous, and hesitant, and later becomes slurred. Giddiness, tendency to faint, obstinate constipation, oliguria, and somnolence are further common symptoms. Typical symptoms are the hypoglycemic tendency and the inability to remain without food for even a short period of time. Impotency and loss of libido occur in the male. In general, the patients consult their physicians very late, since they are indifferent to their illness. Temporary diabetes insipidus may occasionally occur and has been described in about two dozen cases. Quite often it is primarily due to an organic lesion and later to a conditioned polydipsia (AGUILÓ, 1969), rather than to posterior pituitary necrosis and lack of vasopressin (EVANS, 1960).

Failure of the adenohypophysis leads to severe psychological changes which may progress to psychoses. At the beginning, there is a lack of initiative, lack of interest, generalized retardation and apathetic depressive moods, making up the endocrine psychosyndrome. All motivation disappears completely in time. The sexual and motor impulses are lost first. Indifference develops into complete neglect of the surroundings as well as of the person. The patients decline intellectually, the amnestic psychosyndrome develops and they finally lead a no more than vegetative existence. States of the actue exogenous reaction type may be associated with the complete disappearance of psychological functions. These may progress to predominantly paranoid hallucinations, delirium, and finally to coma, usually associated with acute adrenal

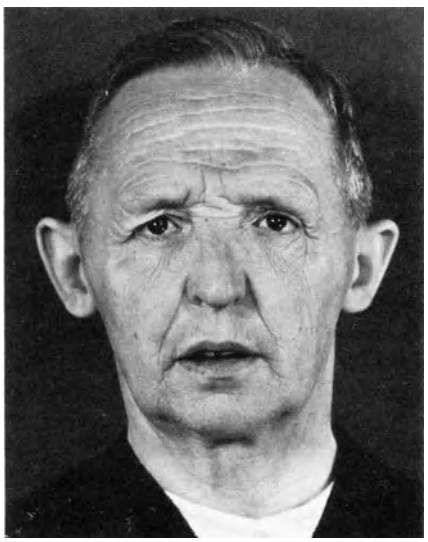
insufficiency (BLEULER, 1964; KIND, 1958; LINDQVIST, 1966).

It is still not known whether substitution therapy, which compensates the somatic failure, can also reverse the psychological disorders completely or only partly improve them.

b) General Examination

The face of the patient with pituitary insufficiency is expressionless, as during sleep. The features are strangely blurred (Fig. 2). The patients appear uninterested, lifeless, and tired.

a



b

Fig. 2a and b. Facial expression in panhypopituitarism. a) 50-year-old female patient with SHEEHAN's syndrome (Prof. SCHÜPBACH, Inselspital, Bern). b) 61-year-old male patient with panhypopituitarism and diabetes insipidus, unknown etiology (TB?)

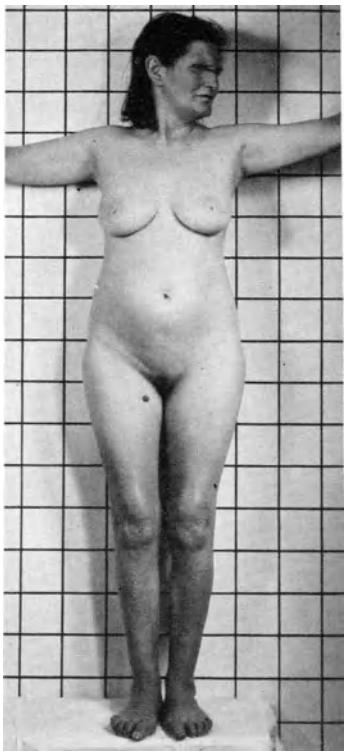


Fig. 3. 52-year-old female patient with Sheehan's syndrome. Complete absence of pubic and axillary hair. Striking pigment deficiency, especially in the areolas (Prof. SCHINZ, Radiological Dept. of the University of Zurich)

The skin can, but need not, show a myxedematous tendency. It is dry, but thin, delicate and "alabaster-like". The hair is dull, bristly, but not prematurely gray. The eyebrows may be absent or may be particularly scanty in the lateral third.

The fallow pallor of the thin, marble-like, translucent skin is striking (Fig. 3). Pigment deficiency is most noticeable in the normally strongly pigmented zones, such as the mamilla, the perigenital and the perianal areas. The lack of pigment is due to diminished melanin formation resulting from the failure of the hypophyseal melanocyte-stimulating hormone (see p. 294ff.). Measurable darkening of the skin can be achieved with MSH in patients with hypophyseal insufficiency. The inability to form melanin is demonstrated by the failure to turn brown after ultraviolet radiation. The cutaneous circulation is reduced; patients with hypopituitarism never blush.

Sweating and sebaceous secretion are also reduced or arrested.

The third characteristic is the loss of body hair (Figs. 3, 4). Pubic and axillary hair are totally absent in severe cases. The axillary hair can disappear within 2 months, whereas the

spontaneous loss of pubic hair takes 1–2 years. In men, growth of the beard and the moustache is scanty and there is no body hair. The diagnosis can be made with a high degree of certainty from these three visible findings; the expressionless face, neither young nor old; the striking pallor; and baldness of the body. Calcifications in the auricle, as in Addison's disease, have been observed (RANDALL, 1963).

The body weight is normal in 3/4 of the cases. SHEEHAN has conclusively corrected the long-established view, based on SIMMOND'S first description, that pituitary failure leads to cachexia (see Table 2).

Table 2. Weight in 103 cases of Simmond's disease. (From SHEEHAN, 1948)

	Fat	Higher than normal	Normal	Medium	Thin	Cachectic
At time of death	9	11	36	19	14	14
6 months before death	9	11	57	11	9	6

Emaciation may occur terminally although there is sometimes a weight gain at the beginning of the disease. Motor inactivity and reduced basal metabolic rate with unchanged appetite are probably the cause of this.

Subnormal temperatures may occur. The fact that patients with Sheehan's syndrome often have a smaller sella (<80 mm^2 in the lateral X-ray) than a control group (MEADOR, 1966) is worth investigating. Involutional processes and greater susceptibility of the smaller hypophysis have been considered.

Circulatory organs: Bradycardia is less pronounced than in myxedema. The hypotension is less severe than in Addison's disease. There is orthostatic hypotension. The heart is smaller than in Addison's disease. The small kidneys and the small liver are due to the splanchnomicria.

Ovarian failure leads to atrophy of the genital organs, and the vaginal smear shows no signs of estrogenic activity. Bleeding, however, may sometimes occur.

In the male, there is a secondary hypogonadotropic hypogonadism with tubular insufficiency at first, followed by interstitial failure (see p. 469 f.).

c) Laboratory Investigation

The diagnosis of a suspected case of hypopituitarism can be verified by demonstrating secondary thyroid, adrenal, and gonadal insufficiency and growth hormone deficiency.

See p. 160 for secondary hypothyroidism and its diagnosis (p. 241 f.).

BMR, radioiodine test, the protein-bound iodine and thyroxine determination can detect the hypothyroidism. The TSH test differentiates between primary and secondary hypothyroidism. Reduced TSH-reserve is demonstrated by the carbimazole test (see p. 242) or more recently, by the TRH-test (see Chap. VI, p. 242).

See p. 325 for secondary adrenal insufficiency. It can be differentiated from primary adrenal insufficiency by the 3-day intravenous ACTH test. Extremely low or absent urinary steroids (0–1 mg 17-keto and 17-hydroxysteroids) are suggestive of a secondary insufficiency. The aldosterone excretion is normal or within the lower limits of normal. Aldosterone secretion does not always rise sufficiently in response to salt deficiency (ROSS, 1960). Demonstration of an increased or decreased gonadotropin excretion is a good way of distinguishing primary from secondary hypogonadism (testes, p. 469 f.; ovaries, p. 585 ff.). Estimation of gonadotropin is of great diagnostic value especially in women after the menopause.

Impaired diuresis in hypopituitarism is partly due to the adrenal insufficiency. On the other hand, failure of growth hormone also causes a reduction in glomerular filtration and renal plasma flow. The defect can only be partially corrected by substitution with cortisone and thyroxine (FALKHEDEN, 1963). A pronounced hyponatremia of 110–120 mEq/l is not uncommonly found in untreated cases of pituitary insufficiency, especially in response to stress such as surgery. Strangely, this hyponatremia is well tolerated, and regresses with cortisone alone. The pathogenesis is not completely clear (BETHUNE, 1965; GASTINEAU, 1967). Renal sodium loss is not usually present, and the serum urea, in contrast to the dehydration in ADDISON'S disease, remains low. Excessive water retention has been suspected to be due to inadequate vasopressin secretion (AUBRY, 1965) since lack of cortisone causes a fall in the osmotic stimulus threshold. The fact that water deprivation does not increase the sodium concentration and that it is possible to correct the disorder with cortisone alone makes the overproduction of vasopressin appear unlikely. The extracellular space is enlarged. Water overloading, which

was previously recommended as a diagnostic test, is dangerous, involving the risk of water intoxication with brain edema and epileptic fits. Unexplained hyponatremia should suggest pituitary insufficiency and is more pronounced in hypopituitarism due also to the failure of growth hormone. The insulin tolerance test best demonstrates the deficient counter-regulation. The blood sugar falls rapidly to low values and does not rise promptly or rises only inadequately. The typical rise in the level of growth hormone is absent. This test, however, also involves a certain amount of risk and should be used cautiously. Glucose for intravenous injection must always be ready to terminate the test.

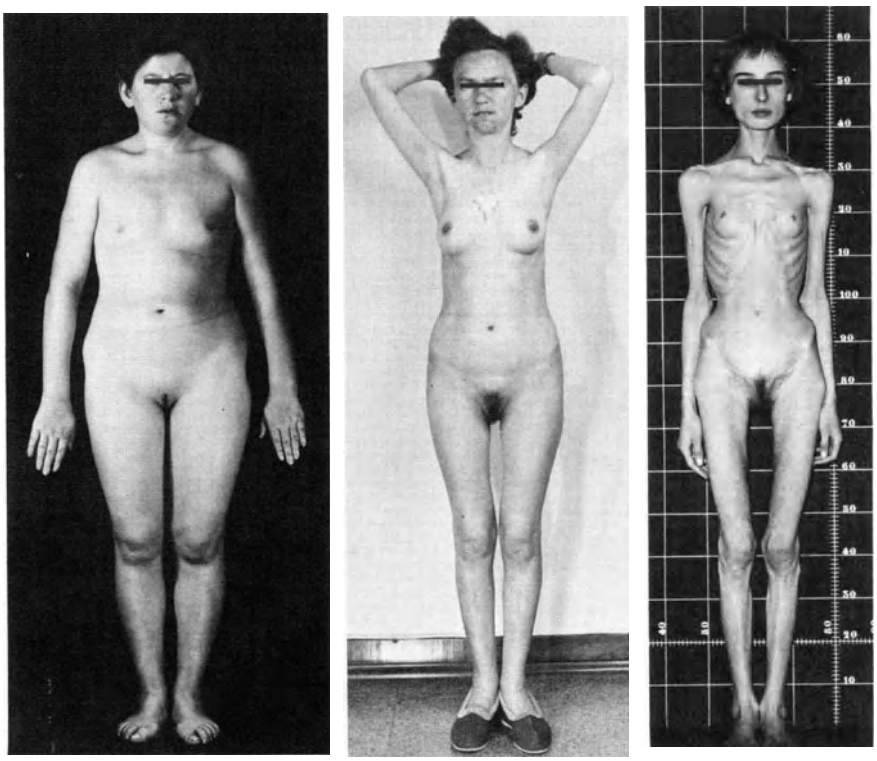
Blood findings: the erythrocyte sedimentation is normal. There is mild anemia, at first hypochromic and later hyperchromic, due to failure of the adrenal glucocorticoids and a pituitary factor. The white blood cell smear shows an increase in eosinophils and lymphocytes.

Achylia, which may prove to be refractory to histamine, has sometimes been observed.

6. Differential Diagnosis

Panhypopituitarism must first be differentiated from post partum endometrial amenorrhea, occuring very seldom. In the latter condition there are no clinical signs of failure of the thyroid and adrenals. Hormone estimations are normal. The differentiation between pronounced anorexia nervosa and hypopituitarism is not difficult. The question of pituitary function in anorexia often comes into consideration because of the wrong dogma which has existed for years that pituitary insufficiency leads to cachexia. Anorexia does, however, always have some features in common with pituitary insufficiency; the basal metabolic rate is always reduced, and there is amenorrhea in both conditions.

In anorexia, however, there is a hypometabolism without hypothyroidism. Steroid excretion is diminished in anorexia, but never to the same extent as in hypopituitarism. The adrenals are not found to be atrophic, and the adrenal insufficiency is only relative. The amenorrhea has the same cause in both conditions, and the gonadotropins are usually not demonstrable in anorexia (see p. 591). In anorexia, FSH production ceases under central nervous system influences. Emaciation is suggestive of anorexia, and makes hypopituitarism unlikely (Fig. 4). In typical cases of anorexia the skin is covered with lanugo hair. Pubic and axillary hair may be scanty but is never completely



a b c

Fig. 4a–c. Differential diagnosis of hypopituitarism. a) 26-year-old female patient with hypopituitarism, due to a chromophobe adenoma. b) 35-year-old female patient with the sprue syndrome. Chloasma-like pigmentation of the forehead and chin, axillary hair absent, pubic hair scanty. c) 19-year-old female with anorexia nervosa (KspZ)

absent as it is in pituitary insufficiency. The psychological changes in the two diseases are very different. The anorexic patient is shy and uncommunicative, but is not apathetic, and can be very lively and enterprising. The physical deterioration leads only terminally to apathy. Differentiation can be difficult in the terminal stages of both illnesses. The insulin tolerance test with growth hormone determinations makes differentiation possible. This test is, however, not without risk. In anorexia, the blood sugar will return to normal in response to hypoglycemia, whereas in hypopituitarism, the blood sugar usually remains low until glucose is given.

The malabsorption syndrome may simulate hypopituitarism. Scanty pubic and axillary hair, adynamia, anemia and low ketosteroid excretion are common to both conditions. However, the waxy pallor of hypopituitarism is absent in sprue (Fig. 4b), and in contrast, there is quite often pigmentation of the skin.

Differentiation from primary myxedema can be difficult when the secondary hypothyroidism dominates the clinical picture. The TSH test, the TRH test and the demonstration of the failure of other endocrine systems establishe the diagnosis.

Primary adrenal insufficiency is distinguishable mainly by the pigmentation. "White" Addisonians can be difficult to differentiate from hypopituitarism since the basal metabolic rate can also be reduced in Addison's disease, and gonadal dysfunction may also occur. The ACTH-test repeated over 3 days can differentiate the two diseases. Clinical distinction between hypopituitarism and Schmidt's syndrome (primary hypothyroidism and adrenal cortical insufficiency (see Chap. XVIII) can be difficult. This syndrome is probably underlaid by autoimmunological factors and often occurs with diabetes mellitus. The presence of gonadotropin, primary hypothyroidism in the TSH-test, primary adrenal insufficiency indicated by the ACTH-test, and serum antibodies to the thyroid and adrenal tissues suggest Schmidt's syndrome.

Hypoglycemic states can involve islet-cell adenoma in the differential diagnosis. Evidence of thyroid, gonadal, and adrenal insufficiency proves the pituitary cause.

Finally, in the male, a differential diagnosis between primary or secondary hypogonadism and hypopituitarism has to be made. The differentiation is based on the estimation of the gonadotropins, the testicular biopsy and the demonstration of hypothyroidism and adrenal insufficiency.

7. Special Forms

a) Partial Hypopituitarism

The diagnosis of partial hypopituitarism has been facilitated by the development of diagnostic tests. It occurs more commonly than panhypopituitarism in chromophobe adenomas and after therapeutic hypophysectomy. The effects are dependent upon the extent of the destruction and the duration of the illness. They can also arise after failure of the hypothalamic regulation centers. Partial generalized insufficiency can occur which is only detectable by the different reserve tests, or there may be a selective failure of every single adenotropic hormone and of the growth hormone. Not infrequently, partial hypopituitarism is present at the beginning and may progress to panhypopituitarism over the course of months or years. Hypogonadotropic hypogonadism was considered to be the most frequent partial hypopituitarism (see p. 469), isolated secondary hypothyroidism to be less common (see p. 160), and isolated secondary adrenal insufficiency even rarer (see p. 325). The last condition may also arise after successful removal of an adreno-

Table 3. Differential diagnosis between anorexia mentalis and hypopituitarism. (After ESCAMILLA)

	Anorexia	Hypopituitarism
Symptoms common to both diseases:		
Secondary amenorrhea (FSH absent)	+	+
Asthenia	+	+ +
Hypotension	+	+ +
Hypometabolism (reduced BMR)	+	+ +
Symptoms occurring in one disease only:

Eosinophilia	0	+ +
Average age	21	41
Onset	After puberty	After pregnancy
Insulin tolerance	Normal	Reduced
ACTH-test	Normal	Normal, only after repeating 3 times

cortical adenoma. Recently, however, isolated failure of growth hormone without clinical symptoms appears to be the most common adult endocrine disorder secondary to chromophobe adenoma. This failure can only be demonstrated by the radioimmunological methods for estimating growth hormone in combination with the insulin tolerance test (see p. 123) (RABKIN, 1966). Selective failure can occur in all combinations (DAYER, 1959). Among 69 chromophobe adenomas there were 10 cases showing no failure, 16 cases with failure of all 3 adenotropic hormones, 22 cases of one isolated failure, (17 hypogonadism, 3 hypothyroidism, 2 adrenal insufficiency) and 21 cases of secondary failure of 2 glands (OBERDISSE, 1957). Secondary hypogonadism and secondary adrenal insufficiency appear to occur more frequently together than is attributable to chance and have been collectively termed "basophil failure" (MADDOCK, 1951).

Isolated failure of the growth hormone leads to pituitary dwarfism. For discussion of selective failure of TSH in pseudohypoparathyroidism the reader is referred to Chap. XIV.

Selective secondary hypothyroidism may cause pituitary impairment leading to adrenal cortical insufficiency. Thus it may simulate panhypopituitarism.

Hypopituitarism, due probably to a hypophysitis caused by autoimmunological factors, can occur with other immunological disorders in the organism (HUME, 1967) (see Chap. XVIII).

A strange form of partial hypopituitarism with giantism and normal or increased growth hormone effects has been described by GOLDMAN, 1963, and SARVER, 1964.

b) Pituitary Dwarfism

A. PRADER and M. ZACHMANN

Pituitary dwarfism is due to an inhibition of growth associated with a deficiency of somatotropic hormones. It begins during infancy. Since differentiation between a hypothalamic disorder and pituitary insufficiency is impossible in some patients, it would be more correct to speak of "hypothalamo-pituitary" dwarfism. Unfortunately, the term "pituitary dwarfsm" is often used rather uncritically for all cases of small stature. It must be stressed that pituitary dwarfism should only be diagnosed when growth hormone deficiency is demonstrable. Patients affected by this deficiency are uncommon in comparison to the frequency of small stature.

Thyroid, adrenocorticotropic and gonadotropic functions are disturbed as well as growth in classic cases. There are, however, patients with isolated growth hormone deficiency and intact function of all other anterior pituitary hormones. Such cases are probably not very rare, but they can only be detected by refined diagnostic methods. Apart from this, there are also known forms of growth hormone deficiency combined with TSH, ACTH or gonadotropin deficiency. Thus, pituitary dwarfism is possible throughout this spectrum, from isolated growth hormone deficiency to the complete picture of panhypopituitarism.

The following forms of pituitary dwarfism can be differentiated on the basis of clinical and etiological features:

1. Isolated growth hormone deficiency presents as dwarfism in the presence of intact function of all the other anterior pituitary hormones. The clinical picture is hardly different from that in other types of nonendocrine dwarfism (primordial constitutional dwarfism, Chap. XIX). The differentiation from other forms is, however, of importance because of the therapeutic possibilities in the case of a growth hormone deficiency. There are idiopathic (sporadic) and hereditary (recessive inheritance; RIMOIN, 1966) forms of isolated growth hormone deficiency. Since puberty, although delayed, arises spontaneously in these patients, they are also described as "sexual ateliotics" in older classifications (GILFORD).

2. Growth hormone deficiency with multiple anterior pituitary insufficiency can also occur idiopathically or can be inherited. Boys are affected by the idiopathic form more frequently than girls. (This also applies to the form described in 1., above.) This form of pituitary dwarfism may be due to cerebral trauma during birth or to asphyxia at birth in many cases. The possibility of an organic disorder must be considered particularly in cases with multiple failure; an intra- or suprasellar tumor, usually a craniopharyngioma, can cause this form of pituitary dwarfism (Fröhlich' dystrophia adiposogenitalis in the original meaning of the term). Other organic causes include malformations in the region of the pituitary or hypothalamus and finally, traumatic damage (fracture of the base of the skull with hypophyseal hemorrhage or direct traumatic influence on the pituitary). Patients suffering from multiple failure with gonadotropin deficiency were formerly also referred to as "asexual ateliotics" (GILFORD).

3. A secondary, symptomatic growth hormone deficiency occurs with severe general disease and also occasionally with malnutrition. Primary hypothyroidism can also lead to inhibition of growth hormone secretion, as can corticosteroids, which would at least partly explain the small stature in Cushing's syndrome

and following long-term corticosteroid therapy with high doses. A temporary growth hormone deficiency occasionally results in small stature in children brought up in unfavorable social conditions, particularly in children deprived of maternal affection (POWELL, 1967, "emotional deprivation", Chap. XIX).

4. The possibility of a functional deficiency of growth hormone in the presence of normal secretion (peripheral resistance or inactive growth hormone) has not been fully studied. Thus, for example, peripheral resistance to growth hormone is assumed to be the cause of the small stature of pygmies, in whom normal growth hormone concentrations were found in the plasma during stimulation tests. Apart from this, there also appear to be hereditary forms of dwarfism where high levels of GH are found (LARON, 1968) but where presumably a mediator, the sulfation factor or somatomedin (see p. 88), is deficient.

Growth in patients with pituitary dwarfism is usually normal in the first two years of life and then becomes progressively slower (Fig. 5). On rare occasions, the growth deficit appears in the first months of life. Body weight and length are usually normal at birth. When gonadotropins are absent, the pubertal growth spurt and postpubertal termination of growth fail to occur. The majority of patients with multiple failure continue to grow throughout life, although the increase after the 20th year is only a few cm. The adult height of untreated patients lies between 100 and 140 cm.

As a rule, there is mild obesity in spite of a definite lack of appetite in all forms of pituitary dwarfism. This is a reflection of the absence of the lipolytic action of growth hormone. The obesity involves the trunk in particular (Fig. 6). Body

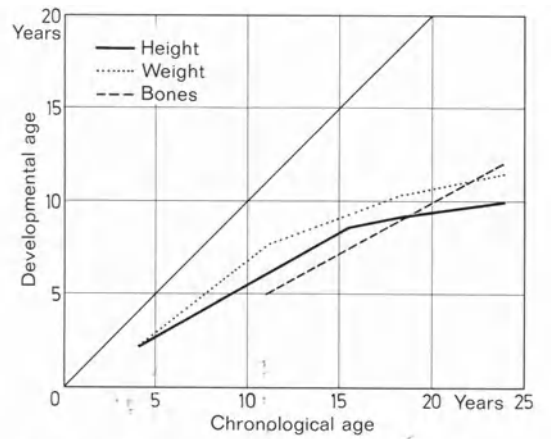

Fig. 5. Development of height, weight and bones from 5th to 24th year in a man with pituitary dwarfism. Note the general retardation of development and the continuous growth even after 20th year

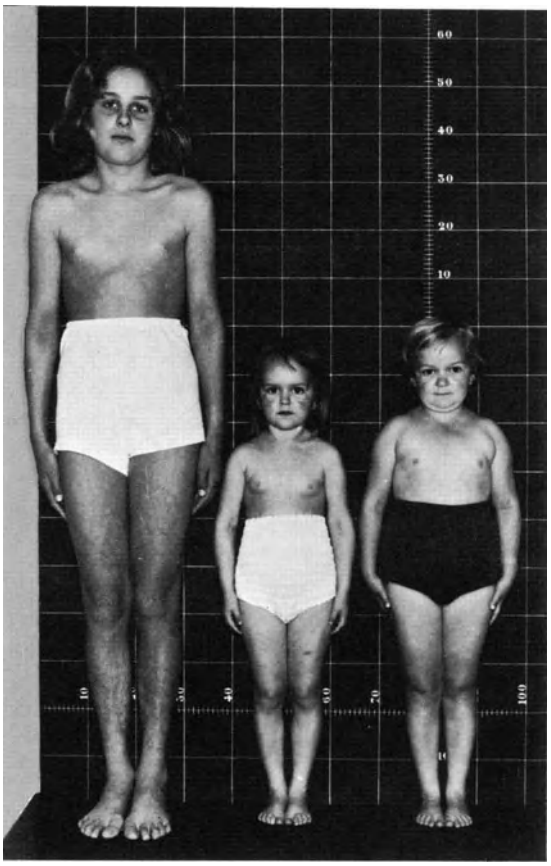

Fig. 6. Two girls with familial pituitary dwarfism (isolated growth hormone deficiency) and a girl of normal height of about the same age

	Age	Height age	Bone age
Healthy girl	14	14	–
Patient, center	13.9	3.7	8.3
Patient, right	13.4	4.1	10.5

proportions usually correspond to normal values, except that the head is relatively large. Despite the small stature, slightly eunuchoid proportions develop after the 10th–15th year when gonadotropin is also deficient. Hands and feet are often exceptionally small and doll-like (acromicria) and the face retains the round shape and the soft, doll-like features of an infant.

Bone development is retarded. The degree of retardation varies individually and is greater in the presence of a TSH deficiency. As a rule, bone development and increase in height are retarded to roughly the same extent. Development of the paranasal sinuses is also delayed. The *sella* is occasionally enlarged in cases with tumors. In other cases it is often smaller, but no diagnostic importance can be attributed to this finding.

Necrosis of the head of the femur, which is reminiscent of Perthes's disease, is another skeletal finding occasionally found in association with a simultaneous TSH deficiency (see p. 170). Development of the teeth is also definitely retarded, though usually to a lesser extent than the bone development.

The *skin* is tender, thin, and often rather dry. The turgor is sometimes slightly reduced and the extremities tend to be cool. During the third decade or later, the skin of untreated patients shows fine folds and wrinkles, especially the face, giving the patients a senile appearance in striking contrast to the infantile body stature.

Intelligence is commensurate with age, so that in contrast to hypothyroid dwarfs, these children can usually keep up quite well in school as long as their physical strength is adequate and hypoglycemic attacks do not arise. Psychological infantilism is often present, which is especially pronounced in cases where puberty fails to develop (see also gonadal dysgenesis, Chap. XII). The sense of shame is often extreme, as is the sensitivity of these patients to disparaging and insulting remarks. This indicates just how much patients suffer from their appearance and from the fact that they are taken to be younger than they actually are.

Except in cases with a suprasellar tumor, few pathologic findings can be detected in the *nervous system*. An uncharacteristic, slight abnormality is occasionally found in the electroencephalogram. In cases where tumors are present, endocrine symptoms may precede the neurological ones, which are often not apparent until school age or early adulthood since the craniopharyngioma grows slowly. These symptoms can appear at any time in the case of other tumors, which are, however, very uncommon. Signs of a tumor are: headache, vomiting, visual disturbances, loss of visual fields (mainly bitemporal hemianopsia), papilledema, bursting of cranial sutures and enlargement of the sella. Since craniopharyngiomas usually become calcified, a suprasellar calcium shadow on the X-ray is particularly typical (Fig. 7).

Metabolic findings are best classified by the individual anterior pituitary hormones. It must be mentioned that, as in acquired pituitary insufficiency in the adult, no parathyroid insufficiency has been observed.

Growth hormone deficiency causes few direct metabolic findings which can be recognized: phosphorus and alkaline phosphatase in the serum may be diminished and cholesterol may be elevated. Nitrogen excretion in the urine is often higher than in healthy subjects but can only be assessed if the patients keep to a consistent diet. Single estimations of growth hormone

Fig. 7. Suprasellar calcification in craniopharyngioma

in the plasma are of little value since the concentration is subject to extremely wide physiological variations. Multiple estimations after stimulation of growth hormone secretion are therefore essential. Stimulation can be produced by insulin hypoglycemia, intravenous administration of arginine, a protein meal, or other stimuli. In the healthy subject the growth hormone concentration in the plasma then attains a maximum 30–60 minutes after insulin, and somewhat later with other methods of stimulation. Absolute values vary according to the laboratory. Fasting levels vary between 0 and 5 ng/ml plasma, and after maximum stimulation, the levels are between 10 and 20 ng/ml or higher. If the plasma concentration in a patient with dwarfism increases significantly or fasting values are very high a growth hormone deficiency can be excluded with certainty. If there is no rise, deficiency is possible but not yet confirmed. In doubtful cases, a nitrogen retention test can help. This test is based on the more pronounced metabolic action of growth hormone in patients with endogenous deficiency than in control cases with intact pituitary function. The long duration is a disadvantage associated with this test; patients receive a consistent diet chosen by themselves for 10 days. The first 5 days are used as a control period for estimation of the mean nitrogen excretion. Over the next 5 days, growth hormone is given intramuscularly every day in a dose of 2 mg/m^2 body surface area and the mean nitrogen excretion is calculated from the 2nd to the 5th day of the treatment period. The nitrogen retention as a percentage of the mean nitrogen excretion during the control period gives a good demarcation between patients with growth hormone deficiency and those without (PRADER, 1968).

Thyroid insufficiency is rarely manifest in the presence of *TSH deficiency*. The patients frequently give the impression of being alert and active and show no signs of the typical skin symptoms. Constipation may also be absent. Not uncommonly, the skin is found to be suspiciously dry and rough. Less frequently there are changes reminiscent of Perthes's disease in the head of the femur. PBI and radioiodine investigations give low values. Uptake of ^{131}I becomes normalized after 3 days' treatment with TSH, or sometimes a week of treatment is necessary. Blood pressure and basal metabolic rate (to be interpreted with reservation in children) are reduced, but are never as low as in classic primary hypothyroidism. The Achilles' tendon reflex time is prolonged. Serum cholesterol is increased, but this must not be interpreted as a sign of TSH deficiency only, since it is also elevated in isolated growth hormone deficiency. This is also applicable to phosphorus and alkaline phosphatase values, which are often reduced. See p. 123f. for the relation between growth and serum phosphorus.

ACTH deficiency seldom leads to manifest impairment of adrenocortical function although latent insufficiency can be demonstrated under increased stress. This is indicated by the case history in which there is occasionally a record of tendency to collapse and to become exhausted during great physical exertion and generalized illnesses. Individual patients suffer from hypoglycemic attacks, especially during childhood, as a result of the simultaneous failure of growth hormone and ACTH. The fasting blood sugar is slightly diminished or normal. More thorough investigation of carbohydrate metabolism yields findings similar to those in acquired pituitary insufficiency in the adult (p. 96); the rise in blood glucose after administration of insulin is definitely delayed. It may, however, be absolutely normal in single cases, even in the absence of growth hormone and ACTH. On the other hand, the rise in plasma cortisol after insulin administration is always inadequate in the presence of ACTH deficiency. If there is a history of hypoglycemic states, the insulin tolerance test must be carried out initially with only half the conventional insulin dose (2 U/m^2) because of the danger of hypoglycemic shock (Chap. XIII). In contrast to insulin, which causes liberation of ACTH by higher centers, high doses of the synthetic preparation, lysin-vasopressin, probably act on the pituitary, causing direct release of ACTH. A theoretical differentiation can thus be made between a hypothalamic and a pituitary lesion by comparing the cortisol increase after insulin and that after lysin-vasopressin. In fact, there is often no rise in plasma cortisol after insulin in cases with suprasellar tumors, and a normal increase after lysin-vasopressin. Experience with this test is, however, still limited. Delayed water excretion in the water tolerance test and the return to normal after administration of synthetic depot ACTH for 1–2 days are further characteristics of an ACTH deficiency. Electrolyte concentrations in the serum are usually normal, whereas the sodium is often slightly elevated in the sweat and the sodium/potassium quotient is raised. Excretion of 17-ketosteroids and 17-hydroxycorticosteroids is unaltered in the infant, but persists at the infantile level in later life. See Chap. VII, p. 385ff. for other examinations of the pituitary-adrenocortical system. In summary, ACTH deficiency in pituitary dwarfism leads to a latent adrenocortical insufficiency which is usually less severe than in Sheehan's syndrom. Development of the gonads and genitalia remains at an infantile stage in pituitary dwarfism with simultaneous *gonadotropin deficiency*. Secondary sexual characteristics fail to develop. Excretion of testosterone, 17-ketosteroids and gonadotropin correspond to that in the healthy infant. In other words, there is a severe hypogonadotropic hypogonadism (p. 469). The complete absence of sexual hair shows that not only gonadal function, but also the production of androgenic adrenocortical hormones is impaired (see adrenarche, Chap. XIX). Gonadotropin deficiency can, however, only be unmistakably recognized by clinical examination when the patients have reached the bone age at which puberty normally begins (boys approximately 13, girls approximately 11 years, Chap. XIX). Since bone development is generally significantly retarded in growth hormone deficiency, puberty is also often delayed in isolated growth hormone deficiency.

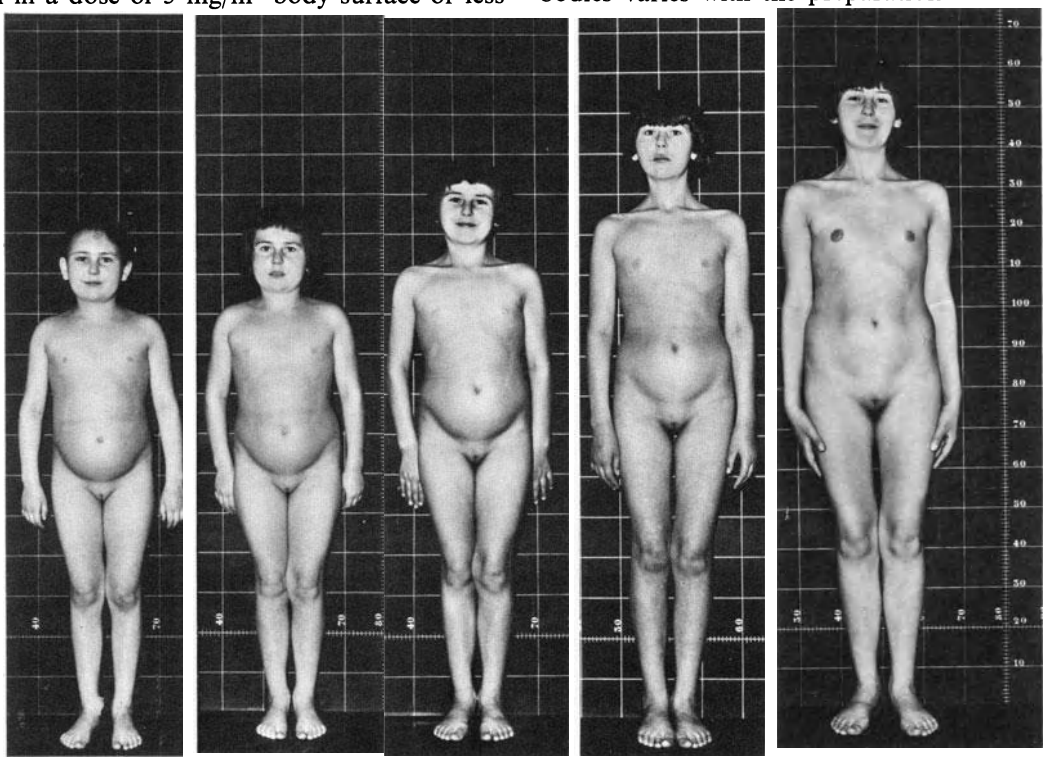
The *diagnosis* is easy in the adult. Practically no other diagnosis need be considered in the case of a dwarf with open epiphyses and no secondary sexual characteristics. The situation is much more difficult in the child, especially in the case of an isolated growth hormone deficiency; it is almost impossible to differentiate pituitary dwarfism from the much more common forms of dwarfism by clinical examination alone (Chap. XIX). The insulin tolerance test, with estimation of glucose, growth hormone and cortisol in the plasma, is particularly valuable in the assessment of this situation, since growth hormone deficiency and ACTH deficiency can be detected at the same time. Refer to Chap. XIX for a discussion of the differential diagnosis of dwarfism.

As far as duration of life is concerned, the *prognosis* is good. If treatment is not started

soon enough, the dwarfism, infantile appearance, and limited physical energy, impose severe restrictions on the patient's way of life. The physical capacity is usually astonishingly good, especially if there is no ACTH deficiency. The prognosis must be assessed with caution in cases with tumors, since recurrences or neurological complications are possible with craniopharyngiomas for example.

Apart from neurosurgical intervention when tumors are present (p. 122), continuous substitution therapy is the only possible form of treatment. The theoretically correct treatment consists of administration of pituitary growth hormone and the missing adenotropic hormones. For the moment, however, this can be realized only in some cases.

An impressive acceleration in growth rate can be achieved with *human growth hormone*, and normal adult height can be attained if treatment is started early enough (Fig. 8). Unfortunately, the hormone has not yet been synthesized, so that it is available only as extracts from human pituitary glands. Therapeutic possibilities are therefore limited to a few centers, and the amounts available are not sufficient to treat all patients with pituitary dwarfism. Two injections of an active preparation in a dose of 5 mg/m^2 body surface or less per week are sufficient to produce an optimal effect on growth (e.g. in the case of extracts prepared according to RABEN, WILHELMI or ROOS, 1 mg contains about 1.5 USP units). As a rule, a growth rate much faster than the normal rate is observed during the early months of treatment. Thus, not only is normal growth restored, but "catch-up" growth also occurs. Afterwards, the rate of growth slowly decelerates and assumes a normal level appropriate to the age (Fig. 9). Growth hormone promotes bone maturation in addition to growth. In contrast to anabolic steroids or testosterone, it accelerates bone maturation to a lesser extent than gain in height. Successful treatment also results in the reduction of subcutaneous fatty tissue. In spite of this, weight increases in the same way as height, an indication that muscle mass is increasing while adipose tissue is decreasing. Antibodies to growth hormone arise in a certain percentage of treated patients. In many cases they are unimportant, but they can arrest growth, especially when high titers can be demonstrated. Little is known about the cause of the formation of antibodies. It is probable that a certain denaturation of the growth hormone during extraction has some effect, since the frequency of the occurrence of antibodies varies with the preparation in use. The



$10^{11}/_{12}$ $12^{8}/_{12}$ $14^{7}/_{12}$ $17^{0}/_{12}$ $19^{0}/_{12}$

Fig. 8. Action of human growth hormone in a girl with pituitary dwarfism (panhypopituitarism following surgical treatment of a craniopharyngioma at the age of 10 years 11 months). Pigmentation of the mamilla at the age of 19 is due to the additional treatment with estrogens

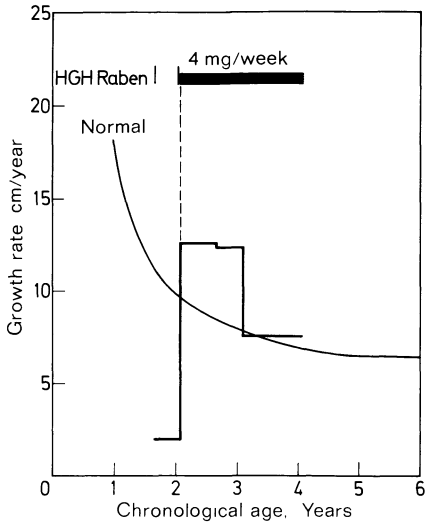


Fig. 9. Action of human growth hormone on the growth rate in a boy with pituitary dwarfism (idiopathic isolated growth hormone deficiency). At first the rate of growth is greater than normal ("catch-up" growth) and then it becomes normal for the age

tendency to form antibodies, however, also appears to have genetic reasons. *Attempts at promoting growth with anabolic steroids and testosterone* are only justified when human growth hormone is unavailable. These preparations often have a temporary favorable effect. Since they frequently promote bone maturation to a greater extent than growth, they have a less favorable effect than human growth hormone on the future adult height. Their use in substitution therapy for gonadotropin deficiency will be discussed. The question of using TSH for *substitution in TSH deficiency* does not arise, since the preparations available eventually become inactive. It is therefore necessary to institute treatment with thyroid extracts (preferably with Na-L thyroxine or a mixed preparation of L-thyroxine and triiodothyronine). The dose necessary varies widely for individual patients. A small daily dose of 50–100 µg is usually given at first, and is adjusted according to the serum cholesterol and the reflexogram of the Achilles tendon. Growth hormone can only be fully effective in a euthyroid state.

Substitution for ACTH deficiency is absolutely essential when hypoglycemic episodes occur. Regular intramuscular administration of synthetic depot ACTH can be considered (e.g. 0.05 mg Synacthen Depot every 2–3 days). Oral administration of hydrocortisone (e.g. 6.25 to 12.5 mg twice daily) or prednisone (1.25–2.5 mg twice daily) is simpler. Since glucocorticoids have a growth-inhibiting action, the dose should be kept as low as possible (ACTH is perhaps better in this respect). When correct indications and dosages are applied the physical state can be successfully improved and hypoglycemic attacks prevented without causing CUSHING'S symptoms or impairing growth. Bearing in mind the remarks above about treatment with anabolic steroids and testosterone, *substitution with sexual steroids* should be postponed as long as possible in hypogonadism, until a body height appropriate to the onset of puberty has been achieved with growth hormone therapy. In practice, however, commencement of the treatment must be adjusted to the psychological state. Treatment with gonadotropin would theoretically be preferable in these cases too, since this is the only therapy which permits maturation of the gonads. Such a treatment is, however, complicated and expensive. It is simpler to start with sexual steroids which bring about secondary sexual characteristics and when possible also a pubertal growth spurt. Later, when growth ceases, administration of human gonadotropins can be considered to produce gonadal maturation and possibly fertility. Refer to Chap. XII for gonadal dysgenesis, the selection and dosages of sexual steroids and gonadotropin (p. 599ff.) the ovaries, and (p. 475) the testes, and p. 475ff. for hypogonadotropic hypogonadism. It is interesting to note that the androgenic and growth-promoting action of testosterone is often much reduced in the presence of a simultaneous growth hormone deficiency compared with that in other patients.

The recent determination of the amino-acid sequences of some hypothalamic releasing hormones and the possibility of preparing some of these compounds synthetically opens new aspects with respect to the treatment of patients with "hypothalamic" rather than "pituitary" dwarfism.

So far, synthetic TRH and, to some extent, LHRH are available for research. It is conceivable that in the future it will be possible to treat some "hypothalamic-pituitary" dwarfs with the appropriate releasing hormones, notably with GHRH, rather than with human growth hormone and the other hormones mentioned above. GHRH will probably be easier to synthesize than human growth hormone, which is a much larger molecule. In this way, a larger number of patients could benefit from successful treatment, while the limited quantities of human growth hormone could be reserved for the patients with true "pituitary" dwarfism.

c) The "Empty Sella Syndrome" (KAUFMAN, 1968; CAPLAN, 1969; BRISMAN, 1972)

The pituitary function in this uncommon syndrome (see also p. 92) may be entirely normal

or there may be a partial pituitary insufficiency, usually not clinically manifest, affecting especially growth hormone and luteinizing hormone in stimulation tests. The pituitary is flattened and located in the lower posterior part of the sella. The sella may vary from normal radiological or anatomical appearance to globular, balloon-shaped forms with thinning of the posterior processus clinoidei. In about half the cases the main symptom is recurrent rhinorrhea and occasionally visual symptoms have been observed, resulting from dislocation, stretching or kinking of the optic nerves (OLSON, 1972). The syndrome can be detected by pneumoencephalography and is more common in females.

d) Hypopituitarism due to Hypothalamic Disorders

α) Dystopia of the Posterior Pituitary

Undisturbed contact with the neurohypophysis is essential for perfect development and function of the adenohypophysis. This is seen in dystopia of the posterior pituitary, a rare syndrome with pituitary insufficiency and various malformations (PRIESEL, 1927). Three different forms of dystopia of the posterior lobe of the pituitary are possible when the migration of the posterior lobe to the sella is prematurely arrested. In the tuberal form, the posterior lobe lies at the tuber cinereum, in the infundibular form, it is in the hypophyseal stalk, and in the opercular form it is on the anterior lobe. Opercular and infundibular dystopia do not necessarily produce symptoms. The adenohypophysis may remain small in the tuberal form, and usually a partial hypopituitarism develops, with stunted stature, hypogonadism, partial adrenal insufficiency, and various malformations, especially of the urogenital tract and of the heart. Secretion or regulation of STH, the gonadotropins, and to some extent of ACTH is probably impaired. Thyrotropin appears to be released normally. A striking frontotemporal baldness affecting women as well as men, cataracts and creatinuria are suggestive of a relationship to STEINERT's myotonic dystrophia. The syndrome can only be suspected on the basis of clinical examination. Dystopia of the posterior lobe is to be proved by necropsy.

β) Dysplasia of the Sella Turcica

In general, a small or normal sella turcica is of no significance, whereas an abnormally flat sella seems to indicate hypophyseal malformation (LUNDBERG, 1966). Hypogonadism, dwarfism, impaired ACTH regulation, cataract, and frontotemporal baldness can occur in varying degrees of severity and in different combinations.

γ) Chronic Inflammatory Processes

such as sarcoidosis, tuberculosis, the Schüller-Christian disease, and further metastases can lead to selective failure of the adenotropic pituitary hormones and particularly to hypogonadism (see p. 469f.). For hypopituitarism combined with diabetes insipidus in hypothalamic processes, the reader is referred to p. 93.

e) "Functional Hypopituitarism"

Different authors have assumed that the adenohypophysis limits its function as regulator of the metabolic processes in undernourishment and starvation, resulting in functional hypopituitarism. This assumption is only correct in very special conditions. Hunger usually only causes a failure of the gonadotropins, which is a sensible economical move. On the other hand, true hypofunction of the thyroid gland cannot be demonstrated in starvation. Although the basal metabolic rate is usually reduced, there is only hypometabolism without hypothyroidism. The capacity to take up iodine, the serum thyroxine, and the histological findings in the thyroid glands of starved subjects are not indicative of hypofunction. The adrenals in man are found to be normal or even hypertrophic. Although steroid excretion is reduced, true adrenal insufficiency cannot be proven. Finally, histological findings in the hypophysis show displacement of the different cells types [deviation to the left and eosinophilia (UEHLINGER, 1948)], which suggest overexertion of the organ rather than hypofunction.

Hunger leads to an illness which is different from true hypopituitarism. Only the unfortunate fact that cachexia was formerly equated with hypopituitarism forced comparisons between this condition and starvation. The impressive term, "hunger-induced pseudohypophysectomy" was coined on the basis of too few convincing animal experiments and should be avoided. Trials with hormone substitution are unsuccessful in these cases, as they are in anorexia nervosa.

8. Course and Prognosis

Since hypophyseal failure is compatible with life, patients with hypopituitarism can live for many years without substitution. It is true, however, that their working capacity decreases and they finally become invalids. The life

expectancy is affected primarily by the development of intercurrent diseases. Resistance to all types of stress is reduced, since the hypophysio-adrenal system no longer functions. Febrile illnesses, vomiting with diarrhea, and minor operations may precipitate a crisis at any time, and the patients may die in coma. The patients become sleepy, fall into stupor and later become comatose, with epileptic fits due to hypoglycemia. In pituitary coma, they are stiff and bent or completely flabby. The pulse is hardly perceptible, there is bradycardia and the heart sounds are very weak. The breathing is slow, often only minimal. There is severe hypothermia and the body temperature may fall as low as 32 °C. Then it can be measured only rectally with special thermometers. The nose and extremities are cold, the skin pale and dry with no trace of prespiration. As in myxedema coma, hyperkapnia is the cause of unconsciousness by way of inhibition of the respiratory center and weakness of the respiratory muscles; thickening of the alveolo-capillary membranes by myxedematous infiltration may also be involved. Hypoglycemia due to inadequate gluconeogenesis and absence of lipolysis caused by growth hormone failure also contribute to the coma. Finally, hypotonia and shock play some part on the coma due to lack of cortisone and therefore ineffective noradrenaline. If the patients fall into coma, the prognosis is unfavorable even now. The therapy is the same as in myxedema coma (see p. 162f.). Untreated patients live for an average of 10–15 years. A few isolated cases have survived for over 40 years. The substitution therapy now available can replace the missing hormones almost completely, so that life expectancy approaches that of healthy individuals when this treatment is given.

9. Therapy

a) Substitution

Substitution with the deficient adenotropic hormones, FSH, LH, TSH, and ACTH is unsuitable for long-term treatment. TSH preparation cease to be effective after long-term administration due to the formation of antibodies. The daily injections of depot-ACTH are tiresome, and substitution of the hormones of the secondary glands is preferable. Adrenal failure must be corrected first of all. A daily oral dose of 12.5–25 mg cortisone acetate makes the patients feel better and more enterprising. The apathy disappears, and the patients recover their interest in life and become more active. Cortisone restores their resistance. Intelligent patients should be taught to adjust their cortisone requirements for themselves. The administration must be greatly increased, 4–8 fold, in physical exertion or in illness. If oral administration is no longer possible due to nausea the patient must consult his doctor at once to obtain i.v. or i.m. injections of cortisone hemisuccinate or water-soluble prednisolone. Substitution of the thyroid hormones is next in importance and should always be started only a few days after the introduction of cortisone therapy. A dose of 0.1–0.3 mg of Na-l-thyroxine compensates the myxedematous features, restores the patient's working capacity, and makes the cold feeling disappear. It is advisable to start with a dose of 0.05 mg and to reach the optimal dose over the course of some weeks or months. In contrast to ADDISON'S disease, it is not necessary to supplement the cortisone with DCA or fluorocortisol, since the adrenals are still capable of maintaining a reduced aldosterone secretion. The crisis in hypopituitarism must be treated basically in the same way as the addisonian crisis (see p. 330f.). When hypothyroidism is pronounced, i.e. when the temperature is subnormal, the condition must be treated as in myxedema coma (see p. 162f.). The same precautions and substitutions are applicable in minor and major surgery as in the case of primary adrenal insufficiency (see p. 122 for substitution therapy during hypophyseal operations).

It must be determined individually for each patient whether gonadal hormones should be given in addition to the thyroid and adrenal substitution treatment. Spontaneous recurrence of menstruation has been observed during cortisone and thyroxine treatment (ENGSTROM, 1961). In general, one should avoid the cyclic use of ovarian hormones. Restoration of menstruation presents a stress to the patient, and should only by considered for psychological reasons. (E.g. 1 mg stilbestrol may be given for 25 days per month.) Long-acting depot testosterone may be given every 4 weeks to male patients. This improves the well-being of the patient and may restore libido and potency. The administration of testosterone to the woman, which may have the unpleasant side effects of virilization, is only justified in special cases. A trial with 2.5–5 mg fluoxymesterone is indicated in cases with loss of libido. The physiological significance of the adrenal androgens on the psyche shows individual variation. There are experienced authors who advocate testosterone therapy in women with hypopituitarism. Since HMG (see p. 600f.), a human gonadotropin with a FSH-effect, has become available, it has become possible to maintain gonadal

function in the woman as well as in the man with HMG and HCG, despite complete hypophyseal failure. Pregnancy and normospermia are thus possible. This treatment is costly in time and material for both doctor and patient, and is only rarely possible. Whether the therapeutic use of effective growth hormone, once it becomes available, will eventually be justified in adult hypopituitarism is questionable. The patient substituted with cortisone, thyroxine, and sex hormones is physically and psychologically fully efficient.

b) Restitution of the Atrophy

In postpartum necrosis, there is only one way of causing the remaining anterior pituitary lobe of the hypophysis to hypertrophy, and it is rarely possible; this is pregnancy. If the patient succeeds in conceiving again (SCHNEEBERG, 1960; MARTIN, 1970) the remainder of the hypophysis shows signs of a physiological hypertrophy which does not regress after the pregnancy. A new pregnancy does not always have this effect, however, and in isolated cases where the disease has not been of long standing, it is difficult to demonstrate that success is due to the pregnancy.

F. Hyperfunction of the Adenohypophysis

1. Classification

Hyperfunction of the pituitary-adrenocortical system is described on p. 332ff. Only prolactin and STH have been shown to produce an illness due to the overproduction of pituitary hormones. See Chap. XIX for the premature, but not excessive, gonadotropin production in pubertas praecox.

For information on reactive pituitary adenomas in hypothyroidism see p. 154, and for a discussion on pituitary adenomas following adrenalectomy in Cushing's syndrome see p. 356.

The overproduction of growth hormone leads to pituitary gigantism if the epiphyseal cartilages are still open, and to acromegaly if the epiphyseal cartilages have fused.

2. Syndrome of Galactorrhea and Amenorrhea with Low Gonadotropin Excretion (AHUMADA-ARGONZ-DEL CASTILLO; FORBES, HENNEMAN, GRISWOLD and ALBRIGHT)

The syndrome of persistent galactorrhea and amenorrhea, in the absence of pregnancy and acromegaly, is due to overproduction of prolactin. A pituitary tumor is detected in about 50% of cases. Prolactin overproduction has been shown to occur in an extirpated tumor (FRIESEN, 1972), and recently, greatly elevated serum prolactin levels have been shown in nearly all patients with this syndrome and other types of galactorrhea. The adenoma, which was classified primarily as chromophobe, contains cells which can possibly be stained specifically. Either it produces too much prolactin, or regulation by the prolactin-inhibiting hypothalamic factor (PIF) is impaired. See p. 30 for persistent lactation with amenorrhea and decreased gonadotropin excretion after pregnancy (Chiari-Frommel syndrome). See p. 592 for glactorrhea induced by neural or pharmacological factors. Of FORBES' 15 patients, 9 had never been pregnant, 8 showed symptoms of a pituitary tumor, and the biopsies revealed a chromophobe adenoma in 3 cases. The symptoms arose between the 20th and 30th years in all the patients. Obesity, hirsutism and seborrhea are almost always present. The levels of 17-ketosteroids are usually slightly elevated; the gonadotropin excretion is reduced or absent, whereas it is normal during amenorrhea caused by lactation. There are signs of estrogen deficiency. In contrast to acromegaly, the serum phosphorus is always normal. No elevation of prolactin serum levels results from arginin infusion or hypoglycemia. A few cases of galactorrhea have been found associated with a craniopharyngioma. In others there have been tumors interrupting the continuity to the hypothalamus (GUINET, 1961). See Chap. XIX for galactorrhea and pubertas praecox in hypothyroidism in childhood.

Galactorrhea can occur during treatment with chlorpromazine, imipramine, reserpine, and ovulatory inhibitors or after pituitary stalk section which is explained by the lack of PIF.

L-Dopa stimulates growth hormone secretion but inhibits that of prolactin. Patients with the Forbes-Albright syndrome and other conditions causing galactorrhea have been treated with L-Dopa which has normalized prolactin and gonadotropin levels (TURKINGTON, 1972; BESSER, 1972) but had inconsistent effects on galactorrhea.

Galactorrhea and hyperprolactinemia are usually accompanied by low or absent gonadotropins, amenorrhea in women and impotence in men. There seems to be a reciprocal mechanism controlling the secretion of prolactin and gonadotropins.

The ergot alkaloid 2-Br-α-ergocryptine is a potent inhibitor of prolactin (FLÜCKIGER, 1968) in normal women as well as in patients with the Forbes-Albright syndrome (DEL POZO, 1973; BESSER, 1972). It acts directly on the

pituitary and not via the hypothalamus (FLÜCKIGER, 1972).

Patients with galactorrhea, high prolactin and low gonadotropin levels, and amenorrhea or impotency were normalized by treatment with 3 to 10 mg brom-ergocryptine p.o. daily. The prolactin and gonadotropin levels normalized after one month, and galactorrhea disappeared and menstruation was restored in the second month. After six months of treatment one patient with the syndrome became pregnant (BESSER, 1972; DEL POZZO, 1973).

Potency was reestablished in one of two men with chromophobe adenoma and hyperprolactinemia (BESSER, 1972).

3. Pituitary Gigantism

A. PRADER and M. ZACHMANN

During growth, an acidophil pituitary adenoma does not give rise to acromegaly but rather to gigantism (Fig. 10). In addition to the gigantism, acromegalic features may arise during the course of puberty, and combinations of gigantism with the complete picture of acromegaly in adulthood are possible even in young patients.

This is an extremely rare disease and possibly occurs more frequently in the male. A pathological acceleration of growth usually arises shortly before or around the onset of puberty. Nevertheless, patients have been described whose symptoms started long before puberty. The youngest patient in whom accelerated growth has been reported was five months old (the Alton giant described by BEHRENS and BARR in 1932).

If left untreated the illness results in symptoms of a deficiency of all adenotropic hormones in addition to the excessive growth hormone production, and usually leads to death in the second or third decade or even earlier. The initial isolated growth acceleration is characteristic. Bone development is not accelerated or only slightly, so that growth may not only be accelerated but also continue for an abnormally long time. Puberty usually follows a normal course at first but may be subject to disorders during the later course due to displacement of the gonadotropin-producing cells. Hypogonadotropic hypogonadism (see p. 469 f.) and eunochoid proportions may result from this. Symptoms of over-production of growth hormone can be replaced by those of progressive insufficiency of all adenotropic hormones over the course of years.

The laboratory findings correspond in general to those in acromegaly in adulthood: serum inorganic phosphorus may be elevated to values over 5–6 mg%. Growth hormone concentration in the plasma has only been investigated by radioimmunological methods, in a few cases, and fasting levels of 100–300 ng/ml were found, about one hundred times higher than normal. It was not possible to produce further stimulation of growth hormone secretion by intravenous injection of insulin. Nor is the plasma concentration reduced by a glucose tolerance test (oral or intravenous). Furthermore, both oral or intravenous glucose tolerance tests and administration of tolbutamide lead to a marked rise in plasma insulin concentration, as in the healthy subject. The blood sugar curve is often pathologic following the glucose tolerance test, being similar to that obtained in frank or chemical diabetes. In contrast to acromegaly in the adult, however, a frank diabetes mellitus is rarely present.

Primordial or constitutional gigantism and cerebral gigantism (SOTOS) are the most important conditions for the differential diagnosis (see Chap. XIX). General signs of elevated intracranial pressure, direct pressure effects of the tumor.

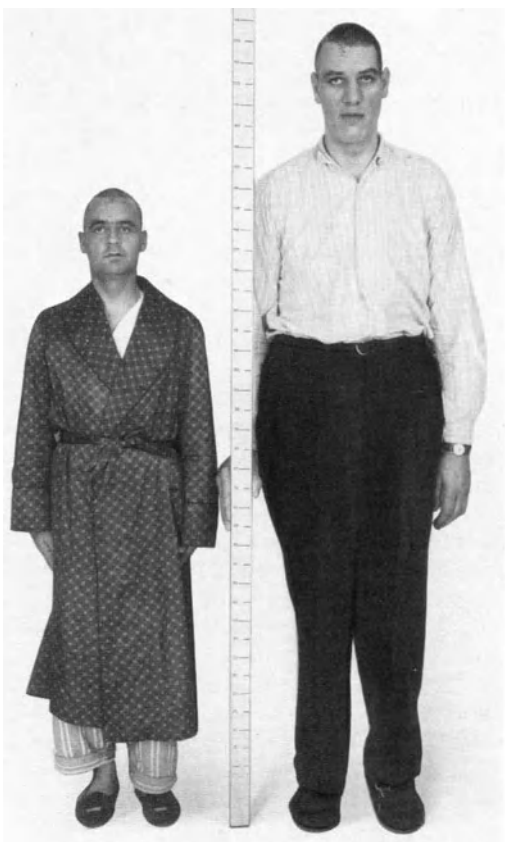

Fig. 10. 24-year-old giant with acromegaly, 210 cm in height and weighing 145 kg, with eosinophilic pituitary adenoma, and increased growth since the 16th year, next to a man 170 cm tall

such as enlargement and extension of the sella (which often arise late), impaired vision, and bitemporal hemianopia are important for the diagnosis. These valuable diagnostic indications may, however, be absent since the tumors are often very small. Diagnosis is then only possible on the basis of the greatly raised growth hormone concentration in the plasma and the blood sugar and insulin estimated during a glucose tolerance test. All these tests yield normal results in other forms of gigantism.

Surgical removal of the tumor or radiation of the hypophysis (externally or by implantation of e.g. yttrium) are possible methods of causal therapy. The therapeutic result, however, is generally disappointing. It is known that in acromegaly in adulthood, high concentrations of growth hormone in the plasma may persist even after surgical removal of the hypophysis. This has also been observed in a patient with pituitary gigantism. The prognosis must therefore be subject to caution even if the tumor appears to have been completely removed. Substitution therapy for the resulting secondary adrenocortical insufficiency and hypothyroidism is often necessary after radical surgery.

4. Acromegaly

a) Occurrence and Incidence

Acromegaly, like all other endocrine diseases except diabetes mellitus and thyroid dysfunction, is a relatively uncommon disease. Statistics from large hospitals show one case of acromegaly in 2000 to 15000 admissions. A total of 36193 patients seen at the Medical Clinic in Zurich in 10 years included 45 cases of acromegaly. About 20% of patients with pituitary tumors develop acromegaly. The disease affects all races and is most common in the 3rd and 4th decades of life, though it may occur at any age.

The disease usually begins soon after puberty and the sexes are equally affected. It has been claimed that 25 cases of this disease have been observed in children under 15 years, but the condition may be confused with constitutional abnormalities. The few reports of familial occurrence may be due to confusion with the constitutional acromegaloid (see p. 114). Repeated reports of the occurrence of acromegaly in only one of homozygous twins make a hereditary factor appear unlikely.

b) Etiology and Pathogenesis

Acromegaly is due to overproduction of growth hormone which can be measured radioimmunologically. The reason for it is almost always a tumor-like growth of the eosinophil cells which produce STH. It is not known for certain whether certain cases of acromegaly can arise from a disorder of the hypothalamic regulation by way of the adenohypophysis, possibly due to tumor formation after acidophilic hypertrophy and hyperplasia caused by chronic overstimulation.

Two types of acromegaly can be differentiated according to the plasma growth hormone. In one type, the overproduction is uninfluenced by metabolic stimuli (see p. 89f.). In the other type, which is much more frequent, the growth hormone level can be made to fall with glucose and be elevated by hypoglycemia, or there may even be a paradoxical rise in growth hormone after a glucose load (LAURENCE, 1970). It is not known whether a different pathogenesis is involved in the latter condition of whether the autonomy is due to lesions of the hypophyseal stalk (GLICK, 1965). These considerations may have some therapeutic implications. There is no clinical differentiation. As a rule, there is some correlation between the size of the sella and the overproduction of growth hormone, but large sellas may be found in the presence of low growth hormone concentrations, and normal-sized sellas may be present in active acromegaly. In the female the disease appears to be most common in the 2nd and 5th decades (SOENKSEN, 1967). The overproduction of growth hormone leads to an increased growth of the skeleton and connective tissues, the musculature, the internal organs, the blood vessels, and the skin. As long as the epiphyseal cartilages are still open the accelerated growth results in gigantism. Acromegaly results after fusion of the epiphyses. Destruction of the remaining cells of the adenohypophysis may result in failure of individual or of all adenotropic hormones, giving rise to the combined picture of acromegaly and hypopituitarism. In a few cases, increased prolactin has also been demonstrated as well as increased growth hormone. The symptom of galactorrhea is probably attributable to the former.

Among the numerous attempts to explain the pathogenesis of acromegaly, KEETH's atavistic hypothesis (ATKINSON), is of speculative interest. It states that acromegaly is a regression into the phylogenetic stages of Neanderthal man or the anthropoids. The development of the extremities, the prognathia and the excessive pneumatization of the sinus are in fact characteristic of these men and animals. LOUIS BOLK's hypothesis of fetalisation considers acromegaly as a regression into a phylogenetically older phase, due to the absence of inhibitory effects which increase with advancing civilization.

c) Pathologic Anatomy

α) Pituitary

Most frequently, acromegaly or gigantism is due to an acidophil tumor of the pituitary. It may include other cells with adenotropic activities. Not infrequently, there may also be a chromophobe adenoma. In the adenomas, however, growth hormone granulas may still be revealed by electron microscopy. The tumor is not necessarily in the anterior hypophysis, but may be in the region of the pharyngeal roof or the sinus sphenoidalis. Sometimes, there is only hyperplasia of the acidophils with no proper tumor formation but with clear-cut enlargement of the hypophysis. Occasionally, the disorder responsible for the uncontrolled STH production has to be sought in an extracranial region (bronchial carcinoma with ectopic hormone production, see Chap. XVI). Acidophil adenomas may reach a considerable size and can destroy the adjacent bony structures, such as the sphenoid and base of the skull. Genuine carcinoma with metastases has only exceptionally been observed. The remaining hypophyseal tissue is compressed and destroyed; the tumor tissue itself is also often affected by necrosis and bleeding. The tumor cells can be very irregular and their nuclei are often of different size. The differentiations and generative polymorphia may thus be pronounced, so that even "hypophyseal sarcomas" are mentioned in earlier literature.

β) Other Endocrine Glands

Hyperplastic processes often occur if the pituitary tissue is not destroyed by the tumor. In about 50% of cases the thyroid gland is enlarged and a diffuse or nodular goiter may develop. The cause may be the growth hormone effect, the increase in TBPA (see Chap. VI, p. 143) or a low inorganic iodine level due to an increase in iodine clearance (MUKHTAR, 1971). The parathyroids may also be enlarged and demonstrate true adenomas. The hyperplasia is possibly due to the elevated serum phosphate level. The adrenal cortex is usually hyperplastic and sometimes contains cortical nodules. The medulla, on the other hand, is not thought to be involved in this enlarging process. Exocrine tissue and pancreatic islands, generally the B-cells, are very active and degranulated. Infiltration by glycogen can also be observed in untreated cases. In the gonads, regressive changes usually predominate, Nevertheless, a few tumors have also been found. Acidophil pituitary adenomas may be combined with other different endocrine tumors; they are often found in the true, hereditary endocrine adenomatosis of the WERMER type (see Chap. XVIII).

γ) Other Organs

The other internal organs also increase in size. Splanchnomegaly results. Involvement of the heart may be excessive, giving rise to myocardial fibrosis. The skeleton is particularly affected. After skeletal maturation is complete, the growth impulse affects mainly the remaining cartilagenous areas and the extremities. The cartilage of the ribs, the marginal border of the vertebral and invertebral discs, and of the joints proliferate. In addition, they show a pronounced tendency to ossify, and even the auricular cartilage shows this feature. The damage to the articular cartilage leads to deforming arthrosis. Hyperostosis and increased bone formation, and to a lesser extent increased bone resorption with osteosclerosis, develop in the skeleton.

These lead to an increased bone width, normal or increased cortical bone but decreased trabecular bone (RIGGS, 1972).

Tendon and muscle insertions are frequently thickened.

d) Clinical Picture and Symptoms

α) History and Psychic Changes

The patient consults his doctor only rarely because of the change in appearance. The acromegalic changes develop so slowly over the course of years that the patient himself hardly notices them, whereas his acquaintances sometimes do. The statement from an adult patient that he suddenly has to buy larger shoes (when flat feet can be excluded) and larger gloves is of great diagnostic value. Persistent headaches are a common symptom and are seldom absent. It is independent of cerebral compression, and the genesis is unknown. Visual disturbances often cause the acromegalic patients to consult the doctor (see p. 112).

Tiredness and muscular weakness only develop after long duration of the illness. They can be the most prevalent complaints. Amenorrhea in the female and loss of libido and potency in the male are almost always present. Pregnancy is, however, possible. Onset of the disease in connection with a pregnancy is not uncommon. Diabetes mellitus (see p. 113f.) occurs in one fifth of acromegalic cases.

The skeletal changes may cause backache. Paresthesia in the form of formication or numbness in the upper extremities are often

present. Their pathogenesis is unexplained. They are not due to hyperostoses in the region of intervertebral foramina. Vasomotor rhinitis is common, often with a secretion tinged with blood. Bulimia, polydipsia, and polyuria are not sufficiently severe to cause the patient to consult the physician.

Galactorrhea due to overproduction of prolactin and STH is uncommon in female patients and extremely rare in male acromegalic patients.

Acromegaly usually leads to profound psychological changes which make up a form of the endocrine psychosyndrome but with a special variation. Contrary to widespread opinion, these changes are not psychoses. There is no relation to schizophrenia, manic depressive psychosis, or epilepsy. The incidence of these psychoses is not higher in the relatives of acromegalic patients than in the normal population (BLICKENSTORFER, 1951). Nor is there any genetic connection between acromegaly and the constitutional anomaly of acromegaloidism (p. 114), in which psychopathy often occurs. The acromegalic character changes are not due to the physical disfiguration alone, and cannot be fully explained by the cerebral compression either. Character changes typical to acromegaly can occur in patients who pay little attention to their disfiguration and do not suffer from it. On the other hand, these changes have been noticed in patients in whom there is no cerebral compression. The psychopathy in acromegaly consists in character changes and episodic changes in mood in association with changes in the sphere of drive. The character changes present as apathy, loss of initiative, lack of motivation, and egocentricity. The patient becomes withdrawn, secluded and odd. Passive cheerfulness can be present one moment, and melancholic resignation and animosity the next. Their affectivity towards the outer world fades, and using the simile of the BLEULER school (KELLER, 1949), "they sound like an orchestra behind a thick curtain". The patients find their inability to communicate subjectively painful and are often depressed at the beginning of the illness. During the course of the illness, they become resigned to their destiny, and ultimately euphoria may often develop. Indifference, fear, and distrust are expressions of long episodes of depression. They are interrupted by bursts of mood changes such as irritability, anger, and restlessness. Sexuality and libido are usually reduced in both sexes, and potency is reduced in the man. The initial increase which is often mentioned is not quite certain. The disappearance of the sexuality is explained by the gonadal failure.

Increases in hunger and thirst can be explained by the metabolic disorders (see p. 113). Contrary to widespread opinion, the intellect is hardly impaired in acromegaly. The bradyphrenia may simulate oligophrenia. These psychological changes are due to growth hormone itself or to metabolic disturbances induced by it. The character changes, once developed, usually remain uninfluenced or admit of only slight improvement. Acromegalic patients often need psychotherapy. The rare patients in whom acromegaly is accompanied by persistent lactation may develop a pronounced maternal instinct in addition to the psychological changes described above (BLEULER, 1964).

β) General Examination

Severe acromegalic disfiguration of a face is so obvious that the diagnosis can be made at first glance (Figs. 11–12). The coarse features give a threatening and sinister appearance, even, when some apathetic placidity is present (Fig. 12). The figures of Punch and Polichinelle-Pulcinella show acromegalic features. The lower jaw is greatly enlarged and the chin protrudes. Prognathism with widely separated teeth develops. The lower incisors come to lie in front of the upper (supraclusion). The large nose is thickened and puffy, and the supra-orbital projections and the zygomatic arches protrude a long way forward. The ears are fleshy and large, and excess skin lies in broad folds on the forehead. The tongue is also involved in the general tissue growth and is deformed and large. It looks like a piece of raw meat and leads to thick speech. The lips, particularly the lower, are large and pendulous.

Fig. 11. 38-year-old female patient with acromegaly. Incipient facial changes. Eosinophil pituitary adenoma verified at operation (Prof. KRAYENBÜHL, Neurosurgical Clinic, Zurich)

Fig. 12. 35-year-old female patient with acromegaly. Advanced facial changes (Prof. KRAYENBÜHL, Neurosurgical Clinic, Zurich)

A soft tissue type in which the facial changes are predominantly due to growth of the cutis and subcutis must be differentiated from a bony type. Usually both elements contribute to the acromegalic changes. PIERRE MARIE spoke of the type "en carré" or the type "en long"

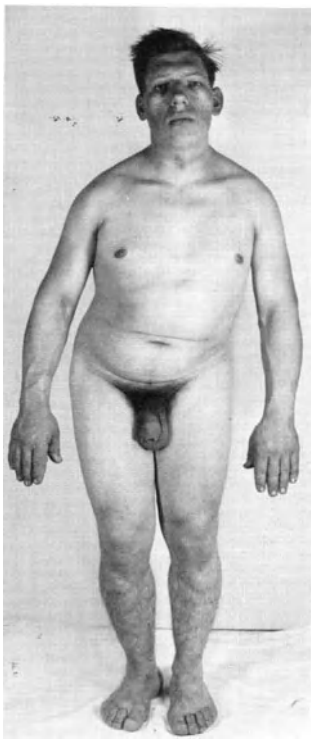

Fig. 13. 29-year-old male patient with acromegaly (Prof. KRAYENBÜHL, Neurosurgical Clinic, Zurich)

depending on the transverse or longitudinal expansion of the face.

After the changes in the face, those in the hands and feet are most striking. The soft tissues are more involved than the skeletal structures. The fingers are sausage-shaped and the hand looks like an animal's paw (Fig. 13).

The kyphotic thoracic vertebral column causes the acromegalic patient to hold his head bent forwards. The barrel-shaped, deep thorax may protrude towards the sternum forming a pigeon chest.

The average height of acromegalic patients exceeds that of the comparable population, probably because the disease usually begins before epiphyseal fusion occurs.

Hyperfunction of the cutaneous appendage organs leads to hyperhidrosis and to seborrhea. Increased pigmentation is found in about half the cases. Sometimes pronounced hirsutism is seen in women due to direct stimulation of the hair follicles by growth hormone. See p. 113 for urinary steroids.

γ) Changes in the Organs

Skeleton: The acromegalic changes in the skeleton are most striking.

The cranial deformity can be recognized externally. All the cranial measurements are increased, including the intracranial capacity. The patients often notice that their hats become too small. The external occipital protuberance and the supraorbital pads are protruding. The cranial sutures are closed. There is almost always diffuse hyperostosis. Localized hyperostosis is less common and is associated with a thickening of the os parietale (LANG, 1961). The frontal sinuses are strikingly large and often extend sidewards. The sella is usually widened with a surface area of 120–230 mm^2 on the X-ray plate. The normal sella, in contrast, is 9–12 mm deep and 12–15 mm long, and has a surface area of 50–120 mm^2. A normal-sized sella can, however, be found in acromegaly. In 6% of cases, it is absolutely intact. It is distended at first, and then if the pituitary grows further suprasellarly, the dorsum of the sella is raised. The anterior and posterior clinoid processes atrophy. There is no connection between the size of the sella and the growth hormone production. See MUNDINGER (1967) for the methods of estimating the size of the sella. The tumors mainly extend towards the sphenoidal sinus and erode the clivus. The dorsum of the sella becomes elongated and also atrophic. The entrance to the sella is often only insignificantly widened, in contrast to the X-ray findings in chromophobe pituitary adenomas.

A distinction between the so-called *Troell-Junet* syndrome and the more usual form of acromegaly is only justified when osteoclasia of the compact bone and osteolysis of the spongiosa are histologically demonstrable as well as the diffuse hyperostosis of the roof of the cranium. Clinical differentiation between this syndrome and acromegaly is not easy. In addition to the acromegalic changes, toxic goiter, diffuse hyperostosis of the roof of the cranium, and diabetes mellitus have also been mentioned.

Growth hormone promotes endochondral and periostal bone growth. The endochondral growth, where still present, is elevated. Inactive foci are reactivated. Therefore, the cartilages of the ribs grow most, causing the ventral expansion of the thorax. The activity of the acromegaly can be assessed from biopsies of the bony-cartilaginous junctions of the ribs. An acromegalic rosary may be formed. The periosteal bone growth produces exostoses, which are most pronounced at the insertions of the ligaments and tendons. In general, the osseous transformation is increased. This can also be shown by means of ^{47}Ca (BELL, 1967). Anabolism usually exceeds the catabolic process. Pneumatization of the frontal and maxillary sinuses and of the mastoid processes increases. There is marked internal bony resorption, whereas externally, appositional bone growth is in progress. This increased transformation produces changes in the bone structure so that osteosclerosis as well as osteoporosis can occur. The osteolytic process can be so pronounced at individual points that cysts are formed, e.g. in the epicondyls. Most of the hyperostoses, those on the lower jaw, at the end phalanges, at the epiphyses, and on the metatarsals, are periostal in origin. However, hypostosis may also occur, so that the metacarpals may either be thickened or become thinner in the cortex. Growth of the cartilage produces irregular protuberances in the region of the joints, which may give rise to a picture similar to that in arthrosis deformans. The changes in the vertrebral bodies are of a different type and are most pronounced in the lower thoracic vertrebrae. New osseous tissue is deposited around the vertebral body like a collar, predominantly ventrally, due partly to reactivation of the cartilaginous border ridges, and partly to periostal growth. The intervertebral discs also grow from the perichondrium. Primitive cartilage is thereby converted into hyaline cartilage. At the same time changes occur in the intervertebral discs, calcification and ossification may arise. Kyphosis of the thoracic vertebral column with compensatory lordosis of the lumbar vertebrae develops. The cartilage tends to become ossified. The rib cartilages can be completely ossified as well as the auricles. The joints also become involved in this cartilaginous change and arthrosis deformans often occurs. Arthrosis in the knee joints may be the patient's main symptom.

The patho-anatomical skeletal changes can be summarized as follows:

1. Increased cartilaginous proliferation. Revival of cartilaginous growth when body growth is complete. This growth impulse is most noticeable in the ribs and articular cartilages. Carpals and tarsals can merge together.
2. Periostosis with thickening of the ligamentous and tendinous insertions.
3. Osteoporosis and osteosclerosis, occasionally in association with true osteolytic processes and cystic formations.
4. Hyperostoses with expansion of individual skeletal areas, especially of the extremities.
5. Hypostosis with rarefaction of individual bones.
6. Articular changes in the form of cartilaginous defects in the region of hypertrophic cartilage, resulting in arthrosis deformans.

Splanchnomegaly. The internal organs are also involved in the generalized growth. The size of the heart and liver are particularly striking. The gastrointestinal tract is longer and its volume is increased. Megacolon may arise. The larynx also grows. The voice is therefore deep and rough. In addition, it has a nasal tone due to the proliferation of the soft tissues in the nose. The vessels are wide and their walls thickened; varicosis is frequent. The lymphatic tissue and thymus are hyperplastic in over 50% of cases. Nodular or diffuse euthyroid goiters of medium size are found in one third of cases. The incidence of larger goiters is no higher than in the normal population.

Circulatory system. In one third of cases, there is hypertension of uncertain pathogenesis with diastolic values of over 100 mm Hg. Cardiac enlargement is not always a feature of the splanchnomegaly, since both degenerative cardiac diseases and infarcts appear to occur more frequently, and the enlargement only indicates dilatation or hypertrophy (HAMWI, 1960).

Nervous system. Impaired vision and loss of visual fields have been observed in 40% of acromegalic cases. Bitemporal hemianopsia is the typical loss of visual fields. Homonymous hemianopsia or concentric narrowing of the visual field and scotomas also occur occasionally. Papilledema is extremely rare. Paralysis of the ocular muscles and other neurological disorders (see p. 109 f.) can occur with the suprasellar expansion and hemorrhages of the tumor

(HOWARD, 1965). Vision and visual fields can, however, also be intact in fully-developed acromegaly. The pathogenesis of the paresthesia has not been explained (see p. 109). Paresis with hyporeflexia due to hypertrophic neuropathy has been described (STEWART, 1966).

e) Metabolic Changes

See p. 123 f. for the inorganic serum phosphorus. Calcium turnover in the skeleton is increased (BELL, 1967).

The positive nitrogen balance during the active phase is of little clinical diagnostic value. Excretion of creatine and creatinine is increased, but this is not very specific. Gonadotropin excretion is usually found to be normal. This does not explain amenorrhea and loss of libido and potency, wich are frequently found. Slight albuminuria is found in 25% of cases, even in the absence of demonstrable renal failure. Glomerular filtration and plasma flow are increased in keeping with the enlarged extracellular space (IKKOS, 1956).

Basal metabolic rate: It is often stated that the BMR is increased in two-thirds of cases. There are usually only slight deviations of +14 to +18% and these do not indicate a diagnosis of hyperthyroidism. Estimation of the BMR in altered stature is problematic, but elevated values are found in such cases whether standards of weight, height, or cell mass are used (IKKOS, 1956) (see p. 240 f.). Occasionally, increases of over 60% have also been found. This is due to a hypermetabolic state in the absence of hyperthyroidism. This has been demonstrated by radioiodine tests, by the failure to respond to antithyroid drugs, and finally, by the histological examination of goiters removed surgically. There are no clinical signs of overactivity. The radioiodine uptake is found to be either normal or slightly elevated (HAMWI, 1960). On the other hand, the ratio 2/48 h uptake is usually raised. The level of thyroxine-binding protein is usually reduced, that of thyroxine-binding albumin raised, and PBI and thyroxine levels may be low. The T3-resin uptake is usually normal (ROTH, 1967). The increased metabolism must therefore be due solely to the increased quantity of growth hormone.

The adrenocortical steroids and their derivatives in the urine are usually normal. Slight elevations are due less to adrenal hyperplasia than to an increase proportional to the total body weight. The increase in response to ACTH and methyrapone is correspondingly normal as a rule (LIM, 1964), as is the inhibition produced with dexamethasone (HAMWI, 1960), unless the illness is combined with CUSHING'S syndrome or an adrenogenital syndrome (MAUTALEN, 1965).

Diabetes mellitus. Frank diabetes is found in 20% of acromegalic cases, and in 10% the glucose tolerance is reduced. The diabetes may be mild or severe. It is usually not very responsive to insulin, and there is no tendency to acidosis.

Table 4. Frequency of the acromegalic symptoms. (After DAVIDOFF)

Acral enlargement	100%
Sella enlargement	93%
Headaches	87%
Menstrual anomalies	87%
Amenorrhea	73%
Elevated BMR	70%
Visual disturbances	62%
Hyperhidrosis	60%
Hypertrichosis	53%
Skin pigmentation	46%
Increase in weight	39%
Loss of libido	38%
Asthenia	33%
Paresthesia	30%
Hypotension (< 120 mm Hg systolic)	30%
Polyphagia	28%
Cutaneous fibromas	27%
Glycosuria	25%
Polydipsia	25%
Goiters	25%
Diabetes	12%
Loss of body hair	7%
Galactorrhea	4%
Breasts underdeveloped	4%

The diabetes arises on average 10 years after the onset of the first acromegalic symptoms. A certain predisposition seems to be necessary in addition to the acromegaly, for the diabetes to become overt, since the incidence of diabetes in relatives of diabetic acromegalics is considerably higher than in those of nondiabetic acromegalics. Three different stages can be distinguished in the development of the diabetes. At first, glucose tolerance is normal. During the glucose tolerance test, insulin release is prompt but excessive. Later, the insulin output is delayed, and glucose tolerance is normal or reduced. Both stages are reversible with successful treatment. In the third stage, the insulin concentration in the blood is already at a maximum during the fasting state and cannot be increased further (SOENKSEN, 1967). Acromegalic patients not reacting to a glucose infusion with increased insulin release may be latent diabetics or prediabetics (LUFT, 1967). The hyposensitivity to insulin is not explained by the increase of free fatty acids (BECK, 1965).

The renal glucose threshold is usually high. The pathogenesis of acromegalic diabetes has been explained by the metabolic properties of

STH. This inhibits glucose absorption by the musculature. As long as sufficient insulin is present for the glucose to be used for tissue synthesis, carbohydrate metabolism is balanced. Diabetes results when the B-cells of the pancreas fail due to constitutional weakness during persistent over-exertion.

Table 5. Synopsis of examinations

1. History
   Changes in appearance: by examining previous photographs.
   Sexual function: loss of libido and potency.
   Complaints: headaches, tiredness, paresthesia, hyperhidrosis.
2. General examination
   a) Alterations in the shape of the head, trunk and extremities.
   b) Body measurements: height, weight, length of the upper and lower body sections, span, diameter of the head, chest and wrist, size of shoes and gloves, possibly a plaster impression of the teeth.
   c) Ophthalmoscopy, examination of vision and of visual fields.
3. X-ray examinations
   Skull, pneumoencephalography, lateral view of the thoracic vertebral column, possibly hands and feet.
4. Laboratory investigations
   Serum phosphorus, sugar and protein in the urine, fasting blood-sugar and if normal, glucose tolerance test. BMR, if elevated, radio-iodine test, thyroxine, estimation of growth hormone during the insulin or glucose tolerance test.

f) Course and Prognosis, Special Forms

The onset is insidious, although acute forms of the disease with a course of 2–4 years have been described. The symptoms arise in three groups. Excessive growth first becomes apparent and is followed by pressure symptoms of the pituitary tumor, especially those involving the optic nerve and chiasma; symptoms related to the circulatory organs and metabolic disturbances are the last to arise (diabetes, polyphagia, polyuria).

The life expectancy in untreated acromegaly is 13 years on average. The cause of death is most often cerebral compression and hemorrhage in the tumor. Diabetic complications are second in frequency as the cause of death, and the third most frequent cause is cardiac failure in the presence of a hypertrophic but functionally inferior myocardium. The illness can become stationary at any time, and can also have an intermittent course. Finally, hyperpituitarism can be converted into hypopituitarism, where the tumor destroys the remaining pituitary tissue and ultimately degenerates. The signs of hypopituitarism may then be superimposed on the clinical picture of acromegaly (see p. 93). Tiredness, apathy, hypogonadism, hypothyroidism, and finally adrenocortical insufficiency complete the picture. These forms are described as burnt-out acromegaly. Forms of acromegaly combined with thyrotoxicosis, CUSHING's syndrome, neurofibromatosis, or amyotrophic lateral sclerosis have also been described. The acromegalic changes can be limited to one side of the body or to one organ, such as the tongue or the big toe. Such presentations can only be explained by a different response of the endorgans to STH.

BAILY and CUSHING described a case of "fugitive acromegaly", an intermediate form between true acromegaly and the chromophobe adenoma. In the clinical histories of 6 cases there was not a single symptom pointing to hyperfunction of the anterior pituitary lobe. The acromegaloid features appear to have been constitutional anomalies.

g) Differential Diagnosis

The diagnosis presents no difficulties in fully-developed acromegaly when it can be established that the patient's appearance has changed. The condition can, however, be extremely difficult to differentiate from an acromegalic constitution, so-called acromegaloidism. The appearance of the acromegaloid subject can be very similar to that of the acromegalic, although the soft-tissue thickening is never so pronounced. Proof that the patient has changed in appearance is important in the diagnosis of acromegaly. Earlier photographs are especially valuable. The acromegaloid with mild to pronounced characteristic features usually displayed these features even as a child (Fig. 14). The sella is not enlarged, and there are no metabolic deviations. It is not an illness but a constitutional anomaly. Nor is there any genetic connection between acromegaly and acromegaloidism, which does not occur more often in the families of acromegalics than in the normal population.

Acromegalic features occur in cerebral gigantism (SOTOS) and in idiopathic gingival fibromatosis and hypertrichosis (GORLIN, 1964).

The differential diagnosis can also include Paget's disease due to the cranial changes, hypertrophic osteoarthropathy with periostial osseous proliferations, pachydermoperiostosis, and finally, leprosy with leonine facies. Differentiation from myxedema should hardly present any difficulties though it was included in the differential diagnosis by PIERRE MARIE.

Usually difficulty is not encountered in the diagnosis of acromegaly but in deciding whether the disease is still active or has come to a stand-

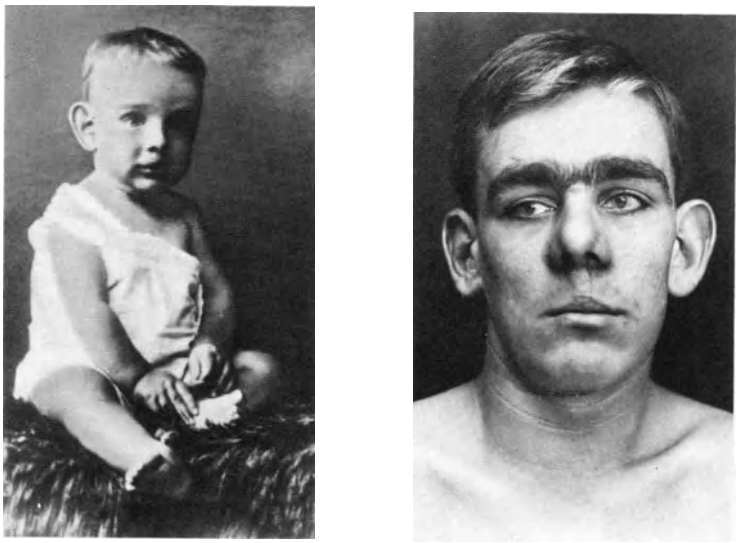

Fig. 14. 23-year-old male patient of acromegaloid constitution. Acromegaloid features already detectable in babyhood (Prof. SCHÜPBACH, Inselspital, Bern)

still. This question is not answered by the appearance, and the history is often no help since growth is slow. The detection of headaches, severe sweating, polydipsia, polyphagia and a raised BMR are of importance. An elevated serum phosphorus is a finding of value since it may indicate an overproduction of growth hormone and becomes normal again with the inactivation of the process. Normal phosphate values do not, however, exclude activity. The activity can best be assessed by measuring the growth hormone during the insulin and glucose tolerance tests. The concentration of HGH and the severity of the illness are not always compatible.

h) Treatment of Acromegaly

Treatment of acromegaly must be directed at the following 3 symptom groups:

1. neurological disorders, especially loss of visual field, and headaches;
2. subjective and objective symptoms of endocrine hyperfunction;
3. concomitant endocrine failure.

The therapeutic problems have been solved only for the 3rd group of symptoms (see p. 105 f.). The degree of success with neurological disorders is very much dependent on the extent of the tumor. The prognosis for neurological disorders is good after surgical removal of a tumor limited chiefly to the sella when it has been diagnosed early. The problem of how to treat the endocrine hyperfunction has not yet been satisfactorily solved (KOZAK, 1966). The symptoms may regress following radiation, and tumor growth may be arrested. Objective remissions can only be demonstrated by the fall or normalization of plasma growth hormone and have not been successfully achieved with conventional or high-voltage irradiation, or with implantation of ^{90}Yt whether or not combined with ^{192}Ir, and not always by operation (GLICK, 1965; LINFOOT, 1965; ROTH, 1968). Even in the so-called burnt-out cases, where there is a clinical remission, growth hormone may still be increased (GREENWOOD, 1965). A final evaluation of the therapy will not be possible until large comparative series of growth hormone measurements are available. In general there is a tendency to radical treatment, even when hypopituitarism must be expected.

There are now six possible methods of treatment.

α) Surgical Removal of the Tumor

This procedure is indicated (1) if neurological disorders are present or (2) if the symptoms do not regress after irradiation or the objective symptoms progress. The neurosurgical transfrontal approach (RAY, 1964) and the rhinological transethmoidal-paranasal approach are both possible (NAGER, 1936; GUIOT, 1958; HAMBERGER, 1960; ESCHER, 1965). More recently, a microsurgical transnasal-transphenoidal approach has been introduced (HARDY, 1969; 1973). The transfrontal approach should be considered when there is suprasellar extension of the tumor and when the neurological failure is extensive as it gives the necessary better vision. When only endocrine hyperfunctional symptoms have to be treated, the transphenoidal operation is

less of a strain to the patient. Meningitis and liquorrhea have been observed occasionally as complications of the rhinological transphenoidal procedure.

If surgery is indicated and the surgeon and patient are agreed, removal of the tumor must be as nearly as possible complete. The tumor is in a capsule and is usually curetted out with a blunt scalpel and sucked off. The capsule in the suprasellar region is resected and that in the sella is left untouched. When the tumor is poorly demarcated total removal of the adenohypophysis must be considered, since it might otherwise infiltrate into the healthy tissue (RAY, 1964). This procedure involves the danger of failure and a higher risk or recurrences if carried out too sparingly. Postoperative irradiation is usually recommended. In 75–80% of the patients endocrine substitution therapy is required postoperatively or after postoperative irradiation (RAY, 1914; ELKINGTON, 1967). Diabetes insipidus is only present when the hypothalamic nuclei are involved and generally does not occur after the removal of the eosinophil adenoma, in contrast to the situation following operations for craniopharyngiomas. Temporary polyuria of different types (see p. 52f.) has been seen when the posterior lobe has been injured (RANDALL, 1960). We recommend prophylactic substitution (see p. 122) for every operation on the diseased pituitary since a latent insufficiency, which can never be excluded, can become manifest under the stress of surgery.

The operative risk is greatly dependent on the extent of the tumor (HEIMBACH, 1964; MARGUTH, 1964). There is practivally no operative mortality today for tumors restricted to the sella. The risk increases with the extent of the tumor, and tumors are inoperable beyond a certain size.

β) Irradiation

X-ray therapy places no great stress on the patient, and there is no mortality. Eosinophil pituitary tumors are relatively radiosensitive, more so than the chromophobe adenoma and the craniopharyngioma. High-voltage therapy (cobalt, betatron) is preferable. The dose must be high, but the surrounding tissues must be protected by applying irradiation from 4–6 fields. Pendulum irradiation can be used or the patient rotated. The X-rays are applied once daily for 2–4 weeks. In order to prevent damage to the brain and optic nerves, the dose to the hypophysis must be kept below 4000 rad.

The patient's symptoms may regress following irradiation. Objective remissions of the endocrine hyperfunction occur. In one large series the elevated plasma growth hormone was unaffected (GLICK, 1965), while in another series a considerable fall was seen in the growth hormone level (ROTH, 1970; LAWRENCE, 1971). Loss of visual fields can regress, but often only after a preliminary temporary deterioration. Impaired vision is an indication for surgery. Nonetheless, when only subjective symptoms are of importance, a trial with irradiation can be tried first. When no definite success is achieved after 2 months, surgery can then be considered. Radiation arachnoiditis hardly ever presents a problem.

γ) Proton-Beams and α-Particle Irradiation

The measurable limits of accelerated atomic nuclei with their slight diffusion, the narrowly restricted Bragg-effect, can produce sharply localized necroses without endangering the surrounding tissues. Complete pituitary elimination can be achieved by this method. Experience will show to what extent it is applicable in the treatment of pituitary tumors. The method is dependent on large atomic acceleration plants which are available for medical purposes in only a few centers, so that only carefully selected patients can be considered (LAWRENCE, 1963, 1965, 1970).

δ) Isotope Implantations

Stereotactic methods (MUNDINGER, 1967) are used to implant several rods or pellets of beta-radiating yttrium^{90} into the hypophysis via the transethmoidal, the transnasal, or the transfrontal route. The yttrium may possibly be combined with iridium^{192}. A dose of 100000 rads is used for complete pituitary elimination and 20000 rads for treating the tumor. This method with yttrium^{90} involves a relatively slight stress for the patient. This method does not have a great future since success is too uncertain, recurrences occur too often, and the complications are too severe. Meningitis, pituitary abscesses, delayed development of liquor fistulas, and lesions of the optic nerves are the most serious disadvantages of this method (GREENWOOD, 1965).

ε) Stereotactic High Frequency Electro-Coagulation

Bipolar high frequency electro-coagulation involves little stress for the patients and can bring about complete elimination of the intrasellar pituitary. Temporary complications rarely develop. The borehole is closed with muscular grafts (ZERVAS, 1965).

ζ) Cryohypophysectomy

It has been clamed that complete pituitary elimination can be achieved by stereotactic infliction of 2–6 deliberate lesions with a local temperature of −180°. Side effects such as diabetes insipidus and visual disturbances are thought to be only temporary (RAND, 1964). The use of this method for tumors must be further investigated. Until now, it has been possible to normalize growth hormone in acromegaly only in some cases, and complications can occur (DASKE, 1966).

ϑ) Treatment with Drugs

Although success has been reported with estrogens, particularly in extremely high doses, in the treatment of acromegaly (ALMQUIST, 1961; MCCULLAGH, 1955), the results are not convincing. Estrogens do not lower the plasma growth hormone; however, they do have a certain inhibitory effect on the periphery. Medroxyprogesterone-acetate in a dose of 40 mg daily, lowers the growth hormone level and may improve the clinical symptoms (LAWRENCE, 1970). Chlorpromazine has the same effect, which suggests the disease is hypothalamic in origin (KOLODNY, 1971). It remains to be seen how reliable these treatments will be. There was an attractive idea that human growth hormone changed slightly by extraction might used to produce antibodies in acromegalic patients; it was hoped that these antibodies would neutralize the patients' own growth hormone but an attempt at therapy based on this idea proved unsuccessful (PRADER, 1966). "Hypophyseostatics" with tolerable toxicity (KOVACS, 1964) are still not available. Hydroxypropiophenone has proved to be ineffective. GRIH (somatostatin) has acute effects (HALL, 1973).

η) Indications for the Choice of Therapy

Providing there are no vital contraindications, the transfrontal or transethmoidal removal of the tumor is indicated in the presence of neurological disturbances, particularly the loss of visual fields. Pressure on the chiasma can thus be eliminated. Whether the transfrontal or the transphenoidal route or both have to be chosen depends on the suprasellar extent of the tumor seen by pneumoencephalography. Other neurological failures, such as paralysis of the abducent and oculomotor nerves resulting particularly from hemorrhage into the tumor can only be counteracted by immediate surgical intervention. Regression of loss of the visual fields can also be achieved with irradiation and with yttrium implantation (MOLINATTI, 1962). As a rule, an interval of 2 to 3 months is necessary before the success of the treatment can be assessed. In each case, however, the decision will be made individually according to the intra- and especially the suprasellar extent of the tumor, the age and general condition of the patient, the nature of the symptoms, and to whether there is concomitant endocrine failure. Surgery is indicated when irradiation produces no success within 2 months.

The object of treatment is firstly to correct the neurological failure or to at least prevent its progress, and secondly to relieve the subjective symptoms, such as headaches, hyperhidrosis, paresthesia and psychic effects, which can sometimes be very severe. The changes in the soft tissues sometimes regress considerably with successful treatment (ROTH, 1967). Regression of the osseous deformities has also been reported, but in practice, this can hardly be expected. Apparent endocrine failure is irreversible almost without exception and must be substituted. Diabetes mellitus of short duration can regress, whereas diabetes mellitus of longer duration is only alleviated or remains uninfluenced.

G. Hormonal-Inactive Pituitary Tumors

1. Pathological Anatomy

a) Chromophobe Adenomas

Different statistics show that these tumors account for 6–7% of all brain tumors. They are the most common type of pituitary tumors. Small adenomas, which are only demonstrable with systematic microscopic examination of the pituitary, are much more frequent. The adenomas may remain restricted to the sella, but it is not unusual for them to invade the surrounding structures and they advance relatively often into the base of the brain. True metastases seldom occur. Alveolar, trabecular and papillary adenomas can be differentiated according to the cell arrangements; and the so-called fetal adenomas, the clear-cell, the small-cell, and the cylinder-cell adenomas can be distinguished by the cytology. Regressive changes, particularly cystic formations, are common. On the other hand, calcifications are rare. The endocrine significance of chromophobe adenomas has increased considerably in the last few years. As already mentioned, the chromophobe cell state may reflect a particular endocrine activity, since the cells do not store their secretion, thereby becoming chromophil, but secrete it continually.

b) Cysts

Small cysts containing colloid are particularly common in the marginal area between the anterior and posterior lobes but are of no importance. The large cysts, on the other hand, are of clinical importance. They may be intra- or suprasellar or involve both sections. They may be ciliated epithelium cysts with mucus cells or pavement epithelium cysts. Simple epidermoid cysts are only lined by pavement epithelium, whereas demoid cysts also have cutaneous appendages. Ciliated epithelium cysts contain fluid and occasionally mucus. Pavement epithelium cysts, on the other hand, contain crumbly or mushy substances. Devitalized areas may release a foreign-body reaction. Calcifications and ossifications have been observed, especially in dermoid cysts.

c) Craniopharyngiomas

These tumors are also occasionally described as adamantinomas or as Erdheim tumors. Like the cysts, they too can be extra- or intrasellar. The tumors are occasionally partly solid but are usually composed of multilocular cysts. They occasionally form an almost unilocular cyst which may attain considerable proportions. The histology shows that the tumors consist of epitheloid cellular rods. In the periphery of these, the cells are palisade-like and are arranged in rows, whereas in the center more network-like structures and cysts are found. Calcification and regressive changes are usually pronounced. The tumors grow slowly, but may attain considerable size, destroying the surrounding tissue and the pituitary in particular.

d) Teratomas

Teratomas may exceptionally occur in the pituitary region. They affect the epiphyseal areas much more frequently, however.

e) Metastases

The posterior lobe is most affected by metastases, which are common in some forms of tumors. Carcinomas of the breast and bronchus tend to metastasize particularly in the hypophysis. Carcinoma of the stomach then follows. Usually the metastasizing tumor dominates the clinical picture to such an extent that signs of pituitary failure hardly become manifest. Diabetes insipidus is, however, not so uncommon in metastasizing carcinomas of the breast.

2. Clinical Features

a) Endocrine-Inactive Chromophobe Adenoma

In contrast to the eosinophil adenoma, the chromophobe adenoma does not often produce headaches. These are caused by pressure on the hypophyseal capsule or by expansion of the tumor into the hypothalamus with compression of the 3rd ventricle, giving rise to occlusive hydrocephalus. Impaired vision is common. At first, the blind spot enlarges, and color vision, especially for red, decreases in the periphery.

Fig. 16. P. 1024/35, 45-year-old man, chromophobe adenoma of the anterior pituitary lobe protruding from the sella in the shape of a mushroom (view of the base of the skull from above)

The upper temporal quadrant is the first to be lost, followed by the lower temporal. Bitemporal hemianopsia develops, which is often asymmetrical, one eye usually being more affected than the other. Homonymous hemianopsia of the optic tract has also been observed in the adult. Vision decreases and central scotomata develop. Primary optical atrophy develops, leading to complete blindness first in one eye and eventually in both. Paralysis of the ocular muscles can arise, particularly those involving the III and IV cranial nerves. In two-thirds of all cases there is suprasellar expansion whose extent can be certified by a pneumoencephalogram. Pneumoencephalography should be performed in every case of enlarged sella for this reason, and also to exclude the "empty sella syndrome". All possible neurological disorders may then develop, in addition to visual disturbances. These include palsies, hyperreflexia, ataxia, paracusis and deafness. The risk involved in surgery increases with suprasellar expansion, and the operability decreases (HEIMBACH, 1959). Hypothalamic invasion by the adenoma results in diabetes insipidus, somnolence, and disorders in temperature regulation. The protein in the cerebrospinal fluid may be increased. When the suprasellar tumor expands into the 3rd ventricle, occlusive hydrocephalus develops. This may become manifest in papilledema. The X-rays always show a widened sella, ranging in shape between a bowl and a balloon. The entrance of the sella is widened, the dorsum sellae is often raised and usually more or less destroyed. All these symptoms, headache, paralysis of the occular muscles, visual loss, collapse, stupor and coma, can develop in hours. They can be explained by hypophyseal "apoplexy", i.e. spontaneous or traumatic hemorrhage into the tumor. The cerebrospinal fluid may be strongly hemorrhagic or only slightly tinged, and the cell count and protein may be increased. Immediate massive substitution therapy and neurosurgery to relieve pressure can save vision and life (LOCKE, 1961). Localized hemorrhages cause partial endocrine insufficiency and may regress spontaneously (WRIGHT, 1965). Aneurysms, especially of A. carotis interna, may mimic the chromophobe adenoma radiologically and endocrinologically (WHITE, 1961). The slow onset of symptoms often allows the diagnosis only after 3, 5 or 7 years, depending upon whether problems of vision, headaches, or endocrine insufficiency predominate (FUERST, 1966). In an enlarged sella pneumoencephalography may occasionally reveal an empty sella syndrome (KAPLAN, 1969). (See also p. 103f.).

Endocrine symptoms: Endocrine-active tumors are encountered among the chromophobe tumors, and give rise to symptoms of Cushing's syndrome (see p. 344), acromegaly (see p. 109), galactorrhea, amenorrhea and very occasionally to symptons of hyperthyroidsm (GUBLER, 1963; LAMBERG, 1969). LAMBERG has shown that this rare form of hyperthyroidsm (KAPPELER, 1959) is due to TSH overproduction. As a rule, however, chromophobe adenomas are endocrine-inactive. Pressure and compression of the active cells can, but need not, give rise to partial or complete pituitary failure. The chromophobe adenoma leads to overt endocrine failure in one third of cases, and to diminished reserves with preserved basal secretion in one third, while in the remaining third endocrine function is unaffected. Growth hormone and gonadotropin secretion is the most frequently disturbed, followed by ACTH and TSH secretion (NIMAN, 1967). Insufficiency of the posterior lobe with diabetes insipidus has rarely been observed in the chromophobe adenoma.

b) Craniopharyngioma

A craniopharyngioma can occur at any age but shows a predisposition for the young, under 20 years of age, whereas pituitary adenomas occur almost without exception after the 20th year. The craniopharyngioma often contains large cysts. Depending on the direction of growth, visual disturbances or occlusive hydrocephalus due to obstruction of the 3rd ventricle may develop. Symptoms of endocrine failure can also arise due to destruction of the hypothalamic nuclei. The clinical picture is different in the various age groups. In the infant the suprasellar tumor, which usually involves the 3rd ventricle, interrupts the cerebrospinal fluid circulation and blindness results from compression of the chiasma. During puberty, physical development of most patients is retarded. Occlusive hydrocephalus is rare in this age group. Beyond 20 years, the chiasma syndrome dominates the clinical picture, usually combined with sexual dysfunction and disturbances in water equilibrium (diabetes insipidus, adipsia). Supra- and intrasellar calcifications on the X-rays are suggestive of a craniopharyngioma (Fig. 7). They can sometimes appear as mottling and sometimes as bowl-shaped above the sella. Occasionally, a calcified cystic wall can be demonstrated. The sella is often not extended but may be.

Endocrine symptoms: The craniopharyngioma gives rise to destruction of the hypothalamic nuclei with impaired formation and release of the neurohormones, with the result that regulation of the secretion of the anterior pituitary hormones is also impaired. Diabetes

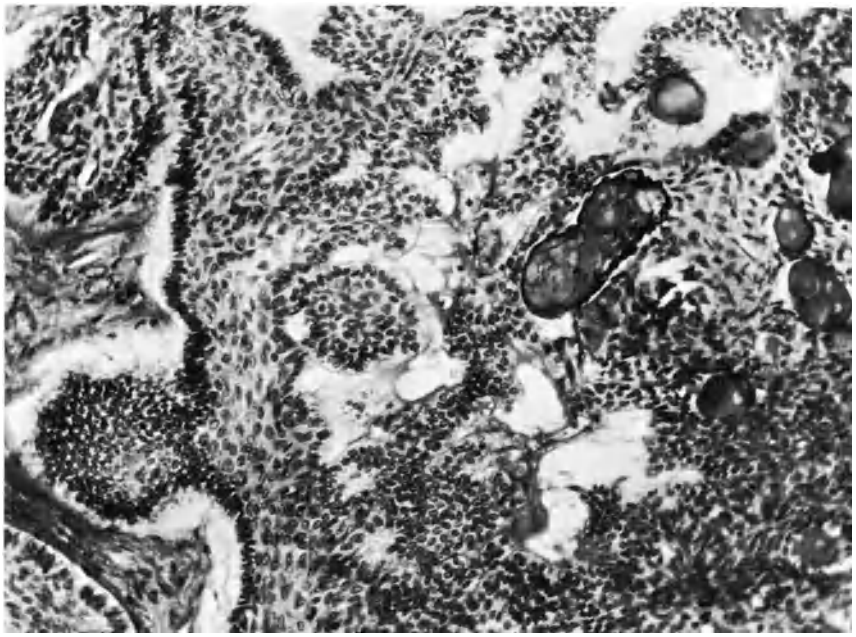

Fig. 17. S 774/52, 8-year-old boy. Craniophryngioma with large calcium inclusions (right of picture). HE staining, 300:1

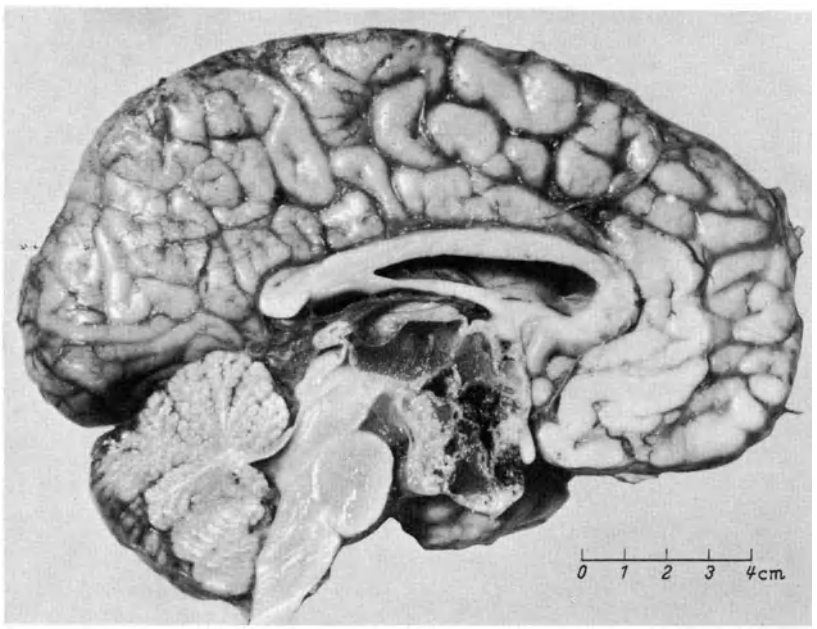

Fig. 18. S 774/52, 8-year-old boy. Craniopharyngioma at the base of the brain with adhesions to the region of the 3rd ventricle

insipidus is common. Growth and maturation are retarded. Hypogonadism occurs frequently, whereas secondary hypothyroidism and secondary adrenal insufficiency have been less frequently observed. Pubertas praecox occurs in a few cases, probably due to the stimulation of hypothalamic centers. See p. 106f. for galactorrhea. Adipsia (see p. 55f.) with chronic hypernatremia has been observed (MATSON, 1964; RICHTER, 1970). The endocrine failure is usually more pronounced after surgerey even if the operations are successful from the neurological aspect (KRAYENBÜHL, 1962).

3. Therapy

Neurosurgical removal of the tumor and X-ray irradiation can be considered in treatment of the chromophobe adenoma. Chromophobe adenomas are not very radiosensitive. 4000–6000 r must be applied to the focus within 30 days. Good results are thought to be obtained with high doses of ultra-hard irradiation (4000 r at 2000 kV) in more than 50% of cases but it is not unusual for the adenomas to be cystic and therefore radiorefractory. They are also usually well-defined and can in the main be removed surgically providing there is no great suprasellar expansion. No time should be lost in trying irradiation in loss of visual fields. The therapy which gives the best results at present is radical surgical removal of the tumor followed by irradiation. As stated on p. 115, the slight endocrine failure, which can be substituted, is more acceptable than the risk of limited success or recurrences.

Table 6. Substitution therapy for operations on the hypophysis

1. At the beginning of anesthesia slow infusion of 1 liter 2 : 1 physiologic glucose/physiologic NaCl solution with 50 mg cortisol hemisuccinate given over 8 hours. A further liter of 2 : 1 physiologic glucose to physiologic NaCl with 50 mg cortisol hemisuccinate given over the next 16 hours.
2. Measure fluid intake and urinary output for 24 hours. Specific gravity and, if possible, body weight to be checked daily. To prevent dehydration due to postoperative diabetes insipidus, the fluid intake should be approximately 0.5 liter more than the urinary output. The body weight should remain reasonably constant. Hematocrit, blood electrolytes and proteins must be estimated in doubtful cases and in unexplained fever (thirst fever). Fluid administration to be adjusted to the findings.
3. On the 1st postoperative day, if the patient can swallow, one 25 mg tablet of cortisone acetate morning and evening. When swallowing is not possible, slow infusion of 1 liter 2 : 1 physiologic glucose/physiologic NaCl solution with 50 mg cortisol hemisuccinate.
   One half 25 mg tablet of cortisone acetate is given morning and afternoon from the 2nd postoperative day.
4. Depending on the course of the illness, all substitution is withdrawn after 1–3 weeks but preferably after 3 months, possibly in hospital. Adrenal, thyroid, and gonadal function is examined. Long-term substitution therapy is decided upon in the presence of complete failure of the anterior lobe of the pituitary. This usually consists of:
   $2 \times {}^1/_2$ tab. cortisone acetate and
   0.2 mg Na-l-thyroxine
   250 mg Depot-Testosterone i.m., monthly in male patients.
   Pediatric doses:
   at 8 years: $^1/_2$ the adult dose
   at 2 years: $^1/_4$ the adult dose

NB: Oral cortisone or intravenous cortisol is preferable to prednisolone or prednisone because of the slight sodium-retaining effect. Prednisolone or prednisone can be used in a $^1/_4$ dose when cortisol and cortisone are unavailable.

Craniopharyngiomas are practically insensitive to radiation. Radical surgical removal of these benign, well-defined tumors involves a high mortality due to the damage which may be expected in the surrounding areas of the brain. Often, only palliative operations achieving removal or partial resection of the very large cysts occasionally present are possible. Palliative treatment of the occlusive hydrocephalus resulting from the craniopharyngioma may become necessary. As a rule, the Torkildsen operation is indicated, in which the cerebrospinal fluid circulation is restored by the insertion of a rubber or polyethylene tube leading to ventriculo-cisternal or ventriculo-atrial shunts. The tube overcomes the obstruction and establishes free communication. Whether hypopituitarism is demonstrable or not preoperatively, extirpation of a pituitary adenoma or of a craniopharyngioma must, as a matter of precaution, be carried out under complete substitution therapy. Table 6 gives the procedure to be adopted.

Almost 50% of patients with pituitary tumors treated surgically or with radiation have clinically apparent mild or pronounced pituitary insufficiency. More thorough investigation reveals failure in four-fifth of cases. See p. 52f. for postoperative diabetes insipidus and polyuria. Nevertheless, only one third of the cases in a large investigation series received substitution therapy. The hormones of the deficient glands should be substituted without hesitation if even the slightest symptoms appear (ELKINGTON, 1967). If no endocrine disorders are demonstrated, a gradual reduction of the substitution therapy should be tried 1–3 weeks postoperatively at the earliest. As a rule, however, a check-up should be undertaken in the hospital 3 months after the operation to decide whether pituitary function has remained intact or recovered after the relieve by the operation.

4. Diagnosis of the Anterior Pituitary Function

The function of the anterior pituitary can be assessed largely by the function of the 3 endocrine glands under its control. Normal function of the gonads, the thyroid gland, and the adrenal cortex indicate normal anterior pituitary function. Thus, pituitary insufficiency is unlikely in a woman with normal menstruation. In the male, the sperm count is a sensitive indication of pituitary function since pituitary insufficiency causes an immediate fall.

Estimation of the adrenotropic hormones and the tests for pituitary reserve have been discussed in the chapters dealing with the individual organs.

Direct and Indirect Estimation of Growth Hormone Activity

a) Biological Determination

Biological methods (GEMZELL, 1959) permitted the detection of only a very high concentration of growth hormone in the plasma, whereas the introduction of the radioimmunological methods for peptide hormones has made it possible to estimate normal basal values and daily variations. Since then estimation of the growth hormone in the plasma has only become significant in the diagnosis of active acromegaly.

b) Radioimmunological Determination

The radioimmunological methods of estimation are described in detail under the method for insulin, whose estimation was first achieved by BERSON and YALLOW (see p. 814). These methods exploit the property of endogenous growth hormone of competitively inhibiting the combination of growth hormone labeled with ^{131}I with specific antibodies. Growth hormone of the added plasma is deduced from the ratio of the free labeled growth hormone to that bound to the antibodies. Separation of the free from the antibody-bound growth hormone is achieved either by electrophoresis (GLICK, 1963; HUNTER, 1964) or by precipitation of the growth hormone bound to the antibodies with antigamma globulin serum (double-antibody precipitation method) and subsequent centrifugation (UTIGER, 1962; BODEN, 1967). These methods can detect concentrations of 0.5 ng/ml, and all give consistent normal values of 0–3 ng/ml after 12 hours' fasting.

With certain reservations, the plasma concentration of growth hormone measured radioimmunologically is the most specific method for evaluation of the growth hormone secretion. This is true providing a flawless radioimmunological method can detect values around 1 ng/ml. Normal adult values after 12–14 hours of fasting and absolute rest lie between 1 and 3 ng/ml. Values of 8–103 ng/ml are found in acromegaly (BODEN, 1967). Elevated values, however, are not definite proof of acromegaly, since any physical task, and probably emotional stress as well, can cause a ten-fold or more increase. In addition, a few values within the normal range have been found in acromegaly. Considerable diurnal variations occur (CRYER, 1969). Also, the low fasting level permits no differentiation between the normal state and pituitary insufficiency. Therefore, only the stimulation or inhibition tests permit definite differentiation.

c) Stimulation Tests

Stimulus for the release of growth hormone can be provoked by 0.1 U/kg body weight (4 U/m^2 body surface) insulin or in insulin-insensitive acromegalics, 0.3 U/kg body weight i.v. Hypoglycemia is still the most reliable, but must consist in a fall of about 50%. Blood sugar and growth hormone must be determined at 0, 15, 30 to 90 and 120 minutes (FRANTZ, 1964; CAPLAN, 1968). Alternatively, 1 g of tolbutamide can be injected i.v. over 3 minutes, which will provoke a maximal rise in growth hormone 10–70 minutes after the nadir of blood sugar (BODEN, 1967); whereas normally the growth hormone concentration will rise from very low or zero values up to supranormal values after 1 hour, in the acromegalic the elevated values are scarcely influenced, which indicates an autonomic or a maximal growth hormone secretion. Sometimes, however, there is an exaggerated increase or a paradoxical decrease, indicating that hypothalamic control is not excluded (CRYER, 1969). An insufficiency can be diagnosed if there is no increase in growth hormone after stimulation, or only an insufficient one. Stimulation can also be realized by an infusion of 0.5 mg arginine per kg body weight i.v. (PARKER, 1967), which is less unpleasant for the patient and does not involve the same risks in pituitary insufficiency. Glucagon also stimulates growth hormone secretion (see p. 90). A glucagon stimulation test has been described (1 mg i.m.); it is thought to be innocuous and reliable in distinguishing between patients deficient in growth hormone and normals (MITCHELL, 1970). Experience will show which of these stimulation tests will be the most useful.

d) Inhibition Test

The glucose inhibition test is usually used for the diagnosis of acromegaly. After a glucose load of 100 g in the normal, the growth hormone decreases during the first hour and increases again after 180 to 240 minutes. The growth hormone of the acromegalic patient is usually hardly affected, if at all (BECK, 1965; ROTH, 1967; EARLL, 1967; BODEN, 1968). However, a decrease or even a paradoxical increase may be observed (CRYER, 1969; EARLL, 1967; LAWRENCE, 1970). As a rule, fasting values of over 8 ng/ml are found in active acromegaly.

e) Nitrogen-Retention Test (see p. 100)

f) Plasma Phosphate

The plasma phosphate is much simpler to measure but a less reliable indicator. Growth

hormone leads to an elevated phosphate concentration of over 3.5 mg% in the plasma due to increased phosphate reabsorption in the renal tubulus. The phosphate can, however, vary between normal and very elevated values in the same person (HAMWI, 1960). Elevated phosphate levels are also found in children during growth, in pregnancy, and in nephropathies, as well as in hypoparathyroidism. Thus, it is only of limited value in evaluation of the growth hormone activity.

g) Sulfation Factor (see p. 88)

h) Hydroxyproline Excretion

The amino acid hydroxyproline is an important constituent of collagen. Hydroxyproline, which is mostly bound in polypeptides, is excreted in the urine. It can be relatively simply estimated after hydrolysis with concentrated hydrochloric acid. The excretion in the 24-hour urine must be estimated after 2 days of a diet containing no meat or gelatine. Normal values are relatively constant, and are between 15 and 50 mg/24 (see also Chap. XIV).

The excretion appears to be proportional to collagen turnover, and probably corresponds to the content of soluble collagen in the tissues. According to the metabolic situation the hydroxyproline excretion reflects collagen formation, or decomposition of the finished collagen, or both.

Hydroxyproline excretion is increased in states where bone is being formed and where bone is being broken down. The excretion is also occasionally increased in rheumatoid arthritis, in scleroderma, dermatomyositis, rheumatic fever, the Marfan syndrome and lathyrism.

Values far above the normal limits are found in growing children, particularly before puberty (PROCKOP, 1967).

Greatly elevated values are found in Paget's disease, hyperparathyroidism, hyperthyroidism, and acromegaly. The excretion is normal after inactivation of the acromegaly. Administration of parathormone, thyroxine, or growth hormone leads to an increase in hydroxyproline excretion.

Highly elevated values have been found in active acromegaly, and estimation of the hydroxyproline excretion provides a valuable criterion in the assessment of the activity of the disease in addition to the direct measurement of growth hormone.

The excretion is not significantly reduced in pituitary insufficiency and is not suitable for the diagnosis of states of endocrine hypofunction.

Increased excretion of unbound hydroxyproline is found in the rare condition hydroxyprolinemia, in which there is congenital deficiency of the enzyme hydroxyproline oxidase (EFRON, 1965).

i) Biopsy of the Ribs

In active acromegaly, biopsy of a rib at the junction of the cartilage and bone shows endochondral osteogenesis in the form of groups of vesicular cartilage cells (SULLIVAN, 1963).

VI. The Thyroid Gland

H. BÜRGI and A. LABHART

With Contributions by

CHR. HEDINGER, G. KISTLER, A. PRADER, and G. TÖNDURY

A. Historical Dates

1543 VESAL described the thyroid gland.
1606 PARACELSUS related cretinism to the thyroid gland (published posthumously).
1786 PARRY described hyperthyroidism (published posthumously 1825).
1802 FLAIANI described hyperthyroidism.
1820 COINDET introduced iodine into the treatment of goiter.
1833 BOUSSINGAULT recommended iodine for the prevention of goiter.
1835 GRAVES described hyperthyroidism.
1836 KING assumed the presence of an internal secretion of the thyroid.
1840 BASEDOW gave a classic description of the Merseburg triad (exophthalmos, goiter and tachycardia).
1852 CHATIN justified the theory that iodine deficiency caused goiter, by proving a diminished iodine content of the drinking water in endemic areas.
1873 GULL described the classic picture of myxedema.
1878 ORD related it to atrophy of the thyroid gland.
1882 First description of the complications of thyroidectomy in man by the REVERDIN brothers.
1883 KOCHER described "cachexia strumipriva" (postoperative myxedema).
1886 MOEBIUS found that Graves' disease was due to hyperfunction of the thyroid gland.
1888 Report of the Myxedema Commission of the Clinical Society of London.
1891 MURRAY successfully treated myxedema with injections of thyroid extract.
1893 FRIEDRICH VON MÜLLER demonstrated a negative metabolic balance in hyperthyroidism.
1895 MAGNUS-LEVY recognized that the oxygen consumption at rest was elevated in thyrotoxicosis and reduced in myxedema and that the basal metabolic rate following the administration of desiccated tissue was increased.
1896 BAUMANN showed that iodine was a constituent of the thyroid gland.
1899 OSWALD isolated thyroglobulin as a component of the thyroid.
1910 MARINE and LENHART succeeded in preventing goiter by using iodine in animal experiments.
1912 GUDERNATSCH recognized the acceleration of metamorphosis caused by thyroxine.
1913 PLUMMER described the toxic adenoma.
1914 KENDALL succeeded in purifying and crystallizing the thyroid hormone, thyroxine.
1917 First successful iodine-prophylaxis of goiter in man by MARINE and KIMBALL.
1918 AUB, DUBOIS, BENEDICT, and HARRIS introduced the measurement of basal metabolic rate as a clinical method.
1922 PLUMMER introduced iodine treatment for hyperthyroidism.
1926 HARINGTON established the chemical constitution of thyroxine.
1927 HARINGTON and BARGER synthesized thyroxine.
1927 SMITH showed the existence of thyrotropin in the pituitary gland.
1928 CHESNEY, CLAWSON and WEBSTER discovered goitrogenic substances in different types of cabbage.
1940 Introduction of radioactive iodine for the clinical evaluation of thyroid function by HERTZ, ROBERTS, MEANS, and EVANS.
1942 ASTWOOD systematically examined goitrogenic substances and introduced thiouracil into the treatment of hyperthyroidism.
1942 HAMILTON and LAWRENCE introduced radioactive iodine into the treatment of the thyroid gland.
1952 Discovery of triiodothyronine by GROSS and PITT-RIVERS and ROCHE, MICHEL, and LISSITZKY.
1956 ADAMS, PURVES, and MCKENZIE independently found the long-acting thyroid stimulator (LATS) in the serum of thyrotoxic patients.

1956 ROITT, DONIACH, CAMPBELL, and HUDSON discovered thyroid antibodies in Hashimoto thyroiditis.
1970 GUILLEMIN and SCHALLY successfully isolated thyrotropin releasing hormone (TRH) from hypothalamic extracts.
1970 GILLESSEN and co-workers established the chemical constitution of TRH and synthesized the hormone.

B. Embryology, Gross Anatomy, and Histology

G. TÖNDURY and G. KISTLER

Embryology. The anlage of the thyroid gland, like that of the hypophyseal glandular lobe, appears very early in embryonic life. In the human embryo 3.5 to 4 mm in length, an entodermal outpocketing forms in the floor of the oral cavity, just beneath the buccopharyngeal membrane and between the first pair of pharyngeal pouches. At the bottom of this small pit an epithelial bud protrudes into the underlying mesenchyma. The primordium becomes displaced caudally, but remains attached to the floor of the pharynx by the *thyroglossal duct*. During this descensus, the originally compact bud becomes bilobed and differentiates into a mass of irregularly arranged epithelial cords, which later form the isthmus and the lateral lobes of the gland. When the primordium reaches the level of the uppermost tracheal cartilage, the thyroglossal duct becomes fragmented. A *cranial* fragment, the *lingual duct*, remains attached to the tongue initially but usually disappears at later stages. Occasionally however, salivary gland-like structures and small colloid-filled follicles develop from its epithelium. The point of origin of the duct forms the *foramen cecum*, an enlarged pit which persists, in about 50% of the population, in the midpoint of the sulcus terminalis between dorsum and radix linguae. The *distal* fragment of the thyroglossal duct gives rise to the pyramidal lobe. In the eighth week, small rounded or elongated cavities begin to appear in the thyroid cords. They develop into the primary thyroid follicles, which acquire colloid at the beginning of the third gestational month and become functional soon afterwards (GREENBERG, 1970).

Gross Anatomy. The thyroid gland consists of a left and a right lobe which are connected across the median plane by the narrow isthmus. The lateral lobes are conical in shape. The base is usually on a level with the fourth or fifth tracheal ring. The apex, which is directed upwards, usually reaches the oblique line of the thyroid cartilage. The isthmus usually covers the second and third tracheal rings, but may also be higher or lower. The pyramidal lobe varies widely in size and shape, occasionally extending up to the hyoid bone. The gland is situated at the level of the fifth to seventh cervical and the first thoracic vertebrae. Its medial surface is in close contact with the larynx and trachea. Its posterolateral surfaces are related to the esophagus and the neurovascular tracts of the neck. Anteriorly, the thyroid is separated from the sternothyroid muscles by the pretracheal fascia. A connective tissue capsule is closely applied to and inseparable from the glandular parenchyma. An additional, outer and thicker capsule encloses the larger branches of the thyroid blood vessels and the parathyroid glands. Small aberrant fragments of thyroid tissue are sometimes found outside this outer capsule, mostly along the obliterated thyroglossal duct (so-called accessory thyroid glands).

The thyroid gland is a highly vascular organ. It is usually supplied by two pairs of arteries, the branches of which anastomose freely with each other. The *superior* thyroid artery arises on each side as the first branch of the external carotid. It supplies the upper, anterior, and lateral portions of the lateral lobes. The *inferior* thyroid artery is a branch of the thyrocervical trunk which in turn arises from the first portion of the subclavian artery. It supplies the inferior, posterior and medial parts of the organ on either side. In its course to the thyroid gland, the inferior thyroid artery crosses the *recurrent laryngeal nerve* of the vagus and the *sympathetic trunk*, which often forms a loop around it, the ansa thyreoidea. The recurrent laryngeal nerve ascends, on the left side, in a groove between the trachea and the esophagus, and, on the right side, along the trachea. At the level of the first tracheal ring, it gives off the inferior laryngeal nerve which runs in front of, or behind the branches of the inferior thyroid artery to supply the intrinsic muscles of the larynx. Ligation of the arteries during thyroidectomy therefore involves some hazard to the recurrent laryngeal nerve. Occasionally, there is a fifth artery, the unpaired *arteria thyreoidea ima*, which arises from the arch of the aorta or from the brachiocephalic trunk and ascends to the isthmus. The veins form a rich network on the surface of the organ and on the front of the trachea. From this plexus, a superior, a middle and an inferior thyroid vein arise. The former two end in the internal jugular vein, the latter in the innominate vein. A dense capillary network surrounds the thyroid follicles. Closely applied to the capillaries are numerous branching lymph vessels which run

in the interfollicular connective tissue, often along the arterioles, to a network in the capsule of the gland. From here, larger lymph vessels extend to the thoracic duct and to the right lymphatic duct.

Numerous autonomous nerve fibers derived from the middle and inferior cervical ganglia of the sympathetic trunk penetrate the capsule, mostly together with the arteries. In the interfollicular spaces, they form a dense network of nonmyelinated nerve fibers, whose endings terminate in close proximity to the follicles.

Histology. At an embryonic age of about eight weeks, the epithelial cords of the thyroid primordium disintegrate into small vesicles, the *primary* or two-cell follicles, which contain small amounts of colloidal material. From these, rounded or rod-shaped *secondary* (definitive) follicles sprout out and enlarge. The follicles of the mature gland measure up to 1 mm in diameter. They contain a gelatinous colloid and are lined by a simple epithelium, the depth of which varies widely according to the functional state of the gland. At the peak of *secretory* activity (Fig. 1a), the epithelial cells are columnar in shape. Mitochondria and numerous clear vesicles appear to accumulate in the apical portions of the cells and the Golgi complex is found in a supranuclear position. The colloid produced in the cells is secreted into the follicle cavity, where it gradually becomes concentrated. At this point, the epithelial cells assume a cuboid or flattened shape (Fig. 1b) corresponding to a resting state. *Resorption* of the colloid from its storage site seems to be initiated by liquefaction of its outermost portions. The cells again become cuboidal or columnar and their cytoplasm turns foamy (Fig. 1c). Empty follicles are characterized by their star-shaped lumen. It is assumed that they are able to refill the follicle cavity with colloid within a few hours.

Each follicle is enclosed by a very thin basal membrane and a delicate network of reticular fibers. In addition, it is surrounded by a capillary plexus and by numerous blind terminations of lymphatic vessels. The interstitial arterial network of the thyroid gland is rich in regulatory structures such as subendothelial bundles of epitheloid muscle cells, as well as arteriovenous anastomoses. Veins and larger lymphatics accompany the arteries. A large number of sympathetic nerve fibers originate in the middle and superior cervical ganglia and run along the larger blood vessels; they are presumed to be vasomotor.

A population of larger cells which do not stain as well is regularly observed in both the follicular epithelium and the interfollicular spaces. When stained by the silver nitrate method of CAJAL, these so-called *parafollicular cells* (mitochondria-rich cells, C cells) display a large number of small brown or black granules. As recent investigations have shown, these cells produce the hormone thyrocalcitonin (Chap. XIV).

Fig. 1a–c. Morphologic variations of the epithelial cells depending on the functional state of the thyroid gland. a) secretory phase, columnar cells; b) resting state, flattened epithelium; c) resorption of the colloid, cuboidal to columnar epithelial cells and vacuolization of the colloid within the follicle cavity. [With permission of Prof. CHR. HEDINGER: Normale und pathologische Anatomie der Schilddrüse, Verh. dtsch. Ges. inn. Med. **66,** 13 (1960)]

Electron microscopy reveals a large number of *microvilli* and occasional single cilia at the apical surface of the epithelial cells. Their shape varies widely according to the functional state of the follicle. The microvilli of resting cells are short and straight; those of secreting or resorbing cells appear larger and pleomorphic. Laterally, the follicle cells are joined by typical junctional complexes. Some small infoldings of the plasma membrane are regularly observed in the basal regions of the epithelium. In the active cell, the Golgi apparatus is composed of flattened saccules and numerous vesicles and vacuoles. It is usually situated above the relatively large nucleus which occupies the basal cytoplasmic region. The endoplasmic reticulum consists of elongated, rough-surfaced cisternae and a large number of small vesicles. Ovoid or rounded mitochondria, multivesicular bodies, and vacuoles of varying size are randomly distributed within the cytoplasmic ground substance.

The uptake of iodine from the blood plasma and its oxidation within the epithelial cells are discussed on p. 139. Independently of these processes, which are still poorly understood, thyroglobulin fragments are synthesized on the ribosomes of the granular endoplasmic reticulum. They are carried within small vesicles to the Golgi region, where they seem to be coupled to carbohydrates (NADLER, 1964). The vesicles then reach the apical surface of the epithelial cell and their membrane fuses with the plasma membrane. Iodination of the thyroglobulin seems to occur at the moment when the content of the vesicle is emptied into the follicle cavity (Fig. 3). Resorption of the thyroglobulin-bound hormone molecules takes place again at the apical surface of the cells, where colloid droplets of varying size are found to be phagocytozed. While, in resting cells, the lysosomes are randomly distributed throughout the cytoplasm, in cells engaged in resorption they accumulate in the apical portions of the cytoplasm, where they are observed to fuse with the phagocytozed colloid droplets. After breakdown of the thyroglobulin by the hydrolytic enzymes, the hormones thyroxine and triiodothyronine are carried in molecular form to the basal portions of the epithelial cells and reach the capillary network and the terminations of the lymphatic vessels by a yet unknown pathway.

C. Biochemistry and Physiology

1. Chemistry of the Thyroid Hormones

The thyroid gland secretes two iodinated amino acids with hormonal activity, L-thyroxine (T_4) and 3,5,3′-L-triiodothyronine (T_3). The structural formulas are given in Fig. 2. The two benzene rings are joined by an ether linkage which forms an angle of 110° at the oxygen atom. The three-dimensional structure of thyroxine and triiodothyronine have recently been established by X-ray crystallographic analysis (CAMERMAN, 1972). The two benzene rings are in planes almost perpendicular to each other and the four iodine atoms of thyroxine form the apices of a distorted tetrahedron.

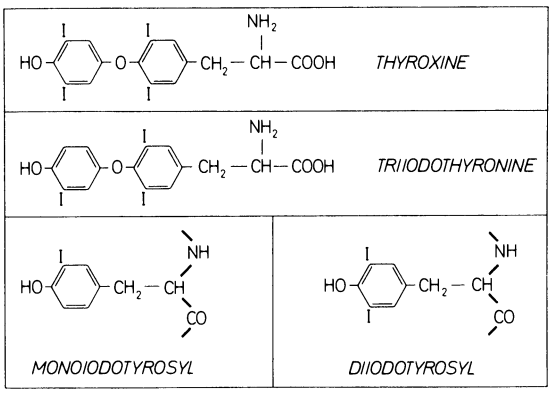

Fig. 2. Chemical formulas of thyroid hormones and their precursors. Mono- and diiodotyrosine are shown as amino acid residues, since they occur mainly as part of the protein thyroglobulin. The peptide linkages are shown by thick lines

Thyroxine and triiodothyronine are poorly soluble in water at neutral pH. They are soluble in 0.1 N NaOH and also in ethanol or methanol rendered alkaline by ammonia.

The natural compounds are levorotatory. The dextrorotatory stereoisomers have only a weak thyromimetic activity of about 1/20 that of the natural hormones. It has been said that D-thyroxine differs qualitatively in its effects from L-thyroxine, and in particular that it lowers serum lipids much more than it affects oxygen consumption and basal metabolic rate (BANSI, 1962). In view of the fact that D-thyroxine had to be given in high doses to lower serum lipids and that the preparations tested may have contained appreciable quantities of L-thyroxine as a contaminant, these claims are certainly open to question.

Numerous hormone analogues have been prepared, and some have been found to be hormonally active, although in most cases less so than the parent compound when compared on a weight basis (MONEY, 1960; JØRGENSEN, 1971) but some, such as 3'-isopropyl-3,5-diiodothyronine are definitely more active than triiodothyronine. Natural breakdown products of tyroid hormones, such as tetraiodothyroacetic acid

(tetrac) and triiodopropionic acid (triprop), are also hormonally active. Their exact physiological activity is difficult to evaluate as they have different half-lives, membrane permeabilities and distribution volumes. The requirements for thyroid hormone activity of an analogue have been specified as follows: 1. the thyronine skeleton; 2. diiodo- or dibromo substitutions in the 3 and 5 positions; 3. bulky substitutions (e.g. iodine, isopropyl) in the 3′ position (BARKER, 1971).

2. Hormone Biosynthesis and Release

Dietary iodine intake shows wide geographic and day-to-day variations. In regions of iodine deficiency it can be as low as 10 µg per day. In the U.S.A. the daily intake varies between about 100 and 1000 µg (ODDIE, 1970) and there are reliable data to show that iodine consumption is rising (PITTMAN, 1969). 100 µg per day is considered a sufficient, 200 µg an optimal iodine supply. Most of the dietary iodine is supplied as iodide, and some as organic or molecular iodine. The latter is reduced to iodide during intestinal absorption. The plasma level of inorganic iodide depends largely on the dietary intake and is between 0.1 and about 1.0 µg/100 ml. The extrathyroidal iodide space in man is about 38% of body weight. Iodide is filtered in the renal glomerula and partially reabsorbed in the renal tubuli. The renal clearance is 15 to 55 ml/min, with an average of 35 ml. It is diminished in uremia, but otherwise the renal iodide clearance is quite constant in a given subject. Gastric mucosa and the salivary glands are extrathyroidal tissues which can concentrate iodide. The iodide concentrated in this way is secreted back into the alimentary tract and is reabsorbed in the gut. Substantial amounts of iodide may be lost in the breast milk.

a) Thyroidal Iodide Uptake

Besides the kidney, the only organ clearing significant amounts of iodide from the blood is the thyroid (Fig. 4). Unlike the renal iodide clearance, which is very constant, the thyroidal clearance is highly adaptable. On average it amounts to about 25 ml/min, but in conditions of iodine deficiency or of thyroid gland hyperfunction the clearance rises to over 100 ml/min. Iodide is actively transported across the basal thyroid cell membrane against an electrochemical concentration gradient (step 1, Fig. 3). The concentration within the cell is 5 to 300 times higher than that in the plasma, the exact value depending on the functional state of the gland. Iodide transport requires energy, which is supplied by ATP. Inhibition of membrane-bound ATPase by ouabain abolishes active

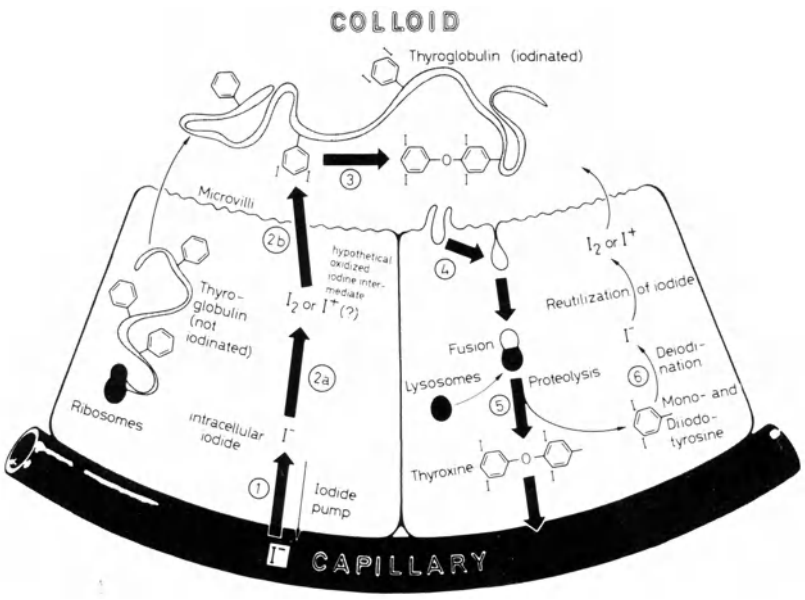

Fig. 3. Schematic representation of thyroid hormone biosynthesis and release. The individual steps are numbered as follows: 1. Active transport of iodide from the blood into the thyroid cell. 2a. Oxidation of the intrathyroidal iodide by a peroxidase to an as yet unidentified oxidized iodine intermediate. 2b. Transfer of this oxidized iodine intermediate to a tyrosyl residue of thyroglobulin. 3. Coupling of two diiodotyrosyl residues within thyroglobulin to form thyroxine. 4. Endocytosis of colloid. 5. Fusion of colloid droplets with lysosomes. Hydrolysis of thyroglobulin with release of free thyroxine and free iodotyrosines. 6. The free iodotyrosines are deiodinated within the gland by a specific deiodinase. The iodide thus recovered is reincorporated into thyroglobulin

iodide transport (WOLFF, 1964). Several authors have postulated the existence of a specific iodide carrier, but conclusive isolation has not been achieved (see WOLFF, 1964, for review). TSH enhances active iodide transport after a lag of several hours. On the other hand, active iodide transport may also be controlled by extrapituitary factors, probably involving so-called thyroid autoregulation. Several monovalent anions specifically inhibit iodide transport. The most potent of these is perchlorate (ClO_4^-). Others include nitrate (NO_3^-) and thiocyanate (CNS^-). They are thought to act by competitive inhibition of the active iodide transport, but in the case of thiocyanate the mechanism may be more complex and is not completely clear. Iodide transported into the cell is rapidly metabolized to organic iodine. In normal circumstances the process of organic iodination is so efficient that inorganic iodide concentration in the gland remains very low. Therefore the rate-limiting step in the synthesis of organic iodine is that of transport of iodide. When organic iodination fails for some reason, iodide can leave the gland again, probably by simple passive diffusion. A second source of thyroidal iodide is mono- and diiodotyrosine, two amino acids resulting from thyroglobulin hydrolysis. They are quantitatively deiodinated within the gland by a potent deiodinase, and most of the iodide produced is reutilized for organic iodination. There is some evidence that this so-called endogenous iodide is confined to a different compartment than the iodide transported from outside (second iodide pool; HALMI, 1962; NAGATAKI, 1963).

b) Organic Iodination

The iodide transported into the cell is rapidly incorporated into thyroglobulin (step 2a and 2b, Fig. 3). It must be stressed here that the iodination takes place on the tyrosyl residues of the protein, and not on the free amino acid tyrosine. The sites of substitution are the carbon atoms number 3 or 5 of the tyrosyl ring. When one atom of iodine is substituted, monoiodotyrosyl is formed, with two iodine atoms diiodotyrosyl. The cellular site of the reaction is still a matter of dispute. By radioautography, injected radioiodine can be detected in organic form in the lumen of the follicles within seconds after the injection (NADLER, 1955), which was earlier used as an argument that iodination of thyroglobulin occurred in the follicular lumen. More recently it has been demonstrated that certain cellular organelles are capable of carrying out organic iodination, and the process is now located by most authorities at the interphase between cell and colloid. The cell membrane contains numerous microvilli, which might be the organelles involved in iodination (BEN-ABDELJLIL, 1967). Iodide as such cannot be incorporated into thyroglobulin. Rather it must

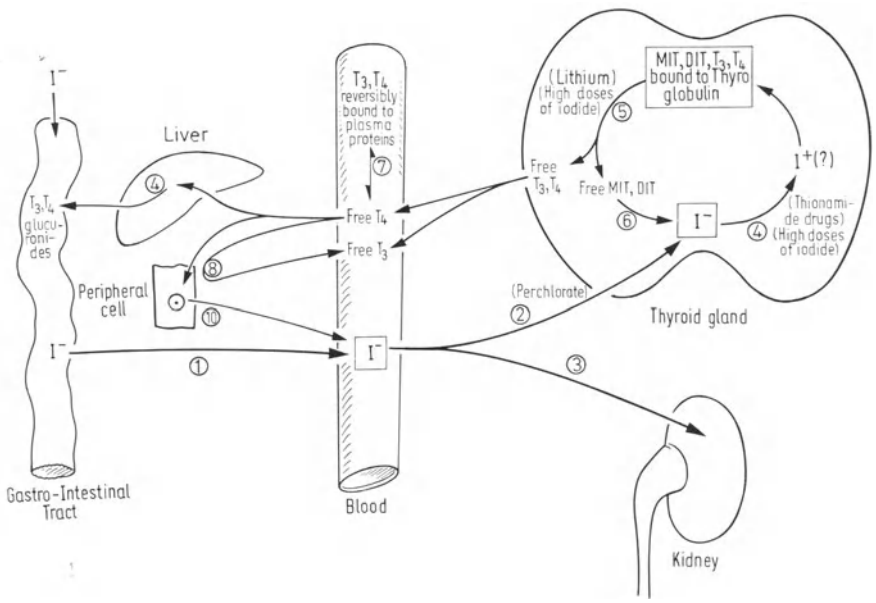

Fig. 4. Main pathways of iodine and thyroid hormone metabolism. 1. Uptake of iodide from the gastrointestinal tract. 2 and 3. Clearance of iodide from the blood by the thyroid and the kidney. 4. Incorporation of iodide into organic compounds of thyroglobulin. 5. Hydrolysis of thyroglobulin. 6. Deiodination of iodotyrosines. 7. Reversible protein binding of thyroid hormones to specific proteins of plasma. 8. Peripheral conversion of thyroxine into triiodothyronine. 9. Conjugation of thyroid hormones with glucuronide in the liver. 10. Deiodination of thyroid hormones by peripheral cells. Inhibitory drugs are indicated in brackets

be oxidized to some more electrophilic intermediate substance. Despite intensive research the exact nature of the iodinating intermediate has not yet been elucidated. MAYBERRY (1964) has presented good arguments suggesting that it is molecular iodine (I_2). Others, however, have claimed that kinetic data are more compatible with a mechanism involving a free iodine radical ($I^{\cdot}$) (NUNEZ, 1969). Finally, hypoiodous acid (HIO^+) or iodinium ion (I^+) are also possible intermediates (HARINGTON, 1944). Whatever the intermediate is, it must be extremely short-lived, since the only forms of iodine found in the thyroid are organic iodine or iodide. Although in chemical systems organic iodination with oxidized iodine intermediates takes place spontaneously, there is now little doubt that the process is catalyzed enzymatically in the thyroid gland. The enzyme involved is most probably a heme-containing peroxidase which has recently been isolated in several laboratories (COVAL, 1967; TAUROG, 1970; DANNER, 1971; POMMIER, 1972). The enzyme is firmly bound to particles which sediment with the microsomal fraction, and relatively drastic procedures are necessary to render it soluble. The various procedures used by different investigators for solubilization probably account for the considerable variations in the chemical properties (molecular weight, heme content, k_m, etc.) from one laboratory to the other. The enzyme uses iodide and hydrogen peroxide as substrates, the latter being generated, for example, during the oxidation of flavin nucleotides. The enzyme may catalyze both the oxidation of iodine, and the transfer of the oxidized intermediate onto thyroglobulin (NUNEZ, 1969; POMMIER, 1973; see p. 283).

c) Coupling Reaction (step 3, Fig. 3)

In theory, thyroxine could be synthesized by the tetraiodination of thyronine, but this pathway is very unlikely, mainly because thyronine has never been found in thyroid tissue. Since v. MUTZENBECHER (1939) had shown that under slightly alcaline conditions diiodotyrosine condenses spontaneously to yield an appreciable amount of thyroxine, this has been the generally accepted pathway of thyroxine biosynthesis (HARRINGTON, 1944; DEGROOT, 1965). The coupling may proceed by the phenoxide ion of one diidotyrosine attacking ring carbon number 1 of a quinoid intermediate of the other diidotyrosyl residue, as envisaged by HARINGTON (1944). Very recently, LAMAS (1972) has reported good evidence that this coupling reaction is also catalyzed by the above-mentioned heme-peroxidase. Since both the subtrate (diiodotyrosine) and the product (thyroxine) of the reaction are part of the thyroglobulin molecule, it seems likely that the reaction involves two peptide-bound diiodotyrosyl residues. However, other reaction schemes involving one peptide-bound diiodotyrosyl and one free derivative, probably diiodohydroxyphenylpyruvic acid, also seem possible (MELTZER, 1961; KOJ TOI, 1965; BLASI, 1969; OGAWARA, 1972). While thyroxine arises from the coupling of two diiodotyrosine molecules, triiodothyronine can be synthesized by the coupling of one monoiodotyrosine to one diiodotyrosine, but this appears to be a minor pathway of triiodothyronine biosynthesis. Recent investigations have shown that the normal human thyroid gland secretes very little triiodothyronine. A large part of this hormone is produced peripherally by the monodeiodination of thyroxine (see p. 143).

d) Thyroglobulin and the Significance of Hormone Stores

Thyroglobulin obviously occupies a central place in the biosynthetic pathway of thyroid hormones, since both the iodination of tyrosyl residues and the coupling reaction proceed on this protein. It has a molecular weight of 660000 and a sedimentation coefficient of 19 S. A small amount of closely related protein with a sedimentation coefficient of 27 S, possibly a dimer of the 19 S protein, is always demonstrable in normal glands. Thyroglobulin contains about 10% carbohydrate. The amino acid and carbohydrate composition of human and other thyroglobulins has been analyzed in great detail (SPIRO, 1970; ARIMA, 1972).

The subunit structure of thyroglobulin is complex and not yet fully elucidated. In an alkaline medium and after reduction of the disulfide bonds thyroglobulin dissociates into 4 subunits of 165000 molecular weight (EDELHOCH, 1965; DE CROMBRUGGHE, 1966). Whether all the subunits are similar or whether the molecule is asymmetric (LISSITZKY, 1968) is still a subject of debate, and much smaller subunits have recently been described (ROLLAND, 1972). The peptide subunits are assembled separately on the ribosomes; the carbohydrate units are added in the endoplasmic reticulum (SPIRO, 1966, 1969) and in a last step the fully assembled protein is iodinated (SEED, 1965; NUNEZ, 1965; VECCHIO, 1972). Normal human thyroglobulin has an iodine content of about 0.2 to 0.7%. Each molecule contains about 120 tyrosyl, 5 monoiodotyrosyl, 3 diiodotyrosyl and 1 to 2 thyroxyl residues. The average triiodothyronine content is less than one residue per mole (ROLLAND, 1972). It must be stressed here that the thyroid

hormones are *covalently* linked to thyroglobulin by peptide bonds, in contrast to their state in plasma, where they are reversibly associated with certain proteins by *non-covalent* bonds (see below).

Thyroglobulin is secreted into the peripheral blood, possibly via lymphatics, in only minimal amounts, except in certain inflammatory and hyperfunctional states of the gland, where significant serum concentrations have been measured (TORRIGIANI, 1969; VAN HERLE, 1973). A small amount of iodinated protein unrelated to thyroglobulin is also present in the normal thyroid. This protein shares many properties with serum albumin (ROBBINS, 1959). It is probably synthesized in the thyroid gland itself (OTTEN, 1971).

The thyroid gland contains remarkably large stores of hormone. The normal iodine content of the gland is about 10 to 20 mg, 30% of which are contained in thyroxine. With an average thyroxine iodine secretion of 50 µg/day (see below) the thyroxine stores would thus be enough to maintain euthyroidism for 50 to 120 days in theory. These large hormone stores are of practical importance, since they explain why antithyroid drugs which block hormone synthesis do not have an immediate effect on thyroid hormone secretion.

e) Hormone Release, Hormone Secretory Rate

Thyroxine and triiodothyronine are stored in the colloid as peptide-linked amino acids of thyroglobulin. When hormone is to be released, small droplets of colloid are engulfed by streamers growing from the apical cell membrane (step 4, Fig. 3). The droplets move into the cell by a process called endocytosis. The colloid droplets then move toward the basal cell pole, fusing en route with primary lysosomes. These particles are thought to contain the proteolytic enzymes necessary for the hydrolysis of thyroglobulin (step 5, Fig. 3). The thyroxine and triiodothyronine thus liberated diffuse into the blood, while mono- and diiodotyrosine are immediately deiodinated within the gland (step 6, Fig. 3) by a potent and quite specific deiodinase (DUMAS, 1973). A large part of the iodide arising is reincorporated into thyroglobulin. It is still matter of discussion whether trace amounts of iodotyrosines leak out from the thyroid. Mono- and diidotyrosine have been identified in peripheral blood in concentrations of about 1 µg/100 ml (WEINER, 1967). More recently radioimmunoassay has yielded a serum concentration of about 250 ng/100 ml for diidotyrosine (NELSON, 1972). The source of these plasma iodotyrosines is not known and it is not at all certain that it is the thyroid.

In the past few years it has been established beyond all doubt that the thyroid gland also secretes iodine in a nonhormonal form. In the dog this has been identified as iodide (NAGATAKI, 1969) generated within the thyroid gland by the deiodination of mono- and diiodotyrosine. There is now convincing evidence that a "nonhormonal iodine leak" of this kind also exists in the normal human gland (WARTOFSKY, 1971; BÜRGI, 1973).

The process of hormone release can be inhibited by pharmacological doses of iodide. The biochemical reaction underlying this iodide effect is totally unknown. The effects of several pharmacological agents on thyroid hormone release have been studied in an *in-vitro* system by WILLIAMS and WOLFF (1971). Colchicine is a potent inhibitor of thyroid hormone release in this system, which suggests that the microtubular-microfilamentous system is involved in the process. A short review on thyroid hormone release has been written by DEISS (1968).

TSH is the main controlling factor for hormone release. In the absence of TSH, hormone release remains minimal. One of the first effects of an injection of TSH on the thyroid is stimulation of endocytosis leading to an increase of colloid droplets within 1 min. Secretion of hormone into the blood follows rapidly (WILLIAMS, 1972).

The mean daily secretory rate for thyroxine in younger persons is about 80 µg per day, corresponding to 52 µg of iodine (ODDIE, 1966). GREGERMAN (1962) has shown that the thyroxine secretory rate declines with age from 80 µg per day at age 20 to about 45 µg per day at age 80.

Due to methodological difficulties the production rates of triiodothyronine are less well established. The best estimates available vary from 20 to 60 µg per day, corresponding to 12–36 µg of iodine (NICOLOFF, 1972; ODDIE, 1971; WOEBER, 1970). As outlined on p. 143 more than 50% of this is now thought to arise outside the thyroid from peripheral deiodination of thyroxine.

3. State of Thyroid Hormone in Plasma, and Disorders of Hormone Binding Plasma Proteins

The concentration of thyroxine in serum of normal persons varies between 5 and 11 µg per 100 ml (3.3 to 7.2 µg iodine per 100 ml). The normal value for triiodothyronine varies widely according to the method of measurement used. STERLING (1969) originally used competitive protein binding and obtained a mean value of

about 220 ng/100 ml. More recent studies using radioimmunoassays (ODDIE, 1971; MITSUMA, 1971; LIEBLICH, 1972; MCCONNON, 1971) or chemical iodine measurement (HORN, 1972) have yielded substantially lower values of 100–150 ng/100 ml serum.

In plasma, 99.97% of thyroxine and 99.70% of triidothyronine circulate bound to proteins. The bonds between protein and hormone are non-covalent, in contrast to the covalent bonds of the hormones to thyroglobulin within the thyroid. This means that the small free hormone fraction in plasma is in dynamic equilibrium with the protein-bound hormone and that ^{131}I-labeled hormone added to plasma rapidly binds to the proteins. Three proteins are involved in the binding: 1. thyroxine-binding globulin (TBG), an alpha globulin, which under specified experimental conditions binds about 60% of the circulating thyroxine. Its molecular weight is 58000*. At full saturation it can bind approximately 20 µg of thyroxine per 100 ml plasma; 2. thyroxine-binding prealbumin (TBPA), with which about 30% of the circulating thyroxine is associated. At full saturation it can bind up to 200 µg of thyroxine per 100 ml plasma; 3. albumin, which binds about 10% of the thyroxine and has a capacity of over 1000 µg per 100 ml plasma. New measurements taken in pH conditions closer to the *in-vivo* situation have shown that TBG probably binds more and TBPA less of the circulating thyroxine (WOEBER, 1968). Triiodothyronine binds less strongly to TBG than thyroxine and probably not at all, or only to a limited extent to TBPA (DAVIS, 1972). The theoretic and clinical implications of the reversible hormone binding to plasma proteins have been reviewed by OPPENHEIMER (1968) and amply discussed in Chap. I of this book (p. 4).

Most authors have found that the thyroid functional status correlates much more closely with the tiny fraction of free hormone than with the protein-bound or total plasma hormone (ROBBINS, 1967). Unfortunately, only specialized research laboratories can measure the free hormone, and most clinicians have to rely on measurements of the concentration of the total hormone. As has been outlined in Chap. I, in accordance with the law of mass action, alterations of serum proteins may elevate or lower the total plasma hormone concentration with no change in the functionally relevant free hormone level. Thus estrogens, now widely used in oral contraceptives, increase the concentration of TBG and cause misleadingly high values of the protein-bound iodine or the total serum thyroxine. The same situation is found in pregnancy, in porphyria (HOLLANDER, 1967), and in infectious hepatitis (VANOTTI, 1959). A rare hereditary disorder with high TBG levels has also been reported (BEIERWALTES, 1959; FLORSHEIM, 1962; REFETOFF, 1972; HODGSON, 1972), sometimes associated with goiter (SHANE, 1971). The reverse is true in patients treated with diphenylhydantoin, a drug which displaces thyroxine from its TBG binding sites and leads to low values for the total serum thyroxine (LARSEN, 1970). TBG levels are also lowered by high doses of corticosteroids and androgenic and anabolic steroids. Salicylates in high doses displace thyroxine from TBG and TBPA and lower the serum total thyroxine concentration (LARSEN, 1972). Stress and fever appear to lower the concentration of TBPA. During acute infections this may temporarily produce decreased binding of hormone to plasma proteins and a reciprocal increase of hormone binding to tissues (DE RUBERTIS, 1972). Androgenic steroids increase the concentration of TBPA. An hereditary decrease in the concentration of TBG has been described in several kindreds. When properly looked for, the defect is not so rare. Affected persons are usually detected incidentally. They have a low total serum thyroxine, but are euthyroid by all other criteria. The defect may be transmitted as an autosomal dominant (HEINONEN, 1970) or more frequently as an X chromosome-linked recessive (TORKINGTON, 1970; NUSYNOWITZ, 1971; REFETOFF, 1972). In the newborn and in the aged more thyroxine is bound to TBG and less to TBPA (SCAZZIGA, 1966). The significance of this finding is not clear. It certainly does not explain the decreased turnover of thyroxine in the elderly (BRAVERMAN, 1966).

4. Peripheral Hormone Metabolism, Conversion of Thyroxine to Triiodothyronine

The half-life of thyroxine in serum is 7 days, that of triiodothyronine 1 day (NICOLOFF, 1972), the difference probably reflecting the different proportion of serum hormone bound to proteins. The half-life of thyroxine is increased in hypothyroidism and decreased in hyperthyroidism. The distribution space of thyroxine is approximately 10 liters, that of triiodothyronine 43 liters (WOEBER, 1970). The liver contains one third of the total extrathyroidal thyroxine, which can rapidly exchange with the plasma thyroxine. Phenobarbital increases hepatocellular binding of thyroxine and stimulates the

* A much lower value has recently been reported (STERLING, 1971).

metabolic breakdown and the turnover rate of thyroxine, but does not alter the plasma concentration of free or protein-bound hormone (OPPENHEIMER, 1968). Only traces of the hormones can be found in the cerebrospinal fluid (CSF).

The thyroid hormones are inactivated mainly in the liver, kidney, brain, and muscle. A good review on thyroid hormone breakdown is given in a paper by PITTMAN (1973). Four processes are responsible for thyroid hormone metabolism:

1. Conjugation of the phenolic hydroxyl group with glucuronic or sulfuric acid. The conjugates are mainly excreted in the bile and a large proportion can be recovered in the feces, although most of the iodine atoms have been removed by deiodination, as discussed below. The ether linkage between the two thyroxine rings appears to remain largely intact during catabolism (PITTMAN, 1970).

2. Oxidative deamination and decarboxylation of the alanine side chain, processes taking place in the liver and in the kidneys. A relatively specific triiodothyronine aminotransferase has recently been demonstrated in these tissues (SOFFER, 1973).

3. Deiodination by a dehalogenase which is different from the enzyme which deiodinates iodotyrosines. This process is very active and has been extensively studied. When labeled thyroxine is given by injection, 80 to 90% of the iodine is excreted in the urine as iodide and the remainder appears in the feces (INGBAR, 1955). Deiodination of thyroxine takes place in muscle, liver, and kidney tissue. In liver part of the iodide is incorporated into butanol-insoluble, probably protein-bound compounds (KOZYREFF, 1970). The products of processes (2) and (3), thyronine and thyroacetic acid, have been unequivocally identified in human urine (PITTMAN, 1972).

An obligatory intermediate in the total deiodination of thyroxine appear to be the monodeiodinated derivatives. Since the deiodination occurs random in the α- or β-ring of the thyroxine molecule, these monodeiodinated intermediates are either the hormone 3,5,3'-triiodothyronine or the hormonally inactive 3,3',5'-triiodothyronine. Half of the degraded thyroxine may thus theoretically be converted to hormonally active triiodothyronine. Only recently has this pathway of triiodothyronine biosynthesis been recognized (STERLING, 1970; PITTMAN, 1971; BRAVERMAN, 1970; SCHWARTZ, 1971; SURKS, 1973). Measurements in man have shown that between 30 and 45% of the degraded thyroxine yields triiodothyronine. This accounts for at least half, if not all of the triiodothyronine produced in the body. The fact that most of the triiodothyronine is produced in extrathyroidal tissues fits well with recent observations that the normal human thyroid gland contains very little triiodothyronine (CHOPRA, 1973). SCHWARTZ (1971) has put forward the daring hypothesis that thyroxine is inactive per se and needs to be converted to triiodothyronine to exert its hormonal effects. Propylthiouracil inhibits the peripheral conversion of thyroxine to triiodothyronine (OPPENHEIMER, 1972, p. 266). Whether this effect is relevant to its antithyroid action in clinical use remains to be established.

4. About 8 μg thyroxine and 3 μg triiodothyronine are excreted unchanged in the urine. This pathway has only recently been explored and offers great promise as a diagnostic test for thyroid function (CHAN, 1972; BURKE, 1972).

5. Mode of Action of Thyroid Hormones

Both clinically and biochemically, thyroid hormones display a confusing multitude of effects on the most varied tissues. Despite considerable research efforts no common denominator or simple biochemical mechanism has yet been detected that could explain all thyroid hormone effects by a unified concept. It now appears that in order to understand thyroid hormone action it is necessary to consider processes as varied as its effects on the cell nucleus, on RNA-synthesis and on cell differentiation, its stimulation of protein synthesis at the translational (ribosomal) level, its effects on mitochondrial respiration and protein synthesis, and finally its influence on the adenyl cyclase system of certain cell membranes individually.

Thyroid hormones bind to many components of peripheral tissues, e.g. to mitochondria in the liver (HOCH, 1968), to soluble cytosol proteins of the kidney (STERLING, 1972), and in the case of triiodothyronine, to nuclei of kidney and liver cells (GRISWOLD, 1972; OPPENHEIMER, 1972). Specific binding sites are present in the anterior pituitary for triiodothyronine but not for thyroxine (SCHADLOW, 1972).

In GRISWOLD'S (1972) experiments, thyroxine injected into tadpoles bound rapidly and firmly to the chromatin of liver cell nuclei. Chemically the bound hormone appeared unaltered. If the tadpoles were kept at 4°C the binding did not take place, which is compatible with the finding that its action on enzyme induction is also inhibited by low temperature. Whether the transfer of thyroxine to the nucleus is similar to that of steroid hormones (p. 15), requiring a soluble cytoplasmic receptor, remains to be established.

The binding sites for thyroid hormone have so far not been further characterized and it is doubtful whether they are all true hormone receptors. Most of the studies have been performed with isotopically labeled thyroid hormones and in some instances it was not easy to remove bound radioactivity from the alleged receptors, as would be expected if the hormone-receptor interaction was reversible, as is postulated by the general theory of hormone action.

Thyroid hormones are also metabolized by many of the tissues they affect (TATA, 1961; MORREALE DE ESCOBAR, 1967, see p. 266; see also preceeding section). OPPENHEIMER (1971) has studied the relationship of thyroid hormone metabolism to thyroid hormone action. Increased hepatic thyroxine metabolism induced by phenobarbital in his experiments was not associated with an increased hormone effect, and he concluded that hormone breakdown was not essential for hormone effect. GALTON (1962), however, has demonstrated that thyroxine has no calorigenic effect in poikilothermic animals which do not metabolize the hormone. The provocative view that thyroxine has no effect *per se,* but must be converted peripherally to thyroxine to be active (SCHWARTZ, 1971) is still a matter of considerable debate. The latest review on all aspects of thyroid hormone action dates back to 1962 (HOCH).

a) Effects on Mitochondria and Respiration

The most conspicuous action of thyroid hormones is their ability to increase oxygen consumption and heat production. This effect is demonstrable in liver, kidney and muscle, but not in the gonads, genital organs, brain, and lymphatic tissue (BARKER, 1952). The ineffectiveness in the latter tissues cannot be attributed to a lack of penetration of hormone, since labeled thyroxine can be recovered from these tissues after injection.

The cellular sites of respiration are the mitochondria, small organelles with a rather complex structure and biochemistry (TAPLEY, 1967). In connection with thyroid hormone action, two fundamental properties of oxidation in mitochondria must be briefly recapitulated. The first is that normally for each atom of oxygen consumed the mitochondrion produces three high energy phosphate bonds as ATP, leading to a so-called P/0 ratio of about three. This phenomenon is known as "coupling" of respiration. The second property of mitochondrial respiration is that of "control" by the amount of substrate available, such as ADP. This control can be demonstrated *in vitro* by the fact that in the absence of ADP (so-called state 4) mitochondrial oxygen consumption is substantially lower than in its presence (state 3). The ratio of state 3 to state 4 respiration is called the "respiratory control ratio".

Ever since the demonstration that thyroid hormone *in vitro* uncouples oxidation, i.e. decreases the number of high-energy phosphate bonds in proportion to the oxygen consumed (HOCH, 1954; LARDY, 1954; MARTIUS, 1955), it has been argued that this constituties its basic mode of action. However, there are several observations which are hard to reconcile with this view. Firstly, high, unphysiologic concentrations of thyroxine are necessary to uncouple respiration. Secondly, D-thyroxine, which has only a low activity *in vivo*, is as effective an uncoupling agent as L-thyroxine. Thirdly, dinitrophenol, a potent uncoupling agent, though increasing oxygen consumption, does not reverse the other symptoms in hypothyroid patients. Lastly, treatment of thyroidectomized animals with thyroxine does not decrease the P/0 ratio (BRONK, 1962). Although there has been one report of uncoupled respiration in mitochondria from hyperthyroid patients (ERNSTER, 1959), this has not been confirmed in later careful studies (STOCKER, 1968). Stocker also found a normal respiratory control ratio in the mitochondria of hyperthyroid patients, which is in contrast to animal experiments, where thyroxine given *in vivo* lowers the respiratory control (HOCH, 1967; VOLFIN, 1969; KIMATA, 1971). The current prevailing view is that thyroid hormone undoubtedly increases oxygen consumption, and may depress the respiratory control ratio, but that it does not cause uncoupling in concentrations that occur in physiological conditions or in hyperthyroidism.

More recently it has been recognized that thyroid hormone stimulates protein synthesis in mitochondria. This effect occurs within 3 hours of a thyroxine injection, i.e. much earlier than the stimulation of ribosomal protein synthesis discussed below (PRIMACK, 1970). VOLFIN (1969) found that thyroxine specifically stimulated the synthesis of a few distinct mitochondrial proteins. The relationship between this early protein synthesis and the stimulation of respiration is not clear. KAPLAY (1971) reported that he eluted a protein from thyroxine-stimulated mitochondria which, when added *in vitro* to untreated mitochondria, enhanced their oxygen consumption. BUCHANAN (1971), in contrast, found that thyroxine stimulated oxygen consumption in mitochondria even when mitochondrial protein synthesis was blocked with chloramphenicol or puromycin.

Finally it has been observed that thyroxine produces swelling of mitochondria *in vitro* (LEHNINGER, 1959, 1962; GREIF, 1962). This effect is not specific and can be elicited with insulin. Its significance is unknown. ISMAIL-BEIGI (1971) has related the calorigenic effect of thyroid hormone to the transport of Na^+ or K^+ across the cell membrane. He found that thyroid hormone did not stimulate oxygen consumption in liver tissue when the Na^+ or K^+ transport was inhibited by ouabain. He proposed that the primary effect of thyroid hormone was the stimulation of Na^+ transport, which in turn necessitated a higher oxygen consumption to provide the required energy.

b) Effects on Cellular Differentiation, Growth, and Protein Synthesis

The effects discussed under this heading are all interrelated biochemically and are therefore best treated together. Probably one of the most spectacular hormone effects known to biologists is the induction of the metamorphosis of tadpoles by thyroxine. Indeed it seems that the only function of thyroid hormone in anurae is to assure proper metamorphosis. The study of this phenomenon has come a long way from the classic morphologic and embryologic investigations towards a biochemical understanding of the processes involved. An excellent example is provided by the work of COHEN and co-workers (PAIK, 1961; COHEN, 1970), who studied the appearance of the enzymes necessary for urea synthesis in the liver. These enzymes are not present in the tadpole. They have provided conclusive evidence that thyroxine is necessary for this enzyme induction and that its site of action is the cell nucleus, where it stimulates the synthesis of DNA-dependent RNA polymerase, an enzyme necessary for the production of mRNA (GRISWOLD, 1972, see Chap. I).

The fact that hypothyroid children have a decreased growth rate which is restored to normal by thyroid hormone treatment has its biochemical correlate in the stimulatory effect of thyroxine on protein synthesis. Within 2 hours after administration of triiodothyronine to animals by injection, the microsomal protein synthesis in the liver is enhanced (SOKOLOFF, 1968). This "early" effect on protein synthesis is dependent upon the presence of mitochondria or an ATP-generating system in the incubation medium (CARTER, 1971). It should not be confused with the rapid stimulation of mitochondrial protein synthesis described in the previous section, since it is clearly an effect on ribosomal function. The effect is independent of mRNA synthesis; it precedes any change in mRNA concentration in the cell and it is not blocked by actinomycin D. Thus it must be a hormone action at the translational (ribosomal) level (see also Chap. I). An independent "late" effect on protein synthesis in the liver can also be observed (SOKOLOFF, 1964; TATA, 1966, 1967, 1968). This late effect is independent of the presence of mitochondria, but requires the synthesis of mRNA. It is therefore thought to be due to a hormone effect on the transcription of RNA in the cell nucleus, analogous to changes observed during anuran metamorphosis. Thyroid hormone effects on the enzymes of the central nervous system are discussed on p. 147.

c) Effects on the Cardiovascular System and on the Adenyl Cyclase System

It is a familar clinical observation that thyroid hormone increases the heart rate and widens the pulse pressure. In hyperthyroidism the stroke volume usually increases but occasionally remains constant or decreases. The cardiac output increases, and, although the peripheral vascular resistance decreases, the mycocardial workload becomes greater. The cardiac output increases more than would be expected on the basis of the enhanced peripheral oxygen consumption (DE GROOT, 1970). Increased excitability of the cardiac conductive tissue is found before a change in heart rate (ZAIMIS, 1969). Premature beats and auricular fibrillation occur frequently in hyperthyroidism (cf. p. 184, 207).

The effects of thyroid hormone on the heart are reversed in part by beta-adrenergic blocking agents (see p. 150 and p. 197). In many ways the effects of thyroid hormones on the heart resemble those of catecholamines. It is now firmly established that the catecholamine actions on the heart are mediated by the adenyl cyclase system (Chap. I), and it therefore seemed logical to look for a similar mechanism in the case of thyroid hormones. The first hypothesis to be examined was whether thyroid hormone simply acted by increasing the myocardial sensitivity to catecholamines. This view was clearly refuted by observations that thyroid hormone affected the contractility regardless of the level of circulating catecholamines (BUCCINO, 1967) and that the dose-response curve for epinephrine on papillary muscles of hyperthyroid cats was identical to that obtained with tissues from normal cats, both when cyclic AMP generation was measured and when contractility was used as a measure of response (LEVEY, 1969). A second question was whether the amount of adenyl cyclase was controlled

by thyroid hormone. Although myocardial total adenyl cyclase was slightly diminished in hypothyroidism, this was not thought sufficient to account for the effects of thyroid hormones (LEVEY, 1971). Most evidence now points to a direct stimulation of adenyl cyclase by the thyroid hormones independent of that of catecholamines (LEVEY, 1969). This complex problem has recently been well reviewed by LEVEY (1971), but his view has been challenged by recent work of WILDENTHAL (1972), who maintained fetal mouse hearts in organ culture and was therefore able to study the effects of thyroid hormone in carefully controlled catecholamine concentrations. Exposure of the explanted hearts to triiodothyronine for three days did not change their basal beating rate, but sensitivity to norepinephrine was significantly enhanced. Further research is necessary on this difficult question.

d) Effects on Lipid and Adipose Tissue Metabolism

Thyroid hormones enhance the degradation of cholesterol, and to a lesser degree its synthesis. As a result, serum cholesterol is low in hyperthyroidism and high in hypothyroidism. It has also been known for some time that thyroid hormone increases lipolysis and the release of free fatty acids in adipose tissue (CHALLONER, 1970). KRISHNA (1968) has suggested that this effect is due to an increased amount of adenyl cyclase by *de-novo* synthesis of enzyme protein. a view corroborated by CALDWELL'S (1971) findings.

e) Thyroid Hormone Effects on the Central Nervous System and on Neuromuscular Function

In view of the profound neurologic changes observed in hyper- and hypothyroidism there can be no doubt that thyroid hormone affects brain and nerve metabolism. Hypothyroidism produces a general slowing of most cerebral functions, although orientation in space and time and recognition of objects are maintained intact except in the severest cases. The biochemical substrate for this phenomenon is not known. Since thyroid hormones have no influence on cerebral O_2 consumption (BARKER, 1952) it cannot be explained by decreased energy metabolism. It may be related to the stimulatory effect of thyroid hormone on cerebral protein biosynthesis (GELBER, 1964). In adult men or animals, hypothyroid changes in cerebral function are entirely reversible with thyroid hormone substitution. This is not true of cerebral changes produced by hypothyroidism in fetal life or during infancy. It is a common clinical observation that congenitally hypothyroid children remain mentally retarded despite thyroid hormone substitution if there has been any delay in instituting the treatment. Recent advances in neurobiochemistry have provided detailed information on the development of the central nervous system. It appears that cerebral maturation proceeds in a series of steps with the synthesis of particular proteins, enzymes, and lipids, each appearing at a relatively fixed point in fetal or infantile life. In rats, WYSOCKI (1972) has studied the appearance of two enzymes associated with myelin formation in the nervous system, UDP galactose: sphingosine galactosyl transferase, and 2′:3′ nucleotide 3′-phosphohydrolase. Both enzymes are present in reduced amounts in brains of hypothyroid neonate rats. Regular thyroid hormone substitution from the first day of life onward brings the enzyme back to normal. If thyroid hormone substitution is not started until the 8th day of life the enzymes remain irreversibly low. Unfortunately, comparable information is not available for man and we do not known the exact time when thyroid hormone lack produces irreversible brain damage.

Muscular contraction is impaired in hypo- as well as in hyperthyroidism. An extreme form is observed in Japan where there is a strikingly high incidence of acute attacks of hypokalemia and muscular paralysis (p. 186). In a careful study of thyroid hormone effects on the neuromuscular junction, HOFMANN (1972) showed that the membrane potentials of hyperthyroid muscles were decreased. This may explain the susceptibility of hyperthyroid patients to hypokalemic paralysis. Very few electrophysiological changes were observed in hypothyroid nerve-muscle preparations, and no explanation was found for the clinically important slowing of reflexes in hypothyroidism.

f) Other Thyroid Hormone Effects

Thyroid hormone increases calcium and phosphate turnover and calcium loss in both stools and urine. Osteoblasts and, even more, osteoclasts become activated in hyperthyroidism, producing a measureable increase of the alkaline phosphatase of serum (EPSTEIN, 1968). Hyperthyroidism is also often associated with osteoporosis. However, hypothyroid patients tend to become hypercalcemic easily under calcium loads. Patients who suffer from hypoparathyroidism and hypothyroidism after thyroid sugery usually show a decreased requirement for vitamin D when properly substituted with thyroxine. Thyroxine treatment markedly enhances bidirectional transport (in particular

influx) of magnesium and calcium in liver slices (WALLACH, 1972).

Thyroid hormone has a complex effect on carbohydrate metabolism. In high doses thyroxine diminishes the liver glycogen content, while in small doses it enhances glycogen synthesis. Oral glucose tolerance tests are sometimes abnormal in hyperthyroidism. This may be due partly to a more rapid intestinal sugar absorption and partly to increased gluconeogenesis (HEITZMANN, 1971). Thyroid hormone probably enhances glucose metabolism in adipose tissue (BUTTERFIELD, 1964). Hyperthyroidism increases the caloric and therefore the insulin requirement in concomitant diabetes.

During hyperthyroidism, urinary creatine excretion is increased and creatinine excretion decreased. The reverse is true in hypothyroidism. The synthesis of creatine is probably not changed, but creatine cannot be retained in the tissues in hyperthyroidism due to inhibition of creatine phosphokinase (KUHLBÄCK, 1957; ASKONAS, 1959).

Thyroid hormones produce a proliferation of lymphatic tissue. The thymus is often atrophic in hypothyroidism and enlarged in hyperthyroidism, but this may also be due to associated autoimmunologic processes.

Thyroid hormone stimulates hemoglobin synthesis *in vitro* in bone-marrow cultures (FUHR, 1970). This may have some connection with the anemia often present in hypothyroidism, but doctors will object that moderate unexplained anemia is also a feature of hyperthyroidism. Thyroid hormone added to erythrocytes *in vitro* increases their content of 2,3-di-phosphoglyceric acid by an activation of 1,3-di-phosphoglyceric acid mutase. Since the former compound has a profound influence on oxygen transport in blood, this effect may have some clinical importance (SNYDER, 1970).

6. Control of Thyroid Hormone Biosynthesis and Release

The main factor controlling thyroid function is TSH. In addition, the thyroid has the capacity for limited autonomous control.

a) Hypothalamic Control, TRH

It was recognized long ago that neural factors were involved in the control of TSH secretion in laboratory animals. For example, a low ambient temperature, stress of any other kind and a change in atmospheric pressure* were recognized as being capable of increasing thyroid hormone secretion under appropriate conditions. After small lesions at specific sites of the hypothalamus, rats showed signs of hypothyroidism and a lowered serum thyroid hormone concentration, though the TSH feedback was not completely abolished and the animals were still capable of responding to a goitrogen with thyroid hyperplasia. It is from these observations that the concept of the neuroendocrine control of TSH secretion has evolved (BROWN-GRANT, 1957, 1960, 1967; AVERILL, 1961; GUILLEMIN, 1964). Further studies have culminated in the isolation of a tripeptide from porcine (NAIR, 1970) or ovine (BURGUS, 1970) hypothalamus, which after injection into animals or man or after addition to the incubation medium of surviving pituitary slices causes the release of TSH. The chemical formula of this tripeptide, which has been termed thyrotropin-releasing hormone (TRH), is L-(pyro)glutamyl-L-histidyl-prolinamide. The hormone can now be chemically synthesized in large quantities and the easy availability has led to numerous publications on its effects and the development of a very useful clinical test (ANDERSON, 1971). Short reviews have been published by BURGUS (1970) an HERSHMAN (1971).

The main features of the hypothalamic control of TSH secretion are as follows: Upon neural inputs, which can also be generated by implanted electrodes, the hypothalamus secretes TRH into the venous blood, where its concentration can be measured by bioassay (WILBER, 1970). Before being diluted in the total circulating blood volume TRH reaches the anterior pituitary via a small system of portal vessels and produces a rapid release of TSH. Feedback control by thyroid hormone probably operates on several loops of this complex system. One loop, probably the main one, functions by a direct effect of thyroid hormone on the anterior pituitary. This is nicely demonstrated by the fact that TSH secretion is greatly increased upon injection of a standardized amount of TRH in hypothyroid patients and decreased or absent in hyperthyroid patients. In addition, receptors for triiodothyronine have recently been observed in the pituitary (SCHADLOW, 1972, p. 251). A second feedback loop goes to the hypothalamus, where thyroid hormone inhibits the release of TRH, but at present this loop is more difficult to demonstrate experimentally. The first loop (thyroid-pituitary) can operate in the absence of TRH, although TSH secretion is diminished. In other words, TRH changes the set point of the pituitary response to the circulating thyroid hormone level.

* It must be emphasized that in man the same stimuli provoke no or only a limited response of TSH secretion.

b) Anterior Pituitary. TSH

The function of the normal thyroid gland is controlled by thyrotropin (thyroid stimulating hormone, TSH), which is produced by the basophil cells of the anterior pituitary gland. TSH for diagnostic and research purposes is usually prepared from pituitary extracts. Highly purified preparations have been made from such extracts, and LIAO (1971) has recently reported the primary structure of bovine TSH. The hormone contains 15% carbohydrate and consists of two peptide chains, one of which (the alpha chain) is identical with the alpha chain of luteinizing hormone (LH). Hybrids between TSH-beta and LH-alpha have normal biologic activity on the thyroid comparable to that of recombined TSH-alpha and TSH-beta (PIERCE, 1971). The molecular weight of the hormone is 28000. Even the purest preparations are found not to be homogeneous when tested by sensitive methods such as gel electrophoresis. This microheterogeneity is probably not the result of variations in the primary amino-acid sequence, but rather of a varying amide or carbohydrate content. The potency of TSH preparations is usually measured in a bioassay and expressed in units of an international or a comparable USP standard. More recently, a limited supply of a standard containing human TSH, so-called HTRS-A, has become available (see REICHERT, 1970, for comparison of both standards). The purest TSH preparations have potencies of 20–40 U/mg, exceptionally 100 U/mg (BATES, 1960 and 1968). Human and bovine TSH show incomplete immunologic cross-reactivity. In the mouse bioassay, human and bovine TSH give different standard curves.

TSH affects numerous parameters of the metabolism of the thyroid gland. Within minutes after injection or addition to an incubation medium, stimulation of colloid endocytosis, of glucose oxidation, of phosphate incorporation into lipids and of RNA synthesis are easily measured. The last effect is probably a consequence of increased ribose availability due to oxidation of glucose via the pentose monophosphate pathway, but the other effects seem to be independent of each other. TSH also enhances synthesis of thyroglobulin and incorporation of iodine into organic compounds. On the whole, TSH-induced colloid endocytosis predominates over thyroglobulin synthesis, and TSH-stimulated glands are characteristically poor in colloid and thyroglobulin. Active iodide transport is also stimulated by TSH, but this effect has proved more difficult to demonstrate, because it has a latency of several hours. Finally, TSH causes growth of the thyroid gland. Most, if not all, effects of TSH are mediated by the adenyl cyclase-cyclic AMP system and can be reproduced by the addition of cyclic AMP or derivatives (J. B. FIELD, 1968; BURKE, 1971). Cyclic AMP-dependent protein kinases have also been demonstrated in thyroid tissue (RAPPAPORT, 1971). Recent short (FIELD, 1968; BURKE, 1971; LIBERTI, 1971) and extensive (DUMONT, 1971) reviews on TSH action are available. An interesting feature of unknown physiologic significance is that TSH also has extrathyroidal effects. Notably it enhances lipolysis in adipose tissue (FREINKEL, 1961).

TSH can now be measured in human serum by a specific radioimmunoassay. Most assays use rabbit antisera against human TSH, rarely against bovine or porcine TSH. The human TSH research standard A is the reference source. Initially the assays were not sensitive enough to measure TSH in all normal subjects (ODELL, 1967). In the meantime, sensitivity has been improved and TSH is now dectectable in most, though still not all, sera of normal persons (HALL, 1971; PATEL, 1971). Normal values vary considerably from one laboratory to the other due to the fact that each research group uses its own antibody and sometimes also individual standards. The most sensitive assays now detect any values over 0.5 μU/ml (HALL, 1971, PATEL, 1971) and the normal range extends from unmeasurable to about 5 μU/ml. Values over 10 μU/ml are clearly above the normal range in most current assays. The reliability and clinical usefulness of the TSH radioimmunoassay are now well established (HERSHMAN, 1971; MAYBERRY, 1971), although problems of sensitivity and specificity still persist, particularly in the low and low normal range. It is difficult to understand, for example, that many laboratories measure normal values in sera of frankly thyrotoxic patients (BECKERS, 1971), when low or unmeasurable values would obviously be expected. In addition, bioassay measurements give consistently lower values in normal sera than the immunoassay (ADAMS, 1972). Technical improvements to the latter method have recently overcome some of the difficulties (PATEL, 1971).

The TSH distribution space is about 50% larger than the plasma volume. The serum half-life of injected TSH is 30–100 min in euthyroidism. It is longer in hypothyroidism and shorter in hyperthyroidism (ODELL, 1967). ODELL (1967) found a mean daily secretory rate of 165 mU, while BECKERS (1971) reported a value of 420 mU/day and attributed his higher value to the borderline low iodine intake of his normal subjects.

As anticipated, the plasma TSH concentration shows a close inverse correlation with the concentration of the free portion of serum thyroxine (REICHLIN, 1967), and very high values are found in primary hypothyroidism. In fact, the TSH immunoassay has been most useful in detecting borderline cases of thyroid failure, since TSH levels are often frankly elevated when the serum total thyroxine is still in the normal range.

In the first 24 hours after birth TSH in plasma shows a sharp rise to high levels and returns to normal after one or two days. The values then remain very constant throughout childhood and adult life. In rat diurnal variations of TSH secretion have been demonstrated by BAKKE (1965). Such variations were not detectable in man initially (ODELL, 1967; LEMARCHAND, 1969; WEBSTER, 1972), but NICOLOFF (1970) has recently obtained good evidence for a diurnal rhythm of thyroidal iodine release, which he attributes to oscillations in TSH secretion. From very recent measurements it appears that TSH levels are very constant throughout night and day except in the early morning hours, when a short marked peak is observed (VANHAELST, 1972). Unlike rats, humans do not react to exposure to cold with secretion of TSH (ODELL, 1967), except in children in whom severe hypothermia is induced for heart surgery (WILBER, 1970).

c) Thyroid Autoregulation

Evidence for thyroid autoregulation independent of TSH stems largely from experiments in hypophysectomized rats subjected to iodine deficiency, and little is known about its importance in man. Thus it has been found that the thyroid gland may control its hormone secretion in response to small changes in the plasma iodide level or the total thyroidal iodine content before changes in circulating TSH become apparent (STUDER, 1965, 1966; STEIGER, 1969). Hypophysectomized rats are still capable of increasing active iodide transport in response to iodine deficiency (HALMI, 1956), and it has been postulated that an iodinated organic iodine intermediate, if present in sufficient amounts, will depress active iodide transport. In iodine deficiency this organic iodine compound would be diminished and iodide transport activated. INGBAR (1972) has written a concise review on thyroid autoregulation.

d) Prostaglandins, Biogenic Amines and Autonomic Nervous System

Prostaglandin PGE-1 reproduces practically every effect of TSH on thyroid slices *in vitro* by activating adenyl cyclase (ZOR, 1969). In mice, epinephrine, norepinephrine, 5-hydroxitryptamine, and even electrical stimulation of the cervical sympathetic trunk cause colloid droplet formation (MELANDER, 1972). Vagal stimulation has also been shown to induce hormone release (ISHII, 1968). In isolated thyroid cells epinephrine and serotonin stimulate organic iodination and glucose metabolism (MAAYAN, 1968, 1971). The vascular blood supply of the thyroid also appears to be influenced by the autonomic nervous system (SÖDERBERG, 1959; LEAK, 1970). The physiologic importance of these effects is not yet known.

7. The Thyroid in Relation to Other Endocrine Glands

a) Adrenal Medulla

The effects of thyroid hormones, particularly on the heart, resemble those of catecholamines. Alpha-receptor blocking agents, such as phentolamine, may diminish the tachycardia, hyperhydrosis, and tremor of hyperthyroidism even while not affecting oxygen consumption and cardiac index. Beta-receptor blocking drugs also produce an impressive improvement of the tremor, tachycardia, and other symptoms of hyperthyroidism, including the increased cardiac index (HOWITT, 1966; PIETRAS, 1972) and reduced circulation time (GROSSMAN, 1971). This may be interpreted as indirect evidence that the thyroid hormones act via the catecholamines, e.g. by sensitizing the tissues to the effects of epinephrine. However, present experimental evidence (WILSON, 1966; ZAIMIS, 1969; see also section on mode of action of thyroid hormones) is not compatible with this view, and it is now generally accepted that thyroid hormones exert a catecholamine-like effect *per se*.

In some experimental conditions epinephrine may enhance the synthesis and release of thyroid hormones (FALCONER, 1965, 1967, see also preceding section). Norepinephrine increases thyroid blood flow and produces an increase in the volume of the gland, possibly by constriction of the small veins (MOWBRAY, 1960).

Epinephrine enhances the peripheral degradation of thyroid hormone in rat (GALTON, 1965), but in man the reverse may be true. The problems of thyroid-catecholamine interrelations have been reviewed by LEAK (1970).

b) Adrenal Cortex

Cortisol breakdown is enhanced in hyperthyroidism. Due to the feedback mechanism,

which leads to an increased secretion of ACTH and hypertrophy of the adrenal cortex, normal cortisol concentration in plasma is maintained. The excretion of 17-hydroxycorticoids is also increased. In hypothyroidism, the metabolism of the adrenal cortical hormones by hydrogenation is decreased, and the excretion of 17-hydroxycorticoids is reduced.

In severe hypothyroidism, the decreased metabolic clearance of cortisol leads to hypotrophy of the adrenal cortices via decreased ACTH secretion, with adrenal insufficiency in times of increased requirements. The response in the ACTH-test is variable, but the metopyrapon test reveals a normal ACTH reserve.

Cortisone in high doses inhibits the rate of secretion of the thyroid hormones, increases the renal iodine clearance, and diminishes the binding of thyroxine to thyroxine-binding globulin. On the other hand, in patients without adrenal glands, ACTH has a stimulating effect on the uptake of ^{131}I by the thyroid gland.

c) Ovaries

Estrogens increase the concentration of thyroxine-binding globulin in plasma. As outlined in the section on thyroid hormone transport, this produces a rise in the protein-bound iodine or the serum total thyroxine. However, the concentration of free thyroxine in plasma remains constant, and the euthyroid state is maintained. A resin T_3-uptake test in the hypothyroid range will alert the doctor to the fact that the increased serum total thyroxine reflects a change in thyroxine-binding globulin rather than hyperthyroidism. Hormonal contraceptives containing estrogens have the same effect.

d) Testes

Androgens and anabolic synthetic steroid hormones, in contrast to estrogens, lower the thyroxine-binding globulin. The serum total thyroxine becomes lowered, but the T_3-resin test changes in the opposite direction, assuming hyperthyroid values. The free serum thyroxine remains constant.

e) Thyroid Gland and Pregnancy

In pregnancy the thyroid gland may increase in size, but how often this occurs and whether it only takes place in areas of limited dietary iodine supply is still controversial. Due to the action of estrogen the total serum thyroxine rises and the resin T_3-uptake test is shifted into the hypothyroid range (see above). The free serum thyroxine again remains constant.

The basal metabolic rate increases during pregnancy. This is probably not due to a true hypermetabolic state, but reflects increased metabolic mass due to the fetal tissues, or increased cardiac work. The radioiodine uptake of the thyroid is moderately increased in pregnancy, but the significance of this finding is unknown (STEIN, 1973).

Fertility is much reduced in hypothyroidism. If pregnancy does occur, miscarriage or fetal malformations are frequent. Occasionally even a severely hypothyroid woman gives birth to a perfectly normal child. In contrast, mild to moderate hyperthyroidism has very few deleterious effects on pregnancy and the fetus, but this does not mean that the management of hyperthyroidism during pregnancy is easy, nor that it should be neglected. Children born to hyperthyroid mothers sometimes suffer from neonatal hyperthyroidism, allegedly due to placental transfer of LATS, which can be measured in the plasma of the offspring (p. 200). The condition clears spontaneously parallel to the disapperance of LATS from the plasma of the newborn.

TSH does not cross the placenta from mother to child or in the reverse direction. TSH-like substances can be extracted from human placental tissue, but their physiologic significance is totally unknown (see section on hyperthyroidism, p. 209).

The important question as to what extent thyroid hormones do cross the placenta has not yet been satisfactorily settled. In the human fetus the concentration of thyroid hormone in plasma is much lower than in maternal plasma, especially in the first two trimesters. However, fetal thyroxine-binding globulin is equally low, and therefore the crucial free thyroxine concentration could be the same on either side of the placental barrier in theory. More recently, careful measurements of free thyroxine in the maternal and fetal circulation from the 8th to the 24th week of gestation have established that before the 10th week no free thyroxine is present in the fetus. The concentration then rises rapidly, but there is no correlation with the maternal concentration (GREENBERG, 1970). When labeled thyroxine is admistered by injection to the mother, most of the ^{131}I is recovered in the fetus as iodide, and only a very small part as hormone. ROBIN (1972) has given an excellent short review of the problem. In his own experiments ^{131}I from labeled thyroxine injected into pregnant sheep appeared in the fetus mostly as iodide and only in small amounts as thyroxine. He concluded that there was a small but significant two-way flux of thyroxine across the placenta. Treatment of hyperthyroidism with

antithyroid drugs during pregnancy may produce fetal hypothyroidism and goiter despite the fact that the mother is intentionally left slightly hyperthyroid. In our view, all this evidence taken together confirms that thyroid hormones cross the placental barrier from mother to fetus to a very limited extent if at all, despite claims to the contrary (RAITI, 1967). The fetus is therefore dependent on its own production of thyroid hormone; since most antithyroid drugs, including iodide, cross the placental barrier, this greatly complicates the treatment of hyperthyroidism during pregnancy.

Iodide is actively transported across the placenta into the fetal circulation. This transport can be inhibited by thiocyanate (MYANT, 1958). Pharmacological doses of iodide administered to the mother, e.g. for the management of asthma, have produced severe fetal hypothyroidism and goiter (p. 167).

8. Changes of Thyroid Function in Diseases of Other Organs

a) Diseases of the Liver

In obstructive jaundice, conjugates of thyroxine, particularly glucuronides, circulate in the plasma and may elevate the level of protein-bound iodine (VANOTTI, 1959). Hepatitis and acute intermittent porphyria increase the thyroxine-binding globulin level and therefore the protein-bound iodine and the total serum thyroxine. In cirrhosis the thyroidal radioiodine uptake is sometimes increased, probably due to deficient dietary iodine intake associated with the poor nutritional status of alcoholics. The reverse, a low radioiodine uptake, has also been described in patients with cirrhosis (HOLLANDER, 1967). The variations of thyroxine-binding globulin in chronic liver disease are unpredictable, so that the total serum thyroxine may be normal, elevated or decreased (HOLLANDER, 1967). MCCONNON (1972) recently investigated the effect of liver cirrhosis on thyroid hormone turnover. He found that the production rate of triidothyronine was doubled in cirrhosis, whereas that of thyroxine was decreased by about 30%.

b) Renal Disease

In renal insufficiency iodide clearance by the kidney is decreased. Since an oral dose of radioactive iodine is divided between the thyroid gland and the kidney, the obvious consequence of renal disease might seem to be increased thyroidal uptake. This reasoning does not, however, take into account that the plasma iodide level rises due to impaired renal iodide clearance. This in turn lowers the thyroidal iodide clearance, either by autoregulation or by the TSH feedback system. Therefore thyroidal radioiodine uptake is in fact normal in most cases of kidney disease even in anephric patients (ODDIE, 1970). In the nephrotic syndrome the total serum thyroxine is often low. Whether this is due to a loss of hormone in the urine or to a loss or decreased synthesis of thyroxine-binding globulin (CRUCHAUD, 1954; RASMUSSEN, 1958) is not yet known. Usually the free thyroxine in the serum remains normal and a euthyroid state is maintained (HERMANN, 1972).

Increased amounts of TSH are excreted in the urine of rats rendered nephrotic by puromycin (IFF, 1969). Some clinical features of chronic uremia are similar to those of hypothyroidism, and FANKHAUSER (1968) has found some evidence of secondary hypothyroidism in about one third of uremic patients.

D. Hypothyroidism in the Adult

1. Classification

As with the other endocrine glands controlled by the anterior pituitary, hypofunction of the thyroid gland can be divided into a primary form due to failure of thyroid tissue itself and a secondary form due to a deficiency of TSH secretion. Plasma TSH is elevated in the former and low in the latter case. In primary hypothyroidism the thyroid gland is already under intense stimulation by endogenous TSH, and injection of TSH has no further stimulatory

Table 1. Thyroid diseases with hypothyroidism. The nomenclature, but not the classification, of the American Thyroid Association is used (WERNER, 1969)

1. *Primary hypothyroidism*
   - a) Idiopathic myxedema (chronic lymphocytic thyroiditis, atrophic variant)
   - b) Aplasia or ectopism of thyroid tissue
   - c) Destruction of thyroid tissue by
     - Surgery
     - Radioiodine
     - External radiation
   - d) Drug-induced hypothyroidism
     - Thionamide drugs
     - Perchlorate
     - Iodide (high doses)
     - Others (lithium etc.)
   - e) Inborn errors of hormonal synthesis (familial goiter)
   - f) Endemic cretinism, hypothyroid variant
2. *Secondary hypothyroidism*
   - a) Thyrotropin deficiency
     - Isolated
     - Panhypopituitarism
   - b) Thyrotropin-releasing hormone deficiency

effect. In secondary hypothyroidism the thyroid responds well to exogenous TSH. Myxedema describes alterations in the skin that are often but not always found in hypothyroid patients. Some authors use the term interchangeably with hypothyroidism, others only for severe forms of the disease.

Endemic cretinism occupies a special place in the classification. Hypothyroidism does not explain all its features and incidentally is not always present in endemic cretins (p. 215).

Our nomenclature roughly follows that adopted by the American Thyroid Association (WERNER, 1969), but the classification is somewhat different (Table 1).

2. Primary Hypothyroidism

a) Etiology

α) Idiopathic Hypothyroidism (synonyms: spontaneous or primary thyroid atrophy; chronic thyroiditis, atrophic variant)

This is the commonest form of spontaneous hypothyroidism in the adult and is now considered the end result of a chronic inflammatory process. Of the patients with this form of hypothyroidism 83% have serum antibodies to components of thyroid tissue, an incidence only surpassed in chronic lymphocytic thyroiditis (97%). Most authorities now agree that idiopathic hypothyroidism is the end result of a process basically similar to chronic lymphocytic thyroiditis (DONIACH, 1963; BASTÉNIE, 1972) and that it is an autoimmunological disease. Just how many patients with chronic lymphocytic thyroiditis progress into myxedema is not known. Only a few patients with idiopathic hypothyroidism give a history of a transient goiter, such as would be expected if they had suffered from classic chronic lymphocytic thyroiditis. Therefore the suffixes asymptomatic or atrophic variant have been coined to differentiate this disease from the ordinary chronic lymphocytic thyroiditis. Patients with idiopathic hypothyroidism and those with chronic lymphocytic thyroiditis often give a family history of the disease. Relatives of patients have an increased incidence of serum antibodies to thyroid tissue, but only a few have overt thyroid disease.

Women are afflicted with idiopathic hypothyroidism five times as frequently as men. More than 70% of cases are diagnosed after the age of 50 (BASTÉNIE, 1972). Children, however, are also affected in rare cases. A few cases of Graves' disease progressing spontaneously into idiopathic hypothyroidism later have been observed (MEANS, 1963).

BASTÉNIE (1971) has recently described a subclinical or asymptomatic variety of this form of hypothyroidism, which he found associated with early coronary artery disease. Subacute nonsuppurative thyroiditis occasionally causes transient hypothyroidism, but only very few of these patients ultimately develop permanent myxedema (IVY, 1961).

On pathological examination (Fig. 35, p. 225) the thyroid gland of a patient with idiopathic hypothyroidism is usually small in size (< 20 g). The histological picture varies between the extremes of lymphocytic thyroiditis with mostly intact follicles to a dense fibrous tissue with few epithelial cells left (BASTÉNIE, 1972).

β) Hypothyroidism due to Aplasia or Ectopism of Thyroid Tissue (is discussed on p. 166)

γ) Hypothyroidism due to Thyroid Destruction

With the increasing use of radioiodine therapy for thyrotoxicosis this will probably soon be the most frequent cause of hypothyroidism. The original claims by some authors that elaborate calculation of the dose or administration of low doses will prevent this complication of treatment with radioiodine has not been substantiated by careful studies. The prevailing view now is that the dose probably affects the incidence of hypothyroidism after one or two years, but that thereafter an additional 2 to 5% of the patients become hypothyroid each year irrespective of the dose (see section on hyperthyroidism and also the excellent short review by GLENNON, 1972).

The thyroid gland is usually considered quite resistant to external radiation and occasional cases of hypothyroidism after X-ray therapy have been attributed to concomitant autoimmune disease (MARKSON, 1965). More recently GLATSTEIN (1971) has found that of 174 patients with malignant lymphoma who received high-dose radiation to the neck area 44% had elevated TSH levels and 25% became frankly hypothyroid.

Subtotal thyroidectomy for Graves' disease or euthyroid goiter was recognized as a cause of hypothyroidism nearly a century ago by KOCHER (1883). The reported incidence varies widely from study to study (see section on treatment of hyperthyroidism). A high incidence was reported by MICHIE (1972). He found that 49% of 278 patients subjected to surgery for Graves' disease 2 to 6 years previously had become hypothyroid. The incidence of hypothyroidism in his study was clearly related to the size of the thyroid remnant left by the surgeon. This last contention contrasts with

HARGREAVES' (1968) observation that postoperative hypothyroidism correlated more closely with the degree of lymphocytic infiltration of the gland and with serum thyroid antibodies than with the size of the thyroid remnant. MICHIE (1972) found that most of his patients who became hypothyroid did so within 4 months of the operation and that very few later developed myxedema. However, there is no general agreement on this point and others have suggested that the incidence of hypothyroidism probably rises in a cumulative fashion, as after radioiodine therapy (see p. 194).

δ) Drug-Induced Hypothyroidism

The most frequent cause of this form is overdosage of antithyroid drugs during treatment of thyrotoxicosis. Thionamide drugs and perchlorate are both potential causes. Hypothyroidism is occasionally induced by drugs whose primary effect is not on the thyroid gland. Sulfonyl ureas used in the treatment of diabetes have been found to produce hypothyroidism as a side effect; HERSHMANN (1968) has pointed out that these drugs also displace thyroxine from its binding sites on plasma proteins, which lowers the serum thyroxine concentration and may lead to an erroneous diagnosis of hypothyroidism. Since the introduction of lithium into the treatment of manic-depressive illness an increasing number of cases of goiter and/or hypothyroidism due to this drug have been reported (SCHOU, 1968; CANDY, 1972). The thyroid lesion is reversible after discontinuation of lithium. The exact mechanism of action is not yet clear, but so far it has been established that the lithium ion is actively transported into the thyroid cell and inhibits active transports of iodide and colloid droplet formation after TSH stimulation (BERENS, 1970; BURROW, 1971; WILLIAMS, 1971). The basic effect of lithium may be inhibition of thyroidal adenyl cyclase.

In thyrotoxicosis, pharmacological doses of iodine have a rapid antithyroid effect, but the normal thyroid gland usually tolerates large doses of iodine without adverse effects or with only a minimal decrease of hormone secretion (VAGENAKIS, 1973). However, in the past 25 years it has been recognized that occasional euthyroid patients develop severe but reversible hypothyroidism when given pharmacological doses of iodide, e.g. in the treatment of asthma, (PARIS, 1960; BEGG, 1963; MURRAY, 1967). This problem of iodide-induced goiter and hypothyroidism has been exhaustively reviewed by WOLFF (1969). The normal thyroid gland is known to escape from the effects of iodide by shutting off active iodide transport, thereby preventing the build-up of excessive iodide levels in the cell. In susceptible persons this autoregulatory control of active iodide transport fails for unknown reasons. Patients with chronic lymphocytic thyroiditis and patients with Graves' disease who have been treated with radioiodine are particularly prone to the development of iodide myxedema (BRAVERMAN, 1969, 1971). Iodide seems to be particularly inhibitory on thyroid function when it is combined with another drug which has a weak antithyroid effect itself. Many patients with iodide goiter in a study in England were taking a widely prescribed antiasthma preparation (Felsol powder) which contains iodopyrine and phenazone. The latter is a weak antihyroid drug and is probably ineffective by itself, but it greatly potentiates the effect of the iodine component (PASTERNAK, 1969). An endemic form of iodide goiter, usually without hypothyroidism, is known as coast goiter in Japan (SUZUKI, 1965). The anticonvulsant drug aminogluthetimide has occasionally produced hypothyroidism (RALLISON, 1967).

ε) Hypothyroidism due to Inborn Errors of Hormone Biosynthesis

This group of thyroid diseases, also grouped under the name of familial goiter will be discussed in detail in the section on childhood hypothyroidism (p. 167). Deficient production of thyroid hormone means that circulating TSH levels are very high in these patients. The thyroid is therefore under maximal stimulation and goiter develops soon after birth. Since in most other forms of hypothyroidism the gland is small or even nonpalpable, the combination of goiter and hypothyroidism arouses the suspicion of an inborn error of metabolism. In some cases the defect is only partial and hypothyroidism is mild or absent.

b) Incidence of Hypothyroidism

The overall true incidence is difficult to establish. In Zurich the incidence was calculated at 0.25% in outpatients and 0.2% in inpatients. MEANS (1963) cites an incidence of 0.01 to 0.08% for inpatients in the U.S.A., and also states that it is one eighth as frequent as thyrotoxicosis. In centers where radioiodine is the preferred treatment for Graves' disease the incidence of hypothyroidism must be expected to rise in the future. Women are affected 5 to 7 times more frequently than men. The incidence rises with the age of a patient population and may reach 1.9% among geriatric patients.

c) Pathologic Anatomy of Various Organs in Hypothyroidism

In primary hypothyroidism the anterior pituitary is under intense stimulation to secrete TSH. The morphologic counterpart to this is a measurable increase in the size of this gland and an increase in the number of the so-called beta-2 cells, a subclass of basophil cells previously known as amphophil (RUSSFIELD, 1955) or PAS-positive gamma cells (EZRIN, 1959). In long-standing primary hypothyroidism nodular hyperplasia may arise in the anterior pituitary, sometimes developing into true adenoma (MÖSLI, 1968). The gonads remain poorly developed in childhood hypothyroidism. In rare cases, however, premature menstruation and galactorrhea have been observed and ascribed to concomitant increases in the secretion of gonadotrophic hormones and prolactin (see p. 158).

Other morphologic changes in hypothyroidism are found mainly in the skin, the musculature and the skeleton. Strictly speaking, the term myxedema describes the edematous swelling of the corium of the skin with deposits of mucoid material, in particulate acid mucopolysaccharides, and an increase in mast cells. The same changes occur in skeletal and smooth muscles and in the myocardium. Deposits in these structures are not only extracellular but also occur as basophil inclusions in the cells. Skeletal changes occur mainly in childhood hypothyroidism and result in retarded bone age. The epiphyseal growth zones remain noncalcified for a long time, and if ossification does eventually begin, it is irregular, producing the picture of epiphyseal dysgenesis. The abnormal ossification in the hip often leads to impairment of joint function resembling that in Perthes' disease or in osteoarthritis.

d) Clinical Picture in Primary Hypothyroidism

α) History and Mental Changes

The onset is insidious and overt hypothyroidism does not develop until a large part of the thyroid tissue has been destroyed. The pathologic process in the gland precedes the appearance of overt hypothyroidism by years. Hypothyroid patients rarely mention symptoms spontaneously. Since they are often over 60, they are simply considered senile or sometimes even insane by their relatives, and a high index of suspicion is needed to make the diagnosis in mild cases.

One of the earliest complaints is intolerance of cold. The patient feels uncomfortable in a well-heated room, wears more clothes than previously and uses an extra blanket at night. He also perspires less than before.

Changes in mental function are sometimes noticed by the patient himself, often by his relatives. The patients complain of fatigue (not a very specific symptom) and they sleep a lot, preferably in a well-heated room. The mental changes are often quite similar to those in cerebral atherosclerosis. The functions of memory and critical judgement are impaired. In early stages the patient may be capable of good judgment and of making decisions, but his thought processes are slow. The sexual drive is diminished. In later stages a state of mental dumbness with loss of interest in the surroundings and of most previous personality traits prevails. Occasionally the mental changes progress into acute delirium which is clinically indistinguishable from delirium due to exogenous causes, but can be differentiated by the presence of slow waves and low voltage in the EEG. The delirium may progress to stupor and coma. Other patients show changes identical to those in classic manic-depressive or acute schizophrenic psychosis. In some cases this may be due to a true underlying psychosis which becomes manifest in thyroid failure (BLEULER, 1964).

In mild cases mental processes may not be slowed down. Occasionally the symptoms are more similar to those of excitation and even suggest the diagnosis of hyperthyroidism at first.

β) General Appearance

It has been said that hypothyroid patients all look alike. Indeed full-blown cases can be unmistakably recognized at first glance from the typical facies (Fig. 5). The individuality of the

Fig. 5. 72-year-old woman with severe myxedema

facial features is diminished. Mimic movements are few and slow, although still present, in contrast to Parkinson's disease. The patients look sleepy, but happy. No other endocrine disease changes the facies of a person so completely as myxedema.

The voice is characteristically low pitched and hoarse with a nasal undertone, and the speech is slow and monotonous, badly articulated like that of a person under the influence of alcohol. These changes are sometimes so characteristic that the experienced physician can make the diagnosis when speaking to the patient on the telephone.

γ) Skin

Cutaneous vasoconstriction and myxedema makes the skin waxy and pale. Sometimes it has a pink or yellowish undertone due to the deposition of carotene, the hepatic conversion of which to vitamin A is impaired. Carotene can also be the cause of a peculiar malar flush which looks rather like badly applied make-up. Swelling is particularly noticeable in the eyelids and produces narrowing of the palpebral fissures. In addition, the upper eyelid is often slightly ptotic, an effect ascribed to a decreased tone of Mueller's muscle, which is innervated by the sympathetic nervous system. The tongue is thickened and immobile, sometimes even protruding. Scalp hair becomes coarse and fragile, and loses its luster. It falls out easily and frontotemporal baldness ensues. The eyebrows fall out completely or more often only on the lateral part. Myxedematous changes are often found diffusely in the entire skin but sometimes remain localized in a few well-demarcated areas, particularly over the anterior aspect of the legs. Myxedema is characteristically nonpitting, but in the lower extremities true interstitial pitting edema is observed, sometimes to a grotesque degree. The skin is cool, dry, rough, and scaly, with increased cornification on the elbows and knees. Skin changes have recently been quantitatively evaluated by BLACK (1972). He found that the thickness was measurably increased and that the collagen content was normal. The fingernails are thin and brittle and grow slowly. The body temperature falls to 35–36.5°C (95.0–97.7°F), and in extreme cases potentially fatal hypothermia develops. Contrary to popular belief, generalized obesity is only rarely found in hypothyroidism, but localized accumulation of fat over the clavicles does occur (Fig. 13). Beard and pubic hair growth is diminished, although not to the same degree as in hypopituitarism. Wound healing is delayed.

δ) Thyroid Gland

In idiopathic hypothyroidism the thyroid gland is usually not palpable and goiter is only rarely recorded. However, CASSIDY (1970) reviewed 234 cases of nontoxic goiter and made the unexpected finding that 15% were hypothyroid. Thus, the presence of a goiter does not exclude the possibility of hypothyroidism. The association of a large goiter and hypothyroidism is suggestive of an hereditary defect in hormone biosynthesis (p. 167).

ε) Cardiovascular System and Plasma Lipids

In severe myxedema the heart is diffusely enlarged due to myxedematous infiltration of the myocardium, loss of tone, and dilatation of all cavities. Thyroxine treatment alone may bring about a reduction in heart size. In advanced cases, pericardial or pleural effusions and sometimes ascites are present. The heart sounds are diminished. Classically there is bradycardia, but this sign is not always present. Contrary to many textbook statements the blood pressure, in particular the diastolic pressure, is moderately elevated in 50% of cases of hypothyroidism (MEANS, 1963). The stroke volume and cardiac output are diminished, but in contrast to the situation in cardiac failure the arterio-veinous oxygen difference remains normal. Manifest heart failure is infrequent and, when it is present, is often due to additional factors.

In mild cases the electrocardiogram shows flattening, and occasionally inversion, of T-waves. The QT interval remains normal, but the PQ interval and QRS complexes sometimes become wider. In advanced cases the characteristic low voltage appears. This cannot be attributed solely to increased electrical resistance of the myxedematous skin, as measurements with deep-needle electrodes have shown. The electrocardiographic changes are most probably related to the myxedematous changes in the myocardium.

Plasma cholesterol is usually elevated in hypothyroidism, but due to the wide normal range this laboratory sign is of little diagnostic value. The rate of cholesterol synthesis appears to be normal (or even slightly low) in hypothyroidism, and the cause of the high plasma level appears to be slower removal. Triglycerides are also elevated, but frank hyperlipemia is rare. The cause of the hypertriglyceridemia is a low fractional triglyceride removal rate, possibly due to a low postheparin lipolytic activity (NIKKILÄ, 1972; TULLOCH, 1973). KIRKEBY (1972) has recently undertaken a detailed reassessment of serum lipids in hypothyroidism

and compared the findings to carefully matched controls. In addition to the facts already known he has shown that the qualitative distribution of plasma triglycerides and phospholipids in fatty acids is not much changed by hypothyroidism, while in hyperthyroidism a decrease in the proportion of linoleic acid was noted. A diet low in saturated fat may reduce the cholesterol, but not the triglyceride plasma level. Thyroid hormone treatment normalizes both values (O'HARA, 1966).

The relationship of hypothyroidism and the concomitant hypercholesterolemia to coronary artery disease is complex. Autopsy findings of severe myxedema without coronary atherosclerosis have been reported (NICKERSON, 1960 see ref on myxedema coma). Atherosclerosis is rare in juvenile hypothyroidism. Excellent studies by a Belgian group have recently cast come light on the question (VANHAELST, 1967; BASTÉNIE, 1967, 1971). They found that autopsy revealed severe coronary atherosclerosis in 84% of hypothyroid patients, while the incidence in carefully matched controls was only 46%. When patients whose myxedema had been treated were excluded, coronary infarcts were rare in hypothyroidism. Infarcts were recorded in 6 patients, 4 of whom had recently been started on thyroxine medication. Thus it seems that the hypometabolism of hypothyroidism protects these patients from myocardial infarction, despite severe atherosclerosis. Patients with so-called asymptomatic atrophic thyroiditis are at a disadvantage in this respect (BASTÉNIE, 1967). The disease is defined by clinical euthyroidism with normal (or borderline low) thyroid function tests, thyroid serum antibodies and confirmation of atrophic thyroiditis at autopsy. These patients seem to be particularly prone to coronary infarcts, since the syndrome was recorded in 20% of men and 50% of women admitted to hospital for coronary infarction, an incidence much higher than that found in matched controls. Although this statement has since been qualified insofar as asymptomatic thyroiditis was only a risk factor for coronary heart disease in women (BASTÉNIE, 1971), there is still an overall impression that patients with asymptomatic thyroiditis in whom coronary atherosclerosis is not associated with the "protective" effect of hypometabolism have a greater risk of myocardial infarction. Similar conclusions were reached by FOWLER (1967, 1970).

HEINONEN (1972) has expressed disagreement with this concept. In a health survey covering over 3000 people in Finland he identified 53 with severe coronary heart disease. In this group the incidence of thyroid antibodies was no higher than among carefully matched controls. The discrepancy between his results and those of BASTÉNIE will have to be settled by further studies.

One of the clinical consequences is that coronary insufficiency may become manifest when substitution therapy with thyroid hormone is instituted in a myxedematous patient. Treatment should therefore begin with very low doses, and in the patient over 50 years of age it is often necessary to compromise over the final maintenance dose, which should be such that the patient remains borderline hypothyroid (p. 165), because on full substitution many patients suffer from intractable angina pectoris.

ζ) Alimentary Tract

The poor appetite is compensated by the diminished metabolism so that there is no loss in body weight. Difficulty in swallowing and the feeling of a lump in the throat are often early symptoms of hypothyroidism. The submaxillary salivary glands are sometimes moderately enlarged. Obstinate constipation results from the reduced food intake, reduced metabolism and sluggish peristalsis. In 50% of cases there is histamine-refractory achlorhydria. The number of parietal cells in the fundus of the stomach is reduced, and true pernicious anemia is frequently found. The intestinal atony leads to the disturbing symptoms of flatulence and meteorism, and abdominal pains can simulate an ileus. True ileus due to fecal impaction is a much-dreaded complication. The incidence of hiatus hernia is increased.

Morphologic changes in the liver are quite non-specific (KLION, 1971).

η) Lungs

Lung function in hypothyroidism has been studied by WILSON (1960). The main finding was decreased diffusion capacity for CO. More recently, GIORGETTI (1973) has found that the alveolo-arterial difference in partial oxygen pressure during respiration of 100% oxygen is greatly elevated in myxedematous patients. Induction of hyperventilation decreased the alveolo-arterial pO_2 difference and the abnormalities were reversible after thyroid hormone treatment. The most likely explanation for these findings is an increase in intrapulmonary vascular shunts, which may be due to underventilation or atelectasis of small pulmonary segments.

ϑ) Blood

Cutaneous vascoconstriction causes hypothyroid patients to look very pale. This may be why

the early literature described anemia as a frequent complication of hypothyroidism. More recent studies have yielded completely normal hematological findings in two-thirds of patients with hypothyroidism, apart from the fact that most patients have a decreased total red-cell mass associated with the decreased blood volume (TUDHOPE, 1960). Several forms of anemia have to be considered in connection with hypothyroidism.

In so-called "uncomplicated" anemia of hypothyroidism the hemoglobin is moderately low. There is normocytosis or slight macrocytosis (TUDHOPE, 1960). Plasma iron is moderately lowered and the plasma iron turnover rate is decreased. Incorporation of iron into erythrocytes is normal, as is the erythrocyte survival time (KIELI, 1967). The bone marrow may be moderately hypoplastic (AXELROD, 1951). Thyroid hormone substitution therapy reverses all these hematological changes. The pathogenesis of this type of anemia is not entirely clear. Most authors relate it to decreased oxygen requirements and a consequent drop in erythropoeitin levels. Recently it has also been shown that thyroid hormone stimulates hemoglobin biosynthesis in bone-marrow culture (FUHR, 1970). The observation that thyroid hormone stimulates 2,3-diphosphoglyceric acid synthesis in red cells may also be relevant in this context (SNYDER, 1970).

Iron-deficiency anemia with all the associated hematological findings is present in 15% of patients with hypothyroidism. In most cases it can be related to the severe menorrhagia which often accompanies hypothyroidism in women. These patients need iron therapy and hormonal substitution to completely normalize the blood findings.

Pernicious anemia is found in 8% of patients with hypothyroidism, in comparison to 0.35% of matched controls. The incidence is higher in idiopathic hypothyroidism than in hypothyroidism following thyroidectomy or radioiodine treatment (10% as against 4%). The original claims that thyroid hormone substitution improves absorption of vitamin B_{12} (LEITHOLD, 1958) were not confirmed by subsequent studies (TUDHOPE, 1960, 1962). The present view is that these patients suffer from true pernicious anemia and that idiopathic hypothyroidism is pathogenetically related to this disease. The fact that true pernicious anemia is also more frequent in patients with Graves' disease may explain the above association between postsurgical or post-radioiodine hypothyroidism and pernicious anemia. Antibodies to mucosa of the gastric fundus and intrinsic factor are prevalent in patients with idiopathic hypothyroidism, as they are in pernicious anemia. They are rare in control subjects. Patients with pernicious anemia do quite often have serum antibodies to thyroid tissue, however. Gastric mucosal biopsies in hypothyroid patients revealed a reduction in the number of parietal cells and lymphocytic infiltrates (IRVINE, 1962). Nearly 50% of patients with hypothyroidism suffer from histamine-refractory achlorhydria. Both pernicious anemia and idiopathic hypothyroidism are currently viewed as disorders of autoimmunity, possibly related to a generalized defect of immune tolerance. The two conditions are clinically similar and clinical differential diagnosis may be difficult at times. It is advisable to assess the thyroid status of every patient suffering from pernicious anemia. In addition, whenever thyroid hormone and iron substitution do not cure anemia of hypothyroidism, intestinal vitamin B_{12} absorption or serum vitamin B_{12} levels should be measured.

Leukocytes and platelets are normal in hypothyroidism. The erythrocyte sedimentation rate is usually accelerated.

ι) Genital Organs and Gonads

Hypothyroid women often suffer from menorrhagia, but ammenorrhea is also encountered. Sterility in both sexes is common, but occasional pregnancies do occur in hypothyroid women (see STANBURY, 1972, for review). The sexual drive is usually reduced and impotence is not uncommon. A total of 12 cases of amenorrhea and galactorrhea associated with hypothyroidism have been reported (VAN WYK, 1960). They all developed post partum. EDWARDS (1971) has added a further case which occurred when the patient took oral contraceptives. Prolactin levels were high and returned to normal under thyroxine treatment, as did the other clinical symptoms.

Occasionally men suffer from coincident hypogonadism and hypothyroidism (BALZE, 1962).

κ) Muscles and Joints

The strength of the hypotonic and very often pseudohypertrophic musculature is reduced. Muscle pain and stiffness are common complaints. Tapping the muscle produces the typical pseudomyotonic reaction in the form of a slow contraction changing into a hard muscular ridge. These contractions never outlast the voluntary innervation as they do in myotony.

The tendon reflexes are characteristically very sluggish, and the recording of the ankle

jerk shows a typical curve, which is useful in diagnosis. Hypothyroidism can produce severe histological changes in muscle characterized by peculiar mucoid deposits between and within muscle cells. The serum creatine phosphokinase (CPK) is elevated, indicating muscular damage (GRAIG, 1965). Similar changes occur in smooth muscle. They may lead to degenerative changes in the media of large blood vessels and to rupture of the aorta. Hypothyroidism may be associated with myasthenia gravis (BRONSKY, 1967; Chap. XVII).

Arthralgia, joint swelling, synovial thickening and joint effusions are sometimes the prominent features of hypothyroidism, and such patients are referred to rheumatology units before the diagnosis of hypothyroidism is established (BLAND, 1970). Most of the symptoms disappear during thyroid hormone substitution therapy.

λ) Nervous System (see also p. 155)

Cerebellar dysfunction with ataxia and intention tremor occur occasionally. Sensory disturbances are more common, and the patients often complain of numbness and paresthesias. Compression of the median nerve with carpal tunnel syndrome is often encountered. The protein concentration in the cerebrospinal fluid, particularly that of gamma globulin, is frequently elevated.

Partial deafness is a frequent finding in adult hypothyroidism. The pathogenesis is not quite clear. It appears to be due to a conductive defect associated with swelling in the eustachian tube. Sensorineural deafness has been ascribed to degenerative changes in the mucosa of the cochlea (RITTER, 1967) and sometimes to changes in the labyrinthine fluid composition.

μ) Kidney, Electrolytes and Body Fluids

Morphologically the kidneys may show deposits of mucopolysaccharides in the intercapillary space and in the basal membranes of the tubuli. Electron microscopic examination reveals thickening of the glomerular and tubular basal membranes (CASSANO, 1964). SALOMON (1967) has performed repeated biopsies and shown that these changes are reversible under appropriate treatment with thyroid hormone. Clinically, oliguria is sometimes observed and is attributed to a low fluid intake. Slight proteinuria is often present. Laboratory examination of kidney function has revealed a decrease of glomerular filtration rate and renal plasma flow.

These changes in kidney function rarely lead to overt electrolyte disturbances. Occasionally, however, particularly in severe myxedema and in myxedema coma, dangerous hyponatremia develops (AIKAWA, 1956). Superficially this form of hyponatremia resembles that seen in the syndrome of inappropriate secretion of antidiuretic hormone (ADH), since plasma osmolality is low and urine osmolality high. The disturbance was therefore initially ascribed to inappropriately high levels of antidiuretic hormone (IVY, 1965; PETTINGER, 1965). Further studies however have shown that the pathogenesis of this electrolyte disturbance is far more complex and cannot yet be fully explained. So far it is established that the hyponatremia is dilutional, i.e. total exchangeable body sodium is normal or slightly increased and total body water is definitely increased. Although resetting of the osmoreceptors to a lower level may play some role, and maintain the serum sodium at borderline low levels by the secretion of ADH, the control of ADH secretion is not lost. When given a water load these patients are perfectly capable of diluting their urine to 60 mOsm/l (DISCALA, 1971; DERUBERTIS, 1971), although the peak urine flow and the free water clearance are lower than in controls. The minimum urine osmolality reached is slightly higher than in normal persons. The best explanation for the hyponatremia of hypothyroidism so for available is that it is due to a decreased volume and solute delivery to the distal diluting tubular segment (DERUBERTIS, 1971; DISCALA, 1971). Decreased glomerular filtration and increased proximal sodium reabsorption may both contribute to this decreased volume delivery to the distal tubule.

It must be added that a relative lack of corticosteroids may also be involved in the hyponatremia, but this is less well established (see DISCALA, 1971, for a short review).

ν) Diagnostic Weight of the Various Clinical Findings

BILLEWICZ (1969) has made an extensive mathematical analysis of the significance of the various clinical findings for the diagnosis of hypothyroidism. He has developed a very useful diagnostic index allowing confirmation or rejection of the diagnosis of hypothyroidism with great accuracy on clinical findings alone, which may thus render expensive laboratory tests unnecessary. Symptoms which are significant for the distinction between hypo- and euthyroidism are diminished perspiration, preference for warm ambient temperatures, hoarseness of the voice, paresthesias, and dry skin. The most significant signs are slowness of the ankle

jerk, slow movements on undressing, and dry rough skin on the forearms. Contrary to popular belief, weight gain has practically no diagnostic value.

ξ) Thyroid Function Tests

Serum thyroxine can vary from the low normal range to pratically unmeasurable levels, depending on the severity of the disease. In primary myxedema the serum triiodothyronine is relatively less lowered than the serum thyroxine, because the high TSH level favors the synthesis of triiodothyronine over that of thyroxine (McConnon, 1971). The resin T_3-uptake test yields results in the hypothyroid range. The ankle reflex time is prolonged (p. 241) and the basal metabolic rate is below -15%. Radioiodine uptake is low at two hours and not much higher at 24 hours. Administration of TSH (p. 242) does not increase the serum thyroxine or radioiodine uptake. TSH levels are invariably very high in primary hypothyroidism. Indeed, the serum TSH seems to be the most sensitive index of thyroid failure, since it is often elevated in borderline cases where the other tests still yield values in the normal range (p. 161). Positive tests for serum antibodies to thyroid antigens provide strong support for a diagnosis of primary hypothyroidism (Vallotton, 1967). Several authors have attempted to assess the reliability of the various thyroid tests in establishing the diagnosis of hypothyroidism (Rives, 1965; Fitzgerald, 1966; Gordon, 1970; Chew, 1962). The serum hormone level (serum thyroxine or protein-bound iodine), the basal metabolic rate and the 24-hour radioiodine uptake all had an almost equally high rating in their agreement with the final diagnosis (based on all tests and on the clinical findings). The resin T_3-uptake, the ankle reflex time, and the serum cholesterol were less useful in diagnosis, but it must be added that in a recent study the ankle reflex time had the highest rating (Fraigu, 1972).

Intense stimulation of the remaining thyroid tissue by TSH leads to a relative increase in triiodothyronine secretion compared with that of thyroxine. It has even been claimed that primary hypothyroidism can be distinguished from secondary failure by the relatively normal levels of serum triiodothyronine in primary hypothyroidism (McConnon, 1971).

3. Secondary Hypothyroidism

Secondary hypothyroidism occurs most frequently in the setting of panhypopituitarism, the causes of which are listed in Chap. V (p. 92f.). Occasionally, TSH deficiency is the predominant feature of a pituitary lesion, and gonadal and adrenal function are less compromised (Sampson, 1954; Sawin, 1966; Odell, 1966). In such cases it may be difficult to differentiate secondary hypothyroidism from primary myxedema on clinical grounds.

Miyai (1971) has described a rare cause of secondary hypothyroidism in two hypothyroid children of a consanguineous marriage. They both suffered from congenital isolated deficiency of TSH secretion with intact secretion of the other pituitary hormones.

It seems likely that in the future some cases of secondary hypothyroidism will have to be classified as due to hypothalamic rather than to pituitary damage. Such cases have recently been well documented by Pittman (1971) and Shenkman (1972). The patients were able to secrete TSH following pituitary stimulation effected by the injection of thyrotropin releasing hormone (TRH), and the defect was thought to be at the level of TRH secretion. The availability of synthetic TRH and of a TSH radioimmunoassay will probably make the TRH stimulation test (p. 242) a routine procedure in the assessment of panhypopituitarism, particularly in childhood. Most children with idiopathic deficiency of growth hormone and TSH tested so far have shown a brisk rise in serum TSH after injection of TRH. They presumably suffer from hypothalamic damage (Costom, 1971; Foley, 1972, 1972b).

The differentiation of secondary from primary hypothyroidism is of more than academic interest and influences the choice of treatment for the patient. In secondary hypothyroidism, due to the frequent coexistence of adrenocortical insufficiency, thyroid hormone substitution may provoke a potentially fatal adrenal crisis if corticosteroids are not given simultaneously.

The clinical sign most useful in differentiation is the white, almost transparent, and finely wrinkled skin of secondary hypothyroidism, as opposed to the coarse, thick, dry, and slightly yellowish skin of primary myxedema. Amenorrhea, atrophy of the testes, adrenal insufficiency and tendency to hypoglycemia all are points indicative of secondary thyroid failure. Pubic and axillary hair are sparse in primary hypothyroidism, but their complete absence is additional support for the diagnosis of secondary hypothyroidism. Urinary corticosteroid excretion is moderately diminished in primary myxedema, but very low in panhypopituitarism. In hypopituitarism the thyroid gland retains a certain degree of autonomic function, so that thyroid failure is

rarely as severe as it sometimes is in primary myxedema. In complete failure of the thyroid gland the basal metabolic rate may fall to −40%, whereas in secondary failure it is rarely below −30%. The presence of serum antibodies to thyroid antigens provides strong support for the diagnosis of primary hypothyroidism (VALLOTTON, 1967). On average, serum cholesterol is less elevated in secondary than in primary hypothyroidism, but in the individual patient this sign is of little value for differentiation.

The diagnosis of secondary hypothyroidism is established by the finding of a low or low normal serum TSH concentration. In primary hypothyroidism serum TSH is always elevated. Where TSH measurements are not available, the TSH stimulation test will show a good response of the serum thyroxine and the radioiodine uptake to repeated injections of bovine TSH (p. 242). It must be added that long-standing primary hypothyroidism may impair the function of the anterior pituitary (BRAUNMAN, 1968; LESSOF, 1969) and the term myxedema of the pituitary is sometimes used to describe this condition.

4. Borderline Hypothyroid States

The severity of hypothyroidism can vary between barely impaired thyroid function and complete failure of hormone secretion. The diagnosis of slight hypothyroidism is usually very difficult and should never be made on the basis of a single abnormal test. The clinical picture and several thyroid function tests should be evaluated. It should be borne in mind that each of these tests has a relatively wide "normal" range, and that therefore a value in the low normal range may mean real hypothyroidism for one patient but euthyroidism for another. The most sensitive index of mild primary hypothyroidism currently known is probably the serum TSH concentration, which is often elevated when most other tests still yield results in the normal range. If the TSH radioimmunoassay is not available, the TSH stimulation test (p. 242) is sometimes very helpful.

a) Hypometabolism without Hypothyroidism

This condition is found in patients with anorexia nervosa and during starvation. Serum thyroxine and radioiodine uptake are usually normal, indicating that the lowered basal metabolic rate is not due to thyroid deficiency. The existence of a "functional" type of hypopituitarism as an adaptive phenomenon during starvation remains to be established. A slight decrease in the basal metabolic rate may occur in adrenocortical insufficiency and in male hypogonadism.

b) Borderline Secondary Hypothyroidism, Lack of TSH Reserve

A syndrome with some features of hypothyroidism, such as cold intolerance, fatigue, constipation, anemia and menstrual irregularities, was described in the nineteenth century and termed "myxoedeme fruste" or "hypothyroïdie bénigne chronique" (HERTHOGE, 1899). More recently this condition has been ascribed to resistance of the peripheral tissues to thyroxine (KURLAND, 1955; GOLDBERG, 1960), but subsequent studies have not confirmed this concept (LEVIN, 1960; SIKKEMA, 1960; JEFFERIES, 1961). WYSS (1963) and STUDER (1964) have observed that patients with these symptoms often show a diminished rebound of radioiodine uptake after a 7-day course of carbimazole und have suggested that the condition is due to a diminished TSH reserve. This TSH reserve test has not, however, been reproduced in other laboratories and has been abondoned (POWELL, 1966; SCHNEEBERG, 1966). The syndrome therefore needs to be reevaluated by measuring serum TSH levels following TRH stimulation.

c) Diminished Thyroid Reserve (JEFFERIES, 1956)

This formerly rather vague syndrome can now be more exactly defined as the presence of elevated TSH levels together with normal thyroid function tests and only intermittent slight clinical symptoms of hypothyroidism. It is most often observed after radioiodine treatment for hyperthyroidism (SLINGERLAND, 1972; STERLING, 1971), in chronic lymphocytic thyroiditis (GHARIB, 1972) or after subtotal thyroidectomy (HEDLEY, 1972). A borderline euthyroid state is often maintained in these circumstances despite a low serum thyroxine level, thanks to a normal or slightly elevated serum triiodothyronine concentration (STERLING, 1971). In an analogous situation in endemic goiter DELANGE (1972) has measured triiodothyronine concentrations up to 250% of normal.

5. Myxedema Coma (see Table 2)

Myxedema coma was recognized as the end stage of hypothyroidism over 90 years ago (ORD, 1880), but only in the last decades has it received appropriate clinical attention. An exhaustive review of 122 cases has been prepared by LEON-SOTOMAYOR (1964).

Table 2. Treatment of myxedematous coma

1. If arterial pCO_2 is over 50 mm Hg, endotracheal intubation or tracheostomy and assisted respiration. Relief of bronchial airway obstruction.
2. Administration of corticosteroids in an intravenous drip, e.g. cortisol hemisuccinate 100 mg in the first 3 hours, then 10 mg per hour until the patient regains consciousness.
3. Triiodothyronine 12.5 µg every 12 hours by i.v. route, or if not available, by nasogastric tube.
4. If hypoglycemia is present, correct with 50 ml 40% glucose in water. Maintain blood sugar by an infusion of glucose made isotonic or hypertonic in saline. Glucagon may also be given in a dose of 1 to 2 mg every hour.
5. If hyponatremia is present, treat with either hypertonic NaCl infusions or with fluid restriction or both.
6. In case of severe arterial hypotension give a slow infusion of plasma or albumin in physiologic NaCl. Norepinephrine or isoproterenol may be tried, but involve the risk of cardiac arrythmias.
7. Careful slow rewarming by not more than 1 °C (1.8 °F) per hour, without heating blankets.
8. If available, institute continuous ECG monitoring. Cardiac glycosides can be given if overt heart failure is present, but little is known about the proper dose in myxedematous coma.
9. If infection is established give an antibiotic.

The lack of thyroid function is compatible with most vital functions, although at a diminished level. Precipitating factors, such as exposure to cold, infections, treatment with barbiturates or phenothiazines, are therefore necessary to lower body temperature, impair alveolar ventilation and to send the patient into coma. Severely hypothyroid patients fall into progressively longer periods of deep sleep until they can no longer be aroused. The body temperature falls to 32–35 °C (89.6–95 °F). It must be recalled here that hypothermia can only be recorded if a special thermometer is used. Severe electrolyte and body fluid disturbances are always present, particularly hyponatremia (see p. 159 for the pathogenesis of hyponatremia). Pericardial and pleural effusions are often found. Bradycardia and arterial hypotension are usual. The tendon reflexes show extremely slow relaxation.

An important factor contributing to the coma is alveolar hypoventilation leading to elevated arterial carbon dioxide tension. The pathogenesis is not entirely clear, but impairment of the medullar respiratory center function, disturbances of neuromuscular transmission, weakness of respiratory muscles, elevation of the diaphragm due to abdominal gas, and accumulation of bronchial mucus may all be contributory factors. The carbon dioxide retention usually precedes hypothermia. The latter may cause disturbances of atrioventricular conductance and severe arrhythmia.

Patients in myxedema coma should always be considered as being in a state of adrenocortical insufficiency with the corresponding lack of resistence to stress of any kind. In primary hypothyroidism hypoglycemia is usually not present, but there may be severe hypoglycemia when myxedema coma is superimposed on panhypopituitarism.

Primary and secondary myxedema coma are difficult to differentiate on clinical grounds. Thin, finely wrinkled, and parchment-like skin, absence of pubic and axillary hair and atrophic testes point to secondary hypothyroidism, while thick skin, edema of the legs and face and a large tongue are indicative of primary hypothyroidism. Distinction between the two forms is irrelevant to the immediate treatment, and the exact nature of the endocrine defect can be established at leisure after the patient has recovered.

Besides the measurement of body temperature with a special termometer the following laboratory tests should be ordered in a case of myxedema coma: Hemoglobin or hematocrit and red cells, blood sugar, serum electrolytes and urea, arterial oxygen and carbon dioxide tension and oxygen saturation of the hemoglobin. A blood culture, a chest X-ray and a urine culture should be obtained to rule out infection which may be present despite hypothermia and low white cell counts. Blood should also be taken for thyroid function tests (serum thyroxine, resin T_3-uptake test), but therapy should not be delayed if their results are not immediately available. Whenever possible patients with myxedema coma should be admitted to an intensive care unit and treatment started immediately. Thyroid hormone substitution is started with triiothyronine, which has a more rapid onset of action than thyroxine. The hormone can be given by gastric tube, but since intestinal absorption may be impaired due to shock, intravenous administration is preferable. There are no commercial preparations available for intravenous use and the solution has to be prepared by the hospital pharmacy as follows: the sodium salt of triiodothyronine is weighed and dissolved in a few drops of 0.1 N NaOH. The solution is then diluted in 5 ml of 1 or 2% solution of human serum albumin in 0.15 M NaCl and sterilized by filtration through millipore. Alternatively, sterile instruments and dilution solution can be used. For the first two or three days 12.5 µg up to a maximum of 25 µg triiodothyronine are given by injection every 12 hours. Overdosage of thyroid hormone carries the risk of fatal cardiac arrhythmia and coronary infarction, but in desperate cases of coma several

authors have recommended higher doses of up to 100 μg triiodothyronine every 12 hours. HOLVEY (1964) has successfully treated 7 patients with single doses of 100 to 500 μg L-thyroxine by the i.v. route followed by lower maintenance doses. Recent studies in noncomatous hypothyroid patients have confirmed that large intravenous thyroxine doses (up to 750 μg initially) are well tolerated and lead to a much more rapid restoration of the deranged metabolic functions (RIDGWAY, 1972). It remains to be seen whether this treatment can be safely recommended for the comatose patient.

Although it is difficult to establish the presence or absence of adrenocortical insufficiency in myxedema coma, corticosteroids should always be administered in generous doses for the first few days of treatment. The recommended dosage is 100 mg of a water-soluble cortisol preparation (e.g. cortisol hemisuccinate) in slow intravenous infusion over the first three hours, followed by 10 mg every hour until the patient regains consciousness. A water-soluble prednisolone preparation in a dose four times lower may be substituted for the cortisol preparation.

Hypoglycemia, if present, should be treated by intravenous infusion of glucose. This may present a problem if the patient has concomitant hyponatremia, since the usual 5% glucose solution will add a large quantity of free water and may aggravate water intoxication. Glucose should therefore be given in a concentrated solution in such cases, or in a glucose solution made 0.15 or even 0.3 M in NaCl by the addition of NaCl.

Hyponatremia may necessitate either fluid restriction, as in the case of true inappropriate secretion of ADH, or administration of hypertonic NaCl solution. Since the total body sodium is not known in an individual case, it is impossible to know which measure to apply first, and it may be necessary to proceed by trial and error.

Arterial hypotension is another difficult therapeutic problem. Therapy can begin with careful slow infusion of plasma or albumin solutions. Pressor amines such as norepinephrine have been recommended, but two facts limit their usefulness. The peripheral vasculature is already maximally constricted in myxedema coma, and pressor amines will have little additional effect. Moreover, they can induce cardiac arrhythmias. In theory, beta-receptor stimulants such as isoproterenol ought to be more useful, but their use in myxedema coma has not yet been assessed to our knowledge.

Hypothermia is treated by slow rewarming at a rate of not more than 1 degree C (1.8 degree F) per hour, avoiding the use of a heating blanket. If rewarming is too rapid, sudden peripheral vasodilatation may produce irreversible shock.

Respiratory acidosis with an arterial pCO_2 of over 50 mm Hg necessitates an endotracheal or a tracheostomy tube and appropriate respiratory assistance.

The prognosis of myxedema coma is very grave. The condition has a fatal outcome in 40% of cases despite all attempts at treatment.

6. Clinical Differential Diagnosis of Hypothyroidism

The diagnosis of severe hypothyroidism is simple in most cases, but a borderline case may escape the attention of even the experienced doctor. Several studies have estimated that an average of 3 to 4 years elapses between the onset of the first symptoms and the diagnosis of hypothyroidism.

Patients with acute glomerulonephritis or with the nephrotic syndrome may occasionally be mistakenly thought to be suffering from hypothyroidism. Pallor, edema, a puffy face, cardiomegaly and anemia are features common to both hypothyroidism and chronic renal disease. Albuminuria may be present in hypothyroidism, but not hematuria. The fact that low serum-binding proteins in the nephrotic syndrome lead to a decrease of the serum hormone level makes the differentiation even more difficult. In terminal renal disease the renal iodide clearance is greatly reduced, but despite this, thyroidal radioiodine uptake is usually normal, probably due to a concomitant increase in the serum iodide level (p. 152). FANKHAUSER (1968 see p. 254) has described mild secondary hypothyroidism of obscure origin in one third of patients with severe chronic renal insufficiency.

Encephalitis with stupor has occasionally been mistaken for hypothyroidism. A slight increase in the protein concentration of the cerebrospinal fluid, as is found in hypothyroidism, may help to confuse the picture, but in general fever and tachycardia are strong arguments against the presence of hypothyroidism. True secondary hypothyroidism due to hypothalamic damage may occur in encephalitis. Parkinson's disease may sometimes mimic hypothyroidism. As outlined in a previous section (p. 157) true pernicous anemia is often found in patients with primary hypothyroidism. Pallor, atrophic muscosa of the tongue, and achlorhydria and paresthesias are frequent in both conditions. In myxedema the tongue is large, whereas it is of normal size in pernicious anemia.

7. Course and Prognosis of Hypothyroidism

Myxedema takes an extremely chronic course. Complete lack of thyroid tissue is compatible with life for some years. After a long period of chronic illness hypothyroidism ends in death in myxedema coma, which is often precipitated by infections, exposure to cold, or administration of sedatives (p. 161). Cases who remain untreated for years are rarely encountered today. The famous report of the Myxoedema Commission (1888) stated that the life expectancy of a patient with untreated myxedema was 10 to 15 years after onset of the disease. Adequate treatment often restores all functions to normal and some famous cases have survived for many years. One of RAVEN's patients (1894, 1924) had been ill and bedridden for 20 years. She recovered promptly after treatment and lived another 30 years, to die at the age of 94. BURGESS (1946) treated a patient successfully over 52 years.

According to MEANS (1963), full-blown myxedema is always due to complete athyroidism. Even small remnants of thyroid tissue may maintain a borderline thyroid function, until they too become atrophic. Since destruction of the thyroid tissue is a slow process in primary idiopathic hypothyroidism, the severity of myxedema is always correlated to the duration of hypothyroidism. Acute spontaneous hypothyroidism has frequently been reported, but it has not been established whether this occurs in primary idiopathic hypothyroidism. Spontaneous remissions are seen after thyroiditis and sometimes after subtotal thyroidectomy. After thyroidectomy and after radioiodine treatment the signs of hypothyroidism may develop quite rapidly.

8. Treatment of Hypothyroidism (Table 3)

Na-L-thyroxine is our drug of choice for long-term substitution therapy. It is relatively cheap and has a constant and well-standardized potency. Its absorption after oral administration is about 70% in both euthyroid and hypothyroid subjects (HAYS, 1968; READ, 1970). EVERED's (1973) careful studies in which the dose of thyroxine was slowly increased until the elevated TSH levels of primary myxedema had returned to normal (probably the best criterion for euthyroidism) have shown that the full replacement dose is 100–200 µg daily. The doses of 200–400 µg recommended in most textbooks are too high and produce slight hyperthyroidism. Oral thyroxine takes effect after about 3 to 5 days (RIDGWAY, 1972) and the effect slowly disappears 7 to 10 days after cessation of treatment. The serum half-life is about 7 days. This slow disappearance is an advantage in most cases. It allows administration of the drug in a single daily dose. In cases where the patients are unreliable, the drug can be given under the surveillance of a doctor or nurse every 7 days in a dose of 1 to 2.5 mg (BERNSTEIN, 1969).

Since the availability of L-thyroxine the desiccated thyroid preparations have lost much of their popularity, but are still often used in the U.S.A. Although it must be conceded that some brands are very reliable in their hormone content and have been used in the same dose over years, the fact that most pharmacopeias require only a statement of their iodine content has limited their usefulness. Since desiccated thyroid contains variable amounts of mono- and diiodotyrosine and iodide as well as thyroxine and triiodothyronine, a constant iodine content does not guarantee a constant hormone content. Some preparations have shown great variability in intestinal absorption, and others have lost their potency during storage.

Triiodothyronine, with its serum half-life of 1 day, has a more rapid onset of action within a few hours to 3 days. After discontinuation of treatment its effect ceases within 3 to 5 days. These properties are useful in the treatment of myxedema coma, in the triiodothyronine suppression test (p. 242) and in cases where it is necessary to interrupt and resume therapy quickly for radioiodine uptake tests or for radioiodine treatment of thyroid cancer.

Recently, thyroid hormone preparations containing a mixture of the two hormones thyroxine and triiodothyronine in a ratio of 4:1 have become commercially available. The claim that they allow more "physiological" and better tolerated treatment has been disproved by a carefully controlled study (SMITH,

Table 3. Preparations for thyroid hormone replacement therapy and their dosage

	Mean adult full replacement dose (day)	Half-life in plasma	Onset of effect (days after start of treatment)	Duration of effect after cessation of therapy
Na-L-thyroxine	0.1 –0.2 mg	7 days	4 days	10 days
Na-L-triiodothyronine	0.06–0.12 mg	1 day	¼ to 3 days	5 days
Desiccated thyroid	60–180 mg	–	4 days	10 days

1970). Surprisingly, this mixture produces unphysiologically high triiodothyronine levels in serum, while substitution with thyroxine alone produces near-normal triiodothyronine levels (SURKS, 1972; EVERED, 1973).

The full substitution dose for thyroxine is 100–200 μg in most adult patients, but the range is 100–600 μg. A dose of 60 μg of triiodothyronine is about equipotent to one of 100 μg of thyroxine. In mild or moderate cases the initial dose is 50 μg of thyroxine per day. After one or two weeks it is increased by increments of 25 μg until optimal substitution is reached. In severe myxedema, in patients over 60 years of age, and in cases of coronary heart disease the initial dose should be low, e.g. 12.5 μg or at most 25 μg per day. The dose is increased by small increments at intervals of not less than 2 weeks until satisfactory substitution is achieved. In older patients, especially in the case of coronary atherosclerosis, it is customary not to aim at full substitution, but to keep the patients borderline hypothyroid. If angina pectoris, palpitations or cardiac arrhythmias arise at the onset of therapy, treatment is stopped and resumed at half the dose after a few days.

The optimum substitution dose should be determined mainly by the clinical state of the patient. Cold intolerance and fatigue should disappear and the pulse should become normal. Palpitations, tachycardia, loss of weight, nervousness and insomnia are signs of overdosage. Laboratory tests may sometimes be necessary to determine the proper dose. The ankle reflex time has proved to be a useful and quick indicator of therapeutic effectiveness. Other authors prefer to measure the basal metabolic rate. Most textbooks recommend that the serumthyroxine should be in the borderline hyperthyroid range during optimal substitution therapy with thyroxine. Recent studies, however, recommend to maintain the serum thyroxine in the normal range (EVERED, 1973). Serum thyroxine is very low (1–2 μg/100 ml) when the patient is given triiodothyronine and should be in the normal range when desiccated thyroid is given.

When the optimal dose has been determined for a patient it should be given for the rest of his life, and patients should be carefully instructed not to discontinue treatment. Physical activity and cold weather cause a moderate increase in the hormone requirement and the dose should be varied accordingly. Early in the treatment patients often tend to forget to take their medication regularly or discontinue treatment completely. They should therefore be seen at frequent intervals at first. Later, six-monthly check-ups are sufficient, but the doctor has a responsibility to follow up the patients throughout their lives.

Concomitant heart failure should be treated with cardiac glycosides. If the patients are not fully substituted with thyroid hormone, the digitalis dose should be kept low.

Secondary hypothyroidism needs the same treatment as primary hypothyroidism with the important exception that substitution with cortisone is mandatory and should be started before thyroxine therapy in order to avoid an adrenal crisis. The treatment of myxedema coma is discussed on p. 161.

E. Hypothyroidism in Childhood

A. PRADER, A. LABHART, and H. BÜRGI

Hypothyroidism in childhood deserves a special section because of its high incidence and particular features, notably its effects on growth and mental development. After diabetes mellitus hypothyroidism is the most common endocrine disorder of childhood. It is more frequent than hyperthyroidism in children,

Table 4. Causes of hypothyroidism in childhood

I. Primary hypothyroidism

1. Thyroid aplasia, ectopic and hypoplastic thyroid (congenital, nonfamilial thyroid aplasia, sporadic cretinism).
2. Acquired childhood and neonatal hypothyroidism.
   a) Treatment of mother during pregnancy with antithyroid drugs or excess iodide (reversible);
   b) Idiopathic hypothyroidism (spontaneous primary thyroid atrophy; chronic thyroiditis, atrophic variant).
3. Genetic defects in thyroid hormone biosynthesis and thyroid hormone end organ response (familial goiter with hypothyroidism).
   a) Failure of active iodide transport;
   b) Defect of organic iodination. When associated with nerve deafness: Pendred syndrome;
   c) Defect in iodotyrosine coupling;
   d) Deficiency of iodotyrosine dehalogenase;
   e) Deficiency of thyroidal protease;
   f) Abnormal plasma iodopeptides;
   g) Unresponsiveness of thyroid to TSH;
   h) Unresponsiveness of peripheral tissues to thyroid hormone.
4. Endemic cretinism, hypothyroid variant.

II. Secondary hypothyroidism

Any of the defects below can be due to a lesion either of the anterior pituitary or of the hypothalamus.

1. Tumors of the hypothalamus or the pituitary gland;
2. Inflammatory, granulomatous or traumatic lesions of the hypothalamus or pituitary gland;
3. Idiopathic deficiency of TSH secretion, often combined with defective growth hormone secretion. Probably hypothalamic in origin in most cases;
4. Isolated hereditary TSH deficiency (rare).

while in the adult the reverse is true. The clinical features peculiar to childhood hypothyroidism arise from the fact that in addition to the effects known in the adult it severely impairs physical and mental development. The resulting picture is so striking that it is usually easy to decide in an adult hypothyroid patient whether his hypothyroidism started in childhood or later.

A classification of childhood hypothyroidism is given in Table 4. The individual causes of childhood hypothyroidism are discussed below.

1. Aplastic, Hypoplastic and Ectopic Thyroid Gland

This is the most common cause of hypothyroidism in children. Thyroid ectopism has been recognized more and more frequently since all "athyrotic" children have been carefully scintiscanned for iodine-concentrating ectopic thyroid tissue. About 50% of these children are found to have a retrolingual thyroid (Fig. 6). The thyroid gland arises during embryogenesis from the thyroglossal duct, a ventral outgrowth of the cranial entoderm. Ectopic thyroid tissue may be found anywhere along the path of this anlage down to the final location of the gland, sometimes even far below the normal site of the gland, e.g. in the lower mediastinum (Fig. 7). The most common location is the base of the tongue as a so-called retrolingual goiter, which is usually very small, but is occasionally large enough to produce dysphagia and other local symptoms (Fig. 6). Only 17% of patients with a retrolingual thyroid demonstrated by scintigraphy are hypothyroid, but if the ectopic thyroid is the only thyroid tissue, hypothyroidism is relatively common. In the early years of life intense stimulation of ectopic thyroid tissue may suffice to maintain marginal euthyroidism,

Fig. 6. Lingual goiter in a 42-year-old woman with congenital hypothyroidism. (From M. P. KÖNIG: Die kongenitale Hypothyreose und der endemische Kretinismus, Springer 1968)

but in many cases hormone supplies fail to meet the demands in the growing organism, e.g. in puberty, and hypothyroidism follows.

The radioiodine turnover in the stimulated ectopic retrolingual tissue may be greatly accelerated. Thus radioiodine uptake is rapid, but the tracer leaves the gland again at a fast rate. Scintiscanning should therefore be performed in an early phase of the iodine uptake. Due to the rapid turnover the level of radioactive protein-bound iodine (PB ^{131}I) is fairly high after 24 hours. The salivary glands, which also concentrate iodide, have to be carefully shielded during scintiscanning to avoid false-positive results.

Surgery is not normally necessary in retrolingual goiter. Treatment with thyroxine suppresses the elevated TSH levels, and the hyperplastic thyroid tissue is deprived of its growth stimulus and shrinks. Only if this therapy fails is surgery indicated (NEINAS, 1973; see p. 283).

Unilateral aplasia of a thyroid lobe is rare. It is occasionally simulated by a toxic nodule suppressing the activity of the remaining tissue. Scintiscanning after TSH injection reveals the dormant tissue on the contralateral side in such cases.

The thyroglossal duct sometimes gives rise to cysts, which occasionally become infected. When they are treated by surgery the whole of the thyroglossal duct should be removed to avoid recurrences. The possible sites of ectopic thyroid tissue are shown in Fig. 7.

Thyroid tissue in an ovary, so-called struma ovarii, is part of a teratoma. It is very rare and is seldom diagnosed before laparotomy, unless scintiscan of the abdomen is performed (p. 210).

The etiology of thyroid aplasia or ectopism is not known. The question as to whether maternal thyroid antibodies which cross the placenta may damage the fetal thyroid is a matter of debate (BLIZZARD, 1960; CHANDLER, 1962). Most mothers of athyrotic children have no thyroid antibodies, and most mothers with thyroid antibodies have normal children. Thyroid aplasia and hypoplasia occur sporadically in most cases and only very rarely is there a familial incidence (CHILDS, 1954; BERNHEIM, 1961). The mothers of athyrotic children usually have a normal thyroid function, but there is an increased incidence of hypo- and hyperthyroidism in their families. Both sexes are equally affected and it has not been possible to incriminate exposure to toxins and infectious agents (toxoplasmosis) as a cause (ANDERSEN, 1969).

A few cases of hypothyroidism acquired during fetal life due to radioiodine treatment of the mother have been reported (FISHER,

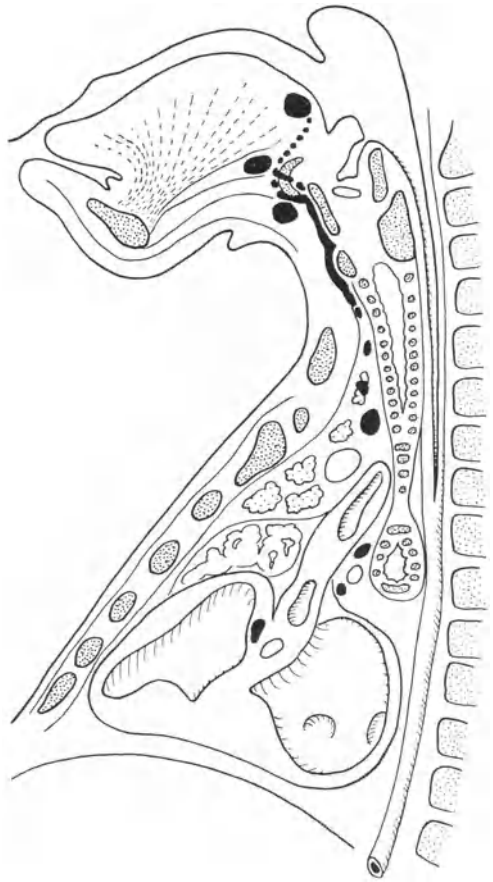

Fig. 7. Schematic representation of the most frequent locations of dystopic thyroid glands. (From S. C. WERNER: The thyroid, New York 1955)

1963). Treatment of the mother with antithyroid drugs may produce fetal hypothyroidism and goiter. Both are rapidly reversible after birth, but it is not known whether the episode of fetal hypothyroidism leaves traces in later life in the form of subtle mental retardation. Treatment of the mother with pharmacological doses of iodide, e.g. for asthma, may produce fetal hypothyroidism and goiter. The condition has a serious prognosis (CARSWELL, 1970).

2. Acquired Childhood Hypothyroidism

Hypothyroidism of the newborn due to maternal drug treatment has been discussed above. Hypothyroidism due to drug treatment of the child itself is very rare, due to the rarity of thyrotoxicosis in childhood. Two causes should be considered when hypothyroidism develops in a previously healthy child. The first is the failing function of a hitherto unrecognized ectopic and/or hypoplastic thyroid gland. This is reported to occur frequently during puberty. The second cause is idiopathic hypothyroidism due to spontaneous atrophy of the thyroid gland, also called chronic thyroiditis, atrophic variant (WINTER, 1966). The pathogenesis of this disease, which is probably autoimmune in nature, has been discussed with that of adult hypothyroidism.

Cystinosis, a rare generalized metabolic disorder which usually leads to death in renal insufficiency, has recently been found to cause hypothyroidism. Four out of 16 patients studied by CHAN (1970) were frankly hypothyroid. Autopsy revealed severe thyroid atrophy with cystine crystals in epithelial cells.

The differentiation of acquired hypothyroidism from the congenital form is not usually difficult. In the acquired form, growth and mental development are normal during the first years of life and the signs and symptoms are similar to those of the disease in adulthood. Slowing of mental functions is present, but the mental retardation is much less pronounced. Irregularities in the bones and body proportions are also less conspicuous than in the congenital form.

3. Genetically Determined Defects of Thyroid Hormone Biosynthesis or Action

Thyroid hormone biosynthesis and action occur in a sequence of several steps (p. 139), each of which may theoretically be the site of an hereditary defect. The defects known to date are listed in Table 4. An exhaustive review on the subject has been written by STANBURY (1972), and it is his classification which is used in this discussion. All the defects known so far are of the autosomal recessive type. Consanguinity of the parents is often demonstrated and siblings are frequently affected.

The clinical picture is very similar in most defects, with the exception that peroxidase deficiency is often associated with nerve deafness (Pendred syndrome, see below). Goiter is occasionally present at birth, but usually develops during early childhood. It becomes very large and can no longer be overlooked by adolescence. Hypothyroidism may be mild or marked, but is rarely as severe as in congenital aplasia of the thyroid. The symptoms and signs are the same as for the other forms of childhood hypothyroidism. It can safely be said that the occurrence of a large goiter in a hypothyroid child is almost diagnostic of one of the hereditary defects.

Pathological examination of the thyroid gland usually shows a multinodular goiter with all the histological signs of intense stimulation by TSH, i.e. very sparse colloid with a micro-

follicular picture. Trabecular epithelial parts are also found. Polymorphism of epithelial cell nuclei is often encountered, and sometimes the picture might be interpreted as that of a malignant tumor, but metastases are practically never seen.

a) Deficient Active Iodide Transport (STANBURY, 1960; WOLFF, 1964)

This is a rare cause of hereditary hypothyroidism. The thyroid is unable to accumulate iodide from the blood in this condition, and the defect can be imitated pharmacologically by the administration of perchlorate, a drug that competitively inhibits active iodide transport (p. 140). MEDEIROS (1972) has described two patients with a partial defect. There is no complete biochemical explanation for the defect as yet. It is konwn that active iodide transport requires energy supplied by a membrane-bound Na^+- or K^+-activated ATPase. However, it is unlikely that the latter enzyme is absent, since this is hardly compatible with cell survival. The salivary glands, which normally also actively accumulate iodide are also affected. The diagnosis is made from a lack of thyroidal accumulation of radioactive iodide and by the low PB ^{131}I level in the serum after a dose of radioiodide; it is confirmed by a lack of radioiodide accumulation in saliva when compared to the plasma concentration and finally by *in-vitro* incubation of excised thyroid tissue. GILBOA (1963) has clearly shown that the subsequent steps of thyroid hormone synthesis are intact. He administered large doses of iodide to a patient, which raised the plasma iodide to such levels that enough iodide penetrated into the thyroid gland by passive diffusion to make active transport unnecessary. Production of normal amounts of thyroid hormone was thus possible and the patient became euthyroid. However this is not the recommended routine treatment, since overdosage of iodide led to hyperthyroidism in this case.

b) Defective Thyroglobulin Iodination (Iodine Organification) and Pendred Syndrome

Many patients with this defect have been reported since it was originally described by STANBURY (1950). It now appears that this is a heterogeneous group of disorders. The two features common to all cases are the occurrence of goiter and the fact that radioiodine accumulated by the thyroid gland can be discharged by the administration of perchlorate (see p. 243). With the elucidation of the steps necessary for iodination of thyroglobulin (p. 140) it has become customary to describe the disease as due to deficiency of thyroidal peroxidase, the enzyme presumably necessary for the oxidation and organification of iodine. However, as will be seen below, the term peroxidase deficiency does not cover all defects described in this disorder, and should therefore be used with caution.

HAGEN (1971) has classified patients with defects in iodide organification as follows: in *type A* thyroid peroxidase is completely absent (VALENTA, 1973). The patients are severely hypothyroid cretins with a very low plasma hormone level. Administration of perchlorate leads to discharge of all accumulated iodide. In *type B* (Pendred's syndrome) the patients are euthyroid (MILUTINOVIC, 1969), have a goiter and suffer from nerve deafness. Perchlorate discharges part of the radioiodide and peroxidase activity is normal (LJUNGGREN, 1973; BURROW, 1973). *Type-C* patients are euthyroid, have a goiter, a partial perchlorate discharge and abnormal peroxidase. Enzyme activity is absent *in vitro* when tested in normal conditions, but the addition of hematin, the alleged prosthetic group of the enzyme, partially restores enzyme function. A defect in the binding of the prosthetic group to the apoenzyme has been postulated (HAGEN, 1971; NIEPOMNISZCE, 1972 and 1973).

REINWEIN (1970) has described a case of defective iodide organification where the thyroid predominantly secreted triiodothyronine. It has not been established to which of the above classes his patient belongs. It is possible that predominant triiodothyronine synthesis is merely a consequence of the intense TSH stimulation and the low degree of thyroglobulin iodination, which are necessarily present in all hypothyroid patients. This leads to a preferential synthesis of monoiodotyrosine and consequently of triiodothyronine. BELLABARBA (1972) has described 4 patients with almost selective triiodothyronine secretion, but the nature of the underlying biochemical defect was not specified.

The cause of deafness in Pendred's syndrome has not yet been established.

c) Failure of Iodotyrosine Coupling

The last step in the biosynthesis of thyroxine is the coupling of two diiodotyrosyl residues of thyroglobulin to form thyroxine. Details of this reaction are not yet fully understood (p. 141). Several patients showing good evidence for the failure of iodotyrosine coupling have been described. They all had a goiter, were moderately or borderline hypothyroid and had a high thyroidal radioiodine uptake (STANBURY, 1963). A large fraction of the radioiodide taken up by the thyroid was rapidly lost again in non-

hormonal form. SHIMAOKA (1972) recently described a case with failure of iodotyrosine coupling who secreted the unusual iodocompound diiodo-p-hydroxyphenyl lactic acid, an alleged intermediate in the coupling reaction. It remains to be seen whether this compound is found in other cases.

Diagnosis of coupling failure is based mainly on the exclusion of other defects and on the demonstration of labeled mono- and diiodotyrosine but not of thyroxine in thyroid tissue excised after the administration of radioiodine. This pattern of iodine distribution can also be simulated by iodine deficiency, which must therefore be excluded by measurement of thyroidal and urinary ^{127}I content.

d) Failure of Iodotyrosine Deiodination

A normal molecule of thyroglobulin contains about 2 residues of thyroxine and 10 to 15 residues of mono- and diiodotyrosine. When thyroxine is to be released the whole thyroglobulin molecule is hydrolyzed into its constituent amino acids. Mono- and diiodotyrosine, neither of which has any hormonal activity, are immediately deiodinated within the gland and most of the iodide thus liberated is reutilized for thyroglobulin iodination without leaving the gland (p. 142). If the iodotyrosines are not deiodinated their iodine cannot be reutilized and they diffuse out of the gland and are excreted in the urine. A number of patients meeting the criteria for a defect of deiodination have been described (MCGIRR, 1959). All of them had a goiter, were either frankly or borderline hypothyroid, and were mentally retarded. After a dose of radioiodine the thyroidal uptake was high and turnover of the isotope was rapid. Labeled iodotyrosines, normally absent, were found in the urine. The diagnosis is confirmed by the administration of ^{131}I-labeled mono- or diiodotyrosine. Normally only traces of the label appear in the urine in the form of the injected compound and most of the urinary ^{131}I is iodide, presumably because the deiodinating enzyme is also present in various extrathyroidal tissues including the liver. STANBURY (1972) has presented presumptive evidence that heterozygotes can also be detected with this test. NAKAJIAMA (1971) has recently described patients in whom he thought that diiodotyrosine deiodination was deficient while that of monoiodotyrosine was normal. The defect was thought to be transmitted as an autosomal dominant, in contrast to the findings in all other sibships reported so far.

Since severe dietary iodine deficiency can cause some of the same clinical findings and radioiodine turnover values, this condition has to be carefully excluded by measurement of urinary ^{127}I before the diagnosis of failure of iodotyrosine deiodination can be accepted.

The reason why these patients are hypothyroid is not immediately apparent. All the steps of hormone biosynthesis and release are in fact intact and the defect is located in a side reaction of iodine metabolism. This side reaction is, however, very important for the preservation of iodine stores, and when it is impaired the gland suffers severe iodine deficiency. The accuracy of this interpretation was clearly demonstrated by VAGUE (1962), who treated patients with Lugol's solution. The increased iodine supply led to a complete normalization of thyroid function, confirming that hormone biosynthesis and release were proceeding normally.

e) Diminished or Altered Thyroglobulin Synthesis

A number of case reports have appeared where a defect in thyroglobulin synthesis was postulated (see STANBURY, 1972, for review). Some of the patients had a thyroglobulin with altered physicochemical properties, while others produced no distinct iodoprotein at all, and still others synthesized and iodinated albumin, which in normal thyroids is present in only small amounts. Two cases of complete absence of thyroglobulin biosynthesis have recently been well documented by LISSITZKY (1973). This group of defects thus does not appear to be homogeneous with regard to the basic defect. Clinically the patients are hypothyroid or borderline euthyroid and have a goiter. The radioiodine uptake is high. The diagnosis is made by biochemical examination of excised thyroid tissue. It must be borne in mind that any condition that leads to intense and prolonged TSH stimulation of the thyroid gland, e.g. iodine deficiency or other inborn defects of hormone synthesis, will produce a hyperplastic goiter depleted of colloid and thyroglobulin. The causes of thyroglobulin depletion mentioned above therefore have to be rigorously excluded before the diagnosis of deficient thyroglobulin synthesis can be accepted. In a rat goiter MONACO (1973) has ascribed the lack of thyroglobulin synthesis to a defect in one of the enzymes necessary for the addition of carbohydrate to the protein. It is conceivable that similar defects occur in man.

f) Abnormal Iodinated Serum Peptides

Several patients with hypothyroidism, mental retardation, goiter, and a high level of protein-bound iodine have been detected. Analysis of their serum iodine has revealed that a large part is not extractable into butanol (thyroxine is extracted almost 100% into butanol). The

abnormal iodinated substances were identified as peptides which migrated with albumin on paper electrophoresis. Hydrolysis of these peptides with trypsin yielded mono- and diiodotyrosine. Such iodinated peptides are also present in the serum in chronic lymphocytic thyroiditis, in thyroid cancer, and occasionally in endemic goiter. The basic biochemical defect and the mode of inheritance are not known (DEGROOT, 1958; WERNER, 1960; LAMBERG, 1963; STANBURY, 1972).

g) Rare Inborn Errors

STANBURY (1968) described an 8-year-old congenitally hypothyroid patient with no goiter whose thyroid failed to respond to TSH injected *in vivo* and also to TSH added *in vitro*. He postulated a defect in thyroid responsiveness to TSH, but other interpretations of the findings are also possible.

REFETOFF (1967, 1972) investigated families in which several members had small goiters, were borderline hypothyroid, had nerve deafness, and, surprisingly, had a high circulating thyroid hormone level. He thought the syndrome was due to an end-organ resistance to thyroid hormone action. A characteristic radiologic findings was stippled femoral epiphyses. Basically similar cases were observed by LAMBERG (1973) and BODE (1973).

REINWEIN (1963, 1964) reported a case of goiter with deaf-mutism where the synthesis of thyroxine was normal, but the release of the hormone from thyroglobulin was impaired. Biochemical examination of the gland suggested that the condition was probably due to a deficiency of thyroid protease.

4. Secondary Hypothyroidism in Childhood

The causes of secondary hypothyroidism in childhood are listed in Table 4. It rarely occurs as an isolated TSH deficiency and is most frequently associated with growth hormone deficiency in the syndrome of pituitary dwarfism (p. 98ff.). The availability of synthetic thyrotropin releasing hormone has made it possible to show that in the majority of cases the disease is of hypothalamic rather than pituitary origin (p. 160).

5. Clinical Features of Childhood Hypothyroidism

a) Features in the Neonate

The success of substitution therapy is dependent mainly on early diagnosis of hypothyroidism in the neonate, which justifies special attention to the early signs. The athyrotic or hypothyroid neonate usually shows none of the classic clinical features of hypothyroidism, and the differential diagnosis against Down's syndrome may be very difficult (p. 176). That an athyrotic neonate suffered from hypothyroidism during fetal life is often documented by two facts: first, the bone age is slightly retarded at birth; secondly, mental retardation may become manifest in later life, even when thyroid hormone replacement is started immediately after birth. Both facts support the view that maternal thyroid hormones cross the placenta in insufficient amounts and that the fetus is therefore dependent on its own hormone supply.

Pregnancy is sometimes prolonged in the case of a hypothyroid child. Weight at birth is often slightly above average. Body length at birth may be less than normal, normal, or even above normal. Prenatal bone maturation is sometimes retarded, which is easily demonstrated by the lack of calcification in the distal femoral epiphysis at birth. Occasionally a large tongue and a puffy red face resembling that in Cushing's disease is noted. Very often the physiologic neonate icterus is prolonged (icterus prolongatus).

In the first few weeks of life the first symptoms of diminished metabolism become apparent. The baby is conspicuously quiet, needs a lot of sleep, becomes a poor nurser and is constipated. He is unusually good-tempered, rarely cries and lies still in bed. In spite of the feeding problem the baby looks well-nourished (Fig. 8). Gradually, physical and mental retardation with motor inactivity, flaccidity of the musculature, protrusion of the abdomen (often associated with umbilical hernia), and the yellow, dry and thickened skin become increasingly apparent. The baby does not kick, and smiles and lifts his head later than normal. His face becomes puffy and the tongue is enlarged (Fig. 8). The hair is dry and grows slowly. The neck is usually too fat to permit proper palpation of the so-called "bare trachea" in thyroid aplasia. Temperature and pulse rate tend to be low. All these symptoms are sufficiently developed by the second month to raise the suspicion of hypothyroidism in the experienced doctor.

b) Features in Early Childhood

In the second six months of life the symptoms become so marked that even mild cases can be readily diagnosed. All symptoms gradually become worse in subsequent years.

The mental and physical development of these children is greatly retarded. They are unusually peaceful, sometimes almost stuporous. All their actions are extremely slow. They are severely constipated. Apart from the skin changes, which will be discussed later, physical exmination reveals striking abnormalities. The head is large and brachycephalic. The facies is broad and puffy and the features are coarse. The expression is dull and content. The forehead is low and covered by thick wrinkles. The nasal bridge is broad and flat and the

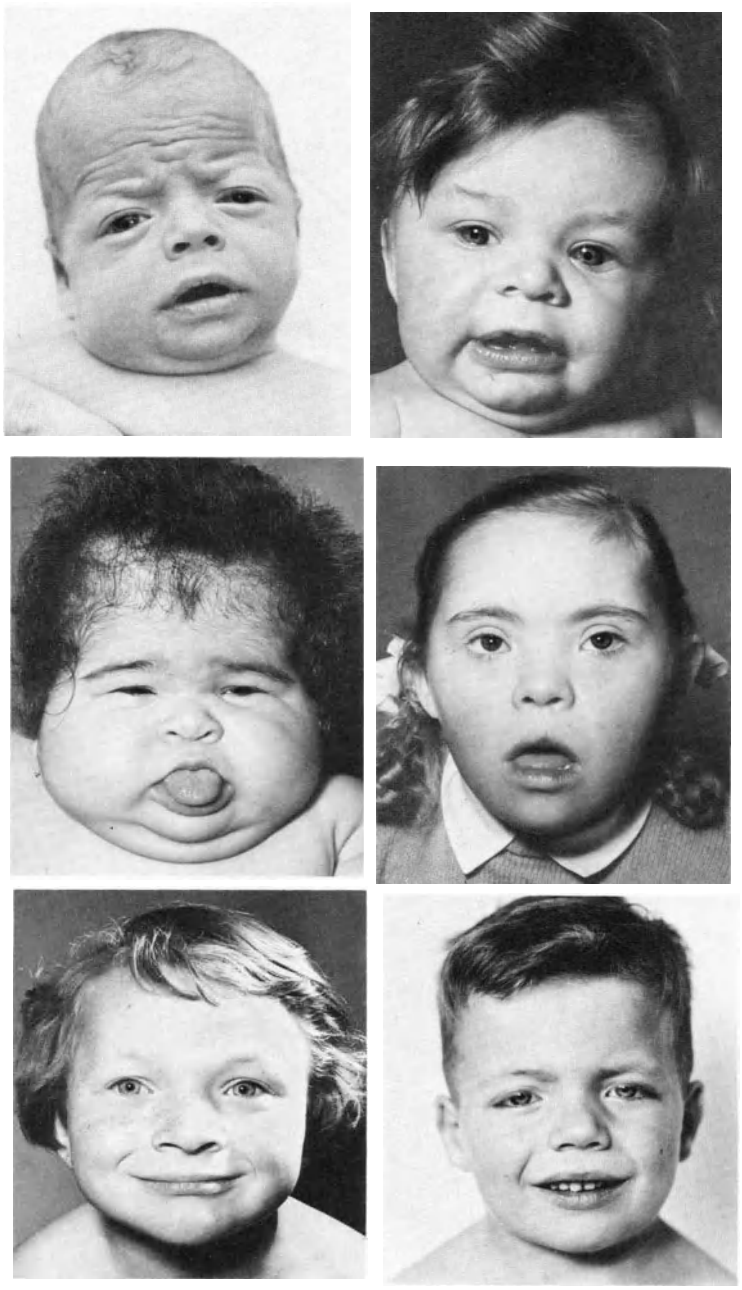

Fig. 8. Facial expression in congenital hypothyroidism and in Down's syndrome in childhood. Top left: age 2 months, untreated thyroid aplasia. Top right: age 5 months, untreated moderate hypothyroidism. Middle left: age 2 years, thyroid aplasia, untreated. Middle right: age 7 years, Down's syndrome. Bottom left: age 7 years, hypothyroidism, on insufficient replacement therapy. Bottom right: age 7 years, thyroid aplasia, on insufficient replacement therapy. Note the enormous difference between thyroid aplasia and moderate hypothyroidism in babyhood (top figures). At age 7 the facial expression in insufficiently treated hypothyroidism is not strikingly abnormal, but still shows the round face and the broad features. Note also the difference between hypothyroidism and Down's syndrome. In contrast to hypothyroidism Down's syndrome causes slanted eyes and an epicanthal fold. The mouth is also enlarged and but not to the same degree as in hypothyroidism

nostrils point forewards instead of downwards. The interocular distance is increased. The mouth is large and the lips and tongue are thickened and swollen (Fig. 8). Dental eruption is delayed. Defects in dental enamel are frequent, as is dental caries. The hair is dry. Speech is slow and badly articulated and the voice is hoarse. Deafness may later be noted in Pendred's syndrome (p. 168). Occasionally the trachea can be palpated despite a fat neck, and there is an impression that there is no overlying thyroid tissue ("bare trachea"), but this, of course, is an unreliable sign for the absence of the thyroid.

The body is not only short, but also fat and plump. The extremities are short and the abdomen protruding.

c) The Specific Symptoms of Developmental Retardation

Thyroid insufficiency, even of a slight degree, causes marked retardation of physical and mental development. This is particularly true in children with thyroid aplasia, who at the age of 10 years may physically be at the stage of babyhood, if they have never been treated. They rarely reach the age of 20 and die much earlier in most cases.

In hypothyroidism the retardation of growth is characterized mainly by delayed bone development and maturation, and delayed development of body proportions. The body proportions as measured by the length of the upper segment (symphysis to head), the lower segment (symphysis to feet) and the span (fingertips to fingertips with extended arms) remain infantile (cf. Chap. XIX), i.e. the extremities are too short (Figs. 10, 13, 14). This is in contrast to dwarfism from other causes. The head is too large in relation to the body and retains its infantile shape. This results in the typical brachycephalic head with coarse facial features.

Fig. 9 shows growth, weight gain, bone development and intelligence in a case of severe hypothyroidism, expressed in terms of developmental age correlated with chronological age (Chap. XIX). As a rule, bone age is more and weight age (due to slight obesity) less retarded than height age. The dental age is not shown. It is usually less retarded than the other parameters, although a delay in dentition is almost always demonstrable. Intelligence age varies widely from case to case, but rarely exceeds height age.

If all the parameters discussed are considered together hypothyroidism produces a characteristic developmental type after the age of early babyhood (Fig. 10). This type again

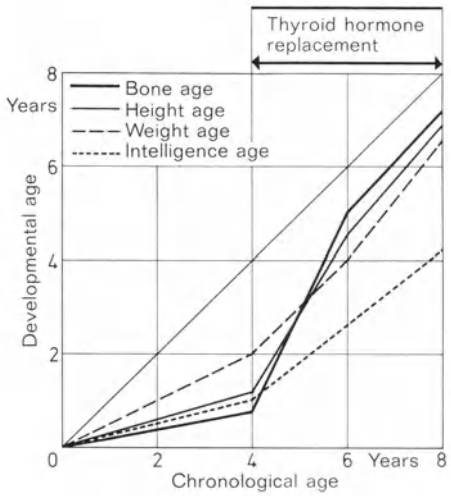

Fig. 9. Schematic representation of growth, weight gain, development of bones and intelligence in a case of severe congenital hypothyroidism. Treatment was started at age 4 (KspZ)

changes in a characteristic fashion upon optimal thyroid substitution therapy (Fig. 9). Bone age is accelerated more than weight age, and mental development will ultimately be least influenced by thyroid hormone treatment (p. 176). In untreated cases puberty is delayed in

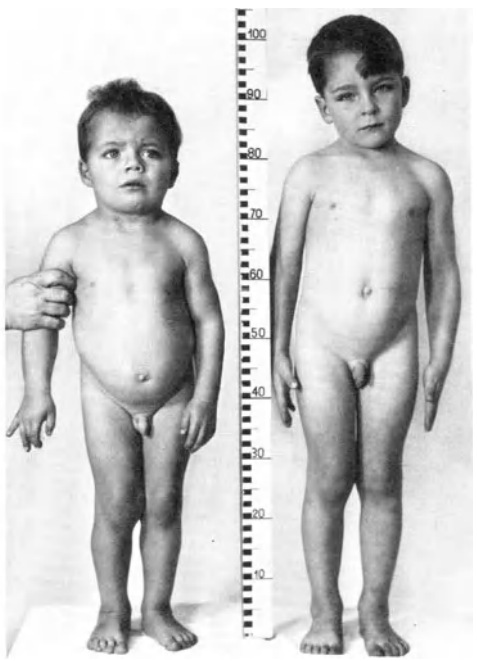

Fig. 10. Twins, age 4½ years. The boy on the left suffers from inadequately treated thyroid aplasia, the one on the right is healthy. Note the short stature, the protruding abdomen, the large brachycephalic head, the broad coarse face, the thick neck, and the infantile proportions. In the affected child the ratio of the upper to the lower segment is 1.4:1, in the healthy twin it is 1.26:1

accordance with the delayed bone age. Sometimes it is incomplete or fails to occur at all. (The relationship between puberty and bone age is discussed in Chap. XIX.)

d) Skeletal Changes

The slow longitudinal growth of long bones (short extremities) and the retardation of bone development have already been mentioned. This retardation is apparent in delayed appearance of ossification centers, fontanelle closure, pneumatization of skull bones, and epiphyseal closure. An X-ray of the hands should always be made for determination of the bone age (Chap. XIX); in addition to the delayed apperance of ossification centers the plate will show other typical features, such as the intensively calcified preparatory zone of calcification at the ends of the diaphyses (Fig. 11). Substitution therapy causes bone growth, but this zone remains visible for a long time as a densely calcified transversal "growth line" (Fig. 11). Corresponding circular lines will be visible in the ossification centers. This intensive calcification of bone has been attributed to the slow growth of the bone matrix due to reduced osteoblast activity (low alkaline phosphatase) together with a relatively good supply of calcium. This leads both to an intense calcification of bone and to a reduction in intestinal calcium absorption, as is documented by the low urinary calcium excretion. This explains why rickets, i.e. diminished calcification of the bone matrix, virtually never occurs in hypothyroidism, and also why vitamin-D intoxication is easily produced. These changes probably also cause the osteosclerotic changes and the soft tissue calcifications occasionally observed in untreated patients with thyroid aplasia.

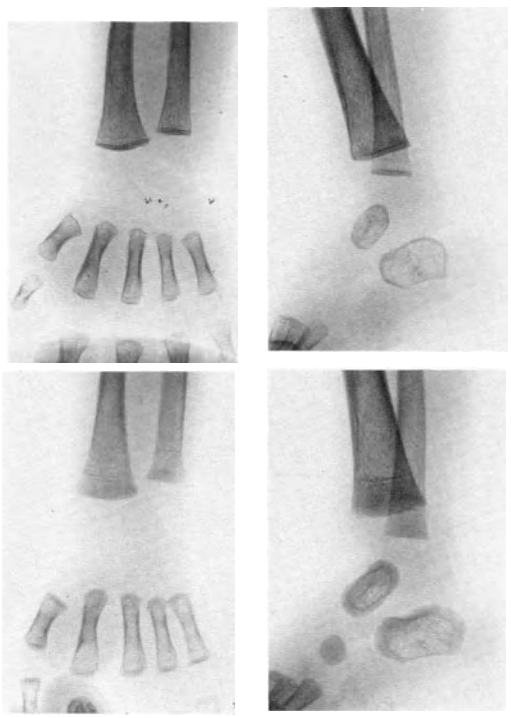

Fig. 11. X-rays of hands and feet in a case of congenital hypothyroidism. Top: At age 9 months, just prior to treatment. Bottom: At age 11 months, after two months of treatment. The phase of slow growth preceding treatment can still be recognized after treatment from the dense transversal line in the long bones and from the dense circular line in the talus and calcaneus (KspZ)

Another typical skeletal change is the irregular multicentric calcification of ossification centers, the so-called epiphyseal dysgenesis or "cretinoid osteochondropathy". This sign becomes particularly marked during intense substitution therapy, which produces a rapid calcification of the epiphyses. It can be observed in all epiphyses and ossification centers, but is most typical in the femoral head. This radiologic finding is very similar to that in Perthes' disease, but differs from it in always being bilateral. The femoral head becomes completely calcified during therapy, but severe deformity with coxa vara always persists (so-called cretinous hip, Figs. 12, 31, p. 220). The hip deformities contribute to the clumsy gait of most congenitally hypothyroid patients.

Localized bone changes occur in the spine in the form of thoracal kyphosis with wedge-shaped compression of the second lumbar vertebra. The sella turcica is often enlarged, probably due to hyperplasia of the anterior pituitary (increased TSH secretion, see p. 155).

e) Skin Changes

As in cases of adult hypothyroidism, the skin has a yellowish to dirty brown color. It feels thickened, rough and dry. In older children grayish, dirty-looking hyperkeratotic knees are often seen. The skin of the extremities is not only cool, but sometimes frankly cyanotic. Histologic examination reveals increased metachromasia and increased numbers of mast cells.

The subcutaneous fat is usually well developed, but of a peculiarly flaccid firmness. In severe cases of hypothyroidism striking collar-like supraclavicular fat deposits develop (Fig. 13).

Scalp hair is sparse, dry and thickened (Fig. 8). After the age of two years, marked hypertrichosis with lanugo-like hair on the back and on the extensor surfaces of the extremities often develops, pubic and axillary hair remaining absent until puberty.

All changes in the skin, hair and subcutaneous fat are reversed by substitution therapy.

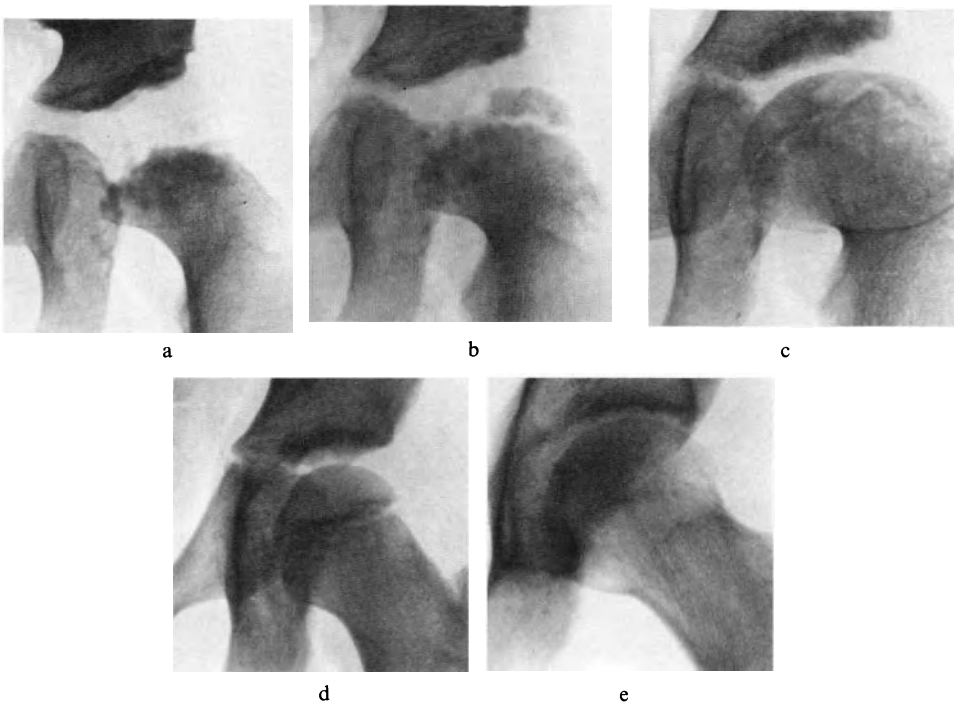

Fig. 12. a to c) Hip joint of a boy with congenital hypothyroidism at age 12, 14, and 17 years. Thyroid hormone treatment was instituted shortly after the first picture. d, e) Hip joint of healthy boys at age 11 and 14 for comparison. Note the very deficient ossification which rapidly improves after treatment, but still remains irregular. The femoral head is grossly deformed (KspZ)

Fig. 13. Patient with congenital thyroid aplasia at age 22 years. The height is 105 cm. Note the typical facial expression, the developmental retardation and the collar-like supraclavicular fat. (Prof. E. MARTIN, Prof. B. COURVOISIER, Policlinique médicale de l'université de Genève)

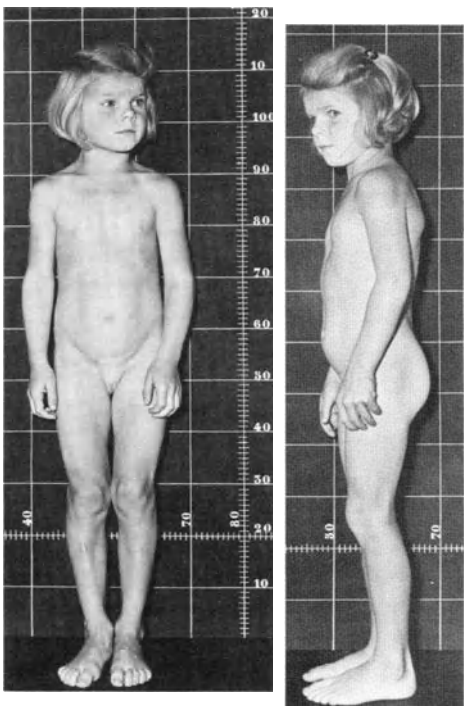

Fig. 14. Congenital hypothyroidism, inadequately treated. The girl, age 8 years, has a mental and physical development corresponding to a 4-year-old. Note the typical facial expression and spastic stature with slightly flexed extremities

f) Neuromuscular System

In the infant and the young child the musculature is usually underdeveloped and flaccid. This explains the large, protruding abdomen. In the older child, and occasionally in the infant, there is generalized muscle hypertrophy with muscular rigor. The result is an almost athletic appearance associated with clumsy movements. In the rare cases of the Kocher-Debré-Sémélaigne syndrome, muscular hypertrophy dominates the clinical picture (DEBRÉ, 1935; CROSS, 1968; MEDEIROS, 1972). All movements are slow and clumsy. The patients keep their stiff limbs in a slightly flexed position (Fig. 14). They stand and walk with flexed knees and with their feet turned in. There is a peculiar lack of spontaneous involuntary movements. Tendon reflexes are very active, but the relaxation phase is prolonged. A pseudomyotonic reaction is often elicited by tapping the muscles (p. 158).

The electroencephalogram shows slowed activity with diminished potentials. Even the treated patient may have general dysrhythmic brain activity which parallels the irreversible mental retardation to a certain degree.

g) Cardiovascular System and Blood

The pulse rate is low and blood pressure is reduced with few exceptions. The heart is occasionally enlarged (myxedematous heart, see p. 156), which is attributed partly to myxedematous changes within the myocardium and partly to concomitant anemia. The electrocardiogram is often normal. Occasionally the same changes are seen as in the adult (low voltage, see p. 156).

Anemia is almost always present. As in the adult (p. 157) it may be either hypochromic or hyperchromic. A constant finding is hypoplastic hypocellular bone marrow. Serum iron may be elevated due to diminished incorporation into hemoglobin. The hyperchromic anemia, which responds only to thyroid hormone substitution, is probably more characteristic of hypothyroidism, while hypochromic anemia is rather nonspecific and may be related to alimentary iron deficiency. The white blood picture may be normal or show lymphocytosis. True juvenile pernicious anemia has been reported to coexist with childhood hypothyroidism (OLIVER, 1969).

h) Metabolic Changes

A lowered basal metabolic rate is as characteristic as in adult myxedema. Due to technical difficulties and uncertainty about normal values in children with dwarfism, the basal metabolic rate is of no great clinical importance.

In contrast, the measurement of the serum thyroxine concentration and radioiodine uptake studies are as important in children as in adults. Normal values are very comparable to those of adults.

As in the adult, an increase in beta-lipoproteins, with hypercholesterolemia and hypercarotenemia, is present in older children. Hypercholesterolemia is absent, however, in most babies and is infrequent in small children. On the other hand, the serum alkaline phosphatase is often diminished in the small child (normal values for children: 30 to 140 IU). This is due mainly to decreased osteoblast activity, and possibly also to hepatic changes. Calcium and phosphate in the serum are usually normal. Rare cases have shown hypercalcemia with osteosclerosis (ROYER, 1954).

Urinary excretion of creatine and calcium are reduced.

Urinary steroid excretion and tests of adrenal cortical function may indicate slight secondary adrenocortical insufficiency. The cortisol secretion rate is diminished (KENNY, 1967). Growth hormone secretion shows a less pronounced rise in response to hypoglycemia. These findings are comparable to those in pituitary dwarfism, but differ in that they are reversible by thyroid hormone substitution.

Occasionally pubertas praecox occurs (VAN WYK, 1960), which has been ascribed to an overlap between the feedback of gonadotropins and TSH. In girls this may be accompanied by galactorrhea (p. 158) with elevated prolactin levels. Thyroid hormone substitution reverses the signs of early puberty.

i) Differential Diagnosis

After infancy, untreated cases of athyroidism and hypothyroidism are immediately and easily recognized. The cretinoid features, physical and mental retardation, characteristic skeletal proportions, skin changes, slow pulse, and low blood pressure all combine to give an unmistakable picture. Of course the clinical spectrum reaches from complete athyroidism to mild failure, according to the nature of the thyroidal defect. Nonetheless, mental and physical retardation is a mandatory sign, even in mild cases. Hypothyroidism must therefore be suspected in every case of dwarfism and mental retardation.

Severe untreated cases are now rarely encountered later than babyhood, because the correct diagnosis is usually made. However,

untreated babies and badly treated older children are still frequently encountered.

Measurement of the ankle reflex time is a simple and reliable procedure. In hypothyroidism the reflexes are definitely prolonged, but it must be borne in mind that normal values are lower in children than in adults (p. 241).

Most important for the establishment of the diagnosis in small babies is the measurement of serum hormone concentrations and of the radioiodine uptake. If the values are not clear-cut and the suspicion of hypothyroidism persists, a TSH stimulation test should be performed, and if possible also a TRH stimulation test (p. 242). A TSH test must also be performed in cases where thyroidal ^{131}I uptake is already suppressed due to thyroxine treatment. If the stimulation tests cannot be performed in doubtful cases, one must resort to establishing the diagnosis from the failure or success of thyroid hormone substitution therapy given over several weeks. A clear-cut improvement of signs takes place only in hypothyroidism.

In babies, hypothyroidism is often mistaken for rickets. Growth is retarded in both diseases, but otherwise signs are completely different, in particular the bone changes seen on X-ray and alkaline phosphatase in the serum (elevated in rickets, lowered in hypothyroidism).

Chondrodystrophy and gargoylism (Hurler's syndrome) are also occasionally confused with hypothyroidism, the signs they have in common being dwarfism and a large head with coarse features. In chondrodystrophy the extremities are short, as they are in hypothyroidism, and gargoylism is often associated with mental retardation. In both diseases, however, all other features of hypothyroidism in particular the cutaneous and cardiovascular changes and the metabolic abnormalities, are absent.

For the differential diagnosis of dwarfism the reader is referred to Chap. XIX.

The differential diagnosis is also difficult in cases with marked mental retardation and some degree of physical retardation but without the symptoms of severe hypothyroidism. Some disorders due to brain damage and several metabolic diseases have to be considered in these cases (phenylketonuria and others). For the inexperienced doctor the differential diagnosis from Down's syndrome often proves very difficult. In both conditions patients have a dull facial expression with plump features, a wide mouth and a large, protruding tongue. The epicanthal fold and the slanted eyes, however, distinguish Down's syndrome from hypothyroidism (Fig. 8). Moreover, in Down's syndrome these are already present at birth, whereas in hypothyroidism the development of the typical facies takes several weeks. Muscular hypotonia, short stature, constipation, hoarse voice, and mental retardation in Down's syndrome may contribute to the confusion with hypothyroidism, but the motor inactivity, the skin changes and the cardiovascular changes are absent. On the contrary, children with Down's syndrome are often hyperactive and agitated. Another distinctive sign is the high frequency of congenital heart disease in Down's syndrome and its rarity in hypothyroidism. Occasionally both diseases are found simultaneously in one patient (HARRIS, 1967). In such cases the typical hypothyroid signs have been found in addition to the diagnostic chromosomal changes (trisomy 21).

6. Treatment and Prognosis

Treatment of childhood hypothyroidism must be by full oral hormone substitution. In acquired hypothyroidism the aim of normal physical and mental development is more easily achieved than in congenital hypothyroidism, where normal physical and mental development is only possible if substitution therapy is begun within the first months of life and consistently maintained in an adequate dosage throughout the growth period. Delayed institution of therapy, interruptions, or inadequate dosage will seriously compromise the final result. The following guidelines are therefore meant primarily for the treatment of congenital hypothyroidism. A change of doctor is often detrimental to the patient. The new doctor will find no signs of hypothyroidism if the child has been properly treated, and may consider treatment unnecessary. Months often pass before the developmental retardation becomes manifest and the error is recognized. Such interruptions are deleterious for the development of a child and are to be avoided at all costs. In case of doubt about the original diagnosis it is wise to continue treatment until the previous patient data are obtained or until the diagnosis is confirmed by a TSH test (p. 242).

Unfortunately, even an early diagnosis and correct continous treatment do not always guarantee normal mental development. As in endemic cretinism, this must be attributed to prenatal brain damage which is incompletely reversible. If treatment is started late or not continued consistently a clear improvement can be observed, but never a full normalization of development. Unfortunately, most patients with congenital hypothyroidism who reach adulthood belong to the latter group. Basal metabolic rate,

pulse, blood pressure and serum lipids have become normal, and constipation and skin symptoms have been corrected. Nontheless, short stature (Fig. 10), a plump broad facies (Fig. 8), general slowness, decreased fitness, slow and clumsy speach and varying degrees of mental retardation persist. Puberty is delayed, but otherwise normal. Only extremely few patients have a completely normal mental and physical development fitting them for normal schooling and professional training.

Experience has shown that years of treatment are needed to catch up with normal growth and that normal mental development can only be assured by early and regular treatment with proper dosage (Fig. 9). Therefore substitution therapy *during the whole of the growth period, in particular in infancy, is given at the highest dose that can be tolerated.* This principle is abandoned only in children in whom treatment was started late; when the doctor is convinced, on the basis of the results of several months of full treatment, that complete normalization of mental development cannot be achieved, the dose may then be reduced if the patient becomes more placid and more easily manageable. After the age of 10, athyrotic cretins who have never been treated and have remained at the stage of an infant are best left without therapy, since their mental retardation can no longer be improved. Thyroxine treatment in such cases can convert a passive, quiet patient into an agressive, restless one who needs continuous supervision.

The preparation of choice for the treatment of childhood hypothyroidism is L-thyroxine. Some doctors still use the time-honored desiccated thyroid, which is difficult to standardize, while others prefer a mixture of L-thyroxine and triiodo-L-thyronine. As outlined in a previous section (p. 164) this mixture has no real advantages. For a 9-year-old the average dose is 200 µg thyroxine, or 200 mg desiccated thyroid. The dose for a two-year-old is about one half, for an infant about one third and for a neonate about one fifth of the above amount. The usual procedure is to start with half the estimated dose and increase to full substitution after 2 to 3 weeks. The medication is given in one dose per day. The dose is adapted for each case from the above values by trial and error. The correct dose is the highest one tolerated without signs of hyperthyroidism such as agitation, restlessness, tremor, tachycardia, perspiration, insomnia and diarrhea. Correct dosage produces normal physical activity and normal body functions. In infants symptoms of hypothyroidism disappear within a few weeks and lethargy, lack of appetite, skin changes, pulse and constipation are greatly improved. An initial weight loss is regularly seen. Hair often falls out but grows again rapidly without the previous thickening and dryness. Growth and physical development become normal. After a delayed onset of therapy, an accelerated "catch-up" growth is often seen. The ankle reflex time is a good index of the effects of substitution therapy, providing age-adjusted normal values are used (p. 241). The serum total thyroxine can also be helpful, (cf. p. 165). The measurement of serum cholesterol is less recommended as a guide to therapy. Growth and bone age should be monitored at six-monthly or yearly intervals. With proper substitution therapy instituted early, both parameters progress normally. Bone age may sometimes get ahead of growth. If this tendency becomes marked, early epiphyseal closure may occur. To prevent this, the dosage is slightly reduced.

In the relatively rare cases of hereditary defects of hormone biosynthesis it is often necessary to resort to total thyroidectomy because of pressure symptoms and because of the danger of malignancy in the huge nodular goiter. In cases with only small goiters, thyroxine substitution therapy alone is sufficient. In the defect of active iodide transport (p. 168) and of dehalogenase (p. 169) euthyroidism can also be achieved by giving high doses of iodide (Gilboa, 1963; Vague, 1962). This treatment is of academic interest, but involves the risk of inducing hyperthyroidism, especially in the former syndrome. The routine treatment in these cases is therefore by thyroxine.

F. Thyrotoxicosis

1. Definition, Classification, and Basic Thyroid Hormone Kinetics

When the amount of thyroid hormone available to responsive tissues exceeds physiologic limits, a more or less characteristic clinical picture termed thyrotoxicosis or hyperthyroidism ensues. The serum concentration of triiodothyronine and in most cases also of thyroxine is elevated in hyperthyroidism, except in cases where there is an additional disturbance which lowers the binding proteins of serum, e.g. congenital TBG deficiency or treatment with diphenylhydantoin (p. 143). In such cases it is necessary to measure or estimate the free hormone, which should always be elevated. It is generally agreed that the serum half-life of thyroxine is shortened in hyperthyroidism, while that of triiodothyronine is given as near normal in some studies (McConnon, 1971; Nicoloff,

1972) and shortened in others (WOEBER, 1970). All reports agree that the production rates of both hormones are elevated in hyperthyroidism, except in the rare instances of isolated triiodothyronine-thyrotoxicosis (p. 200). The secretion of nonhormonal iodine, "the iodide leak", is greatly increased in hyperthyroidism (WARTOFSKY, 1971).

The thyroxine-binding capacity of thyroxine-binding prealbumin (TBPA) in serum is decreased by about 40% in patients with hyperthyroidism. In most, though not all, patients thyroxine-binding globulin (TBG) is also lowered (INADA, 1967).

In most cases thyrotoxicosis is due to overproduction of thyroid hormone by the thyroid gland, and very rarely to exogenous hormone administration. The diseases producing thyrotoxicosis are listed in Table 5. The overwhelming majority of cases of thyrotoxicosis are due either to toxic diffuse goiter (Graves' disease) or to toxic nodular goiter. All other causes of hyperthyroidism are rare.

Table 5. Classification of the American Thyroid Association of thyroid disease with thyroid hyperfunction (WERNER, 1969)

1. Toxic diffuse goiter (Graves' or Basedow's disease)
2. Toxic uninodular goiter
3. Toxic multinodular goiter
4. Nodular goiter with hyperthyroidism due to exogenous iodine (Jod-Basedow)
5. Exogenous thyroid hormone excess
6. Tumors
Adenoma of thyroid, follicular
Carcinoma of thyroid, follicular
Thyrotropin-secreting tumor of the pituitary
Hydatidiforme mole with secretion of a thyroid-stimulating substance

In the unselected patient material of the outpatient department of the University of Zurich, three cases of hyperthyroidism were diagnosed among 1000 patients in 1957. In 1964 the incidence was 6 cases per 1000 patients*. In the Department of Medicine, one case of thyrotoxicosis was seen per 100 inpatients. Estimates of the incidence of Graves' disease, the ratio between toxic adenoma and Graves' disease and age and sex distributions are given below.

2. Toxic Diffuse Goiter (Graves' Disease, Basedow's Disease)

The hallmark of this form of hyperthyroidism is a group of almost specific extrathyroidal signs which are not due to thyroid hormone excess and which are absent in other forms of thyrotoxicosis. The most obvious of the changes independent of hormone excess are exophthalmos and periorbital edema, while the other two signs of Basedow's classic Merseburger triad, goiter and tachycardia, are directly related to thyroid overactivity. Other changes independent of thyroid hormone excess are thyroid acropachy, localized myxedema and some other skin changes (see below).

Graves' disease can arise in a normal gland or sometimes in a previously euthyroid multinodular goiter. For obvious reasons the coincidence of Graves' disease and multinodular goiter is more often seen in regions where goiter is endemic (LAMBERG, 1969).

a) Incidence

An extremely careful study on the incidence of Graves' disease in Minnesota has recently been reported from the Mayo Clinic (FURSZYFER, 1970, 1972). The annual incidence per 100000 inhabitants was 19.8 for the entire population and 36.8 for females. From 1935 through 1967 the incidence was remarkably stable, in contrast to the decreasing or increasing incidences in other reports, including reports on epidemics of Graves' disease during world war II in Europe (GREENWALD, 1966). The epidemiologic data on which these reports of epidemics are based are not beyond suspicion (see FURSZYFER, 1972; for review).

All reported series agree that there is a large preponderance of females. In FURSZYFER'S (1972) study the ratio was about 5:1. Graves' disease is rare before the age of 20. Its incidence rises rapidly to reach a peak in the 30-year-old, and then remains almost at a plateau up to the age of about 70. In a very recent study from Denmark, where laboratory screening tests were performed on very broad indications (RONNOV, 1973), the yearly incidence was 14/100000 for the population below the age of 60. For people over 60 the incidence, surprisingly, was seven times higher.

b) Etiology and Pathogenesis

Histological studies suggested early that Graves' disease was characterized by *diffuse* hyperfunction of all the thyroid tissue. This impression was confirmed later when scintiscanning of the thyroid after radioiodine administration showed an increased isotope uptake evenly distributed throughout the tissue. This contrasts with the findings in toxic nodular goiter, where hyperfunction remains localized to parts of the thyroid gland.

* We are grateful to Prof. W. SIEGENTHALER for these data.

Attention therefore naturally became centered on humoral or neural factors as possible causes for the diffuse hyperfunction. An obvious candidate as a humoral factor was pituitary TSH. However, observations that suggested quiescence rather than hyperfunction of the pituitary thyrotrophs, and in particular the occurrence of Graves' disease in hypopituitary patients (FAJANS, 1958; PAZIANOS, 1960; TAUNTON, 1964), provided strong arguments against TSH as a causative factor. More recently, exact measurements by radioimmunoassay have established that serum TSH levels are low in Graves' disease (SCAZZIGA, 1968; PATEL, 1971). This is not to deny that in certain extremely rare cases diffuse toxic goiter may be due to hypersecretion of TSH by a pituitary adenoma (p. 209).

α) Long-Acting Thyroid Stimulator (LATS)

In his search for a humoral factor causing thyroid hyperfunction, ADAMS (1957, 1958, 1965) injected serum of patients with Graves' disease into guinea pigs. He noted that some sera strongly stimulated thyroid activity of the recipient animals and concluded that they contained a pathologic humoral factor. MCKENZIE (1967) soon confirmed this finding by the use of a simpler assay in mice. In his now classic bioassay, mice are first injected with radioiodine, and then after one day to allow for uptake of the isotope into the thyroid gland, the endogenous secretion of TSH is suppressed by the injection of thyroxine, and two days later the test material, usually serum or a concentrate of IgG immunoglobulin, is administered by intraperitoneal injection. Blood is taken just before and at intervals after the injection. The radioactivity in blood, which corresponds to a large extent to the labeled thyroid hormone secreted by the gland, is measured as an index of thyroid function. While the injection of pure TSH produces a rapid rise of the blood radioactivity with a peak at two hours, sera from thyrotoxic patients cause a slow rise with a peak between 8 and 24 hours (MCKENZIE, 1972). The magnitude of the effect is expressed as a precentage of the base-line radioactivity. A rise to 300% of the base-line value 8 hours after the injection is usually considered proof of the presence of thyroid stimulating activity. The technical aspects and the numerous modifications of the MCKENZIE assay have been extensively studied by FLORSHEIM (1970).

Because of the slow onset and prolonged duration of action, MCKENZIE (1967) coined the term Long-Acting Thyroid Stimulator (LATS) for the factor present in the sera of patients with Graves' disease. In the past 15 years most of the research concerned with the etiology and pathogenesis of Graves' disease has been focused on LATS, and an enormous amount of literature has accumulated. The following discussion will touch on only a few aspects of LATS. For more detailed information the reader should refer to one of the reviews available (BURKE, 1968; MCKENZIE, 1967, 1968, 1972; OCHI, 1968; BURKE, 1971).

Fractionation of sera from thyrotoxic patients soon revealed that LATS resided in the γ-globulin fraction and had a sedimentation coefficient of 7S; more detailed analyses confirmed that it was a true IgG immunoglobulin. Both the light an the heavy chain are necessary for biologic activity, but the light chains seem to be less specific as they can be replaced by light chains from other IgG molecules (BROWN, 1968). LATS is produced *in vitro* by lymphocytes from patients with Graves' disease (MCKENZIE, 1967). LATS activity is only partially inhibited by antisera to either λ- or κ-type light chains alone. Both antisera combined will produce 100% inhibition of LATS. This suggests that LATS contains both λ- and κ-type chains and is therefore not produced by a single clone (KRISS, 1968).

LATS duplicates practically every effect of TSH on the thyroid. It produces hyperplasia of the thyroid gland in mice (OCHI, 1969), and stimulates cell mitosis in rat thyroid explants *in vitro* (GARRY, 1970). It stimulates the human thyroid gland when injected into healthy volunteers (ARNAUD, 1965). LATS, like TSH, probably acts via the adenyl cyclase-cyclic AMP system (p. 11) (KANEKO, 1970; BURKE, 1971). LATS stimulates glucose oxidation via the pentose shunt and phosphate incorporation into lipids in a manner indistinguishable from TSH (BURKE, 1971).

Although there exists no doubt that LATS is a true antibody, its corresponding antigen has not yet been clearly identified. Sera of rabbits immunized against human thyroid microsomes contain a thyroid-stimulating activity similar to that of LATS (SOLOMON, 1968 and 1970). LATS can be absorbed onto and reeluted from particulate thyroid cell components which sediment with the microsomal fraction (KRISS, 1964; PINCHERA, 1970). More recently, it has been found that LATS also binds to soluble (nonparticulate) components of thyroid cells (SMITH, 1970; SCHLEUSENER, 1971). These soluble cell components are more abundant in the thyroid on a quantitative basis than the microsomal ones, although they bind less LATS per mg of protein (AMINO, 1971). LATS can be dissociated again from the soluble cell com-

ponents by maneuvers that break up antigen-antibody complexes. SCHLEUSENER (1971) and CHOPRA (1971) have suggested that the soluble cell-sap component which combines with LATS corresponds to solubilized lipoprotein material from the cell membrane. Several such lipoproteins which bind LATS have recently been purified by SATO (1972).

LATS is not always detectable in sera from patients with Graves' disease. In several series of unselected patients with Graves' disease the incidence of LATS varied between 10% and 50% when the serum was tested without first being concentrated. When 15-fold concentrates of IgG are prepared from the patient sera, LATS is found in about 80% of cases (CARNEIRO, 1966). The failure to find LATS in the remaining 20% of patients is probably best explained by the insensitivity of the mouse bioassay. Indeed, ADAMS (1971) presented good evidence that LATS-negative sera from patients with Graves' disease all contain an IgG immunoglobulin which reacts with human but not with murine thyroid extracts. He suggested that this globulin, named *LATS protector*, stimulated the human thyroid gland, but did not react with the mouse thyroid gland and was thus not detectable in the ordinary bioassay (SHISHIBA, 1973).

Patients with pretibial myxedema (p. 187) usually have high titers of LATS (KRISS, 1964), although this is not an undisputed point (SCHERMER, 1970). The initial association of severe ophthalmopathy with high LATS titers has not been confirmed by later studies (p. 201). There is no very close correlation between the incidence of LATS and the severity of thyrotoxicosis, but patients with all three cardinal manifestations (thyroidal, cutaneous, ocular) have a higher incidence than patients with only one feature (LIPMAN, 1967). After treatment with antithyroid drugs (PINCHERA, 1969) or after thyroidectomy (see p. 194) the concentration of LATS tends to decrease, while after radioiodine therapy it rises temporarily (PINCHERA, 1969).

At first glance the presence of LATS offers an obvious explanation for the pathogenesis of thyroid hyperfunction in Graves' disease. Surprisingly, in recent years several authors have expressed well-founded doubts about the concept that LATS causes the thyroid hyperfunction of Graves' disease. Eloquent reviews have been written both supporting (HALL, 1970; MCKENZIE, 1972) and rejecting (CHOPRA, 1970) a pathogenic role for LATS. Neonatal hyperthyroidism is an experiment of nature which provides strong evidence in support of the involvement of LATS. It is a very rare disease and occurs only in babies of mothers who have very high LATS titers. LATS is present in the serum of the newborn, and the titer declines spontaneously in parallel with disappearance of hyperthyroidism (MCKENZIE, 1964; SUNSHINE, 1965). The argument that LATS remains undetectable in 20% of patients despite the use of IgG concentrates is easily countered by pointing to the insensitivity of even the refined bioassays. However, the strongest argument against a causative role of LATS is the fact that it often remains detectable in serum when patients go into remission or when the thyroid gland becomes normally suppressible by triiodothyronine again (see p. 191 for suppression test) (CHOPRA, 1970; SELLERS, 1970; SIVERSTEIN, 1970). The dispute over the role of LATS in Graves' disease has not yet been satisfactorily settled.

It must be mentioned that LATS also occurs in patients with euthyroid ophthalmic Graves' disease (p. 202) and in cases of idiopathic hypothyroidism (LIDDLE, 1965). The spontaneous progression of Graves' disease into idiopathic hypothyroidism has been observed in few cases (LEVITT, 1954) and was described by old clinicians as "burning out" of thyrotoxicosis. LATS has occasionally been found in euthyroid relatives of patients with Graves' disease (WALL, 1969).

β) Other Immunologic Abnormalities in Graves' Disease

It has long been known that the thymus is enlarged in Graves' disease, and recent publications have re-emphasized the presence of cervical lymph node enlargement (MAHAUX, 1969). Classic antibodies to either thyroglobulin or thyroidal microsomal antigen can be demonstrated by conventional techniques in about 60% of patients with Graves' disease. The titers are rarely as high as in chronic lymphocytic (Hashimoto's) thyroiditis. With the aid of a very sensitive competitive binding radioassay, MORI (1971) found antimicrosomal antibodies in 98% and antithyroglobulin antibodies in 89% of patients with Graves' disease, while in control subjects the incidence of both antibodies was only about 20%. In chronic lymphocytic thyroiditis, MORI (1971) found an identical incidence of antibodies. This supports the view that the two conditions are etiologically related, or in other words, varying manifestations of the same underlying disease process. Several pairs of monozygous twins have been reported, one of whom suffered from Graves' disease and the other from chronic lymphocytic thyroiditis (JAYSON, 1967;

DONIACH, 1967; CHERTOW, 1973). Both diseases can coexist in one individual (FATOURECHI, 1971).

WERNER (1972) found by immunofluorescence that IgG, IgM and IgE as well as complement was deposited along the basement membranes of diffuse toxic goiters. Recently, VOLPE (1972) and LAMKI (1973) provided evidence of delayed cell-mediated autoimmunity to thyroid antigens in patients with Graves' disease.

Patients with Graves' disease have a relatively high incidence of antibodies to parietal gastric cells and intrinsic factor (DONIACH, 1963), and they suffer from pernicious anemia about 5 times more frequently than controls (p. 188).

Cutaneous reactivity to tuberculin and to dinitrochlorobenzene appears to be absent in most patients with Graves' disease, which points to a defect in delayed-type hypersensitivity (BRODY, 1972).

In summary, a number of immunological abnormalities are present in the sera of most patients with Graves' disease, viz. classic complement-fixing antibodies to well defined antigens, a peculiar antibody which acts as a thyroid stimulator, and finally disturbances of delayed hypersensitivity. The true antibody nature of LATS has long been doubted by immunologists, but the present evidence leaves little doubt on this point. All these facts suggest that Graves' disease is a disorder of autoimmunity in which immune tolerance towards the thyroid and other tissues breaks down.

γ) Familial Incidence

Familial incidence of Graves' disease has been well documented (BARTELS, 1941; MARTIN, 1951), but the exact mode of genetic transmission has not been established. It appears that the liability to develop thyroid antibodies is inherited by polygenic control (Editorial Brit med. J. 1973). About one quarter to one fifth of patients have near relatives also suffering from the disease. As outlined above, Graves' disease and chronic lymphocytic thyroiditis may occur in the same family. HASSAN (1966) has reported 4 pairs of identical twins who suffered from Graves' disease. In each pair of twins, both had identical autoantibodies in the serum. SKILLERN (1972) has recently written a concise review on the genetics of Graves' disease.

δ) Triggering External Events

Graves' disease may follow sudden or prolonged psychological stress. Many authors have therefore emphasized the importance of the central nervous system in the etiology of the disease. Severe fright induced in wild rabbits has produced tachycardia, hyperthermia, exophthalmos and stupor. This so called "Schreck-Basedow" rapidly leads to death (EICHHOFF, 1949). However, the presence of true hyperthyroidism in this syndrome has never been well documented; the protein-bound iodine has been found to be normal (SCHÄFER, 1965; OBERDISSE, 1967).

Depending on the authors, psychological trauma is incriminated as a cause of Graves' disease in 4% to 97% of cases. No carefully controlled studies have been reported, however, and the issue remains unsettled. The influence of the nervous system on the thyroid gland has been reviewed by MCKENZIE (1967).

Weight-reducing diets, especially when combined with the administration of thyroid hormone, have been accused of triggering Graves' disease, but again controlled studies are not available. In so-called "Jod-Basedow" ingestion of large amounts of iodine produce hyperthyroidism. Interest in this syndrome has recently been revived (p. 209), but it should be remembered that "Jod-Basedow" is not true Graves' disease, but nodular goiter rendered toxic by an excessive iodine supply.

c) Pathologic Anatomy of the Thyroid and Pituitary Glands

In most cases of Graves' disease the thyroid is enlarged. As a rule the hyperplasia is diffuse, but when Graves' disease is superimposed on pre-existant euthyroid nodular goiter the gland may be multinodular (so-called "struma basedowificata") and the distinction from toxic nodular goiter on pathologic grounds alone may be difficult. The vascularity of the thyroid gland is increased. The follicles vary widely in size and shape, and contain little colloid. The epithelial cells increase in depth and form papillary structures. Lymphoplasmocytic infiltrates with germination centers are seen in the stroma (Fig. 15). Some epithelial cells become enlarged and contain granular, slightly acidophilic cytoplasm and a bizarre nucleus (so-called oncocytes, oxyphils, or Hürthle cells). OLEN and KLINCK (1966) found a surprisingly high incidence (2.5%) of thyroid carcinoma, sometimes of only microscopic size, in a series of toxic diffuse goiters. Such carcinomas should therefore always be looked for carefully in surgical specimens.

Changes in the anterior pituitary gland are not very striking. Degenerative changes of the chromophilic cells have sometimes been observed.

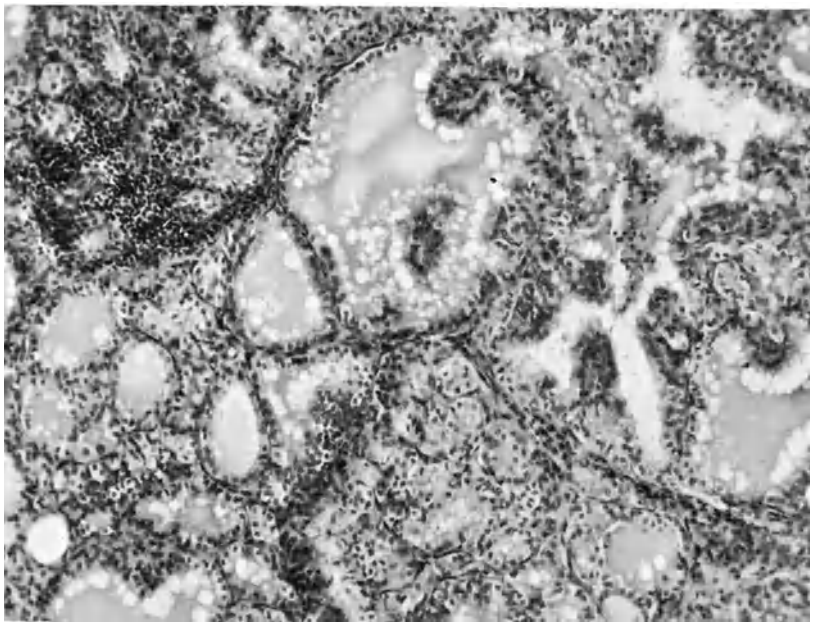

Fig. 15. Histologic picture of a goiter from Graves' disease. Note the wide variation in follicle size, the diminished colloid content, the infoldings of the epithelium into the lumen and the elongated epithelial cells. A lymphocytic infiltrate is seen at upper left (Hematoxilin-Eosin, × 140)

d) Clinical Features

α) History and General Clinical Findings

In some cases, Graves' disease develops insidiously over some months or years, but more often it has a sudden onset within a few days. The symptoms are often quite nonspecific, and are sometimes difficult to differentiate from those of patients with "functional" emotional disturbances. As a rule, patients with functional emotional conditions complain of severe subjective distress with few objective findings, while in patients with Graves' disease the changes are often first noted by the relatives before the patient mentions any symptoms. Nervousness, fatigue and insomnia are frequently reported, but they are of course nonspecific. On questioning the patient admits to increased perspiration. Warm intolerance may become apparent in the use of less blankets at night and less clothes during the day. Palpitations and sometimes exertional dyspnea may be prominent. Some patients complain of hair loss. Increased appetite combined with loss of weight is very suggestive of hyperthyroidism.

Emotional and mental changes are almost always present. There is generalized irritability and emotional tension. The patient may be hyperactive, sometimes euphoric, but easily fatigued. He complains of difficulty in concentrating. Some patients are frankly hyperkinetic and cannot sit still for a moment. The sexual drive sometimes increases initially and then decreases. The patient himself is often aware of his mental changes. In extreme forms patients become frankly manic, or psychotic,

Fig. 16. 37-year-old woman with Graves' disease of 7 years duration and class 1 ophthalmopathy. The patient had developed pretibial myxedema during a first course of drug treatment. Three years later a subtotal thyroidectomy was performed because of a recurrence of hyperthyroidism. With the improvement of hyperthyroidism the pretibial myxedema worsened and the patient developed proptosis, clubbing of fingers and swelling of interphalangeal joints (acropachy). Radioiodine treatment finally provided complete control of hyperthyroidism, but the ophthalmopathy and the pretibial myxedema remained unchanged

or delirious. Sometimes the disease is indistinguishable from acute schizophrenia. Patients occasionally become hypoactive and depressed (apathetic thyrotoxicosis; THOMAS, 1970; see p. 199).

On physical examination the patient strikes the examiner by his tense facial expression (Fig. 16). He looks scared. He enters the room with hyperkinetic, badly coordinated movements and answers questions quickly and overzealously. During ward rounds he may reveal the nature of his illness by shooting up in bed and sitting up as soon as the doctor approaches.

β) Thyroid Gland

Goiter is almost always present, although in some cases the thyroid gland remains surprisingly small. The enlarged gland is usually clearly visible, since most patients are thin. Palpation shows it to be diffusely enlarged, both lateral lobes, the isthmus, and sometimes the pyramidal lobe being affected. It is usually two to four times as large as normal (40 to 80 g), but in young patients the goiter may become much bigger. When Graves' disease is superimposed on a previously euthyroid goiter (LAMBERG, 1969, p. 260), the gland may be multinodular and the clinical differentiation from toxic multinodular goiter may be quite difficult unless clear-cut ocular and dermal changes are present.

The goiter of Graves' disease is of characteristic fleshy or rubbery firmness. It rarely causes local pressure symptoms or pain. The increased vascularity produces a systolic bruit and a continous humming murmur in about two-thirds of cases, while in euthyroid goiter this is a rare finding.

γ) Ocular Changes (cf. p. 201)

Protusion of the bulbi (exophthalmos) is found in about one quarter of all cases. Very often the exophthalmos is unilateral or is more pronounced on one side. For objective assessment the exophthalmos should be measured with a special instrument, e.g. the Hertel exophthalmometer, in every patient. Values of more than 20 mm (corneal apex to lateral orbital rim) represent probable exophthalmos, and values of more than 23 mm definite exophthalmos. The eyelids may be swollen, puffy and sometimes grossly edematous (periorbital myxedema, Fig. 18). In severe cases, chemosis and corneal ulcers may be present. Few diseases need be considered in the differential diagnosis. Protrusion of the bulbi may be due to a genetically transmitted trait. Sometimes it is due to a retrobulbar neoplasm, and rarely to accumulation of lipids, as in Hand-Schüller-Christian disease. When a retrobulbar tumor is present, the resilience of the bulbi is often diminished, while in endocrine ophthalmopathy the bulbs may be displaced backward by gentle pressure.

Lid retraction produces the characteristic stare (Fig. 16), a sign which is independent of the presence of exophthalmos. When the patient is instructed to follow the examiner's finger as

Fig. 17. 37-year-old patient with Graves' disease and class 3 ophthalmopathy. One year after subtotal thyroidectomy there was worsening of the ocular signs. Note the edema of the upper lid with protrusion of the lis nasally

Fig. 18. 66-year-old euthyroid patient with class 6 endocrine ophthalmopathy of 16 years' duration. Surgical decompression provided only temporary relief. The patient was blind in the right eye. (Courtesy of Prof. WITTMER, Kantonsspital Zürich)

it is moved downwards in front of him, the typical lid lag becomes apparent, i.e. a narrow white rim of the sclera becomes visible between the upper lid and the cornea (Graefe's sign).

Due to infiltrative changes of extra-ocular muscles, disturbances of eye movement appear in severe cases (Fig. 19). The earliest sign may be weakness of convergence and consequent diplopia on viewing near objects (Moebius' sign).

The eye changes, in particular exophthalmos, periorbital edema, and muscle involvement, take a course which is quite independent of that of the thyroid hyperfunction. In extreme cases they may ultimately develop into malignant exophthalmos. The pathogenesis, clinical course and treatment of endocrine ophthalmopathy are discussed in detail on p. 201.

δ) Cardiovascular System

Cardiovascular manifestations are prominent in thyrotoxicosis, and untreated patients suffer from and often die of heart disease.

The biochemical relationships between thyroid hormone and the heart have been outlined in detail on p. 146. Graves' disease is a classic example of a high-cardiac-output state. The cardiac output is significantly more raised than one would expect on the basis of the increased oxygen consumption of the peripheral tissues (DEGROOT, 1970). GRAETTINGER (1959) has analyzed the hemodynamics of patients with long-standing hyperthyroidism, both with and without heart failure. The cardiac output of seven patients in failure was normal in four and elevated in three.

Tachycardia is an almost obligatory sign of thyrotoxicosis. Characteristically the pulse rate remains high during sleep. Sometimes premature beats or paroxysmal supraventricular tachycardia are present. The pulse rate is usually between 100 and 120, but in severe cases it may reach 160. β-Adrenergic blockers and guanethidine reduce the pulse rate in hyperthyroidism (HOWITT, 1967; GROSSMAN, 1971), but as outlined on p. 146, this is no proof that thyroid hormone acts via catecholamines.

The diastolic blood pressure is low and the systolic blood pressure may rise, especially in older patients. The wide pulse pressure produces systolic sounds over the great arteries. The hyperdynamic cardiovascular state causes bothersome palpitations to the patients, particularly after physical exercise. The apical cardiac impulse is forceful and sometimes displaced to the left, which is often mistaken for a sign of left ventricular hypertrophy. Cardiac sounds are loud, and a short systolic murmur (systolic scratch) is heard along the left sternal border. Diastolic murmurs are rare. Auricular fibrillation is frequent in older patients. Exertional dyspnea and retrosternal pressure are frequent symptoms, but true angina pectoris is rare.

The study by SANDLER (1959) provides convincing evidence that thyrotoxicosis may damage an otherwise normal heart. Of his 462 thyrotoxic patients treated with ^{131}I, 150 had heart disease. Of these, 86 had associated hypertensive, coronary or valvular heart disease. In 64 patients there was no "organic" heart disease, and the cardiac symptoms were attributed to thyrotoxicosis alone. Auricular fibril-

a b c

Fig. 19. a) 28-year-old man with hyperthyroidism due to Graves' disease. b) Iatrogenic hypothyroidism 6 months after subtotal thyroidectomy. c) 6 years later; proptosis and paresis of the m. rectus superior on the right side. The patient had taken his thyroid hormone replacement inconsistently. Class 4 ophthalmopathy

lation and congestive heart failure were very frequent in this group.

It is important to realize that the response of the heart to digitalis glycosides is altered in hyperthyroidism (BUCCINO, 1967). It is a familiar clinical observation that in hyperthyroidism with auricular fibrillation the ventricular rate has a poor response to conventional doses of digitalis. This has been borne out by careful studies in man and dog. FRYE (1961) compared the response to digoxin in euthyroid patients with auricular fibrillation before and after administration of 225 μg triiodothyronine per day. The dose of digoxin necessary to maintain a ventricular rate of 70 was approximately 0.2 mg/day in the euthyroid and 0.8 mg/day in the hyperthyroid state. Interestingly, the higher dose was tolerated without side effects. Clinically, his subjects exhibited only mild signs of thyrotoxicosis while under triiodothyronine. It may therefore be anticipated that in severe hyperthyroidism the digoxin requirement may be even higher. According to MORROW (1963) the digitalis requirement of the thyrotoxic dog heart is increased only if the atrioventricular refractory period is measured as an index, while the contractile force responds normally to conventional digitalis doses. The dose of ouabain causing ventricular arrhythmia was about 50% higher in dogs rendered hyperthyroid (MORROW, 1963).

The electrocardiogram shows the afore-mentioned arrhythmias and also some nonspecific changes in the ST-segment. In about 50% of cases autopsy reveals myocardial changes such as hypertrophy, edema, localized necrosis, fibrosis and sometimes lymphocytic infiltrates.

ε) Respiratory System

Hyperthyroid patients often complain of dyspnea on exertion, even when there is no heart failure or pulmonary disease. Pulmonary function studies have revealed decreased compliance and increased functional residual capacity but otherwise few significant changes. The best explanation available for the dyspnea is that it is caused by weakness of the respiratory muscles due to thyrotoxic myopathy (STEIN, 1961; MASSEY, 1967). These changes are reversible after treatment.

ζ) Neuromuscular System

Hyperthyroidism has profound effects on the central and autonomous nervous system, causing increased irritability, nervousness, insomnia, tremor, increased perspiration and many other signs or symptoms which are often also present in patients with simple "functional" complaints or emotional instability.

The fine tremor, one of the cardinal signs, varies widely in intensity. Its frequency is about 8–10/sec. Sometimes it will only be revealed by palpation of the out-stretched hands. Tendon reflexes are brisk and relaxation is quick. This sign may be quantitatively evaluated by recording the ankle jerk (p. 241).

In its extreme form, thyrotoxicosis leads to generalized encephalopathy (p. 198). Cerebellar dysfunction has sometimes been reported. It is reversible after treatment. Polyradiculitis, optic neuritis and Parkinsonism do not occur with a higher frequency than in a control population. Non-specific electroencephalographic changes are often present. They may persist even when the hypothyroidism is properly treated (SIERSBAEK, 1972).

Muscular weakness is prevalent in hyperthyroidism, but it is often only revealed by careful examination. On specific questioning the patient admits that he has to pull himself with his hands when climbing stairs. The muscular signs of hyperthyroidism resemble those of myasthenia gravis, while hypothyroidism produces a picture more reminiscent of myotonia. The clinical changes are difficult to explain on a biochemical or electrophysiologic level (HAVARD, 1963), but peripheral neuropathy (LUDIN, 1969) and a loss of motor units per motor neuron (MCCOMAS, 1973) have been implicated.

NOSEDA (1967) found signs of chronic hyperthyroid myopathy in about 20% of cases with Graves' disease and in 10% of patients with toxic nodular goiter, while RAMSAY (1966, 1968) detected evidence of muscular dysfunction in almost 100% of cases.

In *chronic thyrotoxic myopathy*, fatigue, muscular weakness sometimes to the extent of paresis, and muscular atrophy are prominent and may be the presenting symptoms of Graves' disease. The muscles of the shoulder and pelvic girdles and the small hand muscle are the ones predominantly affected. A typical sign is the "signe du tabouret" recorded by French clinicians; the patient is unable to stand up from a low chair without using his hands. The onset of myopathy can be rapid, within weeks, or insidious, extending over years. The severity bears little relation to the degree of thyroid hyperfunction, but it is usually reversible after treatment of the latter. The exact biochemical basis of the muscular dysfunction is not known. Thyrotoxic patients excrete elevated amounts of creatine in urine. A greater fraction of an exogenous creatine load is excreted in the urine than in normal subjects. These changes may be related to disturbances in mitochondrial res-

piration (p. 145), but careful examination of muscle mitochondria from patients with thyrotoxic myopathy have yielded no positive evidence supporting this assumption (STOCKER, 1968).

Pathological examination shows the muscles to be edematous. The interstitial space is filled with fat cells and lymphocytic infiltrates. The muscle fibers are atrophic, the nuclei swollen. Transverse sections show semilunar intracellular inclusions of mucopolysaccharides.

Acute thyrotoxic myopathy occurs superimposed on thyrotoxic crisis and presents with a picture of bulbar paralysis with impaired swallowing and speech.

Myasthenia gravis may coexist with thyrotoxicosis and the association is more frequent than can be attributed to chance (ENGEL 1972). When present together, the two diseases progress independently. Patients with myasthenia gravis develop hyperthyroidism quite frequently, while hyperthyroid patients become myasthenic quite rarely, but still more frequently than can be attributed to chance. It is interesting to note that the thymus may be enlarged in both diseases.

Thyrotoxic periodic muscle paralysis is a very rare complication of hyperthyroidism. It seems to be observed most frequently in the Far East (OHINAKA, 1957; OKIHIRO, 1965; SHIZUME, 1966; MCFADZEAN, 1967; ENGEL, 1972). The symptoms are identical to those of periodic hypokalemic paralysis, and signs may appear in rest periods after muscular exertion, after psychologic stress, or during exposure to cold. Weakness of the lower extremities is prominent. The episodes last about 12 hours. They are not always accompanied by hypokalemia, but arteriovenous differences of the potassium concentration have been found (SHIZUME, 1966). After treatment of the hyperthyroidism, the attacks of paralysis abate. RESNICK (1969) studied one patient who had an elevated aldosterone secretion rate in addition to the classic findings.

In endocrine ophthalmopathy, dysfunction of the extra-ocular muscles may be prominent. This disorder is discussed in detail on p. 201.

η) Bones and Joints; Calcium Metabolism

Osteoporosis is a frequent finding, especially in older patients. MEGLIOLI (1966) found radiologic evidence of osteoporosis in about 7% of cases. FRASER (1971) found that decreased radiologic bone density was particularly frequent in thyrotoxic women over 50. In younger patients, treatment of thyrotoxicosis improved the bone demineralization, but in the older patients the changes persisted and fractures were seen.

The pathologic anatomical changes in the bones are diverse. Fibro-osteoclastic foci eroding the cortical spongial bone are frequent. Signs of osteomalacia with osteoid brims are occasionally seen. Classic osteoporosis sometimes also occurs.

Calcium and phosphorus excretion in stool and urine is increased (KRANE, 1956; HARDEN, 1964). Serum calcium and phosphate are usually within normal limits, but moderate hypercalcemia is by no means rare (KOENIG, 1959; BAXTER, 1966). Severe hypercalcemia which responds well to corticosteroid administration is rare (SATALINE, 1962; HARPER, 1970). Many theories have been proposed to explain the hypercalcemia of Graves' disease, but none is entirely satisfactory (PARFITT, 1970). Calcium balance is usually negative and it has been claimed that the administration of 2 g of calcium per day will reverse this.

After thyroidectomy serum calcium often falls to hypocalcemic levels. An obvious explanation is that the parathyroid glands have been inadvertantly removed or severed. However, MICHIE (1971) has shown that a more frequent cause of transient post-thyroidectomy hypocalcemia is increased calcium uptake by the calcium-depleted bones.

Thyroid acropachy is a very rare complication of Graves' disease. In many ways it resembles hypertrophic osteoarthropathy of chronic pulmonary disease, and it presents with swelling and clubbing of the distal phalanges. There is cuff-like hypertrophy of subperiostal bone, especially in the phalanges and the distal ends of the bones of the arms and legs. Thyroid acropachy is often associated with pretibial myxedema and exophthalmos. The lesions may be tender. There is no effective treatment for the disorder.

ϑ) Skin

In its function as thermoregulatory organ the skin has to dissipate the extra heat produced by hyperthyroidism, a process which explains many of the dermal signs. The skin feels warm and moist. Perspiration may become excessive even after moderate exercise. The signs are most conspicuous in the palms. Warm moist hands are very suggestive of hyperthyroidism, but are frequently also found in patients with febrile infections. Cold hands virtually exclude the diagnosis of hyperthyroidism. The face is usually pale, but intermittent flushing sometimes occurs. Sometimes patchy erythema of the face and trunk is seen. Dermographia is often present sometimes leading to urticaria and itching. The skin is thin and soft. Hyperpigmen-

tation similar to that seen in Addison's disease is sometimes a prominent feature. KIRKEBY (1963) has attributed this sign to an increased ACTH level allegedly necessary to maintain the high cortisol secretory rate in hyperthyroidism. Some patients suffer from widespread vitiligo (OCHI, 1969).

The scalp hair is thin and brittle. Hair loss, sometimes progressing to alopecia is a frequent sign. There is often premature graying of the hair.

Some patients suffer from separation of the distal end of the nails from the underlying bed (onycholysis, Plummer's nails).

Localized pretibial myxedema (Fig. 20) is a peculiar dermal change which is histologically identical to the skin changes of hypothyroidism. The deeper dermis contains swollen fibers and is infiltrated by mucilagenous material, mostly hyaluronic acid (SISSON, 1968). It is seen in 3–4% of patients with Graves' disease and is often associated with ophthalmopathy. Its relation to LATS has been discussed on p. 180.

Fig. 20. Pretibial myxedema in the same patient as shown in Fig. 16. The lesion is much more severe on the right side. The case history is summarized in Fig. 16

Localized pretibial myxedema presents as plaques 5–20 cm in diameter over the lateral or anterior aspects of the legs. Sometimes they extend to the dorsal aspect of the feet. The fact that the hair follicles are retracted makes the lesions look like pigskin. No effective treatment is available. Sometimes the lesions clear spontaneously. Systemic corticosteroids will produce regression, but only for as long as the medication is given. Good results have been claimed by KRISS (1967) with topical steroid application.

ι) Gastrointestinal Tract and Liver

The frequency of bowel movements is increased in most patients with Graves' disease (BAKER, 1971), and about one third have diarrhea. The cause is increased peristalsis of the intestines.

If diarrhea is severe, steatorrhea may be present. It disappears after treatment of the hyperthyroidism (CRANE, 1966). Steatorrhea is due to agreatly increased fat intake and not to malabsorption (THOMAS, 1973). Appetite is increased and some patients really crave for food. In rare cases, however, patients are anorectic. Achlorhydria refractory to histamine and serum antibodies to gastric parietal cells are found in about one third of patients. Antibodies to gastric parietal cells and intrinsic factor are present less frequently, and frank pernicious anemia occurs in about 2% of cases (p. 188).

Liver function is only mildly impaired in most cases of thyrotoxicosis. In exceptional cases jaundice with unconjugated hyperbilirubinemia develops. GREENBERG (1964) has attributed this to a concomitant disturbance of bilirubin transport or conjugation which becomes manifest with the increased erythrocyte turnover in thyrotoxicosis. Serum transaminases are often slightly elevated and bromsulfthalein retention is pathologic in about half of the cases (WEBER, 1968). Alkaline phosphatase is also often elevated, but this may be due to bone disease.

In patients who die of thyrotoxicosis, severe liver changes with centrolobular necrosis or even massive hepatic necrosis are found. Some of the changes resemble those of circulatory failure, and one theory postulates that decreased liver perfusion inadequate to meet the increased metabolic needs is responsible for the liver pathology. Many of the changes must be attributed to terminal events indirectly related to thyrotoxicosis, and percutaneous liver biopsy in moderately ill patients has revealed a far less impressive picture. KLION (1971) found only mild nonspecific changes, such as infiltration of the portal tracts by lymphocytes and moderate steatosis. Electron microscopy showed enlarged mitochondria.

κ) Lipid and Carbohydrate Metabolism

The effects of thyroid hormone on lipid metabolism have been briefly reviewed on p. 147.

Serum cholesterol is often lowered in hyperthyroidism. NIKKILÄ (1972) found elevated plasma triglycerides, which he attributed to

increased synthesis. Post-heparin lipolytic activity was high in his studies. Interestingly, some of the triglyceride abnormalities did not return to normal after treatment of hyperthyroidism.

The effects of thyroid hormone on glucose metabolism are complex and not fully understood. On one hand thyroid hormone appears to enhance peripheral glucose consumption, on the other it stimulates gluconeogenesis (p. 148). Glucosuria is found in about 38% of thyrotoxic patients, a much higher incidence than in controls. However, only 2 to 3.3% of thyrotoxic patients suffer from overt diabetes mellitus, an incidence similar to that in the population as a whole (KOSAK, 1971).

λ) Blood and Lymphatic System

Mild anemia not responsive to the administration of vitamin B_{12}, folate or iron is a frequent finding in hyperthyroidism. The pathogenesis is not known. Compared to thyrotoxic patients with normal hemoglobin, the anemic patients have a decreased incorporation of iron into red cells (RIVLIN, 1969).

Achlorhydia and antibodies to gastric parietal cells and intrinsic factor are often found in Graves' disease (WILLIAMS, 1966: ARDEMAN, 1966; WANGEL, 1966), and frank pernicious anemia occurs in about 2% of cases, about 5 times as frequently as in a matched control population (SCHILLER, 1968, FURSZYFER, 1971).

Lymphocytosis is often present in the peripheral blood and the cervical lymph nodes may be enlarged (MAHAUX, 1971). In some cases the enlarged nodes may progress into true lymphoma (ULTMANN, 1963). The spleen is palpable in one third of cases and the thymus is often enlarged (MICHIE, 1967).

Warfarin-induced hypoprothrombinemia is enhanced by thyrotoxicosis (VAGENAKIS, 1972). Hypoproteinemia and edema have been described (PINCHERLE, 1965).

μ) Kidney

Moderate polyuria is probably caused by increased glomerular filtration due to renal hypercirculation. The response to vasopressin is normal, but there is slight impairment of the mechanism of urine concentration, possibly because the sodium concentration in the medulla is diminished (CUTLER, 1967). The maximal tubular reabsorption of glucose is enhanced. If hypercalcemia is present, reversible impairment of kidney function and sometimes renal acidosis may occur (LABHART, 1968).

ν) Other Endocrine Glands

Men with Graves' disease sometimes suffer from gynecomastia (LARSON, 1963; ASHKAR, 1970), which is reversible after treatment of the hyperthyroidism. The cause of gynecomastia appears to be estradiol-17β, which is moderately elevated in most male patients and markedly so in those with gynecomastia (CHOPRA, 1972).

Of patients with Addison's disease 3–4% also suffer from Graves' disease, a coincidence which is about 10 times higher than is attributable to chance (KAPPELER, 1965; GASTINEAU, 1965; BURKE, 1965).

Cortisol turnover is greatly increased in thyrotoxicoses and its half-life is shortened. Bursts of cortisol secretion are greatly increased in frequency in thyrotoxic patients (GALLAGHER, 1972).

Hyperthyroidism in pregnancy is discussed on p. 199.

ξ) Natural Course of Graves' Disease

In some cases Graves' disease has an insidious onset, but often the patient reports a sudden onset, often related to emotional stress. Owing to the fact that almost every patient in whom the disease has been diagnosed receives one form of treatment or another, few studies on the natural course are available. The early clinicians knew that Graves' disease took an unpredictable course with periods of continuous mild hyperthyroidism, acute exacerbations, complete remission and severe relapse. In about 10% of patients the disease progressed relentlessly and ended in death. In men the prognosis was considered to be much more serious than in women. MURRAY (1903) followed 40 cases regularly over a period of 11 years; 7 patients died of the disease, 2 remained stationary, 14 were improved to some extent, 8 were greatly improved and 9 recovered fully. Of the latter group, 2 patients had a relapse later. The relatively benign course of thyrotoxicosis has recently been confirmed by a small study (MCLARTY, 1971).

In rare cases Graves' disease develops into spontaneous hypothyroidism, probably due to superimposed atrophic thyroiditis.

σ) Differential Diagnosis and Diagnostic Value of Clinical Features (Diagnostic Indices)

Many patients referred to thyroid centers for suspected hyperthyroidism turn out to be euthyroid, and the most frequent diagnosis in these cases is neurotic personality disorder or anxiety state. Tachycardia, palpitation, tremor,

hyperhidrosis, dermographia are common in both psychiatric and thyrotoxic patients. A good distinctive clinical sign is that in the thyrotoxic the moist hands are always warm, while in the neurotic they are cool.

Chronic infections, neoplasia and pheochromocytoma are often associated with hypermetabolism and weight loss, and may therefore be mistaken for hyperthyroidism. A typical lid lag which is often present in these states may add to the confusion. Severe diabetes mellitus typically presents as weight loss with increased appetite and must of course be ruled out in cases of suspected thyrotoxicosis.

A high cardiac output or a hyperkinetic heart are also observed in pheochromocytoma, Paget's disease, fibrous dysplasia of bone (FISCHER, 1970), arteriovenous fistulas, beriberi heart disease and sometimes in subvalvular aortic stenosis (GORLIN, 1962; SLOMAN, 1967).

Lead intoxication with weight loss, tremor, mental changes and diarrhea may occasionally be mistaken for thyrotoxicosis. Intoxication with dinitrophenol typically leads to hypermetabolism. A single very interesting case of idiopathic hypermetabolism attributed to a defect of respiratory control in muscle mitochondria has been described by LUFT (1962). Weight loss, muscular weakness and hyperpigmentation of the skin are common to both Addison's disease and Graves' disease.

The experienced doctor will have no trouble in differentiating the above states from true Graves' disease by clinical observation and will therefore spare the patient additional expensive laboratory tests in most cases.

The signs and symptoms discussed above do not all carry the same weight in differentiating euthyroid from hyperthyroid patients. CROOKS (1959) has developed a very useful diagnostic index based on discriminant function analysis, which allows confirmation or exclusion of hyperthyroidism on clinical grounds alone in most cases. This index is particularly useful for doctors who are not very familiar with thyroid disease; a certain numerical value or weighting is assigned to each sign or symptom, according to its discriminant significance. GURNEY (1970) has extended this index to include some psychiatric items, which allows clearer separation from neurotic disorders and anxiety states. It is striking that both these diagnostic indices omit some textbook symptoms or signs of Graves' disease, e.g. diarrhea or hair loss. Obviously, these features do not have enough discriminant function. It is a common observation that the clinical diagnosis of hyperthyroidism is more difficult in older patients (HARVEY, 1971). In the elderly, thyrotoxicosis rarely presents with all the classic manifestations, and oligo- or monosymptomatic forms are often seen, e.g. forms with predominantly cardiac or predominantly mental signs. GURNEY (1970) has taken account of this fact by incorporating an age-correction factor into his diagnostic index.

π) Laboratory Tests

It is customary, although not strictly necessary, to confirm the clinical diagnosis of Graves' disease by at least one or two laboratory tests. In clinically doubtful cases several tests are usually carried out.

Not all tests carry the same weight for the distinction between euthyroidism and hyperthyroidism. The discriminant functions of different tests have been compared in several studies (see p. 244). Most authors have found that the "best" single tests are the radioiodine uptake within a short interval (2 to 4 hours) and tests measuring thyroid hormone concentration (serum total thyroxine in combination with the T_3 resin uptake). The basal metabolic rate obtained an intermediate rating and the serum cholesterol a rather low one in most of the above studies.

In patients for whom the usual laboratory tests give equivocal results it is customary to carry out a triiodothyronine suppression test (p. 242). This test will distinguish between a high radioiodine uptake due to dietary iodine deficiency and one due to Graves' disease.

In rare patients the diagnosis is established only by a therapeutic trial with antithyroid drugs but this procedure is hardly justified today.

e) Treatment of Graves' Disease

Even mild hyperthyroidism due to Graves' disease should always be treated. Three basic forms of treatment are available:

antithyroid drugs,
subtotal thyroidectomy,
radioiodine.

All three effectively reduce the production of thyroid hormones. In recent years it has become possible to enhance the effectiveness and the rapidity of onset of the above treatments by sympatholytic drugs, which block some of the peripheral manifestations of thyrotoxicosis without reducing the secretion of thyroid hormone per se.

Although we shall attempt to give certain guidelines, the choice of treatment cannot be rigidly prescribed, since it is the subject of heated debate even among authorities.

In some centers, particularly in the U.S.A., most patients are treated with radioiodine. In Europe, including the United Kingdom, patients are more evenly distributed among thyroidectomy, antithyroid drug therapy and radioiodine. Several factors, including the system of medical care in the population, are undoubtedly responsible for the differences. Radioiodine treatment does not require admission to hospital and only infrequent follow-up visits are necessary. This may be one reason for its popularity in the U.S.A., where the enormous costs of hospital admission are not borne by a national health service. Another source of bias is the referral practice of the family doctors. Patients referred to a nuclear medicine department or to a surgical service will obviously be much more likely to obtain the specific form of treatment in which the given service specializes.

α) Antithyroid Drugs

Thionamide Drugs are the most frequently used. They are all derivatives of thiourea, which is itself a weak antithyroid drug. Table 6 lists the three preparations currently most prescribed, propyl-(or methyl-)thiouracil, carbimazole and methimazole, together with their mean dosage. Fig. 21 gives their chemical formulas.

Thionamide drugs inhibit the incorporation of iodide into the organic compounds of thyroglobulin, i.e. they interfere with the formation of mono- and diiodotyrosyl residues, the two precursors of the thyroid hormones (Fig. 3, p. 139). As outlined on p. 140, organic iodination is catalyzed by a peroxidase which uses hydrogen peroxide and iodide as substrates. Since the exact molecular mechanism of the iodination reaction has not yet been worked out, the mode of action of thionamide drugs is not known. The drugs themselves are reducing agents, and they may act simply by reducing the oxidized iodine intermediate (I_2 or I^+) as rapidly as it is formed by the peroxidase. Other possible mechanisms have been discussed by ASTWOOD (1955). In an exhaustive review, MALOOF (1963) has suggested that the iodinating intermediate is actually sulfenyl iodide ($-S-I$) attached to a cysteyl residue of a protein. Thionamide drugs may inhibit the formation of sulfenyl iodides by forming mixed disulfides with the SH groups of the protein involved.

There are indications that thionamide drugs also inhibit a further step of hormone synthesis, namely the coupling reaction (p. 141). This effect is more difficult to demonstrate experimentally.

MORREALE DE ESCOBAR (1967) has pointed out that propylthiouracil inhibits the peripheral deiodination of thyroxine by an extrathyroidal effect in rat. Whether this effect also occurs in man is not yet known (BINSWANGER, 1966; FURTH, 1966). Very recently OPPENHEIMER (1972) has amply confirmed these findings and added evidence that propylthiouracil blocks the peripheral conversion of thyroxine to triiodothyronine. Since he considers triiodothyronine the only active form of thyroid hormone, these observations are possibly of great clinical importance. In a recent study, VAN PILSUM (1973) found that methimazole markedly reduced the effectiveness of thyroxine replacement in thyroidectomized rats.

Oral methimazole is rapidly absorbed in man and peak plasma levels are reached 30 min after ingestion; the serum half-life varies from 150–360 min. The drug is accumulated in the thyroid and the adrenal glands (PITTMAN, 1971). Carbimazole is rapidly converted into methimazole and accumulated in this form in the thyroid gland (MARCHANT, 1972b). The sulfur atom of ^{35}S-labeled methimazole is rapidly oxidized to sulfate (MARCHANT, 1972a).

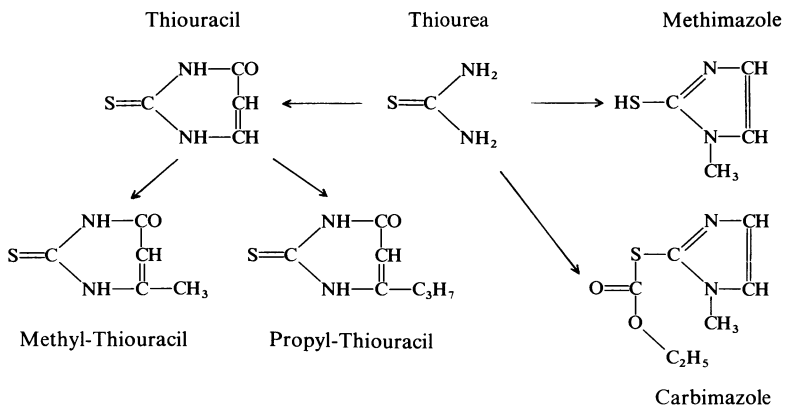

Fig. 21. Chemical formulas of the most common antithyroid drugs

We use the following indications for administration of thionamide drugs:

1. As a preparation for subtotal thyroidectomy, often in conjunction with iodine (p. 193);
2. In Graves' disease in children or adolescents;
3. In Graves' disease in pregnancy, when subtotal thyroidectomy is not possible;
4. Occasionally after radioiodine treatment to hasten the attainment of euthyroidism, if this is necessary.

Other endocrinologists accept much wider indications for antithyroid drug therapy, and use it as the treatment of choice in all cases where it is not contraindicated (VANDERLAAN, 1972). Hypersensitivity to the drug is an absolute contraindication. Relative contraindications are large goiters (long-term results are usually poor and the goiter may grow and cause pressure symptoms during treatment), relapse after a previous full course of antithyroid drugs or after subtotal thyroidectomy, and unreliability of the patient or impossibility of frequent follow-up visits.

There is general agreement that if one decides upon drug therapy of Graves' disease, the treatment should last for at least 12 months. It is not known whether the drugs alter the basic disease process in any way, and actively induce remission. From the few data available on the natural course of the disease we rather suspect that thionamide drugs allow the patient to be maintained in an artificially euthyroid state while waiting for a spontaneous remission (p. 188).

The initial dose should be relatively high and divided into three 8-hourly doses (Table 6). As soon as signs of improvement appear the dose is rapidly tapered and the maintenance dose established by trial and error. In many cases it is possible to maintain treatment by a single daily dose (GREER, 1965). Weekly checkups are necessary at first. Later the patient should be seen every two to four weeks. The clinical state is usually an adequate indication of the effect of treatment, but the total serum thyroxine should be measured at intervals to confirm the clinical findings. The usual radioiodine uptake test cannot be carried out during drug treatment. Leukocyte counts should be obtained at each patient visit, although this is not an infallible method of avoiding agranulocytosis, since this complication may develop very suddenly.

The patient usually notes some improvement after one week of treatment, and euthyroidism is reached after 4–10 weeks (CHEVALLEY, 1954). The onset of action is slow because thionamide drugs block the biosynthesis but not the release of thyroid hormone. Hormone secretion can therefore continue until the relatively large hormone stores are exhausted (p. 141). Thionamide drugs interfere with organic binding of iodide and thus greatly inhibit the thyroidal uptake of ^{131}I when measured at the conventional 2- and 24-hour intervals. However, they have little influence on the 10- or 20-minute uptake, which represents mostly iodide transport across the cell membrane (p. 139). Since this transport is under the control of TSH, it decreases when triiodothyronine is given to a normal person. In Graves' disease triiodothyronine does not have this effect, since the thyroid gland operates independently of TSH control. This property has been used by ALEXANDER (1970) to decide whether a patient under treatment has entered remission, in which case the drug may be stopped with no danger of relapse. Although the test did not allow him to ascertain the outcome in every case, it did statistically separate the group of relapse-prone patients from the group of patients that remained in remission. Of the "suppressed" patients, only 31% had a subsequent relapse, while 76% of the "nonsuppressed" patients relapsed. CASSIDY (1970) and LOWRY (1971) have published similar results. Since the test does not completely separate the relapse-prone patients from those going into remission, and since it is not simple, we do not recommend it for routine use. We think it is as well to stop treatment after 12 months and then wait and see whether the disease relapses. CHOPRA (1970) has studied the correlation between the presence of LATS and the nonsuppressibility of thyroid function. His failure to find any such correlation

Table 6. Dosage of antithyroid agents. Dose in mg/day

	Methyl- or propylthiouracil	Methimazole, carbimazole	Perchlorate[a]
Initial dose during first 10 days (divided into three 8-hourly doses)	300–400	30–60	1000–1500
Maintenance dose (given in one or two daily doses)	25–100	2.5–15	200–600

[a] The routine use of perchlorate is not recommended, except in special circumstances (see text).

is a strong argument against the causative role of LATS in Graves' disease.

Recurrence, unfortunately, is quite frequent. In HERSHMAN'S (1966) series of 176 patients with a follow-up of 6 to 23 years 45% had a recurrence, which appeared within the first year after discontinuation of the drugs in most cases. ALEXANDER (1973) has published essentially similar results. In a study from Japan, SHIZUME (1970) has confirmed the high relapse rate. He found the rate of permanent remission was high when the following features were present: 1. Small goiter; 2. Short duration of symptoms; 3. Reduction in goiter size during drug treatment; 4. Positive suppression test at the conclusion of the drug treatment.

A *relapse* after drug treatment should *not* usually be treated by a second course of drugs, because the chance of a second relapse is more than 75% (MCLARTY, 1969). Patients in relapse should therefore undergo ablative therapy, whether with radioiodine or by surgery. The latter approach led to satisfactory control of hyperthyroidism in most of MCLARTY'S cases, but produced an unusually high incidence of surgical complications (MCLARTY, 1969). A few authors prefer to treat relapses by continuous drug administration, if necessary over 20 years (VAN DER LAAN, 1972).

Side effects of thionamide drugs occasionally necessitate discontinuation of treatment. The drugs are inherently goitrogenic in normal persons and animals, because they interfere with thyroid hormone synthesis. TSH secretion is thus enhanced, and TSH in turn produces growth of the thyroid gland. In the treatment of Graves' disease the goitrogenic effect is rarely a problem, because TSH secretion is suppressed anyway as long as the thyroid hormone level in the blood is elevated. Growth of the gland under drug treatment is usually a sign that the patient has become hypothyroid and the dose should be reduced. Some authors prefer to continue on the high drug doses in such cases and to add thyroxine treatment to suppress TSH. However, we do not think that this procedure is justified, since it is desirable to give the lowest effective dose of thionamides (see below).

Skin rashes, pruritus, urticarial febrile reactions, drug fever and granulocytopenia are occasionally observed. In a series of 184 patients treated with methimazole, CHEVALLEY (1954) observed skin rashes, urticaria or fever in 5 and granulocytopenia in 3. Granulocytopenia was reversible in all 3 cases. The incidence of complications was dose-related and rose steeply at a daily dose of more than 40 mg, an observation confirmed by BARTELS (1952) and recently by WIBERG (1972), who observed toxic reactions in 9 out of 25 patients treated with methimazole in a dose of 120 mg daily. In the studies the drug was given to most patients for a short period of a few weeks to a few months. Reports on the toxicity during a one-year treatment are not available. Agranulocytosis is a much-dreaded complication of treatment, but fortunately it is very rare with the usual dose. Cholestatic jaundice has been reported in a few isolated cases (FISCHER, 1973). Mild toxic reactions sometimes disappear on dose reduction, but it is usually necessary to discontinue treatment. A switch from one thionamide drug to another may be tried (e.g. from methimazole to propylthiouracil), but there is often cross-sensitivity. Since carbimazole is rapidly converted within the body into methimazole (MARCHANT, 1972b), there is little point in changing from one of these drugs to the other. In rat, prolonged treatment with thionamides has produced thyroid adenomas and rarely carcinomas. The histological changes produced in man by antithyroid drugs have been analyzed by WEGELIN (1948).

Perchlorate has been successfully used in the treatment of Graves' disease (GODLEY, 1945; MORGANS, 1954), but due to the high incidence of toxic reactions (KREVANS, 1962; JOHNSON, 1965) it has never become popular. The mechanism of action differs from that of thionamides, since it inhibits iodide transport across the thyroid cell membrane (p. 139). We use perchlorate only for diagnostic purposes in cases of suspected peroxidase deficiency (p. 243) and in the very rare instances of hypersensitivity to all thionamide compounds where surgery and radioiodine treatment are also not feasible.

In recent studies, *lithium carbonate* has shown great promise as an antithyroid agent (TEMPLE, 1972). Its mode of action is complex, but it seems more or less established that it inhibits hormone release, probably by interfering with colloid droplet formation. It therefore has a much more rapid onset of action than the thionamides and it approaches iodide in its efficacy (see below). Due to its side effects, which make continuous monitoring of blood levels mandatory, it cannot yet be recommended for routine use (see also p. 154).

Pharmacological doses of iodide were first noted by PLUMMER (1923) to improve symptoms of thyrotoxicosis and to reduce the risk of subtotal thyroidectomy, at that time the only available treatment for Graves' disease. WOLFF (1969) has made a substantial contribution to the understanding of this paradoxical effect of iodide and has masterfully reviewed the literature. The minimal dose of iodide producing an inhibition of thyroid function in man is 5–10 mg/day, which is 100 to 200 times the minimal daily dietary allowance. The inhibitory

serum level in man is approximately 20 µg/100 ml (REINWEIN, 1960). There are several sites of action: 1. Iodide inhibits the formation of organic iodine from iodide. In this respect its site of action is the same as that of thionamides. 2. Iodide inhibits the release of thyroid hormone from preformed hormone stores of the colloid. This unique property makes iodide the antithyroid drug with the most rapid onset of action equalled perhaps only by lithium (TEMPLE, 1972). Indeed WARTOFSKY (1970) has shown that iodide, unlike thionamide drugs, inhibits thyroid hormone secretion immediately in Graves' disease. The site of this iodide effect is not yet known. It is suspected to be either the step of colloid endocytosis or that of lysosomal thyroglobulin hydrolysis (p. 142), but no convincing proof has yet become available. A consequence of this iodide effect is reaccumulation of colloid in colloid-depleted glands in Graves' disease (RAWSON, 1945). 3. Iodide is said to reduce the vascularity in the hyperfunctioning thyroid gland, thereby facilitating surgery. No objective data are available on this effect.

In normal persons the antithyroid effect of iodide is very shortlived and hypothyroidism does not appear despite prolonged treatment e.g. of asthmatics who take iodide as an expectorant. The reasons for this "escape" have been analyzed by BRAVERMAN (1963) and by WOLFF (1969). Iodine excess causes the thyroid gland to shut off active iodide transport by an autoregulatory mechanism ("iodide pump", cf. p. 139). This lowers the intrathyroidal iodide concentration and relieves the gland from the blocking effect of iodide. In thyrotoxicosis this adaptation of the iodide pump does not readily take place for some unknown reason and there is a prolonged block of thyroid function. In NAGATAKI's (1970) study involving 12 patients treated with iodide alone, hyperthyroidism was well controlled in all patients during the first 6 weeks of treatment. However, half the patients "escaped" between the 6th and 14th weeks of therapy despite continued iodide administration. Occasionally, apparently euthyroid patients become hypothyroid when given pharmacological doses of iodide. This so-called iodide myxedema has been discussed on p. 154.

The minimum effective dose of iodide is 5–10 mg/day, but usually much higher doses of 20–200 mg are given to be on the safe side. The preparations most frequently used are saturated solution of potassium iodide (SSKI), which contains 750 mg of iodide/ml, or Lugol's strong iodine solution, which contains 100 mg potassium iodide plus 50 mg iodine (I_2) per ml. The usual dose is 5 drops of SSKI twice daily or 0.5 ml of Lugol's solution twice daily per os. In most cases it is useless to give larger doses (FRIEND, 1960). If necessary potassium iodide may be given in a slow intravenous infusion over 24 hours. In most cases iodide is given in combination with thionamides, but it should never be given with perchlorate as this abolishes the iodide effect.

β) Subtotal Thyroidectomy

Until the advent of antithyroid drugs, subtotal thyroidectomy was the only available form of treatment, but it was a very dangerous procedure with a high incidence of postoperative thyroid crisis and a high mortality. Many surgeons therefore preferred to remove a small part of the gland in each of several operations, or to limit the operation to ligation of the thyroid arteries. This grim outlook was dramatically changed when PLUMMER (1923) introduced iodine into the preoperative treatment of Graves' disease (p. 192). With proper management the operative mortality is now near zero (MCNEILL, 1968). We use the following indications for the operation: 1. Patients under 25 who are not adequately controlled by antithyroid drugs (the age limit is arbitrary; many centers use higher limits, and a few go as low as 20 years); 2. Patients with large nodular goiters causing pressure symptoms; 3. Patients with fast-growing firm goiters and suspected malignancy. Previous thyroid surgery is a relative contraindication, since the results of a second operation are very poor (MCLARTY, 1969; HEDLEY, 1970a). Many consider severe ophthalmopathy a contraindication, but the connection between thyroidectomy and exacerbation of ocular changes is not universally accepted.

The important point in the preoperative management is that *the patient be handed over to the surgeon in the euthyroid state*. This is usually achieved by giving a thionamide drug (e.g. carbimazole or methimazole in a dose of 45 mg per day) over two to four weeks. When the patient is clinically euthyroid and the serum thyroxine is in the normal range he may be subjected to surgery. Iodine therapy can be given in conjunction with thionamides (p. 192) with two aims in mind: 1. acceleration of the appearance of euthyroidism; 2. Reduction of the vascularity of the gland, which is said to make the operation easier. However this latter iodine effect is not undisputed and we therefore do not give iodine routinely unless the surgeon specifically wishes us to. To be on the safe side the drugs should also be given for 3 or 4 days after surgery, but they may then be rapidly

tapered and discontinued altogether. If exceptional circumstances make it necessary to operate on a patient who is not yet completely euthyroid, anesthesia must be induced and maintained with great care. Hyperthyroid patients are very sensitive to sympathomimetic drugs and to atropine, which should be given in low doses or replaced by scopolamine. The use of ether and nitous oxide in preference to cyclopropane or fluothane is recommended.

The internationally accepted procedure is subtotal intracapsular thyroidectomy. A remnant of 4 to 10 g is left lining the posterior face of the capsule. Since the parathyroid glands are usually located in this part of the thyroid they are left intact by this procedure in most cases. The incidence of complications is low when the operation is performed by an experienced surgeon. Permanent hypoparathyroidism develops in 1–2% of cases in most series (DAVIS, 1961; MCNEIL, 1968). Transient hypoparathyroidism and latent hypoparathyroidism may be more frequent. Transient postoperative hypocalcemia does not necessarily mean hypoparathyroidism, since it is often due to a greatly increased calcium uptake by the osteoporotic bones (MICHIE, 1971).

The obvious explanation for the effectiveness of the operation is that it greatly reduces the number of active thyroid cells. Lately, however, HEDLEY (1971) has made the provocative suggestion that the operation improves the underlying autoimmune disease. This contention is based on the lower incidence of LATS in postoperative patients. His results are subject to the drawbacks of any retrospective set-up and will therefore have to be confirmed by additional studies.

The incidence of postoperative hypothyroidism seems to be closely related to the weight of the thyroid remnant (MICHIE, 1972). It may therefore be as low as 6.5% (MCNEILL) or as high as 49% (MICHIE, 1972), depending on the surgeon's policy. Most patients become hypothyroid within 4 months of the operation and most authors have found no evidence of a cumulative rise comparable to that after radioiodine treatment (MICHIE, 1972; HEDLEY, 1970a). In one study, however, there was a cumulative rise of hypothyroidism of 1.7% per year over 10 years (NOFAL, 1966). There may be a positive correlation between the presence of thyroid antibodies in serum (BUCHANAN, 1962) or the degree of lymphocytic infiltration of the gland (HARGREAVES, 1968) and the occurrence of postoperative hypothyroidism, but this point remains to be confirmed. Diminished thyroid reserve (as defined on p. 161) may be present in many patients who are capable of maintaining a euthyroid state only thanks to elevated TSH levels (HEDLEY, 1970b).

Recurrent thyrotoxicosis is found after surgery in 2–30% of patients (see HEDLEY, 1971, for short review). The treatment of choice for postoperative relapse is radioiodine, since both a second operation and antithyroid drugs are ineffective in controlling the disease in most cases (MCLARTY, 1969; HEDLEY, 1970a).

γ) Radioiodine

Radioiodine may be administered either per os or intravenously. In Graves' disease 30–90% of the radioactivity will rapidly be taken up by the hyperfunctioning thyroid gland, while the remainder will be excreted in the urine. The radioiodine is slowly lost from the gland into the blood as labeled hormone. The most frequently used iodine isotope, ^{131}I, has a physical half-life of 8 days. Its decay produces both β-particles with a mean tissue pathway of about 1 mm and γ-quanta. The β-particles are responsible for 90% of the therapeutic effect; on being absorbed they destroy thyroid tissue without affecting neighboring organs. The γ-ray emission of ^{131}I is used mainly for diagnostic purposes. The chemical amount of iodine introduced into the body by radioiodine treatment is so small that it has no biochemical or pharmacological effect (1 mCi of carrier-free ^{131}I = 0.01 μg iodine).

Indications for radioiodine vary from one center to the other. In some clinics radioiodine is used whenever it is not contraindicated and 80% or more of patients with Graves' disease are treated in this way. As far as risks (except hypothyroidism), costs, and inconvenience to the patient are concerned, radioiodine is indeed unsurpassed by any other treatment for Graves' disease.

There are several contraindications to the use of radioiodine. Since the fetal thyroid accumulates iodine from the third month of gestation onwards, radioiodine should never be given during pregnancy. Radioiodine is excreted into the milk and should therefore not be given to a nursing mother.

The thyroid gland appears to be very sensitive to the carcinogenic effect of radiation in childhood. Radioiodine should therefore not be given to patients under the age of 25 (this is an arbitrary limit). Relative contraindications are large diffuse and large nodular goiters with rapid radioiodine turnover, since unduly high doses of radioactivity have to be applied, producing whole-body irradiation in excess of permissible limits.

Strong *indications* for radioiodine are:

1. Recurrent hyperthyroidism after thyroidectomy. In these cases radioiodine is the treatment of choice (p. 194);
2. Recurrent hyperthyroidism after drug treatment. In these cases the options are radioiodine or surgery;
3. Severe ophthalmopathy. Radioiodine is often preferred in these cases, but reliable evidence that this form of treatment causes less progression of the eye disease is hard to come by.

We consider as *relative indications* all cases of established Graves' disease in patients over age 25, whether with diffuse or with nodular goiter.

There are several potential *risks* in radioiodine therapy:

1. Carcinogenic effect on the thyroid tissue;
2. Production of leukemia due to bone marrow irradiation;
3. Production of recessive mutations due to gonadal irradiation;
4. Hypothyroidism.

All these risks have to be weighed against those of surgery or drug treatment. It is now safe to say that the first three potential risks listed above are negligible, while the fourth, hypothyroidism, remains a real problem. Although isolated cases of thyroid neoplasia after radioiodine treatment have occurred (SHELINE, 1962; BAKER, 1969; LIMA, 1970), it is generally agreed that the incidence is extremely low, and probably no higher than in a control population. MCDOUGALL (1971) has recently reviewed the literature on this subject. Chromosomal changes have been found in the lymphocytes of radioiodine-treated patients (CANTOLINO, 1966), but in two very carefully followed series of 10000 and 20000 patients the incidence of leukemia was no higher than in the general population (POCHIN, 1960; SAENGER, 1968).

The radiation dose received by the gonads in the course of radioiodine treatment (about 20–30 rad) is in the same order of magnitude as the dose received during a gastrointestinal radiologic examination. The genetic risk to the population induced by radioiodine is only a tiny fraction of that produced by radiation from natural sources, and the expected rate of mutations in the descendants of radioiodine-treated parents is only minimally higher than in untreated parents. We agree therefore with HORST (1960) that, with the exception of Graves' disease in childhood, the indication for radioiodine treatment should be made dependent on the calculated whole-body dose rather than on an arbitrary age limit.

The report of DUNN (1964) has drawn attention to the alarmingly high incidence of postradioiodine hypothyroidism, a phenomenon which has been well studied in recent years. In DUNN'S report, 20% of patients were hypothyroid after one year and the incidence of hypothyroidism subsequently rose by about 2.5% per year to reach 45% after 14 years There was no indication that this rise levelled off. In another series 70% were hypothyroid after 10 years (NOFAL, 1966). There is no doubt that the incidence of hypothyroidism is related to the dose of radioiodine (HAGEN, 1967; SMITH, 1967; GOOLDEN, 1969), but GLENNON (1972) has recently examined 55 patients treated before 1951 with very low doses of 3 mCi or less. Although the incidence of hypothyroidism remained quite low for 5 years, it then started to rise at a rate of 3.4% per year, reaching a cumulative incidence of 48% after 17 years. Glennon suggested that the dose influenced the incidence of "early" hypothyroidism during the first years, but that the subsequent cumulative rise was independent of the amount of ^{131}I. In Zurich, with the dosage calculated as outlined below, the rate of increase of hypothyroidism was 1.6% per year (ENGELBRECHT, 1970). According to more recent results from the same group (KAESTNER, 1973) this low incidence may be due to the fact that their sample included an appreciable number of patients suffering from Graves' disease with nodular goiters. Indeed, patients with nodular goiters appeared to be much more resistant to the development of hypothyroidism than those with diffuse goiters (1.6% as against 14.7% at 5 years). A similar difference had already been found by VIHERKOSKI (1970), but toxic adenomas were not rigorously excluded in his series.

The exact mode of action of ^{131}I has not yet been established, but it is generally assumed that it damages the thyroid cell nucleus and thereby interferes with cell division (GREIG, 1965). Since there is probably a slow turnover of cells, inhibition of cell replication will progessively diminish the number of active cells. In order to avoid nuclear irradiation, another iodine isotope, ^{125}I, has recently been used in experimental studies. This isotope has a half-life of 60 days. It has a complex decay scheme with the energy dissipated by γ-emission (7%) or by internal conversion (93%). The latter produces soft X-rays or low-energy β-particles, both with a very short tissue pathway of about 0.5 μm. Since most of the radioactive iodine in the thyroid gland is within the colloid, the apical cell pole receives most of the radiation, due to the short pathway, while the basal cell pole, which contains the nucleus, is left intact.

Several groups of investigators have therefore used ^{125}I for the treatment of Graves' disease, and th theoretic and practical aspects have been c ncisely reviewed by McDougall (1971) and also in an Editorial in the Lancet (1972). The studies so far have shown that ^{125}I effectively controls hyperthyroidism, but with respect to hypothyroidism the results have been rather disappointing, since the percentage appears to be as high as or even higher than after ^{131}I (McDougall, 1971; Werner, 1970). At present, therefore, ^{125}I remains an experimental form of treatment.

The high risk of hypothyroidism after radioiodine places a great responsibility upon the doctor. First of all he has to inform the patient of this risk and to tell him about the most common symptoms of hypothyroidism. Second, the patient *must be followed up for the rest of his life* and examined by the doctor at least once each year. Failure of the patient to keep his appointment should make the doctor suspect that he has become hypothyroid, and every effort should be made to contact him and to bring him under medical supervision. It is the fact that hypothyroidism is latent for some years, develops insidiously, and may easily be mistaken for cerebral arteriosclerosis in older persons that makes this lifelong follow-up mandatory. Regional follow-up schemes have been devised in Scotland (Philp, 1968). Once it is diagnosed, hypothyroidism is so easy and cheap to treat that in our view its occurrence is no reason not to use ^{131}I.

Numerous methods are in use for the calculation of the *dose of* ^{131}I. All the methods use at least one variable, the estimated thyroid weight, in the computation. Thus, in most centers in the United States the gland weight is estimated by several observers by palpation and 80–160 μCi of ^{131}I per g weight are given. The calculations used in Zurich include several other variables, in an attempt at more exact control of the radiation energy delivered to the tissue. The following unit is in use as a measure of the radiation energy:

rad (radiation absorbed dose): 1 rad corresponds to 100 erg of energy delivered to 1 g of tissue.*

The following 5 factors or variables are considered in calculations of dosage for individual cases:

1. Physical properties of ^{131}I: The β-emission energy, which is the one relevant to its therapeutic effect, is 0.205 MeV, including conversion electrons (Marinelli, 1948). With additional components of the isotopic decay, in particular γ-emission, the total energy is 0.248 MeV (Perry, 1950). One mCi of ^{131}I delivers 0.56 rad/hour in 1 g of tissue, provided the isotope distribution is homogeneous.

2. Volume or weight of the thyroid gland, which may be estimated by palpation or by planimetry of thyroid scintigrams. We use the following formula: Weight = 0.323 × average height of lobes × surface of gland in a dorsoventral scintiscan (Allen, 1952; Doering, 1958). The mean deviation of this estimation from the weight found at autopsy was 10% (Gauwerky, 1959).

3. Percentage or fraction of the ^{131}I dose taken up by the thyroid. Several measurements must be taken after a diagnostic dose to obtain the peak uptake.

4. Distribution of ^{131}I *within the thyroid tissue.* Since radioiodine is unevenly distributed in thyroid tissue (Levene, 1955) the resultant intrathyroidal dose lattice is nonuniform. Dose maxima at certain sites can be 3.4 to 25 times greater (mean 10 times greater) than the calculated average dose (Sinclair, 1956). The dose minima may be quite important, since they may allow the survival of normal thyroid tissue which will maintain euthyroidism.

Gross inhomogeneity of radioiodine distribution such as occurs in nodular goiters usually calls for an increase in the dose of ^{131}I.

5. Rate of release of radioiodine from the thyroid gland. This is included in the final formula as effective half-life (T_{eff}), which is obtained from the equation:

$$T_{eff} = \frac{T_{biol} \times T_{phys}}{T_{biol} + T_{phys}}$$

where T_{biol} is the biologic and T_{phys} the physical half-life. The biologic half-life can be determined directly from serial epithyroidal measurements of radioactivity or estimated from the PB ^{131}I, which correlates closely with T_{biol}.

The final formula used in Zurich for the dose in μCi ^{131}I (D) is:

$$D = \frac{W \times \text{rad}}{19.4 \times T_{eff} \times U}$$ (modified from Oeser, 1961)

where W = thyroid weight (grams), T_{eff} = effective half-life (days), U = thyroid uptake of ^{131}I (fraction of dose), rad = the desired radiation dose, as outlined in Table 7. The factor 19.4 contains several simple transformations (hours to days, rep to rad, half-life into mean life).

We vary the radiation dose according to Table 8, e.g. grade I in patients with severe exophthalmos in whom high doses might ag-

* 1 rad ≙ 1.07 rep (roentgen equivalent, physical).

Table 7. Guidelines for radioiodine dosage in Graves' disease (SCHNEIDER, 1965). (See text for explanation)

	I	II	III	
Very small goiter	3000	5000	7000	rep
Goiter < 120 g	4000	7000	10000	rep
Goiter > 120 g	5000	9000	12000	rep

Table 8. Indications and contraindications for various forms of treatment of thyrotoxicosis

1. Radioiodine
   a) Never during pregnancy;
   b) Never under age 25, except in a few special cases;
   c) Treatment of choice for relapse after operation.
2. Subtotal thyroidectomy
   a) Always in rapidly growing goiters with suspected malignancy;
   b) Often in large nodular goiters with pressure symptoms (radioiodine may be an alternative).
3. Thionamide drugs
   a) Always preoperatively before thyroidectomy, often in conjunction with iodine;
   b) In all cases of Graves' disease during childhood;
   c) Always in thyrotoxic crisis, in combination with iodine;
   d) In most cases during pregnancy (thyroidectomy is an alternative). Never give iodide during pregnancy;
   e) Sometimes as an adjunct after radioiodine to hasten appearance of euthyroidism;
   f) In selected adult patients as a 1-year course;
   g) Not recommended in cases of relapse after a first course of drugs or after surgery.

gravate the eye problem and grade III in elderly patients with heart failure, in whom rapid control of thyrotoxicosis is desirable.

The results of radioiodine treatment are usually quite satisfactory if the high risk of hypothyroidism is disregarded. Thyrotoxicosis is controlled within 3 to 6 months in most cases. After this time a second dose can be given if needed. The slow onset of action is a disadvantage, but control is obtained more quickly by beginning administration of a thionamide drug or iodine (HAGEN, 1967) 10–14 days after the ^{131}I dose.

Quite a number of patients are pretreated with thionamide drugs before the decision to use ^{131}I is made; this is then usually given two to three weeks after the drug has been stopped. GOOLDEN (1969) found that in such cases pretreatment with methimazole or propylthiouracil lowered the cure rate of ^{131}I, while carbimazole had no such effect.

Some patients show a transitory exacerbation of thyrotoxic symptoms, and LAMBERG (1959) and VIHERKOSKI (1970) have stressed the danger of thyrotoxic crisis after ^{131}I. In our experience, however, this is a very rare complication. A few patients complain of pain in the neck region between the second and tenth day after ^{131}I.

δ) Ancillary Treatment: Antiadrenergic Agents, Sedatives

The primary aim in the treatment of thyrotoxicosis is the reduction of thyroid hormone secretion. However, in recent years drugs have become available which decrease the peripheral effects of thyroid hormone excess and they have been successfully used in cases where rapid control of disturbing or dangerous signs or symptoms is desirable. We would like to emphasize at the onset that although the patient may be greatly improved by such treatment, this does *not* render treatment directed at the thyroid gland itself unnecessary.

The drugs most frequently used are the sympatholytic agent guanethidine, the β-blocking agent propranolol, and the α-blocking agent phentolamine, or a combination of these (STOUT, 1969; BECKER, 1972). In double blind trials β-blocking agents successfully improved several signs and symptoms of hyperthyroidism, such as palpitations, nervousness, tachycardia, tremor, perspiration, and shortening of the ankle jerk (SHANKS, 1969; GROSSMAN, 1971). The usual oral dose of propranolol is 40–160 mg per day. Propranolol does not interfere with any of the thyroid function tests except the ankle jerk; in particilar it does not affect radioiodine uptake (HADDEN, 1969), so that it can be given in conjunction with radioiodine. Although propranolol affords good relief of many thyrotoxic symptoms, it should not be given alone, since only few patients are satisfactorily controlled (MCLARTY, 1973).

An important question is whether β-blocking agents may be given to thyrotoxic patients with heart failure. This will be discussed in the section on thyroid crisis (p. 198), a situation in which these agents are now of great importance.

In agitated patients phenobarbital or diazepam may be prescribed. Diazepam has been specifically examined and found *not* to interfere with thyroid function tests (CLARK, 1971).

ε) Choice of Treatment

Our guidelines for the indications for the various forms of treatment are summarized in Table 8, and the advantages or disadvantages of each procedure are compared in Table 9.

f) Special Forms and Complications of Graves' Disease

α) Thyrotoxic Crisis (Thyroid Storm)

This is a much-dreaded complication of Graves' disease. MCARTHUR (1947) has defined it as

Table 9. Advantages and disadvantages of the various forms of treatment

	Antithyroid drugs	Radioiodine	Subtotal thyroidectomy
Reliability of antithyroid effect	Very good	Good	Good
Time required to reach euthyroidism	4–8 weeks	3 months	1 week
Cost	Moderate	Low	High
Hospital stay	No	No	Yes
Follow-up visits	Every month	Every 6 months	Every year
Risk of permanent hypothyroidism	0	25–70%	6–50%
Risk of relapse	50%	10%	6–25%
Mortality	<1%	0	<1%

a *potentially fatal exacerbation of all thyrotoxic symptoms.* An elevation of rectal body temperature to at least 38.8 °C is considered an obligatory sign. The exact cause of thyrotoxic crisis is unknown, but a sudden release of massive amounts of thyroid hormones is probably implicated. We recently observed one case with a serum thyroxine concentration of 50 µg/100 ml. Some authors contend that thyroid crisis often occurs in patients whose serum hormone level is no more elevated than in ordinary thyrotoxicosis. They therefore think that massive thyroid hormone excess is not the decisive factor in the pathogenesis (DILLON, 1970), but we suspect their opinion may have to be reevaluated when triiodothyronine concentrations during thyroid crisis become known.

Among 2033 thyrotoxic inpatients admitted to the Massachussetts General Hospital between 1921 and 1946, MCARTHUR (1947) found 36 cases of thyrotoxic crisis. In 25 patients the crisis was "surgical", i.e. it occurred after subtotal thyroidectomy. In the remaining 11 patients the crisis was classified as "medical" i.e. occurring after infection, trauma or anesthesia. As Graves' disease is now more often correctly diagnosed and treated thyroid crisis has become quite rare.

LAMBERG (1959) has carefully analyzed the symptomatology. Most symptoms involve the cardiovascular or the central nervous system, or both. In the so-called *cerebrobulbar* form the patient becomes agitated, confused, or sometimes comatose (ROIZEN, 1971). Bulbar palsy may become a prominent symptom. In the *cardiac* form tachycardia, auricular fibrillation, heart failure, pulmonary edema and shock predominate. *Gastrointestinal* signs with diarrhea are often present, sometimes as an isolated feature. The skin of the patient is red and hot. There is massive perspiration and the body temperature may rapidly rise to 40 °C or more. Hypokalemia with peripheral palsy has been described (LOGOTHETIS, 1962).

Without proper treatment, the crisis is lethal in 100% of cases (LAHEY, 1928). In recent series the mortality has been lowered to 60% (LAMBERG, 1959) and even to 28% (WALDSTEIN, 1960). This is probably due to two factors: 1. Earlier recognition of the crisis, and 2. Availability of personnel trained in intensive care and availability of potent antithyroid drugs.

Treatment of thyrotoxic crisis must begin without delay (Table 10). Blood should be taken for electrolyte determinations and for thyroid hormone measurements, and treatment should be started without waiting for the results of the latter tests. Whenever possible patients should be placed in an intensive care unit

Table 10. Synopsis of clinical features and treatment of thyrotoxic crisis.

Clinical findings

Increase in signs and symptoms of thyrotoxicosis
Fever with temperature over 38° C up to 41° C or more
Perspiration, later dehydration
Agitation, confusion, coma
Bulbar palsy (particularly IXth nerve)
Tachycardia, heart failure

Treatment

Blood should be taken for thyroid function tests, but treatment must *not* be delayed until the results are available.

1. Antithyroid agents (always give a *and* b)
   a) Methimazole or carbimazole 30 mg every 6 hours p.o. or by gastric tube. If available, methimazole (Favistan®) can be given intravenously.
   b) Iodine: Saturated solution of potassium iodide 3 drops every 6 hours or Lugol's strong iodine solution 1 ml every 6 hours. (If necessary: Potassium iodide 0.5 g in 5% glucose or 0.9% NaCl by slow i.v. infusion over 24 hours).
2. Fluid and electrolyte replacement, based on monitoring of central venous pressure and 12-hourly serum electrolyte measurements.
3. In cases of severe fever cooling blankets or "surgical" hypothermia.
4. Sedation: Phenobarbital, diazepam, chlorpromazine, reserpine, alone or in combination.
5. Oxygen 2 liters per minute by nasal catheter.
6. Propanolol 40 to 80 mg p.o. every 6 hours or 1/8 this dose i.v. In older patients and cases of severe heart failure lower doses should be tried first.
7. Digitalis glycosides in relatively high doses (exact dosage guidelines not available).
8. Cortisone acetate p.o. or Cortisone hemisuccinate i.v. (by slow infusion) 200 mg per 24 hours.
9. Antibiotics if infection suspected.

until the crisis is well under control. Antithyroid drugs must be given in high doses, e.g. methimazole or carbimazole, 30 mg every 6 hours. Due to its rapid effect iodine is still the basis of treatment and should always be added to the above drugs (INGBAR, 1966) in a dose of 500 mg of iodine, either as SSKI or as Lugol's strong iodine solution (see p. 193), given in 4 divided doses. If necessary potassium iodide can be given in an intravenous drip over 24 hours, and if available methimazole can be given by i.v. injection.

Dehydration and electrolyte disturbances are treated by adequate fluid therapy. Since perspiration is greatly increased, large amounts of fluid and NaCl must be replaced. Since heart failure is often present, central venous pressure must be monitored during fluid replacement. In rare cases plasma or albumin solutions are necessary to avoid circulatory collapse.

In cases of heart failure or auricular fibrillation with tachycardia, digitalis glycosides must be given by the intravenous route. The patients usually tolerate large doses, but unfortunately no exact dosage guidelines are available. Oxygen (1 to 2 liters/min) should be given through a nasal catheter.

If hyperthermia threatens to be fatal, cooling blankets (or if not available moist blankets and a fan) should be applied. Sometimes proper surgical hypothermia supervised by an anesthetist must be instituted.

Since relative adrenocortical insufficiency may be involved, we always give large doses of cortisone, either per os or as cortisone hemisuccinate in a slow i.v. infusion over 24 hours (200 to 300 mg per day).

β-Receptor blocking agents are probably a major advance in the treatment of thyrotoxic crisis, but their impact on the outcome has not yet been statistically evaluated. BUCKLE (1968) used β-receptor blockade in two patients who had deteriorated despite all other forms of treatment and noted dramatic improvement. Propranolol is the drug most frequently used. The recommended dosage is 40–80 mg every 6 hours per os or about one eighth of this dose by the i.v. route. Obviously there is some reluctance to use β-adrenergic blockade in older patients where heart failure may coexist. In our limited clinical experience, however, β-adrenergic blockade has improved rather than worsened heart failure, probably by slowing the heart rate and allowing better ventricular filling. Two experimental studies support this view. WIENER (1969) found that propranolol improved the left ventricular efficiency in thyrotoxic subjects, and PIETRAS (1972) reported that the same drug did not increase left ventricular end diastolic pressure in thyrotoxic patients even in cases where it was clearly elevated before propranolol. Before the availability of β-receptor blocking agents guanethidine was widely used.

Infection should be looked for as the possible triggering factor of thyroid storm and in case of suspicion an antibiotic must be given after sampling of blood, sputum and urine for bacteriologic examination. Subtotal thyroidectomy is sometimes advocated but is contraindicated in our opinion.

Most patients in thyrotoxic crisis need large doses of sedatives. Phenobarbital, chlorpromazine, diazepam, and reserpine have all been used either alone or in combinations. DILLON (1971) has successfully used reserpine alone without an antithyroid drug, but we would not recommend this as a routine treatment. Peritoneal dialysis (HERRMANN, 1969) or plasmapheresis (ASHKAR, 1970) effectively removes thyroid hormone from the body, but we still consider them as experimental forms of treatment. A review on the treatment of thyroid storm is given in Table 10.

β) Apathetic Thyrotoxicosis

A case has been made for the classification of patients who instead of being nervous or agitated become quiet, depressed and apathetic into a separate subgroup. The literature on this form of Graves' disease has been reviewed by THOMAS (1970) and in an editorial in the LANCET (1970). Most of these patients are in older age groups and many have cardiac symptoms. In some cases the clinical picture was so misleading that the diagnosis of myxedema was considered (RONNOV, 1973). Thyrotoxicosis is often severe in such cases and may lead to death in heart failure if not treated. Apathetic thyrotoxicosis may even occur in the setting of thyroid storm.

γ) Graves' Disease in Pregnancy

In most cases Graves' disease takes a mild course during pregnancy. There is no evidence that pregnancy aggravates thyrotoxicosis. On the contrary, in many cases pregnancy probably has a beneficial effect on Graves' disease. This may be due to the increased levels of estrogen, which have been shown to ameliorate symptoms of thyrotoxicosis (ZANINOVICH, 1972).

The diagnosis of hyperthyroidism in pregnancy should be made largely on clinical grounds. Radioiodine uptake tests should not be performed in pregnancy. The basal metabolic rate is usually elevated to +20 or +30% at the end of a normal pregnancy and is therefore difficult to interpret.

Serum total thyroxine measurements give elevated values in the second and third trimesters of pregnancy, because estrogens cause an increase of TBG (p. 143). The resin T_3 uptake test in contrast falls into the hypothyroid range.

Iodine is actively accumulated by the fetal thyroid from about the 80th day of gestation onward (GREENBERG, 1970). Radioiodine treatment is therefore strictly contraindicated.

In mild cases of thyrotoxicosis sedatives provide adequate control of the symptoms during pregnancy. Subtotal thyroidectomy after a short course of antithyroid drugs (*without* iodide) is also feasible from the 2nd up to the 6th month.

Thionamide drugs may be given, but they have the disadvantage that they cross the placenta, while the maternal thyroid hormone does not pass to the fetus or only to a limited extent. Thus the drugs may produce fetal hypothyroidism and goiter while the mother is still hyperthyroid. There seems to be no ideal solution to this dilemma in theory, but in practice good results are obtained with the lowest possible dose, e.g. 5–10 mg of methimazole or 50 to 100 mg of propylthiouracil per day. The patient should be left slightly hyperthyroid and the total serum thyroxine should be kept at about 15 µg/100 ml. Some authors recommend the administration of triiodothyronine together with the thionamide drugs in the hope that it may cross the placenta. We can see no theoretic or practical advantage in this procedure.

Pharmacological doses of iodide should never be given, since this procedure involves the risk of fetal and neonatal hypothyroidism, a condition with a grave prognosis (p. 167).

BURROW (1972) has written a short monograph on the interrelation between thyroid gland and pregnancy.

δ) Graves' Disease in Neonates and Children

Hyperthyroidism in the newborn is extremely rare. In most reported cases the mother has also suffered from Graves' disease and had very high LATS titers (MCKENZIE, 1964; SUNSHINE, 1965; GAUTHIER, 1968). As an IgG immunoglobulin, LATS crosses the placenta into the fetal circulation. LATS slowly disappears from the blood of the baby and symptoms of hyperthyroidism abate in parallel without treatment. In a few exceptional cases the disease persists for years (HAYLES, 1972).

In children thyrotoxicosis is quite rare when compared with the incidence in adults. The question as to how it is best treated remains open. Radioiodine is considered contraindicated due to the potential risk of carcinogenesis (p. 195), but its use has nontheless been discussed by SAXENA (1965). In one series of 25 children treated with ^{131}I a papillary carcinoma developed in one.

Subtotal thyroidectomy after drug pretreatment offers the advantage of less frequent relapses, but postoperative myxedema was found in 25% of cases (HAYLES, 1967 and 1972).

After thionamide medication relapses are less frequent in childhood than in adult Graves' disease, and we therefore consider it the treatment of choice in children. The dose is the same as in adults, adjusted according to body surface area. The various aspects of childhood thyrotoxicosis have been reviewed in a short editorial in the British Medical Journal (1965).

ε) Thyrotoxicosis with Excessive T_3 Secretion (T_3-Toxicosis)

Triiodothyronine was discovered in 1953, about 40 years later than thyroxine, and remained neglected for a long time because its concentration in serum was too low to be measured by conventional techniques. With the publication of a method for its measurement STERLING (1969) opened a new era in clinical thyroid research.

Numerous publications have since appeared on this hormone, which LARSEN (1972) has recently reviewed. Due to its higher activity (per mg weight), triiodothyronine plays an important physiologic role and it has even been suggested that thyroxine per se is inactive, unless it is peripherally deiodinated to triiodothyronine (p. 145).

Cases of typical clinical thyrotoxicosis with a normal level of protein-bound iodine in serum (which represents mainly thyroxine) were first recorded a long time ago. By measuring the serum triiodothyronine STERLING (1970) established that these patients suffered from isolated oversecretion of triiodothyronine. In his series, most patients had toxic nodular goiters, but subsequent investigators observed the condition in many cases of Graves' disease (IVY, 1971; HOLLANDER, 1972). There are no clinical features which distinguish thyrotoxicosis due to excess T_3 from the conventional form, and the diagnosis must therefore be made on the basis of triiodothyronine measurements. Sometimes the condition progresses to conventional hyperthyroidism with elevated thyroxine levels (HOLLANDER, 1971). It has also been observed in children (MITSUMA, 1972) and in thyroid carcinoma (SUNG, 1973).

g) Endocrine Ophthalmopathy

α) Definition and Classification

Thyroid hormone excess of any etiology (Graves' disease, toxic nodular goiter, thyrotoxicosis factitia) produces certain nonspecific eye signs, notably lid retraction. This so-called *noninfiltrative* ophthalmopathy is attributed to hyperactivity of the sympathetic nervous system, which is thought to produce contraction of Müller's superior palpebral muscle, but this explanation is not universally accepted.

In contrast, *infiltrative* ophthalmopathy occurs only in patients with Graves' disease, and the severity bears little relation to the degree of thyroid hormone excess. Humoral factors other than thyroid hormone are probably important in its pathogenesis. The American Thyroid Association has recently adopted a classification of the eye changes in Graves' disease, which is presented in its abridged form in Table 11 (WERNER, 1969).

Table 11. Abridged classification of ocular changes of Graves' disease (WERNER, 1969). Each class usually includes the involvements of the preceding class. Each class may be graded mild (a), moderate (b), marked (c) or absent (0). Note that proptosis occurs twice in this classification, first in the mild, benign form of class 1, where it is not considered a bad prognostic sign. When there are additional signs of soft tissue involvement, proptosis becomes part of severe (class 3 to 6) ophthalmopathy

Class	Definition
0	No signs or symptoms
1	Only signs, no symptoms (signs limited to upper lid lag and proptosis)
2	Soft-tissue involvement (symptoms and signs)
3	Proptosis
4	Extra-ocular muscle involvement
5	Corneal involvement
6	Sight loss (optic nerve involvement)

β) Pathogenesis

As stated above, the infiltrative ophthalmopathy bears little relation to thyroid hormone excess and it cannot be produced by the exogenous administration of thyroid hormone. Involvement of both eyes and sometimes the coexistence of related changes in the pretibial skin early suggested that humoral factors played a pathogenic role. When the serum of patients with exophthalmos was injected into some fish species (fundulus, goldfish, carp) or guinea pigs it did in fact produce proptosis and in some assays also an increased sulfur-^{35}S uptake by the so-called Harderian gland. This gland only exists in rodents and is *not* an analog of a lacrimal gland. Rather it corresponds to a part of retro-orbital tissue. The serum factor causing proptosis in the test animal has been termed exophthalmos-producing substance (EPS). EPS may be present in both the serum and the pituitary gland of patients with exophthalmos. In serum of patients with severe ophthalmopathy both very high and low titers have been found by the fish bioassay.

BRUNISH (1962) reported a molecular weight of 40000 for EPS as determined by ultracentrifugation. Whether the EPS of serum is identical with the EPS of the pituitary is open to question (MCKENZIE, 1968). EPS and LATS (p. 179) are certainly not identical. They can be separated in serum by polyvinyl block electrophoresis or by gel filtration. Antibodies to EPS do not inactivate LATS. The physiological significance of EPS has been seriously questioned in recent years. Two important criticisms have been that EPS was tested in a species far removed from man, and that all EPS preparations extracted from the pituitary always contained considerable TSH activity. Recently, however, KOHN (1971) has prepared EPS practically devoid of TSH activity by treating pure bovine TSH with pepsin. He speculated that EPS in thyrotoxicosis could be produced by limited proteolysis of TSH within the pituitary gland. This proteolytic derivative of TSH binds to isolated plasma membranes of retro-orbital tissue. The binding is enhanced by a second humoral factor, presumably a gamma globulin, present in the serum of patients with exophthalmos (WINAND, 1972).

In initial reports LATS was found more frequently and also in higher titers in patients with ophthalmopathy (ADAMS, 1957; WERNER, 1961; KRISS, 1967), and it is probably still correct to say that the incidence of LATS is very high in sera of patients with all three cardinal (thyroidal, ocular, cutaneous) manifestations of Graves' disease (LIPMAN, 1967). However, in a later study, MCKENZIE (1968) found no good correlation between eye changes and the incidence or titer of LATS, an observation which was confirmed by HALL (1970) in euthyroid patients with so-called "ophthalmic Graves' disease" (see below).

By the leukocyte migration test, MAHIEU (1972) found evidence of delayed hypersensitivity to retrobulbar tissue protein in 9 out of 10 patients with progressive exophthalmos, but in none of the controls.

A completely new view of the problem may have been opened up by SEGAL (1973). He observed that an appreciable proportion of manic depressive patients treated with lithium developed a condition undistinguishable from endocrine ophthalmopathy.

In summary, there is some evidence for an autoimmune basis and for a pituitary origin of endocrine ophthalmopathy, but more research is necessary to clarify the etiology (see SMELSER, 1962; WERNER, 1972, for reviews).

γ) Incidence, Pathologic and Clinical Features

Mild eye changes (class I, Fig. 16) are found in about 50% of patients with Graves' disease. Severe involvement (classes 2 to 6, Fig. 17 to 19) is much rarer and has an incidence of about 5% or less. Most reported series of severe ophthalmopathy have a male: female ratio of 1 : 1 or 1 : 2. Since the sex ratio for Graves' disease as a whole is 1 : 5, this points to the fact that male thyrotoxic patients are more prone to the development of serious eye trouble. The involvement is often more severe on one side, although strictly unilateral disease is rare.

In most patients the eye trouble starts at the same time as thyroid hyperfunction, but cases where the ophthalmopathy precedes or follows the onset of hyperthyroidism are by no means rare. In the cases where ophthalmopathy develops in euthyroid patients some discrete changes of thyroid function are often dectected by radioiodine studies. The radioiodine uptake, though within normal limits, often remains nonsuppressible by triiodothyronine administration (IVY, 1972). Also, the $PB^{131}I$ is often elevated, indicating an increased radioiodine turnover. The incidence of thyroglobulin antibodies is quite high in such euthyroid patients. They often have some associated clinical features of Graves' disease, such as goiter, vitiligo or a family history of hyperthyroidism (HALL, 1970).

On histologic examination the mucopolysaccharide and water content of all retrobulbar tissues appears increased. There is more connective fibrous tissue, usually at the expense of adipose tissue. Perivascular infiltrates of mast cells are often seen. All retrobulbar tissues (fat, connective tissue, muscles, lacrimal glands) contain infiltrates of lymphocytes and plasma cells. There is interstitial edema in the extraocular muscles which may progress to degeneration of the muscle fibres with loss of cross striation (see reviews by WEGELIUS, 1957; SMELSER, 1962; RILEY, 1972, see p. 283).

Upper lid retraction (Dalrymple's sign) is the most obvious change in *class I* ophthalmopathy. It is attributed to the increased sympathetic tone causing contraction of Müller's muscle (HAMBURGER, 1972), but since the retraction often persists in patients rendered euthyroid this explanation is not entirely satisfactory. Upper lid retraction may sometimes only become manifest when the patient follows the examiner's finger moving downward in front of him (Graefe's sign). This sign is not very specific. Slight swelling of the lids is often present in class I disease (Fig. 16), but gross swelling (Fig. 18) almost always signifies severe ophthalmopathy (grades 2 to 6).

Protrusion of the eye bulbs (exophthalmos, proptosis) is often present in mild (class I) cases. In severe cases (classes 3 to 6) it can be very mild or sometimes grotesque. It can be measured objectively by the Hertel ophthalmometer, which is applied to both lateral rims of the orbita. The values obtained give the distance from the orbital rim to the apex of the cornea. Values higher than 20 mm represent probable, values above 23 mm proven, exophthalmus. The width of the bony base on which the ophthalmometer reposes should always be recorded to assure reproducible measurements over some time in a given patient. Retraction of the upper lid may simulate the presence of proptosis, but when the lower lid is retracted below the limbus of the cornea and the lower part of the sclera therefore becomes visible, true proptosis is almost always present (Figs. 16 and 17). The cause of the proptosis is an increase in retrobulbar tissue, which sometimes shows myxedematous swelling as well as lymphocytic infiltration. The differential diagnosis of proptosis includes retrobulbar tumors, infiltration of the retrobulbar tissue by lipids in histiocytosis (Hand-Schüller-Christian disease), vascular aneurysms, venous thrombosis, hemangiomas. Some people can push their eyeballs forward voluntarily by contraction of the superior oblique muscles (BERMAN, 1966).

In endocrine exophthalmos the bulbi can be pushed some way back into the orbita by gentle pressure, while such resiliency is absent in cases of retrobulbar tumors. In case of doubt angiography of the carotid artery or the vena angularis is very useful in establishing the presence of a tumor (YASARGIL, 1957; KRAYENBÜHL, 1962). In recent years, ultrasound scanning has proved valuable in the differentiation of endocrine ophthalmopathy from retrobulbar tumors (OSSOINIG, 1969; COLEMAN, 1972). Mild exophthalmos is occasionally present in Cushing's disease (MORGAN, 1958), in liver cirrhosis (SUMMERSKILL, 1968), and in acromegaly. Progressive myopia may occasionally simulate exophthalmos.

Discrete swelling of the eyelids is a frequent finding in patients with Graves' disease. Sometimes the swelling is grotesque and disfiguring (Fig. 18). In addition there may be chemosis, increased lacrimation and a "gritty" feeling.

Hematomas, allergic dermatitis, and leukemic infiltrates all have to be considered in the differential diagnosis of lid swellings.

Moderate and severe forms of ophthalmopathy often involve the extra-ocular muscles. Sometimes the function of only one muscle is impaired (Fig. 19 c), but in severe cases there is total ophthalmoplegia. The disturbance in ocular motility is always myogenic and never due to disease of the central nervous system (ESSLEN, 1961). Paresis of extra-ocular muscles due to other factors may be differentiated by electromyography (HUBER, 1967). On pathological examination the muscles are swollen and densly infiltrated by lymphocytes. The muscle fibers show gross degenerative signs with loss of cross-striation. Occasionally the mucles are transformed into rigid fibrous bands.

In its severest form ophthalmopathy presents with lid swelling, chemosis, protrusion of retrobulbar tissue laterally in the lower lid, quasi total immobility of the bulb, keratitis due to incomplete lid closure (lagophthalmos), and finally progressive deterioration of vision. The latter is usually due to pressure on the optic nerve.

δ) Course and Treatment of Ophthalmopathy

The course of ophthalmopathy is unpredictable and bears little relation to thyroid function. As stated above, the ocular involvement remains mild (class 1) in most patients with Graves' disease. With either drug or radioiodine treatment the proptosis increases slightly over the course of more than three months (KOUTRAS, 1965) and may then stabilize or regress. In a few patients the ophthalmopathy suddenly worsens without apparent cause. This may happen when the patient is hyperthyroid, euthyroid, or more often when he is hypothyroid (HAMILTON, 1967). Abrupt treatment of thyrotoxicosis is thought to worsen the ophthalmopathy (ARANOW, 1965), but HAMILTON (1967) was not able to confirm the widely held belief that subtotal thyroidectomy is a worse offender in this respect than radioiodine. Since it appears essential to avoid iatrogenic hypothyroidism, KOUTRAS (1965) recommended routine prescription of 200 μg of L-thyroxine daily during antithyroid drug or radioiodine treatment of patients with eye changes, but in a subsequent study he found little evidence of any beneficial effect (KOUTRAS, 1970). The erratic spontaneous course and the relatively rare occurrence of severe infiltrative ophthalmopathy render the evaluation of any form of treatment extremely difficult.

Mild forms (class 1) of ophthalmopathy cause no discomfort to the patient and need no specific treatment. Cosmetic problems may arise, especially in women, but they should not be an indication for active treatment, since results are unsatisfactory. The patient should be reassured about the generally benign nature of the eye changes by his doctor.

In severe forms of ophthalmopathy the doctor should carefully talk over the problem with the patient and inform him about the unpredictable course and the available therapy.

Local treatment, although of limited value in changing the underlying disease process, is of prime importance since it may save the patient's eyesight by preventing keratitis. Whichever of the subsequent forms of general treatment is chosen, local treatment should always be given. The patient should wear protective glasses during the day. Eyedrops containing 0.25% methylcellulose should be applied several times daily and also during the night to keep the bulbs moist. When there is incomplete spontaneous lid closure the patient may benefit from adhesive tapes over the lids during the night. Lateral surgical closure of the lids (tarsorrhaphy) may improve lid closure in selected patients. Elevation of the head in bed diminishes accumulation of edema fluid. Diuretics are often prescribed, but their value has never been objectively assessed. CROMBIE (1967) has recommended the use of eyedrops containing 10% guanathidine, and KOUTRAS (1970) has confirmed that they reduce the width of the palpebral fissure. IVY (1972) had equally good results, but less side effects, with a 5% solution. However, the effect is not very marked. Moreover, guanethidine eyedrops have no effect on proptosis. In his careful study, KOUTRAS (1970) found no evidence of any beneficial effect on palpebral fissure or exophthalmos when prednisolone eyedrops were used or metraonidazole was given per os. We do not recommend local injection of corticosteroids or other agents, although GARBER (1966) has reported good results.

Treatment of thyroid hyperfunction must be carefully supervised in order to avoid iatrogenic hypothyroidism. We generally prefer to give radioiodine since gradual attainment of euthyroidism renders supervision easier. Some authors give radioiodine in small repeated doses. In the majority of cases the ophthalmopathy remains stationary after radioiodine or sometimes improves with a latency of several months.

Prednisone benefits many cases of severe ophthalmopathy (WERNER, 1966), but we usually reserve this treatment for emergency cases where vision is threatened by severe keratitis or optic nerve atrophy, or when there is a rapid progression of extra-ocular muscle paralysis. High doses of 50–100 mg/day are necessary for

such patients, and WERNER (1966) recommends even higher doses (up to 140 mg) in refractory cases. The prednisone should be tapered to the lowest effective dose after 2 to 3 weeks. It should be given for at least 4 weeks, but no guidelines exist as to whether it should then be stopped or whether it should be continued for several months. The mode of action of prednisone is not known. GREEN (1963) and PLIMSTONE (1964) have reported a decrease in LATS levels during prednisone medication, but since the role of LATS in the eye disease is controversial, this is no satisfactory explanation for the prednisone effect. In some cases prednisone brings about a dramatic improvement of the ophthalmopathy.

Immunosuppressive therapy with azathioprim may lower LATS levels. It has shown benefical effects on the eye changes in one study (WERNER, 1967a) and no effect in others (HADDAD, 1967; BURROW, 1970).

X-ray treatment directed toward the orbital space with antiinflammatory doses of 800 – 1000 rad has often been recommended, and HORST (1960) was able to completely eliminate the use of operative decompression procedures by this means in a large series of cases, but others have not had equal success. More recently DONALDSON (1973) has had very good results with higher radiation doses of about 2000 rad applied by supervoltage. It remains to be seen whether this is tolerated without any late adverse effects.

Hypophysectomy and pituitary irradiation have been popular for some time and the term "thyrohypophyseal syndrome" was coined under the assumption that endocrine ophthalmopathy was caused by a pituitary factor (LAMBERG, 1957). Most centers have abondoned this form of treatment due to lack of efficacy.

Total thyroidectomy and radioablation of the thyroid gland are advocated by CATZ (1965) and by BAUER (1966). This treatment is based on the attractive hypothesis that infiltrative ophthalmopathy is an autoimmune process which is kept active by the presence of antigens in the thyroid gland. Other authors (WERNER, 1967b; PEQUEQNAT, 1967; VOLPÉ, 1969) have not, however, been able to produce the same good results as Bauer. This form of treatment therefore remains controversial.

When control of thyroid hyperfunction and prednisone therapy have failed to arrest the progression of malignant ophthalmopathy, and in particular when vision deteriorates, *surgical decompression* must be performed. The indications for decompression are progressing decrease of vision or visual field defects and severe kreatitis, both resistant to medical management. This treatment, formerly considered a heroic last-resort measure, should not be delayed too long, since modern surgical techniques have greatly improved the results. Even with the availability of modern techniques, operations should *never* be undertaken on cosmetic indications. Many authorities consider surgery the only really effective form of treatment of severe proptosis. The choice of operative technique depends on the surgeon available. Neurosurgeons will perform the Naffziger (1932) operation (RILEY, 1972). An extradural approach is used to perform a transfrontal craniotomy and the ceiling of the orbital cavity is then opened. The bone is removed and a longitudinal incision is made in the fascia to allow expansion of the compressed orbital content.

We agree that a transantral approach (OGURA, 1962) with removal of the floor and lateral walls of the orbita is now probably the best surgical approach (*Editorial, Brit.med.J.* 1972; DESANTO, 1972). This procedure avoids a craniotomy and in our limited experience it has provided dramatic relief.

In a few selected cases with diplopia stationary over two years, corrective surgery on the extraocular muscles is possible. Alternatively, prism spectacles sometimes afford some relief.

3. Toxic Nodular Goiter (Toxic Adenoma, Plummer's Disease)

Graves' disease is characterized by diffuse hyperfunction of all the thyroid tissue and by certain almost specific extrathyroidal (ocular and dermal) signs.

In contrast, in toxic nodular goiter the hyperfunction remains localized to parts (nodules) of the thyroid gland and there are no extrathyroidal signs except those due to thyroid hormone excess.

Toxic nodular goiter should be strictly differentiated from Graves' disease occurring in a formerly euthyroid multinodular goiter (p. 178). Before scintiscans combined with T_3 suppression or TSH stimulation tests were available, the differentiation between these two forms of hyperthyroidism was often a matter of guesswork. Although the presence of ophthalmopathy is virtual proof of Graves' disease, its absence does not establish the diagnosis of toxic nodular goiter.

PLUMMER (1913) was the first to suggest that thyrotoxicosis could be produced by hyperfunction of thyroid nodules, but clinical differentiation between toxic nodular goiter and Graves' disease subsequently proved very difficult. The autoradiographic studies of COPE (1947) definitely established toxic nodular goiter

as an entitity, and HORST (1960, 1967), by improving on the scintiscanning technique drew attention to its relatively high frequency; he has accumulated experience with more than 300 cases within a relatively short time.

a) Incidence

In the large thyroid centers of the U.S.A. only a few cases of toxic adenoma are diagnosed each year, but an older study from the Presbyterian Hospital in New York City reports that of 2431 hyperthyroid patients operated upon between 1924 and 1944, 753 suffered from toxic nodular goiter (WERNER, 1971). Even if one admits that a considerable proportion of these may have been cases of Graves' disease in nodular goiters, the incidence of toxic nodular goiter is still appreciable. HALL (1970), without giving his source of information, cites that in the United Kingdom 5% of all cases of hyperthyroidism are due to toxic adenoma. A recent English study has estimated that toxic adenoma accounts for about 8% of all cases of hyperthyroidism (FERRIMAN, 1972). HORST (1960, 1965, 1967) found toxic adenoma in 30% of patients with hyperthyroidism in both Hamburg and Zurich. Hamburg is entirely free of endemic iodine-deficiency goiter, while Zurich still suffers from some mild iodine deficiency with a relatively high incidence of euthyroid goiter. In the Salzburg (Austria) area, where goiter is endemic, toxic adenomas account for 46% of all cases of hyperthyroidism (POHL, 1973). The reason for the discrepancy in incidence between continental Europe and the United Kingdom and U.S.A. is not readily apparent. Iodine-deficiency goiter may predispose to the development of toxic adenoma, as suggested by the high incidence in Salzburg. However, iodine deficiency cannot explain the high incidence in Hamburg. The discrepancy may be due partly to different scintiscanning techniques (p. 208). The female : male ratio in HORST's (1967) series was 6 : 1 and in POHL's (1973) series 8 : 1. Toxic adenoma does occur as early as the third decade of life, although this is rare. The peak incidence is between 60 and 70. In Zurich, 7% of toxic adenomas were found in recurrent goiter after previous thyroidectomy for euthyroid goiter (HORST, 1967).

b) Pathologic Anatomy and Pathophysiology

HORST (1967) found uninodular goiter in 75% and multinodular goiter in 25% of his cases. Whether toxic adenomas should be considered as true neoplasms or as part of a nodular goiter is a question of semantics, since it is always quite difficult to differentiate nodules of a multinodular goiter from true follicular adenomas on pathological grounds (p. 228).

Radioiodine investigations suggest that toxic adenomas are not under TSH control. If triiodothyronine is given to the patient to completely suppress TSH secretion, the adenoma will still take up radioiodine, while the surrounding thyroid tissue becomes inactive (Figs. 22, 23 b). When the thyroid hormone production of the adenoma causes only a borderline hyperthyroid state, the TSH secretion is not entirely suppressed and the surrounding thyroid tissue is still visible in the scintiscan (Fig. 23 a, so-called "compensated" toxic adenoma of HORST (1960)). In compensated toxic adenomas clinical signs

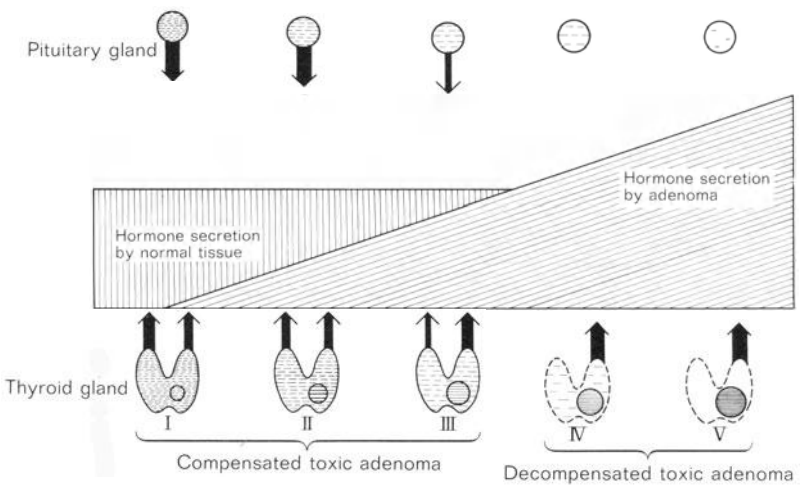

Fig. 22. Development of a warm nodule into a toxic adenoma of increasing size and with increasing thyroid hormone output. As the thyroid hormone hypersecretion progresses the TSH release successively declines and the remaining thyroid tissue becomes inactive. (BAY, 1965)

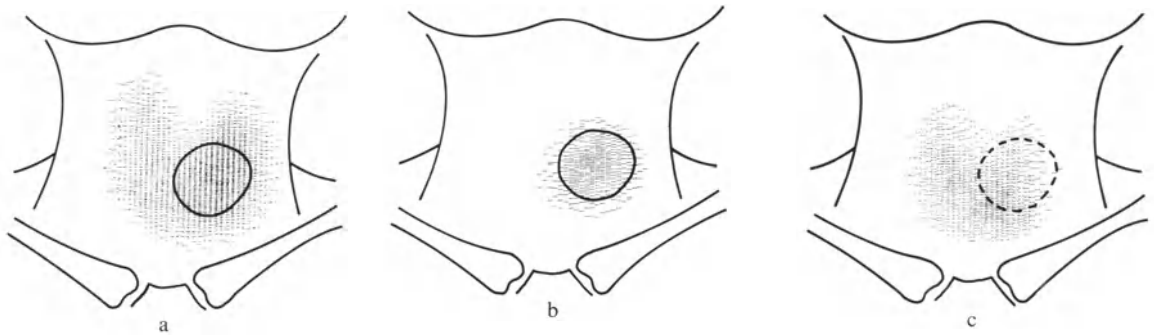

Fig. 23a–c. So-called "compensated" toxic adenoma. a) Scintiscan shows that the palpable nodule takes up more radioiodine than the surrounding tissue. b) Repeated scintiscan after short triiodothyronine treatment. Only the nodule takes up ^{131}I. c) Repeat scintiscan 3 months after radioiodine treatment. The nodule is "cold". (Courtesy of Dr. H. RÖSLER, Inselspital, Bern)

are often discrete and thyroid function tests are within normal limits. However KARLBERG (1973) has shown that in these patients TSH secretion after injection of TRH (p. 242) is impaired, which constitutes the most sensitive evidence of thyroid hormone oversecretion. If the adenoma causes frank hyperthyroidism, endogenous TSH secretion is entirely suppressed and the surrounding glandular tissue does not take up radioiodine. Injection of bovine TSH for several days will activate the remaining thyroid tissue which then becomes visible on the second scintiscan (Fig. 24, so-called "decompensated" toxic adenoma of HORST (1960)). Decompensated toxic adenomas are usually larger than compensated adenomas. Evolution from the compensated to the decompensated stage has been observed in a few cases. After inadequate radioiodine treatment a decompensated toxic adenoma may become compensated again.

The accelerated iodine turnover of toxic adenomas causes the phenomenon of "*emptying*". If the scintiscan is repeated one or two weeks after the diagnostic radioiodine dose, the adenoma appears "cold" (i.e. to contain no radioactivity) while the remaining tissue does still contain appreciable radioactivity.

The fact that functioning adenomas must have a certain size (usually 2 cm in diameter) to produce toxic symptoms suggests that the tissue mass probably plays a critical role in the thyroid hormone oversecretion. Recently, ERMANS (1971) has drawn attention to another critical factor. For several months he gave 500 µg of iodine daily to 4 euthyroid patients with warm nodules. In all 4 patients the serum hormone level rose into the thyrotoxic range, and 3 patients became clinically hyperthyroid. It thus appears that the nodules have lost their capacity to adapt to moderate iodine loads. They pick up any iodine presented to them and transform it into thyroid hormone.

The biochemical basis of the escape of toxic adenomas from TSH control is not known. BURKE (1972) and LARSEN (1973) examined toxic nodules in vitro. Surprisingly the nodules responded to TSH added *in vitro*, but the response was exaggerated. This suggested TSH hypersensitivity rather than autonomy.

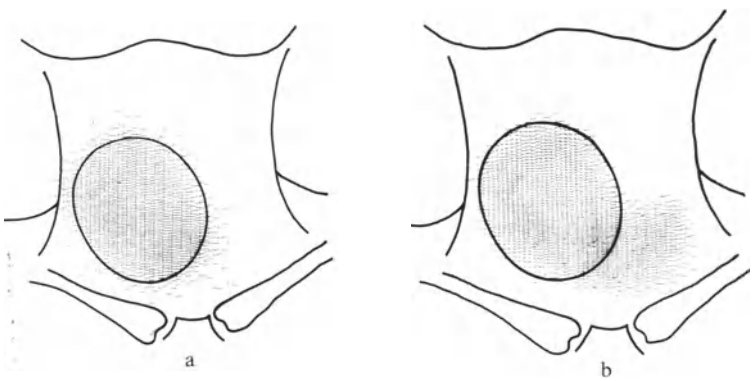

Fig. 24a and b. Large "decompensated" toxic adenoma. a) Initial scintiscan. There is no radioiodine uptake in the left lobe. b) Repeat scintiscan after a course of TSH injections. The left lobe is now clearly visible. (Courtesy of Dr. H. RÖSLER, Inselspital, Bern)

c) *Clinical Features of Toxic Nodular Goiter*

While in typical Graves' disease the patient presents with severe weight loss, nervousness, overactivity, diffuse goiter and exophthalmos, the characteristic picture of toxic adenoma is much more subtle: the classic presentation is that of an elderly woman with only minimal weight loss, a uninodular goiter and with some "functional" signs unusual for her age, such as warm moist hands, a stare and tachycardia (Table 12).

Table 12. Comparison of clinical features in toxic nodular goiter and Graves' disease

	Toxic nodular goiter (HORST, 1967) (%)	Graves' disease	
		VIGIER (1964) (%)	WAYNE (%)
Irritability, nervousness	72	90	59
Palpitation, tachycardia	56	95	75
Thermophobia, perspiration	41	70	68
Weight loss	25	95	52
Diarrhea	10	50	8

The onset of the disease is insidious and cannot be accurately established in most cases, in contrast to the onset in Graves' disease. An average of 5 years elapses from the beginning of the first symptoms to when the patient seeks medical advice. In one study, in 27% of "compensated" adenomas and 7% of "decompensated" adenomas the diagnosis was made incidentally during the diagnostic work-up for a supposedly euthyroid goiter (HORST, 1967).

The most frequent complaint is increased irritability (Table 12). Palpitations, tachycardia and heat intolerance follow on the list of clinical features. Weight loss is present in only 25% of cases. Very often the clinical picture is oligosymptomatic and the patient consults his doctor for nonspecific cardiac symptoms. Paroxysmal or chronic auricular fibrillation is frequent.

Occasionally mental changes with depression or loss of libido predominate. With the chronic slow onset the patient is often well adapted to his disease and has no subjective symptoms. In a few cases however, the picture of full-blown hyperthyroidism develops. Myopathy is present in about 10% of patients. Endocrine ophthalmopathy with exophthalmos has never been observed with toxic adenoma in either the Hamburg series or the Zurich series. In contrast, however, lid lag and a stare do occur.

Although the thyroid hormone secretion of compensated toxic adenomas is by definition not enough to entirely suppress the endogenous TSH release, it can still produce mild clinical signs and symptoms, in our experience related to the cardiovascular system in most cases. The reason for this is not readily apparent, and more research on the serum concentrations of thyroxine and triiodothyronine (in particular the free hormone fraction) in this form of toxic nodular goiter is certainly necessary.

Table 13. Synopsis of clinical features and treatment of toxic nodular goiter compared to Graves' disease (HORST, 1967)

	Graves' disease	Toxic nodular goiter
% of all cases of thyrotoxicosis (Zurich)	70	30
History	Rapid onset in many cases	Insidious onset, oligosymptomatic
Clinical findings	Diffuse goiter (occasionally multinodular goiter), all degrees of severity of hyperthyroidism. Ophthalmopathy in about 50% of cases	Uninodular goiter in most cases, few symptoms and signs of mild grade. No ophthalmopathy
Diagnosis	Can be established on clinical grounds in most cases. Serum thyroxine elevated. LATS positive in 20–50%	Clinical diagnosis difficult. Serum thyroxine and basal metabolic rate often borderline elevated. LATS always negative
Treatment	Radioiodine: 7000 to 10000 rad Subtotal thyroidectomy, Thionamide drugs	Radioiodine: 20000 to 30000 rad under T_3 protection. Selective operative resection of adenoma
Risks of treatment	Radioiodine: Hypothyroidism 25–70% Surgery: Hypothyroidism 6–50% Hypoparathyroidism Recurrent nerve palsy Drugs: Toxicity in ca. 5%	Radioiodine and operation: practically nil
Relapse rate	Radioiodine: 10% Surgery: 6–25% Drugs: 50%	Radioiodine and surgery: practically nil

d) Course of Toxic Nodular Goiter

Unlike Graves' disease, toxic adenomas have no tendency to spontaneous remission. With time the adenomas may grow, secrete more hormone and produce more symptoms. SILVERSTEIN (1967) has followed 9 cases over 2 to 7 years and has found that the course is variable, but generally benign. The course may be influenced by fluctuations in dietary iodine supply which in turn cause variations in thyroid hormone output (p. 206). Toxic adenomas of long standing may show degenerative cystic and necrotic changes in the center, which have been attributed to increased tissue pressure (BAY, 1965). Enough functioning tissue usually remains at the periphery of the nodule to maintain thyroid hormone oversecretion. Spontaneous cures are rare.

e) Diagnosis and Laboratory Tests

Uninodular goiter with discrete signs of hyperfunction and without ophthalmopathy arouses a strong suspicion of toxic adenoma, which in HORST'S (1967) series was confirmed in 80% of such cases. The PBI (representing mostly thyroxine) is usually slightly elevated (BAY, 1965). STERLING (1970) published several cases with isolated oversecretion of triiodothyronine. The basal metabolic rate does often not exceed the normal limits. In a series of 53 cases it was +18% in "decompensated" and +8% in "compensated" toxic adenomas. The ankle reflex time is slightly shortened.

The radioiodine uptake is within normal limits in many cases. In HORST'S (1967) series the mean uptake was 33% at 2 hours and 50% at 48 hours (the mean normal value in Zurich being 19% and 45%). In a parallel series of patients with Graves' disease Horst found uptakes of 53 and 62% at 2 and 48 hours respectively. The PB ^{131}I at 48 hours is grossly elevated to a mean of 1.26%/liter (mean normal 0.08%/liter).

The diagnosis is established by tracer studies combined with a scintiscan (Figs. 23, 24). Repeat scintiscans are performed after triiodothyronine suppression in cases of "compensated" adenomas or after TSH stimulation in cases of "decompensated" adenomas. Most commercial scanners have a relatively high cutoff (amount of radioactivity recorded as zero on the printout) with a superlinear (highcontrast) printout for radioactivity exceeding the cut-off point. This results in "sharp" scintiscans with no background. However, details, e.g. a warm nodule within the gland, may be overlooked with this technique and HORST (1960) therefore recommends a low cut-off with a linear low-contrast print-out. Only extensive studies of this type allow definite differentiation between true toxic adenoma and Graves' disease in a multinodular goiter. The differentiation has important therapeutic consequences.

f) Treatment of Toxic Nodular Goiter

Since, unlike Graves' disease, toxic adenomas do not remit spontaneously, drug therapy would have to be lifelong. Thionamide drugs are of course effective in inhibiting the thyroid hormone biosynthesis of toxic adenomas. In selected cases they may be given as a temporary measure until a definite form of therapy is applied. The available modes of curative treatment are radioiodine and surgery. Both modes of treatment differ from those applied in Graves' disease. An important point is the much better prognosis with respect to posttherapeutic hypothyroidism.

The treatment of choice in our view is *radioiodine* with ^{131}I given under triiodothyronine suppression to protect the normal thyroid tissue. The dose must be high, namely 20000 to 30000 rad, as compared to 10000 rad in Graves' disease. Lower doses are ineffective or only transform a "decompensated" into a "compensated" adenoma. The average dose is 30000 rep/adenoma. The TSH effect following the TSH stimulation test must have worn off before the therapeutic radioiodine dose is given. Protective triiodothyronine therapy is indicated in all cases. Although in "decompensated" adenoma the normal thyroid tissue does not accumulate radioiodine initially, it will soon start to do so, when the adenoma slows down its hormone secretion in response to treatment. Triiodothyronine is started on the day before treatment at a dose of 20 µg every 6 hours, and is continued for 10 days. If cardiovascular symptoms represent a contraindication to triiodothyronine treatment, reaccumulation of ^{131}I into the normal tissue can be blocked by perchlorate started 48 hours after the radioiodine.

With correct treatment the success rate approaches 100%. Posttherapeutic hypothyroidism is extremely rare. Recurrences have been seen in few cases. The whole-body dose is usually lower than in the treatment of Graves' disease, despite the fact that the radiation dose to the adenoma tissue is three times greater. Proof of cure are the disappearance of clinical signs and symptoms and the absence of radioiodine accumulation in a follow-up scintiscan in the region of the adenoma, while uptake in the surrounding parenchyma is normal. The toxic adenoma must have been transformed into a "cold" region.

Surgery is indicated in the following circumstances: 1. When there are "cold" areas (i.e. areas with no ^{131}I uptake) in the nodules or other signs arousing the suspicion of malignancy. Several cases of malignant degeneration of toxic adenomas or of cold malignant nodules coexisting with benign toxic adenoma have been reported (GUINET, 1971). This is the main reason why French authors prefer surgical treatment for toxic adenoma. 2. When the radioiodine turnover in the adenoma is such that the necessary ^{131}I dose is so high as to produce a whole-body dose above permissible limits. 3. In adolescents and children.

The operation consists of selective removal of the adenoma with conservation of all the normal thyroid tissue. The thyroidal arteries need not be ligated and the risks of postoperative myxedema, hypoparathyroidism or recurrent nerve palsy are negligible (ZUKSCHWERDT, 1963). The question as to whether preoperative medical control of the hyperthyroidism is as necessary in toxic adenoma as in Graves' disease is not yet settled. During the selective removal of the adenoma the blood vessels can be carefully ligated, and the risk of large amounts of hormone being released is low. According to experience in Hamburg and Paris, 60 toxic adenomas were resected without prior drug pretreatment with no serious complications. FUCHSIG (1968) observed one case of thyroid crisis in 100 operations for toxic adenoma.

4. Rare Causes of Hyperthyroidism

a) Hydatidiform Mole

In normal pregnancy thyroidal radioiodine uptake and total serum thyroxine concentration are both increased. The former is still largely unexplained, while the latter is due to raised thyroxine-binding globulin (TBG) level. Thus, the free thyroxine remains normal.

In molar pregnancy similar changes occur, but they are more pronounced. Interestingly enough, most patients are clinically euthyroid, even though the free thyroxine concentration is increased (ODELL, 1963; GALTON, 1971), but cases with severe clinical hyperthyroidism have also been reported (HERSHMAN, 1971).

The observation that patients suffering from hydatidiform mole or chorionic carcinoma are sometimes hyperthyroid and that the thyroid hyperfunction is cured by removal of the tumor has led to a search for thyrotropic factors in chorionic tissue (BURGER, 1967). Two unrelated substances have been characterized. One can be extracted from molar tumors (and serum of patients). Its onset of action in the mouse bioassay is between that of TSH and that of LATS. It is immunologically different from TSH and it is not an immunoglobulin (HERSHMAN, 1970; GALTON, 1971). The other substance occurs in normal placenta and has been called chorionic thyrotropin. It has the same molecular weight as TSH and cross-reacts with TSH antibodies (HERSHMAN, 1970). Hyperthyroidism with a circulating TSH-like substance has also been seen in a patient with a testicular embryonal carcinoma (STEIGBIGEL, 1964).

b) Thyroid Carcinoma

Thyroid carcinomas very rarely produce thyroid hormone. Nonetheless, several cases which have caused clinical hyperthyroidism have been reported (HUNT, 1960; STUDER, 1961; FEDERMAN, 1964; GHOSE, 1971).

c) TSH-Secreting Pituitary Tumors

As a rule TSH secretion by the pituitary is suppressed in thyrotoxicosis. With the availability of TSH radioimmunoassay a few cases of TSH-secreting pituitary tumors have been detected. In one case the adenoma produced concomitant acromegaly (HAMILTON, 1970 and 1972). Two cases reported by FAGLIA (1972) suffered from isolated TSH oversecretion. The case studied by MORNEX (1972) suffered from hypopituitarism due to the adenoma. One of EMERSON's cases (1972) was attributed to oversecretion of TRH.

d) Iodide-Induced Thyrotoxicosis ("Jod-Basedow")

The pioneers in the thyroid field, COINDET, RILLIET, KOCHER (1910) and DEQUERVAIN observed many cases of iodide-induced thyrotoxicosis. Later this form of thyrotoxicosis was somehow forgotten, and many doubted whether it really existed. STANBURY (1954) recalled attention to the condition when one of his endemic goiter patients in Argentina developed severe hyperthyroidism under an iodine supplement of 1.5 mg per day.

ADAMS (1968) implicated LATS in the pathogenesis, but we think that the German term "Jod-Basedow" is misleading. The disorder is most probably not due to Graves' disease. KOCHER (1910) never observed exophthalmos in his cases. The pathophysiologic basis are probably functioning autonomous thyroid nodules which have escaped control by TSH. These nodules cannot produce excess thyroid hormone as long as the dietary iodine supply

is inadequate or in the low normal range. As soon as the dietary iodine is raised, the nodules avidly pick it up and synthesize excess hormone. The amount of dietary iodine producing hyperthyroidism is generally thought to be 5 mg/day or more. However, ERMANS (1971) has recently produced iodide-induced hyperthyroidism with as little as 0.5 mg/day. CONNOLLY (1970) observed a sharp rise in the incidence of thyrotoxicosis in Tasmania where goiter was endemic after the bread had been iodized to supply about 150 μg of iodine per day, and similar observations are recorded in the American literature of the 'twenties (see review by STANBURY, 1954).

In our view, the occurrence of iodide-induced thyrotoxicosis is no argument against the use of iodine in the prevention of endemic goiter, but it suggests that it might be wise to supplement low doses during the first decades. KOCHER (1910) himself recommended small doses of iodide for the prevention of iodide thyrotoxicosis.

The belief that iodide-induced thyrotoxicosis only develops in areas of iodine deficiency has been badly shaken by a recent report by VAGENAKIS (1972). He gave large doses of iodide to 8 patients with euthyroid goiter who resided in Boston, an area where the iodine supply is known to be more than adequate. Four patients developed hyperthyroidism, which was severe in two cases. The hyperthyroidism worsened initially when the iodide was withdrawn.

e) Factitious Thyrotoxicosis and Struma Ovarii

Voluntary excess thyroid hormone intake is rare. ROSE (1969) published three cases, all of them women. The patients persistently denied thyroid hormone intake, but this was demonstrated beyond all doubt by a high serum PBI with a very low thyroidal radioiodine uptake. All three patients were severely neurotic. KIRKEBY (1972) reported a patient who attempted suicide by ingesting 40 mg of thyroxine. He survived the intoxication.

Struma ovarii is an extremely rare cause of hyperthyroidism (BROWN, 1973).

G. Endemic Thyroid Disease

Two closely related clinical syndromes are grouped under the heading of *endemic thyroid disease*: endemic cretinism and endemic euthyroid goiter. The two are related by their pathogenesis, in which dietary *iodine deficiency* plays a dominant, although not an exclusive role. Endemic goiter can occur in areas where there is no endemic cretinism. It is a manifestation of *moderate* iodine deficiency. Endemic cretinism is seen only in areas where there is concomitant endemic goiter. It is a manifestation of *severe* iodine deficiency. Goiter is arbitrarily defined as endemic when 20% or more of children between the ages of 12 and 14 years have a palpable thyroid gland.

The iodine content of food and drinking water shows wide geographic variations. Inland regions, and especially mountainous regions, are particularly iodine-deficient. The areas with iodine deficiency are largely identical with areas of previous glaciation (MERKE, 1965). It is suggested that the water melting from the glaciers has washed out the iodine from the soil covered by ice. In the Canton of Valais (Switzerland), for example, endemic thyroid disease was much more prevalent at the bottom of the valley than in the villages situated higher up on the slopes (MERKE, 1967). The latter areas had not been glaciated. Geological surveys in Greece have shown that "goitrous" villages are often situated on noncalcareous rock and obtain their water from superficial polluted wells. The surrounding soil binds iodine firmly (MALAMOS, 1971). Maritime regions are generally iodine-rich.

The classic endemic regions were the Alps, the Pyrenees, and the Himalayas. In the past decades foci of severe endemicity have been found in the South American Andes, in the Congo, in New Guinea and in Thailand. Goiter was endemic in the region of the Great Lakes in the U.S.A., but cretinism did not occur. Cretinism has been or is still found in the other regions mentioned above. Endemic thyroid disease constitutes a major public health problem in many countries. It has therefore received the attention of large organizations and a number of good reviews are available (WHO, 1960; KÖNIG, 1968; RICCABONA, 1972). The latest findings have been collected in a symposium edited by STANBURY (1972).

1. Endemic Euthyroid Goiter

a) Etiology

As outlined above, dietary iodine deficiency is the major etiologic factor in endemic goiter. The renal clearance for iodide is fixed (30–40 ml/min) and the plasma iodide level therefore depends solely on the dietary iodine intake.*

* The fact that the iodide clearance of the thyroid gland is highly variable does not modify this statement. In a steady state the thyroid returns to the plasma the same amount of iodine, in the form of hormones, as it takes up. The hormones are deiodinated peripherally to iodide.

With a plasma iodide concentration of 0.1 μg/100 ml the thyroid function remains normal and no goiter develops. At this serum concentration 50 μg of iodide are lost each day in the urine when the clearance is 35 ml/min. Another 20 μg of iodine lost in the stools will give 70 μg/day, the minimum amount of dietary iodine necessary for normal thyroid function. Most authorities add a safety factor for individual variations of renal clearance and for periods of increased demand (pregnancy), and recommend an iodine intake 200 μg/day (WAYNE, 1964). Populations with average daily intakes of below 40 μg usually have at least some degree of endemic goiter.

The iodine-deficiency theory is based on several facts: 1 In endemic regions the iodine content of the drinking water (FELLENBERG, 1933) and the urinary iodine excretion (which is a good measure of the intake) are both low (LAMBERG, 1962); 2. Iodine supplements, whether in the form of iodine added to table salt or of iodized oil injections, have effectively eradicated endemic goiter in some countries; 3. Iodine deficiency produces goiter in experimental animals.

Several facts seem at first glance not to be compatible with the iodine-deficiency theory: 1. Not all people in an endemic area develop goiter. A possible explanation for this is that there is wide interindividual variation in the iodine intake. In Glasgow, for example, values from 40–1 000 μg/day were measured (WAYNE, 1964). Moreover, the renal iodide clearance may be elevated in some people who develop goiter (CASSANO, 1961). Partial enzyme defects which are not expressed in iodine abundance may become manifest in iodine deficiency. Thus, slightly pathologic perchlorate discharge tests have been found in goitrous subjects. BECKERS (1962) found a decreased proteolytic activity in the thyroid glands of goitrous individuals; 2. In regions of mild to moderate endemicity, goiter is more prevalent in women than in men. Sex-linked alterations in thyroid metabolism or some influence of female sex hormones may be proposed as an explanation, but there is no reliable proof of this.

Goiter in an endemic area often occurs in families. This, however, is no reliable argument for an hereditary etiology of endemic goiter, since familial occurrence may be explained by common dietary habits in all members of a family. The minor role of hereditary factors is documented by observations that people immigrating into an endemic area develop goiter, while in people leaving the endemic area the goiter sometimes regresses.

The opponents of the iodine-deficiency theory also cite the following good arguments: 1. Closely related populations with an identically low iodine intake have widely diverging goiter prevalence rates. A good example is Idjwi Island in Zaire (formerly Republic of Congo). In the southwest of the island, the incidence of goiter is much lower than in the north, although both populations are exposed to a similar degree of severe iodine deficiency (DELANGE, 1968); 2. In several surveys the prevalence of goiter was found to correlate poorly with the iodine content of the drinking water (DAY, 1972). Correlation of goiter with water hardness, fluoride content, or in some studies pollution of the drinking water (GAITAN, 1969) was better; 3. COSTA (1963) has observed epidemics of goiter unrelated to iodine deficiency in Italy from 1940 to 1948; 4. Some populations seem to adapt to severe iodine deficiency without goiter formation or other signs, except for an elevated ^{131}I uptake (ROCHE, 1959; LAMBERG, 1962; CHOUFOER, 1963).

One explanation for all these discrepancies is that in addition to iodine deficiency, populations may be exposed to varying amounts of goitrogenic substances. In Idjwi Island and other parts of Africa cassava is an important foodstuff. The roots of this plant contain a substance (cyanogenic glucoside) which releases cyanide, which is detoxified within the body to thiocyanate (CNS^-) and this acts as a goitrogen by inhibiting thyroidal iodide transport (EKPECHI, 1965). Goitrin (vinyl-thiooxazolidon) is another goitrogenic substance found in food. It inhibits iodination of thyroglobulin, as do the thionamide drugs. It is present as progoitrin in several plants such as cabbage, turnips and rape, and is liberated from its precursor by vegetable or bacterial enzymes. Plants containing progoitrin are rarely ingested by man in amounts sufficient to cause goiter. However, the milk of cows fed on certain plants of the Brassica family contains sufficient goitrin to cause goiter in man (CLEMENTS, 1960).

Other weak goitrogenic substances are nitrate (NO_3^+) and calcium ion (Ca^{++}). Lithium is a relatively potent goitrogen (SCHOU, 1968) (p. 154). Some otherwise healthy people cannot perceive the bitter taste of the goitrogen phenylthiocarbamide. It has been suggested that this hereditary variant predisposes them to the intake of natural goitrogens and therefore to goiter formation (KITCHIN, 1960).

The currently prevalent, although not universally accepted, opinion on the etiology of endemic goiter is that iodine deficiency usually has a dominant role. Naturally occurring goitrogens are additional factors which may greatly modify the quantitative effects of iodine defi-

ciency. Only very few endemic regions are known where the iodine supply is adequate.

We must add that iodine excess can also cause goiter (p. 154). In Hokkaido (Japan), where the residents of the coastal area consume 10000 to 20000 µg of iodine/day in algae, iodine-induced goiter is endemic (so-called coast goiter, SUZUKI, 1965; cf. p. 154).

b) Pathogenesis and Pathophysiology

The mechanisms by which iodine deficiency produces goiter have been extensively studied and reviewed by STUDER (1965, 1968, 1974). The normal human thyroid gland contains appreciable stores of iodine which would be sufficient to provide the body with hormone for several months. However, STUDER's studies (1974) have shown that thyroid hormone secretion falls rapidly when iodine input into the gland is prevented in some way. The basis of this rapid adaptation is the subdivision of the thyroidal organic iodine pool into several compartments. Fast-turnover compartments contribute a large part of the daily hormone secretion. As soon as these compartments are depleted, hormone secretion diminishes, serum hormone level falls slightly and TSH secretion is triggered long before the gland as a whole is significantly iodine-depleted. TSH in turn stimulates many processes in the thyroid gland, the end result of which is a massive increase in the thyroidal iodide clearance. Instead of taking up 30% of a radioiodine dose, as in iodine-replete areas, the gland now takes up 80% or 90% of the dose. Correspondingly less radioiodine is lost in the urine. Only recently has it been possible to measure an increase in serum TSH levels in goitrous subjects from areas where the condition is endemic (BUTTFIELD, 1966; ADAMS, 1968; COBLE, 1970). TSH is probably the main factor in the adaptation to iodine deficiency, but so-called thyroidal autoregulation, which is difficult to demonstrate in man, may also be involved. The result of these adaptive mechanisms is that in general the *total* iodine content of the whole gland is within normal limits. The iodine content/g thyroid weight, however, is greatly diminished, and the degree of iodination of thyroglobulin (µg iodine/mg thyroglobulin) is equally low. This degree of iodination of thyroglobulin is a critical factor in hormone synthesis. At the low degrees found in goiter most of the iodine is in the form of the early hormone precursor monoiodotyrosine. Little diiodotyrosine and even less hormone are formed (ERMANS, 1968). Thus the low degree of iodination of thyroglobulin initiates a vicious circle, since the little iodine available is inefficiently utilized. On hydrolysis of thyroglobulin a large amount of iodoamino acid precursors and little thyroid hormone are released. The precursors (or the iodide generated from them) may leave the gland and contribute to the increased non-hormonal iodine escape found in endemic goiter (ERMANS, 1963). The preponderance of monoiodotyrosine over diiodotyrosine is more favorable for the formation of triiodothyronine than for that of thyroxine. Increased triiodothyronine secretion has been found in iodine-deficient rats by STUDER (1965, 1968). More recently DELANGE (1972) has demonstrated serum triiodothyronine levels twice as high as normal in endemic goiter subjects, while the thyroxine level was half the normal value. Since triiodothyronine is much more active (per unit weight) this allows efficient and economic maintenance of a euthyroid state.

TSH stimulation in endemic areas produces typical radioiodine turnover data: a rapid and high thyroidal radioiodine uptake and a relatively rapid release of labeled hormone with a high PB ^{131}I. ERMANS (1963) found this was not so in an appreciable number of goitrous subjects. These so-called "slow secretors" took up radioiodine equally avidly but released it very slowly, and the PB ^{131}I was low normal. The reasons for the difference between fast and slow secretors are different iodine content and compartmentalization of iodine within the thyroid gland.

The cause of thyroid enlargement in iodine deficiency is the continuous TSH stimulation. STUDER (1965, 1968, 1974) has shown that hypophysectomized rats do not develop goiters when exposed to iodine deficiency. Neonatal goiter (weight > 3 g) is not uncommon in areas where the condition is endemic. In most cases (except in very severe iodine deficiency) goiter develops during childhood. In boys the goiter sometimes regresses after age 12 or 14. In girls the goiter increases in size until age 17 or 18 and then remains stationary. Pregnancy and lactation bring about further increases. The enlargement of the gland is at first *diffuse*, and later the diffuse hyperplasia progressively gives way to multinodular hyperplasia. The nodules probably arise from so-called lobules, groups of 20 to 40 follicles bound together by connective tissue. Why some lobules become hypertrophic and others atrophic is not clear. TAYLOR (1952) found out by autoradiography with ^{131}I that in multinodular goiter there was a marked heterogeneity of the ^{131}I fixation within follicles and nodules. Nodular goiter is notoriously difficult to produce in experimental animals.

c) *Incidence of Endemic Goiter*

Despite the spectacular success of iodine supplementation in certain countries, there are still an estimated 200 million people who suffer from endemic thyroid disease. The incidence of goiter in different areas varies from 90% to 0.4%. The data on endemic goiter incidence have been reviewed by KELLY (1960) and KÖNIG (1968).

In areas of severe iodine deficiency both sexes are equally affected with goiter. In areas of moderate or mild deficiency women predominate in a ratio of 6 : 1. The sex difference has never been satisfactorily explained.

d) *Pathologic Anatomy*

The anatomical picture in euthyroid goiter is dominated by polymorphism and heterogeneity. Diffuse enlargement or nodule formation may combine with colloid accumulation or parenchymatous hyperplasia to give diffuse or nodular colloid goiters, or diffuse or nodular parenchymatous goiters, or any combination within a single gland. A single nodule within an otherwise normal gland is called an adenoma. There is probably no basic difference between a nodule in a multinodular goiter and a single adenoma, but it is generally said that the structure of an adenoma is more uniform in histologic appearance and that it compresses the surrounding tissue. In multinodular hyperplasia the nodules are sometimes less well defined, but even experienced pathologists will have difficulty in differentiating adenomas unequivocally from nodules (cf. p. 228).

The microscopical picture in parenchymatous goiter is characterized by many very small follicles, in colloid goiter by huge follicles sometimes attaining the size of cysts. The cyst walls may form papillary infoldings. Solid epithelial structures (trabeculae) are seen in both types.

In addition, degenerative changes with hemorrhage and necroses may add to the polymorphism of the goiter.

e) *Clinical Features of Euthyroid Goiter*

In many patients, endemic (and sporadic, see p. 221) euthyroid goiter causes few symptoms, and it is often an incidental finding in a health survey or a physical examination performed for an unrelated disease. Sometimes the patient himself has noted swelling of the neck. Large nodular goiters may cause severe airway obstruction by pressure on the trachea.

For palpation of the goiter the patient should sit in a relaxed position with the head tilted slightly backward. He is asked to swallow while the physician bimanually palpates the neck either from behind or from in front of the patient. A glass of water should be at hand to allow repeated swallowing. The size, firmness, and shape of the gland are evaluated and the presence of any nodules is recorded. A simple classification of goiter size is used in most surveys of goiter prevalence (Table 14). For more refined purposes goiter size may be given as gland weight as estimated by palpation (by an experienced doctor) or by measurements from scintiscans (p. 196).

Table 14. Simple system for grading the size of euthyroid goiter. (Modified from: HUNZIKER, 1920; WESPI, 1942; PEREZ, 1960)

Grade 0:	Gland not palpable, not visible, less than 4 times normal size
Grade I:	Gland palpable, not usually visible, more than 4 times normal size
Grade II:	Gland palpable and easily visible
Grade III:	Very large goiter, easily visible at some distance

The neck circumference over the thyroid cartilage should also be recorded. It is of little value for estimating goiter size, but may allow monitoring of the effects of treatment in a given person. Vascular bruits or murmurs arouse a strong suspicion of thyroid hyperfunction, but they also occur occasionally in large euthyroid goiters.

The normal thyroid is not palpable, except for the isthmus, which may be palpated in thin people. By definition, goiter is present when the gland is easily palpable or visible. Slight pressure over large goiters during palpation may elicit stridor as a sign of tracheal compression. A chest X-ray should be obtained to diagnose any intrathoracic extension of a goiter. If it is not clear whether an upper mediastinal mass is a goiter, fluoroscopy may be helpful. In goiter the mass moves upwards on swallowing. Suspected airway obstruction may be documented by X-rays of the neck and trachea. Large intrathoracic goiters can cause recurrent nerve palsy and Horner's syndrome (this is a sign of malignancy in most but not all cases) or even upper venous congestion.

Goiter in the neonate often causes airway obstruction, which may be relieved by tilting the child's head backward. In neonates goiter regresses rapidly with iodine or thyroxine therapy.

f) *Laboratory Tests in Endemic Goiter*

As outlined on p. 212, the hallmark of iodine-deficiency goiter is a high thyroidal radioiodine

uptake combined with a euthyroid clinical status, as documented by normal ankle reflex time and basal metabolic rate. The serum thyroxine (or the PBI) may be low normal or sometimes frankly subnormal. Euthyroidism is maintained by a normal or elevated triiodothyronine concentration (p. 212). Occasional subjects are hypothyroid (BUTTFIELD, 1966).

g) Prevention of Endemic Goiter

MARINE (1920) was the first to demonstrate on a large scale that endemic goiter could be prevented by iodine supplementation. Before preventive measures are taken, iodine deficiency must of course be established as the cause of goiter in a given area. Good measures of iodine intake are the iodine content of the drinking water and of locally grown food, but the simplest measure of iodine intake is probably the urinary iodine excretion. In a steady state it is almost equal to the intake, since only small amounts (10–20 μg/day) are lost in the stools).

As discussed on p. 211, endemic goiter is present in areas where the average daily iodine intake is below 40 μg per day. In optimal conditions, allowing for a generous safety factor, the daily allowance should be 200 μg to ensure normal thyroid function in most people, but iodine prophylaxis has already given good results with a much lower supplementation.

As the result of a compromise between supporters and opponents of iodine supplementation, the table salt was supplemented with only 5 mg of KI/kg salt in Switzerland from 1923 onward. Although this raised the intake by only 38 μg/day, the results were spectacular. No more cretins were born and checks for deaf-mutism* in 8-year-old school children revealed a markedly reduced incidence 8 years after the introduction of iodized salt (WESPI, 1945). The incidence of goiter in school children fell from 50% to a few percent. By 1950, nodular goiters, which before iodine supplementation were common in school children, were found only in people over age 25. Military statistics are particularly valuable, since with universal military service every male Swiss is seen by a medical board at age 19. Recruits from areas with endemic goiter had a goiter incidence of almost 100%. After iodine supplementation it fell to 14%. Between 17 and 65 per 1000 men were found unfit for service because of goiter before iodine supplementation, as compared to 1 per 1000 after.

Iodine supplementation was raised to 10 mg KI/kg in parts of Switzerland in 1953, and in the whole country from 1962. Neonatal goiter was present in 30% of babies in the Canton of Aargau before iodine supplementation in 1951*; its incidence gradually fell to 6% within 4 years of the introduction of the lower (5 mg/kg) supplementation regimen, to disappear completely with the higher (10 mg/kg) regimen (WESPI, 1966). The sales of iodized salt have fallen in Switzerland, from 90% at its peak to 80% of all table salt currently sold, but the widespread availability of frozen fish and other sea food probably compensates for this decrease (MERKE, 1968). If iodination of salt is discontinued altogether, the amount of dietary iodine falls back to goitrogenic levels (PODOBA, 1972).

In the U.S.A., where there is no fear of "Jod-Basedow", the iodine supplementation in the salt is much higher, 20–200 mg/kg. In consequence the iodine intake is very generous, although wide regional variations still persist (ODDIE, 1970).

The KI of iodinated salt may be oxidized on storage to I_2, which is then lost by sublimation. In some areas the more stable potassium iodate is therefore preferred. In Tasmania flour is used as a vehicle and the iodine reaches the population mostly in the bread (CONOLLY, 1970).

Iodine supplementation represents a big technical problem in underdeveloped areas with rural self-sufficient economy. Salt is not used at all, or it is produced locally and the large-scale distribution of iodinated salt is virtually impossible. A useful alternative is the intramuscular injection of 2 ml (adult dose) of iodinated poppy-seed oil, which provides a depot of 950 mg of iodine. The results have so far proved satisfactory in many parts of the world (PRETELL, 1972), but since the injections have to be repeated every 2 to 5 years, the task is formidable, especially in countries where there is a shortage of medical personnel.

The results of iodine prophylaxis have largely supported MARINE'S assertion that "simple" goiter is one of the most easily avoided diseases. Despite this, the paradox remains that even advanced countries, such as France, Germany and Austria were very reluctant to introduce iodine supplementation, and very slow in doing so. The fear of iodide-induced thyrotoxicosis ("Jod-Basedow", see p. 209) played an important role in the heated arguments which preceded the introduction of iodized salt in Switzerland. In Tasmania CONOLLY (1970) observed a sharp

* Deaf-mutism can be used as a valid indicator of endemic cretinism, as discussed by QUERIDO (1972).

* The Cantons were free to decide whether and when to introduce iodized salt. Some, such as Canton Aargau, were quite late in doing so.

rise in the incidence of thyrotoxicosis after the iodine intake was raised by 150 µg per day by the iodination of bread. In more recent studies the importance of the phenomenon has been played down, and PRETELL (1972) observed only 1 case among 2000 Peruvian subjects injected with iodized oil. Others have found a much higher incidence of "Jod-Basedow", and its exact importance remains to be established by further studies. In any case, "Jod-Basedow" should be no argument against iodine prophylaxis, but its occurrence perhaps suggests that low doses should be given during the first decades of supplementation. It is unfortunate that no exact figures are available on the incidence of thyrotoxicosis during the years of introduction of iodized salt in Switzerland.

h) Treatment of Endemic Goiter

Most patients with endemic goiter are euthyroid and have few symptoms, and the question as to whether treatment is necessary at all is therefore justified. Basically, we agree with MEANS (1963) that "there seems little sense in carrying a grapegruit-sized tumor about in one's neck for a lifetime when it can easily be removed". However, this statement is subject to considerable qualification, and the decision of whether or not to treat an endemic goiter depends largely on the medical and surgical resources available. Obviously, surgical treatment of all goiters in an area where the condition is endemic is impossible in many underdeveloped countries, so that treatment has to be reserved for goiter causing severe pressure symptoms and airway obstruction.

Medical treatment can be tried first, but it is often ineffective in colloid nodular goiters. *Iodine* in a dose of 200 to 300 µg per day may be tried, e.g. 6 drops of a 0.1% KI solution ($\triangleq$ 230 µg I). In children the dose can be raised to 500 µg/day. Treatment should be discontinued after 3 months if there are no signs of regression.

L-thyroxine, 200 µg/day, is probably preferable to iodine. In younger subjects the goiter sometimes disappears rapidly, but in many cases, especially of long-standing goiter, the results are unsatisfactory. The dose may be increased cautiously to 400 µg/day. If there is no improvement after 3 months, drug treatment should be abandoned.

Surgery should be discussed in cases where medical treatment has been unsuccessful. The surgical procedure consists of subtotal, or sometimes total, intracapsular thyroidectomy, which must be followed by lifelong thyroxine therapy (see below).

Radioiodine has proved a valuable alternative to surgery in patients who refuse operation or in whom the operative risk is judged to be high due to concomitant cardiac or pulmonary disease (RÖSLER, 1965). The dose is 10000–12000 rad (on the average 40 mCi of ^{131}I). In cases of very large goiters weighing over 600 g, the ^{131}I is given in fractionated doses. When the radioiodine uptake is low ($<40\%$) or inhomogeneous, good results have been obtained by previous stimulation with TSH. On average the goiter size diminishes by 50%. In RÖSLER's study (1965), 78% of patients had good and 19% satisfactory results. The incidence of post-therapeutic myxedema was surprisingly low, since only 3% of patients became hypothyroid, an additional 5% presenting with diminished thyroid reserve. Radiation thyroiditis often occurs on the second or third day of treatment and can be quite painful. It responds well to prednisone.

After any form of treatment of goiter, lifelong medication with 200 µg of L-thyroxine/day is indicated. The recurrence rate, which is 15% in untreated cases (JENNY, 1966) is reduced to a minimum by thyroxine (BERGFELT, 1963). Persisting TSH stimulation after surgery is probably responsible for the high incidence of malignant tumors in recurrences of originally benign goiters (EGLOFF, 1961).

2. Endemic Cretinism

a) Definition

The Pan-American Health Organization has adopted the following definition for this syndrome: "The term endemic cretin describes mentally deficient subjects born in an endemic goiter area, who exhibit some of the following characteristics which are not readily explained by other causes: 1. Irreversible neuro-muscular disorders. 2. Irreversible abnormalities in hearing and speech which sometimes lead to deaf-mutism. 3. Impairment of somatic development. 4. Hypothyroidism." This definition is by and large identical to the one DE QUERVAIN and WEGELIN (1936) have given in their classic monograph and which has been used by KÖNIG (1968) in a modified form (Fig. 25).

Thus the only constant clinical feature of cretinism is mental deficiency and in its absence the diagnosis is hard to accept. All other symptoms may be present in very variable degrees which, although all cretins look somehow like siblings, gives each cretin some individuality. In very mild cases the diagnosis can only be suspected and there are no clear-cut criteria or laboratory tests by which borderline

cases can be separated from normal persons. It is still a matter of debate whether endemic iodine deficiency can cause hearing loss without concomitant mental and physical retardation. Although there are no good convincing theoretical arguments to refute this possibility, such patients do not fit the definition of cretins given above.

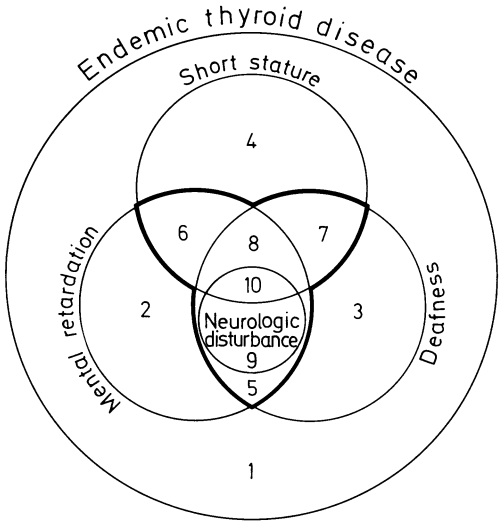

Fig. 25. The clinical features of endemic cretinism. There are at least 10 combinations of the four main signs. The diagnosis of cretinism is usually very difficult to establish in monosymptomatic cases (From KÖNIG, 1968)

Some authors think congenital athyrotic hypothyroidism (p. 166) and endemic cretinism are difficult to separate, but we agree with DE QUERVAIN (1936) that the two diseases are basically different. There is an overlap of many symptoms but differentiation is generally possible on clinical grounds. While the endemic cretin is born as such, with irreversible damage to the hearing organ and to the brain, mental and physical development is only slightly retarded in the congenitally athyrotic child. His height is near-normal in most cases, although bone maturation is delayed. His alertness is reduced, but there are no hearing loss or other signs of neurologic damage.

Thyroid hormone substitution therapy is of little value in improving the central nervous system manifestations of endemic cretinism, although some effect on growth, skeletal maturation and the development of puberty is possible. In contrast, much depends on early substitution therapy in congenitally hypothyroid children, and the brain damage can often be kept to a minimum. When left untreated, congenitally hypothyroid children come to resemble endemic cretins more and more. The differentiation between endemic cretinism and congenital hypothyroidism was first clearly established by DE QUERVAIN and WEGELIN (1936). Their arguments and their signs of differentiation are still valid today. We must acknowledge that in the more recently described area of Idjwi Island, where 90% of cretins are hypothyroid, the endemic cretins can hardly be distinguished from sporadic congenitally hypothyroid patients (DELANGE, 1972). To avoid confusion, it has been suggested that the term "sporadic cretinism" be dropped and replaced by "congenital hypothyroidism".

b) Geographic Distribution and Incidence

Endemic cretinism occurs only in areas where goiter is severely endemic. It is never observed near the sea coast. Some endemic goiter areas, such as the Great Lakes in the U.S.A., have been found to be free of endemic cretinism. Table 15 gives the incidence of endemic cretinism as obtained in surveys over the past 90 years in various areas where goiter is endemic.

Cretinism has been familiar for many centuries in the Alps (Savoy, Piedmont, Steiermark, Salzburg area), in the Pyrenees, the Carpathian mountains, the Caucasus, southern Sweden, Hungaria and Yugoslavia. During the past 70 years endemic cretins have been detected and well studied in many parts of Asia (Himalayas, Sumatra), Africa (Uele, Idjwi Island), and New Guinea (Mulia valley), and in parts of the South American Andes (Gujas, Brazil; Ecuador; Peru) (Table 15).

Table 15. Incidence of cretinism in various endemic areas as established by surveys during the last 35 years. (From KÖNIG, 1968)

Mulia, New Guinea	8.2%	CHOUFOER (1965)
Gornia Josanica, Yugoslavia	6.7%	KICIC (1961)
Blumenstein, Switzerland	3.5%	EUGSTER (1938)
Idjwi, Zaire (Congo)	1.0%	DELANGE (1966)
Canton Aargau, Switzerland	0.6%	EUGSTER (1938)
Uele, Zaire (Congo)	0.1–0.3%	BASTÉNIE (1962)
Piemont, Italy	0.01%	COSTA (1964)
Piemont, Italy	0.15%	Survey of 1883

The incidence of cretinism is very difficult to estimate in a given focus of endemicity, because the symptomatology is so variable. There is a smooth transition from normal persons over mild cretins to severe cretins and it is left very much to the judgment of the individual observer where he wants to draw the dividing line. In Mulia (New Guinea) the incidence was 8.2%. In Idjwi (Republic of

Table 16. Relative incidence of cardinal symptoms of endemic cretinism in various areas. (From KÖNIG, 1968)

	Mental retardation	Deafness	CNS defects (spasticity)	Retardation of bone development	Goiter	Hypothyroidism	Severity of endemic goiter
Uele (Zaire)	Most cases	Occasional	Occasional	Most cases	Occasional	Most cases	Severe
Idjwi (Zaire)	Most cases	Occasional	Occasional	Most cases	Occasional	Most cases	Severe
Mulia (New Guinea)	Most cases	Frequent	Frequent	Rare	Occasional	0	Severe
Himalaya	Most cases	Most cases	?	Occasional	Most cases	0 (?)	Severe
Brazil	Most cases	Occasional	Most cases	Occasional	Frequent	Rare	Moderate
Piemont (Italy)	Most cases	Frequent	?	Occasional	Frequent	Rare	Moderate
Canton Berne (Switzerland)	Most cases	Frequent	Rare	Occasional	Occasional	Occasional	Moderate
Steiermark (Austria)	Most cases	Frequent	Rare	Occasional	Occasional	Occasional	Moderate

Most cases: over 90%; Frequent: over 50%; Occasional: over 10%; Rare: under 10%.

Zaire) it was 0.1%. Both sexes are equally affected, as in endemic goiter, which has an equal incidence in prepubertal boys and girls. The symptomatology shows wide regional differences. In the Himalayas and in parts of Latin America, for example, "nervous" cretinism with spastic diplegia predominates, a form which is rare in Europe (see below, and Table 16).

Endemic cretinism is a vanishing disease in the Alps. In the Canton of Berne, where the nursing homes used to be crowded with cretins, all existing cretins are now aged 55 or more. Only a few cretins have been born during the past 45 years in Steiermark (Austria), and no endemic cretins have been born in the Alps for the past 25 years (KÖNIG, 1968). A decrease in the incidence of endemic cretinism was observed in the late 19th century, long before iodine prophylaxis was introduced. In England the disease had disappeared by 1870 (FAGGE, 1871). In Switzerland endemic cretinism started to decline before iodinated salt was introduced. This is probably due to a change in dietary habits with the importation of iodine-rich food. As discussed by QUERIDO (1972), the studies of WESPI (1945) leave absolutely no doubt that the iodination of salt has been the main factor responsible for the eradication of this disease.

c) Etiology and Pathogenesis

Endemic cretinism only occurs in areas of severe iodine deficiency. The urinary iodine excretion (roughly equal to the iodine intake) is under 15 µg per day in most areas where cretins are born (QUERIDO, 1972). As in the case of endemic goiter, goitrogenic compounds of food and drinking water may also play some part. Mothers of endemic cretins always have a goiter and have lived in an area where it is endemic at least during the pregnancy. In a focus of endemicity, cretinism is often clustered within a few families (EUGSTER, 1938; KÖNIG, 1968). However, hereditary factors certainly play only a minor role. Mothers who have given birth to several cretins have normal children after moving to a village where the condition is not endemic (DIETERLE, 1952); conversely, families who move into an endemic focus have the same incidence of cretinous children as the native population (EUGSTER, 1938). In a series of siblings the younger ones are usually more severely cretinous.

The exact pathogenesis of cretinism remains unknown. The most likely hypothesis is that the iodine deficiency interferes with the early function of the fetal thyroid gland. Between the 80th and 90th days of fetal development, follicular lumina appear in the previously solid thyroid tissue, and thyroglobulin and hormone synthesis get under way. At approximately the same time, TSH and thyroxine become detectable in fetal blood. The concentration of thyroxine in the maternal circulation bears little relation to the concentration in the fetal circulation (GREENBERG, 1970), and it appears that the fetus is dependent on its own hormone production (as discussed on p. 151) and receives little, if any, hormone from the mother. Even if the dietary iodine available were enough to maintain borderline euthyroidism in the mother, the fetus might pass through a phase of perhaps only slight hypothyroidism. At a critical time this could cause irreversible damage to the developing central nervous system.

In later fetal life, lack of thyroid hormone predominantly affects growth and bone maturation. These changes are reversible by thyroid hormone replacement.

This theory is rendered less acceptable by the fact that fetal thyroid hormone lack due to other causes (such as thyroid aplasia) does not produce deafness or irreversible brain damage. Several children in whom hormone replacement was started during the first days

a b

Fig. 26a and b. 69-year-old man. Typical cretinism of alpine type (Collection Prof. D. LOOSER, Winterthur)

of life have been carefully followed and found to have a normal mental development. Only if left untreated do such children become retarded and finally resemble true endemic cretins, but even then nerve deafness is a very rare finding. Alternative mechanisms have therefore been proposed. Some authors think the damage to the inner ear takes place in very early pregnancy, before there is any discernible fetal thyroid function. They think an iodinated compound different from thyroid hormone is necessary for normal maturation of the central nervous system. Moreover, euthyroid cretins often have much more extensive neurologic damage than severely hypothyroid cretins (DELANGE, 1972).

In summary, the pathogenesis of the neurologic deficits of cretinism is only partly explained by a lack of fetal thyroid hormone. Other mechanisms must also be involved.

d) Clinical Features of Endemic Cretinism

All grades are seen, from nearly normal to severely affected individuals. The severity of cretinism is best graded by the degree of mental retardation. In mild cases the patients are able to talk, read and write, and can perform simple tasks. Mild cretins have married and have had children. Moderate cases are capable of communicating with other people with the aid of gestures and a few words. They can only perform very simple work. Severely affected patients are completely deaf-mute and incapable of any work. They need permanent care in nursing homes.

Cretins often have a very *typical appearance* and they have been distinguished from other types of mentally retarded subjects for centuries. They have a round face, generally with an amiable serene expression (Figs. 26, 27) and they often arouse sympathy in other people. A few cretins are depressed or even aggressive (Fig. 28). The slow growth of the skull base with persistent synchondrosis between the sphenoid and occipital bone produces the depressed nasal bridge with apparent protrusion of the cheek and jaw.

The hairline is low, the scalp hair is coarse and fur-like, beard growth is sparse and the

Fig. 27. 68-year-old cretin woman with severe myxedema. The patient had remained infantile in mental development. She was able to read and write and to do needlework. The intelligence age was estimated at 12 years. The patient was affectionate, amiable and grateful. She was the pet of the nursing staff. Height 118 cm, weight 28 kg. Note that she looks much younger than her age and has no gray hair

skin is wrinkled and myxedematous. In typical cases the diagnosis can be made on the spot. In any area, most cretins look like siblings from one big family. Cretins do not look young, nor does age show upon them (Figs. 27, 28). This classic description of the "alpine" type is not applicable to cretins in the Andes, New Guinea, the Himalayas and Africa, where neurologic symptoms often predominate (see below).

Fig. 28. 77-year-old cretin with severe mental retardation. The patient could not talk. The intelligence age was about 3 years. She was suspicious and hostile toward the nursing staff. Height 112 cm, weight 29 kg. Moderate-sized goiter. Slight hypothyroidism

Mental and neurologic damage can assume any degree of severity. Often, but not always, mental and physical disability are parallel. The decreased intelligence, combined with affective and emotional changes and with hypothyroidism, produces a characteristic psychological picture. Cretins are good-humored, sometimes even witty. Their sense of orientation is well developed but they have no notion of numbers or combinations. The sexual drive is diminished in most cases, although occasionally cretinous women have conceived children.

The incidence of deafness varies greatly from one focus of endemicity to the other (Table 16). Its pathogenesis is poorly understood. The pathologic changes in the ear have recently been reviewed by KÖNIG (1972). Deafness is primarily of the nervous type, but middle-ear changes due to faulty bone development are also a contributory factor. Speech can be totally deficient or reduced to a few badly articulated sounds. In mild cases language is quite well developed but the vocabulary remains limited and the voice retains a monotonous intonation.

Mental deficiency is by definition a feature of endemic cretinism. Many observers have the impression that in iodine-deficient areas it may be present with a very high incidence as an isolated sign without the other stigmata of cretinism. In Ecuador, FIERRO-BENITEZ (1972) has shown that children conceived shortly after the introduction of iodine prophylaxis had a higher average IQ than children born during the same period in a neighboring village without prophylaxis, even when obviously mentally deficient subjects were excluded from the study. There was some evidence in this study that iodine supplementation must be started during the first 5 months of fetal life to be effective. However, there is no general agreement as to when exactly the irreversible brain damage takes place. Other investigators have placed the critical time in late fetal life or even the first months after birth.

In some areas such as the Himalayas, New Guinea and Idjwi Island, neurologic symptoms only rarely described in the Alpine cretins predominate. These cretins suffer from spastic pareses of the lower, sometimes also of the upper extremities, with a high degree of motor incoordination resembling that in cerebral palsy.

The significance of *short stature* has probably been overemphasized. Many cretins are near normal in height. In Swiss cretins height of 140 to 150 cm was quite typical. One quarter of European cretins were normal in height and only 7% were shorter than 100 cm. The degree of dwarfism probably parallels the severity of hypothyroidism, and goitrous cretins (see below) with normal thyroid function are often of normal height. Height is said to parallel the goiter size, which probably means that dwarfism parallels the degree of hypothyroidism (see below). As in congenital hypothyroidism, dwarfism is disproportioned, with short extremities. Skull size is small in absolute terms, but is normal relative to height.

Many signs of endemic cretinism are dependent on the degree of concomitant hypothyroidism. Due to motor incoordination, muscular weakness, and cretinous dysplasia of the hip cretins have a slow waddling gait. Spasticity of the legs may occasionally make cretins incapable of walking.

The skin is often thickened, dry, and scaly as in simple myxedema, sometimes with a

brownish hue. After puberty, myxedematous skin changes often regress and leave a coarse wrinkling which, especially on the forehead, contributes much to the typical appearance of cretins (Fig. 26a).

Epiphyseal growth zones may remain open throughout life. In contrast to the clumsy appearance of the cretin while alive, the skeleton reveals a rather light body build (Fig. 30). Despite this, the hands always look plump due to their shortness (Fig. 26b). The impairment of skeletal maturation produces changes in the hip which are quite similar to those in Perthes' disease (Fig. 12, p. 174, Fig. 31). Degenerative changes also occur in the knee. As in congenital hypothyroidism, transversal calcified "growth zones" are seen in the long bones. The humerus may show varus deformity. The musculature is badly developed, which is one of the reasons for the tendency to abdominal hernias. The abdomen is protruding due to muscular weakness and to constipation with flatulence.

There are cretins with goiter and cretins without goiter (Fig. 29). The latter are usually severely cretinous, tend to be hypothyroid, and are shorter in stature. The thyroid gland may be completely atrophic and be replaced by a few fibrous nodules. In such cases hypothyroidism is very frequent. The causes for the atrophy of the gland are not known. It is probably already present at birth. The proportion of hypothyroid cretins varies in different areas where cretinism is endemic (Table 16), but is generally low, except in Idjwi Island, where 90% of cretins are hypothyroid (DELANGE, 1972). In euthyroid cretins the changes in thyroidal function tests are the same as those observed in endemic goiter (p. 213).

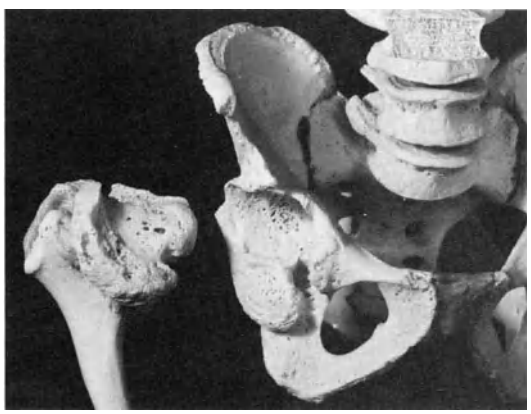

Fig. 31. Hip joint of same patient as Fig. 26, who died at age 80. Severe degenerative hip changes

e) Diagnosis and Differential Diagnosis

In classic adult cases the diagnosis is easy, but in the newborn it can be quite difficult. Children with endemic cretinism have to be differentiated from congenitally hypothyroid children with thyroid aplasia and from those with other forms of mental deficiency, such as Down's syndrome.

f) Course and Prognosis

With good care the life expectancy is virtually normal. Thyroid carcinoma is possibly more frequent in cretins (KÖNIG, 1968), but the cretinous state is not associated with an increased risk of any other potentially lethal diseases.

g) Prevention and Treatment

Prevention is achieved by the same means as that of endemic goiter. Endemic cretinism is eradicated much more rapidly and easily than endemic goiter. In Switzerland no new cretins have been born since the introduction of iodinated salt. Due to a relatively low level of salt iodination, however, goiter remained quite prevalent. There were 30–40 cretinous children in the Canton of Appenzell in 1922. In 1937, 15 years after the introduction of iodinated salt, there were none. The incidence of severe mental retardation among children of school age decreased from 1.4% to 0.4% in the same period. There was a similar fall in the incidence of deaf-mutism in school children (WESPI, 1945).

Treatment of cretins is not very rewarding. Much of the central nervous system damage is irreversible when the cretins are first seen. No data are available on the effects of thyroid hormone therapy started during the first days of life. It is possible that early thyroid hormone substitution could improve the outcome, as in sporadic congenital hypothyroidism (p. 176). In later life thyroid hormone replacement may improve the state of hypothyroid cretins slightly, often at the price of changing a docile patient into an aggressive one.

H. Sporadic Euthyroid Goiter ("Simple" Goiter)

Euthyroid goiter also occurs in areas where the iodine supply is adequate. By definition, euthroid goiter is of course much rarer than in areas where goiter is endemic. It can be multinodular or diffuse and the pathologic findings are exactly identical with those in endemic goiter. The etiology of this form of euthyroid goiter is obscure. In regions where goiter has previously been endemic, and dietary supplementation with a borderline amount of iodine has been introduced, as in Switzerland, it is impossible to decide whether a euthyroid goiter should be classed as endemic (due to persisting borderline iodine deficiency) or sporadic. Euthyroid goiter undoubtedly also occurs when the dietary iodine supply is very generous, as it is in many areas of the U.S.A. In such iodine-replete areas, euthyroid goiter should arouse a much stronger suspicion of malignancy. The pathophysiology of euthyroid sporadic goiter is similar to that of endemic goiter in most respects. The iodine content of the total gland is normal, but the iodine per g gland weight and the degree of iodination of thyroglobulin are low, as in endemic goiter (ERMANS, 1968). It therefore appears that despite adequate dietary iodine supply the gland suffers some form of iodine deficiency; either it cannot accumulate iodide from the blood or transform it into hormone as efficiently as a normal gland, or it loses increased amounts of non-hormonal iodine. The British Medical Research Council (1944) has therefore given the following excellent definition of euthyroid ("simple") goiter: "The immediate cause of simple goiter is failure of the thyroid gland to obtain a supply of iodine sufficient to maintain its normal structure and function. This failure is usually brought about by an absolute environmental deficiency of iodine; it may also be caused by factors which interfere with the availability of dietary iodine or which impose an abnormal demand on the thyroid gland." Biochemical causes of the development of euthyroid goiter despite an adequate iodine supply have of course been looked for. So far none of the gross defects causing familial goiter (see p. 167) has been detected, but subtle defects may well have been overlooked by the techniques available. TUBIANA (1971) has carefully examined the iodine kinetics in 280 cases of euthyroid goiter in the iodine-replete area of Paris. Uptake of both radioiodine and total iodine was higher than in normal individuals. This suggests that the gland is capable of accumulating iodide, but that there is some defect in the intrathyroidal metabolism of iodine.

RAPOPORT (1972) has analyzed the iodine metabolism, the enzymes necessary for hormone formation, and the thyroglobulin structure of a sporadic euthyroid goiter. He found no abnormality typical of the congenital enzyme defects of familial goiter (p. 167).

In a series of 234 cases of so-called nontoxic goiter (a term we try to avoid since it includes hypothyroid and euthyroid goiters) CASSIDY (1970) found that 15% of patients were hypothyroid. In an analogous study from Denmark, AGERBAEK (1973) found a "classic" defect of hormonogenesis in about 10% of patients, while in the remaining 90% no biochemical cause for the goiter was found.

If hormonogenesis is subtly impaired in sporadic euthyroid goiter, the goiter formation must be due to a compensatory rise of TSH levels. Such a rise was actually observed by LEMARCHAND-BÉRAUD (1969).

Clinical features, treatment and prevention of recurrence of sporadic euthyroid goiter are by and large the same as are outlined for endemic goiter (p. 213).

I. Thyroiditis

1. Introduction and Classification

The existence of numerous synonyms for the various forms of thyroiditis has created some confusion in terminology. The American Thyroid Association has recently adopted a standard nomenclature which is presented in Table 17 together with the various synonyms.

Table 17. Nomenclature of thyroiditis according to the American Thyroid Association (WERNER, 1969)

American Thyroid Association	Synonyms
Subacute or acute non-suppurative thyroiditis	Granulomatous thyroiditis Giant cell thyroiditis De Quervain's thyroiditis
Chronic lymphocytic thyroiditis	Hashimoto's thyroiditis Struma lymphomatosa Autoimmune thyroiditis
Chronic invasive fibrous thyroiditis	Riedel's thyroiditis
Acute suppurative thyroiditis	
Chronic nonsuppurative thyroiditis due to specific infection (tuberculosis, syphilis)	

Subacute nonsuppurative thyroiditis and chronic lymphocytic thyroiditis are relatively frequent. All other forms of thyroiditis are extremely rare. The classification given in Table 17 does not include focal thyroiditis, which is quite often seen in large euthyroid (sporadic or endemic) goiters. Focal infiltrates by lymphocytes are often scattered throughout such goiters. Their significance is not known. Similar infiltrates also occur in diffuse toxic goiter (Graves' disease, Fig. 15, p. 182). BASTÉNIE and ERMANS (1972) have prepared a superb authoritative monograph on all aspects of thyroid inflammation.

2. Acute and Subacute Nonsuppurative Thyroiditis

a) Etiology and Incidence

The synonyms for this disease are listed in Table 17. A recent review of the literature has been prepared by GREENE (1971). The incidence of this disease is difficult to establish, and widely varying values have been reported (see GREENE, 1971, for review). All investigators agree that it is much less frequent than Graves' disease and rather less frequent than Hashimoto's thyroiditis. Females predominate in all series, but again the sex ratio varies widely.

The etiology is unknown. Upper respiratory tract infection occasionally precedes the thyroidal inflammation and rises in mumps or coxsackie antibody titers are often recorded. EYLAN (1957) has isolated mumps virus from affected thyroid glands. HINTZE (1964) has observed epidemics of the disease. A virus etiology has therefore often been suggested.

b) Pathology of Subacute Nonsuppurative Thyroiditis

The histological hallmark is focal infiltration with granulomas of histiocytes and giant cells (foreign-body type) associated with a moderate degree of fibrosis (Fig. 32). The granulomas are sometimes difficult to differentiate from tuberculosis. In most cases only a part of the thyroid gland is involved.

c) Clinical Features and Treatment of Subacute Nonsuppurative Thyroiditis

The onset is rather sudden and the patient complains of a painful lump in the neck. Palpation, neck movements and swallowing cause severe pain, often radiating to the jaw or the ears. There is marked general fatigue and fever is common initially. The inflammation starts in a circumscribed area of one lobe, subsides and then resumes in another part of the gland. This wandering of the inflammation is very characteristic and often allows a diagnosis on clinical grounds.

In subacute forms pain may be minimal, and it is difficult to differentiate the enlarged gland from a euthyroid multinodular goiter. Pressure symptoms are quite rare.

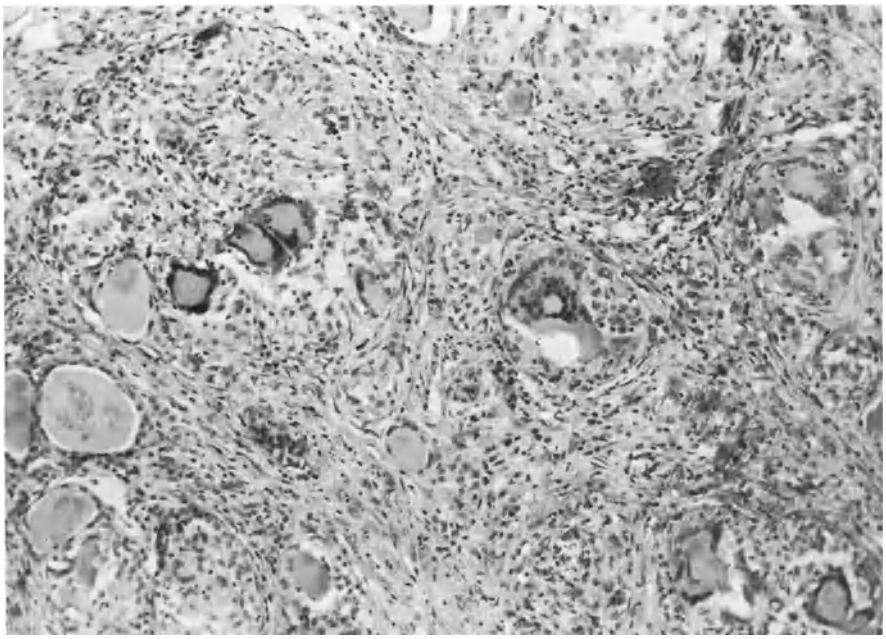

Fig. 32. Histologic appearance of the thyroid gland in nonsuppurative (DE QUERVAIN'S) thyroiditis in a 27-year-old woman. The thyroid tissue is densly infiltrated by granulomas resembling those of tuberculosis. Note the foreign-body type giant cells in contact with remainders of colloid. Hematoxilin-Eosin stain, × 135 (MB 1760/53)

The erythrocyte sedimentation rate is always markedly elevated, sometimes to extreme values. There is moderate leukocytosis with an increase in band forms. Levels of α_2 globulins are elevated. Serum thyroxine is high initially (OGIHARA, 1973, see p. 283) and is sometimes low in later stages. Iodinated proteins leak into the blood and lead to a gross rise in protein-bound iodine. Radioiodine uptake is very low or nil in the beginning, and rebound hyperactivity is seen in the later course. Sometimes the uptake is suppressed only in the affected lobe. Repeated scanning after a few weeks may reveal that the originally suppressed lobe is taking up radioiodine again, while the other lobe is now affected. Thyroid antibodies are not usually present in serum. A rise to low titers is occasionally observed after the disease.

Several diseases have to be considered in the differential diagnosis. Chronic lymphocytic thyroiditis causes less pain or none at all, no fever and no fatigue; moreover high titers of thyroid antibodies in serum are almost always present. Acute suppurative thyroiditis is accompanied by local lymphadenopathy and marked leukocytosis. Pharyngitis, an infected branchial cyst, hemorrhage into a cyst of a nodular goiter, goiter of Graves' disease and thyroid carcinoma have at times been confused with subacute nonsuppurative thyroiditis.

The diagnosis can usually be made on clinical grounds. In doubtful cases it can be established by needle biopsy or the less traumatic fine-needle aspiration (PERSON, 1968). A strong suspicion of cancer is an indication for surgery.

The course of the acute form is usually rapid and self-limiting. Transition to suppurative thyroiditis occurs occasionally in previously goitrous glands. The subacute form lasts several weeks to several months. Patients have been known to suffer from the disease for over a year. Permanent hypothyroidism is extremely rare. Acute nonsuppurative thyroiditis has occasionally been followed by thyrotoxicosis (see CZERNIAK, 1957, for references).

Mild cases are treated with aspirin or phenylbutazone. Moderate or severe cases respond favorably to prednisone. The dose is 40–50 mg/day. Improvement and relief of pain are dramatic. After two weeks the dose is tapered to 15–25 mg, and later to the lowest effective dose. The contraindications and precautions usual in corticosteroid therapy must of course be observed. Treatment can usually be stopped after one or two months, but occasionally it may have to be continued for one year. VAGENAKIS (1970) recommends to stop therapy when the radioiodine uptake of the gland has returned to normal or high values. There is no evidence that thyroid hormone given in addition to prednisone has any beneficial effect. Prednisone treatment probably does not affect the underlying disease process, but it keeps the patient free of symptoms and able

to work while the disease runs its natural self-limiting course.

3. Chronic Lymphocytic Thyroiditis

a) Incidence and Etiology

The clinical impression that the incidence of chronic lymphocytic thyroiditis is rising (McConahey, 1962) has been borne out by a careful epidemiological study from Minnesota (Furszyfer, 1972). The annual incidence rate per 100000 was 6.5 between 1935 and 1944, after which it rose steadily to reach a value of 69 for the period of 1965–1967. The annual incidence of Graves' disease remained constant at 35/100000 throughout this period. Furszyfer considers this increase in incidence as real and not an artefact of improved awareness and better diagnostic facilities. Nève (1972) attributes the reported increased frequency to a widening of criteria used for diagnosis. In the U.S.A, chronic lymphocytic thyroiditis must thus be as frequent as Graves' disease. Although comparable data from continental Europe are unfortunately not available, it is our impression that chronic lymphocytic thyroiditis is much rarer in Switzerland than in the U.S.A. Women predominate in all studies, with ratios varying from 40 : 1 to 10 : 1.

It is fairly well established that chronic lymphocytic thyroiditis is caused by an autoimmune process. Circulating antibodies to components of thyroid tissue are found in most cases (Doniach, 1960). The disease is being associated with other autoimmune disorders, such as pernicious anemia (Schiller, 1967), Graves' disease, rheumatoid arthritis (Becker, 1963; Mulhern, 1966), false-positive tests for syphilis (Shulman, 1964), and others with increasing frequency. The histologic picture is also very suggestive of an autoimmune process. The reasons for the development of an autoimmune process are still poorly understood. Antibodies to thyroid and other tissues are frequently found in relatives of patients with chronic lymphocytic thyroiditis (DeGroot, 1962; Hall, 1962). The basic defect is therefore best described as a genetically determined partial breakdown of immune tolerance.

Chronic lymphocytic thyroiditis has several characteristics in common with Graves' disease. In both instances autoantibodies are present in the serum, although in Graves' disease the titers are usually lower. Some degree of lymphocytic infiltration is also present in the thyroid gland of Graves' disease, and, finally, Graves' disease has been seen in patients with the classic histologic picture of chronic thyroiditis (Fatourechi, 1971). Several pairs of monozygous twins have been reported, in which one twin had Graves' disease and the other had chronic lymphocytic thyroiditis (Jayson, 1967; Doniach, 1967; Chertow, 1973).

The atrophic variant of chronic thyroiditis leads to so-called idiopathic primary hypo-

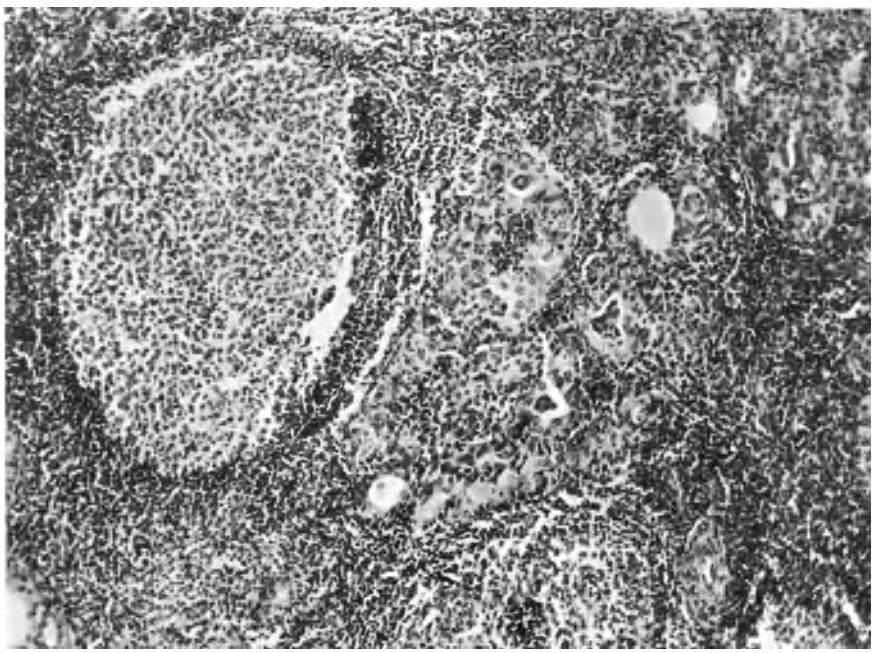

Fig. 33. Histologic appearance of a goiter with chronic lymphocytic (Hashimoto's) thyroiditis. Dense infiltration of the tissue with lymphocytes and lymphatic follicular structures. Woman, age 37. Hematoxilin-Eosin × 135 (MB 11687/54)

Hematoxilin-Eosin stain, × 150 (MB 3189/60). Note the paucity of lymphocytes compared to Fig. 33 and 35.

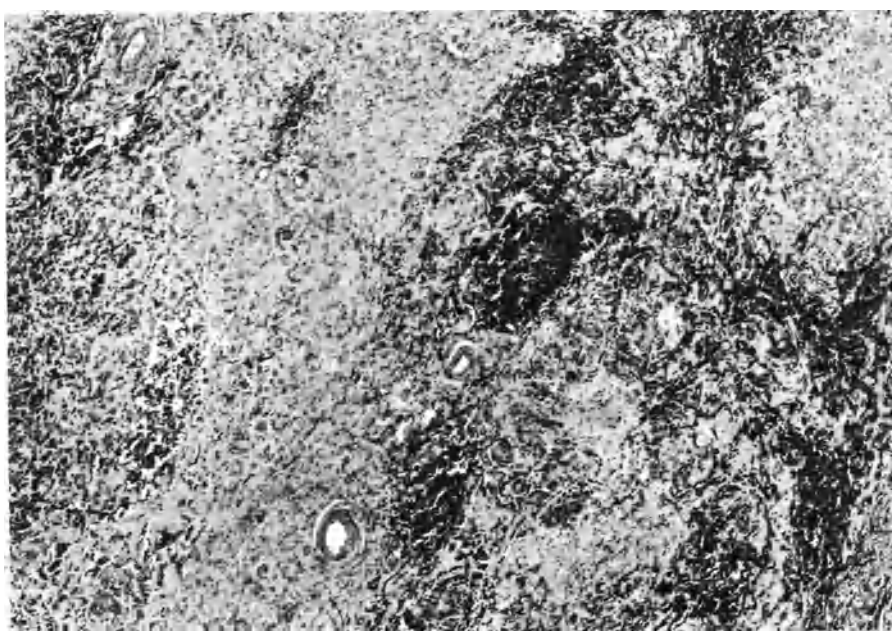

Fig. 35. Atrophic thyroid gland in an 80-year-old woman. The present picture is probably the end result of chronic lymphocytic thyroiditis, atrophic variant. Hematoxilin-Eosin stain, × 65 (SW 1020/62)

thyroidism (p. 153). The whole of the thyroid parenchyma becomes replaced by fibrous tissue (Fig. 35). Basically this variant appears to be due to the same underlying disease process. In both forms there are high titers of thyroid antibodies. The most important difference between the two forms is that in the atrophic variant goiter is absent, while in the classic form it is a necessary criterion for the diagnosis. Some classic cases undoubtedly progress into true atrophic thyroiditis, but how often this happens remains to be established.

In a few cases chronic lymphocytic thyroiditis has progressed into true malignant lymphoma (LINDSAY, 1955; FUJIMOTO, 1967).

b) Pathologic Anatomy of Chronic Lymphocytic Thyroiditis

Focal lymphocytic infiltrates, sometimes with germinal centers, are found in euthyroid (sporadic or endemic) goiters, in toxic diffuse goiters, and sometimes also in thyroid carcinoma. Moreover, moderately high titers of serum antibodies are sometimes present in these conditions. However, these diseases should be strictly differentiated from chronic lymphocytic thyroiditis, in which the lymphocytic infiltration is always diffuse (NÈVE, 1972). The two other criteria which must be fulfilled for the diagnosis are bilateral enlargement of the gland and high titers of serum antibodies.

The infiltrates of chronic thyroiditis consist of lymphocytes and plasma cells. There are numerous germination centers (Fig. 33). The original thyroid architecture is destroyed, with islets of normal parenchyma remaining. Enlarged epithelial cells with an eosinophilic granular cytoplasm (so-called oncocytes, also called Hürthle cells) are often present. Electron microscopy has revealed that these cells are crammed with enlarged mitochondria (NÈVE, 1972). As a rule, multinucleated giant cells are diagnostic for subacute nonsuppurative thyroiditis though they do occasionally also occur in chronic lymphocytic thyroiditis (NÈVE, 1972).

c) Clinical Features and Treatment of Chronic Lymphocytic Thyroiditis

The patients usually presents with a lump in the neck, which has developed over some weeks or months. Goiter is often an incidental finding in a medical examination performed for unrelated reasons. Pain is absent or very mild, but some patients complain of a feeling of pressure. Fever and malaise are absent. Examination reveals a moderately firm goiter, in most cases small. In exceptional cases the goiter becomes very large. Lymphadenopathy is absent. The disease is always diffuse throughout the thyroid, but it may be more prominent on one side. A family history of Graves' disease, goiter or idiopathic hypothyroidism is often obtained. An occasional patient may have typical Graves' disease some years before or after chronic lymphocytic thyroiditis and an unknown proportion of cases develops into severe hypothyroidism due to idiopathic atrophy of the gland.

The laboratory tests reveal normal leukocyte and differential white cell counts. The erythrocyte sedimentation rate is moderately or markedly elevated. The γ globulins of serum are high.

Thyroid function in chronic thyroiditis varies widely. In a group of 51 patients GHARIB, 1972 found that 25 were euthyroid, 22 hypothyroid and 4 hyperthyroid. Association with typical Graves' disease has been reported by FATOURECHI (1972). In cases where the patients become hypothyroid, thyroxine secretion fails first, while near-normal amounts of triiodothyronine maintain a borderline euthyroid state for some time (GHARIB, 1972).

Iodine metabolism shows characteristic changes (BUCHANAN, 1961). The radioiodine uptake is on average within the normal range, but extreme individual variations, from hypothyroid to hyperthyroid values, are typical. The thyroidal iodine pool is always diminished, which leads to an increased fractional iodine turnover and to an elevated PB ^{131}I. The scintiscan may show patchy areas of decreased iodine uptake. The perchlorate discharge test (p. 243) sometimes reveals partial release of trapped radioiodide and suggests some impairment of iodine organification. Due to release of iodoproteins into the blood stream the protein-bound iodine may become elevated despite a normal circulating level of thyroxine. One feature peculiar to the disease is that patients become particularly sensitive to the blocking effects of high doses of iodide, and may become severely hypothyroid when given medication containing iodide, e.g. expectorants for bronchial asthma (BRAVERMAN, 1971; see also p. 154).

The diagnosis of chronic lymphocytic thyroiditis is confirmed by high titers of circulating antibodies to thyroglobulin (so-called tanned red cell test) and complement-fixing antibodies to microsomal antigen. Titers of 1 : 25000 or more in the former test or of 1 : 64 in the latter are virtually diagnostic. Titers of 1 : 2500 or 1 : 16 are suggestive, but may also be found in 50% of patients with Graves' disease. Intermediate or high titers of either one or both antibodies are present in 97% of cases. MORI (1971) used a very sensitive radioimmunologic

technique and found antimicrosomal antibodies in 95% of patients. The diagnosis can be established by biopsy, but the availability of immunological tests has made this superfluous in most cases.

The course of the disease is variable. After a review of the literature, VICKERY (1961) states that about half the cases progress to fibrosis and half remain stationary. In his own 16 cases, which were carefully followed by means of repeated biopsies, 4 showed some increase in fibrosis and 12 remained stationary.

Treatment is indicated in cases with hypothyroidism and when there is a large and troublesome goiter. L-thyroxine in a dose of 0.15–0.3 mg daily will lead to rapid regression of goiter size. A recent long-term follow-up study by PAPAPETROU (1972) has shown that thyroxine treatment does not halt the progressive fibrosis and atrophy of the gland. Administration of thyroxine therefore has to be lifelong. If the patient is euthyroid and is given no treatment he should be notified of the possibility that hypothyroidism may develop insidiously and advised to see his physician at least once a year.

Surgery usually produces permanent hypothyroidism and is indicated only in cases where there is a suspicion of carcinoma.

4. Chronic Invasive Fibrous Thyroiditis (Riedel's Struma)

a) Incidence and Etiology

This is an extremely rare disease which is overdiagnosed by many pathologists, who do not distinguish between this form and atrophic variants of chronic lymphocytic thyroiditis. Originally it was thought that chronic lymphocytic and chronic invasive thyroiditis were the two extremes in a broad spectrum of the same disease, but the two diseases are now separated by clear-cut criteria (see below). Among 42000 patients submitted to thyroid surgery at the Mayo Clinic only 20 cases had chronic invasive thyroiditis (WOOLNER, 1957). Women predominate with a ratio of about 4 : 1.

The etiology is obscure. HARDMEYER'S (1964) original observation that it occurs together with mediastinal or retroperitoneal fibrosis and with TAKAYASU'S arteritis has been confirmed by other authors (RAPHAEL, 1966). HARDMEYER (1964) put forward the hypothesis of a vascular primary lesion.

b) Pathologic Anatomy of Chronic Invasive Thyroiditis

According to WOOLNER (1957) the following criteria describe the pathologic lesion (Fig. 34):

The fibrotic process involves part of the gland, rarely the whole gland. The affected part feels very hard on palpation;

The inflammatory process extends into extrathyroidal surrounding tissues such as neck muscles.

The invasive process completely destroys the affected thyroid tissue. Giant cells are absent.

BASTÉNIE (1972) added two more distinguishing features: the paucity of lymphocytes and the absence of oncocytes.

c) Clinical Features of Chronic Invasive Thyroiditis

Patients affected complain of a rapidly growing goiter which causes severe pressure symptoms and often airway obstruction. There is no fever or malaise. On palpation the thyroid feels very hard ("lignous goiter"). Euthyroidism is the rule. In contrast to chronic lymphocytic thyroiditis, the disease does not respond to thyroxine therapy, and surgery is necessary to alleviate pressure symptoms. After surgery the disease usually subsides or takes a benign self-limiting course. A second operation is rarely required. The preoperative diagnosis in most cases is thyroid carcinoma.

5. Acute Suppurative Thyroiditis

Acute thyroiditis with abcess formation is very rare. Initially it may easily be mistaken for the much more frequent acute nonsuppurative (De Quervain's) thyroiditis. Causative organisms include streptococci, staphylococci, salmonella, E. coli and others.

6. Chronic Nonsuppurative Thyroiditis due to Specific Infection

This form is also quite rare. It may be caused by tuberculosis, syphilis, fungus infection, brucellosis, and occasionally by parasites. It also occurs superimposed on sarcoidosis.

K. Thyroid Neoplasia

1. Benign Tumors

a) Classification

As MEISSNER (1971) has stressed, the numerous subdivisions of follicular adenoma are of dubious value. In most cases the simple classification of the American Thyroid Association (WERNER, 1969, see p. 279) appears entirely satisfactory (Table 18).

Table 18. Classification of benign thyroid tumors.

American Thyroid Association (WERNER, 1969, see p. 279)
Follicular adenoma
Papillary adenoma
Atypical adenoma
Teratoma

b) Follicular Adenoma and Solitary Thyroid Nodules

Follicular adenoma is the most common benign thyroid tumor. It is made up of well differentiated follicles and is indistinguishable from normal thyroid tissue, except that the follicles may be unduly large and the adenoma is surrounded by a capsule. If the adenoma is made up of trabecular structures it is called an embryonal adenoma, if the follicles are very small a fetal adenoma; if the predominant cell type is of the oncocyte variant the terms oxyphilic, or Hürthle-cell adenoma are used. Hürthle cell adenomas are thought by some to be particularly indicative of malignant development (SOLLBERGER, 1957, p. 279), but there is no general agreement on this.

The differentiation of a follicular adenoma from nodules of a multinodular euthyroid goiter is difficult and sometimes impossible. The criteria of WARREN (1953) allow differentiation in many but not all cases (Table 19).

Table 19. Differentiation between nodular hyperplasia and adenoma of the thyroid (WARREN and MEISSNER, 1953)

Nodular hyperplasia	Adenoma
Multiple nodules	Solitary nodule
Nodules badly encapsulated	Well-encapsulated nodule
Variable histologic structure	Uniform histologic structure
Comparable growth rate in adjacent thyroid tissue	Different growth rate than adjacent thyroid tissue
No compression of adjacent thyroid tissue	Compression of adjacent thyroid tissue

The occurence of benign papillary adenomas is doubtful. Tumors with papillary structures are generally malignant with exception of the so-called macropapillary formations in colloid goiters.

Thyroid adenomas often present a functional abnormality since they do not take up radioiodide. The physiologic basis for this has recently been investigated. DE GROOT (1970) found that the "cold" nodules have no iodide-trapping ("iodide-pump") system. DE RUBERTIS (1972) showed that cold nodules were still responsive to TSH when cyclic AMP formation was taken as an index. These studies also suggested a defect of iodide trapping.

A follicular adenoma usually presents clinically as a small soft nodule in the thyroid. It may be detected by an apprehensive patient or as an incidental finding by a doctor in a medical examination performed for other reasons. Lymphadenopathy is absent and euthyroidism is the rule. Some adenomas, however, lead to hyperthyroidism and are called toxic adenomas (p. 204).

A difficult clinical problem is the detection of malignant lesions among the so-called *solitary thyroid nodules* (see Editorial, Lancet, 1964; Editorial, Brit. med. J., 1971). On physical examination, follicular and papillary carcinomas may be indistinguishable from benign nodules, and there are no clinical criteria by which the benign nature of a nodule can be ascertained. It has been said that "cold" nodules, i.e. nodules which do not take up ^{131}I on scintiscans are more likely to be malignant. This is undoubtedly true on statistical grounds, but it does not help in the individual case, since not every cold nodule is malignant and an appreciable proportion of warm or even hot (KENDALL, 1969; GUINET, 1971; FUJIMOTO, 1972) nodules turn out to be cancerous. Scanning with ^{131}Cs may provide some additional information, since practically all nodules cold with ^{131}I and warm with ^{131}Cs are malignant (MURRAY, 1970). Cytological examination of thin needle aspirates may reveal undifferentiated carcinomas, but its value in detecting differentiated carcinomas remains to be established (p. 244).

In practice, therefore, the nature of a solitary nodule is established by a thyroid lobectomy in most cases. This procedure is mandatory in younger people, especially in children, where the likelihood of malignancy within a single nodule was found to be 12.6% (TAYLOR, 1967). At operation a "solitary nodule" often turns out to be part of a multinodular goiter. Surgery is therefore recommended less frequently in areas where euthyroid multinodular goiter is prevalent. In older people the risk of surgery has to be weighed against the likelihood of detecting cancer, although here again, as in children, an appreciable proportion of nodules is malignant.

Any nodule within a multinodular goiter can become malignant (MILLER, 1955). This does not, however, justify the subjection of all patients with a multinodular goiter to

surgery. As WELCH (1966) has aptly calculated, the deaths caused by surgery would outnumber the cases of cancer found.

2. Malignant Thyroid Tumors

a) Classification

Classification of malignant thyroid tumors is still the subject of great controversy. The old continental European classification of WEGELIN (1926), based on detailed pathologic descriptive terms, was unnecessarily complicated. Most of the subclassifications had no clinical relevance. The classification used by British and American pathologists had the great advantage of being simple and more relevant to the clinical behavior of the tumor. However, this classification may have oversimplied the problem, and some tumors found in endemic Alpine areas could not be fitted into any of the Anglo-Saxon entities.

The International Union Against Cancer (UICC) convened an international meeting on thyroid cancer, the proceedings of which were edited by HEDINGER (1969). Much time was devoted to the problem of classification at this conference. A unified tentative system was proposed, but was not officially adopted (UEHLINGER, 1969). More recently, the American Thyroid Association has agreed on another system. It is presented in Table 20 and compared with the classification proposed by EGLOFF and HEDINGER (1964). These authors have carefully reviewed the Swiss histologic material of the last few decades and have greatly simplified the old WEGELIN (1926) classification. As can be seen from Table 20, the two classifications, although not identical, are quite comparable. Controversy exists in fact only over two relatively rare tumors, the metastasizing adenoma and the struma maligna Langhans, which the American authors do not feel merit separate classification. A third tumor, hemangioendothelioma, is never seen in the U.S.A., but it undoubtedly exists in the Alps (see below). Recently WHO in Geneva has proposed a standardized international nomenclature for the histological typing of thyroid tumors (Table 21).

b) Incidence and Etiology

The age-adjusted annual incidence rate per 100000 of thyroid cancer in Finland is 0.8 for men and 2.3 for women. Other countries where goiter is not endemic, such as the U.S.A., have very similar figures (see FRANSSILA, 1971, for review). The relationship of thyroid cancer to endemic goiter is not yet clear. There is no doubt that continuous TSH stimulation in rats or mice (whether produced by TSH injections or by goitrogen feeding) can cause thyroid carcinomas (HERRMANN, 1951). In man there is so far no clear-cut evidence that thiouracil goitrogens cause thyroid cancer (LUNDSGAARD-

Table 20. Classification of malignant thyroid tumors

American Thyroid Association (WERNER, 1969)	EGLOFF and HEDINGER (1964)
Carcinoma	*Epithelial tumors* (cell types may be specified for each tumor: large oxyphilic, cylindric, clear, squamous, spindle, small, giant)
Papillary carcinoma	Papillary carcinoma
Pure papillary	
Mixed papillary and follicular	
Follicular carcinoma	Organoid carcinoma
Pure follicular	Metastasizing adenoma[a]
Clear cell[b]	Struma maligna Langhans[c]
Oxyphil cell (Hürthle cell)[b]	Adenocarcinoma[c]
Medullary carcinoma	Medullary carcinoma
Undifferentiated carcinoma	Anaplastic carcinoma
Small cell	
Giant cell	
Epidermoid carcinoma	
Other malignant tumors	*Nonepithelial tumors*
Lymphoma (specify type)	Malignant lymphoma
Sarcoma (specify type)	Fibrosarcoma, Osteosarcoma
	Hemangioendothelioma[d]
Secondary tumor (specify site of origin)	

[a] The invasive nature of this tumor is not grossly apparent, so-called "low-grade follicular carcinoma".
[b] The justification for this subclassification based on cell types is questionable (see text).
[c] These tumors would be classified as follicular carcinomas in the American and WHO nomenclature.
[d] This tumor is relatively frequent in the Alps. It is only exceptionally seen in the U.S.A.

VI. Tumour-like lesions

HANSEN, 1956). In endemic goiter, a similar continuous TSH stimulation must exist (p. 212). TAYLOR (1971) compared the death rate from thyroid cancer in England to that in Switzerland and concluded that the figure was ten times higher in Switzerland. It is doubtful, however, whether the data from the two countries were entirely comparable. Based on other data FRANSSILA (1971) arrived at an annual mortality rate per 100000 of 0.5 for men and 1.1 for women for thyroid cancer in Finland. On the east coast of the U.S.A., the corresponding figures are 0.3 and 1.6 and in Switzerland 1.5 and 1.6. Thus Switzerland, where goiter was endemic until very recently, has an elevated mortality rate only for men, while the figure for women is comparable to that in areas where the condition is not endemic. Studies from the pathology institutes of Zurich (KIND, 1966) and Berne (WALTHARD, 1963) do not so far substantiate the claim that iodine prophylaxis has greatly reduced the overall incidence of thyroid cancer. They do clearly show, however, that iodine prophylaxis has caused a shift from the less differentiated forms to the more differentiated and less malignant papillary carcinomas, with the overall incidence remaining more or less constant. KIND (1966) has noted a sevenfold increase in the incidence of papillary carcinoma in Zurich between 1940 and 1964. EGLOFF (1961) found a notably high incidence of thyroid carcinomas in patients thyroidectomized years before for an originally benign goiter. This suggested that the TSH stimulation after thyroidectomy contributed to the development of cancer. Few measurements of TSH levels in patients with thyroid cancer have been published. VALENTA (1968) found values that were on average higher than in control persons.

Ionizing radiation is a recognized cause of thyroid cancer. Children appear to be particularly susceptible. This has been conclusively shown in two instances. Thyroid neoplasms (benign and malignant) had an increased incidence in children exposed to radioactive fallout from atomic explosions (SOCOLOW, 1963; CONARD, 1966, 1970) and in children treated with X-ray irradiation for "thymic hyperplasia" (JANOWER, 1971; DE GROOT, 1973, p. 283).

LINDSAY (1965) found several malignant lymphomas of the thyroid in chronic lymphocytic thyroiditis, but CRILE (1962) did not find a similar association

c) Pathologic, Clinical and Prognostic Features

α) Papillary Carcinoma

This is by far the most common malignant tumor in areas where goiter is not endemic, where it makes up roughly 50% of all thyroid malignancies. In endemic areas its relative incidence is less than 10% of all malignant thyroid tumors (WALTHARD, 1963; KIND, 1966). Women are more often affected than men. Papillary carcinoma is the typical thyroid carcinoma of children and young adults. These carcinomas are often very small, 1–2 cm in diameter. Occasionally, multiple cancerous foci are seen within one gland (BLACK, 1960). Initially they are sometimes surrounded by a capsule, but often they show diffuse infiltration of surrounding tissue. Histologically they are made up of a cuboidal or cylindric epithelium arranged in finely ramified papillae. Follicle formation is almost always present. Very typical are the pale, overlapping, so-called ground glass nuclei. The stroma often contains small, calcified spherical bodies, the psammoma bodies or calcospherites. Mixed papillary and follicular tumors generally show the same clinical behavior as pure papillary carcinomas and are classified in the same group (Table 20; LINDSAY, 1960).

Papillary carcinomas metastasize early to the regional cervical lymph nodes (FRANSSILA, 1971). Since they are of low-grade malignancy these metastases were believed for a long time to be "laterally aberrant thyroid tissue" (JOHNSON, 1962). Some authors maintain the opinion

that benign thyroid tissue can occur in cervical lymph nodes (GRICOUROFF, 1962; GÉRARD-MARCHAND, 1964).

Clinical, papillary carcinomas may present as soft, round asymptomatic nodules, so-called *solitary nodules*. The differential diagnosis and management of such nodules have been discussed on p. 228. Older textbooks of medicine or surgery list the following "classic" symptoms and signs of thyroid cancer: rapid growth; firm to hard tumor, which moves badly on swallowing; pain radiating to the ear; recurrent nerve palsy and Horner's syndrome (DE QUERVAIN, 1941). It cannot be overstressed that this is the clinical presentation of advanced undifferentiated cancer as it has frequently been seen in endemic goiter areas. The differentiated tumors which now predominate in areas where goiter is not endemic usually show none of these features. Papillary carcinomas are soft and easily movable, and they cause neither pain nor nerve palsies in the majority of cases. Papillary carcinomas are relatively benign. They remain localized within the neck region for a long time and grow slowly. The survival rate is 75% after 5 years and 50% after 20 years (Fig. 39). Tumors localized within the gland at the first operation have a better prognosis and microscopical tumors have virtually no effect on survival rate (FRANSSILA, 1971; (Fig. 39)). Many papillary carcinomas accumulate iodine and are amenable to radioiodine treatment. Very few papillary carcinomas synthesize thyroid hormones, but in isolated cases they have produced hyperthyroidism (HUNT, 1960; STUDER, 1961; FEDERMAN, 1964).

β) Follicular Carcinoma

About 10 to 20% of thyroid neoplasias are follicular carcinomas. In contrast to papillary carcinomas, these tumors are made up of follicles of various sizes or of combinations of follicles and cords. In contrast to papillary carcinomas, which metastasize to cervical nodes, follicular carcinomas show an early tendency to distant metastases in the lungs and bones (FRANSSILA, 1971). The primary tumor often appears quite benign, which has given rise to the term "*metastasizing adenoma*" in the German terminology. In some series the prognosis of this tumor is equal to that of papillary carcinoma, in others it is slightly worse, although still much better than that of undifferentiated carcinomas (FRANSSILA, 1971; Fig. 39).

Follicular carcinoma cannot be clinically distinguished from papillary carcinoma. Follicular carcinomas usually take up iodine and can be treated with radioiodine.

The term *struma maligna Langhans* applied to tumors of the type originally described by Langhans when goiter was endemic in the Berne area. The criteria included clinical, macroscopic, and histologic features: the tumor always

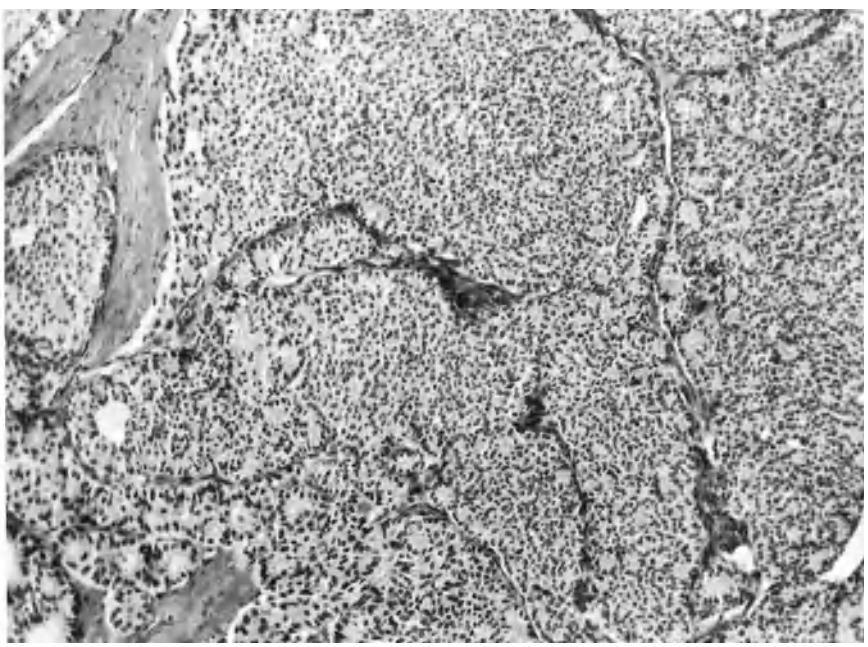

Fig. 36. Follicular carcinoma of the thyroid. The carcinoma is composed in part of trabecular structures. This type would conform to the entity of Struma maligna Langhans of the continental European classification (Table 19). 49-year-old man. Hematoxilin-Eosin, × 140 (MB 1777/55)

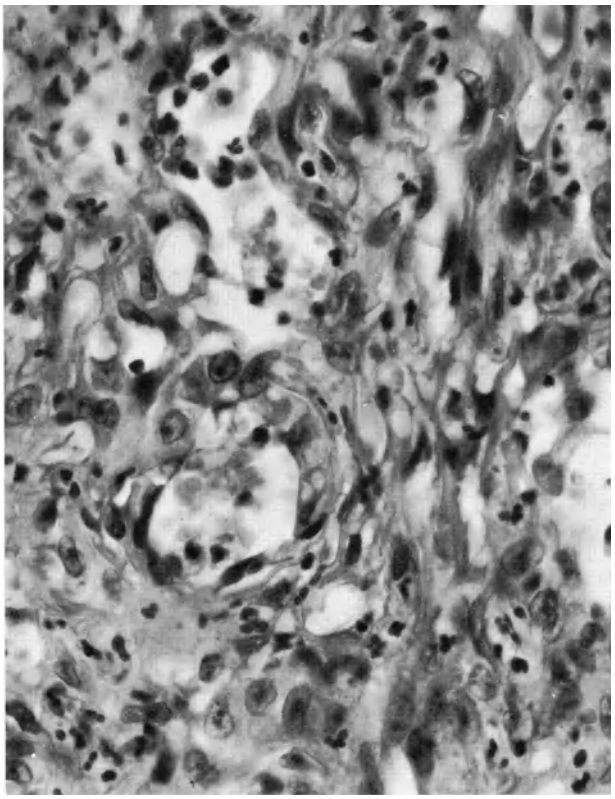

Fig. 37. Hemangioendothelioma in a man aged 77 years. Differentiation of primitive vessels with erythrocytes phagocytized by endothelial cells. Hematoxilin-Eosin, × 300 (MB 1253/53)

arises in a previously goitrous gland; the carcinoma is relatively large (5–15 cm in diameter), well-circumscribed and has a central fibrotic scar. At the periphery it is made up of solid epithelial trabeculae uniform in appearance. In the center it consists of follicles which are much better differentiated than those in simple adenocarcinomas (Fig. 36). Mitoses and vascular invasions are relatively rare. The tumor metastasizes to the lung and bones. After a critical review of the histologic slides of their large Swiss material EGLOFF (1964) maintained the original diagnosis of struma maligna Langhans only in 1/3 of the cases originally diagnosed as such. The remaining 2/3 were reclassified, mostly as poorly differentiated follicular carcinomas. Adherence to EGLOFF'S rigid criteria makes struma maligna Langhans a rare tumor even in the Swiss study, accounting for perhaps 5% of all thyroid malignancies. According to the American and WHO nomenclature the struma maligna Langhans should be classified as moderately differentiated follicular carcinoma.

The subdivisions into *clear-cell follicular carcinoma* and *oxyphil-cell follicular carcinoma* are probably superfluous (MEISSNER, 1971). The last tumor is also called *Hürthle cell carcinoma* and has been thought to be a separate entity, but HORN (1954) has shown that it has the same biologic behavior as ordinary follicular carcinoma.

γ) Medullary Carcinoma

This is a very special thyroid tumor in many respects. It originates from the C cells, which produce thyrocalcitonin (WILLIAMS, 1965, 1966). It is an abundant source of this hormone and has allowed elucidation of its amino acid sequence (NEHER, 1968). Histologically, large amyloid deposits are very characteristic. The cells contain secretory granules (MEYER, 1968; TUBIANA, 1968). Calcitonin levels in blood are elevated. The disease runs in families and affected members can often be detected by elevated blood calcitonin levels long before the tumor is marcoscopically visible (MELVIN, 1971; JACKSON, 1973). Clinically, the behavior of medullary carcinoma is similar to that of other well-differentiated carcinomas. It grows slowly and metastasizes late (Fig. 39).

Medullary carcinoma is often associated with pheochromocytoma (SIPPLE, 1961; WILLIAMS, 1965, 1966; SCHIMKE, 1968). The patients have an

Fig. 38. Patient with medullary carcinoma of the thyroid. The patient had a typical emaciated appearance and fibromas of the tongue, eyelids and lips. (Courtesy of Dr. I. MAC INTYRE, London)

unmistakable emaciated appearance with fibromas of the lips, eyelids and other parts of the body, perioral and palmar pigmentation and severe acne (Fig. 38). At times medullary carcinoma of the thyroid is associated with pheochromocytoma, hyperparathyroidism and Cushing's disease, a syndrome called type 2 multiple endocrine adenomatosis (STEINER, 1968; MARKEY, 1973).

Many aspects of this peculiar tumor have recently been reviewed by HILL (1973).

δ) Anaplastic (Undifferentiated) Carcinoma

These tumors are extremely malignant with rapid growth and spread to distant sites. They are subdivided according to cell type into small or giant-cell carcinomas. In some tumors the cells are spindle-shaped. In Europe such tumors have been classified as sarcomas.

ε) Non-Epithelial Tumors

Sarcomas seemed to be very frequent in the Alpine pathologic material and very rare in the English and American material. HEDINGER (1969) reviewed the slides of 196 cases diagnosed as sarcoma in Zurich and Lausanne. Only 6 cases withstood his rigid criteria, while the others were all reclassified as anaplastic carcinomas. The relative proportion of sacromas among thyroid malignancies in the Swiss material thus declined from 20% to 0.6%, which is comparable to the incidence in other countries.

Hemangioendothelioma (Fig. 37) is virtually never seen in the U.S.A., and its existence has been doubted (CHESKY, 1953; KLINCK, 1969). In the Alps it is not so rare. It is a distinctive thyroid tumor thought by some to be of vascular origin, by others to be a variant of anaplastic carcinoma. Malignant lymphoma of the thyroid is another rare tumor. LINDSAY (1965) has found an association with chronic lymphocytic thyroiditis.

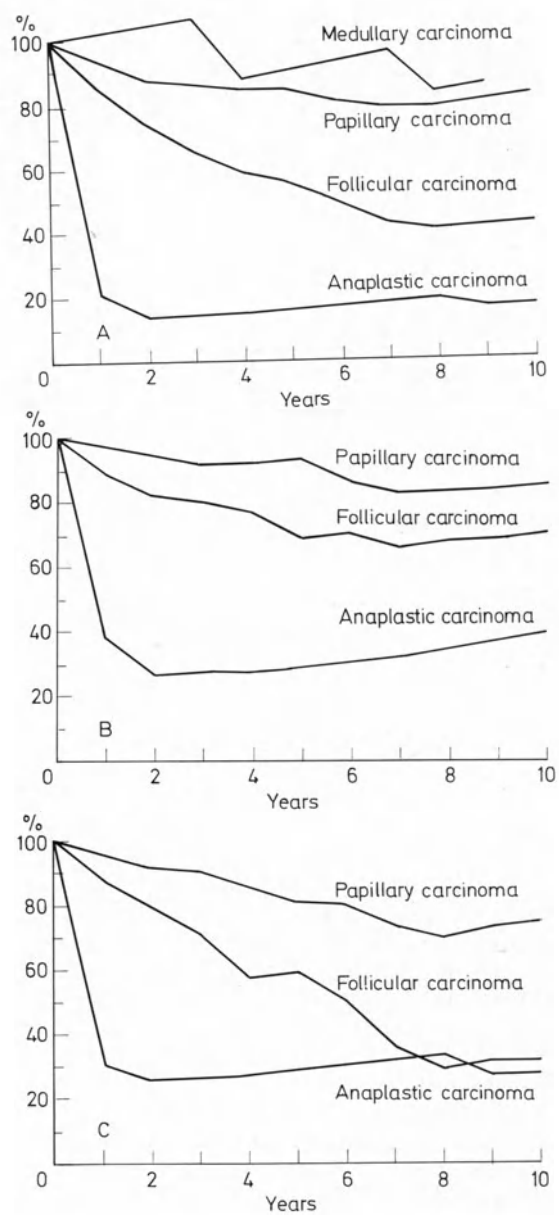

Fig. 39. Relative survival in thyroid cancer according to histologic type. *A* All patients. *B* Patients with intrathyroid tumors. *C* Patients with extrathyroid tumors. (From K. FRANSSILA, 1971)

ζ) Secondary Tumors in the Thyroid

In a careful study SHIMAOKA (1962) found that 8.9% of metastasizing tumors produce secondaries in the thyroid. Metastases are about 10 times more frequent than primary thyroid tumors, but they are rarely diagnosed clinically since they produce no symptoms. There is one exception to this rule. In clear-cell renal carcinoma, metastasis to the thyroid is occasionally the first manifestation of the tumor. It may initially be wrongly diagnosed as a clear-cell so-called postbranchial tumor of the thyroid (HEDINGER, 1967).

d) Treatment of Thyroid Carcinoma

A considerable proportion of thyroid carcinomas retain iodine and are at least partly dependent on TSH stimulation. This permits an unusually wide range of possible methods of treatment from large doses of radioiodine to suppression of TSH secretion by thyroxine administration.

The therapeutic attitude to be adopted in cases of differentiated thyroid cancer is a matter of dispute. Many of these tumors retain responsiveness to TSH, so that it is universally accepted that lifelong suppressive therapy with thyroxine is indicated. Attitudes to additional measures vary between the extremes of hemithyroidectomy followed by a passive "wait and see" and the most vigorous approach consisting of total thyroidectomy with radical neck dissection followed by repeated massive doses of ^{131}I and external radiotherapy. There are good arguments in favor of both approaches and the decision is left to the temperament of the individual physician. Reliable data based on carefully controlled prospective studies are not available. The proponents of the conservative approach argue that differentiated tumors have a slow growth potential and that their approach gives survival rates comparable to other methods (CRILE, 1964, 1966). The patient should therefore be spared the disfigurement of radical neck dissection. The supporters of the other extreme argue that generalization of thyroid cancer is unpredictable and that when it has occured, it is too late for ^{131}I therapy and other measures.

In Zurich we have chosen the following plan for management of thyroid cancer. If a diagnosis of cancer is made, total thyroidectomy is performed, leaving the recurrent nerves and the parathyroid glands intact. Total thyroidectomy is performed in all cases, regardless of whether the disease is bilateral or only unilateral. There are two reasons for this: 1. Many carcinomas are multicentric or have local metastases within the thyroid (BLACK, 1960; ROSE, 1963; WELCH, 1963); 2. Total thyroidectomy is an essential condition for ^{131}I therapy, since any normal thyroid tissue remaining would subtract radioiodine from the malignant tissue. Moreover, malignant tissue only accumulates adequate amounts of ^{131}I if it is properly stimulated by TSH. The hypothyroidism produced by thyroidectomy is a potent stimulus to endogenous TSH secretion.

In cases where the histologic diagnosis of carcinoma is made after the operation a second operation is performed. Local metastases in the adjacent tissue and in the regional lymph nodes are removed, but radical neck dissection with sacrifice of sternocleidomastoid muscles, the accessory (11th) nerve and the internal jugular arteries is not justified. Total thyroidectomy must also be performed in cases where distant metastases are present. POCHIN (1967) has shown that over 50% of differentiated tumors amenable to ^{131}I therapy take up the ^{131}I only after total thyroidectomy has produced hypothyroidism and TSH stimulation.

External radiotherapy may be added when the tumor has infiltrated locally and when regional (but no distant) metastases are present. External radiotherapy is badly tolerated during hypothyroidism, while ^{131}I is only effective in hypothyroid patients. Priority is given to ^{131}I and external therapy is given later. The chances of success of ^{131}I therapy are of course much better with differentiated papillary or follicular carcinomas. Anaplastic carcinomas have been found to take up radioiodine only in exceptional cases, and POCHIN (1967) does not give ^{131}I in such cases. We feel that the decision of whether or not to give ^{131}I should not be made dependent on the histologic type of the neoplasms. It has repeatedly been observed that the tumor may show regional differences in histology and in uptake of radioiodine within one patient. The patient should therefore be given the benefit of the doubt and receive ^{131}I. RAWSON (1965) has observed a sufficient ^{131}I uptake by metastases in 65% of cases pretreated with thyroidectomy and TSH.

According to CRILE (1966) more than half the papillary carcinomas in patients under 40 improve or remain stationary under thyroid hormone therapy, but this does not in our view justify the decision to withhold radiotherapy. In the cases which do progress, the unfavorable course is very often noticed too late to institute an effective program with ^{131}I.

Our practical procedure is the following (Table 22): 1 week after total thyroidectomy

the remaining thyroid tissue is eliminated by 60 mCi of ^{131}I and whole-body autoradiogram and scintiscan are obtained. The patient then receives substitution therapy with 80 to 120 μg of triiodothyronine per day. In selected cases (see p. 234) 4000 rad may then in addition be given over 30 days to the neck region by high energy electron therapy (HORST, 1960).

Table 22. Synopsis of radioiodine treatment of thyroid carcinoma

1. Stop thyroid hormone substitution 2 weeks before planned radioiodine therapy.
2. Give 10 IU of TSH i.m. daily for the last 1 to 3 days before radioiodine.
3. 24 hours after last TSH injection give 150 mCi ^{131}I p.o.
4. Resume thyroid hormone substitution therapy 24 hours after radioiodine.
5. Perform whole-body profile or whole-body scintiscan 48 hours after giving radioiodine.

When surgical thyroidectomy is contraindicated, the thyroid is eliminated by 60 to 80 mCi of ^{131}I given 24 hours after 10 IU of TSH. After 24 hours the patient is started on 80 to 120 μg triiodothyronine per day as above. After 6 weeks the triiodothyronine is discontinued and 2 weeks later ^{131}I is given, again 24 hours after 10 IU of TSH.

Exact calculation of the tumor radiation dose is not possible, since the size of the tumor mass is not known. The dose absorbed depends both on the biologic half-life of ^{131}I in the tissue and on the amount of ^{131}I taken up. Since the latter parameter depends on the iodide clearance of the tissue, which in turn depends on the tissue mass, large or small tumors will derive approximately the same radiation dose from a given serum level of ^{131}I. A uniform standard dose is therefore given which is within permissible limits of whole-body exposure, usually between 100 and 300 mCi. POCHIN (1967) recommends 150 mCi.

Radioiodine is given 2 weeks after discontinuation of triiodothyronine and 24 hours after 10 IU of TSH. Triiodothyronine is resumed 24 hours after the administration of ^{131}I. A whole-body profile or scintiscan is taken 48 to 72 hours after the ^{131}I, and the urinary excretion of ^{131}I is monitored over the first 6 days. The serum radioactivity is measured after 5 days. If it is higher than 0.01% of dose per liter, there is probably still some iodine-trapping tissue.

The procedure is repeated at 3-monthly intervals for as long as the above measurements indicate the presence of tumor tissue. One additional dose can be given when all the active tissue has been eliminated. This is permissible since the whole-body exposure after destruction of all iodine-retaining tissue is very low (30–40 rep). The patient is then placed on life-long therapy with the highest tolerated dose of L-thyroxine, usually 200 to 300 μg per day. At long intervals, test doses of 10 mCi ^{131}I may help detect clinically silent metastases.

Side Effects. General malaise is minimal in most cases. After 2 weeks a short episode of radiation thyroiditis may cause discomfort. Occasionally there is inflammation of the salivary glands or the gastric or bladder mucosa. There may be transient amenorrhea. Bone marrow damage with pancytopenia is reversible, but in 5% it may be necessary to discontinue ^{131}I (POCHIN, 1967). Irreversible bone marrow aplasia is rarely seen, and usually occurs in cases with extensive metastases to the bones. Radiation pneumonitis and fibrosis are seen in cases with pulmonary metastases (RALL, 1957). Leukemia developed in 2% of POCHIN's cases (1967), which this author considers an acceptable risk.

To comply with radiation safety regulations, all persons treated with tumor doses of ^{131}I must be admitted to hospital in units specializing in radiation safety measures.

Results of Treatment. As stated elsewhere the prognosis of thyroid cancer depends mainly on the histologic type. Another important determinant of prognosis is the age of the patient. According to RAWSON (1965) the prognosis is poor in young children and old people. In patients aged 10 to 45 years the prognosis of differentiated cancer is good (see also Fig. 39). Pregnancy has no influence on the course (HILL, 1966).

No controlled studies allowing comparison of the various modes of treatment are available. So far, some encouraging results have been published. One third of the patients with metastases survived for 9 years (BLAHD, 1960), and one half the patients with differentiated tumors survived for 10 years (POCHIN, 1967). HAYNE (1963) recorded that 67% of patients with lymph node metastases and 53% of patients with distal metastases survived 5 years.

In a recent excellent retrospective study VARMA (1970) has compared 133 patients treated between 1933 and 1947 with surgery alone to 310 patients treated between 1947 and 1967 with surgery plus radioiodine. In the combined treatment group the overall mortality for the first 8 years was significantly lower. The effect of the combined treatment was particularly good in patients over 40 years of age.

L. Thyroid Function Tests

In suspected thyroid disorder it is customary to confirm the clinical impression by one or two thyroid function tests. A careful history and physical examination will often suffice to evaluate the thyroid function and will obviate expensive tests, especially in patients who are euthyroid. A number of new routine tests have recently been introduced. Fortunately this has simplified rather than complicated the work-up of thyroid patients. The functional state of the thyroid gland can now be reliably assessed by tests in blood samples in the majority of patients and it is rarely necessary to use the more complicated tests, such as radioiodine tracer studies or the basal metabolic rate. One possible exception is toxic adenoma. It can only be diagnosed with any degree of certainty by tracer studies (p. 204).

Not all tests are equally useful for the differentiation between euthyroid persons and patients with thyroid dysfunction. The "*diagnostic power*" of the various tests and their proper selection are discussed in detail on p. 244 and Table 27.

1. Thyroid Hormones in Serum

It is well to recall at this point that both thyroxine (T_4) and triiodothyronine (T_3) in plasma are reversibly bound to plasma proteins by a dynamic equilibrium (p. 4, p. 142). About 99.97% of T_4 and 99.5% of T_3 are in bound form. Most routine methods measure the total amount of circulating hormone. Since the critical parameter for peripheral hormone effect is the free hormone, it would be more useful to measure the free fraction. This is technically feasible, but is still quite difficult (see below). As outlined on p. 4 (Chap. I) however, the total hormone is quite representative of the free fraction in most cases.

The American Thyroid Association has recently standardized the nomenclature and abbreviations for tests of thyroid hormone in serum (SOLOMON, 1972), and this terminology will be used below.

a) Serum Thyroxine, T_4

In most laboratories this is now measured by the convenient competitive protein displacement method (T_4 [D]) (MURPHY, 1965, 1969). The thyroxine is extracted from a 1 ml sample of serum into an organic solvent which is then evaporated to dryness. The dry extract is taken up in a solution containing small amounts of thyroxine-binding globulin and T_4 labeled with ^{125}I or ^{131}I. After a standard incubation time the labeled T_4 bound to the thyroxine-binding globulin is separated from the free labeled hormone, e.g. by an ion-exchange resin. The thyroxine from the patient sample will *displace* a certain amount of the labeled hormone from the thyroxine-binding globulin. The more hormone contained in the sample, the less labeled T_4 will be bound to the protein. The exact amount of hormone present in the patient serum is read from a standard curve obtained from calibrated samples.

The mean normal value is around 8 µg/100 ml (range 5.5–11.0 µg). The method is very specific and is not influenced by any iodine-containing medications or X-ray contrast media. D-thyroxine, which is sometimes used in the treatment of hypercholesterolemia, interferes with the measurement. The method measures *total thyroxine* (free plus bound). It may therefore give misleadingly high or low values in situations where the binding proteins of serum are altered (p. 4, p. 204).

High values with a euthyroid state are thus found in:

Pregnancy, estrogen treatment, oral contraceptive treatment (elevation lasts for 1 to 3 months after discontinuation of the pill);
Congenital elevation of TBG (p. 143);
Hepatitis (p. 143);
Porphyria (p. 143).

Low values with a euthyroid state occur in:
Hypoproteinemia in nephrotic syndrome;
Congenital deficiency of TBG (p. 143);
Diphenylhydantoin (Dilantin) treatment;
Salicylate treatment (p. 143).

There are several other methods of measuring T_4. A radioimmunoassay (T_4 [RIA]) has recently been developed (CHOPRA, 1971). The principle is the same as in the above assay, but T_4 antibodies are used instead of TBG. This eliminates the extraction step and simplifies the procedure.

Procedures where the amount of thyroxine is estimated by chemical iodine analysis are discussed below (PBI, BEI, T_4 by column).

b) Serum Triiodothyronine, T_3

The concentration of T_3 in serum is about 40 to 80 times lower than that of T_4. This concentration was beyond the limits of chemical analysis for a long time. Improved chromatographic techniques and the use of competitive protein binding, as for thyroxine, have made the exact measurement of T_3 in serum feasible (T_3 [D]). In STERLING's (1969) original technique the hormone is extracted from serum into an organic solvent, separated from thyroxine by two chromatographic steps and finally

incubated with thyroxine-binding globulin solution containing labeled T_3. As in the thyroxine assay, the label is displaced by the T_3 from the patient's serum sample. More recently, this relatively complicated procedure has been replaced by a radioimmunoassay using specific T_3 antibodies (see also p. 143 for references). This has eliminated the cumbersome chromatographic separations and the test may soon become widely available (T_3 [RIA]).

There is some controversy about the true normal value. The original STERLING (1969) procedure had a mean normal of 0.220 µg/100 ml. The more recent radioimmunoassays give average normal values of 0.100–0.150 µg/100 ml.

c) Percent Free Thyroxine, $\%FT_4$, and Absolute Free Thyroxine, FT_4

Consideration of the points mentioned above and discussed in detail in Chap. I (p. 4) makes it apparent that it would be clinically more relevant to know the concentration of the tiny free hormone fraction rather than that of total hormone. This fraction is so small that it is not yet possible to measure it directly by any available method, chemical or immunological.

STERLING (1966) has developed an indirect method. A small amount of labeled T_4 is added to the serum sample, which is then dialyzed against a protein-free buffer solution. Only the free hormone can pass the dialysis membrane. After 24 hours the radioactive T_4 that has passed into the dialysis fluid is measured. It usually amounts to 0.03% of the total radioactivity added (% FT_4). When the total amount of T_4 is measured in the same sample by one of the above methods the absolute content of free T_4 can be obtained by a simple multiplication as follows: $FT_4 = \%\,FT_4 \times \frac{T_4}{100}$.

This method of measuring % free T_4 is laborious and not suitable for routine clinical use.

d) Resin T_3 Uptake, RT_3U

The meaning of this fairly simple test is commonly misunderstood. Because of its name, many doctors think it measures the concentration of T_3, which in fact it does not. The test consists of adding T_3 labeled with ^{125}I or ^{131}I to the patient's serum. After a short incubation, during which the labeled T_3 binds in part to the available hormone binding sites of the binding proteins, the free (unbound) hormone is adsorbed onto an anion-exchange resin and the radioactivity on the resin is measured, (hence the name "Resin T_3 uptake") according to the double equilibrium (CHRISTENSEN, 1960):

$$\text{Protein-}T_3\ ^{125}I \rightleftharpoons \text{free } T_3\ ^{125}I \rightleftharpoons \text{Resin-}T_3\ ^{125}I\,.$$

There are numerous modifications of this test, but in the one most commonly used about 25% to 35% of the added radioactivity goes onto the resin in normal sera. Inspection of the double equilibrium above shows that more radioactivity will go onto the resin when few bindings sites on the protein are available. This is the case in hyperthyroidism, since the excess thyroid hormone occupies binding sites that are normally free. A decrease in free binding sites, and therefore a high resin-T_3 uptake, also occurs when the amount of binding protein in plasma is diminished or when the binding sites are occupied by a drug such as diphenylhydantoin or salicylate. In hypothyroidism, due to a decrease of the serum thyroxine concentration, many binding sites are free. A larger fraction of the T_3 ^{125}I will be bound to the protein and correspondingly less to the resin, i.e. the resin T_3 uptake is low. The same result will also be obtained in cases where the number of available protein-binding sites is increased. This is the case in estrogen or oral contraceptive treatment and during pregnancy. The resin T_3 uptake thus has a *direct* relationship to the serum concentration of thyroxine and an *inverse* relationship to the concentration of hormone-binding protein.

By itself, the T_3-resin uptake is not a very sensitive test for the thyroxine concentration and it should therefore never be performed alone. It should always be combined with the measurement of T_4 in serum. The advantage of the test lies in the fact that it allows the detection of the relatively frequent states with altered hormone-binding protein concentration. If the results of the two tests are compatible, the binding proteins of plasma are normal. If, in contrast, one test indicates hypothyroidism and the other hyperthyroidism, there has been some change in the binding proteins. The various possibilities are explained in detail in Table 23.

e) Free Thyroxine Index, Thyroxine-Resin T_3 Index, $T_4 \times RT_3U$

As discussed above, the combined evaluation of the T_4 concentration and the RT_3U allows a correct diagnosis of thyroid function despite variations in hormone-binding proteins of plasma. The combined tests thus give a better idea of the concentration of the functionally relevant *free* hormone. In many laboratories this fact

is exploited more quantitatively and the T_4* is multiplied by the RT_3U. The thyroxine-resin T_3 index thus obtained is an abstract number which correlates very closely with the *free* hormone concentration (OSORIO, 1962; CLARK, 1965, 1967; RAGAZ, 1967). As outlined above, the direct measurement of the free hormone, though feasible, is too complicated for routine use.

By ingenious modifications the measurement of T_4 by displacement has been combined with the resin T_3 uptake into one simple procedure (ASHKAR, 1972; THORSON, 1972). This yields a value closely correlating with the free thyroxine which is independent from changes in the binding proteins ("normalized serum thyroxine", "T_7", "effective thyroxine ratio").

Table 23. Combined use of T_4 and RT_3U measurements for the diagnosis of thyroid function and of abnormalities in plasma-binding proteins

	T_4	RT_3U
Euthyroidism, normal binding proteins	Normal	Normal
Euthyroidism, elevated thyroxine-binding globulin (pregnancy, estrogens, oral contraceptives).	High	Hypothyroid range
Euthyroidism, low thyroxine-binding globulin (nephrotic syndrome, diphenylhydantoin, salicylates, inherited defect)	Low	Hyperthyroid range
Hyperthyroidism, normal binding proteins	High	Hyperthyroid range
Hypothyroidism, normal binding proteins	Low	Hypothyroid range

f) Thyroxine Iodine (Chromatographic), Thyroxine Iodine by Column, T_4I (C)

In these procedures the thyroxine is separated from other serum components by column chromatography and the iodine in the T_4 fraction is measured chemically by a colorimetric reaction. Since the T_4 molecule contains 65% of iodine, the normal values are 65% of those of the T_4 (D), namely 3.5–7.5 µg/100 ml. Although these methods are better than the PBI (see below), since some iodine contaminants are eliminated, they are still not specific enough and have now been largely abandoned.

g) Protein-Bound Iodine (PBI)

This time-honored test has faithfully served a whole generation of endocrinologists. For a long time it was the best single test for assessing thyroid function (BLACKBURN, 1955). The serum proteins are percipitated with zinc sulfate. Since 99.97% of T_4 is protein-bound, it will coprecipitate with the proteins. The precipitate is incinerated and the iodine in the residue is measured chemically by the ceric ammonium sulfate-arsenious trioxide method (BARKER, 1951). Normal values are 3.5–8 µg/100 ml. Since thyroxine is normally the only iodine-containing compound of serum which precipitates with serum proteins, the test is theoretically an excellent measure of the serum thyroxine concentration, but most radiographic contrast media and some drugs contain iodine, which significantly contaminates the PBI. The factors affecting the PBI have been thoroughly studied (DAVIS, 1966; SÖNKSEN, 1968; FOLDENAUER, 1967). Due to this lack of specificity the test has now become obsolete and has been replaced by the more specific T_4 (D) or T_4 (RIA).

Like the other measurements of serum T_4, the PBI was influenced by variations in hormone-binding protein, e.g. it was high during estrogen treatment, etc.

h) Butanol-Extractable Iodine (BEI)

This method was developed in an attempt to improve the specificity of the PBI. The protein precipitate is extracted several times with acidified n-butanol, in which thyroxine is very soluble (MAN, 1951). The iodine is then measured in the butanol extract. Normal values are 2.1–6.5 µg/100 ml. Now that more specific methods are available, the BEI is of historic interest only.

2. Tests of Radioiodine Turnover

Thyroid hormone is one of the very few iodine-containing substances occurring physiologically in the body. This fact, together with the availability of several radioactive iodine isotopes of convenient physical characteristics, has allowed more detailed assessment of function in the thyroid than is possible for other glands. Radioiodine tracer studies were among the best of thyroid function tests until recently, and a "tracer" was performed in practically every patient with any sort of thyroid disease. Specific measurements of thyroxine and triiodothyronine now allow an equally good or even better assessment of the thyroid state, since these new tests are not subject to contamination by iodine-containing compounds, while the radioiodine tracer tests are heavily influenced by iodine contamination (GRAYSON, 1960). Moreover, the *in-vitro* tests are convenient for the patient, since blood can be taken on a

* Before specific T_4 (D) measurements were available, the PBI was substituted for the T_4.

single visit, while two visits are needed for tracer studies. It is therefore not necessary to perform a tracer study in every case of clear-cut Graves' disease if the doctor has decided on drug therapy or surgery. If the hyperfunction is to be treated with radioactive iodine a preceding tracer study is indicated. Radioiodine tracer studies in conjunction with the T_3 suppression test are very helpful in cases of borderline Graves' disease where the clinical examination and the other tests have given equivocal results. A tracer study is strongly recommended in cases where a toxic nodular goiter (toxic adenoma) is suspected. There is no other reliable way of diagnosing this condition. In euthyroid goiter and in cases of "solitary nodules" (p. 228) scintiscans with ^{131}I may be helpful in detecting cold areas, which raise the suspicion of malignancy.

a) Thyroidal Radioiodine Uptake

A tracer amount of ^{131}I (in the form of the anion iodide) is given to the patient per os. The radioactivity is usually 10 μCi if only the uptake is measured and 50 μCi if a scintiscan is also performed. The uptake into the thyroid is measured by an exactly standardized procedure (IAEA panel, 1962 and 1972) with a collimated detector after 2 hours and after 24 hours (in some laboratories after 48 hours). There are good reasons for the choice of the two intervals; the early (2-hour) uptake is particularly affected in hyperthyroidism, while the late (24- or 48-hour) uptake may be within normal limits. In hypothyroidism, clear separation from euthyroid patients is facilitated by the late uptake. The normal values vary from one area to the other (Table 24). They are inversely related to the average dietary iodine intake of the population. In many parts of the U.S.A. the normal values have steadily declined in the past 15 years due to an everincreasing iodine supply in food (PITTMAN, 1969; CHAPLAN, 1971; SACKS, 1972). A similar phenomenon has occurred in Switzerland (Table 24).

Many iodine-containing foods or drugs can cause misleadingly low radioiodine uptakes. These include potassium iodide, which is present in copious amounts in many cough syrups and asthma tablets, organic iodine compounds such as the antiasthmatic iodopyrine (Felsol powder) and the intestinal antiseptic clioquinol (Enterovioform, Mexaform), the coronary dilatator amiodarone (Cordarone) and practically all radiographic contrast media (except the barium sulfate used for visualization of the intestinal tract), and even swimming pool antiseptics (FREUND, 1966). Some of the organic compounds particularly the water-insoluble contrast media, have half-lives of months to years in the body (see ref. DAVIS, 1966, in section on protein-bound iodine).

Table 24. Normal values for thyroid radioiodine uptake in several laboratories

Place and authors	Year of measurement	Thyroid radioiodine uptake (% of dose ± standard deviation)	
		2 hours	24 hours
Birmingham, Alabama (PITTMAN, 1969)	1959	–	28.6±6.5
	1967	–	15.4±6.5
Berne, Switzerland (STUDER, 1962; STECK, 1972)	1960	29±11	53±13
	1969	15± 6	38±14
Hamburg, Germany (HORST, 1959)	1959	19	44

Antithyroid drugs of the thionamide type greatly depress the radioiodine uptake by inhibiting the incorporation of iodide into thyroglobulin. After prolonged treatment, however, the uptake rises again markedly (STUDER, 1972). Some commonly used drugs have a weak antithyroid effect. This is true of the tuberculostatic agent paraaminosalicylic acid. Sulfonamides and cortisocosteroids in very high dosage may depress the radioiodine uptake, but this effect is rarely of clinical relevance.

Thyroid hormone medication decreases the radioiodine uptake by suppressing TSH release. After thyroxine treatment 3 to 4 weeks should be allowed to elapse before radioiodine uptake is measured. Due to its shorter half-life (1 day) the effect of triiodothyronine wears off more rapidly and an uptake measurement may be done 5 to 7 days after its discontinuation.

Sedatives commonly used in thyrotoxicosis, such as phenobarbital or reserpine, do not change the radioiodine uptake, neither does diazepam (CLARK, 1971) which has been extensively tested in this respect. Radioiodine metabolism in anuria and oliguria, and during peritoneal dialysis has been studied by ODDIE (1970). The results are discussed on p. 152.

b) Labeled Protein-Bound Iodine (PB ^{131}I)

The ^{131}I taken up by the thyroid is incorporated into the very large intrathyroidal stores of organic iodine. From these stores the radioiodine is slowly released back into the bloodstream at a rate of roughly 1% per day. The ^{131}I can be detected in the blood as labeled

T_3 and T_4, most of which is of course bound to the specific binding proteins. It can therefore easily be precipitated by acid and measured as PB ^{131}I. The normal range is 0.05–0.3% of the dose per liter plasma 48 to 72 hours after the tracer dose. In hypothyroidism the PB ^{131}I becomes unmeasurable. In hyperthyroidism it is usually over 0.5%/liter. All iodine-containing drugs which inhibit the radioiodine uptake will of course also invalidate PB ^{131}I measurements. A reduction in the intrathyroidal hormone pool (e.g. after thyroidectomy or radioactive iodine treatment) causes an accelerated passage of the ^{131}I through the thyroid gland. An elevated PB ^{131}I is therefore often found in these states, even when the patient is euthyroid.

c) Scintiscanning of the Thyroid

This method allows localization of the radioiodine within the thyroid gland. It has several uses:

It allows the detection of hot or cold areas within a nodular goiter. Hot nodules are suggestive of toxic adenoma and cold nodules arouse the suspicion of cancer.

The size (or weight) of a goiter can be estimated quite accurately from scintiscans (p. 196). It may also reveal substernal extension of a goiter.

Scintiscan is indispensable in cases of congenital hypothyroidism for the diagnosis of thyroid aplasia or ectopism.

The whole-body scintiscan or the more simple whole-body profile allows detection of metastases of thyroid cancer.

3. Thyroid Uptake of Pertechnate (^{99m}Tc)

Pertechnate anion is actively accumulated by the thyroid gland by the same transport system which traps iodide ("iodide pump"). In contrast to iodide, pertechnate is not incorporated into thyroid organic compounds, and it therefore leaves the gland again by diffusion. The ^{99m}Tc has some physical properties which make it an ideal isotope for short-term diagnostic studies. Due to its short half-life the radiation dose delivered to the body is very low. An i.v. injection of 30–500 μCi of pertechnate (^{99m}Tc) is given, and the radioactivity in the neck is measured by an external detector after 20 min. Correction for the extrathyroidal radioactivity in the other organs in the neck makes it possible to calculate thyroidal uptake of ^{99m}Tc. Normally 0.4–3% of the dose is taken up by the thyroid. In hyperthyroidism the uptake is higher. The test has no value in the diagnosis of hypothyroidism (GOOLDEN, 1971; VAN T'HOFF, 1972).

4. Tests of Peripheral Thyroid Hormone Effect

a) Basal Metabolic Rate (BMR)

The basal metabolic rate is defined as the amount of body heat produced under "basal" conditions, usually expressed as kilocalories per 24 hours. FRIEDRICH VON MÜLLER was the first to suspect that heat production was increased in hyperthyroidism. Shortly afterwards MAGNUS-LEVY verified this hypothesis experimentally. The Americans AUB, DUBOIS, and BENEDICT share the merit of having introduced the measurement of the basal metabolic rate into clinical medicine. For decades it was the only reliable test of thyroid function and it is understandable that doctors are reluctant to abandon it.

The crucial point in the clinical use of the BMR is the validity of the so-called normal values. Unlike any other thyroid function test the normal value of the BMR is proportional to the body surface. Moreover, with a given body surface, it may vary due to varying body composition (ROSSIER, 1951; WEDGWOOD, 1955). The body surface can be estimated according to a formula derived by DUBOIS (1936). More recently, the very accurate standards of FLEISCH (1954) have come to be widely used.

The exact definition of what is meant by *basal* conditions is a matter of debate. Some laboratories insist that the BMR be measured before the patient gets up, which necessarily means that the pátient has to stay in hospital overnight. In other centers the BMR is routinely done in outpatients arriving in the laboratory in the morning before breakfast.

Calculation of Normal Values. Age, sex, height, and weight of the patient are recorded and the normal value is computed with the help of the tables of DUBOIS (1936), FLEISCH (1954), or, in the case of children, of TALBOT (1938). The measured patient value is usually expressed as a percentage deviation from the normal values. The normal range extends from −15% to +15%. In our own laboratory in Zurich the mean BMR for 100 healthy men was +0.9% (standard deviation ±5.5%) and for 100 healthy women +0.004% (standard deviation 6.0%) when the standards of FLEISCH (1954) were used.

Open System. This system requires a more complex laboratory technology. It is more accurate than the closed system, but has not been widely used as a routine method. The subject inspires room air and expires into a bag. The volume, CO_2 and O_2 content of the bag are measured and the calorie production is calculated.

Closed System. The patient is connected to a closed spirometer system filled with pure oxygen. The expired gas is passed through sodium carbonate, which absorbs the CO_2, and the gas is then returned to the spirometer tank. The difference between the initial and the final spirometer volume gives the O_2 consumption. The following 7 rules have to be carefully observed:

1. The whole system, including the patient, must be airtight (mouthpiece, nasal clip, tympanic membrane);
2. The valves must be so arranged as to exclude rebreathing of expired gas;
3. The valves and tubes should present no measurable resistance to gas flow;
4. Constant pressure in the mouthpiece must exclude a slow change of the midrespiratory position;
5. Temperature and water saturation of the O_2 in the spirometer must be constant;
6. The O_2 content of the inspired air should not fall below that of normal room air;
7. The patient must be fasting and relaxed and should breath quietly and regularly.

Falsely high values are obtained if rules 1, 2, 3, 6 and 7 are not observed. In most cases they are due to a leak.

Measuring Procedure:

1. The patient must have fasted for 12 hours before the test;
2. Weight and height are measured. Outpatients are left on a bed in a quiet room for 1 hour;
3. The spirometer is filled with O_2. After temperature and water vapor equilibration of the gas the spirometer is connected to the patient;
4. The respiratory movements are immediately recorded and measurements are started after 1–3 min·
5. The whole measurement lasts 5–15 (average 10) min;
6. The diminution of volume in the spirometer is read and the time period is checked;
7. After reduction of the measured O_2 volume to standard conditions (0°, 760 mm Hg, dryness) the calorie production is calculated. With an empiric respiratory ratio of 0.82, 1 liter of oxygen produces 4825 calories. The value is then expressed as percentage deviation from the expected normal value.

The many simple thyroid tests now available have rendered the BMR almost obsolete, although it is a fairly good thyroid function test. The BMR will undoubtedly remain in use as a research tool, but as a clinical routine it will probably be slowly phased out.

b) Ankle Reflex Time

A slowing of the ankle jerk in hypothyroidism can be observed clinically. The speed of the ankle jerk can be accurately measured by suitable recording instruments, and used as a thyroid test. In the most commonly used instrument the foot of the kneeling patient interrupts part of a light beam which is directed onto a photocell. When the foot moves, the amount of light hitting the cell changes and the process can be easily recorded (Fig. 40). The time from the beginning of the hammer tap to half relaxation is measured. Normal values are between 270 and 330 msec. In hyperthyroidism the values are often lower, but the discrimination is not very good. The test is more reliable for detecting hypothyroidism (RIVES, 1965), where the values are in general over 350 msec. IMBACH (1969) has published normal values for children. The reflex time may be shortened in anxious, tense patients (TSCHUDI, 1966) and during hypoglycemia (ZACHMAN, 1967). It may be prolonged in hyperkalemia (WEISS, 1966), diabetes, late pregnancy anorexia nervosa (FOWLER, 1972) and dermatomyositis.

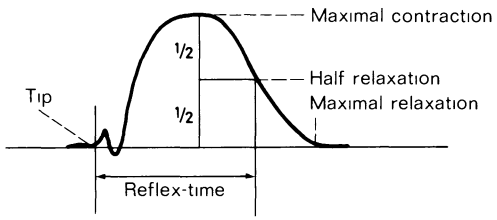

Fig. 40. Ankle reflex registered according to TSCHUDY (1966)

c) Plasma Cholesterol

Plasma cholesterol is undoubtedly elevated in hypothyroidism, probably more so in the primary than in the secondary form (ESCAMILLA, 1953). It has been faithfully passed on as a thyroid test from one textbook to the next. It must be now recognized that there are so many extrathyroidal factors which influence the plasma cholesterol that it should be abandoned once and for all as a thyroid test.

5. Tests of TSH Secretion

a) TSH Radioimmunoassay

LEMARCHAND (1965) and ODELL (1965, 1967) were the first to develop radioimmunoassays for TSH. The technique has meanwhile been greatly improved by work in many laboratories and the clinical usefulness of the TSH radio-

immunoassay is now well established (see HERSHMAN, 1971; MAYBERRY, 1971; Editorial, Brit. med. J., 1971). The normal values vary from laboratory to laboratory as each group uses its own antibody and sometimes its own standard. The most sensitive assays now detect values over 0.5 μU/ml and TSH is measurable in most, though still not all, normal persons (see p. 149 for a more detailed discussion). Values of over 10 μU/ml are clearly above the normal range in most current assays.

The main applications of the radioimmunoassay are: early detection of cases of mild or borderline hypothyroidism ("diminished thyroid reserve", see p. 161), since TSH is clearly elevated when the serum thyroxine is still within the normal range; convenient separation of primary and secondary hypothyroidism; TSH levels are elevated in the primary and depressed in the secondary form.

For the moment, only specialized research laboratories can perform the TSH radioimmunoassay, but the method may soon become widely available.

b) TRH Stimulation Test

The hypothalamic hormone TRH stimulates the secretion of TSH (p. 148). Soon after the determination of its tripeptide structure it was chemically synthesized on a large scale and its diagnostic application has been documented in a flood of publications, only a few of which will be mentioned.

Intravenous injection of TRH causes a rapid rise of the plasma TSH, which reaches a peak between 30 and 40 min and then returns to baseline within 3 hours (ANDERSON, 1971). The response is dose-dependent, but doses upward of 200–400 μg cause a maximal effect (ANDERSON, 1971). A standard dose of 200 or 400 μg is therefore now recommended. TSH rises by an average of 8 μU in males and 12 μU in females (ORMSTON, 1971 a). In hyperthyroidism TRH causes no rise of TSH, while in hypothydroidism there is an exaggerated response (HERSHMAN, 1970; HAIGER, 1971). The test has two main uses: 1. evaluation of pituitary reserve in cases of borderline hypopituitarism. 2. differentiation of pituitary from hypthalamic lesions, particularly in cases of hypopituitary dwarfism (cf. p. 160, COSTOM, 1971).

TRH can also be given orally. It then causes a slower and more prolonged rise in TSH than when given by the intravenous route, but the dose of TRH must be much higher, 1–20 mg (ORMSTON, 1971 b). The prolonged TSH response after oral TRH causes a measurable rise in the serum thyroxine (STAUB, 1971).

c) TSH Stimulation Test

Since the TSH radioimmunoassay is not yet available to all doctors, the time-honored TSH stimulation test will still be used for some time to come. The test is used mainly to distinguish primary from secondary hypothyroidism. The principle is that in primary hypothyroidism the thyroid gland is already maximally stimulated by endogenous TSH and injection of TSH will cause no further stimulation. In secondary hypothyroidism injected TSH causes a marked rise in thyroid activity.

The radioiodine uptake is usually measured as an index of thyroid function. A basal (pre-TSH) 2-hour uptake is measured. Subsequently, 10 IU of bovine TSH (Thytropar, Armour, or 300 U Ambinon, Organon) are injected and a second 2-hour tracer uptake is measured after one day. In primary hypothyroidism there is no rise in the radioiodine uptake. In secondary hypothyroidism the uptake rises by at least 10% and in normal persons by 50%. Repeated TSH injections over 3 days may separate primary from secondary hypothyroidism more clearly (TAUNTON, 1965). The serum thyroxine level usually also rises by at least 3 μg/100 ml in normal persons.

d) TSH Reserve Test with Carbimazole

This test was developed for the detection of cases of diminished thyrotropin reserve (STUDER, 1962, 1964). A basal radioiodine uptake is measured immediately before a one-week course of carbimazole (15 mg t.i.d.) is started. A new tracer dose is given 36 hours after the last carbimazole tablet and the thyroidal uptake is measured again. Due to the TSH secretion provoked by the carbimazole, the second uptake is usually 10–15% higher than the first. This test has not worked well in other laboratories (SCHNEEBERG, 1966; POWELL, 1966), probably due to a higher iodine intake in American subjects. JENSEN (1969) and MORNEX (1970) have much improved the sensitivity of the test by certain modifications. With the advent of the TSH radioimmunoassay and the availability of TRH the test has lost some of its usefulness.

e) Triiodothyronine Suppression Test

In normal persons exogenous triiodothyronine causes a decrease of thyroid activity by suppressing the secretion of TSH. In cases of TSH-independent thyroid function (toxic adenoma, Graves' disease), triiodothyronine does not affect thyroid function (WERNER, 1955).

The basal radioiodine uptake is measured and triiodothyronine (25 µg t.i.d.) is given for one week. In patients with heart disease the dose may be reduced to 40 µg/day for 10–14 days. A second radioiodine tracer is then performed. In normal persons the uptake values decrease by at least 30% (the original uptake being taken as 100%). In thyrotoxicosis there is no decrease of the radioiodine uptake even in borderline cases.

This test is still very valuable in the following circumstances:

1. In the differentiation between an elevated radioiodine uptake caused by iodine deficiency and that caused by Graves' disease;
2. For the establishment of the endocrine nature of exophthalmos in cases of euthyroid ophthalmopathy (p. 202);
3. For the diagnosis of "compensated" toxic adenoma (p. 205). A good review is available on the test (BURKE, 1967).

6. Tests for Inborn Errors of Iodine Metabolism

a) Perchlorate Discharge Test

This test serves to establish the diagnosis of a defect in organic iodination (p. 168). As outlined on p. 140, the iodide transported into the thyroid cell is normally immediately incorporated into organic molecules within the colloid. If this organification fails, iodide accumulates within the gland. If further accumulation of iodide is blocked by perchlorate, the iodide concentration in the gland decreases rapidly because the iodide can leave the gland by diffusion.

A radioiodine uptake is performed and immediately after the 2-hour measurement 0.4–1.0 g of potassium perchlorate is given p.o. The thyroidal radioactivity is measured again 2 and 4 hours later. In normal persons the thyroidal radioactivity remains constant after perchlorate. In defects of organification the thyroidal radioiodide falls by at least 50% (the first value being taken as 100%). Decreases of 10% may indicate partial defects. The test gives a positive (pathologic) result in cases of the familial organification defect (p. 168), during antithyroid drug treatment, in some cases of chronic lymphocytic thyroiditis, and some cases of endemic goiter. In cases of familial goiter the defect should be comfirmed by direct enzyme measurements in the thyroid tissue in all cases where a thyroidectomy is performed (p. 168). (References p. 283).

b) Test for Deiodinase Deficiency

In the familial syndrome, deiodinase is not only deficient in the thyroid, but also in many other tissues, such as liver and kidney. The defect can conveniently be detected in the following way: An i.v. injection with 30 to 50 µCi of ^{131}I-Diiodotyrosine is given and the urine is collected for the next 6 hours. The radioactivity in the urine is analyzed by paper chromatography. Normally the diiodotyrosine is rapidly deiodinated and less than 20% of the urinary ^{131}I is in diiodotyrosine, the remainder being excreted mainly as iodide (ALBERT, 1951; STANBURY, 1956).

7. Miscellaneous Tests

a) Serum Antibodies to Thyroid Tissue Components

These tests are particularly useful in the diagnosis of chronic lymphocytic thyroiditis and of primary idiopathic myxedema. The various antibodies, the corresponding antigens and the tests for their demonstration are listed in Table 25.

Table 25. Thyroid antibodies and methods for their detection. (Modified from KLEIN, in OBERDISSE and KLEIN: Die Krankheiten der Schilddrüse. Stuttgart: Thieme 1967)

1. Colloid antigen 1 (Thyroglobulin)
Agglutination
a) Passive hemagglutination of thyroglobulin-coated tanned erythrocytes.
b) Agglutination of thyroglobulin-coated latex particles or bentonite particles.
Immunofluorescence
Unfixed thyroid tissue sections exposed to fluorescence-labeled serum.
2. Colloid antigen 2 (not identified)
Immunofluorescence (as above)
3. Microsomal antigen
Complement fixation
Immunofluorescence (as above)

Three main antigens are distinguished: thyroglobulin, colloid component other than thyroglobulin and microsomal antigen. In routine practice it is quite sufficient to test for two antibodies (usually antithyroglobulin and antimicrosomal), since a positive response in either one or both tests is obtained in 97% of patients with chronic lymphocytic thyroiditis.

Thyroglobulin antibodies are detected by the sensitive tanned red cell hemagglutination technique. Red cells coated with thyroglobulin are mixed with serial dilutions of the patient's serum and the suspension is examined for hemagglutination. Titers of 1 : 25000 or more are diagnostic for chronic lymphocytic thyroiditis.

The antimicrosomal antibody is detected either by a complement fixation reaction or by immunofluorescence. Titers of 1 : 64 in the complement fixation test are diagnostic for chronic lymphocytic thyroiditis.

Lower antibody titers are found in a number of thyroid disorders, notably in Graves' disease.

b) Measurement of LATS

The significance of LATS and the bioassay method have been amply discussed on p. 179.

The measurement of LATS may be of practical interest in cases of exophthalmos of unknown etiology. As outlined on p. 202, endocrine exophthalmos may occur in euthyroid patients. The presence of LATS in the serum of such patients is strong evidence that they have so-called euthyroid Graves' disease.

c) Thyroid Biopsy, Fine-Needle Aspirates

HAMLIN (1956) and HAWK (1966) have published their experiences with thyroid biopsies performed with the Vim-Silverman needle. A small skin incision is made and the needle is introduced tangentially along the trachea to a depth of 2 cm. The cannula is then advanced and the needle rotated through 180°. A cylinder measuring 1 × 20 mm is obtained. Pressure is applied over the site of biopsy for 5 min. Usually the biopsy causes little pain.

For a long time the main indication for thyroid biopsy was the suspicion of chronic lymphocytic thyroiditis. Most cases can now be diagnosed by the presence of thyroid antibodies in serum.

In suspected cases of thyroid cancer thyroid biopsy is not recommended because of the potential risk of implanting metastases along the needle track. The value of cytological examination of fine-needle aspirates is currently under investigation (GALVAN, 1973).

8. Clinical Indices. Diagnostic Power and Proper Selection of Laboratory Tests

In the great majority of patients hyper- and hypothyroidism can be correctly diagnosed by a careful history and a physical examination. There are two important exceptions to this statement. Both in cases of toxic adenoma and in cases of hyperthyroidism of patients over 60 years of age the clinical diagnosis can be extremely difficult, since often only a few symptoms and signs are present. A wider use of laboratory tests is therefore justified if one of these two conditions is suspected.

Not all clinical features are equally important in the diagnosis of thyroid dysfunction. Some have little, others excellent discriminative function. Several groups have attempted to establish the diagnostic power of each clinical symptom or sign by statistical methods. They have set up "*clinical indices*" in which the presence or absence of each clinical feature is assigned a certain number of plus or minus points. The points for each patient are added up and the sum is compared to a normal previously established range (CROOKS, 1959; BILLEWICZ, 1969; GURNEY, 1970; HARVEY, 1971). Such diagnostic indices are very helpful, especially to the doctor with little experience of thyroid disease. They show which of the innumerable textbook features of thyroid dysfunction are really of clinical importance. The indices have shown, for example, that such commonly taught signs and symptoms as weight gain and constipation

Table 26. Reliability of the most current thyroid function tests for discriminating hypo- and hyperthyroid patients from euthyroid persons. The final impression based on clinical findings and several laboratory tests was considered the correct diagnosis

	Percentage of patients correctly diagnosed			
	Hypothyroidism		Hyperthyroidism

BMR	–	65	–	87
Clinical impression	82.6	–	94.2	–

[a] Normal range adjusted so that in each test an equal percentage of euthyroid people are in the hypothyroid range (false-positives) as there are hypo- or hyperthyroid patients in the normal range (false-negatives).
[b] Normal range adjusted to include 86.5% (±1.5 SD) of euthyroid persons, i.e. each test gives 13.5% false-positives.

in the case of hypothyroidism or hair loss and diarrhea in the case of hyperthyroidism have practically no diagnostic power. Some other conclusions learned from these indices are discussed in the sections on hypothyroidism (p. 159) and thyrotoxicosis (p. 188).

Thyroid laboratory tests must be performed in every case where the clinical examination has given equivocal results. As in the case of clinical features, not all laboratory tests have the same discriminative powers. Several thyroid clinics have determined the value of individual tests by comparing the correlation between the results and the final diagnosis (LUDDECKE, 1958; CHEW, 1962; RIVES, 1965; GORDON, 1970; HARVEY, 1971; FRAGU, 1972). The results of two such studies are shown in Table 26. Of course the value of each test (defined by the percentage of correct diagnoses) depends very much on how the normal range is defined. If narrow limits are given, the test will give few false-negative and many false-positive results, and vice versa. Different definitions of the normal range account at least in part for the discrepancies in the various studies (Table 26).

The *protein-bound iodine* has proved to be one of the best single tests of thyroid function in most studies. No studies comparing the diagnostic value of the newer thyroid hormone measurements (T_4) with that of other tests have yet appeared. But since they are not subject to contamination by compounds containing iodine, an important source of error inherent in the PBI test has been eliminated and the new tests can be expected to obtain a better rating than the PBI, particularly if the T_4 measurement is combined with an RT_3U for the exclusion of disorders of hormone binding to plasma proteins.

The *thyroidal radioiodine uptake* has obtained the same rating as the PBI in most studies. The *BMR* has had an excellent rating

Table 27. Use of thyroid tests in the most common thyroid disorders

	Diagnosis made with reasonable certainty by	Usual additional or confirmatory tests	Tests performed in doubtful cases where diagnosis cannot be established by simpler procedures
Graves' disease	History and physical examination	T_4, RT_3U, possibly ^{131}I uptake and scan.	T_3 suppression test
Euthyroid Graves' disease with ophthalmopathy	History and physical examination	T_4, RT_3U, T_3 suppression test	
Toxic adenoma	Clinical diagnosis difficult. ^{131}I uptake and scan, PB ^{131}I	Repeat scan after T_3 suppression or TSH stimulation	
Triiodothyronine thyrotoxicosis	History and physical examination, T_4, RT_3U	T_3, if not available: BMR; ^{131}I uptake, scan	T_3 suppression test
Primary hypothyroidism	History and physical examination	T_4, RT_3U, thyroid antibodies serum TSH or TSH stimulation test	
Secondary hypothyroidism	History and physical examination. Clinical differentiation from primary form difficult	T_4, RT_3U, serum TSH or TSH stimulation test, thyroid antibodies, other pituitary hormones	TRH stimulation test if hypothalamic origin suspected (pituitary dwarfism).
Thyroid aplasia or ectopism	Neonatal hypothyroidism, absence of goiter. In case of slight suspicion: T_4, RT_3U	T_4, RT_3U, ^{131}I uptake and scan	TSH stimulation test or serum TSH
Familial defect in hormone biosynthesis	Goiter and hypothyroidism in newborn. Affected sibling	T_4, RT_3U, ^{131}I uptake. Perchlorate discharge test. Deiodinase test. Biochemical examination of excised gland	
Euthyroid sporadic goiter	History and physical examination	T_4, RT_3U (^{131}I uptake and scan). Surgery if malignancy suspected	Scan if there is slightest doubt of toxic adenoma
Endemic goiter	History and physical examination	T_4, RT_3U, ^{131}I uptake	Urinary iodine excretion
Chronic lymphocytic thyroiditis	Clinical evaluation. Antibodies to thyroid tissue	Patient may be hypo-, eu-, or hyperthyroid. Therefore: T_4, RT_3U (^{131}I uptake, scan)	Biopsy
Acute or subacute granulomatous thyroiditis	Clinical evaluation: pain, fatigue. Elevated erythrocyte sedimentation rate	Thyroid antibodies (absent) T_4, RT_3U, ^{131}I uptake, scan	Biopsy

in some studies and a low rating in others. The *ankle jerk* appears to be useful for the diagnosis of hypothyroidism, but not very useful in hyperthyroidism. The plasma *cholesterol*, as mentioned earlier, proved to be practically useless as a thyroid function test.

Finally it is noteworthy that in FRAGU's (1972) study the *clinical impression* was unsurpassed by any single laboratory test for the diagnosis of hyperthyroidism, which may be a comfort to the many doctors who have to practice without the luxury of ready access to an endocrine laboratory.

Table 27 gives a summary of the various tests we find most useful for a number of common thyroid disorders.

VII. Adrenal Cortex

A. LABHART

With Contributions by

CHR. HEDINGER, G. KISTLER, J. MÜLLER, A. PRADER, R. SIEBENMANN, G. TÖNDURY, and M. ZACHMANN

A. Historical Dates

1563 BARTHOLOMAEUS EUSTACHIUS SANCTOSEVERINATUS describes the adrenals and recognizes them as an organ in his treatise "De glandulis quae renibus incumbunt".

1855 THOMAS ADDISON gives the classic description of adrenal insufficiency and of the disease which bears his name in his book "On the constitutional and local effects of disease of the suprarenal capsules".

1856 BROWN-SÉQUARD discovers in animal experiments that the adrenals are necessary to life.

1896 SIR WILLIAM OSLER recognizes the efficiency of perorally administered adrenal extracts in ADDISON'S disease.

1926 SMITH demonstrates that hypophysectomy leads to atrophy of the adrenals and EVANS succeeds in preventing this atrophy by the administration of pituitary extracts.

1928–1930 effective adrenal extracts are made by ROGOFF and STEWART, HARTMANN and MCARTHUR, PFIFFNER and SWINGLE.

1932 CUSHING describes the syndrome of pituitary-adrenal hyperactivity.

1933 LOEB discovers disturbances of serum electrolytes in ADDISON'S disease and bases the treatment with sodium chloride on these discoveries.

1937–1952 Isolation, elucidation of the constitution, and synthesis of the adrenal hormones corticosterone, deoxycorticosterone, cortisone and cortisol by REICHSTEIN, KENDALL, WINTERSTEINER and collaborators.

1942 LI and SAYERS isolate ACTH.

1946 SELYE describes the general adaptation syndrome.

1948 HENCH and collaborators detect the anti-inflammatory effect of cortisone.

1953–1955 Isolation and elucidation of the constitution of aldosterone by SIMPSON and TAIT, WETTSTEIN and NEHER, REICHSTEIN and VON EUW. Synthesis by WETTSTEIN and SCHMIDLIN.

1954 CONN describes primary aldosteronism.

1958 GROSS suggests the control of aldosterone secretion by angiotensin.

1960 DAVIS and GENEST confirm the regulation of aldosterone secretion by angiotensin II.

1962 HOFMANN, LI, and SCHWYZER describe the amino-acid sequence of ACTH.

1966 SCHWYZER and SIEBER succeed in synthesizing beta-corticotropin.

B. Embryology, Gross Anatomy and Histology

G. TÖNDURY and G. KISTLER

Embryology. The two main components of the adrenal (suprarenal) gland, the *cortex* and the *medulla*, differ not only in morphology and function, but also in origin. The cortex develops from cells of the coelomic epithelium and is therefore of mesodermal origin, while the chromaffin and sympathetic ganglion cells of the medulla are derived from the neural ectoderm. In amphibians, reptiles, and birds the chromaffin cells are diffusely distributed within the cortical tissue throughout life. In mammals, however, the cortex finally surrounds the medulla like a capsule.

In the four-week-old human embryo, coelomic epithelial (mesothelial) cells situated on both sides between the root of the mesentery and the gonadal anlagen begin to proliferate and to invade the underlying mesenchymal tissue. Here, they differentiate into compact, acidophilic epithelial masses which lose contact with the coelomic epithelium and form the *primitive or fetal cortex* of the suprarenal glands. During the 6th embryonic week, neural ectodermal elements, the pheochromoblasts, start to invade the primitive cortex (see Chap. VIII, p. 419). Soon afterward, they can be observed singly or in small groups between the cortical cells. Early in the third month, the coelomic epithelium proliferates again and a

new wave of mesothelial cells is shed into the underlying mesenchyma. These cells, which are smaller than those of the first wave, surround the fetal cortex to form the *definitive cortex* of the adrenal gland. During the last month of intra-uterine life, the fetal cortex begins to regress. At the time of birth, the suprarenal glands are nevertheless very large, their volume being approximately one third that of the kidneys. In the newborn, the atrophy of the fetal cortex proceeds rapidly, except for its outermost cell layers which appear to be taken up into the zona reticularis of the definitive cortex (see below). In the adult human, the size of the suprarenal glands is only about 1/30 of that of the kidneys.

The function of the primitive suprarenal cortex is still poorly understood. Since the adrenal glands are atrophic in anencephalic infants (in whom the hypophysis is absent), it is assumed that the very large size of the fetal glands is due to the release of adrenocorticotrophic hormone (ACTH) from the fetal pituitary. ACTH secretion by the fetus can also be inhibited by cortisone administration to the mother. In such cases, the fetal suprarenal gland is often found to be hypo- or even atrophic.

Gross Anatomy. In the adult, each of the adrenal glands weighs about 3–5 g. They are situated retro-peritoneally and on the supero-medial aspect of the front of the kidneys. Both glands are surrounded by adipose tissue and by the renal fasciae, to which they adhere firmly. Unlike the kidneys, the glands are not displaced during respiration or changes in posture. The *right* adrenal gland is pyramidal in shape. Its base rests on the kidney and its medial portion projects to some extent behind the inferior vena cava. Behind, it lies against the diaphragm, whereas in front, it is in direct contact with the right lobe of the liver, with the dorsal wall of the vena cava and with the peritoneum. The *left* suprarenal gland is usually semilunar in shape and more flattened. In front, it is in close contact with the splenic artery, with the peritoneum of the lesser sac and with the pancreas. Its dorsal portions rest on the diaphragm.

The phrenic artery supplies the adrenal gland with multiple branches, the *superior* adrenal arteries. The *middle* suprarenal artery reaches the gland directly from the aorta, whereas the *inferior* adrenal arteries emerge from the renal artery. The arrangement of these blood vessels varies widely not only in different people, but also on the two sides of the body. The suprarenal *vein* leaves the gland in the hilus. In addition, some small veins accompany the arteries. The left adrenal vein enters the renal vein, whereas the right vein supplies the inferior vena cava. A number of lymphatic vessels arise in the adrenal medulla. They follow the veins and supply adjacent lymph nodes. In contrast, the cortex contains only a very few lymphatics.

The predominantly *preganglionic, sympathetic nerve fibers* of the adrenal glands arise in the celiac plexus or are branches of the thoracic and lumbar splanchnic nerves. Most of these fibers supply the specific medullary cells; a few of them, however, contact the ganglion cells in the organ capsule and in the medulla. Postganglionic nerve fibers extend to the blood vessels walls. No parasympathetic fibers seem to enter the glands.

Histology. A thick capsule of collagenous connective tissue surrounds the suprarenal gland and extends as trabeculae into the cortex. It contains an extensive arterial plexus which is supplied by the various suprarenal arteries (see above). The cortical arterioles arising from this plexus branch into the sinusoidal capillaries which surround the cords and groups of cortical parenchymal cells. In addition, the capsule and its trabeculae display some lymphatic vessels as well as a nerve plexus. The latter includes a large number of mainly preganglionic fibers and a few sympathetic ganglion cells. Its branches penetrate the cortex in the trabeculae and terminate in the medulla (see Chap. VIII, p. 420). A framework of reticular fibers extends between the trabeculae, the organ capsule and the blood vessels. It supports the specific cortical cells as well as the medullary cells, and surrounds the capillary network of the organ.

The *adrenal cortex* constitutes approximately 80% of the total organ volume and is composed of three easily distinguishable concentric zones. The thin *zona glomerulosa* adjacent to the organ capsule consists of groups of rather small, epitheloid cells which contain a deeply staining nucleus displaying one or two nucleoli. The cytoplasm is acidophilic and contains some small clumps of basophilic material. The small lipid droplets and the elongated mitochondria are randomly distributed throughout the cytoplasmic matrix, whereas the Golgi apparatus is situated in a juxtanuclear position. Both reticular fibers and sinusoidal capillaries surround the cell groups. Electron-microscopically, the zona glomerulosa cells are characterized by an anastomosing network of smooth-surfaced endoplasmic reticulum extending all over the cell body. Only a few profiles of granular endoplasmic reticulum can usually be observed. The mitochondria possess lamellar cristae thus differing from those of the other cortical zones.

The cytoplasmic matrix contains large numbers of polyribosomes and the lipid droplets are often arranged in small groups. The Golgi apparatus does not differ from that of the cells of other organs.

The cell columns of the largest cortical zone, the *zona fasciculata*, are continuous with the cell groups of the zona glomerulosa. Their polygonal cells form long cords which are usually one to two cells thick and are arranged radially to the organ capsule. The individual columns are separated by reticular fibers and by the sinusoidal capillaries. The fasciculata cells often contain two nuclei, and their cytoplasm is characterized by the presence of large numbers of lipid droplets. In routine histological sections, the cytoplasm appears highly vacuolated. When observed under the electron microscope, the cells of this zone display an extensive network of agranular endoplasmic reticulum. A few parallel arrays of granular endoplasmic reticulum are usually situated in the neighborhood of the nucleus (or nuclei). The rounded mitochondria vary considerably in size but are usually much larger than those of the other cortical zones. Their numerous cristae appear as vesicular invaginations of the inner mitochondrial membrane or as vesicles lying free in the mitochondrial matrix. The lipid droplets are dispersed throughout the cytoplasmic matrix. In the Golgi region, which is generally larger than that of the other zones, lysosomes as well as deposits of lipofuscin pigment are often present.

The *zona reticularis* adjacent to the adrenal medulla consists of an anastomosing network of epitheloid cells which vary considerably in size and shape. Within the cell groups, "light" and "dark" cells can be distinguished, the latter presumably being degenerative elements, since they contain hyperchromatic and shrunken nuclei and large masses of lipofuscin pigment. Compared with the fasciculata cells, the light cells of the zona reticularis contain a much smaller number of lipid droplets. The shape of the mitochondria and the amount of agranular endoplasmic reticulum, however, do not differ significantly.

The surface of the cortical cells of the three zones is usually enlarged by small infoldings as well as by numerous small microvilli which project into the intercellular and perivascular spaces. The endothelium of the sinusoidal capillaries is, over large regions, extremely attenuated and fenestrated. The endothelial fenestrae or pores are closed only by a very thin diaphragm which separates the blood from the basal lamina surrounding the sinusoids. A few small bundles of collagen fibrils are dispersed in the perivascular spaces. They correspond to the reticular fibers revealed by light microscopy.

1. Steroid Hormones

The hormones of the adrenal cortex, the gonads and the placenta, provitamin D, cholesterol, bile salts, and the cardiac glycosides are steroids, i.e. structural derivatives of *sterane*, a completely hydrated cyclopentanophenanthrene. Sterane consists of three hexagonal rings and one pentagonal ring, which are designated by the letters A, B, C, and D. Each carbon atom is marked by a number (Fig. 1).

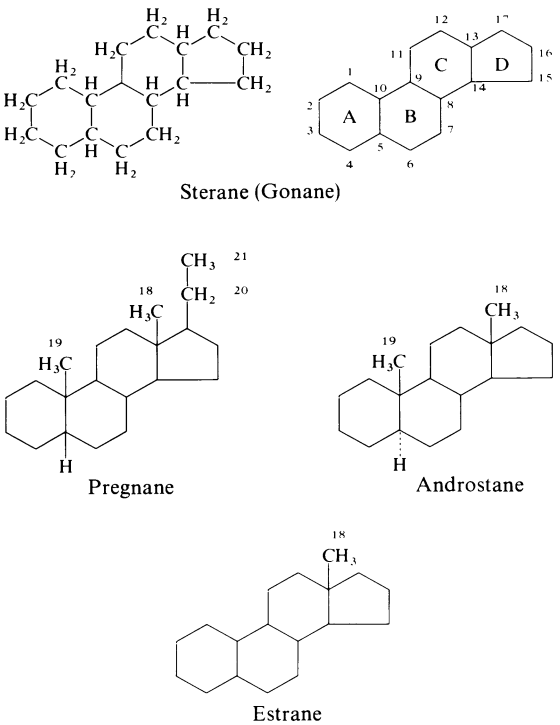

Fig. 1. Basic structures of steroid hormones

The steroid structure can be expanded by a side chain on C-17 and by angular methyl groups on C-10 and C-13. The individual steroid hormones are further characterized by double bonds, hydroxyl, and ketone groups.

The hormones of the adrenal cortex and the corpus luteum have 21 C-atoms and are derived

from *pregnane*, a sterane with two angular methyl groups and an ethyl side chain. The male sexual hormones are derived from *androstane* with 19 C-atoms, the female sexual hormones from *estrane* with 18 C-atoms.

The additional carbon atoms are numbered in a continuous sequence (angular methyl groups: C-18, C-19, ethyl side chain: C-20, C-21).

2. Stereoisomerism and Nomenclature*

Different stereoisomerisms of steroids are due to a number of asymmetric carbon atoms. In general, the stereo structure of a steroid is clearly defined by the nomenclature, because the biological activity is closely related to it. Thus, etiocholanolone, the stereoisomer of the active androgen androsterone, has no androgenic activity but is an active pyrogenic substance (Fig. 5, Chap. IX, p. 448).

Sterane has six asymmetrical carbon atoms. Thus, $2^6 = 64$ stereoisomerisms are theoretically possible. However, in natural steroid hormones rings B/C and C/D are always connected by trans-fusion; the H-atoms or methyl groups on the two angular C atoms are placed on opposite faces of the molecular plane. The rings A and B are combined either by cis- or by trans-fusion. Additional stereoisomerisms are due to side chains, methyl and hydroxyl groups. The methyl group on C-10 has been chosen as the stereo point of reference for the position of such substitutes. It is considered to lie on the near side of the plane of writing and is designated by a solid valency stroke and the affix β. In contrast, substitutes lying on the far side of the plane of writing are designated by dotted valency strokes and the affix α. In natural steroids, the side chain at C-17 is always in the β-position. In a C_{21} steroid, a 17-hydroxyl group is therefore always in the α-position, whereas it can occur in the α- or β-position in a C_{18} or C_{19} steroid. In adrenal cortical steroids, an 11-hydroxyl group is always in the β-position, but 3- or 20-hydroxyl groups can occur in α- or β-position.

Steroids hydroxylated in certain positions can be *conjugated* with sulfuric acid or glucuronic acid. Steroid conjugates are generally inactive. They are always more water-soluble, and usually more rapidly excreted in the urine than unconjugated steroids. For a long time they were considered as breakdown and waste products of steroid hormones. Recently, however, the question of the physiologic role of steroid conjugates was reexamined, since it was found that steroid sulfates were secreted by the adrenal glands into the blood stream and that conjugated androgens were biochemically transformed before being excreted in the urine (BAULIEU, 1965). Conjugation with sulfuric acid is an esterification, whereas conjugation with glucuronic acid is β-glycosidic.

In the chemical nomenclature, one differentiates between so-called *trivial names*, short and convenient designations for individual compounds, and *systematic* names, which are inconvenient but define the exact structure. They are formed by adding pre- and suffixes to the name of the basic carbon structure (Fig. 2) and define the type, number and position of all substitutes. Hydroxyl groups are referred to by the suffix "-ol" or the prefix "hydroxy-", ketone groups by the suffix "-one" or the prefix "keto-" (also "oxo-"). Double bonds are designated by the suffix "-ene"; the localization is given by inserting the number of the first of the two C-atoms involved. When a double bond connects two C-atoms with non-consecutive numbers, both numbers are written. Occasionally, the position of a double bond is denoted by a "Δ" prefix according to an outdated nomenclature system. The position of substitutes on optically active C-atoms are designated by α, β or ξ (unknown). The prefix "allo-" refers to trans-fusion of the A and B rings. The prefixes "desoxy-", "dehydro-", "dihydro-", "tetrahydro-", "epi-" and "iso-" are only used for trivial names. The trivial name of the most important adrenocortical hormone is *cortisol*, synonymous with *hydrocortisone*; its systematic name is

4-pregnene-11β,17α,21-triol-3,20-dione .

Terms such as "*corticoids*", "*corticosteroids*", and "*17-ketosteroids*", are frequently used to describe certain groups of steroids. Corticoids or corticosteroids refer to adrenal cortical hormones with 21 C-atoms which influence electrolyte and carbohydrate metabolism as well as their inactive breakdown products with an intact side chain. The group of 17-ketosteroids includes both the androgenically active and the hormonally inactive C-19 steroids with a ketone group in the 17-position.

Basic information about the structure and nomenclature of the steroid hormones for the non-chemist can be found in the reviews by ZIMMERMANN, KLYNE, MASON, HÜBENER, and STAIB. More detailed information is given by FIESER and FIESER.

* The nomenclature of the steroids is ruled by the recommendations of the International Union of Pure and Applied Chemistry (IUPAC-IUB 1967 Revised Tentative Rules for Steroid Nomenclature. Biochim. Biophys. Acta 1964, 453 (1968)).

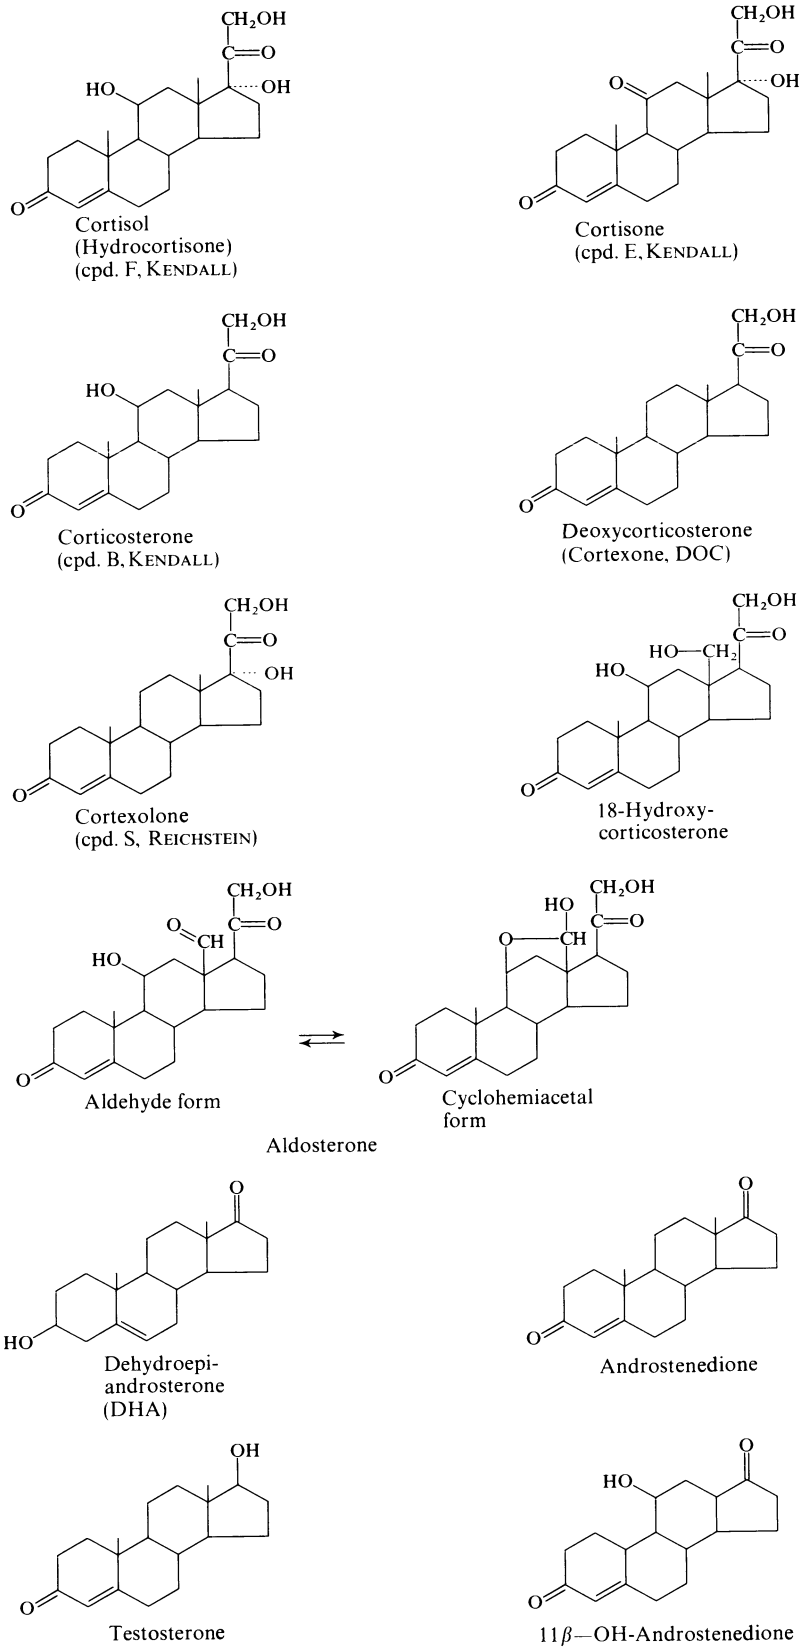

Fig. 2. The most important steroids of the adrenal cortex

3. The Adrenal Cortical Hormones

Among the approximately 70 different steroids which have been isolated from animal adrenal glands, cortisol, corticosterone, and androgens are the main secretory products of the human adrenal cortex. In addition, the mineralocorticoid aldosterone, secreted in small amounts, is of very great physiological importance. Along with these biologically active adrenal cortical hormones, other less active or inactive precursors or byproducts are also found in human adrenal venous blood, such as deoxycorticosterone (cortexone), cortexolone (compound S), 18-hydroxycorticosterone, 17α-hydroxyprogesterone, and 17α-hydroxypregnenolone. The androgen dehydroepiandrosterone is mainly secreted in the conjugated form as a sulfate. It was recently confirmed that the human adrenals secrete testosterone. However, there is as yet no direct evidence for production of estrogens by the human adrenal cortex. Measurable amounts of estrogens have been found in the urine of ovariectomized women, which increased in response to ACTH treatment and disappeared after adrenalectomy.

The concentrations of steroids in adrenal venous blood taken during operations under general anesthesia give only very limited information about normal secretion rates, because the adrenal glands are maximally stimulated by ACTH under these conditions. However, the basal daily secretion rates of the most important adrenocortical hormones have been indirectly determined by isotope dilution methods (see Table 1).

The ratio of cortisol to corticosterone secretion varies among the different species, but also among individuals within the same species. In man, cortisol predominates by a factor of 10:1, whereas in the rat corticosterone is the prevailing glucocorticosteroid.

For a review dealing with the amounts of steroids in adrenal venous blood in man and different animal species see YATES (1962).

4. The Biosynthesis of the Adrenal Cortical Hormones

The biosynthesis of the steroid hormones of the adrenal cortex have been studied most with the following experimental models:

1. Perfusion of adrenal glands *in vitro* or *in vivo*.
2. Incubation of slices of surviving adrenal tissue.
3. Incubation of adrenal homogenates or cell fractions.

These methods are very useful for isotope studies. Biological precursors (acetate, mevalonic acid, steroids) labeled with ^{14}C or tritium are added to the perfusion fluid or the incubation medium. The conversion to radioactive steroids is determined by extraction, isolation, and isotope counting.

The biosynthetic pathway of adrenal cortical hormones from acetyl coenzyme A via cholesterol, pregnenolone, and 17α-hydroxypregnenolone is outlined in Fig. 3. One-step conversions are designated by solid arrows, multistep conversions by dotted arrows. They are catalyzed by specific enzymes (desmolase, isomerase, 3β- and 18-dehydrogenase, 20α-, 22ξ-, 17α-, 21-, 11β-, 18-hydroxylases) and are dependent on coenzymes, such as NADH and NADPH. In the adrenal cortex as well as in other organs, cholesterol can be fully synthesized via the important intermediary products mevalonic acid and squalene. The biosynthetic pathway leading to cholesterol has been mainly elucidated by the investigations of BLOCH. Cholesterol is abundantly stored in the adrenal cortex, but can be only partially utilized for the production of adrenal cortical hormones.

Table 1. Adrenal cortical hormones of man

	Secretion rate (per day)	Concentration in peripheral plasma
Cortisol	15–40 mg	6 –25 µg/100 ml
Corticosterone	1– 4 mg	0.4 – 2.0 µg/100 ml
Aldosterone	50– 250 µg	2 –15 ng/100 ml
Cortexolone (compound S)	100–1500 µg	0.01– 0.11 µg/100 ml
Deoxycorticosterone (cortexone, DOC)	200– 800 µg	2 –10 ng/100 ml
18-Hydroxycorticosterone	150– 450 µg	
17α-Hydroxyprogesterone		
17α-Hydroxypregnenolone		
Dehydroepiandrosterone(-sulfate)	6–9 mg	
Androstenedione		
11β-Hydroxyandrostenedione		
Testosterone		
Estrogens (?)		

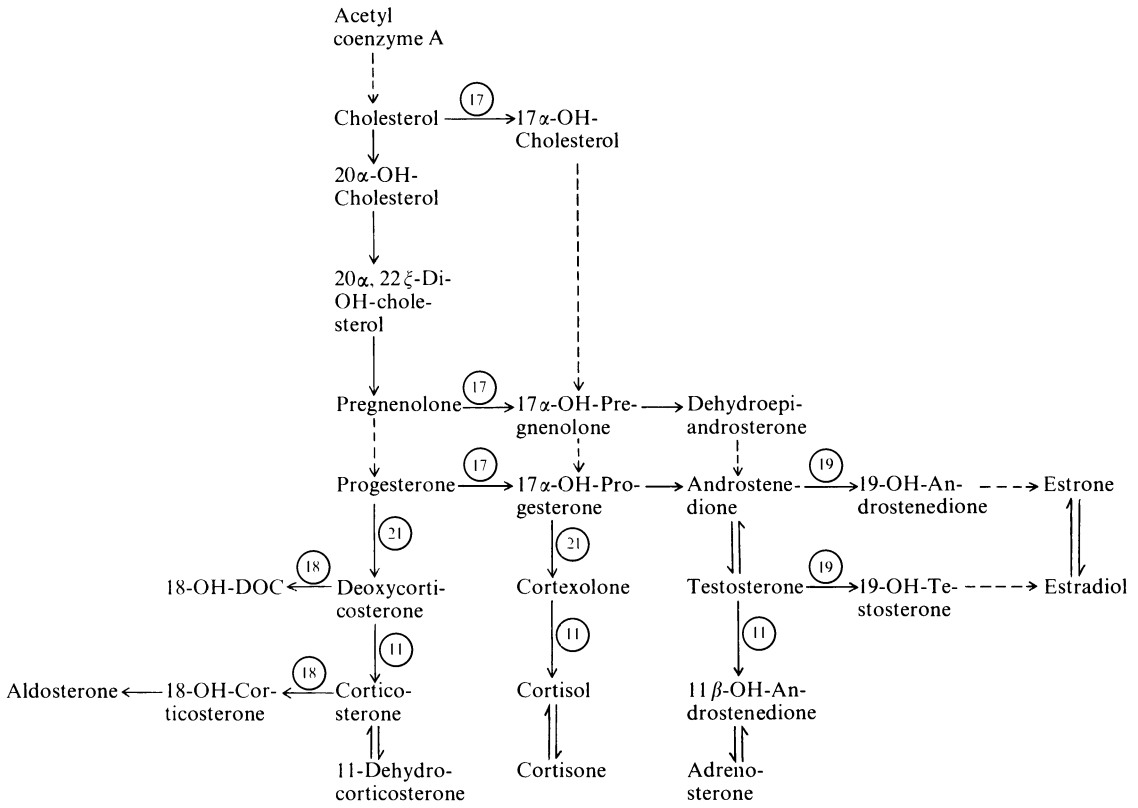

Fig. 3. The biosynthesis of adrenal cortical hormones. (Solid arrows: one-step conversions; broken arrows: multistep conversions. The circled numbers refer to hydroxylases)

Cholesterol is probably the normal precursor of all adrenal cortical hormones. In animals fed with radioactive cholesterol for several weeks the corticosteroids in the peripheral blood had the same specific radioactivity as the adrenal cholesterol and the serum cholesterol even during short-term stimulation with ACTH (WERBIN, 1961; KRUM, 1964).

Addition of ACTH to the perfusion fluid or the incubation medium of adrenal slices increases the steroid biosynthesis *in vitro* by a factor of 5–10, which corresponds to the stimulation of corticosteroid excretion in human urine during ACTH treatment. See p. 296 for the site and mode of action of ACTH.

Aldosterone is formed only in the zona glomerulosa, whereas all other steroid hormones are formed in the inner zones of the adrenal cortex. It is the only steroid with an aldehyde group in position 18. This group is probably formed in two stages, i.e. hydroxylation followed by dehydrogenation. The immediate precursor of aldosterone is most probably 18-hydroxycorticosterone. Aldosterone can occur as either a dihydroxyaldehyde or a cyclohemiacetal (Fig. 2). *In vivo*, however, it probably exists only in the latter form. The physiological significance of 18-hydroxycorticosterone and 18-hydroxy-DOC is unknown, apart from their possible role as precursors of aldosterone. 18-Hydroxy-DOC has a weak mineralocorticoid activity. In the human, the secretion rate of 18-hydroxycorticosterone is twice that of aldosterone. In the rat, 18-hydroxy-DOC is produced in very high amounts, but mainly by the zona fasciculata.

17α-Hydroxypregnenolone or 17α-hydroxyprogesterone appear to be essential intermediates in the biosynthesis of the androgens. A direct conversion of cholesterol to C_{19} steroids has never been demonstrated, though cholesterol sulfate can be converted to pregnenolone sulfate and this to dehydroepiandrosterone sulfate. If estrogens are really produced in the adrenals, androstenedione, testosterone and their 19-hydroxy derivatives are the most probable intermediates, as they are in the ovary and the placenta.

5. Transport of Adreno-Cortical Hormones

At normal concentrations, only a small part of the total blood cortisol and corticosterone is in the free form, i.e. susceptible to dialyzation and filtration.

Most of the 25 percent adsorbed onto the erythrocytes can be separated by washing with physiological saline solution. The uptake by leukocytes is of no quantitative importance.

At body temperature, 90 percent of the plasma cortisol is bound to an alpha-globulin. This protein is called "transcortin" or "corticosteroid-binding globulin" (CBG). It is a glycoprotein with a molecular weight of 52000. Transcortin has a high affinity to cortisol and corticosterone, but its binding capacity is limited. It is fully saturated at a plasma cortisol concentration of 20 µg/100 ml. Up to this concentration, only 10% of the plasma cortisol is in the free form. At higher concentrations, free plasma cortisol increases to 20–30%; the remaining 70–80% are then bound to albumin, which has a low affinity but a large capacity (Fig. 4).

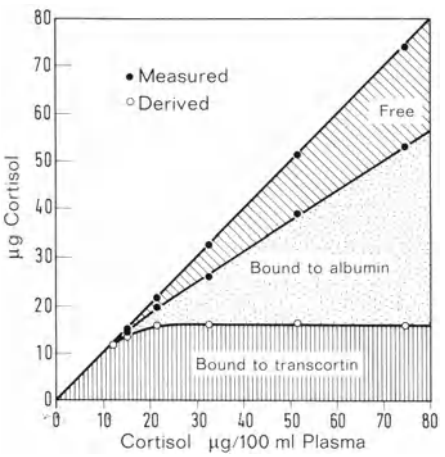

Fig. 4. Protein-binding of cortisol in normal human plasma at 4° C. (From W. H. DAUGHADAY and I. K. MARIZ, 1960)

The binding affinity to transcortin is determined by specific groups of the cortisol molecule. In addition to cortisol and corticosterone, deoxycorticosterone is also bound. On the other hand, transcortin-binding affinity to cortisol metabolites is very low, and aldosterone is bound only to other plasma proteins.

The concentration and binding capacity of transcortin are independent of ACTH. ACTH stimulation of the adrenal cortex induces a relatively larger increase in the free than in the bound plasma cortisol. The transcortin concentration is unaltered in adrenal insufficiency and in Cushing's syndrome, while a striking increase in transcortin level can be induced by estrogens. The amounts of estrogens produced by the ovaries during normal cycles are not sufficient for this effect, but transcortin levels are elevated in response to the high amounts of endogenous estrogens produced during pregnancy or to pharmacological doses of exogenous estrogens (oral contraceptive medication). This increase in plasma transcortin is always coincident with an increase in the plasma cortisol concentration and can at least partially explain why the plasma concentration of corticoids can be up to 3 times higher than normal during the last trimester of pregnancy with no obvious signs of hyperadrenocorticoidism. Conversely, transcortin can be decreased in liver diseases and dysproteinemia, thus accounting for the absence of adrenal insufficiency in spite of very low concentrations of plasma corticosteroids.

Transcortin concentration is much lower in the lymph than in the plasma. It is also very low in the cerebrospinal fluid. Correspondingly, the cortisol content in these two body fluids is lower than in the plasma. The transcortin-bound cortisol is very probably biologically inactive. In the extravascular space there is probably a state of equilibrium between the binding of cortisol to transcortin on the one hand, and to certain cell structures (hormone receptors) on the other hand. The cortisol bound to transcortin is also more slowly inactivated by liver enzymes *in vitro*. This is probably due to competition between binding sites of the transcortin and of the microsomes of the liver cells. Only the free plasma cortisol is filtered by the kidneys; a major part of it is reabsorbed by the tubules. The renal clearance of the free plasma cortisol is 40–50 ml per minute. When renal function is normal, the daily excretion of free cortisol in the urine is a good index of the concentration of the free plasma cortisol.

The physiological role of transcortin probably lies in a sort of buffering effect, which prevents rapid variations of the plasma cortisol level. Transcortin restrains the active cortisol from reaching the target organ and also protects it from rapid inactivation by the liver and excretion through the kidneys.

The plasma aldosterone is predominantly bound to albumin, and also to another protein which is probably not identical to transcortin. The relatively low degree of protein binding of plasma aldosterone could provide a partial explanation for the very low plasma concentration and the short biological half-life of this hormone.

6. Metabolic Breakdown and Excretion of Adrenal Cortical Hormones

In the organism, cortisol is very rapidly converted to inactive steroids by enzymes. Only very small amounts (less than 1%) are excreted

unaltered in the urine. The liver plays the most important part in the inactivation of the steroid hormones. Catabolism by other organs is not quantitatively important. The major reactions of cortisol metabolism usually occur in the following order:

1. Reduction of the double bond between C-4 and C-5.
2. Reduction of the 3-keto group.
3. Reduction of the 20-keto group.
4. Fission of the side chain at C-17.

Most of the cortisol is metabolized to stage 2 (40–50%) or stage 3 (20–30%). Less than 10% is converted to 17-ketosteroids.

Cortisol can be reversibly converted to cortisone in the liver under the action of an 11β-dehydrogenase.

Dihydrocortisone, dihydrocortisol, and their allo-isomers are formed by the action of 5α- and β-reductases. The reduction of the double bond is practically irreversible and is probably rate-limiting for subsequent metabolic breakdown. NADPH is an essential coenzyme. The reaction is also dependent on thyroxine. It is accelerated in hyperthyroidism and delayed in hypothyroidism and in liver diseases.

The second reaction leads to the formation of tetrahydro derivatives by reduction of the 3-keto group. This reaction is reversible. NADPH and NADH are equi-effective coenzymes.

A part of these tetrahydro derivatives is further converted to cortol and cortolone by reduction of the 20-ketone group. Finally, a small percentage is broken down to 11β-hydroxy-17-ketosteroids and 11-17-diketosteroids by side-chain fission.

Inactivation through 6β-hydroxylation occurs mainly in the newborn and only to a small extent in adults.

The action of the enzyme glucuronyl-transferase conjugates the reduced metabolites to uridine-diphosphate glucuronic acid to form glucosiduronates (glucuronides). A very small percentage is conjugated with sulfuric or phosphoric acid. Conjugated corticosteroids are water-soluble and are rapidly voided in the urine by glomerular filtration and probably also by tubular excretion. Approximately two thirds of the total plasma corticosteroids are conjugated. The formation of steroid glucuronides is not restricted to the liver, but can also take place in the kidneys. However, reduction to tetrahydro derivatives occurs almost exclusively in the liver, and generally these metabolites are also conjugated by the liver as soon as they are formed.

Only traces of unconjugated cortisol metabolites are found in the plasma. Nevertheless, steroid hormones can be metabolized extrahepatically, but only at a reduced rate. Steroid catabolism has been shown to occur *in vitro* in fibroblast cultures and also in eviscerated animals.

About 30 to 40% of the cortisol is excreted in the urine as tetrahydrocortisol and tetrahydrocortisone-glucuronide. A further 20 to 30% appears as cortol and cortolone glucuronide. The chemical nature of all the cortisol metabolites has not yet been elucidated. After the intravenous injection of a tracer dose of ^{14}C-labeled cortisol or corticosterone, 70 to 80% of the radioactivity is recovered in the urine within 24 hours and 95% within 72 hours. No radioactive CO_2 is found in the expired air. These findings indicate that the steroid skeleton itself remains intact.

The catabolic pathway of corticosterone is similar to that of cortisol, with the exception

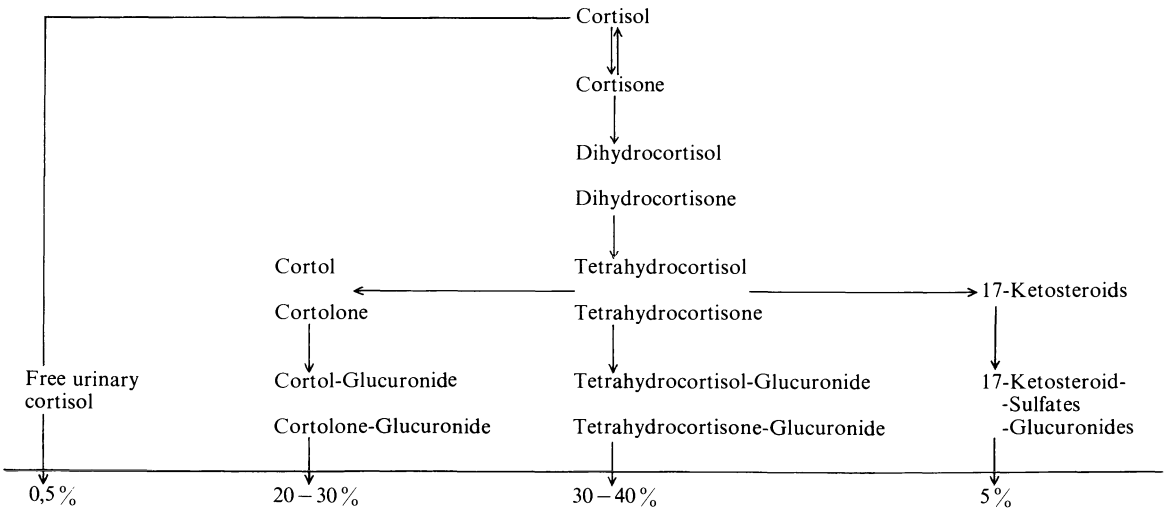

Fig. 5. Catabolism and excretion of cortisol and its metabolites

that no 17-ketosteroids are formed. The adrenals of the newborn secrete corticosterone mainly as the sulfate, and metabolites of this substance have been found in the urine.

Aldosterone is not only converted to tetrahydroaldosterone-3-glucuronide, but also to a so-called "3-oxo-conjugate" which is most probably aldosterone-18-glucuronide*. The conjugation of unaltered aldosterone is also possible outside the liver, mainly in the kidneys. Only very small amounts of free aldosterone are excreted in the urine (less than 0.5% of the aldosterone secreted), whereas the major part is excreted as tetrahydroaldosterone glucuronide (30 to 50%) and aldosterone-18-glucuronide (5 to 15%). In liver diseases and during pregnancy, the ratio of these two metabolites is altered and relatively more aldosterone-18-glucuronide is excreted.

A small percentage of ^{14}C-labeled cortisol or corticosterone given by i.v. injection is excreted in the bile. Most of it is probably reabsorbed by the intestines.

Kinetics of Cortisol Metabolism. When a pharmacological dose of cortisol or a tracer dose of radioactive – labeled cortisol is injected i.v. the logarithm of the plasma cortisol concentration or the logarithm of the specific radioactivity of the plasma cortisol decreases linearly per unit time after a short mixing period. Thus, the removal of cortisol from plasma apparently follows first-order kinetics. However, studies with large pharmacological doses of cortisol and with tracer doses of labeled cortisol lead to different results. Whereas a tracer dose is distributed only in one pool, two pools of distribution have to be assumed to explain the kinetics of a pharmacological dose of cortisol; metabolism apparently occurs in only one of them. The major part of a pharmacological dose of cortisol is probably not attached to transcortin, so that it can leave the intravascular space and only gradually returns to the blood stream.

The kinetics of aldosterone disappearance also indicate the existence of two pools of distribution.

In healthy humans, the biological half-life of plasma cortisol is on average 110 min, that of corticosterone 90 minutes, and that of aldosterone 15 and 35 min**.

The biological half-life of the adrenal cortical hormones is prolonged in liver diseases, in cachexia, in shock, myxedema, as well as during estrogen therapy and during pregnancy. It is also increased in old age, in acute polyarthritis, and in uremia. The biological half-life is decreased in thyrotoxicosis and occasionally in obesity.

The rate of removal of cortisol from the plasma can be mathematically approximated. The calculated removal-rate coefficient corresponds to a clearance and is dependent on the activity of the steroid-5-reductases in the liver, the availability of NADPH, the concentration of plasma cortisol, the binding to transcortin, and the hepatic circulation. However, the last factor appears to be negligible, since the enzymes catabolize cortisol more efficiently when the hepatic circulation is reduced.

The biological half-life of prednisone and prednisolone is almost twice as long as that of cortisol. Halogenation at position 9 delays catabolism. This at least partly explains the increased potency of synthetic fluorated or dehydrogenated steroids. The miscible metabolic pool of cortisol is 1.5 mg, that of corticosterone 0.2 mg, and that of aldosterone 0.01 mg.

Plasma cortisol varies during the day between 6 and 25 µg per 100 ml and plasma corticosterone concentration between 0.4 and 2 µg per 100 ml, whereas the aldosterone level is considerably lower and varies between 2 and 15 ng per 100 ml during unrestricted sodium intake.

7. Structure of Corticotropin (ACTH) and the Melanotropins (MSH)

Corticotropin or ACTH, which regulates the activity and growth of the adrenal cortex, is a polypeptide consisting of 39 amino acids and has a molecular weight of 4540. The structures of human, porcine, ovine, and bovine ACTH are known (Fig. 6). Ovine and bovine ACTH differ in their sequence of the amino acids from number 25 to 33. Porcine ACTH differs from bovine ACTH by having a leucine in the 31-position in place of a serin. Human corticotropin contains the same amino acids as bovine and ovine ACTH, but in a different sequence.

In 1966, SCHWYZER and SIEBER succeeded in synthesizing a complete molecule of β^{1-39} corticotropin. It has the same amino-acid sequence and the same biological activity as the natural purified porcine ACTH (110 U.S.P. units per mg). A synthetic tetracosapeptide, β^{1-24} corticotropin is commercially produced and can be used for diagnostic and therapeutic purposes. This compound contains the first

* This substance has also been refered to as the "pH 1 metabolite" in the literature, because it can be hydrolyzed by acidification to pH 1.

** Depending on the smaller or larger pool of distribution, the real nature of which is still unknown.

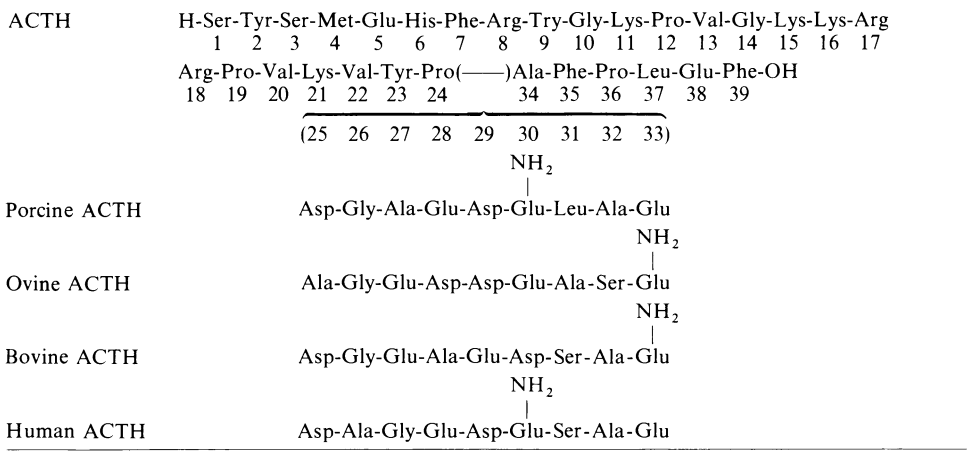

Fig. 6. ACTH structure in 4 different species. (From G. SAYERS, in: Hormones in the blood, 2nd ed., vol. 1, p. 169, ed. by C. H. GRAY and A. L. BACHARACH. London: Academic Press 1967)

24 amino acids of the N-terminal end of the complete corticotropin. Like other polypeptides containing the first 20 or more amino acids of the N-terminal end in natural sequence, it has a biological activity of 100 to 110 units per mg. Its activity per molecule is therefore somewhat lower than that of β^{1-39} corticotropin. Shorter polypeptides have a much lower ACTH activity. Peptides with less than 16 amino acids have no effect on the adrenal cortex, but have an increased MSH activity. Thus, the amino acids at the C-terminal end of the corticotropin molecule appear to inhibit MSH activity.

Recently an immunoreactive ACTH component in plasma and pituitary considerable larger than β^{1-39} ACTH, "Big ACTH" has been identified by gel filtration and ultracentrifugation. It seems to contain within it ACTH covalently linked to the carboxyl group of a basic amino acid of a larger, more acidic, peptide (YALOW, 1973).

The structure of α-MSH is the same in all mammalian species so far investigated. It consists of 13 amino acids, which are identical to the first 13 amino acids of ACTH. On the other hand, β-MSH differs from species to species. Whereas the human hormone consists of 22 amino acids, most animal hormones contain only 18 amino acids. However, the sequence of some of the amino acids also corresponds to that of corticotropin. Synthetic melanotropins have no corticotropic activity. On the other hand, some MSH activity is associated with all the corticotropins (Fig. 6).

Most of the traditional commercial ACTH preparations contained animal corticotropin extracted from pituitary tissue by glacial acetic acid and partially purified by adsorption onto oxycellulose. These preparations have now been replaced by synthetic corticotropins. Long-acting ACTH preparations contain the corticotropin as a zinc salt or dissolved in gelatine and have a prolonged effect lasting 12 to 48 hours following intramuscular injection.

Little is known about the biological inactivation and excretion of ACTH. The form in which ACTH circulates in the plasma is also unknown. ACTH has never been definitely isolated from the urine. Values reported for the biological half-life of corticotropin vary between a few minutes and several hours. The plasma concentration of ACTH in the normal human, measured with the most reliable biological assays, is approximately 0.25 mU per 100 ml in the morning and about 0.11 mU per 100 ml in the evening (NEY, 1963).

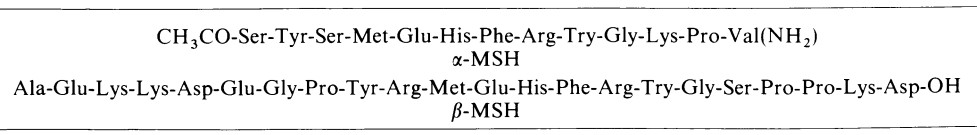

Fig. 7. Structure of human melanocyte-stimulating hormones. (From J. M. WALKER in: Hormones in the blood, 2nd ed., vol. 1, p. 161, ed. by C. H. GRAY and A. L. BACHARACH. London: Academic Press 1967)

A. LABHART and J. MÜLLER

1. Biological Effects of Corticotropin

a) Action on the Adrenal Cortex

ACTH is the physiologically most important regulator of adrenal cortical function. Only in the presence of ACTH can the adrenal cortex synthesize normal amounts of glucocorticoids and androgens and secrete them into the blood stream. In the intact organism, any increase in the secretion of these hormones is due to an elevated ACTH blood level, and any reduction is due to a decreased ACTH concentration. In addition, ACTH plays a supporting role in the regulation of the secretion of the mineralocorticoid aldosterone, although the production of this hormone is controlled mainly by other factors (see p. 297). ACTH regulates the secretion of adrenal cortical hormones by stimulating their biosynthesis. In contrast to the thyroid gland and to the adrenal medulla, the adrenal cortex is unable to store its secretory products and release them on demand. The almost instantaneous elevation of the corticosteroid concentration in the adrenal venous blood induced by an intravenous injection of ACTH is also due to increased production, since the corticosteroid content of the adrenal cortex increases at the same time. Production and secretion of adrenal cortical hormones are practically identical (see Chap. I, p. 3). In addition to regulating the production of steroid hormones, ACTH also controls the size and growth of the adrenal cortex: excessive secretion of ACTH leads to hyperplasia, while failure leads to atrophy. The fact that synthetic ACTH also stimulates adrenal growth and corticosteroid production makes the existence of a separate adrenal growth-promoting hormone appear unlikely.

Experiments with radioactive-labeled precursors of corticosteroids indicate that ACTH stimulates the synthesis of steroid hormones mainly at the stage of the conversion of cholesterol to pregnenolone (STONE, 1954; KARABOYAS, 1965). This step is common to the biosynthesis of all steroid hormones. It is still uncertain whether the effect of ACTH is mediated by the activation of one of the three enzymes involved in this conversion or by an increased availability of the essential coenzyme NADPH. However, intracellular transport mechanisms or morphological changes of the mitochondria may also play an important part. Whereas an intravenous injection of ACTH leads to immediate cholesterol depletion of the adrenal cortex, long-term ACTH administration induces an increased cholesterol content, indicating that ACTH may also stimulate cholesterol biosynthesis. Prolonged ACTH administration also leads to enhanced 11β-hydroxylase activity (GRANT, 1957).

The exact biochemical mechanism of action of ACTH is controversial. According to the classic theory of HAYNES and BERTHET (1957), ACTH stimulates the formation of cyclic AMP. Cyclic AMP activates phosphorylase, which in turn mediates the conversion of glycogen to glucose-1-phosphate. Glucose-1-phosphate is converted to glucose-6-phosphate by phosphoglucomutase. Metabolism of glucose-6-phosphate by the hexose monophosphate shunt results in the production of NADPH, a coenzyme necessary to several steps of steroidogenesis. More recent evidence does not confirm this theory *in toto* (HILF, 1966). However, it has been amply demonstrated that ACTH acutely raises the cyclic AMP content of adrenal cortical tissue. Moreover, cyclic AMP simulates the steroidogenic effect of ACTH on perfused adrenal glands or incubated adrenal tissue.

ACTH also promotes protein synthesis in the adrenal cortex. This effect, however, seems to be related to the chronic growth-stimulating effect rather than to the acute stimulation of steroidogenesis, but ACTH induces a rapid increase of the ribonucleic acid concentration in the adrenal tissue (FIALA, 1956). The corticosteroid-stimulating effect of ACTH is blocked *in vivo* and *in vitro* by puromycin and chloramphenicol (FERGUSON, 1963; GARREN, 1965), which indicates that the acute effects of ACTH are also dependent on the integrity of protein synthesis.

The significance of the high content of ascorbic acid in the adrenal cortex and its rapid disappearance under the influence of ACTH is unknown. Biosynthesis of steroid hormones and the adrenal responsiveness to ACTH are normal in patients with scurvy.

b) Extra-Adrenal Effects

In addition to its action on the adrenal cortex, ACTH exerts specific effects on other tissues, which are demonstrable particularly *in vitro*, but sometimes also in adrenalectomized animals *in vivo*. One of these extra-adrenal actions is the stimulation of the melanocytes, which has already been mentioned (see p. 295).

The best-known extra-adrenal activity of ACTH is its lipolytic action on adipose tissue. In extremely low concentrations it stimulates the hydrolysis of the triglycerides. This effect is probably due to activation of a specific lipase

of adipose tissue, which is not identical to lipoprotein lipase. This action of ACTH is also mediated by cyclic AMP. ACTH as well as catecholamines or glucagon stimulate lipolysis acutely, whereas growth hormone has a delayed action; its lipolytic activity is probably due to the stimulation of lipase synthesis (FAIN, 1965, 1967; VAUGHAN, 1965).

2. The Regulation of Adreno-Cortical Hormone Secretion

a) The Regulation of Aldosterone Secretion

The complex physiological and biochemical control mechanisms which regulate the secretion of aldosterone are only partially known. The original assumption that a specific aldosterone-stimulating hormone regulated the secretion of aldosterone in a similar manner to the way ACTH regulates the secretion of cortisol led to the discovery of the multiple functional relations between the renin-angiotensin system and aldosterone production by the adrenal cortex (GROSS, 1958; DAVIS, 1961; GENEST, 1961; LARAGH, 1960). Angiotensin II does indeed have many properties of a trophic aldosterone-stimulating hormone. Very low doses of angiotensin II stimulate the aldosterone production by isolated adrenal glands *in vivo* and *in vitro* without affecting the production of glucocorticoids. In several diseases associated with secondary aldosteronism the increased aldosterone secretion is very probably due to increases in plasma renin and angiotensin II concentrations. Plasma renin activity is elevated in Addison's disease and depressed in primary aldosteronism. Nevertheless, the analogy between angiotensin II and ACTH is incomplete and the regulation of aldosterone secretion differs from the regulation of cortisol secretion in several respects.

1. Whereas ACTH is the only substance which can stimulate the secretion of glucocorticoids in physiological concentrations, a number of different humoral factors can stimulate aldosterone production.

2. Aldosterone production can be regulated at different stages of the biosynthetic pathway.

3. The regulation of plasma aldosterone concentration does not include a direct negative feedback mechanism.

4. There may be wide species differences in the regulation of aldosterone secretion.

The following factors have been found to stimulate the biosynthesis of aldosterone by incubated adrenal tissue or in perfused adrenal glands directly.

angiotensin II,
elevated potassium concentration,
reduced sodium concentration,
ACTH,
serotonin.

During short-term experiments, all these factors stimulate aldosterone biosynthesis by enhancing the conversion of cholesterol to pregnenolone in the cells of the zona glomerulosa (MÜLLER, 1966). Most of these stimulators act exclusively or preferentially on zona glomerulosa cells, whereas ACTH also acts on the inner zones, thus stimulating the production of glucocorticoids and androgens (MÜLLER, 1970).

In man and in animals, the aldosterone-stimulating effect of ACTH is limited to a few days, whereas the cortisol production is stimulated for however long ACTH is given. The mechanism of this escape of aldosterone secretion from the stimulating effect of ACTH is as yet unknown. Hypophysectomy is followed by an initial decrease of 50–90% in the aldosterone secretion rate, but a return to normal values can be observed after a short period.

A decreased sodium concentration in adrenal arterial plasma directly stimulates aldosterone output. On the other hand, experimental hyponatremia induced by pitressin injection and increased water intake does not enhance aldosterone secretion, probably because renin secretion is simultaneously suppressed by the hypervolemia. By contrast, an increased potassium intake stimulates aldosterone production although plasma renin activity decreases under these experimental conditions (VEYRAT, 1967).

Serotonin directly stimulates aldosterone biosynthesis, but this effect has as yet been demonstrated only *in vitro* (ROSENKRANTZ, 1959; MÜLLER and ZIEGLER, 1968) and it is not known whether this substance is of any physiological significance in the regulation of aldosterone secretion.

Table 2 presents experimental or pathophysiological situations regularly associated with an increased or reduced aldosterone secretion rate. A reduction in the circulating blood

Table 2. Control of aldosterone secretion

Aldosterone secretion	
Stimulating	Suppressing
Sodium depletion	Sodium loading
Potassium loading	Potassium depletion
Hypovolemia (hemorrhage)	Hypervolemia (plasma infusion)
Diminution of cardiac output	Increase of cardiac output
Diminution of renal blood flow	Nephrectomy
Upright posture	Supine posture
Constriction of the inferior vena cava	

volume is probably the stimulus leading to an increased aldosterone secretion, not only after hemorrhage but also in diseases characterized by edema (cirrhosis of the liver, nephrotic syndrome). Hypovolemia leads to an increase in renin production and an elevated level of plasma angiotensin II which then stimulates the aldosterone secretion. The receptors presumably lie in the kidneys, but their exact locations is unknown. They may be located in the juxtaglomerular cells or in the macula densa cells of the distal tubules, which are in the immediate vicinity of the juxta-glomerular cells. It is not known whether these are primarily pressure-, volume-, flow-, or chemo-receptors. An increase in aldosterone secretion in response to upright posture is also secondary to elevated renin production, which is probably mediated by the sympathetic nervous system.

A number of different factors appear to be involved in the adaptation of aldosterone secretion to alterations in sodium intake or sodium balance. A significant decrease in the serum sodium concentration is only observed in severe sodium deficiency. Even a moderate sodium deficiency, however, leads to hypovolemia and thus to an increase in renin production. However, in sodium-deficient sheep an increased aldosterone secretion rate is maintained for many hours after bilateral nephrectomy (BLAIR-WEST, 1964). In addition, the aldosterone-stimulating effect of angiotensin II, potassium ions, and ACTH is considerably more potent in sodium deficiency than in sodium balance, which is due partly to an increased sensitivity of the adrenal cortex and partly to increased activity of the enzymes involved in the conversion of corticosterone to aldosterone (MARUSIC, 1967; MÜLLER, 1968; DAVIS, 1968). Certain parts of the central nervous system also seem to be involved. In sodium-deficient sheep, midcollicular decerebration impairs the rapid decrease of aldosterone secretion in response to resumed sodium intake.

b) Regulation of the Plasma Cortisol Concentration

In the human, the cortisol secretion is directly dependent on the plasma concentration of corticotropin. The cortisol concentration in the plasma and the excretion of urinary 17-hydroxycorticosteroids are linearly correlated to the logarithm of the ACTH concentration in the plasma. The adrenal cortex is maximally stimulated by an ACTH concentration of 3 mU/100 ml. There is a circadian rhythm of ACTH concentration with an average value of 0.25 mU/100 ml at 6 a.m. and a fall to 0.1 mU/100 ml at 6 p.m. (Fig. 8).

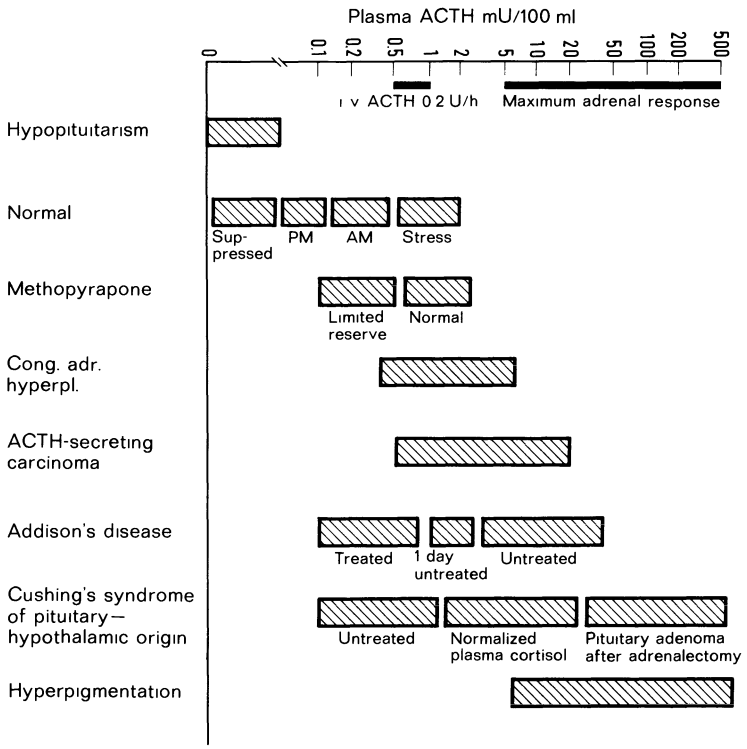

Fig. 8. Plasma ACTH in different clinical conditions. (From LIDDLE, ISLAND, and MEADOR, 1962)

An intravenous infusion of 0.25 units over 8 hours causes a significant rise in urinary corticosteroid excretion measured every 4 hours. A maximum response is elicited by 1 unit. Higher doses have a more prolonged effect. A basal ACTH secretion rate of 0.5 to 1 units per day has been calculated from infusion experiments. The rise in plasma cortisol in the morning is elicited by a dose of ACTH corresponding to a secretion rate of 4 units per day. The approved standard dose for diagnostic and therapeutic purposes is 25 units given in an intravenous infusion over 8 hours.

The plasma concentrations of cortisol or corticosterone are regulated by a control system which can be described in cybernetic terms as a closed-loop control with a negative feedback and a variable set-point. Most of the experimental and clinical data available on cortisol and corticosterone concentrations, secretion rates, metabolism, and excretion easily fit into a theoretical model of this type (YATES and URQUHART, 1962). Peripheral stimuli promoting the secretion of cortisol are integrated in the hypothalamus, elicit the release of a neurohormone (CRF, corticotropin releasing factor), which in turn mediates the secretion of corticotropin by the anterior pituitary gland. ACTH then stimulates the production and secretion of cortisol by the adrenal cortex. When the plasma cortisol concentration has reached the desired level the hypothalamic secretion of CRF is turned off, to keep the plasma cortisol concentration constant. As soon as the concentration of cortisol in the plasma decreases due to degradation by the liver, the inhibitory effect on the hypothalamic regulator ceases, CRF is again secreted, ACTH is released, and more cortisol is produced to restore the plasma concentration (Fig. 9).

This closed-loop control functions very rapidly. Cortisol can be secreted within seconds in response to a stimulus. The negative feedback control is effective within 15 sec.

Even the increased plasma cortisol concentration following acute stress and adrenal hyperplasia following chronic stress are consistent with the hypothesis of a closed-loop control system, if a variable set-point of the hypothalamic regulator is assumed. In chronic stress the system works in the normal way, maintaining an increased plasma cortisol level and an elevated secretion rate. However, an increased ACTH secretion in response to the stress of a surgical operation cannot be inhibited even by high doses of dexamethasone (LIDDLE, 1960). In a more recent publication, YATES (1967) therefore extended his model to include the possibility of a CRF secretion independent of negative feedback control. In this new model, the afferent stimuli are divided into a "corticosteroid-sensitive" and a "corticosteroid-insensitive" class.

Most experimental evidence indicates that the cortisol-sensitive regulator is located in the hypothalamus. Cortisol implants into closely defined sites of the median eminence and the post-optical region inhibit the stress reaction in animal experiments. Although certain animal experiments have suggested that cortisol has a direct inhibitory effect on the pituitary (DE WIED, 1961), cortisol implants are less effective in the pituitary gland than in the hypothalamus. Experiments using a microelectrophoretic technique and involving recordings of the action currents of individual neurons have recently suggested that the inhibitory action of the glucocorticoids is registered by the neurons in the upper central gray matter around the 3rd ventricle (RUF, 1967). A direct

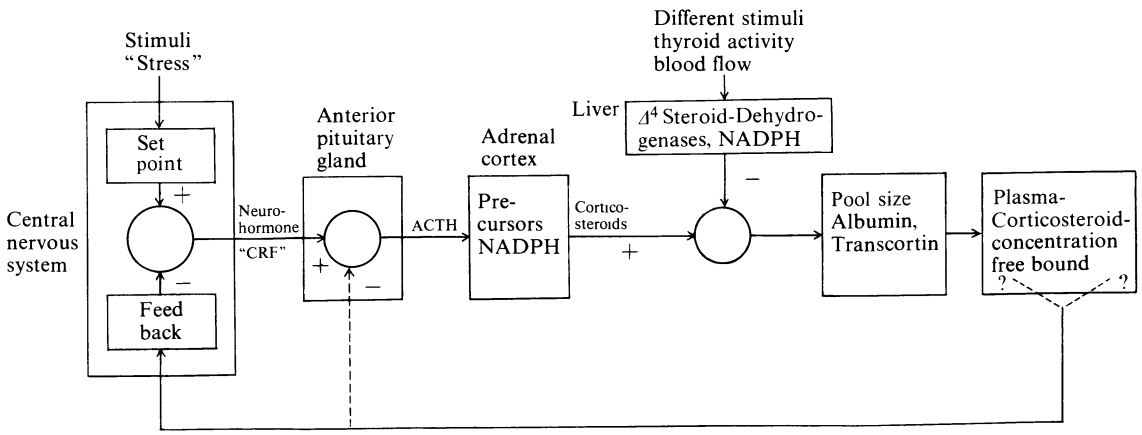

Fig. 9. Closed-loop regulation of the hypothalamic-pituitary adrenocortical system with variable set-point. (Simplified from YATES and URQUART, 1962)

inhibitory effect of cortisol on the adrenal cortex is only manifest at extremely high levels and is of no physiological importance.

c) The Hypothalamic ACTH-Releasing Neurohormone "CRF" (Corticotropin-Releasing Factor)

Information is transmitted from the hypothalamus to the pituitary gland by a humoral signal, since the functional unity is dependent on an intact portal venous system in the pituitary stalk, whereas there are no nervous connections to the anterior pituitary gland. Presumably, the neurohormones are formed in the tuberoinfundibular nucleus and particularly in the median eminence. The exact structure of the natural neurohormone CRF is still unknown. Several attempts to isolate the hormone have failed, mainly because the *in-vivo* and *in-vitro* bioassays used have not been sufficiently specific. Fractionation of hypothalamic and posterior pituitary extracts has yielded two types of active polypeptides which stimulate the production of ACTH *in vivo* and *in vitro*:

α-CRF is less active. It is a polypeptide consisting of 10 amino acids, and is structurally related to α-melanotropin. It is not known whether this substance is hormonally active or promotes ACTH synthesis by being one of its structural elements. A synthetic heptapeptide proved to have CRF activity *in vitro*, but not *in vivo*.

β-CRF, on the other hand, which is obtained from crude posterior pituitary extracts, is active even at extremely low concentrations and has a structure similar though not identical to that of vasopressin. Vasopressin itself exerts a CRF-like action, but only in high concentrations. In the intact animal, it acts predominantly as a stimulator of endogenous CRF secretion.

d) Suppressive Action of the Glucocorticoids on the Hypothalamus

The inhibitory effect of different natural and synthetic adrenal cortical hormones on the hypothalamus generally parallels their glucocorticoid and anti-inflammatory activity. Thus, among the synthetic corticosteroids, prednisone and prednisolone are 5 times more active and dexamethasone 40 times more active than cortisol in suppressing ACTH secretion.

Certain synthetic 21-deoxysteroids have a strong suppressive effect on ACTH secretion, whereas their action on the eosinophils and on carbohydrate metabolism is very weak. Thus, a dissociation of the various activities of synthetic steroids is possible at least in theory.

The administration of high doses of cortisol and cortisone leads to gradual functional impairment and atrophy of the adrenal cortex with a regressive transformation similar to that observed after hypophysectomy (see p. 95). Adrenal atrophy is prevented by the simultaneous administration of corticotropin. In man, a daily dose of 75 mg of cortisone acetate completely suppresses ACTH secretion. Adrenal atrophy develops rapidly. The adrenal response to ACTH is reduced even after a few days and is completely absent after a long-term therapy with high doses of cortisone. After withdrawal of cortisone therapy, the adrenals can only maintain a basal cortisol secretion, and are unable to increase their cortisol output in response to stress. Death due to adrenal failure secondary to cortisone therapy has been described. Adrenal atrophy due to either hypophysectomy or cortisone therapy is generally reversible. Intensive therapy with ACTH for two to four days usually restores adrenal cortical function to normal, even after many years of suppression (see secondary insufficiency, p. 325 ff.).

Certain C_{19}- and C_{21}-steroids have the property of preventing adrenocortical atrophy in rats treated with cortisone. The mechanism of this effect is unknown. It brings to mind the maintenance of the tubular testicular apparatus under testosterone therapy after hypophysectomy. Most of the active compounds are androgens. However, the adrenal atrophy preventing activity is not parallel to their androgenic activity. The effect was not demonstrable in man. It seems to be different from the general anabolic activity common to all androgens.

e) Circadian Rhythm of Plasma Cortisol

In the absence of extraordinary stress, the plasma cortisol concentration of healthy humans varies within certain limits in a fixed diurnal rhythm (5 to 25 μg per 100 ml). Plasma cortisol reaches its peak in the early hours of the morning, between 6 and 9 a.m., and falls continuously

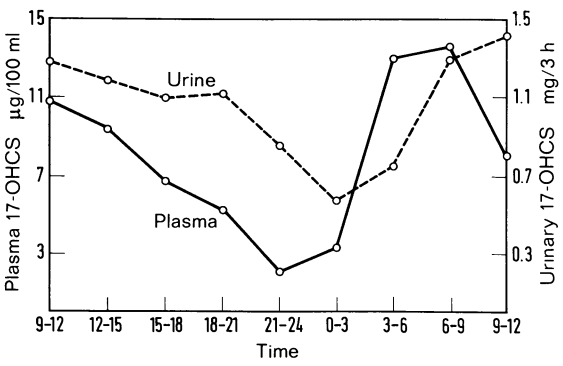

Fig. 10. Diurnal variation of plasma and urinary 17-hydroxycorticosteroids (17-OHCS). Mean values of 8 normal subjects. (From C. L. Cope, 1965; according to R. P. Doe, E. B. Flink, M. G. Goodsell, 1956)

during the day, reaching its lowest level around midnight (Fig. 10). At about 2 a.m. it rises again rapidly. When the urinary excretion of 17-hydroxycorticosteroids is measured every hour, the highest values are observed before noon, the lowest after midnight. The blood eosinophil count follows this rhythm in the opposite direction with a four-hour delay. It is highest during the night, and lowest in the morning. Plasma corticosterone levels follow the same circadian rhythm as plasma cortisol concentrations.

This rhythm is independent of light perception (occurring in blind subjects and in miners) and of physical activity, but is related to the sleep rhythm. After weeks of continuous night work and sleep during the day the rhythm can adapt to the new conditions (ORTH, 1967).

The circadian rhythm is controlled by the central nervous system and is altered or absent in brain diseases. It is mediated by ACTH secretion and disappears following prolonged stimulation or long-term administration of cortisone. The adrenals are more responsive to a standard dose of ACTH during the day than after midnight. This difference, however, disappears when a small amount of ACTH is given before midnight.

In Cushing's syndrome, the diurnal variation is characteristically absent. Abnormalities or absence of the circadian rhythms are also observed in certain psychoses, in cardiac diseases, and in renovascular hypertension. Elevated levels of plasma cortisol due to an increase of transcortin during estrogen therapy or during pregnancy, on the other hand, are characterized by a pronounced diurnal variation.

3. Biological Actions of the Adrenal Cortical Hormones

The physiologically most important adrenal cortical hormones can be divided into three groups according to their biological activity.

Hormones acting predominantly on sodium and potassium balance are called *mineralocorticoids* after SELYE, and hormones affecting carbohydrate and protein metabolism *glucocorticoids*. In both sexes, the adrenal cortex produces hormones with the properties of the male gonadal hormones: the *adrenal androgens*. It is not known whether their weak anabolic, i.e. protein synthesis-promoting, effect is of any physiological significance, or whether they play some part in maintaining normal libido in the woman (see p. 310).

The action of the individual hormones is not always restricted to one type of functions, and their activities can overlap. Cortisol, the most important glucocorticoid in man, also has a weak mineralocorticoid activity; some of its metabolites are slightly androgenic and thus also anabolic. The effect of glucocorticoids on carbohydrate metabolism is generally, but not always, paralleled by their anti-inflammatory, eosinopenic, thymolytic, and ACTH-suppressive activities.

Biological activity is always related to chemical structure. All steroids with mineralocorticoid or glucocorticoid activity are pregnane derivatives with 21 C-atoms, a 3-keto group, a double bond between C-4 and C-5 and an α-ketol side chain at C-17. The glucocorticoid activity is dependent on a hydroxyl or keto group at C-11, and is enhanced by a 17α-hydroxyl group. Adrenal androgens are derived from androstane; they have 19 C-atoms and a keto- or hydroxyl group at position 17. The structural basis of mineralocorticoid activity is still poorly understood.

In theory all the cells in the organism are under the influence of all the adrenal cortical hormones. However, whereas the tubular renal apparatus is the main target organ of the mineralocorticoids, the metabolism of all the cells is considerably influenced by the glucocorticoids.

The effects and activities of natural adrenal cortical hormones and synthetic derivatives of therapeutic value are listed in Tables 3 and 4.

a) Mineralocorticoids

α) Aldosterone

By regulating sodium and potassium balance, aldosterone controls the volumes and the cationic composition of the extracellular and intravascular fluids. Aldosterone receptors are found in the epithelia which are actively transporting sodium and potassium ions, and the most important target organs of aldosterone are the kidneys, the gut, the salivary and the sweat glands. In the human, its main action is on the tubular apparatus of the kidneys. Aldosterone promotes reabsorption of sodium in the distal tubule and leads to increased excretion of potassium and hydrogen ions. Although sodium reabsorption does not quantitatively correspond to potassium and hydrogen excretion, and the ratio of potassium to hydrogen ions is variable, the effect of aldosterone virtually consists of an exchange of sodium ions against potassium and hydrogen ions. According to the investigations of KASSIRER (1967), aldosterone does not directly promote the excretion of hydrogen ions. An additional effect of aldosterone on proximal tubular sodium reabsorption, sug-

gested by indirect evidence (WIEDERHOLT, 1965; HIERHOLZER, 1966), is still controversial. Aldosterone also promotes the excretion of magnesium and ammonium ions. The increased formation of ammonium in aldosteronism is, however, a result of the hypokalemia.

In primary aldosteronism or after prolonged administration of high doses of aldosterone (in man, 1 to 3 mg/day for 2 weeks), a compensatory mechanism for sodium retention, but not for potassium loss, can be observed. This so-called escape phenomenon only concerns the kidneys and does not involve the salivary and sweat glands. It is absent in diseases associated with edema (nephrosis, cirrhosis of the liver). The escape phenomenon is partly due to hemodynamically increased glomerular filtration. However, since it is also effective when glomerular filtration is decreased, other mechanisms must be involved. The escape phenomenon may be due to the action of an unidentified sodium excretion-promoting hormone, the so-called third factor, originating in the hypothalamus or the kidneys (BRICKER, 1967; LICHARDUS, 1966; JOHNSTON, 1967; MARTINEZ-MALDONALDO, 1967; DÖLLE, 1968; FREAZIER, 1968).

The mucosal epithelium of the toad bladder is functionally similar to the mammalian distal tubular epithelium. It reabsorbs sodium and water from the urine and thus initiates their transport into the interstitial fluid. This activity can be reproduced in vitro and can be stimulated by vasopressin or aldosterone (LEAF, 1955; CRABBÉ, 1961). However, there is no exchange between sodium and potassium in this tissue. When aldosterone is added to the incubation medium in extremely small amounts (3×10^{-10} to 10^{-7} mol per liter), there is a dose-dependent increase in sodium transport after a latency period of 1 to 2 hours. The action of aldosterone is associated with binding of the hormone to the nuclei of the mucosal epithelium cells, which can be demonstrated by autoradiography (PORTER, 1964). Binding occurs within 30 to 45 min. Aldosterone can be competitively dissociated from the active binding sites by other steroids with mineralocorticoid activity, as well as by aldosterone antagonists (progesterone, spironolactone). The inhibitory effect of certain antibiotics suggests that the action of aldosterone on sodium transport involves the synthesis of a deoxyribonucleic acid-dependent ribonucleic acid. It is assumed that under the influence of this RNA a specific short-lived protein is synthesized, which facilitates the entry of sodium into the mucosal cells. Stimulation of the sodium transport by aldosterone requires the presence of specific energy-supplying substrates (pyruvate, acetoacetate). Aldosterone is chemically unaltered while exerting its biological effect. Although the mammalian kidney is only partly comparable to the toad bladder, experiments with this model have yielded valuable information on a general mode of action of the mineralocorticoids.

Outside the kidneys, aldosterone also inhibits sodium excretion and promotes potassium excretion in the salivary and the sweat glands and in the gut. However, it is uncertain whether aldosterone can also directly influence the sodium and potassium transport across the plasma membranes of other cells. It is also uncertain whether aldosterone has a direct vasotonic effect and whether its digitalis-like positive inotropic action on the myocardium is physiologically important.

In physiological doses, aldosterone has no effect on carbohydrate metabolism, no anti-inflammatory properties, no suppressive effect on ACTH secretion, and no clear-cut eosinopenic effect, and it does not alleviate pigmentation in Addisonian patients. Due to the low aldosterone concentration in the plasma, its glucocorticoid activity, which is only approximately one third that of cortisol, is not apparent.

According to the normal daily secretion rate, the normal maintenance dose for an adrenalectomized man is 100 to 300 μg given subcutaneously or intramuscularly, 1 to 2 mg taken sublingually or 3 mg taken orally. Aldosterone is, however, seldom used for chronic maintenance therapy, since an equivalent oral dose of 0.1 mg of 9α-fluorocortisol is much more convenient and economical.

Aldosterone deficiency leads to hyperkalemia, hyponatremia, hypovolemia, hypotension, and metabolic acidosis, and aldosterone excess to hypokalemia, metabolic alkalosis, hypokalemic dysfunction of the kidney tubules with hyposthenuria, and hypertension. Aldosterone has no direct negative feedback effect on aldosterone production by the adrenal cortex or on renin production by the kidneys. However, an indirect feedback axis leads from sodium retention to hypervolemia and to the suppression of renin production. Long-term administration of mineralocorticoids results in atrophy of the zona glomerulosa of the adrenal cortex.

β) Deoxycorticosterone (Cortexone)

Deoxycorticosterone is a biological precursor of corticosterone and aldosterone and is only found in traces in the adrenal venous blood. It generally has the same mineralocorticoid effects as aldosterone, but is 20 to 40 times less active. On the other hand, it has no glucocorticoid activity.

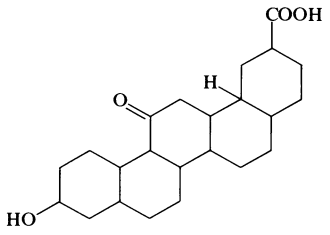

Fig. 11. Structure of β-glycyrrhetinic acid

Glycyrrhicic acid from licorice juice has a pronounced mineralocorticoid activity, but no glucocorticoid activity. Excessive intake, e.g. in the form of cough drops or in certain soft drinks, can lead to a disease very similar to primary aldosteronism (Fig. 11).

γ) Mineralocorticoid Antagonists

A natural adrenal cortical hormone which promotes sodium diuresis in physiological concentrations by inhibition of aldosterone action on the renal tubules has so far not been discovered in man. Progesterone in high doses corresponding to the secretion rate in advanced pregnancy, 17α-hydroxyprogesterone and testosterone can competitively inhibit the action of aldosterone on the kidneys and other target organs. By contrast, 3β,16α-dihydroxyallopregnane-20-one is inactive in man. Synthetic steroids of the spironolactone group are more effective aldosterone antagonists. They act only in the presence of mineralocorticoids and have no natriuretic effect in adrenalectomized animals not treated with mineralocorticoids (Fig. 12).

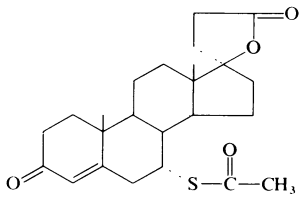

Fig. 12. Structure of the aldosterone antagonist spironolactone (aldactone)

Triamterene, a pteridine derivative, has a similar action to spironolactone, but is also effective in the absence of mineralocorticoids. It is, therefore, not a true aldosterone antagonist.

The substance 3-(1,2,3,4-tetrahydro-1-oxo-2-naphthyl)-pyridine (SU 9055, Ciba) directly inhibits 18-hydroxylation and leads to a decrease in aldosterone secretion and to an increase in corticosterone secretion. Heparin and natriuretic heparinoids act by indirect inhibition of aldosterone biosynthesis. The reader is referred to p. 302 for a discussion on the natriuretic "third" factor, which may be a hormone.

b) Glucocorticoids

α) Corticosterone

Corticosterone is a natural adrenal cortical hormone with glucocorticoid and mineralocorticoid properties. When taken orally, its activity is very weak, but it is more effective when administered parenterally. It has a weak aldosterone-like effect on sodium and potassium balance. It has a slight effect on glucose tolerance and protein metabolism. Eosinopenic and anti-inflammatory activities are absent.

β) Cortisol

Although the text below only refers to cortisol, cortisone and numerous synthetic corticosteroids have the same physiological and pharmacological activities.

The metabolic action of cortisol supplies glucose to the body by the transformation of proteins. Thus, the overall effect of cortisol is an ergotropic one, directing metabolism from a phase of growth and storage towards increased physical activity and energy consumption. Very little is known about any cellular or molecular base of the mode of action. The reader is referred to the reviews by WEISSMANN (1964), WEBER (1968), and RAY (1968).

1. Effect on Carbohydrate Metabolism. Cortisol stimulates gluconeogenesis, i.e. the formation of carbohydrates from amino acids by mobilization and degradation of protein. Gluconeogenesis makes it possible for blood glucose levels to be kept constant during fasting without depletion of the glycogen stores of the liver.

Newly formed glucose is partially converted to fat under the influence of insulin. The glucose turnover rate is thus accelerated, the blood sugar elevated by 10 to 20 mg%, and glucose tolerance and insulin sensitivity decrease. However, carbohydrate metabolism is still firmly controlled as long as the pancreatic islets are functionally intact.

So-called "steroid diabetes", i.e. a benign form of diabetes with a low incidence of ketosis, a low sensitivity to insulin and a decreased renal threshold for glucose, develops in only 20% of patients treated with high doses of cortisone. It is striking that 20 to 25% of the Western population are estimated to be predisposed to diabetes mellitus.

Gluconeogenesis is maintained mainly by the liver with slight contributions by the kidneys and the intestinal epithelia.

The mechanism of action is not clear. Under the influence of cortisol, the content of certain

glycolytic enzymes, as well as of glutamate-pyruvate-transaminase, fructose-1,6-diphosphatase, glucose-6-phosphatase among others, increases in the liver. However, this may be the consequence of increased availability of substrates rather than the primary effect of cortisol. The effect on gluconeogenesis is not blocked by inhibitors of protein synthesis, such as actinomycin D (for literature see RAY, 1968).

Cortisol increases the very low physiological glycosuria (by 50 to 200 mg/24 hours) by simultaneously raising blood sugar and glomerular filtration rate. On the other hand, glucose reabsorption in the proximal tubule is not inhibited. The maximum capacity for tubular glucose reabsorption remains unaltered (FROESCH, 1958).

Cortisol apparently also has a permissive effect on the glycogenolytic action of adrenaline; i.e. normal glycogenolysis due to adrenaline is only possible in the presence of cortisol.

An earlier assumption that cortisol inhibits peripheral glucose degradation has not been confirmed. The increased level of pyruvic acid in the blood is due to increased glucose turnover rather than to decreased catabolism. Glucose uptake is inhibited only in the isolated adipose tissue (see below).

2. Effects on Protein Metabolism. Cortisol leads to a negative nitrogen balance which can be alleviated by a high intake of carbohydrates or protein. As demonstrated by studies with labeled albumin, protein degradation is increased, and is not fully compensated by a simultaneously increased protein synthesis. The synthesis of ribonucleic acids and of certain enzymes involved in protein metabolism in the liver is accelerated. Protein degradation also occurs outside the liver.

Cortisol increases amino-acid excretion. The kidney threshold for amino acids remains constant, but the plasma concentration increases. Cortisol promotes the excretion of uric acid without affecting its serum concentration. According to studies with isotopically labeled uric acid, this is due to an increase in uric acid clearance.

The negative nitrogen balance induced by the catabolic effect of glucocorticoids can lead to bone, muscle or skin damage, as well as to growth impairment in children. Degradation of bone matrix and osteoporosis, muscular waste, atrophy and vulnerability of the skin are manifestations of the negative protein balance induced by long-term therapy with high doses of cortisol or cortisone, or by Cushing's syndrome. Experiments with thymocytes have yielded valuable information about the mode of action of cortisol through RNA and DNA (see p. 305) (MAKMAN, 1967).

3. Effect on Lipid Metabolism. Cortisol has an indirect effect on lipid metabolism by its action on carbohydrate metabolism. Adrenalectomy is followed by loss of appetite and thus by lipid depletion in the organs. After exhaustion of the carbohydrate stores, fat is used mainly as a source of energy, because in the absence of glucocorticoids proteins are not accessible. *In vitro*, cortisol inhibits glucose uptake by isolated adipose tissue. This decreases the rate of glycerophosphate formation and thus the re-esterification of free fatty acids to triglycerides, resulting in an increased output of free fatty acids. In the intact organism, this effect is overcompensated by an increased insulin secretion leading to fat deposition, as for instance in Cushing's syndrome (see p. 340ff.).

4. Effects on Electrolytes. Cortisol acts in a similar manner to the mineralocorticoids on urinary and plasma electrolytes by promoting sodium retention and potassium excretion, but is approximately 1000 times less potent than aldosterone. This effect, however, is dependent on the mode of administration, the dosage, and the duration of cortisol administration. In low doses, cortisol can promote sodium diuresis. Cortisol and cortexone, given simultaneously in low doses, have an additive, and not a competitive effect on electrolytes. The serum potassium may be elevated despite an increased excretion of potassium in the urine, which indicates that high doses of cortisone primarily promote the transport of intracellular potassium into the extracellular space. In the healthy human, the effect is most marked early in cortisone therapy. With continued administration, it gradually decreases and may finally become reversed, resulting in sodium loss and potassium retention. Potassium retention may be due to increased glycogen storage in the liver. The loss of intracellular potassium is compensated by the uptake of sodium and hydrogen ions from the extracellular space, which leads to metabolic alkalosis. The excretion of H-ions is not directly influenced by cortisol, but depends on phosphate excretion. Nor is any promoting effect of cortisol on bicarbonate reabsorption demonstrable. The alkalosis is therefore only a result of altered potassium distribution.

Calcium and phosphate excretion are stimulated by cortisol. They exceed the expected values calculated from the nitrogen balance. This is partially due to increased phosphate clearance. In addition, cortisol promotes calcium excretion into the gut, and inhibits

intestinal and renal tubular reabsorption and calcium mobilization from the bones. In healthy subjects, this hypocalcemic action is effectively compensated by the normal mechanisms regulating calcium homeostasis. However, in various diseases, cortisol and its derivatives can lower an increased blood calcium level. Hypercalcemia is occasionally observed in adrenal cortical failure (see p. 318f.).

5. Effect on Water Homeostasis. The inability to achieve rapid diuresis in response to a water load has long been recognized as a symptom of Addison's disease and has been used as a diagnostic test (see p. 391). Normal rapid water diuresis is restored by cortisol therapy but not by treatment with mineralocorticoids such as cortexone or aldosterone.

The deficient water diuresis in adrenal failure is not due to delayed absorption from the gastrointestinal tract, but rather to insufficient excretion through the kidneys. The diuretic effect of cortisol is partly due to increased glomerular filtration. It also acts permissively on water permeability of the distal tubular segments during diuresis. An effect on vasopressin action is probable (see Chap. IV, p. 49).

6. Effects on Tissues. Cortisol does not act uniformly on all the tissues, since the sensitivity of the cells to cortisol varies according to their origin and their stage of development.

In general, tissues arising from entoderm are little affected, whereas mesenchymal and ectodermal epithelial components are strongly influenced. The action of cortisol depends very much on the species, and information obtained from animal experiments can only be extrapolated to human pathophysiology with reservations.

Some tissues are directly affected by cortisol, and others indirectly via metabolic changes. Direct effects have been observed in connective tissue, adipose tissue, the lymphatic system, and blood, and predominantly indirect effects in muscle and bone. On the other hand, connective tissue, in particular the fibroblasts, can inactivate cortisol by conversion and degradation (see p. 293).

Connective Tissue. Undifferentiated mesenchymal tissues are particularly sensitive, in contrast to mature tissues such as granulation tissue of scars, which is hardly affected. Growth of fibroblasts is inhibited. Collagenous fibers are converted into a homogeneous mass. Basic substance is reduced, and its content of acidic mucopolysaccharides is decreased. Elastic fibers are not affected, but appear to be more numerous due to the loss of other tissue components.

The inhibitory effect of cortisol on connective tissue is most pronounced in inflammatory reactions with proliferation of granulation tissue. However, exsudation is affected as well as proliferation. Vascularization is inhibited, capillary permeability is decreased. The infiltration of leukocytes and phagocytes is reduced. Experimental peritoneal adhesion can be prevented by cortisol. Cortisol protects the lysosomes against various noxious influences (WEISSMANN, 1964).

Whenever inflammation is purposeful as in resistance to infection, the anti-inflammatory effect of cortisol is harmful. However, it is of greatest therapeutic importance when the organism might be damaged by the inflammatory process, as in allergic conditions. The anti-inflammatory activity of cortisol is only manifest at doses well above the physiologic range of 20 to 40 mg per day, which corresponds to the endogenous production rate under normal conditions. As a rule, an anti-inflammatory effect can be achieved only with doses of over 75 mg of cortisol per day in adults and 45 mg/m^2 in children.

Wound healing is closely related to inflammatory processes and is also inhibited by the anti-inflammatory action of cortisol. In particular, cortisol impairs the formation of granulation tissue, but hardly affects epithelization. In practice, however, wound healing is not much affected in patients treated with high doses of cortisol. Healing of the operation wound following adrenalectomy is not much delayed, even with daily doses of 50 to 100 mg of cortisol.

SELYE contrasted the anti-inflammatory action of glucocorticoids with the inflammatory effect of mineralocorticoids. Large doses of cortexone promoted inflammatory processes in animals following unilateral nephrectomy or during excessive salt intake. This effect was suppressed by cortisol. However, it is very questionable whether mineralocorticoids play any role in the pathogenesis of inflammatory diseases (see p. 311).

Muscles. Cortisol is necessary for normal muscular activity. Excessive cortisol leads to atrophy and fibrosis due to protein degradation.

Lymphatic Tissue and Thymus. During cortisol therapy, lymphocytes disappear from the lymph nodes and from the thymus. Reticular tissue shrivels. The nuclei become pyknotic, and the reticular network is destroyed. The rarity of intermediate forms between immature and ma-

ture lymphocytes and signs of degeneration of the mother cells indicate that the formation of lymphocytes and thymocytes is impaired. Cortisol also affects the lymphocytes, reducing their cytoplasm, destroying the nuclei, and inhibiting mitosis. Recent investigations on the influence of cortisol on thymocyte metabolism give some insight into the mode of action of glucocorticoids on protein and RNA metabolism, and into the role of these biochemical events in the immunization process. In rat thymocytes exposed to cortisol *in vivo* or *in vitro*, RNA, DNA and protein synthesis are reduced, and the transport of precursors of nucleic acids and proteins across the cell membrane is delayed. This inhibitory effect can only be observed when the medium contains a source of energy. Cortisol injected *in vivo* causes a further reduction in the activity of the DNA-dependent RNA polymerase and thus in ribosomal-protein synthesis (MAKMAN, 1967). All these effects are interdependent. Cortisol also produces signs of degeneration in the mast cells and causes a reduction of their number.

An effect of cortisol on phagocytosis of the reticuloendothelial system is controversial.

7. *Effect on Blood Cells.* Blood cells are influenced by cortisol. Cortisol leads to an increase of total leukocytes, but reduces the numbers of eosinophils and lymphocytes. It increases the number of thrombocytes. The effect on the red blood cells is less distinct: adrenalectomy leads to normochromic, normocytic anemia with increased osmotic resistance of the erythrocytes, which can be prevented by cortisol administration. Whereas polycythemia can be a manifestation of Cushing's syndrome, it has not been observed to result from cortisol administration.

Eosinophils. The eosinophil count is usually in inverse proportion to the cortisol concentration in the plasma, but the individual variations in this parameter are very wide (for diurnal variation see p. 301).

Eosinopenia induced by cortisol is of some diagnostic importance. It can be observed after oral as well as after intravenous administration of cortisol, and reaches a maximum within 4 hours. The resorption of cortisol given by i.m. injection is too slow to provoke a distinct eosinopenic effect. The eosinophils return to the original level as the cortisol concentration falls in the blood. The eosinophil count remains low in the presence of constant high cortisol concentration.

The mechanism of the eosinopenic effect of cortisol is still not clearly understood. The following possibilities have been considered:

1. Inhibition of supply from bone marrow.
2. Fixation and decomposition in specific organs (spleen, lungs, reticuloendothelial system).
3. Direct destruction by cortisol.

Observations on an influence of cortisol on the eosinophils of bone marrow are contradictory. The eosinopenic effect of cortisol is manifest even in the absence of the spleen. An increased number of degenerative forms of eosinophil leukocytes in body fluids has been observed during cortisol administration. However, extensive investigations have excluded a direct effect of cortisone and cortisol on the eosinophils. The eosinopenic action of cortisol is abolished when the reticuloendothelial system is blocked. *Cortisol appears to sensitize the eosinophils to destructive forces independent of the adrenals and also to inhibit the efflux of the eosinophils from organs in which they are formed, stored, or degraded.* Cortisol may attack the enzyme systems of nucleic acid metabolism. For mast cells see p. 305.

Lymphocytes. In contrast to the eosinophil count, the lymphocyte count returns to normal after a short period of time in spite of continued cortisol administration. It is uncertain whether cortisol destroys lymphocytes or whether the lymphopenia is due to the inhibition of efflux from the reticuloendothelial system. The lymphopenic action affects the lymphocytes in the blood-stream as well as the fixed lymphocytes of the lymphatic tissue and the thymus.

Neutrophil Leukocytes. The neutrophil leukocyte count increases under the effect of cortisol. This is due to stimulation of the bone marrow, and long-term cortisol therapy can lead to myeloid hyperplasia. Fatty infiltration of the bone marrow, with increased erythroblasts and decreased myeloblasts, has also been observed during cortisol therapy.

Thrombocytes. The thrombocyte count is increased by 30 to 60% within 6 hours after cortisol administration. The other clotting factors are not influenced.

8. *Effect on Circulation.* Cortisol is probably involved in blood pressure regulation, for hypotension is a sign of Addison's disease and hypertension of Cushing's syndrome. However, whereas cortisol can restore normal blood pressure in adrenal failure, hypertension cannot be induced in healthy subjects even by long-term administration of cortisol in high doses unless they have a predisposition. Cortisol

does not affect plasma renin and angiotensin levels. On the other hand, there is a synergism between noradrenaline and cortisol. Cortisol has a permissive effect on noradrenaline action. Noradrenaline raises blood pressure only in the presence of cortisol. Deoxycorticosterone is ineffective. Cortisol can lead to morphological alterations of the blood vessels. In experimental animals it induces vascular reactions similar to those observed in the Kimmelstiel-Wilson syndrome in diabetics. In man, changes reminiscent of diabetic retinopathy have been observed during cortisol administration. Capillary resistance increases, but increased fragility of the large vessels leads to suffusions: this is frequently observed in Cushing's syndrome.

There seems to be some connection between the action of cortisol on vessels and arteriosclerosis. Serum cholesterol is not changed by cortisol. Nevertheless, arteriosclerosis has been observed in 11-year-old children after long-term administration of cortisone in high doses. On the other hand, cortisol apparently has no influence on the S_f 10-20-lipoproteins, which are related to arteriosclerosis.

9. Effects on the Gastrointestinal Tract. Cortisol promotes the production of hydrochloric acid and pepsin by the stomach, but not regularly. The increased excretion of uropepsin is due to increased clearance. Neither the first vagal phase nor the second phase of hydrochloric acid secretion is mediated by increased cortisol secretion. On the other hand, cortisol appears to stimulate the sensitivity of the gastric mucosa to histamine and to increase the number and height of its parietal cells. Gastric ulcers occur more frequently during high-dose cortisol therapy. They are rarely found in untreated Addisonian patients, but are not more frequent in Cushing patients than in normals. Even achylia does not prevent the development of cortisol-induced ulcers. The pathogenesis is uncertain. Cortisol appears to alter the composition of the gastric mucus, thus affecting its protective action on the gastric mucosa (SPIRO, 1960).

10. Effects on the Nervous System. In animals, high doses of cortisol can lead to chromatolysis and cytoplasmatic vacuolization in the regions of the hypothalamic paraventricular and supraoptic nuclei.

Retardations in the electroencephalogram of Addisonian patients disappear during cortisone maintenance therapy. In Cushing's syndrome and after treatment with high doses of cortisone, abnormalities not due to changes in glucose metabolism are observed in the electroencephalogram. Cortisol increases the excitability of the brain. This is seen in the lowered threshold for the induction of generalized convulsions by an electric shock. Deoxycorticosterone has the opposite effect.

Cortisol therapy can lead to the development of an endocrine psychosyndrome characterized by chronic changes in mood and motivation, excessively uncertain temper, and sudden compulsive urges, which may develop into a short-term psychosis.

The stimulation of appetite by cortisol is possibly due to increased carbohydrate turnover.

11. Effect on Pregnancy. In rats but not in monkeys, malformation of the fetus has been observed after treatment with high doses of cortisol during pregnancy. In humans, fetal damage has not yet been observed following treatment with cortisone or ACTH in normal anti-inflammatory doses during pregnancy. Intensive treatment during the last month of pregnancy may result in temporary adrenal insufficiency of the newborn (hypoglycemic coma).

12. Correlation with Other Endocrine Glands. Cortisol inhibits TSH secretion at a suprahypophyseal level (WILBER, 1969). For correlation with catecholamines, see Chap. VIII, p. 424.

13. Effects on the Whole Organism. Cortisol plays a significant role in the defense mechanism of the body and in nonspecific as well as specific resistance. The lack of resistance in patients with adrenal failure has been known since ADDISON's classic description. The classic bioassay for adrenocortical hormones is based on increased tolerance of poisons in adrenalectomized animals.

Little is known about the mechanism of this striking increase in nonspecific resistance under the influence of cortisol. Its metabolic effects may play a role, in particular the rapid availability of glucose and the influence on enzyme systems. See also general adaptation syndrome, p. 310.

On the one hand, the effect of cortisol on specific resistance, i.e. immunity, is related to its anti-inflammatory effect. The anti-inflammatory action (p. 305) is not restricted to inhibition of local inflammatory processes, but also pertains to general reactions, such as fever and other general toxic manifestations. However, resistance is not always increased by these anti-inflammatory effects, but may also be diminished, because the impairment

of an inflammatory reaction can be harmful and promote the propagation of infectious agents (BEISEL, 1969).

On the other hand, cortisol may inhibit the formation of antibodies when it is administered prior to the antigen, possibly through inhibition of protein synthesis or by some effect on the antigenic stimulus. This effect is probably related to the involution of the thymolymphatic apparatus. Cortisol may enhance the transport of antibodies into the intracellular space.

Cortisol suppresses allergic reactions by altering the reactivity of the tissues. The antigen-antibody reaction itself cannot be inhibited. It affects the formation of histamine, but not the action of formed histamine. Cortisol impairs the conversion of kininogen to kinin by kallikrein (see Chap. XV).

γ) Cortisone

Cortisone has been isolated from the adrenal cortex, but is found only in traces in adrenal venous blood and in peripheral blood. Cortisol is partly converted to cortisone before it is inactivated by the liver. Conversely, cortisone can also be converted to cortisol. In principle, cortisone has the same physiological activities as cortisol, but is approximately 25 to 50% less active. In contrast to cortisol, cortisone has no anti-inflammatory effect when applied locally.

δ) Synthetic Corticosteroids

The introduction of halogen atoms or methyl groups and the reduction with formation of new double bonds lead to qualitative and quantitative changes in the activities of cortisol, thereby increasing the desired therapeutic properties and diminishing or abolishing undesirable side-effects.

Dissociation of the various activities is possible in principle. Thus, the sodium-retaining activity, unwanted in anti-inflammatory therapy, has been successfully removed. On the other hand, the anti-inflammatory effect has not yet been dissociated from the harmful catabolic and gluconeogenetic activities, which are always in proportion to the therapeutic effect. Also, ACTH suppression always parallels the anti-inflammatory activity in all compounds used in therapy, although some corticosteroids are known which actively suppress ACTH secretion but have only minimal effects on the eosinophils and on glucose metabolism (KENDALL, 1963).

The following alterations of the cortisol molecule are of therapeutic importance:

– Reduction of the A ring (double bond between C-1 and C-2) increases glucocorticoid activity and decreases mineralocorticoid activity.

– Fluorination in position 9α greatly increases the glucocorticoid activity, but enhances the mineralocorticoid activity even more strikingly.

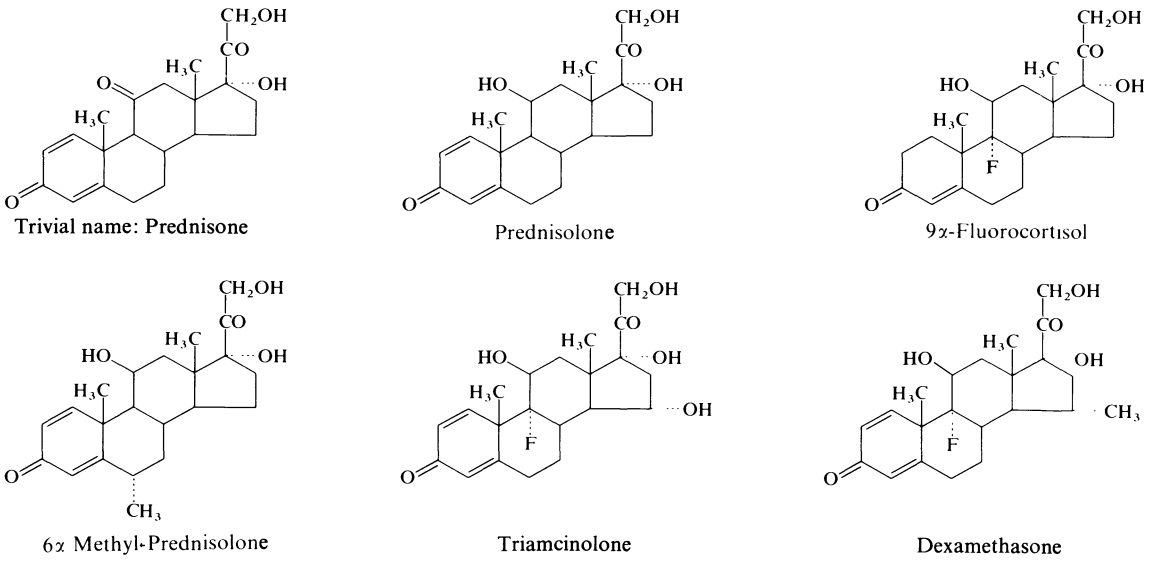

Fig. 13. Structures of the most important synthetic corticosteroids

– Methylation in 6α increases glucocorticoid activity.
– Methylation or hydroxylation in 16α decreases the mineralocorticoid activity.

The following synthetic corticosteroids are of therapeutic importance:

Prednisone, Prednisolone. These are the two synthetic steroids most frequently used today. Their glucocorticoid activity is 4 to 5 times greater than that of cortisol, whereas their mineralocorticoid activity is much lower. Even when given in high anti-inflammatory doses their sodium- and water-retaining effect is negligible. Their other side-effects, such as hyperglycemia, negative nitrogen balance leading to osteoporosis, peptic ulcers, rounding of the face, and acne, parallel their increased therapeutic effect.

Dexamethasone. Among the corticosteroids used in therapy, dexamethasone has the highest anti-inflammatory, hyperglycemic and ACTH-suppressive activity per mg. Sodium-retaining activity is completely absent. Since its metabolites in the urine are quantitatively negligible, this compound is useful for the diagnostic dexamethasone-suppression test (see p. 389), as well as for suppressive therapy in which the excretion of urinary steroids is used as a parameter of pituitary activity.

Table 3. Steroids with equivalent antiphlogistic activity

Cortisone	25 mg
Cortisol (hydrocortisone)	20 mg
Prednisone	5 mg
Prednisolone	5 mg
Methyl-prednisolone	4 mg
Triamcinolone	4 mg
Paramethasone	2 mg
Dexamethasone	0.75 mg
Betamethasone	0.75 mg
Water-soluble preparations:	
Cortisol-hemisuccinate	
Prednisolone-hemisuccinate	
Prednisolone-Na-tetrahydrophthalate	
Methyl-prednisolone-hemisuccinate	
Dexamethasone-phosphate	

The glucocorticoid activities of other synthetic corticosteroids, such as triamcinolone, methyl-prednisolone, paramethasone, and betamethasone, are between those of prednisone and those of dexamethasone. These compounds offer no advantages. They are characterized by differences in protein binding and in biologic half-life. It is not known whether this is of therapeutic importance (see Chap. XX).

Fluorocortisol. 9α-Fluorocortisol has a high glucocorticoid activity but an even more potent mineralocorticoid activity, equal to that of aldosterone. It can only be used locally as an anti-inflammatory agent, because of its potent sodium-retaining activity.

However, it is fully active as a mineralocorticoid when given orally and is therefore very useful as a supplement to cortisone in maintenance therapy of adrenal failure (see p. 329).

Table 4. Effects of adrenocortical hormones

Mineralocorticoids:	Sodium retention
	K^+-, H^+-, Mg^{++}-, NH_4^+-excretion
	Expansion of extracellular space
Glucocorticoids:	Increase of glucose turnover
	Elevation of blood sugar
	Promotion of gluconeogenesis
	Diminution of glucose tolerance
	Catabolic activity
	Promotion of glomerular filtration
	Eosinopenic activity
	Lympholytic activity
	Antiphlogistic activity
	Immunosuppressive activity
Androgens:	Pubic and axillary hair of the woman
	Excessive amounts:
	Acne
	Anabolic and virilizing activity

c) Adrenal Androgens

Little is known about the physiological importance of the secretion of adrenal androgens (dehydroepiandrosterone sulfate, androstenedione, 11β-hydroxyandrostenedione), which is considerable both in man and in woman. The anabolic effect of these predominantly weak androgens becomes important only when they are secreted in excessive amounts. ALBRIGHT's term "N-hormone" (nitrogen-retaining hormone) is not applicable to these androgens. It is still uncertain whether dehydroepiandrosterone, which, strangely, is secreted mainly as a sulfate, has any biological function at all or is merely a by-product of corticosteroid synthesis. The concentration of this compound in the plasma is almost as high in the newborn as in adults, but rapidly decreases to levels too low for assay after birth. It reappears in both boys and girls at the time of puberty, reaches a maximum between the ages of 20 and 40, disappears again in advanced age. The diurnal variation parallels that of cortisol. It is possible that dehydroepiandrosterone first promotes the spurt of growth during puberty in girls (see Chap. XIX) and then terminates it.

The only definite physiological effects of the adrenal androgens are the production and maintenance of pubic and axillary hair, and the stimulation of the sebaceous glands in the woman. The assumption that the psychosexuality of the woman is dependent on adrenal androgens is only partially true. The isolated loss of these hormones does not always affect the sexuality of the mature woman. The individual life history appears to be more important. Androgens are less important than estrogens. They are not important to the psychological maturation of girls (BLEULER, 1964).

Recently, the possibility has been considered that certain metabolites of steroid hormones may be of physiological or pathological importance. Thus, it is known that androsterone lowers serum cholesterol. Steroid metabolites can be active as coenzymes of various dehydrogenases. New possibilities have been suggested by the discovery that etiocholanolone and other steroid metabolites with 5β-H configuration (pregnanolone, pregnanediol, 11-ketopregnanolone, lithocholic acid) can produce fever in man. Intramuscular injection leads to a local inflammation, but not to an increased plasma concentration of this steroid. In contrast, elevated levels of plasma etiocholanolone are found during the periodic attacks of fever in patients with so-called etiocholanolone fever. This is probably due to an impairment of androgen metabolism and conjugation of genetic origin (see Chap. IX, p. 449). Moreover, C_{19}- and C_{21}-steroids and their metabolites, such as etiocholanolone and pregnanolone, can promote the synthesis of porphyrin (KAPPAS, 1968).

4. The General Adaptation Syndrome

According to SELYE'S theory of the general adaptation syndrome, various stresses, such as cold, heat, exhaustion, hunger, infection, intoxication and somatic and psychic trauma, lead to specific alterations in the organism, depending on the type of stress, and to a stereotype response of the organism in the form of a clearly defined syndrome. The most striking manifestations of this general adaptation syndrome are involution of the thymolymphatic apparatus, eosinopenia, gastroduodenal ulcers, hyperplasia of the adrenal cortex with depletion of lipids and cholesterol, and increased excretion of corticosteroids in the urine.

A major role within this mechanism of adaptation is played by the pituitary adrenocortical system, as is suggested by the fact that several important manifestations of the syndrome, i.e. eosinopenia, involution of the lymphatic system and increased secretion of adrenocortical hormones, are not observed after hypophysectomy or adrenalectomy. The development of gastro-duodenal ulcers is not dependent on the integrity of the pituitary adrenal system. Their pathogenesis is not known.

The course of the general adaptation syndrome is characterized by three distinct phases: During the first phase, the so-called alarm reaction, adaptation is not yet developed. This stage is characterized by shock, hemoconcentration and increased capillary permeability. In response to shock, counterdirectional changes occur. The second stage, increase in resistance, is characterized by optimal adaptation. The third phase is the stage of exhaustion, when adaptation is lost again.

The mechanism of adaptation is as follows: A damaged area of the organism informs the pituitary adrenal system through a primary mediator of unknown nature. The pituitary reacts by releasing ACTH, which activates the adrenals.

According to SELYE, the adaptation syndrome can be beneficial or harmful to the organism, depending on the conditions. During the phase of resistance, the defense against other noxious influences may be either increased or decreased. SELYE called the first process crossed resistance and the second crossed sensitization. Thus, even in the stage of resistance, the defense against all nocuous influences is not increased.

This part of SELYE'S theory has been confirmed by clinical experience. It explains why patients with adrenal failure due to Addison's disease or hypopituitarism are defenseless against additional stress and can die in shock during infection, accidents, or surgery.

The theory of the general adaptation syndrome has also solved the problem of the connection between the thymus gland and sudden death. In cases of sudden death, an enlarged thymus gland and strongly developed lymph nodes are generally found. This has led to the term "status thymolymphaticus". The overdeveloped thymus and lymphatic tissue used to be considered a direct cause of sudden death. However, during the First World War it was observed that status thymolymphaticus was also a common finding in youths dying from war injuries. Thus, the pronounced development of the thymus and the lymphatic system is normal in youths, whereas the atrophy of these organs found at autopsy is the result of prolonged illness.

The overactivity of the pituitary adrenocortical system during the stage of resistance evoked by stress leads to shrinkage of lym-

phatic and thymus tissue. It is uncertain to what extent the status thymolymphaticus may also be due to insufficiency of the pituitary adrenal system. It is possible that individuals with status thymolymphaticus cannot respond adequately to stress with an increase in the activity of the pituitary adrenal cortical system.

Clinical investigation of the reaction to stress by the human organism with an intact pituitary adrenal cortical system has largely confirmed SELYE's experimental findings. Both muscular work and hypoglycemia lead to an increase in plasma corticosteroids. Surgery can cause a rise in plasma corticosteroids, but so can anesthesia alone, or even the strain of the preoperative day. Psychological strain in soldiers awaiting a battle, or the psychological excitement of sport contests rather than the physical exertion, lead to increased cortisol secretion. A submaximal rise in plasma corticotropin accounts for the rise in plasma cortisol during surgical operations.

In particular, acutely developing illnesses accompanied by pain cause a rapid rise of plasma cortisol, which is due rather to the pain than to the organic lesion. Analgesic treatment brings the plasma corticoids back to normal. An elevation in plasma cortisol is characteristic in myocardial infarction, pancreatitis, aortic aneurysm, pulmonary edema, renal infarction and diabetic coma. However, it is not pronounced in chronic febrile conditions where there is septicemia but no acute complications. In other diseases, an increase in plasma cortisol may be entirely absent despite an intact pituitary adrenal system, according to a normal ACTH test. Finally, the extreme agonal increase in plasma cortisol immediately before death is not due to a final stimulation of the extremely overactive adrenal cortex, but rather to insufficient catabolism by the damaged liver. Similarly, a postoperative rise in plasma cortisol is due partly to increased secretion, but partly also to delayed degradation and inactivation.

Whereas it is true that the pituitary adrenal system is activated by stress, the usefulness of this reaction and the possible therapeutic value of cortisol and ACTH in this situation is still debatable.

First, there is no correlation between the extent of adrenal stimulation and the severity of the stress or the damage to the organism. The fact that the degree of adrenal reaction is dependent on the subjective effects of stress, in particular pain and fright, rather than on physical damage leads one to doubt the usefulness of this reaction in the defense of the body against stress. Recovery from surgery is not dependent on the level of plasma cortisol. Patients with moderately increased plasma cortisol can recover rapidly, whereas even a high plasma cortisol cannot prevent a fatal outcome. A slight increase in plasma steroids does not indicate an unfavorable course of the illness. It is therefore not reasonable to stimulate the system further by ACTH or to administer cortisol. An intact pituitary adrenal system is always capable of producing the cortisol needed for the defense reaction. In some cases, suppression of this system may be preferable (hypothermia, anabolic hormones).

Finally, experiments have shown that cortisol plays only a permissive or conditioning role in the metabolic events following stress. As demonstrated by INGLE, the negative nitrogen balance induced by stress depends on the presence of cortisol, but is quantitatively related only to the extent of damage and not to the amount of cortisol present.

Administration of cortisol to improve nonspecific resistance is only indicated in established pituitary or adrenal insufficiency. This statement does not apply to the pharmacological use of cortisone and prednisone as anti-inflammatory drugs when this is clearly indicated (see Chap. XX).

Besides describing this specific manner of reaction of the organism, SELYE has also attempted to explain a number of diseases (polyarthritis, periarteritis nodosa, nephrosclerosis, myocarditis) on the basis of the general adaptation syndrome by assuming overshooting, i.e. a harmful reaction of the organism in response to noxious agents. He proposed that the mineralocorticoids promoted inflammation while the glucocorticoids had anti-inflammatory properties. The anti-inflammatory hormones would be stimulated by ACTH, the pro-inflammatory hormones by somatotropin or by an adrenoglomerulotropic hormone. The diseases of adaptation would thus result from a dysfunction of the adaptation syndrome, i.e. from either too much or too little of the pro- or anti-inflammatory hormones, or from a shift in their ratio. Finally, the responsiveness of the end-organs might be altered by the influence of conditioning factors, thus leading to pathological reactions. Although SELYE has tried to support his theories by extensive experimental evidence, they are not consistent with clinical experience. Experimental induction of inflammation by pro-inflammatory hormones is not possible in intact animals, but only in animals subjected to partial nephrectomy or salt loading. Although these experimental changes are morphologically similar to diseases of adaptation, they cannot be compared to human diseases. Moreover, it can be argued that chronic stress

does not lead to diseases of adaptation in the human.

Since the beginning of this century, the problem of defense has fascinated the most eminent physiologists and clinicians. CANNON, HESS, and HOFF have centered their studies on the role of the autonomic nervous system. A first ergotropic phase aimed at immediate action and dominated by the sympathetic nervous system is followed by a trophotropic, parasympathetic recovery phase aimed at restitution. The nervous system plays a central role in the regulation of this mechanism of defense.

SELYE deserves the credit for recognizing and emphasizing the importance of the endocrine system, and in particular that of the pituitary adrenal system, in defense. There are striking parallels between SELYE's model and that of CANNON, HESS, and HOFF. Accoding to both theories, the organism switches its metabolism from construction to performance in the interest of rapid action; in the emergency reaction this is achieved by secretion of adrenaline and increased activity of the sympathetic nervous system, and in the general adaptation syndrome by secretion of glucocorticoids which shunt away the available substrates from protein synthesis to glucose production. In this situation, adrenal medulla and cortex serve the same purpose, with adrenaline and the sympathetic nervous system responding immediately and the adrenal cortex coming into action when stress is prolonged and metabolism must be readjusted. The theory of the general adaptation syndrome has had a very stimulating effect on modern medicine, since it emphasizes the reactivity of the organism in illness. The primary noxious agent is not as important as the way in which the organism reacts to it. SELYE has brought back the "terrain" to the center of attention.

E. Adrenocortical Insufficiency

1. Classification

As an organ of central importance in homeostasis, the adrenal gland itself has a high capacity for adaptation to the needs of the organism. Its size depends on the degree of stimulation by the pituitary gland (see p. 296). A manifold increase in its volume can be observed after chronic hyperfunction; inactivity of the pituitary gland leads to reversible atrophy of the organ. Even fragments of normal adrenals can maintain an adequate hormone production. Overt symptoms of chronic insufficiency can only be observed when over 90% of the organ has been destroyed. The adrenal gland has a very high capacity for regeneration. Extensive resection is known to have been followed by considerable regeneration during ACTH stimulation.

The term adrenocortical insufficiency includes all conditions in which hormone production does not meet hormone requirements, whether these are due to functional disorders of the pituitary adrenal system or to destruction of the organ. The differentiation between primary and secondary adrenal insufficiency is of major theoretic and therapeutic importance.

Primary adrenocortical insufficiency is caused by damage of the adrenal cortex itself. In *secondary* insufficiency, the stimulation by the pituitary gland is insufficient. The adrenal cortex itself is intact, but may be atrophic.

Acute adrenocortical insufficiency, or Addisonian crisis, is a special illness and necessitates special treatment. It can arise from primary as well as from secondary chronic adrenal insufficiency.

The term "relative adrenal insufficiency" does not define a clinical entity and should be avoided (see p. 327).

2. Primary Chronic Adrenal Cortical Insufficiency, Addison's Disease

The disease of adrenal failure described by ADDISON in 1856 is characterized by a slow onset and a chronic course. Acute exacerbations and crises, however, may occur at any time during the course of the disease. Not infrequently, it is the acute crisis which leads to the diagnosis. Classic Addison's disease, however, is typically a chronic illness.

a) Incidence

Addison's disease is rare. In five years, this diagnosis was made in only 8 of 66841 patients attending the Medical Outpatients' Clinic of Zurich University Hospital. Between 1958 and 1963, there were only 31 cases of Addison's disease among 17620 hospital admissions to the Department of Medicine. According to foreign statistics, the incidence of Addison's disease is 1 per 4000–6000 hospital admissions. General statistics of the cause of death, which are not very reliable, show one case of Addison's disease in 250000 deaths. In the 5 years from 1948 to 1952, 12 cases of Addison's disease were observed among 8413 autopsies carried out by the Department of Pathology of the Zurich University Hospital. In an epidemiological study, the morbidity of the disease among the adult population of England was estimated to be 0.04‰ (MASON, 1968).

The incidence of the disease appears to be increasing slightly. However, this is probably only an apparent increase due to improved diagnostic methods. Some statistics show a predominance of male over female patients in a ratio of 2 : 1 (PASCHKIS, 1967; THORN, 1951). According to other authors, the disease is equally distributed between the two sexes (SOFFER, 1961). The age group from 30 to 50 is particularly prone to the disease. The disease is uncommon in the very aged and in children under 15. Combined statistics of Zurich and Baltimore give an incidence of only 2 cases of Addison's disease in 143000 patients under 15. An increased familial incidence of the disease is typical for primary adrenal atrophy and related syndromes (see below). The fact that certain races (negroes, Spaniards) are particularly affected may be related to the higher incidence of tuberculosis in these populations.

b) Etiology, Pathogenesis, and Pathologic Anatomy

Addison's disease is caused by destruction of the adrenal cortex. As stated on p. 312, at least 90% of the cortex must be destroyed before the typical signs of insufficiency become apparent.

Among the causes of Addison's disease, tuberculosis seems to be decreasing. The ratio of tuberculous to non-tuberculous destruction of the adrenal cortex is shifting in favor of the latter form. GUTTMAN (1930) found an incidence of tuberculosis of nearly 70% among the 566 cases he observed personally or reviewed from the literature. In Switzerland it is still the most frequent cause of Addison's disease.

Primary or cytotoxic idiopathic adrenocortical atrophy, whose etiology had been completely unexplained until recently, is now increasing in importance. In Switzerland it is not uncommon, but has not reached the relative frequency found in the United States, where FRIEDMAN (1948) observed 10 cases of tuberculous Addison's disease and 15 cases of primary adrenocortical atrophy in a study carried out at the Armed Forces Institute of Phatology from 1941 to 1946. According to a more recent epidemiological study, the incidence of tuberculous Addison's disease is 0.012‰ and that of primary atrophy is 0.027‰ among the adult population of England (MASON, 1968).

Other bilateral infections of the adrenal cortex, degenerative and inflammatory processes, such as mycosis (blastomycosis, histoplasmosis, coccidiomycosis) and tumor metastases are of minor importance as causes of Addison's disease (less than 10%, GUTTMAN, 1930).

α) So-Called Primary, Cytotoxic, or Idiopathic Adrenocortical Atrophy ("Immune Adrenalitis")

Radiological evidence of adrenal calcification is never found in so-called primary adrenal cortical atrophy. Autopsy reveals no evidence of caseation, no signs of specific inflammation, such as tuberculosis or histoplasmosis, or of other rare causes of adrenocortical destruction such as hemorrhage or tumor metastases, but extensive lymphocytic infiltration with severe atrophy of the adrenal cortex. Occasionally, the adrenals are enlarged with striking lymphocytic infiltration. Whereas the female: male ratio for the incidence of tuberculous Addison's disease is given variously as 1 : 1 or 0.6 : 1, the incidence of primary adrenal atrophy is quite definitely higher in women, with a sex ratio of 2.5 : 1. Although primary adrenocortical atrophy can occur at any age, it is more often found in younger patients than tuberculous Addison's disease and is not uncommon before the age of 20. Familial occurrence is common in primary adrenal atrophy, but rare in tuberculous Addison's disease.

Circulating organ-specific antibodies to microsomes and mitochondria of human adrenals are found in over 50% of patients with primary adrenocortical atrophy (leading article, 1967), and in 88% of female patients. In tuberculous Addison's disease, some investigators have never found antibodies, and others only in a few instances. These antibodies are organ-specific but not species-specific and can be determined either with the relatively insensitive immunofluorescence method according to COONS or with the complement fixation test (ANDERSON, 1967; BLIZZARD, 1967; IRVINE, 1967). Consequently the term "autoimmune adrenalitis" is currently used for primary adrenal atrophy. Some investigators have succeeded in inducing inflammatory lesions of the adrenals in guinea pigs by injecting homologous or autologous adrenal tissue together with FREUND's adjuvant. However, it is occasionally possible to induce lesions of this kind by means of the adjuvant alone (ANDERSON, 1967; IRVINE, 1967).

The majority of patients with primary adrenal atrophy or autoimmune adrenalitis prove to have besides the antibodies to adrenal tissue also antibodies to thyroid, gastric mucosa and intrinsic factor; antibodies to the parathyroids are also occasionally found (see Chap. XVIII). However, antibodies to components of the cell nuclei, which are typical of the so-called collagen diseases, are only rarely found in Addison's disease. These diseases also are not more frequent in Addisonian patients. The reader

is referred to Chap. XVIII for a discussion of the hypothetical pathogenesis of autoimmune polyendocrinopathy.

β) Adrenal Tuberculosis

The adrenals may be greatly enlarged and extensively caseated. Occasionally, the caseation may extend to the surrounding adipose tissue. However, very shrivelled, fibrous and scarred organs may also be found. Cortical remnants with hyperplastic areas are often detectable only by microscopy. The medulla is usually completely destroyed. Extensive calcification such as would be detectable by X-rays is rarely present, and was found at autopsy in only three out of 32 cases by GSELL and UEHLINGER (1933). The adrenals are practically always infected by way of the bloodstream from a primary tuberculous complex or a postprimary tuberculous focus, except in the very rare placental infections with fatal outcome during early infancy. Since adrenal tuberculosis progresses very slowly and becomes manifest only after destruction of 90% of the adrenal cortex, the time lapse between tuberculous dissemination into the adrenals and the development of overt adrenal insufficiency, i.e. Addison's disease, may be many years; according to GSELL and UEHLINGER between 7 and 27 years. Tuberculous Addison's disease is therefore a typically adult disease. In one third of the cases examined by GSELL and UEHLINGER, the adrenal tuberculosis was the only active focus. In a further third, Addison's disease was associated with urogenital tuberculosis, and in a quarter with tuberculosis of bones and joints. Secondary miliary tuberculosis originating in the adrenals is only seldom observed, in older patients with poor resistance. Pulmonary tuberculosis has a benign course in Addison's disease, whereas tuberculosis of extrapulmonary organs remains progressive.

γ) Other Inflammatory or Parasitic Diseases of the Adrenals

All other types of inflammation which can lead to adrenal failure are of minor importance against tuberculosis, at least in Switzerland (see p. 313). However, extensive destruction of the adrenals, and thus Addison's disease, may be due to fungal infections, such as histoplasmosis, coccidiomycosis, and blastomycosis, or to parasites such as Echinococcus alveolaris, which is not uncommon. Syphilis often spreads to the adrenals, particularly in the congenital form, and in rare instances may cause fatal adrenal failure in infants.

δ) Changes in Other Organs

In Addison's disease, the number of sparingly granulated mucoid cells in the *pituitary* gland is increased, while there is a decline in the number of densely granulated, markedly basophilic cells. See p. 316 f. for notes on the pigmentation. Hyperplasia of the lymphatic system with enlargement of the thymus is often seen in primary or secondary insufficiency. Apart from generalized cachexia, there are no other significant morphological changes in the organs.

c) Clinical Features

α) History

Although familial occurrence is rare, it has been described in several instances.

Addison's disease begins gradually, and patients are usually unable to say exactly when the illness started.

Fatigue. Fatigue is an obligatory and early symptom. In contrast to neurasthenic tiredness, it is characterized by organic muscular weakness (adynamia) and increased fatigability. Addisonian patients can be efficient in the morning, but they become exhausted towards evening after the day's demands, whereas the neurasthenic is generally aware of fatigue mainly in the morning ("le triste du matin") and improves in efficiency during the day. Adynamia varies in severity from a barely perceptible decrease in muscular efficiency to near paralytic muscular weakness necessitating complete bed rest. Ascending symmetric palsy has been observed. In the advanced stages of the illness, adynamia affects the whole of the musculature. It becomes manifest in the facial expression. Speech is slowed down, the voice becomes weak, and the heart sounds are hardly audible.

Often the fatigue first becomes apparent as an unusually slow convalescence or as a severely weakened state in minor infections or gastrointestinal disorders.

An objective assessment of the degree of muscular weakness can be obtained by means of the dynamometer. Progression and success of treatment can be assessed by repeated measurements. FLEISCH'S bicycle ergometer yields exact data on the muscular function and the fatigability.

The muscular weakness is due partly to an electrolyte disturbance, but mainly to impaired carbohydrate metabolism. An uncommon but impressive symptom, which may dominate the clinical picture, is muscular pain, particularly in the calfs and flanks. In rare instances, spasm

of the flexor muscles of the limbs is observed, particularly in elderly patients, which regresses with cortisone therapy. Paresthesia may also occur. Periodic joint pains without inflammatory signs have also been observed. There are no morphologic changes and the cause is unknown. Muscular wasting is no more severe than in other chronic illnesses.

A Lowered Gustatory Threshold for Salt is demonstrable in most patients not treated with cortisone and is often associated with salt hunger.

Weight Loss. The second obligatory symptom is weight loss. Extreme emaciation is not always found, and there are rare cases of overweight Addisonian patients. But weight loss is always present in the history of untreated patients, and the diagnosis is doubtful if weight increases or remains constant. Weight loss is partially due to dehydration. Addisonian patients drink strikingly little, which is a protective measure against excessive sodium loss. However, weight loss is mainly a consequence of anorexia which varies in severity and may progress to continual nausea and frequent vomiting.

Gastrointestinal Disturbances. Irritation of the gastrointestinal tract is common but not obligatory in advanced stages of the disease. It becomes apparent as weight loss, fat intolerance, nausea, vomiting, constipation and periodic diarrhea, and finally in uncharacteristic abdominal pains, sometimes chronic and sometimes acute, which can lead to a mistaken diagnosis of peptic ulcer, cholecystopathy, or chronic appendicitis. The gastrointestinal disturbances are probably due to the increased secretion of sodium chloride into the intestinal lumen (see p. 302). Reduced production of hydrochloric acid and pepsin by the gastric mucosa, and sometimes histamine-refractory achylia (see Chap. XVIII) may also be involved. Insufficient resorption of fat may also cause weight loss, even without clinically manifest steatorrhea. Cortisone therapy normalizes the fat resorption. Vomiting and diarrhea are dangerous because they can precipitate a crisis by water and sodium loss.

Hypoglycemia. Complaints of numbness, dizziness, or fainting may be due partly to the hypotension (see below), but are often manifestations of hypoglycemia, particularly when accompanied by the typical symptoms of sudden weakness, cold sweat, trembling, hunger, and pallor, and disappear promptly upon administration of rapidly absorbed carbohydrates. These symptoms are generally observed after fasting, in the early morning, or before meals, but occasionally even 1 to 2 hours after meals rich in carbohydrates. Hypoglycemia occurs frequently in gastrointestinal disorders.

The tendency to hypoglycemia is due to the lack of glucocorticoids and disappears upon treatment with cortisone. When glucose is urgently needed, it cannot be made available quickly enough, since gluconeogenesis and glycogen mobilization from the liver are impaired. The blood sugar levels at which symptoms of hypoglycemia become apparent are higher in Addisonian patients (about 60 to 80 mg%) than in healthy subjects (50 mg%). The fasting blood sugar concentration of Addisonian patients is usually in the low normal range. Attacks of hypoglycemia are observed in about half the patients.

Nycturia. Nycturia is a frequent symptom of the impaired diuresis (see p. 305) with larger volumes of urine during the night than during the day. It is the only symptom resulting from the disturbed renal function.

Mental Changes. Mental changes may be noncharacteristic, appearing as mental fatigability, retardation, and inability to concentrate, and can be the main symptoms of the illness. One of our patients with Addison's disease had been treated by a psychologist for inability to concentrate for 6 months before consulting a doctor. According to STOLL and BLEULER, advanced stages of the mental disorder are characterized by persistent personality changes and an amnestic psychosyndrome; in rare instances acute severe psychoses develop. Depressive moods, lack of initiative, and indifference are the main characteristics of the personality changes in untreated patients. However, alterations of mood and drive in the opposite direction, resulting in euphoria, excitement, and tension, are also observed. Sexuality and appetite are often reduced. As in other cerebral diseases, the amnestic syndrome consists mainly of reduced attention and impaired memory, and is caused by disturbed cerebral metabolism. Acute psychoses of the exogenous reaction type (coma, delirium, dazed condition, excitement, confusion, and hallucinations) may occur in Addisonian crisis. Mental changes regress when adequate maintenance therapy is not started too late. Lack of adrenal androgens sometimes has a negative influence on women's psychosexuality. In these cases, temporary androgen substitution therapy may be indicated.

The disturbances of cerebral function can be objectivated by a pathologic electroence-

phalogram. Mental symptoms disappear and electroencephalograms become normal upon treatment with cortisol or cortisone, but not with deoxycorticosterone. Spastic paraplegia has repeatedly been observed (HARRIS-JONES, 1955; PENMAN, 1960).

β) Physical Examination

1. Pigmentation. Pathologic pigmentation of the skin is the most obvious sign, and is rarely absent. When fully developed, it allows diagnosis at first glance. It is caused by an increase of the normal skin pigment, melanin, and its catabolite, melanoid, and differences from normal complexion are only quantitative (Fig. 14).

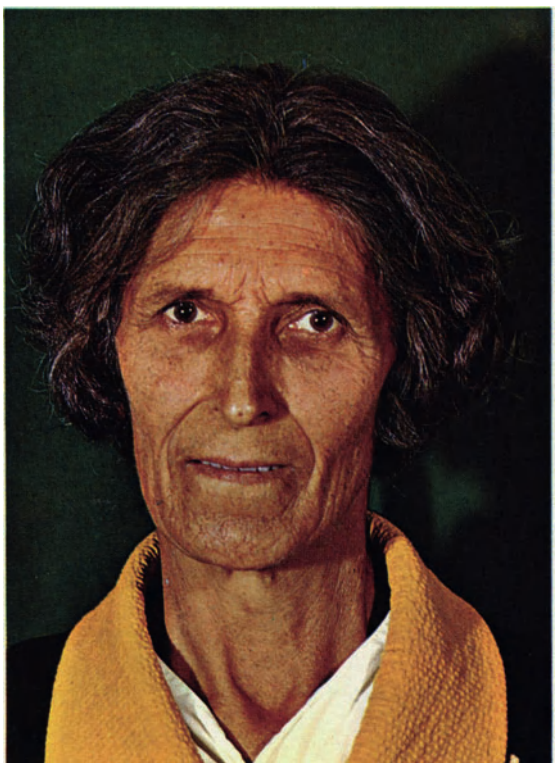

Fig. 14. 59-year-old woman with Addison's disease. Extreme brown pigmentation of the skin, marked weight loss

Slight qualitative changes in the form of an olive gray tinge due to diminished capillary circulation and a relative increase of reduced hemoglobin are, however, possible (Fig. 15). The degree of pigmentation depends more on the patient's individual ability to form pigments than on the duration and severity of the disease. Healthy Mediterranean types may present the same type of pigmentation as Addisonian patients, including the pigmental spots of the buccal mucosa which are often considered to

Fig. 15. 15-year-old girl with Addison's disease. Pale, brownish grey complexion, multiple pigmentous nevi in the face and on the neck. Fatigue and severe orthostatic hypotension. After substitution therapy complete remission; the patient became a nurse, married and had two children

be pathognomonic for Addison's disease. On the other hand, increased pigmentation may be completely absent in extremely light-complexioned blond or red-haired patients, or be limited to an increase in the number and size of freckles (white Addison's disease). The decisive factor in the diagnosis is thus not the degree of pigmentation, but an increase which is not explained by exogenous causes. Often, the patients first become aware of the hyperpigmentation when a suntan does not fade as usual after exposure is discontinued.

The increase in pigmentation usually affects the whole body with a predilection for certain areas. These are 1. areas exposed to light, 2. areolas of the nipples, perianal and perigenital regions, 3. skin folds and areas subjected to pressure and friction, and 4. scars acquired after the onset of the illness. Scars which were present before the illness usually remain pale. The dark palmar lines become conspicuous (Fig. 16). The knees, elbows, and knuckles, and areas subjected to pressure from belts and braces take on a dirty grayish-brown color. The characteristic spotty pigmentations of the buccal

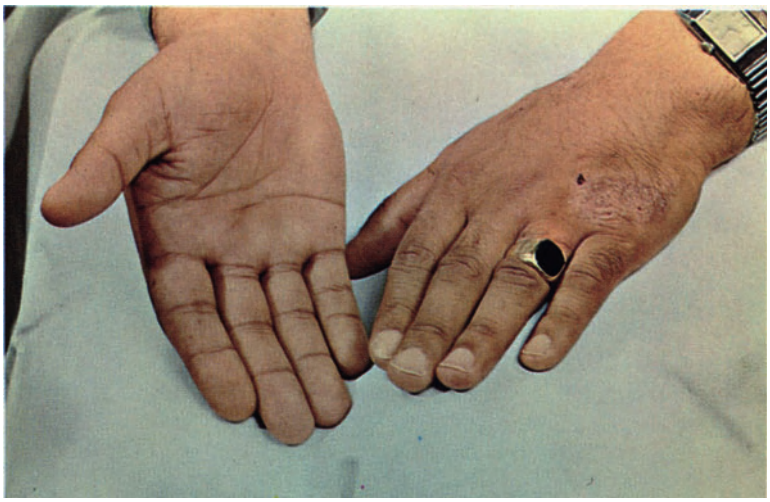

Fig. 16. 35-year-old man with Addison's disease. Pigmentation of the palmar lines and of the finger joints

mucosa can vary from the size of a grain of rice to that of a coin, and from brown to blue-black in color. They are most often found on the inside of the cheeks, frequently on the gums and lips and may also appear on the tongue, the palate, and on the vaginal and rectal mucosa. However, they are never pathognomonic for Addison's disease. Increased pigmentation includes the hair. Darkening of the hair is suggestive of Addison's disease. Besides the diffuse pigmentation, spotty pigmentation in the form of dark brown to black freckles on the face and chest is occasionally observed. Finally, in 10 to 20% of cases, a pigment anomaly appears in the form of vitiligo with irregularly localized areas where pigment is completely absent (Fig. 17).

A perceptible increase in pigmentation appears within three months after total adrenalectomy. However, it may precede the other clinical manifestations of Addison's disease by up to 10 years.

As discussed on p. 295 f., formation of melanin in man is controlled by the melanocyte-stimulating hormone of the anterior pituitary gland (MSH) and ACTH. Addisonian pigmentation is found whenever excessive amounts of ACTH are produced or administered; thus, apart from Addison's disease, after adrenalectomy, in the congenital adrenogenital syndrome and after long-term ACTH administration. Pigmentation decreases in panhypopituitarism and in secondary adrenocortical insufficiency. At present, it is still uncertain to what extent human hyperpigmentation is caused by increased MSH, ACTH, or both (see p. 295).

Pigmentation may be fully developed in latent Addison's disease (see p. 324), because

Fig. 17. 24-year-old patient. Vitiliginous form of skin pigmentation in Addison's disease

the remaining adrenocortical residue is under constant maximum corticotropin stimulation.

Addisonian pigmentation also regresses markedly during long-term treatment with cortisone, which inhibits ACTH secretion. However, only melanin pigmentation is reversible, whereas melanoid pigment remains constant.

The *skin* is otherwise dry and brittle, in contrast to the skin of neurasthenic patients, which is moist and vasolabile. The skin folds remain elevated due to dehydration.

2. Pubic and Axillary Hair. Pubic and axillary hair is sparse in male Addisonian patients. In

women, it is completely absent or is reduced to a minimum. Body hair does not grow again after shaving. Although the absence of pubic or axillary hair in a woman is very suggestive of adrenocortical insufficiency, it may be due to constitutional factors. This is, however, very rare in white in contrast to yellow races.

3. Circulatory Organs. Hypotension: The absence of mineralocorticoids leads to sodium loss and thus to decreased extracellular and intravasal volumes. In addition, the presence of glucocorticoids is necessary for the tonic action of noradrenaline upon the arterioles and the capillaries. Thus, hypotension, a major feature of Addison's disease, has two separate causes. Systolic blood pressure is generally below 80 and 90, and rarely above 110 mm Hg. Diastolic blood pressure is always below 70 mm Hg. In preexisting hypertension, blood pressure is lowered, but may still be above normal.

A loss of vascular tone becomes particularly apparent as orthostatic hypotension. Whereas in healthy subjects a change from a recumbent to a sitting or upright posture induces an increase in blood pressure (measured after 5 min in each posture), it leads to a decrease in Addisonian patients. Addisonian patients frequently complain of dizziness, palpitations, and tachycardia when maintaining an upright posture. A positive orthostatic test is not, however, conclusive, as it can also be a sign of vegetative lability. Treatment with deoxycorticosterone may restore the plasma volume and vascular tone. However, only treatment with cortisol or cortisone can prevent an orthostatic fall in blood pressure.

A decreased plasma volume leads to a decreased stroke volume and a reduction in cardiac output, leading to a small, soft and retarded pulse. The pulse rate increases rapidly on exertion. The size of the heart is related to the intravasal volume and is reduced in untreated Addison's disease. Adequate therapy brings it back to normal.

The ECG of untreated Addisonian patients is characterized either by nonspecific changes in the repolarisation phase, such as flattened or negative T waves, prolongation of the QT, PR, and QRS intervals, depression of the ST segment and low voltage, or signs of hyperkalemia, particularly during Addisonian crisis, such as high, pointed, symmetrical T waves, usually with normal QT intervals. In treated Addison's disease, ECG findings are usually normal.

4. Pathologic Calcification. Calcification of the adrenals can be detected by X-rays in 23% of Addisonian patients. The position is paravertebral at the level of the 1st lumbar vertebra. It can confirm a diagnosis of Addison's disease, but does not exclude an adequate function of the adrenal cortex.

Striking induration of the auricles may be found in Addison's disease of long duration, occasionally even calcification of the cartilage. This is possibly related to the hypocalcemic effect of cortisol.

γ) Laboratory Findings

Anemia. In uncomplicated Addison's disease, anemia is not severe. It is normochromic and normocytic in type, and the hemoglobin is usually between 60 and 75%. It may be masked by hemoconcentration, especially during Addisonian crisis. All hematological investigations should therefore be repeated after rehydration. See Chap. XVIII for pernicious anemia in adrenocortical insufficiency due to primary atrophy. (Pathogenesis is discussed on p. 306.)

Leukocytes. The total leukocyte count is at the lower limit of normal, between 3000 and 4000. The rise during infections is inadequate. There is a relative lymphocytosis, usually of above 35%, which may even be mistaken for leukemia. Infections lead to lymphopenia. The eosinophils are increased, ranging between 100 and 1000/mm^3 with an average value of 300, i.e. 8 to 10% of the total number of leukocytes (normal value 100 to 250 by direct counting, see p. 386). Addison's disease is not likely when the eosinophil count is below 50/mm^3, but can not be excluded. There are constitutional forms of aneosinophilia.

Sedimentation Rate. Sedimentation rate is often increased, even in the absence of infection. Electrophoresis reveals displacement of albumin by globulins, particularly by gamma-globulins.

Serum Electrolytes. Serum electrolytes are only disturbed in advanced stages of the illness. Normal values do not exclude adrenal insufficiency. In severe cases, there is hyponatremia and, to a lesser extent, hypochloremia, both of which may be masked by hemoconcentration. Hyperkalemia is therefore usually better demonstrable. Values of less than 130 mEq/l of sodium (300 mg%) and of more than 5 mEq/l of potassium are suggestive of adrenocortical insufficiency. The sodium/potassium ratio can be altered even when the sodium and potassium values are still within the normal range. A value of below 30 (both electrolytes measured in mEq/l) is suggestive of adrenal insuffiency (normal value 32). Hyper-

calcemia is frequently, but not regularly, found in untreated Addison's disease (DE LORME, 1964; PRADER, 1959). The generally mild, but sometimes considerable hypercalcemia (up to 17 mg%) may be associated with hypercalciuria, thirst, hyposthenuria, polyuria, and normal or elevated serum phosphate values. Intestinal calcium absorption is increased, as is calcium mobilization from the bones. Active calcium excretion through the gut is decreased. The hypercalcemic syndrome disappears with cortisone therapy. According to animal experiments, ionized calcium remains unchanged, whereas protein-bound and complex-bound calcium may be considerably increased.

Urinary, Salivary, and Sweat Electrolytes. Increased sodium excretion in the urine and saliva is even more indicative of adrenocortical insufficiency than a low serum sodium. Whereas urinary excretion is dependent on the dietary sodium intake, estimation of the sodium-potassium ratio in saliva or sweat gives valid information even when the diet is unknown (see p. 391 f.).

Plasma pH. The electrolyte disturbance is paralleled by moderate metabolic acidosis, usually compensated by hyperventilation. It is mainly due to a shift of H-ions from the intracellular into the extracellular space and to deficient ammonium formation and H-ion excretion of the renal tubuli. Severe acidosis is only observed in crisis and in renal failure.

Disorders of Renal Function. The specific renal dysfunction in primary adrenocortical insufficiency consists of three components:

1. Glomerular filtration rate is reduced even when extracellular fluid and plasma volumes are normal. It can only be normalized by cortisol or other glucocorticoids.

2. The patients are unable to produce rapid diuresis. In the healthy subject, a water load of 1 to 1.5 liters is excreted within 4 hours. In adrenal insufficiency, diuresis begins gradually, often during the following night, and the patient is in danger of water intoxication.

Cortisol and other glucocorticoids, but not aldosterone, can normalize diuresis. Deficient diuresis is not due to the reduction of the glomerular filtration rate. Perhaps more antidiuretic hormone is secreted, or its degradation retarded in adrenal insufficiency (AHMED, 1967). Alternatively, cortisol may have a sealing effect on the distal tubular sections and collecting ducts and be necassary for suppression of facultative water reabsorption (KLEEMAN, 1964).

These two types of renal disorder are found in both primary and secondary adrenal failure.

3. Lack of aldosterone leads to loss of sodium and retention of potassium. Finally, during crisis sodium loss leads to dehydration, fall in blood pressure, and shock. Renal circulation decreases and severe renal insufficiency with a rise in blood urea nitrogen develops.

Renal concentrating capacity is only rarely impaired, in contrast to the ability to dilute the urine.

Basal Metabolic Rate. The BMR is usually slightly reduced and varies between -20 and -10%. Thyroid function itself is not impaired, as is indicated by a normal radioiodine uptake and a normal protein-bound plasma iodine. The absence of glucocorticoids, however, leads to retardation of the peripheral metabolic processes.

Carbohydrate Metabolism. Disturbances of carbohydrate metabolism can be recognized both from the history and from stimulation tests (see p. 389). Determination of fasting blood sugar is not very informative.

Urinary Steroids. Determination of 17-ketosteroids, 17-hydroxycorticosteroids, or 17-ketogenic steroids in the urine is highly significant in the diagnosis of adrenal insufficiency. Their failure to respond in the ACTH test is more conclusive than their basal values. Normal values of these three urinary steroid fractions do not exclude adrenal insufficiency, and decreased values may also be due to other factors than adrenal insufficiency.

Plasma Corticosteroids. In advanced Addison's disease, plasma corticosteroids are decreased or too low for assay. However, the values found in Addisonian patients may be within the range of normal diurnal variation. The responsiveness of plasma corticosteroids to ACTH is also more important in the diagnosis of Addison's disease than their absolute values.

Aldosterone. In some cases, determination of the aldosterone excretion or secretion rate can help to differentiate between primary and secondary adrenal insufficiency. Whereas normal aldosterone values are found in secondary adrenal insufficiency, aldosterone is found in the urine of Addisonian patients only in traces, even after salt restriction.

Plasma *renin* is increased in untreated Addisonian patients, even when they are hypotensive; this is probably due to hypovolemia (PEART, 1965).

δ) Test of Adrenocortical Functional Reserve

The laboratory findings mentioned above can be normal in early mild Addison's disease. Tests for assessment of the adrenocortical functional reserve are therefore essential for a definite diagnosis. The ACTH test (Thorn test) is particularly important. This test clearly indicates whether the adrenals are still functioning, to what extent, and how great their functional reserve is. The previously used tolerance tests have been completely abandoned since they are less reliable and more harmful than ACTH tests (see p. 391). It is advisable to treat patients with suspected Addison's disease with dexamethasone, 0.5 mg twice daily to prevent a hypersensitivity reaction to ACTH. However, the eosinophil count is valueless in these conditions. The risk of side-effects can also be reduced by use of a synthetic ACTH preparation.

ε) Review of Diagnostic Procedure

Usually the history, the physical examination including the orthostatic test, and the rapid ACTH test and 48-hour depot ACTH test are sufficient to allow a decision on whether Addison's disease is present or not. If the diagnosis is doubtful, it is advisable to admit the patient to hospital for about 8 days, and weight, pulse rate, and blood pressure must be measured daily during this period. Strong laxatives and morphine are contraindicated. Barbiturates should be given with caution.

Table 5. Frequency of clinical symptoms in Addison's disease. (Based on 94 cases of THORN, 1951)

Weakness and fatigue	100%
Weight loss	100%
Increase in pigmentation	94%
Anorexia	90%
Vomiting	84%
Nausea	81%
Abdominal pains	32%
Obstipation	28%
Diarrhea	21%
Salt hunger	19%
Muscular pains	16%

Table 6. Synopsis of the most important clinical symptoms and laboratory findings in Addison's disease

Clinical symptoms:
Weakness, weight loss, hypotension, increased pigmentation
Laboratory findings:
Pathological results of ACTH-tests, low plasma and urinary corticosteroids, eosinophilia and lymphocytosis, hyponatremia, hypochloremia, hyperkalemia, azotemia, impossibility of quick diuresis

The following examinations are important in the diagnosis of Addison's disease:

1. Hematologic examination: blood smear, sedimentation rate, hematocrit, total protein, sodium, potassium, chloride, urea. Arterial blood: pH, carbon dioxide tension and bicarbonate concentration;
2. Urinary 17-ketosteroids and 17-hydroxycorticoids, plasma cortisol;
3. A two-day 8-hour i.v. ACTH test with determination of urinary steroids, plasma cortisol, or both;
4. X-rays: chest or cardiac teleradiography, abdominal X-ray to reveal adrenal calcification;
5. Renal function tests: creatinine clearance, phenolphthalein excretion;
6. Ergometry, to be repeated after cortisone therapy.

d) Course of Addison's Disease

Untreated Addison's disease has a progressive course over many years. Remission of single symptoms may occur, but the hypotension remains unchanged. Remissions can last for weeks or months. They may be due in part to regeneration of adrenal tissue. More often, the remission is due to an adaptation of the life style to the reduced amounts of hormones produced by an adrenal residue, and thus to a new hormone balance. The disease may thus come to a standstill for many years, persisting as latent Addison's disease with few symptoms (see p. 324). Earlier reports of complete recovery from Addison's disease were probably based on mistaken diagnosis and inadequate laboratory tests. Complete recovery is extremely rare (NORDIN, 1955).

The lack of resistance is characteristic of untreated Addison's disease. The adrenals play a central role in the maintenance of homeostasis (see p. 312). When they are absent, or their functional reserve is exhausted, the organism is incapable of withstanding stress. Physical exertion, trauma, surgery, and infections upset the precariously maintained balance between the production of and the requirement for adrenocortical hormones, leading to collapse and Addisonian crisis. Sudden death may occur at any time without premonitory signs.

Addisonian patients are no more susceptible to infections than healthy subjects, but the course of infections is usually more severe. Allergic diseases often develop at the same time as Addison's disease. The lack of resistance of Addisonian patients is also manifest in intolerance of many drugs, although this may be improved by cortisone treatment. Addisonian

patients are particularly sensitive to narcotics, such as morphine and codeine, and to a lesser extent to sedatives such as bromides and barbiturates. These drugs have to be used carefully and in low doses, particularly when sedatives are needed for restlessness during fever.

e) Pregnancy during Addison's Disease

Important changes in corticosteroid metabolism occur from the second trimester of pregnancy. These are partly due to the increased level of estrogens in the maternal blood. As during therapy with estrogens (see p. 292), the total cortisol concentration in the blood increases. This increase, however, is only due to protein-bound cortisol, whereas the free plasma cortisol remains unaltered. Estrogens also interfere with the enzymatic metabolism of cortisol in the liver. However, whereas estrogen therapy leads to a decreased excretion of urinary steroids, there is a marked increase in the urinary excretion of 17-hydroxycorticoids and 17-ketosteroids in advanced pregnancy, reflecting increased maternal cortisol production (COPE, 1959). The increased urinary levels of aldosterone-18-glucuronide are partly due to the fact that a smaller percentage of secreted aldosterone is converted to tetrahydroaldosterone during pregnancy and more aldosterone is excreted in the form of aldosterone-18-glucuronide. However, the aldosterone secretion rate is also increased, perhaps to compensate the natriuretic effect of progesterone.

NEHER and STARK (1961) have isolated cortisol and cortisone from human placenta, but it is highly uncertain whether the placenta actually releases corticosteroids into the maternal blood. In any case, maintenance therapy cannot be abandoned during pregnancy in an Addisonian patient. Experience has shown that the corticosteroid requirements are increased only immediately before and during delivery.

In the past, pregnancy was rare and hazardous in Addison's disease. Now, however, the incidence of pregnancy is steadily increasing and does not involve any additional risk if adequate maintenance therapy is given.

The daily oral maintenance dose consists of 25 to 50 mg of cortisone acetate and 0.1 mg of fluorocortisol. On the day before and the day after delivery, the daily cortisone dose has to be increased to 200 mg and gradually reduced to the maintenance dose within a week. As a precaution, an intravenous cortisol infusion is started during delivery, as during adrenalectomy. Frequent check-ups are necessary, particularly during the first trimester of pregnancy (weight, edema, blood pressure, blood sugar, electrolytes). The newborn infants of Addisonian mothers weigh 500 g less than normal on average. This is due to the lower maternal blood sugar levels. Pregnancy lasts an average of 13 days longer. Cesarean sections are not usually indicated. There is no cause for anxiety if spontaneous delivery does not occur until two weeks after term. The newborn needs no hormone therapy.

3. Other Forms of Adrenocortical Insufficiency

a) Acute Adrenal Insufficiency, Addisonian Crisis

Any stress increases the organism's requirement for cortisol. If this requirement is not met by increased secretion or administration, disorders with a further stress-producing effect develop, causing a vicious circle in the patient and leading to acute adrenocortical insufficiency. In particular, vomiting and diarrhea can result in massive losses of sodium, chloride and water. Nausea and severe adynamia lasting several days may be the premonitory symptoms of an imminent crisis. However, it can also occur suddenly as a consequence of stress. Acute infectious diseases, physical overexertion combined with salt loss by sweating, and particularly surgery leading to a greatly increased requirement for adrenocortical hormones are dangerous stress situations for Addisonian patients, from which a crisis may develop if appropriate therapy is not instituted. The same applies to secondary insufficiency in panhypopituitarism and to abrupt withdrawal of long-term cortisone administration.

Clinical Features. Addisonian crisis is a very impressive clinical situation. The patient is irritable and restless at first, then becomes increasingly apathetic and finally falls into collapse and coma. There is always a state of extreme weakness, in which even talking is an effort. Dehydration becomes manifest in a dry tongue and dry skin, which can be lifted up in folds. The skin is cold and the body temperature is usually below normal. Development of fever in persisting crisis is a sign of impending death. The systolic blood pressure is below 70 mm Hg, and the diastolic pressure immeasurably low. Pigmentation increases due to dehydration. Circulatory failure adds a cyanotic tint. Vomiting almost always occurs during the crisis. Diarrhea is frequent, and severe abdominal colics, often leading to confusion with acute abdominal processes, may be the predominant feature. Hypoglycemia may cause twitching and choreiform movements. Circulatory collapse leads to renal insufficiency. Azotemia is always present.

Addisonian crisis occurring in patients treated with deoxycorticosterone only in normal or excessive doses is not very different. Dehydration is, however, absent and edema may even be present.

b) "Adrenal Apoplexy": Acute Adrenal Insufficiency due to Hemorrhagic Infarction

Acute adrenal insufficiency due to hemorrhagic infarction occurs in:

1. Newborns;
2. Sepsis, particularly acute meningococcal sepsis, usually in children and rarely in adults (Waterhouse-Friderichsen syndrome);
3. Anticoagulation;
4. Bilateral thrombosis of the adrenal veins;
5. Hemorrhagic diathesis, hypertension.

α) Acute Adrenal Insufficiency in Newborns

The acute adrenal insufficiency of the newborn has been thought to be due to birth trauma. Possibly, however, hemorrhagic diathesis of the newborn (hypoprothrombinemia) is the major factor, and post-natal physiological involution contributes to the susceptibility of the adrenal glands. Adrenal hemorrhage is not uncommon in newborns, and may be considerable. The adrenals are converted into pouches of blood, which are occasionally larger than the kidneys. Most of the infants die within the first days of life. Chances of survival are better in unilateral than in bilateral hemorrhage. A common complication is rupture of hematomas with intra-abdominal hemorrhage. Old hematomas tend to be calcified.

The clinical feature is that of shock in the newborn with tachycardia, irregular pulse, pallor and cyanosis, and cold limbs. Fever and dyspnea may simulate pneumonia, but chest examination is negative.

β) Waterhouse-Friderichsen Syndrome

This syndrome is characterized by the acute onset of lethal sepsis with no noticeable signs of resistance to infection, meningitis, or leukocytosis, with petechial eruptions, and generalized discoloration of the skin reminiscent of postmortem hypostasis, with adrenal hemorrhage ranging from just microscopically detectable to massive bleeding. The patients may be in good health in the morning, fall ill in the evening, and be dead by the following morning. The illness seldom lasts longer than 24 hours. The patients unexpectedly develop high fever and rapidly decline into a state of shock resulting in irreversible circulatory collapse. There are few signs of adrenal insufficiency besides circulatory failure. The eosinophil count is hardly ever increased. Hyponatremia, hyperkalemia, and hypoglycemia are only rarely observed.

As a rule, the adrenals are only slightly enlarged, but they are diffusely or patchily discolored to a deep dark red. They can show all stages of hemorrhagic infiltration, up to complete hemorrhagic infarction of the medulla and cortex. The medulla is necrotic even when the damage is less extensive. Portions of the subcapsular layer of the cortex, however, may still be intact. The cortical tissue shows the features of excessive overactivity with glandular transformations. Cortical necrosis, and particularly hemorrhage of varying extent with inflammatory reactions, are also seen. Thrombi are often seen in the small vessels but rarely in the larger veins.

Pathogenesis. As recognized by BAMATTER in 1935, the illness is almost always due to meningococcal sepsis. The syndrome is only rarely caused by Pfeiffer's bacillus (hemophilus influenzae) or by hemolytic streptococci of group A. The syndrome must be distinguished from meningococcal meningitis, which is associated with leukocytosis and now usually has a good prognosis. According to present theories on the pathogenesis, the disease is due to a process similar to the Sanarelli-Shwartzmann reaction. The vascular endothelia are sensitized by bacterial toxins and react to repeated exposure with intravascular clotting. This leads to hypofibrinogenemia with hemorrhagic diathesis and to infarction.

Originally, treatment with cortisol was recommended in addition to antibiotic and chemotherapeutic therapy, especially when adrenal failure was indicated by an increased eosinophil count as well as by hyperkalemia or hyponatremia. Blocking of intravascular clotting with heparin is now advocated (STUBER, 1961). Cortisol might even be harmful, because it accelerates the Sanarelli-Shwartzmann reaction. Exchange transfusions should be considered. The shock, however, has to be treated with angiotensin II or noradrenaline, and if these agents are not effective, also with cortisol. Until now, no unequivocal case of Waterhouse-Friderichsen's syndrome has been cured, although the prognosis of meningococcal sepsis has improved considerably in this era of chemotherapy and antibiotics.

γ) Adrenal Hemorrhage during Anticoagulant Therapy

Acute adrenal insufficiency caused by adrenal hemorrhage during anticoagulation with di-

coumarol derivatives and particularly with heparin, has been described.

Bilateral adrenal hemorrhage may lead to acute abdominal distress 7 to 10 days after institution of the correct anticoagulation therapy; abdominal pains occur, and meteorism, combined with or immediately followed by muscular defense, fall in blood pressure, pallor, stupor, nausea, vomiting, diarrhea, cyanosis, and shock.

Laboratory findings include leukocytosis with absolute eosinophilia, low serum sodium and chloride, high potassium and blood urea nitrogen, low or unmeasurable plasma and urinary corticoids. The hemorrhagic diathesis may be restricted to the adrenals. Dermatological symptoms, ecchymosis and suffusions are absent.

Immediate substitution therapy can save the patient's life (see p. 330).

Adrenocortical function may recover or may remain permanently damaged.

The pathogenesis is not explained. In some cases, the adrenals may have been previously damaged. An increased secretion of ACTH induced by endogenous or exogenous stimuli may play a role. The time interval between anticoagulation and "adrenal apoplexy" is always 1 to 2 weeks, and the syndrome has not been observed in the further course of long-term anticoagulation.

δ) Thrombosis of the Adrenal Veins

Bilateral adrenal venous thrombosis is rare, and may occur post partum and after severe burns. It has the clinical features of severe shock with very painful abdominal colics and a soft abdomen. Damage to the adrenals may be the primary event in this illness and thrombosis of the veins its consequence.

c) Congenital Chronic Adrenocortical Insufficiency

A. PRADER

The signs and symptoms of congenital chronic adrenocortical insufficiency only rarely appear immediately after birth, usually developing after a few days or weeks. They are nonspecific and consist of vomiting, failure to thrive, weight loss, dehydration, and circulatory failure. After one to three months, an Addisonian pigmentation of the skin can be observed. Beside hemorrhagic infarction of the adrenals (see above), the following three groups of prenatal adrenocortical disorders have to be considered as the cause of this form of adrenocortical failure:

α) Congenital adrenal hypoplasia (see p. 325f.).

β) Congenital adrenocortical hyperplasia (various forms of the congenital adrenogenital syndrome, p. 358ff.).

γ) Congenital *adrenocortical lipoid hyperplasia*. This syndrome, together with the various forms of congenital adrenogenital syndrome, is one of the congenital disorders of steroid biosynthesis with adrenal hyperplasia and is also due to a genetic factor (see Table 16, p. 359). Clinically, this disease is characterized mainly by signs of adrenal insufficiency, appearing at the age of a few weeks (PRADER, 1957), whereas at autopsy the lipoid hyperplasia of the adrenals is the striking feature (SIEBENMANN, 1957). The involvement of the electrolytes is similar to that in Addison's disease, 21-hydroxylase deficiency with salt loss (see p. 369f.) and 3β-hydroxysteroid-dehydrogenase deficiency (see p. 371f.). However, the syndrome differs from 21-hydroxylase deficiency in that the external genitalia are always of the female type, even in patients with a male chromosomal configuration and male gonads. In boys, internal and external genitalia are similar to those in testicular feminization (see p. 726f.). In girls, the genitalia are absolutely normal. As in some other forms of congenital adrenocortical hyperplasia, these children die during the first months of life unless they are treated with cortisol, salt, and perhaps mineralocorticoids (see p. 370). The prognosis is poor, however, even with adequate treatment.

The adrenals are very much enlarged and strikingly yellow. Histology shows extreme adrenocortical hyperplasia with large cells densely filled with lipids. In addition, there are calcium deposits, crystalline lipoid deposits, and multinuclear giant cells. In one case, neither androgens nor estrogens could be found in an extract of adrenocortical tissue. Steroids cannot be detected in the urine of these patients. As in other forms of congenital adrenocortical hyperplasia, the pathogenesis can be explained by an enzyme deficiency leading to a decrease in corticol production. Since no steroids at all are found in these patients, the site of the disorder must be one of the earliest stages of steroid biosynthesis, i.e. one or several of the enzymes involved in the conversion of cholesterol to 5-pregnenolone (Fig. 27, p. 358) must be absent or inactive. Thus, the disease could be due to a deficiency of 20-hydroxylase, 22-hydroxylase, and/or 20,22-desmolase. This enzyme deficiency is not restricted to the adrenal cortex, but also affects the Leydig cells of the testes (PRADER, 1957). This would explain the development of female-type genitalia in boys.

The lack of cortisol leads to adrenocortical failure and to increased ACTH production causing adrenocortical hyperplasia with accumulation of nonutilizable cholesterol, while on the other hand, the absence of androgen production by the fetal adrenals and the fetal testes impedes male differentiation of the genitalia as in 3β-hydroxysteroid-dehydrogenase deficiency (see p. 371 f.) and 17-hydroxylase deficiency (see p. 372).

In girls, it is hardly possible to differentiate lipoid hyperplasia from other forms of congenital adrenocortical insufficiency, such as hemorrhagic infarction of the adrenals, by clinical examination. Differentiation from testicular feminization is possible on the basis of steroid excretion when the patient has male chromosomes. In testicular feminization, the excretion of all steroids is normal for age, whereas in lipoid hyperplasia all steroids are absent. Differentiation from 3β-hydroxysteroid-dehydrogenase deficiency is very simple in both sexes, since in this condition the total 17-ketosteroids, and particularly dehydroepiandrosterone, are elevated. Deficiency of 17-hydroxylase can be excluded in spite of female-type development of the external genitalia, because the electrolyte disorder in these patients is not like that in Addison's disease, but is due to overproduction of deoxycorticosterone (see p. 340) with hypokalemia and hypertension.

d) Latent Addison's Disease (Partial, Potential Addison's Disease, cf. p. 312)

It has long been known that ADDISON'S disease can vary in severity. In view of the slow development of the disease, the patients go through a stage where impaired adrenal function is apparent during abnormal stress before reaching the stage where adrenal failure is manifest under basal conditions.

A latent insufficiency always becomes manifest in situations of stress, such as infection, overexertion, surgery, and trauma. However, the patients are still capable of leading a normal daily life without maintenance therapy. They may feel healthy and even the important symptom of fatigue may be absent or inconspicuous. Symptoms of hypoglycemia are not usually present. Generally, these patients are not aware of their illness as long as they lead a life without undue exertion.

The patients' appearance is not altered except for the skin, which may assume the characteristic pigmentation of Addison's disease at a relatively early stage or merely show increasing numbers of dark brown freckles. Laboratory examinations, however, clearly reveal the insufficient adrenocortical function even at this latent stage of the disease: although the adrenals do function, there is no functional reserve. Urinary 17-ketosteroids and 17-hydroxycorticosteroids may be, but are not necessarily reduced. Plasma corticosteroids are not completely absent, but are in the low normal range. However, neither urinary nor plasma corticosteroids increase under ACTH stimulation. Pathologic results are obtained in any form of ACTH test, including the 8-hour intravenous infusion test repeated over several days: there is no fall in the eosinophil count and no adequate rise in urinary and plasma steroids. Electrolyte disorders are not demonstrable in the blood, saliva, or sweat. These findings indicate that the adrenocortical remnant is capable of producing sufficient amounts of hormones for the basal demands of life only under maximal ACTH stimulation. This explains the pigmentation as well as the pathologic ACTH test. Exogenous ACTH is ineffective because the adrenal cortex is already maximally stimulated by endogenous ACTH.

e) Familial Addison's Disease

There is an increased familial incidence of adrenal insufficiency due to primary atrophy. This disease may be a form of autoimmune polyendocrinopathy (see Chap. XVIII).

Other forms of polyendocrinopathy are Addison's disease associated with hypoparathyroidism, with hypo- or hyperthyroidism, with diabetes mellitus and with pernicious anemia.

f) Addison's Disease with Cerebral Sclerosis

This well-defined syndrome is probably inherited through a recessive gene linked to the X chromosome. So far 10 cases have been observed. The disorder usually becomes noticeable in late childhood (between the ages of 3 and 14) and progresses inevitably to death within months or years. Addison's disease begins with increased pigmentation of the skin and gradually presents all the signs and symptoms typical of *primary* adrenal cortical insufficiency. At about the same time, signs of the neurologic disorder appear. These are ataxia, and myoclonic and choreiform movements, finally progressing to spastic tetraplegia with pyramidal signs, dysarthria and incontinence. The neurologic illness leads to progressive invalidity, the simultaneous organic psychosyndrome to complete dementia. The protein concentration in the cerebrospinal fluid is increased, whereas the cell count is normal.

The pathologic anatomical changes in the adrenals take the form of primary atrophy with few remaining cortical cells. There is no inflammatory infiltration and no scar tissue. The medulla is not altered and the other endocrine organs, particularly the pituitary gland, are intact. There is extensive demyelinization in the cerebellum and the cerebrum; this is sometimes patchy and sometimes diffuse, as in diffuse cerebral sclerosis (Schilder's disease). The pathogenesis is unknown, and simultaneous involvement of two such different organs is puzzling. Antibodies to adrenal tissue have not been found in any of the cases examined. Only the adrenocortical insufficiency can be treated. The brain disease progresses inevitably to death.

g) Selective Deficiency of Single Hormone Groups

Usually all three adrenocortical hormone groups, i.e. the mineralocorticoids, glucocorticoids, and androgens, are deficient in ADDISON'S disease.

Selective absence of *androgens* is a physiologic condition in childhood up to the onset of "adrenarche" between the 8th and 10th years. Isolated complete adrenal androgen deficiency is only observed occasionally in the very aged.

Glucocorticoid and androgen deficiency associated with near-normal aldosterone secretion is typical of secondary adrenocortical insufficiency due to panhypopituitarism, long-term corticosteroid or ACTH therapy, or a cortisol-producing adrenocortical adenoma. Primary adrenocortical insufficiency without hypoaldosteronism has occasionally been observed, particularly in the familial form of the disease.

Selective hypoaldosteronism or analdosteronism occurs rarely. Theoretically, there are two possible enzyme deficiencies which can lead to congenital isolated hypoaldosteronism: these are 18-hydroxylase and 18-hydroxydehydrogenase deficiencies. The patients with isolated hypoaldosteronism and salt loss described by VISSER and COST (1964) were probably suffering from 18-hydroxylase deficiency due to a hereditary autosomal recessive defect.

Congenital hypoaldosteronism and salt loss were attributed to 18-hydroxydehydrogenase deficiency in a case described by ULICK (1964) because the secretion rate of 18-hydroxycorticosterone was found to be increased. An impairment of aldosterone biosynthesis at the level of 21-hydroxylation is at least partly responsible for the salt-losing syndrome observed in certain cases of the congenital adrenogenital syndrome (see p. 369f.). This appears to be a separate disease and also to be genotypically different from simple virilizing 21-hydroxylase deficiency, in which the aldosterone secretion rate is normal or elevated.

Several cases of acquired selective hypoaldosteronism have been described. The pathogenesis is uncertain. Particularly in the cases in which orthostatic hypotension was the predominant clinical feature, the decreased aldosterone secretion rate was probably due to impaired secretion of renin rather than a primary adrenocortical disorder (see Chap. XV) (SLATON, 1967). A decreased aldosterone secretion rate has been observed in cases of pretectal brain tumors. Long-term treatment with heparin, which inhibits aldosterone biosynthesis by an unknown mechanism, can lead to hypoaldosteronism with orthostatic hypotension.

h) Secondary Adrenocortical Insufficiency

α) Panhypopituitarism

Whereas primary insufficiency is due to damage of the adrenals, secondary adrenal insufficiency is caused by pituitary corticotropin deficiency. The adrenal insufficiency in panhypopituitarism is a prototype of this form (see p. 91ff.). As mentioned above, patients with secondary adrenal insufficiency differ from normals and Addisonian patients by a marked pallor of the skin; the disease is further characterized by a preferential failure of cortisol and androgens associated with intact aldosterone secretion.

β) Congenital Adrenal Hypoplasia

Congenital adrenal hypoplasia is regularly found in anencephaly and is associated with underdevelopment and malformation of the pituitary gland. Children with this condition usually die within the first few days of life. Only a few cases of congenital adrenal hypoplasia have been observed in which brain development was normal. The most frequent symptoms, appearing shortly after birth or within a few days or weeks, are anorexia, vomiting, insufficient weight gain, dehydration, cyanosis, and circulatory failure, all of which could as well be due to gastrointestinal or cardiac disorders. Addisonian pigmentation may appear within the first few months of life, which may possibly indicate a primary adrenocortical disorder. As in Addison's disease, serum sodium and glucose concentrations are decreased, whereas the potassium concentration is elevated. Steroid excretion at this age is so low in any case that a distinction between normal and decreased values is very difficult. Death usually occurs within days or months. When the disease is suspected,

oral substitution therapy with a daily dose of 12.5 to 25 mg of cortisone and 1 to 2 g of sodium chloride should be tried. A few cases of isolated glucocorticoid and androgen deficiency have been described (STEMPFEL, 1960). However, similar symptoms and electrolyte disorders in early infancy are more frequently caused by *congenital adrenocortical hyperplasia* (*adrenogenital syndrome with salt loss*, see p. 369 f.). The main characteristics of this disorder are malformation of the female genitalia and an elevated excretion of 17-ketosteroids. Secondary adrenal insufficiency without failure of the other glands regulated by the pituitary, and thus due to an isolated ACTH deficiency may occur spontaneously in rare instances (ODELL, 1960).

γ) Adrenal Insufficiency due to Cortisone Therapy

Adrenal insufficiency secondary to treatment with cortisone, its derivatives, or ACTH, or occurring after surgical removal of a cortisol-producing adrenocortical adenoma, is of great clinical importance. Adrenal insufficiency lasting several days is induced by treatment with cortisone for over a week in a dosage of over 75 mg per day, or with over 15 mg of prednisone given in three to four daily doses. The adrenals secrete a minimal amount of cortisol and are less responsive to ACTH. Although the responsiveness becomes normal within two to three days, the cortisol secretion rate does not exceed basal values since the pituitary reserve of ACTH is minimal. Maximal adrenocortical atrophy can be induced by a dose of 60 mg of cortisol within 15 to 20 weeks. Adrenocortical insufficiency may then persist for weeks and occasionally up to 6 months. As in latent Addison's disease, the patients' resistance is low, and death due to stress has been described. Although the extent and duration of secondary adrenal insufficiency are dependent on the duration and dosage of steroid therapy to some extent, individual factors appear to play a major role. Even the site of the disorder is not the same in all patients. In many patients, there is a temporary phase of hyporeactivity to ACTH and the increase in the plasma ACTH concentration precedes the increase of the plasma cortisol concentration for a few months (GRABER, 1965). But in other cases, deficient ACTH secretion is the predominant disorder (CARREON, 1960; JASANI, 1967). Several cases have also been observed in which no adrenocortical insufficiency was demonstrable after years of corticosteroid therapy in high doses.

A corticosteroid preparation for intravenous administration should always be to hand when patients treated with cortisone up to 6 months previously are subjected to surgery. Preventive corticosteroid therapy is not recommended as a general rule, however, since only 5 to 10% of patients treated with cortisone respond to surgical stress with an inadequate increase in cortisol secretion. The cortisone withdrawal syndrome can, but need not, lead to fatigue and anorexia, nausea and fainting. There is no adrenocortical atrophy after ACTH therapy, but the ACTH reserve of the pituitary is reduced. Serious incidents have been rarely observed. It is advisable to withdraw cortisone or prednisone gradually. In order to reestablish the diurnal variation of plasma cortisol, the night dose is withdrawn first, followed by the evening dose while administration of a single morning dose is continued. Intramuscular injection of long-acting ACTH preparations for 3 to 5 days after or during cortisone withdrawal restores adrenocortical responsiveness, but is of little benefit, since it inhibits pituitary ACTH secretion further.

It has recently been recommended that high pharmacological doses of cortisone be administered intermittently as a single morning dose on alternate days. Another recommendation is that synthetic glucocorticoids with a long half-life be given once daily in the morning. With these methods Corticotrophin secretion recovers after 12 and 36 hours respectively, and adrenal atrophy is thought to be avoided without

Table 7. Synopsis of symptoms and tests in various forms of adrenocortical insufficiency

		Pigmentation	Electrolyte disturbances	Hypoglycemia	Decreased urinary steroids	ACTH tests
Primary:	Addison's disease	+ + +	+	+ +	+ +	−
	Latent Addison's disease	+ +	−	−	+	−
Secondary:	Pituitary insufficiency	− (Pallor)	−	+ + +	+ + +	+ Repeated on 3 successive days i.v.
	Addisonism	−	−	−	+	+ + +

impairment of the therapeutic effect of the corticosteroid therapy.

i) "Addisonism", "Relative Adrenal Insufficiency" ("Benign Hypoadrenia")

A syndrome consisting of rather nonspecific symptoms vaguely reminiscent of ADDISON's disease, such as fatigue, hypotension, weight loss, and tendency to hypoglycemia, may occur from unknown causes or may accompany severe acute or chronic illnesses. In the past, such a condition was often assumed to be due to toxic damage of the adrenals and was refered to by such terms as "Addisonism" (THADDEA) or "benign hypoadrenia" (GOLDZIEHER). This assumption, however, is no longer acceptable, since the adrenals always respond normally to ACTH in these cases. On the other hand, low urinary steroids, which are often observed during severe acute and chronic illnesses as well as in convalescence and anorexia nervosa, must be due either to inadequate pituitary stimulation or to altered metabolism, because they increase normally in response to ACTH.

These conditions are clinically totally different from Addison's disease, latent Addison's disease or secondary insufficiency in panhypopituitarism or after cortisone therapy. They never lead to acute adrenal failure or to dangerous crises. Hormone therapy is contraindicated (see p. 329). The organism is always capable of satisfying increasing demands and adapting even to severe stress. With the exception of low urinary steroids, laboratory findings indicate normal adrenocortical function.

A diagnosis of adrenal insufficiency must never be based solely on noncharacteristic symptoms such as fatigue, hypotension, and weight loss. "Addisonism", as characterized by the symptoms of any severe illness, is not a pathologic entity and is of no clinical importance. Diagnoses of "Addisonism" and "benign hypoadrenia" should be avoided, because they may lead to unnecessary hormone treatment.

Pathologic anatomical findings of "Addisonism" have of course never been described. In one large series of autopsies, such findings as turbid swelling, cystic degeneration, and thrombotic changes of the adrenals were attributed to "benign hypoadrenia" (GOLDZIEHER), but adrenal insufficiency was not clinically substantiated. For similar reasons, the question of to what extent the status thymolymphaticus is due to functional disorders of the pituitary-adrenocortical system is also still unsolved, since the pathologic anatomical findings have never yet been correlated with the results of endocrine function tests in the same patients.

4. Differential Diagnosis of Adrenocortical Insufficiency

Diagnosis can be very easy in fully developed Addison's disease, but very difficult when the symptomatology is incomplete. The differentiation between sprue and Addison's disease can be particularly difficult. The clinical picture of these two conditions can be so similar that differentiation is only possible with the help of laboratory tests. Patients with sprue complain of fatigue, hypotension, weight loss, and diarrhea, which are also characteristic symptoms of Addison's disease. Moreover, objective signs, such as scanty pubic and axillary hair, particularly in women, and even pigmentation can be observed. Pigmentation of sprue, however, can usually be distinguished from Addisonian's pigmentation, because it is dirty gray in coloar, chloasma-like, and localized around the mouth and on the forehead without affecting the buccal mucosa and palmar lines. The diarrhea in sprue is characterized by voluminous, grey-yellow, offensive-smelling, mushy, fatty stools with a greasy gloss. Anemia is more severe in sprue than in Addison's disease and finally, sprue can be suspected when bone pains, indicating osteomalacia, and Chvostek's and Trousseau's signs, indicating tetany, are present. In sprue, the adrenals always respond normally to ACTH. Urinary steroids may be decreased, but the functional reserve of the adrenals is intact. No disorders of sodium and potassium balance or carbohydrate metabolism are demonstrable. A flat blood sugar curve obtained in the oral glucose tolerance test may be due to impaired absorption, as suggested by the normal results of an intravenous glucose tolerance test or an insulin tolerance test.

Chronic interstitial nephritis also has many clinical features in common with Addison's disease. This condition is mainly characterized by tubular damage and is referred to by such terms as renal acidosis, Lightwood-Albright syndrome, diabetes salinus renalis, or salt-losing nephritis, depending on the electrolyte disorder. In this disease, as in Addison's disease, a severe loss of sodium and also of chloride is possible, but it is not due to a deficiency of aldosterone, but to the damaged target organ, the tubules, which can no longer respond to the hormone.

Asthenia, hypotension, anorexia, and anemia are the predominant clinical features of diabetes salinus renalis. Tubular damage can also lead to potassium and calcium deficiency, and thus to pareses and renal osteomalacia. Surprisingly, diffuse and localized pigmentation of the skin, and even buccal mucosal pigmen-

tation of the Addisonian type, may be observed. Its pathogenesis is unexplained. Laboratory findings always permit a differential diagnosis: whereas serum urea nitrogen and nonprotein nitrogen can be elevated in both diseases, serum potassium is increased in Addison's disease and initially normal or decreased in salt-losing nephritis. The ACTH test is always decisive, because it is abnormal only in primary adrenocortical insufficiency. Hypo- and isosthenuria, severe metabolic acidosis, and delayed phenolphthalein excretion are indicative of chronic interstitial nephritis. A patient with renal disease is unable to concentrate his urine, whereas the dilution test is pathologic in adrenocortical insufficiency.

Differential diagnosis concerns the following features of Addison's disease: increased pigmentation is found in sprue and certain forms of nephritis as well as in chronic gastrointestinal disorders (melanosis of gastrointestinal polyposis, Peutz-Jeger syndrome Cronkhite-Canada syndrome), in pregnancy, and during treatment with hormonal inhibitors of ovulation. Persistent hyperthyroidism can also cause pigmentation, due to increased ACTH secretion induced by accelerated metabolism of cortisol. Cirrhosis of the liver can lead to pigmentation similar to that in Addison's disease. Pigmentation due to exogenous causes such as chronic ultraviolet radiation, physical irritation of the skin (cutis vagantium) and vitamin deficiency (pellagra) may be reminiscent of Addison's disease. In rare cases, a metastasizing melanoma may lead to diffuse cutaneous pigmentation. Iatrogenic pigmentation of the skin can result from chronic administration of hydantoin preparations, from alkylating cytostatic therapy of Hodgkin's disease, and also from administration of arsenic, bismuth, gold, and silver. The blue lines induced by chronic lead intoxication have to be differentiated from buccal mucosal Addisonian pigmentation. Biopsies are indicated in doubtful cases. The skin pigmentation of hemochromatosis can usually be distinguished from Addisonian pigmentation by its grayish violet tinge. However, differentiation can be difficult, since melanin is the major pigment present in hemochromatosis also, and iron deposits are not always histologically demonstrable. Hemochromatosis can be differentiated from Addison's disease by the enlarged firm liver and by the diabetes-like disorder of carbohydrate metabolism. Vitiliginous pigmentation can occur in neurofibromatosis and in polyostotic dysplasia with pubertas praecox (Albright's syndrome, see Chap. XIX).

Asthenia is a symptom associated with most illnesses and by itself does not justify suspicion of Addison's disease. The asthenia of neurasthenia and of anorexia nervosa may sometimes be suggestive of Addison's disease. However, neurasthenic symptoms do not have the characteristics of organic fatigue. The ACTH test permits a clear differentiation in ambiguous cases. All chronic infections, particularly tuberculosis and brucellosis, can lead to the type of organic fatigue usually found in Addison's disease.

It is sometimes difficult to differentiate true Addison's disease from the secondary adrenal insufficiency of Simmond's disease, although Addisonian patients are hyperpigmented, whereas patients with hypopituitarism are pale. Secondary adrenal insufficiency can be recognized by hypothyroidism, complete absence of the axillary and pubic hair, absence of electrolyte disorders, and a positive response to the intravenous ACTH test repeated on 3 days.

Adynamia, pareses, and paralysis of myasthenia gravis are immediately alleviated by treatment with prostigmine and tensilone. Myopathy in the apathic type of thyrotoxicosis may resemble Addison's disease, especially since the patients are hyperpigmented. Fatigue and atony combined with increased irritability are common to hyperparathyroidism and Addison's disease.

Hypoglycemia with blood sugar values below 60 mg% can also be due to hypopituitarism and to hyperinsulinism in the adult (see Chap. XIII). Adenomas and hyperplasia of the islet cells, however, lead to overweight and a healthy appearance. In vegetative lability, reactive hypoglycemia never reaches values below 50 mg%. Finally, in childhood, glycogen storage disease and the so-called spontaneous hypoglycemia have to be considered in the differential diagnosis.

Hypotension is very common and by itself does not suggest Addison's disease. It can be due to constitutional factors and is not necessarily a sign of other diseases. See p. 426 for a discussion of orthostatic hypotension due to adrenal medullary insufficiency.

5. Therapy of Adrenal Insufficiency

a) Diet

Dietary therapy with a low-potassium diet and a daily salt intake of 10 to 15 g was important before pure hormones were available. Today, Addisonian patients do not require any special diet.

b) Organ Transplantation

Organ transplantation is completely outdated, at least for the present. Animal adrenal glands

contain only a fraction of the necessary therapeutic dose of cortical hormones and are soon rejected or resorbed by the organism. The few cases of successful homotransplantation are of only theoretic interest. Only when the immunological problems associated with transplantation surgery have been successfully solved will interest in the treatment of primary adrenocortical insufficiency by organ transplants be renewed.

c) Adrenocortical Hormone Preparations

Adrenal tissue extracts are no longer in use.

Deoxycorticosterone has a purely mineralocorticoid effect. Overdosage causes edema, hypertension, and hypokalemia. Deoxycorticosterone acetate in sesame oil is given intramuscularly. A microcrystalline suspension of trimethylacetate esters of deoxycorticosterone has a prolonged activity over 4 weeks. After a single injection of 30 mg, approximately 1 mg per day is absorbed.

Cortisone has a pronounced glucocorticoid and a weak mineralocorticoid activity. Cortisone acetate tablets are administered orally. In contrast to deoxycorticosterone, oral cortisone is completely resorbed, enters the blood stream quickly, and persists for 8 to 12 hours in a sufficient concentration. Oral administration is therefore the method of choice.

Cortisol, like cortisone, has a potent glucocorticoid and a weak mineralocorticoid activity. It is 25 percent more effective than cortisone.

Cortisol acetate tablets are resorbed more quickly than cortisone acetate. In long-term maintenance therapy it has therefore no advantages over cortisone, since it must be taken every 6 hours instead of every 12 hours. It can be used in preference to cortisone when resorption is insufficient or when fast action is required.

Cortisol hemisuccinate can be administered intramuscularly and intravenously even in high concentrations. Intramuscular injection results in an adequate plasma concentration for several hours. During operations and in acute emergencies, it must always be given in an intravenous infusion.

9α-Fluorocortisol is available as the acetate in tablets. It has a strong glucocorticoid and a very strong mineralocorticoid activity. A daily oral dose of 2 mg is sufficient for complete adrenocortical substitution therapy, but leads to sodium retention. A daily dose of 0.25 mg maintains electrolyte balance. Full substitution therapy is provided by 0.1 mg of fluorocortisol combined with 25 mg of cortisone acetate.

d) Substitution Therapy in Addison's Disease (Primary Adrenal Insufficiency)

Modern substitution therapy is simple and rewarding. Weak, bed-ridden patients regain their vigor and can lead a completely normal life. They recover the capacity to perform even hard physical and intellectual work and to take part in sport.

The standard therapy is 25 to 37.5 mg of cortisone acetate orally and 0.1 mg of fluorocortisol orally. Cortisone tablets are taken in two daily divided doses, one at breakfast and one at 4 p.m. to simulate the physiological diurnal variation in plasma concentrations. We usually give 1 tablet of 25 mg of cortisone and 1 tablet of 0.1 mg of fluorocortisol in the morning, and one half tablet of cortisone (12.5 mg) in the afternoon. Often 25 mg of cortisone is sufficient, in rare instances even 12.5 mg. In general, the smallest possible dose which maintains well-being and maximal efficiency should be given. A daily dose of 0.05 to 0.2 mg of fluorocortisol is generally needed. Overdosage leads to edema, and underdosage to weight loss and hypotension. In heart failure, it is sometimes advisable to withdraw fluorocortisol, but to permit unrestricted salt intake.

Instead of fluorocortisol, an intramuscular injection of 25 mg of trimethylcortexone in crystalline suspension can be given every 3 to 4 weeks. Finally, a daily supplement of 5 to 10 g of salt can replace the mineralocorticoids. The natural mineralocorticoid d-aldosterone would have to be given intramuscularly as an acetate in an oily solution in a daily dose of 75 to 150 μg. The maintenance dose of aldosterone would be 20 to 40 times higher for oral administration and 2 to 6 times higher for sublingual administration. Aldosterone is now only rarely used for maintenance therapy.

The use of prednisone or other synthetic steroids instead of cortisone is pointless, since they have no sodium-retaining activity and thus necessitate higher doses of mineralocorticoids at the same time.

Whenever parenteral hormone administration is indicated, cortisol hemisuccinate should be given i.m. twice daily and 2.5 mg of deoxycorticosterone daily by i.m. administration. When cortisol hemisuccinate is not available, 5 mg of prednisolone hemisuccinate or phthalate can be given twice daily as well as 5 to 10 mg of deoxycorticosterone intramuscularly.

It is not advisable to administer cortisone acetate by i.m. injection as a suspension, because it is absorbed too slowly. Tablet implantation has also been discontinued.

In the woman, adrenocortical failure leads to a complete lack of androgens. They do not usually need to be replaced. It is not known whether they have any influence on the psyche. Loss of libido justifies a trial therapy with fluoxymesterone, 2.5 to 5 mg orally.

e) Treatment of Complications

Any additional stress induced by physical exertion, trauma, or acute illness increases the requirement for cortisone. Addisonian patients must be aware that they are exposed to serious danger by every injury, infection, and operation, and they must learn to meet this danger by increasing the cortisone dose. They should always carry a supply of cortisone tablets on them and if possible, cortisol for i.m. injection also. A dose of 75 to 150 mg of cortisone must be taken orally at once in febrile illnesses. If vomiting occurs, a doctor should be consulted and 50 to 100 mg of cortisol hemisuccinate should be given i.m. twice daily. Deoxycorticosterone acetate should be given in a dose of 5 to 10 mg i.m. in oily solution when signs of dehydration are observed. Immediate hospitalization is indicated in every severe illness.

Cortisone is not contraindicated in active or inactive tuberculosis treated with tuberculostatic drugs. However, the patient should be carefully supervised. The unequivocally favorable effect on the general condition outweighs possible impairment of the induration process. However, when cortisone has a clearly negative effect, the patients must be maintained on deoxycorticosterone alone. Under this therapy, they are considerably less resistant to stress, and particular caution is indicated during anesthesia and when morphine preparations are used. In view of the disturbed carbohydrate metabolism, frequent small meals are indicated. A snack containing 50 g of carbohydrate and 25 g of protein should be taken before retiring.

f) Substitution Therapy during Surgery and during Adrenalectomy

Today, even extensive surgery is possible in Addisonian patients under the cover of an intravenous cortisol infusion without a higher risk than in normals. Even total adrenalectomy is not hazardous when performed under adequate substitution therapy. Adrenalectomy in Cushing's syndrome requires a higher dose of cortisol and a slower reduction to the maintenance dose, since the organism has been overloaded with cortisol.

The treatment is outlined in Table 8.

Table 8. Adrenocortical substitution during surgery

1. *Substitution therapy for minor operations (tooth extraction)*
   1 hour before, cortisone acetate, 75 to 100 mg p.o.

2. *Substitution therapy during adrenalectomy and during surgery in patients with adrenal insufficiency*
   Starting from the beginning of anesthesia, intravenous infusion of 1 liter of 2:1 physiological glucose solution/physiological NaCl solution with cortisol hemisuccinate, 100 mg, over 8 hours. During the following 16 hours, again 1 liter of the same 2:1 infusion solution with cortisol hemisuccinate, 100 mg. In hypotension (less than 100 mm Hg systolic) 2nd infusion with L-noradrenaline, 10 mg, or angiotensin II, 10 mg, in 500 ml physiological sodium chloride solution at a rate of 5 to 40 drops per minute, i.e. 0.3 to 2.4 mg of L-noradrenaline and angiotensin respectively per hour. Infusion must never be interrupted.
   1st postoperative day:
   2 liters of 2:1 solution with cortisol hemisuccinate, 50 mg per liter, i.v.
   2nd postoperative day:
   If possible, switch to oral cortisone acetate, 4 × 25 mg.
   3rd postoperative day:
   cortisone p.o., 3 × 25 mg.
   Thereafter, gradual reduction over 3 to 6 days according to clinical criteria to the maintenance substitution dose of 25 to 37.5 mg of cortisone acetate p.o. and 0.1 mg of fluorocortisol p.o.

3. *Substitution therapy during adrenalectomy for Cushing's syndrome*
   Starting from the beginning of anesthesia, an intravenous infusion of 1 liter of 2:1 physiological glucose/physiological saline solution with cortisol hemisuccinate, 200 mg, over 8 hours. In the following 16 hours, 1 liter of the same 2:1 infusion solution with 200 mg of cortisol hemisuccinate.
   In hypotension (less than 100 mm Hg systolic) 2nd infusion with L-noradrenaline, 10 mg, or angiotensin II, 10 mg, in 500 ml of physiological saline solution at a rate of 5 to 40 drops per minute, i.e. 0.3 to 2.4 mg of L-noradrenaline and angiotensin II respectively per hour. The infusion must never be interrupted.
   1st postoperative day:
   2 liters of 2:1 solution with 100 mg of cortisol per liter, i.v.
   2nd postoperative day:
   2 liters of 2:1 solution with cortisol, 100 mg per liter, i.v.
   3rd postoperative day:
   If possible, switch to oral cortisone acetate in a dose of 4 × 50 mg.
   4th postoperative day:
   3 × 50 mg of cortisone, p.o.
   Thereafter, gradual reduction over 2 to 3 weeks according to clinical criteria to a maintenance substitution dose of 25 to 35 mg of cortisone acetate p.o. and 0.1 mg of fluorocortisol p.o.

g) Treatment of Acute Adrenal Insufficiency

Addisonian Crisis. When chronic adrenal insufficiency exacerbates into acute crisis under the influence of infection, trauma or surgery, the patient's life is in serious danger and immediate intensive treatment is necessary. Every delay and every stressful diagnostic procedure can cause death. When the diagnosis is uncertain

and the patient is in a relatively good condition, a blood sample may be taken for the determination of potassium, sodium, chlorides, urea, cortisol, and blood sugar. Afterwards, the following therapeutic procedure should be followed:

Addisonian crisis in a patient treated or overtreated with deoxycorticosterone alone is characterized by symptoms of hypoglycemia together with signs of water retention. There may be edema, high blood pressure, coma, epileptic seizures, and pulmonary edema. Sodium chloride and fluid administration are contraindicated in these cases. Intravenous administration of cortisol in 10% glucose solution and plasma infusions are indicated. If hypokalemia has been demonstrated, KCl, 6 g, is given in enteric-coated tablets or an intravenous infusion of 2 g of KCl in 1000 ml of 5% glucose solution is given within one hour.

Table 9. Therapy of Addisonian crisis (for children reduce doses by 0–50%)

1. Intravenous infusion over 3 hours of 100 mg of cortisol hemisuccinate in 500 ml of physiological saline solution to which 50 ml of a 40% glucose solution can be added. If no water-soluble cortisol preparation is available, prednisolone hemisuccinate or prednisolone phthalate, 25 mg. If intravenous infusion is impossible, cortisol hemisuccinate, 100 mg or prednisolone hemisuccinate, 25 mg, i.m.
2. In hypotension (systolic blood pressure below 100 mm Hg), infusion of 10 mg of noradrenaline or angiotensin II in 500 ml of physiological saline solution at a rate of 5 to 40 drops per minute, i.e. 0.3 to 2.4 mg per hour of L-noradrenaline or angiotensin. It may be advisable to give 500 ml of plasma or blood after rehydration.
3. Continued intravenous infusion of cortisol, 10 mg per hour, until patient is able to drink and to take cortisone tablets orally (4 × 50 mg per day).
4. Gradual reduction of cortisone to maintenance dosage of 25 to 37.5 mg of cortisone p.o. and 0.1 mg of fluorocortisol p.o. within 3 to 6 days.
5. Antibiotics may be necessary.

h) Therapy of Latent Addison's Disease

In these patients, the reduced endogenous production of adrenocortical hormones is adequate to meet the requirements caused by a normal life style. Blood pressure and weight, but mainly the general condition and efficiency indicate whether and in what dosage long-acting deoxycorticosterone, fluorocortisol or cortisol should be given. Even when hormones are not usually needed, the patients must always carry cortisone on them, so that they can take 100 to 150 mg of cortisone at once in case of infection or trauma. If acute insufficiency develops, it must be treated in the same way as the Addisonian crisis.

i) Therapy of Secondary Adrenal Insufficiency in Panhypopituitarism and after Cortisone Treatment

Adrenal atrophy due to ACTH deficiency can usually be reversed by intensive ACTH stimulation even after years. However, maintenance therapy with ACTH has not been very satisfactory, because ACTH always has to be given by injection, whereas cortisone can be taken orally.

In secondary adrenal insufficiency, the secretion of mineralocorticoids is normal under basal conditions. Cortisone alone is sufficient for full substitution therapy. The basal secretion of cortisol may be adequate for a *vita minima*. Every additional stress can precipitate a crisis in these patients. In addition to small doses of cortisone acetate (12.5 to 25 mg p.o.) in panhypopituitarism, sodium-l-thyroxine must be given for the thyroid deficiency and testosterone for male gonadal insufficiency (see p. 105).

See p. 326 for a discussion of secondary adrenal insufficiency after long-term treatment with high doses of cortisone.

When a sudden stress precipitates these patients into acute adrenal insufficiency, cortisol must be given intravenously at once, as in Addisonian crisis, although it promotes further atrophy. ACTH, even when given intravenously, cannot stimulate the atrophic adrenals fast enough to be of use in an emergency situation, and thus cannot replace cortisone. Children receive between half and the full adult dose.

6. Prognosis of Adrenal Insufficiency

The prognosis of Addison's disease has changed completely with the development of therapy. Before 1930, when no specific treatment was available, 63% of Addisonian patients died within $1^1/_2$ years. Between 1930 and 1937, with treatment with salt and adrenal extracts, only 43% died within $1^1/_2$ years. Since deoxycorticosterone has been added to the therapy, only 14% have died within $1^1/_2$ years. The introduction of cortisone has lowered the mortality further. Prognosis is further influenced by additional diseases, such as urogenital tuberculosis. Simultaneous pulmonary tuberculosis is rare. Addison's disease due to adrenal atrophy is thought to have a more favorable prognosis than the tuberculous form of the illness. A slow onset of the symptoms also indicates a better prognosis. Patients who only show an increase in pigmentation and hypo-

tension over a long period of time and have no gastrointestinal or hypoglycemic symptoms may live without hormone therapy for many years. A tendency to hypoglycemia is an ominous sign which calls for immediate treatment. The prognosis, however, is mainly a function of the therapy and the care with which it is carried out. Patients have to be given as much information as possible about their illness. They must be taught to recognize their symptoms and to act accordingly. After the establishment of optimal maintenance therapy we make a point of seeing and examining the patient at first every three months and later once a year.

F. Hyperfunction of the Adrenal Cortex

1. Classification

As shown on p. 288 and in Table 1, the human adrenal cortex produces mainly cortisol, corticosterone, and dehydroepiandrosterone sulfate. Aldosterone, which is produced in small amounts, is of great physiological importance, whereas the other less active or inactive precursors or by-products of adrenocortical hormones which are found in the blood have no clinical significance under normal conditions. Secretion of small amounts of testosterone is proven, and estrogens are probably also secreted.

Thus there are three distinct clinical syndromes of hyperfunction:

1. Excess of mineralocorticoids (primary aldosteronism, Conn's syndrome);
2. Excess of cortisol (Cushing's syndrome);
3. Excess of androgens (adrenogenital syndrome).

A combination of Cushing's syndrome and adrenogenital syndrome can be due to an adrenal adenoma. Combinations of all three syndromes, particularly characterized by massive secretion of precursors, can be caused by adrenal carcinoma. Hirsutism and acne are signs of pure Cushing's syndrome, whereas virilism indicates an associated adrenogenital syndrome.

2. Mineralocorticoid Excess

a) Primary Aldosteronism (Conn's Syndrome)

α) Definition, Incidence

The term primary aldosteronism designates autonomous overproduction of aldosterone by the adrenals. The disease is always caused by an aldosterone-producing tumor of the adrenal cortex* ("aldosteroma", "aldosteronoma"). The classic Conn's syndrome consisted of the symptoms of hypokalemia, such as muscular weakness or periodic pareses and polyuria, and of benign hypertension. However, CONN no longer considers hypokalemia a main feature of the disease. In many patients, hypertension precedes hypokalemia by several years, and CONN has been able to diagnose primary aldosteronism in a few normokalemic hypertensive patients from laboratory findings showing an increased aldosterone secretion rate and a decreased plasma renin activity. However, only very few cases of normokalemic primary aldosteronism have been diagnosed so far.

The incidence of the disease is also still very controversial. In the decade following Conn's first description of the illness (1955), a few hundred cases were described in the literature. Until 1965, primary aldosteronism was considered to be a rare cause of hypertension. In the United States, where about 17 million inhabitants suffer from hypertension, less than 1000 cases of primary aldosteronism had been diagnosed. CONN (1965/1966), however, suggested that actually at least 20% of all patients with "essential" hypertension suffered from undiagnosed primary aldosteronism. This hypothesis was based on the incidence of a raised aldosterone excretion rate in patients with essential hypertension (GARST, 1960) and on the incidence of adrenocortical adenomas found at autopsy of patients with essential hypertension. Although it is quite possible that the disease will be more frequently diagnosed in future due to improved laboratory methods and mass screening of hypertensive patients, evidence presented by a number of other investigators is not compatible with Conn's hypothesis. According to clinical studies carried out with double isotope assays, aldosterone secretion rate is normal in the majority of patients with benign hypertension. LARAGH (1966) did not find a single case of increased aldosterone secretion among 73 patients with benign essential hypertension. Aldosterone excretion rate was normal in 43 patients with benign hypertension studied by KAPLAN (1967). In a prospective study carried out in 90 unselected cases of "essential" hypertension, primary aldosteronism could be excluded by a normal aldosterone secretion rate, a normal plasma renin activity, or both in 87 patients. By contrast,

* Some authors use the term "primary aldosteronism" also for cases of aldosterone excess of unknown etiology associated with bilateral adrenocortical hyperplasia and a decreased plasma renin concentration (p. 339). According to some authors, this disease is as frequent as tumorous primary aldosteronism (GEORGE, 1970).

primary aldosteronism was found in 4 out of 10 patients with hypertension and hypokalemia (FISHMAN, 1968). Moreover, an adrenocortical adenoma found at operation or autopsy of a hypertensive patient does not prove that the hypertension was of adrenal origin. The steroid content of adenomas of patients with essential hypertension was normal, whereas adenomas of patients with primary aldosteronism contained 10 to 100 times more aldosterone and 10 times more corticosterone per unit weight than normal human adrenocortical tissue. Until proved otherwise, primary aldosteronism must therefore still be considered a rare cause of hypertension.

The female sex is affected $2^1/_2$ times more frequently. Two thirds of cases are diagnosed during the 4th and 5th decade of life. The disease can, however, occur at any age. Although juvenile "congenital aldosteronism" with bilateral adrenal hyperplasia is a form of secondary aldosteronism (see p. 339), several cases of primary aldosteronism due to adrenal adenomas during childhood have been described.

β) Pathologic Anatomy

The adenomas occur 2 to 3 times more frequently on the left side than on the right. In 90% of the cases, they are solitary, in 10% they are multiple, and in only 2% are they bilateral. They are usually very small and can therefore not be diagnosed radiologically. The weight of 63% of the adenomas is less than 6 g, and the greatest diameter is less than 3 cm in 86%.

They are composed of cells reminiscent of the zona fasciculata. The adenoma itself and the adjacent cortical tissue show no specific alterations indicative of mineralocorticoid excess. Atrophy of the remaining cortex has, however, been described.

Considerable amounts of aldosterone can be isolated from the tumors, whereas the aldosterone content of the adjacent adrenal tissue is strikingly low. In most cases, however, corticosterone and not aldosterone is found to be the prevalent steroid in tumors causing primary aldosteronism. Considerable amounts of cortisol are also often found which could explain the contralateral atrophy observed in some cases, necessitating temporary substitution therapy.

The kidneys usually show typical signs of hypokalemic nephropathy. In addition, arteriosclerosis resulting from hypertension is often found. Signs of chronic pyelonephritis are not uncommonly observed.

γ) Clinical Features

The leading symptoms are caused by *hypertension* and *hypokalemia*. Headache due to hypertension is rarely absent. Potassium is lost mainly in the urine, but also in the colon (SHIELDS, 1968). Hypokalemia leads to muscular weakness, which may be constant or, frequently, progressing to periodic pareses and paralyses, and also to polyuria, especially during the night, accompanied by isosthenuria and polydipsia, which are not always very pronounced (see Chap. III, p. 56).

Tetany is often, but not always present and, like hypocalcemic tetany in the latent stage can be recognized by positive Chvostek's and Trousseau's signs. It is due either to metabolic alkalosis or to magnesium deficiency. There is usually no edema. Only a few cases of classic Conn's syndrome with edema have been described and a special reason for the edema was found in most of them.

Paresthesia is not uncommon and is probably due to the alkalosis.

Table 10. Frequency of clinical manifestations of primary aldosteronism. (From KOCZOREK, 1964)

a) *Symptoms*	
Polyuria, nycturia	73%
Muscular weakness	71%
Headache	53%
Polydipsia	48%
Intermittent paralysis	25%
Parasthesia	24%
Tetanic seizures	21%
No symptoms	5%
b) *Clinical findings*	
Benign hypertension	100%
Retinopathy I to III	53%
Increased heart size	42%
Trousseau	17%
Chvostek	8%
Atonic pareses	4%

The hypertension is usually benign, although diastolic blood pressure may vary between 90 and 160 mm Hg. The heart is enlarged in only half the cases. Hypertension is not progressive, does not lead to arteriolar necrosis, and produces retinopathy of grade I to III. Papilledema is not found. The symptomatology may, however, be incomplete and there are known cases of surgically verified primary aldosteronism where there were no symptoms at all; the hypertension was discovered at a routine examination and hypokalemia was then detected.

δ) Laboratory Findings

1. Electrolyte Balance. In most cases the main laboratory finding is hypokalemia, which generally varies between 1.4 and 3.2 mEq/l. Normokalemic primary aldosteronism is rare. In most normolkalemic cases, hypokalemia can be provoked by oral sodium loading (200 mEq of Na^+ over several days). Potassium balance is negative and urinary potassium excretion is inappropriately high in relation to the low serum potassium level. The urinary potassium loss is substantiated by the fact that daily potassium excretion is not reduced to 20 mEq or less when a potassium-deficient diet (20 mEq daily) is given or when the serum potassium is below 3 mEq/l. Potassium excretion does not stop completely in healthy subjects, but it is considerably reduced. Characteristic changes in potassium balance can be induced by increase or reduction of sodium intake. When potassium intake is kept constant (100 mEq per day) and sodium intake is increased to 200 mEq per day, there is a marked rise in urinary potassium excretion and a further fall in serum potassium after a few days. This is due to a stimulated sodium-potassium exchange in the distal renal tubules under the influence of an elevated plasma aldosterone. Conversely, potassium excretion decreases and serum potassium rises when dietary sodium intake is restricted and no sodium is available for exchange with potassium in the distal tubules. In time, the negative potassium balance leads to a considerable deficit in total body potassium, and exchangeable body potassium as estimated with ^{42}K may fall to 70% of normal. A very high potassium intake (200 mEq per day) may reduce the potassium deficit to some extent, but does not usually normalize the hypokalemia.

A decrease in potassium excretion and a rise in serum potassium in response to spironolactone are characteristic of primary aldosteronism and help to differentiate this condition from tubular nephropathy with potassium loss.

Hypernatremia is not as common and not as pronounced as hypokalemia. Serum sodium varies between 137 and 160 mEq/l and overlaps with normal values. Exchangeable body sodium, as measured by ^{24}Na, is elevated by an average of 15%. However, interpretation of this parameter is difficult because of the sodium stored in the bones. The extracellular fluid volume is increased and the plasma volume shows an average increase of 15%. There may be some overlap with normal values. A definite decrease in serum sodium or in plasma volume indicates secondary rather than primary aldosteronism.

In primary aldosteronism, the sodium-potassium ratio is often more strikingly reduced in the sweat and saliva than in the urine. However, the sodium content of these two body fluids varies with their secretion rate, and standardization is difficult. The estimation of the sodium-potassium ratio in the sweat related to the secretion rate may be used as a simple diagnostic test for primary aldosteronism in mass screening of hypertensives (GRANDCHAMP, 1967).

Hypomagnesemia of uncertain origin is found in many cases and may increase the predisposition to tetany. The hypokalemia is accompanied by metabolic alkalosis with plasma bicarbonate levels between 24 and 54 mEq/l (average 35) and an increased plasma pH. Although aldosterone promotes the excretion of H-ions, the urine is usually alkaline with a pH between 7 and 7.5.

Polyuria, polydipsia, nycturia, and hyposthenuria are caused by the hypokalemia. The polyuria is not reduced by vasopressin and the urinary osmolality is always lower than the plasma osmolality.

2. Aldosterone. Proof of a pathologically elevated and relatively autonomous aldosterone secretion rate is one of the most important criteria for the diagnosis of primary aldosteronism. In most cases, estimation of urinary aldosterone-18-glucuronide hydrolyzable at pH 1, is sufficient. However, when aldosterone metabolism by the liver is impaired (liver diseases, pregnancy), the aldosterone secretion rate has to be determined. In most cases, the aldosterone secretion rate is moderately increased, to approximately twice the normal value. Massive increases in aldosterone secretion rate are more frequently found in secondary (malignant hypertension) than in primary aldosteronism. Electrolyte status must always be taken into consideration when interpreting aldosterone secretion or excretion rates. An elevated aldosterone excretion rate is pathologic only when the daily sodium intake exceeds 100 mEq (6 g of sodium chloride).

Aldosterone secretion rate in primary aldosteronism is characteristically not or only slightly inhibited by measures leading to increased plasma volume:

daily intake of 200 mEq of sodium (12 g of sodium chloride, possibly in the form of gelatine capsules) for 5 days;

infusion of 2 liters of physiologic saline solution given over 4 hours on each of two consecutive days;

parenteral administration of deoxycorticosterone acetate, 20 mg daily for 3 consecutive days, with normal salt intake.

However, it must be borne in mind that in edematous patients these measures only increase the extracellular fluid volume and have no effect on circulating plasma volume. In this type of secondary aldosteronism, aldosterone secretion is not suppressed, and autonomy may be simulated.

3. Renin, Angiotensin. Determinations of renin activity, renin concentration, or angiotensin II concentration in the plasma are the most important laboratory methods for differentiating primary from secondary aldosteronism, since the increased aldosterone secretion rate is directly attributable to an elevated renin-angiotensin level in almost all known forms of secondary aldosteronism. By contrast, in primary aldosteronism, renin activity, renin concentration, and angiotensin II concentration in the plasma are reduced or in the lower normal range and do not increase in response to sodium deficiency or orthostasis. When a direct estimation of plasma renin is not possible, an angiotensin infusion test may give indirect information about the activity of the patient's renin-angiotensin system. Patients with renovascular hypertension respond only to high doses of angiotensin II by an increase in blood pressure, whereas patients with primary aldosteronism are extremely sensitive and respond even to very low doses. The test, however, is not without risk in hypertensive patients.

4. Carbohydrate Metabolism. Whereas fasting blood sugar levels are usually normal, pathologically reduced glucose tolerance is found in 50% of patients with primary aldosteronism. The glucocorticoid activity of corticosterone, which is often secreted in excess, may contribute to this. It is, however, primarily due to the potassium deficiency. Hypokalemia impairs the formation of glycogen and retards insulin secretion.

ε) X-Ray Examinations

Retroperitoneal pneumoradiography is generally unsatisfactory for the preoperative lateralization of an aldosterone-producing adrenocortical adenoma, because small adenomas are not usually revealed by this technique. Better results can be obtained by selective adrenal phlebography (CONN, 1969). An unequivocal lateralization can be achieved by the determination of aldosterone in adrenal venous plasma from both sides, obtained by vena cava catheterization (MELBY, 1967). However, only very skillful and experienced radiologists are capable of catheterizing both adrenal veins. If preoperative lateralization is impossible or doubtful, the left adrenal should be operated upon first, because most aldosterone-producing adenomas are found on the left side (CONN, 1969).

Suprarenal aortography only occasionally reveals an adrenal tumor, but does disclose renal arterial stenosis.

Recently visualisation and localisation of the adenoma has been achieved by scintillation scanning after administration of ^{131}I-19-iodocholesterol (CONN, 1971).

ζ) Differential Diagnosis

Differential diagnosis of primary aldosteronism must eliminate other causes of first hypokalemia (Table 11) and secondly hypertension.

Table 11. Differential diagnosis of primary aldosteronism

	Blood pressure	Blood		Urine			Aldosterone	17-Hydroxy-corticoids
		K	HCO_3	Renin	K	Volume		
Primary aldosteronism	+		+	−	+	+	+	=
Cushing's syndrome	(+)	−	+		+	+	=	+
Malignant hypertension	+ + +	−	+	+	+	+	+ +	=
Renal hypertension	+ +	−	+	+	+	+	+ +	=
Tubular nephropathy	=	−	−	=	+	+	=	=
Chronic diarrhea Abuse of laxatives	−	−	+		−	−	−	=
Anorexia mentalis	−	−	+		+	−		−
Familial potassium-losing Nephropathy (LIDDLE)	+	−	+	−	+	+	−	=
Juxtaglomerular hyperplasia (BARTTER)	−	−	+	+	+	+	+	=
17-Hydroxylase deficiency	+	−	+	−	+	+	−	−
Iatrogenic:								
Salidiuretics		−	+	+	+	+	+	=
Cortexone	+	−	+	−	+	+	−	=
Liquorice juice	+	−	+	−	+	+	−	=

It must first be determined whether potassium is lost in the urine, in the stools, or by displacement into the intracellular space. As a rule, in primary aldosteronism more than 20 mEq of potassium are excreted in 24 hours, even when the diet is potassium-deficient or the serum potassium is below 3 mEq/l, unless the potassium reserves are completely exhausted after years of illness. Hypokalemia without hyperkaluria is typical of chronic diarrhea, or is suggestive of concealed abuse of laxatives. Much work can be saved by the demonstration of phenolphthalein in the feces or urine. Many laxatives contain phenolphthalein, and feces or urine turn red after alkalization. If salidiuretics are used in addition to laxatives because of the development of edema, the diagnosis becomes difficult, since hyperkaluria as well as an elevated aldosterone secretion rate may then develop. However, urinary potassium excretion decreases when salidiuretics are withdrawn for a few days. Hypokalemia with hyperkaluria and concurrent obstipation are found in anorexia mentalis (ROSSIER, 1955).

When hyperkaluria has been established, a tubular renal disorder has to be excluded. In the absence of a primary renal disease, hypokalemia is always associated with metabolic *alkalosis*, whereas metabolic acidosis is found in most tubular nephropathies, because they often cause impaired hydrogen ion excretion. On the other hand, hypokalemia of long standing can lead to impaired tubular epithelial function with the development of hyposthenuria. Renal disorders which may be associated with hypokalemia are renal acidosis, chronic interstitial nephritis, occasionally chronic pyelonephritis, and congenital tubular diseases, such as Fanconi's syndrome. Whereas these diseases are associated with normal or low blood pressure and metabolic acidosis, the syndrome of familial potassium-losing nephropathy described by LIDDLE (1964) leads to alkalosis and hypertension. The disease seems to be due to a generalized abnormality in membrane sodium transport (GARDNER, 1971).

Hyperkaluria together with metabolic alkalosis primarily suggests iatrogenic hypokalemia. Hypokalemia due to salidiuretic therapy in hypertension is often mistaken for primary aldosteronism. Salidiuretics promote sodium excretion, and thus lead to an increase in aldosterone secretion and excretion rate. *Liquorice juice* has a mineralocorticoid-like activity (see p. 303) and excessive intake (it is a component of certain soft drinks) leads to hypokalemia, hyperkaluria, alkalosis, and hypertension, but to a *decreased* aldosterone secretion rate. Similarly, a decreased aldosterone secretion rate is induced by chronic deoxycorticosterone acetate administration and is also found in Liddle's familial potassium-losing nephropathy.

Finally, when hypokalemia, alkalosis and hyperkaluria are associated with an increased secretion and excretion rate of aldosterone, primary aldosteronism has to be differentiated from secondary aldosteronism. Secondary aldosteronism due to idiopathic edema, nephrosis, cirrhosis of the liver with ascites, and cardiac failure is usually quite easy to differentiate from Conn's syndrome, because blood pressure is normal and severe hypokalemia is rare. It is more difficult to differentiate primary aldosteronism from malignant essential hypertension or renal hypertension due to unilateral stenosis of the renal arteries, which promote aldosterone secretion through the renin-angiotensin system and occasionally lead to adrenocortical hyperplasia. Extremely malignant, progressive hypertension with retinopathy grade IV and papilledema, is not likely to be due to primary aldosteronism, but has been observed in confirmed cases. Whereas hypernatremia is usually found in primary aldosteronism, serum sodium is normal or even decreased in malignant hypertension with secondary aldosteronism. In every case, intravenous pyelography, aortography, and possibly also HOWARD's test to assess the differential sodium excretion of both kidneys must be carried out to exclude renovascular hypertension. A correct preoperative diagnosis is the basis of successful surgery. When plasma renin or angiotensin levels can be determined, high values distinguish renal and malignant hypertension from primary aldosteronism with low renin and angiotensin levels. The angiotensin infusion test, which, however, is not completely harmless in hypertensive patients, can be used to differentiate essential hypertension and primary aldosteronism with a marked response from renal hypertension with a decreased response. In many patients with essential hypertension plasma renin activity is subnormal (FISHMAN, 1968).

Evidence of autonomy of aldosterone secretion, i.e. little or no response to salt loading, salt restriction or volume expansion, strongly support the diagnosis of primary aldosteronism due to an aldosterone-producing tumor. However, aldosterone secretion is not always completely autonomous in primary aldosteronism. Finally, primary aldosteronism has to be differentiated from Bartter's syndrome (1962, see secondary aldosteronism), i.e. juxta-glomerular hyperplasia, which is thought to be due to an extremely decreased vascular responsiveness to angiotensin II, leading to renin excess and secondary aldosteronism without hypertension.

In the rare syndrome of 17-hydroxylase deficiency, the clinical features of hypermineralocorticoidism are associated with signs of hypogonadism (amenorrhea, absence of secondary sex characteristics). Aldosterone secretion rate is decreased, but urinary and plasma 17-hydroxycorticoids and 17-ketosteroids are also very low. In this disease, as in ACTH-dependent secondary aldosteronism, potassium balance and blood pressure become normal under suppressive therapy with low doses of glucocorticoids. Primary aldosteronism has to be distinguished from Cushing's syndrome, which, however, is mainly characterized by the classic features of glucocorticoid excess, whereas hypokalemia is usually moderate. Cushing's syndrome due to ectopic secretion of ACTH by a malignant tumor, however, can be very similar clinically to Conn's syndrome, because hypokalemia is very pronounced and the classic Cushing's signs may be absent. But aldosterone excretion and secretion rate are usually normal or decreased, whereas the urinary cortisol metabolites, such as 17-hydroxycorticoids, are increased in Cushing's syndrome, in contrast to Conn's syndrome.

The diagnosis of primary aldosteronism is difficult, since there are no definite pathognomonic findings. Frequently, a high aldosterone excretion rate due to other factors leads to the wrong diagnosis of primary aldosteronism, even when the estimation has been carried out in the correct conditions with a diet containing at least 6 g of sodium chloride. The differential diagnosis between Conn's syndrome and malignant or renal hypertension is the most difficult. It should always be carried out at a specialized clinical center with adequate laboratory facilities.

A suspected diagnosis of primary aldosteronism should always be substantiated by means of electrolyte balance studies before expensive and time-consuming aldosterone, renin, and angiotensin estimations are carried out.

η) Therapy

When the diagnosis of primary aldosteronism is supported by the classic clinical features and has been confirmed by laboratory findings, and when malignant hypertension and unilateral kidney disease have been excluded, exploratory surgery of the adrenals is indicated. As a rule, substitution therapy with cortisol is not necessary, but it should always be prepared. If an adenoma is found the affected adrenal gland must be removed. Exploration of the opposite side can be omitted, because the tumor is unilateral in 98% of all cases. It is advisable to restore body potassium as far as possible by preoperative treatment with potassium, 200 mEq per day, spironolactone for 7 to 10 days, and sodium restriction. When surgery is contraindicated, spironolactone can be used for chronic therapy. The effectiveness of inhibitors of aldosterone biosynthesis, such as SU 9055 and aminoglutethimide, in the definite or preoperative treatment of primary aldosteronism has not been definitely evaluated. The heparinoid RO 18307 is not yet available for clinical use.

After removal of an aldosterone-producing adrenal adenoma, the metabolic syndrome with hypokalemia disappears within a few days. The blood pressure returns to normal within a few months in two-thirds of cases; hypertension is alleviated in 20% and unchanged in 13% of the patients.

b) Secondary Aldosteronism

α) Definition and Pathogenesis

The term "secondary aldosteronism" refers to increased aldosterone secretion due to extraadrenal causes. In most cases, elevated renin and angiotensin production is responsible for the increase in aldosterone secretion. In diseases with edema, increased renin production is a normal renal response to the decreased circulating blood volume. In cases of malignant renal hypertension, however, in response to an impaired renal circulation, it is pathologic. Hypersecretion of aldosterone alone does not lead to edema. Other factors, such as reduced oncotic pressure or abnormal capillary permeability, must have a primary role in the formation of edema. Aldosteronism in the 3rd trimester of a normal pregnancy is probably physiological and compensates for the sodium diuretic action of progesterone excess.

Since methods for measuring renin concentration or activity in the plasma have become available a few cases of what appears to be secondary aldosteronism have been described, in which renin-angiotensin production is not increased and in which another stimulatory mechanism had to be sought for the elevated aldosterone secretion rate. In some of these cases, the increased aldosterone secretion appeared to be dependent on ACTH. In other cases, the pathogenesis was completely unknown.

β) Aldosteronism Secondary to Edema

1. Nephrotic Syndrome. In the nephrotic syndrome of any etiology, oncotic pressure decreases due to renal loss of albumin, thus facilitating a shift of water and sodium chloride from the capillaries to the interstitial space and impairing

the reentry of these substances into the blood stream. Hypovolemia develops, which is a physiological stimulus of aldosterone production. Aldosterone secretion and excretion rates are usually markedly increased and may reach excessive values. More sodium is reabsorbed in the distal tubules, which further increases the interstitial fluid volume, setting up a vicious circle. It is still not known why this type of secondary aldosteronism does not lead to hypokalemia.

2. *Liver Cirrhosis.* Secondary aldosteronism is usually found in liver cirrhosis with ascites. Transudation from the blood stream leads to hypovolemia, which induces an increased secretion of renin and aldosterone. Moreover, inactivation of aldosterone by the liver is impaired, resulting in high values of urinary free aldosterone and 18-glucuronide, and a relatively decreased excretion of tetrahydroaldosterone.

3. *Idiopathic Edema.* Generalized edema not caused by renal, cardiac, or liver disease and occurring exclusively in women, usually in younger age groups and often characterized by premenstrual exacerbation, must be primarily due to an increased capillary permeability. Aldosterone excretion and secretion rates are not suppressed by intravenous infusion of sodium chloride. Sodium administration does not expand the intravascular volume, since the sodium immediately escapes into the interstitial space. Hypovolemia provides the stimulus for the increased production of aldosterone, occasionally leading to the formation of adrenocortical adenomas. In very severe cases leading to invalidity, subtotal or total adrenalectomy has been attempted. Idiopathic edema is related to cyclic edema, which occurs premenstrually in nervous women. There are intermediate forms of the two conditions. In some cases, occurrence of abnormal proteins has been demonstrated (THORN, 1968; VEYRAT, 1968; GILL, 1972).

4. *Heart Failure.* Cardiac insufficiency is usually accompanied by sodium retention and edema formation. Aldosterone excretion rate is often but not always increased. The secretion rate is normal in most cases. The role of aldosterone in edema formation of cardiac failure is not considered to be very important. The increased renal retention of sodium is thought to be due mainly to hemodynamic factors because renal sodium retention is promoted to a greater extent by anoxemia than by renal ischemia. Since aldosterone secretion rate is usually normal, the existence of aldosteronism secondary to cardiac failure is no longer unanimously accepted. The paradoxical reactions of cardiac patients to sodium restriction or loading are striking. Sodium restriction leads to disappearance of the edema, alleviates heart failure, and decreases aldosterone excretion. On the other hand, sodium loading in preexisting hypovolemia leads to a further expansion of the interstitial volume, increases edema, aggravates the cardiac failure, and induces an additional increase in aldosterone secretion. In heart failure, an inadequate renal blood flow (forward failure) leads to increased renal salt retention, whereas an increased venous pressure (backward failure) has the same effect on the kidneys by diminishing their oxygen supply.

γ) Aldosteronism Secondary to Malignant or Renovascular Hypertension with Renin Excess

Contrary to previous reports, aldosterone secretion or excretion rate is not increased in uncomplicated essential hypertension. However, in hypertensives the response to sodium restriction or sodium loading is blunted. It is still not known whether the diurnal variation in aldosterone secretion is greater in hypertensive patients than in normal healthy subjects.

Complications occurring in the course of essential hypertension, such as heart failure, renal insufficiency, or disorders of cerebral circulation, occasionally lead to an increased aldosterone secretion rate.

Malignant hypertension, which is always rapidly progressive and is characterized by high diastolic blood pressure, papilledema and renal damage due to necrotizing arteriolitis, is almost always associated with a strikingly increased aldosterone secretion rate. Despite manifest renal failure, there is a tendency to develop hypokalemia and alkalosis, so that primary aldosteronism is simulated. In contrast to primary aldosteronism, however, hypernatremia is never found and the serum sodium may even be slightly decreased. In malignant hypertension, aldosterone secretion is presumably stimulated by the renin-angiotensin system.

Excessive aldosterone production is often, but not regularly found in unilateral kidney diseases, particularly in stenosis of the renal artery with frequently malignant hypertension. These diseases are often associated with hypokalemia, but never with hypernatremia.

After surgical removal of the affected kidney, hypertension regresses and aldosterone secretion becomes normal. The increased aldosterone secretion rate is most probably mediated by the renin-angiotensin system. This condition may be mistaken for primary aldosteronism and the differential diagnosis has to be based on the

following tests: intravenous pyelography, Howard's test (comparison of sodium excretion on both sides), aortography, and where possible, determination of renin or angiotensin in peripheral blood, preferably in blood from the right and left renal veins, obtained by venous catheterization.

A few cases of a peculiar illness in which hypokalemia, polyuria and alkalosis are present but not hypertension ("Bartter's syndrome") have been described by BARTTER (1962) and other clinical investigators. This condition was at first confused with CONN's syndrome. The histology of the kidneys revealed hyperplasia of the renin-producing juxta-glomerular cells. BARTTER assumed that the disorder was primarily due to a failure of the blood vessels to respond to angiotensin, which was demonstrable by means of an angiotensin infusion test. This would lead to overproduction of renin and angiotensin, which in turn would stimulate aldosterone secretion and generate secondary aldosteronism. Hypernatremia is not found and the serum sodium may even be decreased. Some authors have suggested that the primary disorder might be renal salt loss or an anomaly in the regulation of extracellular fluid volume (BEILIN, 1967). Similar cases have been observed in association with growth retardation. Some cases may previously have been mistaken for primary aldosteronism with bilateral adrenal hyperplasia.

δ) Glucocorticoid-Suppressible Secondary Aldosteronism

SUTHERLAND (1966) first described a disease which occurred simultaneously in father and son and was characterized by benign hypertension, potassium deficit, increased plasma volume, elevated aldosterone secretion rate, intermittent elevation of urinary 17-hydroxycorticoids and 17-ketosteroids, normal secretion rate of corticosterone and compound S, normal plasma ACTH and low plasma renin activity. Surgery in the father revealed no adrenal tumors. Treatment with dexamethasone, 2 mg per day, led to marked suppression of aldosterone secretion and normalization of blood pressure and serum potassium in father and son. A similar disease was observed by NEW (1967) in a 12-year-old boy. He had a moderately elevated aldosterone secretion rate, reduced plasma renin activity, elevated plasma ACTH concentration and low normal values or urinary 17-ketosteroids and 17-hydroxycorticosteroids with a delayed response to ACTH. Treatment with prednisone in a dose of 10 mg daily suppressed aldosterone secretion and normalized blood pressure and serum potassium.

ε) Secondary Aldosteronism of Unknown Etiology ("Primary Aldosteronism with Bilateral Adrenal Hyperplasia", "Pseudo-Primary Aldosteronism", "Idiopathic Aldosteronism")

Since the determination of plasma renin concentration or activity was introduced as a diagnostic tool for the detection of primary aldosteronism, several cases have been described in which a preoperative diagnosis of primary aldosteronism was based on an increased aldosterone secretion rate and a simultaneous suppression of plasma renin activity and surgery did not reveal a tumor but bilateral adrenal hyperplasia. It must be assumed that an unknown stimulatory principle was responsible for the increased aldosterone secretion rate and the adrenocortical hyperplasia (DAVIS, 1967; SALTI, 1969). This disease occurs almost as frequently as primary aldosteronism due to an aldosterone-producing adrenal adenoma (BAER, 1970). Hypertension is generally not improved by subtotal or total bilateral adrenalectomy. A definite preoperative differential diagnosis between this disease and primary aldosteronism can only be made by the determination of aldosterone in adrenal venous plasma obtained from both sides by catheterization.

ζ) Therapy of Secondary Aldosteronism

Treatment of secondary aldosteronism consists primarily in removing the cause, i.e. treatment of the underlying disease. Occasionally, treatment with aldosterone antagonists, which act on the target organs of aldosterone, or with inhibitors of aldosterone biosynthesis can be helpful. SU 9055, a specific inhibitor of aldosterone biosynthesis, in a daily dose of 4.8 g reduces the elevated aldosterone secretion rate to very low levels and promotes sodium excretion in the urine. The clinical value of this drug has not yet been definitely assessed.

c) Excess of Other Mineralocorticoids

α) 17-Hydroxylase Deficiency

This rare disease is a congenital disorder of corticosteroid biosynthesis. However, it is not characterized by an adrenogenital syndrome, but rather by hypogonadism and hypermineralocorticoidism. Less than 10 cases have been described. Most of these patients have been young women with primary amenorrhea, lack of secondary sexual characteristics, hyperten-

sion, hypokalemia, and metabolic alkalosis. In boys, the disease is characterized by pseudohermaphroditism (NEW, 1970). The secretion of aldosterone, cortisol, androgens, and estrogens is strikingly decreased, while the production of corticosterone, deoxycorticosterone and progesterone is increased. Plasma renin activity is very low, while levels of ACTH, LH and FSH are elevated. Suppressive therapy with dexamethasone (1 to 2 mg per day) or with cortisone decreases corticosterone and deoxycorticosterone production and leads to normalization of blood pressure and potassium balance.

β) Deoxycorticosterone Excess

A case of hypermineralocorticoidism due to a pathologically increased deoxycorticosterone secretion rate with a normal aldosterone secretion rate has been described by BIGLIERI. The 39-year-old female patient had edema, hypovolemia, hypotension, and hypokalemic alkalosis. A bilateral nodular adrenal hyperplasia was found at operation.

γ) 18-Hydroxydeoxycorticosterone Excess

An increased secretion rate of 18-hydroxy-11-deoxycorticosterone (18-OH-DOC) or an elevated urinary excretion rate of tetrahydro-18-OH-DOC was found by MELBY (1972) in patients with benign hypertension, low plasma renin and normal or slightly decreased aldosterone secretion rate. Some of these patients became normotensive under suppressive therapy with dexamethasone (1.5 mg per day).

3. Cushing's Syndrome

a) Definition

The typical clinical features of Cushing's syndrome are always due to an excess of endogenous cortisol or exogenous glucocorticoids. There are various causes of the disease (see below).

The differentiation between Cushing's syndrome without specification of the etiology and Cushing's disease due to a basophilic pituitary adenoma is no longer justified, since the existence of an autonomous basophilic adenoma of the pituitary gland has become questionable.

b) Incidence

Cushing's syndrome is a rare disease. PLOTZ (1952) reported 189 cases, verified by autopsy or hormone determinations, from the literature, SOFFER (1961) 450 cases. At the Department of Medicine of the University Hospital of Zurich, 30 cases of Cushing's syndrome have occurred among 30000 patients within the last 10 years. In the Zurich Children's Hospital, 6 cases were observed among 70000 patients. The syndrome has been observed 15 times in 33000 autopsies carried out during the last 20 years at the Pathology Institute of the University of Zurich. The syndrome is 3 to 4 times more common in women than in men, and often appears following pregnancy. Its incidence is greatest in the 3rd and 4th decades, but it may occur at any age, from earliest childhood (youngest case 4 months old) to senescence.

c) Pathogenesis and Etiology, Pathophysiology

Cushing's syndrome is always caused by an overproduction of steroids with glucocorticoid activity, which are almost exclusively formed in adrenocortical tissue. In some instances, cortisol has been reported to originate from ovarian and testicular tumors which were probably derived from detached portions of adrenocortical tissue.

Glucocorticoid excess can result from:

1. Primary adrenal lesion (adenoma, carcinoma);
2. A disorder of the hypothalamic-pituitary mechanism regulating adrenocortical activity (bilateral hyperplasia);
3. Excessive stimulation of the adrenals by ACTH produced by ectopic tumors (bilateral hyperplasia);
4. Excessive administration of exogenous cortisol or its derivatives (adrenal cortical atrophy) or of ACTH (bilateral hyperplasia).

1. Adenomas (15%) and carcinomas (10%) of the adrenal cortex, and in a few cases of detached adrenocortical tissue in the ovaries and testes, usually grow autonomously, i.e. independently of pituitary control, in the same manner as other benign or malignant tumors. Their steroid production is also autonomous to a great extent and therefore not suppressible in the 8 mg dexamethasone test. The cortisol production of adrenal adenomas can occasionally be stimulated by exogenous ACTH, but only to a small extent, whereas carcinomas are usually not responsive. The cortisol secreted by the tumor suppresses the endogenous ACTH secretion, and thus leads to atrophy of both the ipsilateral and the contralateral adrenal glands. Normal or hyperplastic adrenal glands with small multiple adenomas found at operation indicate that the disease is most probably due to hypothalamic-pituitary factors.

2. Cushing's syndrome with adrenocortical hyperplasia is due to excessive ACTH production by the anterior pituitary gland. Small, or less commonly large, basophilic or chromo-

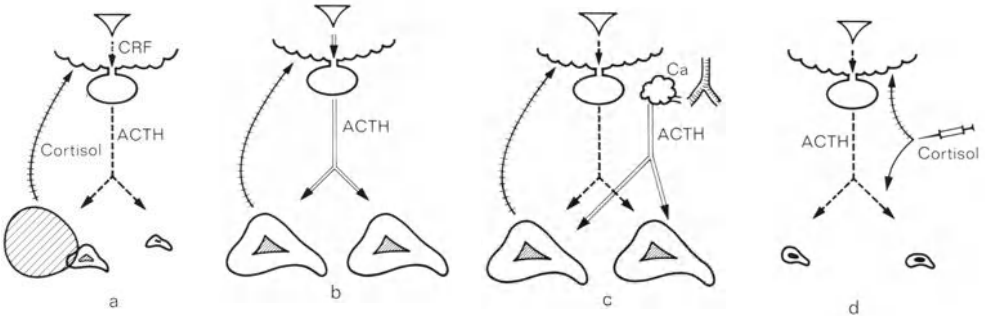

Fig. 18a–d. Causes of Cushing's syndrome. a) Adrenocortical tumor; b) Adrenocortical hyperplasia of hypothalamic origin; c) Adrenocortical hyperplasia due to ectopic ACTH production; d) Exogenous cortisol administration

phobe adenomas may, but need not be found. Occasional invasive extracellular growth of these tumors can lead to lesions of cerebral nerves, in particular of the oculomotor nerve. The existence of autonomous pituitary tumors producing excessive ACTH in proportion to their size is no longer accepted. Since it has been known that these tumors develop particularly often after total adrenalectomy, i.e. after removal of the suppressive influence of cortisol, they have been considered to be hyperplasiogenic, developing under increased stimulation by the hypothalamic corticotropin-releasing factor. Cushing's syndrome with bilateral adrenal hyperplasia is thus due to impaired regulation of ACTH secretion. The hypothalamus is less sensitive to the negative feedback effect of cortisol, i.e. the regulatory circle is set to a higher cortisol level (Fig. 19). Cortisol exerts its suppressive effect on the hypothalamus and the pituitary gland only at higher concentrations.

LIDDLE (1960, 1962) has substantiated this hypothesis by the determination of ACTH in human plasma and by assessing its suppressibility by various concentrations of cortisol and dexamethasone, and has at the same time introduced the dexamethasone suppression tests (see p. 389), which are the most reliable tools currently available for the diagnosis and differential diagnosis of Cushing's syndrome. Whereas in healthy subjects the plasma ACTH concentration varies between 0.1 and 0.5 mU per 100 ml and is thus just measurable by the most sensitive bioassays, it increases 10- to 100-fold in Addisonian patients and returns to the normal range after substitution with cortisol, 30 mg per day. Plasma corticotropin concentration in untreated Cushing's syndrome is slightly elevated or in the upper normal range (NELSON, 1966), since a certain, although insufficient suppression of ACTH release is exerted by the markedly elevated cortisol concentration in the plasma. The diurnal variation is lost, and the absence of the nocturnal fall in ACTH secretion leads to a twofold increase in the daily cortisol output (RETIENE, 1965). After total adrenalectomy in a patient with Cushing's syndrome and under normal substitution with 30 mg of cortisol per day, the ACTH concentration increases markedly. The corticotropin concentration only regresses to normal values when the dose of cortisol is increased several times (8-fold) (Fig. 19).

Thus, therapeutic adrenalectomy and normal replacement therapy in patients with Cushing's

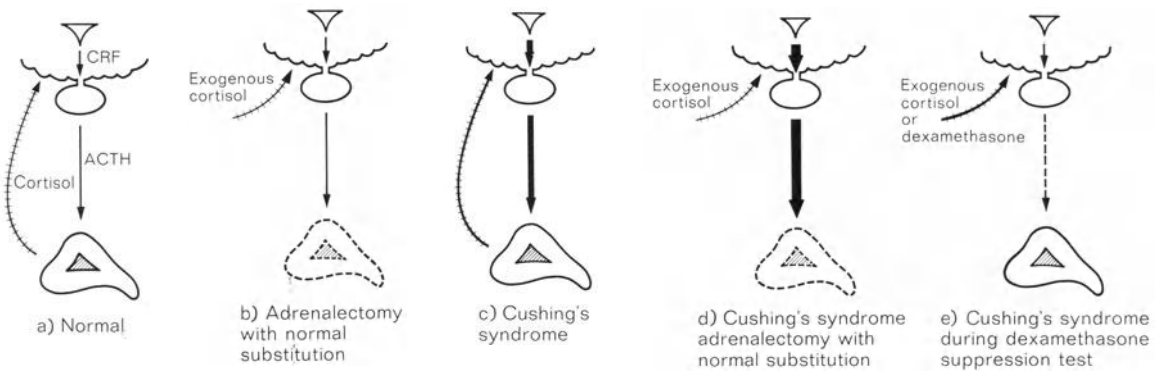

Fig. 19a–e. The hypothalamic-pituitary control of adrenocortical function in normal subjects, in patients after adrenalectomy and in Cushing's syndrome. a) Normal; b) Adrenalectomy with normal substitution therapy; c) Cushing's syndrome; d) Cushing's syndrome after adrenalectomy with normal substitution therapy; e) Dexamethasone suppression test in Cushing's syndrome

syndrome lead to a persistent increase in ACTH secretion, clinically manifested by a striking increase in pigmentation and a tendency to adenohypophyseal adenomas. Pituitary adenomas occurring in patients with Cushing's syndrome after therapeutic adrenalectomy have been observed in dozens of cases. The plasma ACTH concentration is extremely high in these patients, and values of up to 1000 mU per 100 ml have been determined. The circadian rhythm is absent at first, but reappears at an elevated level.

3. Peptides with ACTH activity can be produced outside of the pituitary gland by neoplastic tissue, particularly by bronchial carcinomas and their metastases. As in the second type of Cushing's syndrome, bilateral hyperplasia of the adrenal cortex develops. Strikingly elevated ACTH levels are found in the plasma. These tumors are not affected by feedback inhibition and their ACTH production is not suppressed by cortisol or dexamethasone. Very high ACTH levels and the complete absence of suppression indicate ectopic ACTH production (NELSON, 1966).

4. Excessive administration of cortisol and its derivatives or ACTH for therapeutic purposes leads to the iatrogenic Cushing's syndrome, which differs very little from endogenous cortisol excess.

Hirsutism and acne are more common in iatrogenic Cushing's syndrome due to ACTH administration than during treatment with high doses of corticosteroids.

Cushing's syndrome may exceptionally develop during maintenance therapy with normal doses of cortisone (25 mg per day) when metabolic degradation is impaired, e.g. in secondary hypothyroidism.

Every case of Cushing's syndrome (with the exception of the iatrogenic type) is due to increased cortisol production. The cortisol secretion rate shows a 2- to 3-fold increase. By contrast, the secretion rate of corticosterone is usually not elevated, or only slightly. However, markedly increased corticosterone production has been observed in cases of adrenal carcinoma and in the ectopic ACTH syndrome. The secretion rate of aldosterone is generally normal or decreased (BIGLIERI, 1963; GUINET, 1967).

The metabolic activity of cortisol (see p. 303), i.e. the promotion of gluconeogenesis, leads to a negative nitrogen balance, a tendency to high blood sugar levels, and a pathological result in the glucose tolerance test, which can initially be partly compensated by an increased insulin secretion. The normally minimal glucosuria is increased due to accelerated glucose filtration. On the other hand, peripheral carbohydrate metabolism is not impaired in pure steroid diabetes. Ketosis does not occur and the liver glycogen is increased. The findings of elevated plasma levels of pyruvic acid and lactic acid (HENNEMANN, 1957) may possibly be related to the increased supply of substrates provided by gluconeogenesis. Manifest diabetes with reduced glucose assimilation in the course of Cushing's syndrome probably only occurs in individuals with a genetic predisposition for diabetes. Treatment with cortisone can be used as a screening test for diabetes (see p. 813f.).

d) Pathologic Anatomy

α) Hyperplasia of the Adrenal Cortex

In cortical hyperplasia, both adrenals are usually enlarged but maintain their shape. Enlargement often appears to be trivial. In the older statistics of the weight of normal adrenal glands, too little attention was paid to adrenocortical changes during adaptation to stress and diseases. The allegedly normal values given are therefore too high. If only glands from healthy subjects who have died suddenly and violently are considered, the normal average weight of both adrenals of adults is 10 g, with a range of 6 to 11 g. Thus, a combined weight of 10 g is compatible with adrenocortical hyperplasia.

In *simple hyperplasia*, the cortical structure remains intact, but definite changes in the relative and absolute width of the individual zones are observed.

Since hyperplasia is usually not quite uniform, zones of increased proliferation develop, leading to *nodular hyperplasia*. These nodules can be situated in the cortical tissue itself and are frequently not clearly circumscribed. In the capsular region, they are often sequestered from the cortical tissue and become encapsulated, which leads to a nodular surface of the adrenal. As in other endocrine organs, particularly in the anterior pituitary gland and the thyroid, the transition from nodular hyperplasia to adenomas is gradual.

β) Bilateral Adrenocortical Adenomatosis and Adenomas

The differentiation between nodular hyperplasia and adenomas is particularly difficult in *bilateral adrenocortical adenomatosis* of Cushing's syndrome or adrenogenital syndrome. In typical cases, adrenocortical areas not affected by nodular hyperplasia become atrophic. Adenomas are usually solitary. According to a review by RAPAPORT (Table 12), both adrenals are affected with approximately the same frequency. Bilateral tumors occur in 1 to 2% of cases. In almost

Table 12. Classification of adrenocortical tumors of 278 patients according to their endocrine activity. [After a review by E. RAPAPORT, M. B. GOLDBERG, G. S. GORDAN, and F. HINMAN JR.: Postgrad. Med. **11**, 325 (1952). The figures refer to the statements made in the text which do not quite agree with those in the tables]

	Number of cases	% of all cases	% of the tumors with hormonal activity only
1. Hormonally inactive tumors	43	15.5	–
2. Tumors with androgenic activity	80	28.8	34.0
3. Tumors with Cushing's syndrome	122	43.9	51.9
4. Tumors with estrogenic activity	7	2.5	3.0
5. Tumors with estrogenic and androgenic activity	4	1.4	1.7
6. Tumors with hypoglycemia	3	1.1	1.3
7. Choriongonadotropin-producing tumors	2	0.7	0.9
8. Non-classifiable tumors (insufficient information)	17	6.1	7.2
Total	278	100.0	100.0

2% of the cases observed the tumors have originated from aberrant adrenocortical tissue located near the adrenals and the kidneys, in the retroperitoneal space distal to these organs, and in the genital region (see adrenal dystopia).

Many adenomas do not lead to clinical manifestations and they are found at autopsy more frequently than expected.

Some adrenocortical adenomas become very large and reach a diameter of several cm and a weight of 100 to 200 g, occasionally even of kg. In 20% of cases, the tumors become manifest because of their size and are sometimes palpable. The adenomas are usually round and firmly encapsulated. In contrast to nodular hyperplasia, the adjacent cortical tissue is often compressed; cut surfaces are yellowish brown, lobular and sometimes penetrated by hemorrhage and cysts. Histology of the adenomas shows that they are composed of nests of cells similar in appearance to different layers of the normal cortex. Cells are usually large and often contain lipids and glycogen. The pigment, on the other hand, is not as abundant as in the zona reticularis. Occasional groups of spindle cells resembling pheochromocytoma tissue may be present.

γ) Carcinomas

Adrenocortical carcinomas may be very similar to adenomas both microscopically and macroscopically. Occasional invasion of the capsule and penetrations into the veins can be seen with the naked eye, as in hypernephroid renal carcinoma. Cones of the tumor may reach the vena cava, and this must be borne in mind by the surgeon attempting radical exstirpation. Necrosis and hemorrhage are not uncommon. Microscopic diagnosis is not difficult when the tumors are poorly differentiated and have the characteristic features of carcinoma. However, if the tumors are more differentiated, distinction between adenomas and carcinomas may be very difficult. The structure of carcinomas may be very uniform, and adenomas may be characterized by cellular and nuclear polymorphia due to degenerative changes. In border-line cases, a decision is only possible on the basis of metastases.

The morphology of adrenocortical tumors does not allow any definite conclusions about their endocrine activity. Thus, the histological structure of hormone-inactive tumors may be absolutely identical to that of hormone-active adrenal cortical tumors producing different steroids and leading to corresponding clinical syndromes. Fuchsinophilia according to VINES, and other staining reactions such as Ashbel-Seligman's reaction, are not specific for androgens (BACHMANN, LIEBEGOTT). Apart from the morphologically detectable secondary symptoms, certain conclusions can be drawn from the pathologic anatomical nature of the remaining adrenal tissue. The state of the contralateral adrenal is of special significance, because an atrophy of the ipsilateral adrenal cortex may be due to pressure. Atrophy of the contralateral adrenal cortex caused by suppression of pituitary ACTH secretion is found in more than 70% of cases of Cushing's syndrome due to an adrenocortical adenoma or carcinoma. Contralateral adrenocortical atrophy is observed in approximately 30% of cases with androgen-producing tumors, but never in cases of hormone-inactive tumors.

δ) Metastases

Adrenocortical metastases are common. Only in rare instances do they lead to endocrine failure, and the clinical picture is usually dominated by the manifestations of the metastasizing tumor.

For a discussion ectopic hormone production and Cushing's syndrome see p. 353.

ε) Changes in the Pituitary Gland

Changes in the pituitary gland in Cushing's syndrome are very variable. Only Crooke cells, which can be demonstrated in a large proportion of cases, are characteristic. THOMPSON and EISENHARDT found them in the pituitary glands of 58 out of 63 patients with Cushing's syndrome. They are basophil cells with a peculiar hyalinization of the cytoplasma, with a tape-like hyalinized zone replacing the basophil granules (Fig. 20). The reader is referred to the reviews by PLOTZ (1952) and ROVIT (1969) for discussions of the incidence of pituitary changes.

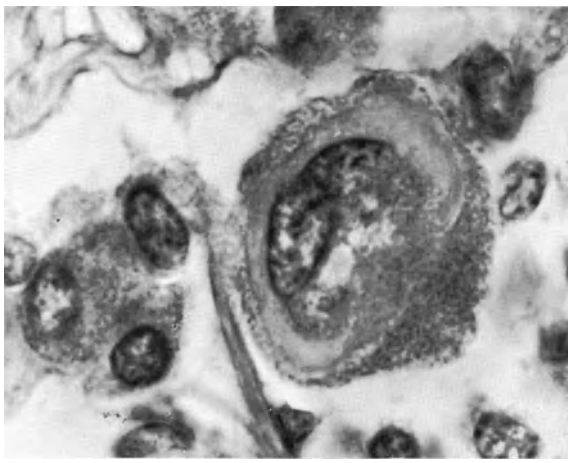

Fig. 20. CROOKE's cell in the anterior pituitary gland in Cushing's disease with anterior pituitary mucoid cell adenoma and bilateral adrenocortical hyperplasia. In comparison with a normal basophilic cell (left side) cytoplasma and the nucleus are enlarged. The perinuclear cytoplasma shows hyaline transformation. The hyaline mass is not stained by periodide leucofuchsin. Marginal remains of granulose cytoplasma. SN 321/55, 32-year-old women. Periodate leucofuchsin orange G stain according to PEARSE, enlargement 1137:1

The multiplicity of the hypophyseal changes becomes understandable when the transformational capacity of the adeno-hypophyseal cells and the different possible pathogeneses of Cushing's syndrome are considered. Basophil and large chromophobe cells, at least the so-called sparsely granulated cells, may correspond to the same type of cells under different functional conditions. Thus it is understandable that in Cushing's syndrome basophil, chromophobe and mixed cell adenomas are found, which may also metastasize in exceptional cases (ROVIT, 1969).

e) Clinical Features

α) History

When taking the case history, the doctor should try to fix the onset of the disease to a certain time. There is always some discontinuity in the life history in Cushing's syndrome. Physical and mental alterations may develop slowly without alarming the patient; but they can also appear quite suddenly, and the patient and his family may become aware of his altered appearance within weeks or days. The patient is always able to state a time at which he had not yet observed the changes. Earlier photographs can be particularly informative, as in numerous other endocrine diseases. The differentiation of Cushing's syndrome from constitutional obesity, which is often associated with hypertension and diabetes, is usually possible just from the history, since constitutional obesity appears in childhood and no striking changes are observed by the patient and his family.

The patients' main complaint is fatigue, which contrasts with the flourishing appearance. Fatigue can progress to adynamia and may finally cause complete confinement to bed. It is of the organic type, i.e. less pronounced in the morning than in the evening.

Back pain with radiation along the costal arch is characteristic of osteoporosis (see p. 349). Kidney-stone or gall-stone colics can occasionally be the first symptoms of the disease: increased calcium excretion promotes calculus formation. When diabetes mellitus becomes severe, the patients may be troubled with thirst, polyuria, and pruritus.

Mental Changes. Mental changes typical of endocrine psychosyndrome usually occur in manifest Cushing's syndrome. Apathia and excitement are frequent. Sexuality is often subdued; in rare cases it may be temporarily increased. Hunger and thirst are usually increased. Acute variations in mood can progress to episodes of psychosis in the patient with Cushing's syndrome. Confusion, hallucination, illusions, and delusional ideas may then occur. Although these psychoses can be very similar to schizophrenia, they must be considered as increases in the variation of mood and drive with progression into the acute exogenous reaction type. Amnestic symptoms are common in Cushing's syndrome. Mental disturbances are not correlated to physical changes. However, the psychopathology of a patient with Cushing's syndrome is closely related to the premorbid personality, and the mental alterations may often be an exaggeration of preexisting peculiarities.

Fig. 21. 31-year-old patient with Cushing's disease due to a basophilic pituitary adenoma. Moon face, rubeosis, acne and moderate hirsutism. Low frontal hair border

β) Physical Examination

There is hardly any other illness as characteristic, impressive, and unforgettable as Cushing's syndrome. The disfigurement of a beautiful and expressive face to ridiculous ugliness by this disease can be a shock to both patient and doctor. The experience of watching the face, characterized by the features of the patient's personality, reemerge from behind the mask of the disease after successful therapy can be just as impressive (Figs. 21–25). Briefly, the nature of the disease is an alteration in metabolism from protein synthesis to excessive glucose production, and thus indirectly to increased fat deposition. This leads to the 7 cardinal signs of Cushing's syndrome (Table 13):

Table 13. The 7 cardinal clinical manifestations of Cushing's syndrome

	Frequency (%)
1. Red, rounded face (plethora, moon face)	90
2. Truncal obesity	85
3. Decreased glucose tolerance-diabetes mellitus	85
4. Hypertension	80
5. Osteoporosis	70
6. Amenorrhea, hypogonadism	70
7. Purple striae, ecchymosis	60

Obesity of the Trunk. Muscles and bones regress and excessive adipose tissue is formed. Obesity of the trunk results, in which the extremities remain thin, but the head, neck, and body, where most of the storage fat is deposited, become thick and unshapely. The peculiarity of this fat distribution cannot be explained by the metabolism. The characteristic body shape of an endocrine disease is due to variable responsiveness of the tissues to a certain hormone. Increased fat deposition in the cheeks

Fig. 22. a) Very severe Cushing's syndrome with truncal obesity, intensely red moon face with teleangiectasias, increased beard and body hair, hypertension up to 200/130 mm Hg. b) The same patient one year after total adrenalectomy (Dr. BIRNSTIEL, Pflegerinnenschule, Zurich)

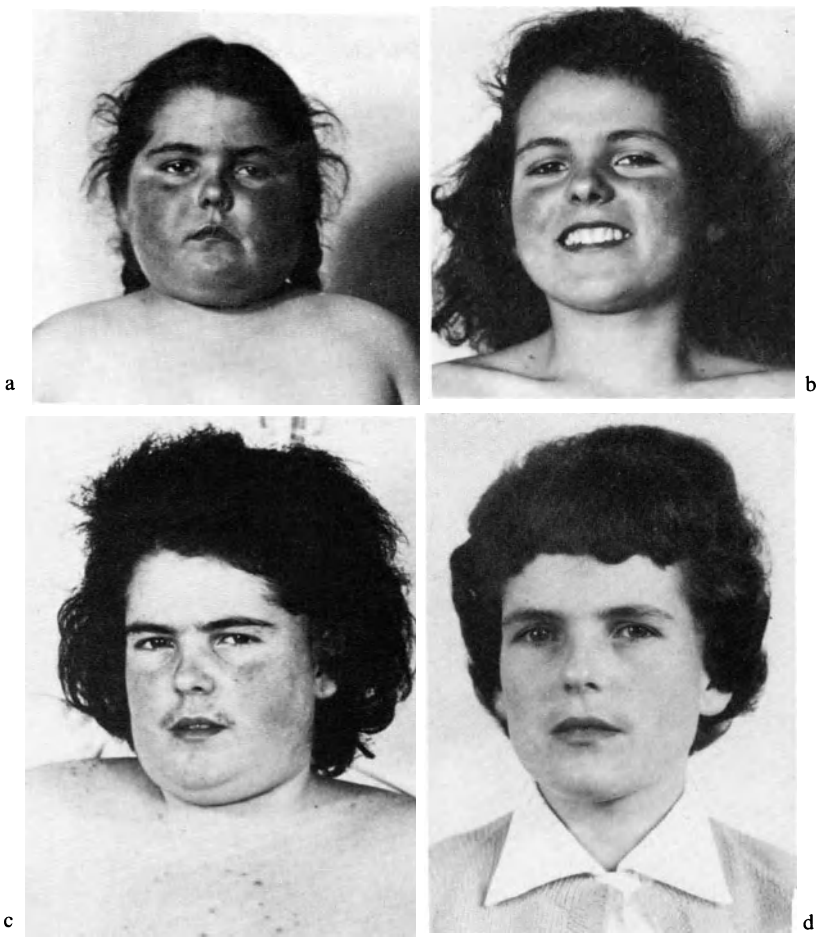

Fig. 23. a) 12-year-old girl with Cushing's syndrome. Arrest of growth and truncal obesity, hypertension 200/120 mm Hg. b) 10 months following X-ray irradiation of the pituitary with complete remission. c) Severe relapse with multiple spontaneous vertebral fractures 9 years later. d) The patient one year after total adrenalectomy (a and b KspZ)

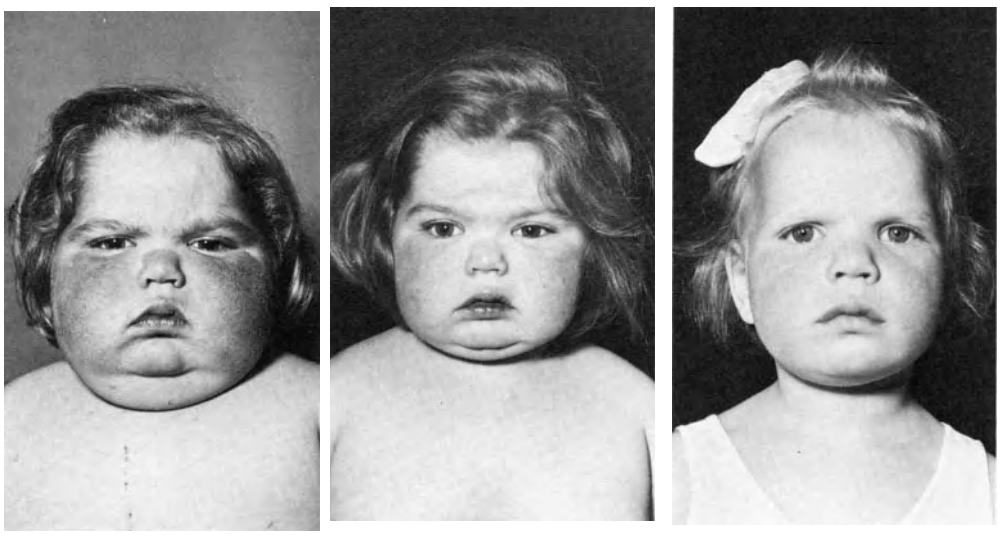

Fig. 24a–c. Alteration of facial expression in Cushing's syndrome. 4-year-old girl with Cushing's syndrome due to an adrenocortical carcinoma. a) Before removal of the tumor. b) One month after the operation. c) 7 months after the operation. (From GROB, PRADER, and ZOLLINGER)

leads to rounding of the face ("moon face") and also to slanting of the eyes and drooping of the corners of the mouth, which then resembles a carp's mouth. Simultaneous expressions of dignity and melancholia, often ridiculous by their contrast are often found in association with extreme forms of moon face, hiding the ears, in children. The striking redness and unnatural gleam of the skin leads to the impression of an unnatural doll's or clown's face (Figs. 21 and 24). Individual traits and sex specificity in the facial expression are suppressed.

The neck appears to be strikingly short, due partly to the collar-like fat deposit and the formation of a double chin, and partly to the pathologic increase of the physiological kyphosis of the thoracic vertebral column. The posture of the patient with Cushing's syndrome is characteristic in profile. The rounded head thrust forward and the short neck lend something threatening to the posture, in grotesque contrast to the portly stoutness of the body and the ugliness of the thin extremities. The panniculus adiposus of the lower abdomen is particularly developed, together with the flaccidity of the reduced abdominal muscles. Typical pendulous abdomen may appear, overhanging the genitalia like an apron. Adipose tissue is developed to a lesser extent in the region of the hips. The thighs are markedly conical. Excessive fat may also be deposited in the breasts, and the shoulders appear to be rounded and drooping. The angle between the neck and shoulder is filled out. An area of special predilection for fat deposit is the lower cervical spine, where a pillow-like fad pad may be formed, the so-called "buffalo hump" (JORES). The obesity may be severe but is not always so; excessive weight increase is not particularly typical of Cushing's syndrome. The total body weight may even be unaltered, so that only the unusual distribution of fat is conspicuous. The picture of flourishing health suggested by obesity and the rosy complexion is not always predominant. The muscular loss may be more impressive than the fat formation and suggest deterioration of the patient by the feebleness in posture. Replacement of the locomotor system by storage tissue is a process of aging, and premature aging is a further feature of this disease. Thus, Cushing's syndrome in a young woman leads to a caricature of the matronly type, and ALBRIGHT has in fact assumed that there is a relative predominance of the glucocorticoids over their anabolic antagonists in the interval between the menopause and the onset of senescence in the life of a woman (menopause-adrenopause). The

a b

Fig. 25. a) 42-year-old patient with slowly developing Cushing's syndrome due to an adrenocortical adenoma. No obesity, moderate rounding and marked redness of the face. b) The same patient 3 years after removal of the adrenocortical adenoma: without weight loss disappearance of the redness, altered facial expression

apparent similarities may thus be based on the corresponding metabolic states rather than be coincidental.

However, comparison with the matronly type does not give any impression of the inscrutable appearance evoked in patients with Cushing's syndrome by their tired and suffering expression combined with the disfiguring fullness of the body.

Reduction of the visual fields due to pituitary tumors, occurs in about 5% of cases (see p. 341). This is sometimes combined with paralysis of the ocular muscles. Whether the intraocular pressure is generally elevated and can lead to glaucoma (BAYER, 1967) has to be investigated in a larger number of patients.

In some cases, pronounced exophthalmus may be caused by increased retrobulbar adipose tissue. The etiology is unknown.

In women and children, all forms of Cushing's syndrome are accompanied by mild hirsutism in most instances. In its mildest form, it is a fine fluff on the upper lip and cheeks. Even in pure cortisol excess, the weakly androgenic cortisol metabolites may lead to hirsutism when they are present in large quantities. Acne is almost always present on the face and upper trunk (see Fig. 23). In pure Cushing's syndrome, the forehead hairline descends further forward, particularly in the lateral areas, where angular baldness due to androgen activity develops. The eyebrows also become bushy with lateral widening.

Skin. In Cushing's syndrome, the skin is thin, stretched, and shiny due to the effect of the fat. When the disease is of long duration, the skin becomes atrophic, as in old people. Its blood supply is ample. It is warm to the touch, oily, and moist. Pyodermia of the seborrhoic skin is frequent and heals poorly. The color of the skin, especially in the face, is a striking dark red, which is frequently described as "plethoric" or "congested". The remaining skin of the body may be mottled and the extremities are usually dark red to cyanotic. The plethoric appearance is not always compatible with the existing polycythemia. It must be due to an expansion of the capillaries and to a partial stasis. In addition to the plethoric tinge, there is increased pigmentation in a few cases, similar to that in Addison's disease, which may be due to the raised ACTH level or to increased MSH secretion by the pituitary gland. However, it never reaches the same severity as in Addison's disease. Violaceous striae are characteristic. Only in pregnancy are they similarly impressive. They are dark red to violet stripes running parallel to the tension lines of the skin. They are due to dilated subcutaneous venous plexuses and perhaps also to extravasates into the subcutaneous adipose tissue shimmering through the overlying stretched and slightly pitted epidermis (Fig. 26). They occur most frequently on the anterolateral parts of the lower abdomen, on the breasts and the thighs, and in the adipose tissue of the axilla. Although they are found only in Cushing's syndrome and in pregnancy in this intensity, they are by no means pathognomonic of these conditions. Any form of obesity, developed rapidly and especially during youth, can give rise to striae, but they are then usually pink rather than dark red and more numerous, but finer (see p. 354). They may also occur during puberty, even without simultaneous obesity.

Fig. 26. Purple striae in Cushing's syndrome (KspZ)

The prediposition to hemorrhage is not only apparent in the violaceous striae, but also leads to the additional or exclusive formation of petechia and patchy suffusions, especially on the extensor sides of the forearms, but also in other areas of the body exposed to pressure. This may finally lead to the picture of hemorrhagic diathesis. In rare cases, hemorrhage into the intestinal lumen may occur, resulting in death. Generally, the skin is more bruisable, and slight injuries may result in extravasation of blood under the epidermis. Neither the striae nor the remaining adipose tissue are exceptionally tender. Edema occurs in approximately half the cases.

The pathogenesis of the cutaneous changes is assumed to be related to the antianabolic properties of cortisol. Violaceous striae can also

be provoked by exogenous ACTH and cortisol. Blood coagulation factors are unaltered. Bleeding time and coagulation time are always normal, whereas Rumpel-Leede's sign may be positive. Hemorrhage is thus due to vascular factors.

Hypertension. Raised blood pressure is an important observation in the general examination. It varies in severity. It rarely leads to the picture of malignant hypertension with nephrosclerosis, albuminuria, renal insufficiency, and apoplexy. Blood pressure values are often only slightly elevated. Apparently some other constitutional factor is necessary for the development of hypertension, since only some of the patients develop hypertension during treatment with high doses of cortisone. The pathogenesis of the hypertension is still unexplained. It must be due to the cortisol excess, because the secretion of mineralocorticoids is not increased. An increased supply of sodium to the arteriolar musculature may play some part, since cortisol impairs the renal sodium excretion. In addition, cortisol is essential for the hypertonic action of noradrenaline (permissive action, see p. 307).

Osteoporosis. Diffuse osteoporosis of varying severity is an important sign of CUSHING'S syndrome. Under the effects of cortisol, the transformation of bone is extensively retarded, with a preponderance of catabolism over anabolism (FROST, 1963). The calcium balance of the body becomes negative since enteral resorption is diminished, and calciuria results from decreased tubular reabsorption. Osteoporosis leads to static deformation of the vertebral bodies, occasionally combined with infractions. Spontaneous fractures of the ribs and vertebral bodies often occur, resulting in conspicuous proliferative callus formation. Wedge-shaped vertebrae may be formed in the thoracic section and fish vertebrae in the lumbar section of the spine. Demonstration of vertebral deformation confirms osteoporosis. It is extremely difficult to diagnose osteoporosis from the diminished shadow density of the bones alone. Osteoporosis is diagnosed much too frequently in corpulent patients whose X-ray pictures are poor in contrast. Demonstration of greatly accentuated borders of the vertebral body, which looks as if it had been drawn in by pencil, may be significant in the differentiation between osteoporosis and apparent radiolucency.

Muscular Atrophy. Atrophy of the muscles is due to the catabolic, antianabolic activity of cortisol. It can lead to complete invalidity, but is reversible by effective therapy. There is creatinuria and a negative nitrogen balance. Severe hypokalemia can contribute to adynamia, particularly in the paraneoplastic Cushing's syndrome.

Diabetes Mellitus. Diabetes mellitus is part of the fully developed Cushing's syndrome. Manifest diabetes is not common (15%); however a diabetic type of altered metabolism can be recognized by determination of blood sugar or a glucose tolerance test in almost every case. So-called "steroid diabetes", is a special type of diabetes mellitus, which is not due to insulin insufficiency, but to cortisol excess. As in the usual form of diabetes, too much glucose is formed, but in contrast to the usual form, peripheral utilization of glucose is normal. Steroid diabetes is benign at first with moderately elevated blood sugar values; the course is stable, and ketoacidosis never develops. Insulin, however, has little effect, and complications are not infrequent despite the apparent benignity. Diabetic angiopathy can develop within a few years of the onset of Cushing's syndrome.

Hypogonadism. Hypogonadism in Cushing's syndrome is primary and not due to gonado-

Table 14. Frequency of clinical manifestations in 450 cases of Cushing's syndrome. [According to SOFFER, DORFMAN, and GABRILOVE: The human adrenal gland (Philadelphia: Lea & Febiger 1961) and in 601 cases according to ROSS, MARSHALL-JONES, and FRIEDMAN: Quart. J. Med., N.S. **35**, 149 (1966)].

Clinical manifestation	Frequency (%)	
	According to SOFFER	According to ROSS
Moon face	88	75
Obesity	86	88
Hypertension	85	
Red face with "plethora"	77	
Amenorrhea in women	77	60
Hirsutism in women	73	65
Muscular weakness	67	61
Purple striae	60	
Hemorrhagic diathesis	59	42
Osteoporosis	58	
Ankle edema	57	
Buffalo hump	54	
Acne	54	45
Backache and other skeletal pains	54	40
Ecchymosis	52	
Mental changes	46	
Pathological fractures	38	
Impaired wound healing, leg ulcers	35	
Polyuria and nycturia	32	
Polydipsia	28	
Kyphosis	25	
Renal calculi	20	
Mild polycythemia	20	
Exophthalmus	14	

tropin deficiency, as was previously assumed. It must, therefore, be due to a direct inhibitory action of cortisol on the ovaries or testes. Amenorrhea often occurs, but is not an obligatory symptom. The corresponding pathologic anatomical finding is premature aging of the ovary. Pregnancy is possible, however, during untreated Cushing's syndrome. In the male, impotence is the predominant symptom. The testes may become smaller. No specific changes have been found in testicular biopsies.

The incidence of clinical signs and symptoms according to the statistics compiled by SOFFER (1961) and ROSS (1966) is shown in Table 14. The figures for individual series, such as those of PLOTZ (1952) and SOFFER (1961), and for our own 50 cases (FLURY, 1971) show only slight deviations.

NUGENT (1964) has proposed a formula based on the occurrence of clinical symptoms and simple laboratory findings for estimating the probability of the disease in patients with a confirmed or suspected diagnosis of Cushing's syndrome. He concludes that even without steroid estimations, the diagnosis can be made or excluded with great probability in half the cases.

Because of its therapeutic consequences, the diagnosis of Cushing's syndrome is of extreme importance and must be unequivocally founded on clinical experience as well as on reliable results of steroid determinations performed in a suitably equipped laboratory. As a rule, the patient has to stay in hospital for 8 to 14 days. A patient in whom Cushing's syndrome is only suspected, must never be referred to a surgeon for exploration of the adrenals. Cushing's syndrome may also be associated with adrenals of normal size, and the formation of scars after surgical inspection impairs or precludes subsequent adrenalectomy. In the fully developed syndrome, the clinical diagnosis is simple; but the patient should only be referred for adrenalectomy when the urinary levels of 17-hydroxycorticosteroids are found to be increased and are not suppressible by dexamethasone in a dose of 2 mg per day. In border-line cases, the decision as to whether Cushing's syndrome is actually present can be extremely difficult and sometimes impossible. In doubtful cases, it is best to wait several months and then repeat the laboratory tests.

γ) Laboratory Findings

ACTH. In patients with Cushing's syndrome of hypothalamic origin, the plasma ACTH levels, as measured by sensitive bioassays, are not usually found to be definitely elevated until the plasma corticosteroids have become normal following adrenalectomy and substitution therapy (NELSON, 1966). In the future, reliable radioimmunological methods of measuring ACTH may become of importance in the clinical diagnosis and especially in the differentiation of Cushing's syndrome of hypothalamic origin from cortisol-producing adrenocortical tumors and from paraneoplastic ACTH secretion.

Urinary Corticoids. Direct assessment of an increased cortisol secretion rate is of primary importance in the laboratory diagnosis of Cushing's syndrome. Urinary cortisol metabolites measured as 17-hydroxycorticoids (Porter-Silber chromogens) or 17-ketogenic steroids are usually found to be elevated (15 to 40 mg instead of 3 to 13 mg per 24 hours). Estimation of urinary corticoids alone does not always confirm or exclude a diagnosis of Cushing's syndrome. Values for urinary corticoids can be in the high normal range in confirmed cases of Cushing's syndrome or slightly elevated in obesity. Base-line excretion of urinary corticoids can only be evaluated in association with clinical findings and other laboratory tests.

Plasma Corticoids. Normal values of unconjugated plasma corticoids, as measured by the Porter-Silber reaction, vary between 6 and 25 μg per 100 ml between 7 and 9 a.m. and fall to 5 μg per 100 ml between 9 p.m. and midnight. The absence of a diurnal variation is suggestive of Cushing's syndrome, but not conclusive. It can also be due to brain tumors, cranial trauma, cardiac insufficiency, or psychosis. However, a normal diurnal variation is not consistent with the diagnosis of Cushing's syndrome.

Free Urinary Cortisol. Normally, less than 1% of the secreted cortisol is excreted unchanged in the urine, i.e. 20 to 150 μg per 24 hours. By contrast, values ranging from 200 μg to several mg per 24 hours are found in Cushing's syndrome.

17-Ketosteroids. The importance of urinary 17-ketosteroids in the diagnosis of Cushing's syndrome must not be overrated. They are elevated in about 50% of cases with adrenal hyperplasia. Strikingly elevated values, ranging between 30 and several hundred mg per 24 hours, are only found in adrenocortical carcinoma, and are generally associated with an increase in the 17-hydroxycorticoids. The 17-ketosteroids may, however, be reduced in adrenocortical adenomas, since the autonomous cortisol pro-

duction by the adenoma suppresses ACTH secretion, thus leading to atrophy of the normal adrenocortical tissue. High relative amounts of dehydroepiandrosterone among the 17-ketosteroids and of tetrahydro-S among the 17-hydroxycorticosteroids in the urine of patients with adrenocortical carcinoma are indicative of qualitative alterations of steroid biosynthesis in neoplastic tissue.

Cortisol Secretion Rate. Determination of the cortisol secretion rate by isotope dilution methods reveals increased 24-hour values, but is not necessary for diagnostic purposes.

Aldosterone, Pregnanediol and Pregnanetriol are not usually excreted in increased amounts. The urinary excretion of corticosterone metabolites and estrogens is occasionally elevated in hyperplasia and in carcinoma. For functional tests of the adrenal cortex, such as ACTH test, methopyrapone test, dexamethasone test, the reader is referred to pp. 385–390.

Plasma Electrolytes. Even in the absence of aldosterone excess, hypokalemia can develop due to the weak mineralocorticoid activity of cortisol, which is produced in excessive amounts. This is usually associated with metabolic alkalosis, with a pH of up to 7.5. The serum chloride concentration is usually low; the sodium level can be low, normal, or elevated. For a discussion of the pathogenesis of hypokalemia and alkalosis see p. 304. Severe hypokalemia is alway suggestive of paraneoplastic Chusing's syndrome. Calcium values are usually in the lower normal range and phosphate is normal or slightly reduced while phosphate excretion index (see Chap. XIV) is elevated. The alkaline phosphatase can be slightly elevated independently of osteoporosis. Hypercalcemia can occasionally occur after adrenalectomy. Thyroid function is normal; BMR and ^{131}I uptake can be decreased, elevated or normal. Serum cholesterol is usually slightly elevated.

Hematological Changes. Morphological changes in the blood are of some diagnostic value when complicated laboratory tests are not available. The eosinophilic leukocytes are most extensively influenced. They disappear entirely or can be present in only small numbers. The simple direct eosinophil count can be of diagnostic value. As a rule of thumb, Cushing's syndrome is unlikely to be present when the eosinophil count is more than 100 cells per mm^3 (normal values 100 to 300 per mm^3). Lymphopenia is almost always present in Cushing's syndrome. Moderate leukocytosis is less characteristic. The effects on the red blood picture are less impressive. Contrary to a prevalent opinion, polycythemia does not occur commonly in Cushing's syndrome. Hemoglobin values of 100 to 120% are often found, but the erythrocyte count is rarely elevated to the levels seen in polycythemia.

Carbohydrate Metabolism. Impaired carbohydrate metabolism can range from slightly reduced glucose tolerance to severe steroid diabetes. A normal fasting blood sugar does not by any means exclude Cushing's syndrome. The glucose tolerance test, however, almost always shows a rise of the blood sugar to values above 180 mg%, and a delayed return to normal. The intravenous insulin test usually reveals an inadequate fall

Table 15. Laboratory investigations when Cushing's syndrome is suspected

1. Single-dose dexamethasone suppression test (p. 389): Plasma corticosteroids at 8 a.m. before and at 8 a.m. after 1 mg of dexamethasone at midnight;
   when pathologic:
2. White and red blood status.
3. Direct eosinophilic count.
4. Serum chemistry: Sodium, potassium, chloride, urea, standard bicarbonate, fasting blood sugar, when normal glucose tolerance test.
   Urine: protein and sugar.
5. 17-ketosteroids, 17-hydroxycorticoids in 24-hour urine collection;
   when elevated:
6. 2 mg dexamethasone suppression test: 3 days 4 times 0.5 mg of dexamethasone, when 17-hydroxycorticoids > 4 mg – Cushing's syndrome.
7. 8 mg dexamethasone suppression test: 3 days 4 times 2 mg of dexamethasone,
   no suppression of corticosteroids: Cushing's syndrome due to tumor.
8. X-rays: skull lateral view, thoracic and lumbar spine lateral view, pelvis.
   Localization of suspected adrenocortical adenoma: retropneumoperitoneum with i.v. pyelography and tomography of the adrenals. Eventually selective phlebography and bilateral adrenal rein plasma cortisol.
9. Plasma corticoids at 8 a.m. and at 8 p. m. normal: 8 p.m. value 50% lower than 8 a.m. value and lower than 25 µg/100 ml; Cushing's syndrome: > than 25 µg/100 ml; both values identical. Perhaps free urinary cortisol (p. 382)

of blood sugar. The plasma concentrations of pyruvic acid and lactic acid are elevated (see p. 303).

δ) Radiology

The diagnosis of Cushing's syndrome is supported by radiography of the adrenal glands. Sometimes a straight abdominal X-ray alone can suggest an adrenal tumor, but diagnosis cannot be confirmed or be excluded by this means.

Only large adrenal tumors displacing the kidney are revealed by intravenous pyelography.

The retroperitoneal pneumogram, however, reveals three-quarters of all tumors, especially when combined with tomography. Differentiation between normal and hyperplastic adrenals is doubtful even with the best technique. The risk involved in the retroperitoneal pneumogram have been reduced to a minimum with the present-day method of using oxygen and presacral insufflation. Under local anesthesia, a pneumothorax needle is introduced to a depth of 3 to 5 cm at the midpoint between the anus and the tip of the coccyx, penetrating the ano-coccygeal ligament. One finger remains in the rectum during introduction of the needle. The simplest method of introducing the oxygen is to use a 50 cm^3 injection syringe and a three-way tap. After control aspiration 1200 to 1500 cm^3 of oxygen is introduced under mild pressure, the whole procedure being monitored by X-ray screening. Tomograms are made 1 to 2 hours later. Adrenal demonstration varies widely individually. Beautiful anatomical pictures of the adrenals can be obtained when the layer of adipose tissue between the kidneys and the adrenals is well developed.

Sometimes, however, the surrounding adipose tissue cannot be separated from the adrenal cortex in spite of a perfect technique, and evaluation of the adrenal size remains impossible. This occurs especially when fibrous changes are present in this area. Adrenal hyperplasia cannot be diagnosed with certainty by radiological means. Normal adrenal size is at the most 3–4 × 4 cm. Hyperplasia, however, can only be considered as being present when enlargement is pronounced and the effective radiographic magnification is taken into consideration. Normal adrenal size does not exclude Cushing's syndrome. Aortography is less suitable than renal angiography for demonstration of the adrenals. Occasionally, an adrenocortical tumor can be revealed by retrograde filling with contrast medium through a catheter introduced into the adrenal veins for bilateral blood sampling for cortisol determination (see p. 335 and Chap. VIII, p. 436).

An X-ray of the sella turcica is always indicated, although it is enlarged in only 10% of cases with Cushing's syndrome of hypothalamic origin. However, it is valuable to have a record of the original size of the sella turcica, because occasionally (6%) pituitary tumors develop after adrenalectomy. During childhood, a cortisol-secreting adrenal adenoma may lead to a small sella, which can become normal after treatment.

Lateral views of the thoracic and lumbar spine are always indicated for the detection of osteoporosis and assessment of its severity. Sometimes it is necessary to complement this with the a.-p. view of the pelvis and ribs, which may often reveal fractures with excessive callus formation.

Differentiation between adrenal hyperplasia and unilateral tumor can be achieved by scintillation scanning following administration of ^{131}I-19-iodocholesterol (BEIERWALTES, 1971).

ε) Special Forms of Cushing's Syndrome

1. Mixed forms of Cushing's syndrome and adrenogenital syndrome may be due to adrenal adenomas or carcinomas. They are rare in adults, but occur frequently during childhood. Hirsutism and acne of various degrees of severity are also found in pure Cushing's syndrome. Virilization, however, is always suggestive of an adenoma or of carcinoma. In these cases, the anabolic action of the androgens can compensate the catabolic effect of cortisol, thus preventing muscular atrophy. The output of abnormal steroid hormones by carcinomas of the adrenal cortex indicates deficiencies of individual enzymes. The majority of these abnormal steroids are precursors of normal hormones and their metabolites, such as compound S, tetrahydro-S, and dehydroepiandrosterone. According to the prevailing hormone, the features of Cushing's syndrome can be overshadowed by virilization, feminization, or hypertension and hypokalemia.

Finally, carcinoma of the adrenal cortex is often not accompanied by any endocrine symptoms, despite excessive steroid production, when most of the steroids are inactive precursors. These tumors can only be recognized when they are large and lead to pressure symptoms. Combined adrenocortical-medullary tumors are extremely rare. Pheochromocytoma may also lead to symptoms reminiscent of Cushing's syndrome, and cortical tumors to increased catecholamine production. Finally, Cushing's syndrome may be due to ectopic ACTH production by the adrenal medulla (MELONI, 1966).

2. Transitory and Periodic Cushing's Syndrome. A few cases of periodic cortisol excess and of spontaneous remission or healing of unequivocal Cushing's syndrome confirmed by hormone determinations have been described. This is extremely rare, so that postponement of treatment is never justified. In particular, conditions similar to Cushing's syndrome, which have been observed occasionally after cranial trauma, in encephalitis, and pulmonary tuberculosis, must not be mistaken for Cushing's syndrome, which can only be diagnosed by an increased secretion of 17-hydroxycorticoids not suppressible by 2 mg of dexamethasone. An "exogenous" Cushing's syndrome can only be induced by ACTH, cortisol or its derivatives.

3. Cushing's Syndrome due to Ectopic ACTH Production in Tumors (Paraneoplastic Cushing's Syndrome). Cortisol excess has been observed in hundreds of patients with non-endocrine tumors. It is characterized by the following features:

1. hypokalemia and alkalosis;
2. malignant course with an average life expectancy of 9 months;
3. clinical features of Cushing's syndrome may be absent;
4. marked pigmentation.

Small-cell carcinomas of the bronchus (50%), thymus (25%), and pancreas (10%) are the tumors most frequently involved, but Cushing's syndrome may also be due to other tumors of other organs, such as the gallbladder, parotids, colon, kidney, trachea, central nervous system, breast, prostate, and even other endocrine glands, such as the thyroid and adrenal medulla. Women are no more frequently affected than men. In about 50% of cases, the appearance typical of Cushing's syndrome and the typical symptoms are absent, although the cortisol secretion is definitely increased and the adrenals are always found to be hyperplastic. The absence of clinical symptoms may be explained by the rapid course. After surgical removal of the tumor, cortisol excess and its symptoms disappear; they reappear with the development of metastases. Hypokalemia and alkalosis, which indicate a considerable reduction of the amount of exchangeable potassium, are due either to the strikingly excessive cortisol production or to the secretion of corticosterone and compound S. CRANE (1966) found a 10-fold increase in the secretion rate of deoxycorticosterone in a case of Cushing's syndrome due to a bronchial carcinoma, but a normal rate in three cases of Cushing's syndrome of hypothalamic origin. The secretion rate of aldosterone is usually lowered. Diurnal variation of plasma cortisol is absent. The elevated excretion of urinary 17-hydroxycorticoids is not suppressed even by 8 mg of dexamethasone.

The pathogenesis of this syndrome has been explained by the demonstration of large amounts of a polypeptide with ACTH activity in the primary tumor, metastases, and blood, and a decreased ACTH content of the pituitary glands in these patients. In some of the tumors, more MSH than ACTH was found, which would explain the extreme pigmentation occasionally observed.

With the exception of the pigmentation, all signs and symptoms of Cushing's syndrome disappear after total adrenalectomy, but the deleterious course is due to the tumors, which are usually extremely malignant. Ectopic ACTH formation by a tumor should always be suspected when Cushing's syndrome is associated with pronounced hypokalemia; when it is found, the patients can be spared the useless adrenalectomy (see Chapter XVI, paraneoplastic syndrome).

4. Recurrent Cushing's Syndrome after Total Bilateral Adrenalectomy. Several well-documented cases of Cushing's syndrome recurring after total removal of both hyperplastic adrenals have been reported. This was probably due to local regeneration of residual adrenal tissue or to ectopic adrenocortical tissue becoming functional under increased ACTH secretion. Ectopic adrenocortical tissue has been found in different organs of the urogenital system, but also in the liver and pancreas. Only in the cases reported by CHAFFEE (1963) and NEY (1966) was ectopic adrenal tissue successfully localized at the lower or upper renal pole and surgically removed. Treatment with pituitary irradiation or methyrapone was attempted in all other cases. In one case described by STAUB (1967), multiple ectopic adrenal cortical regeneration occurred after complete pituitary destruction with radioactive yttrium, probably under the influence of ectopic ACTH produced by a pancreatic tumor.

5. *Primary Adrenocortical Adenomatosis (Nodular Dysplasia).* In a few cases of Cushing's syndrome in which the 17-hydroxycorticoid excretion was not suppressed by high doses of dexamethasone, surgery has revealed multiple nodules of the adrenal cortex and not the expected adrenal tumor. MEADOR (1967) found such alterations in a 14-year-old girl whose sella turcica was reduced in size and in whom no ACTH could be detected in the plasma after bilateral adrenalectomy even with the most sensitive assays. This indicated that the disease was due to a primary adrenocortical disorder.

6. Cushing's Syndrome in Childhood. In a few respects, Cushing's syndrome in childhood differs from Cushing's syndrome in the adult. In childhood, Cushing's syndrome is caused almost without exception by a benign or malignant adrenal tumor. Adrenal hyperplasia occurs in children very seldom. One of the most important features of Cushing's syndrome during childhood is growth retardation due to the antianabolic state of metabolism. This symptom is obligatory and any diagnosis of Cushing's syndrome in a child of normal size and with a regular growth curve is dubious. Osteoporosis can be very extensive. The intervertebral discs can become broader than the vertebral bodies. In the mixed forms, the anabolic action of androgens and the catabolic effect of glucocorticoids may counteract each other.

7. Cushing's Syndrome and Pregnancy. Pregnancy very rarely occurs in active Cushing's syndrome. Diagnosis may be difficult, because the urinary excretion of 17-hydroxycorticoids and 17-ketosteroids and the plasma concentration of corticoids are elevated in normal pregnancy. In contrast to Cushing's syndrome, diurnal variation is maintained during normal pregnancy. Pregnancies in Cushing's syndrome often end in stillbirths. The fetal adrenals are small and the fetal zone is found to be prematurely regressed. There are many reports of adrenalectomy with continuation of the pregnancy in patients with Cushing's syndrome. An exacerbation of Cushing's syndrome due to an adrenal adenoma during pregnancy has also been observed (PARRA, 1966). Pregnancies are usually uncomplicated in women subjected to bilateral adrenalectomy for Cushing's syndrome and fully substituted.

f) Differential Diagnosis of Cushing's Syndrome

In the differential diagnosis of Cushing's syndrome, a combination of simple obesity, essential hypertension, and diabetes must first be considered; these constitutional diseases often occur together. The experienced clinician can recognize Cushing's syndrome from the specific facial expression. In contrast to constitutional anomalies, the case history indicates a definite time at which the illness started and character changes were noted. Differential diagnosis becomes more difficult when obesity is associated with red striae (which are not uncommon in rapidly developing juvenile obesity) and urinary 17-hydroxycorticoids are found to be elevated. Cortisol secretion rate is elevated in overweight subjects, but plasma corticoids and diurnal variation are normal. The 17-hydroxycorticoid excretion may be slightly increased. These patients may demonstrate certain constitutional characteristics (JACOBSON, 1964). After weight reduction, the cortisol secretion rate becomes normal in some patients, indicating that the increased cortisol turnover rate was due to the increased mass of adipose tissue with a higher capacity for lipid-soluble steroids. Striae in juvenile obese patients are said to be more pink than purple in colour, shorter, finer, and more numerous, and to be found not only on the lower abdomen and the hips, but also in the axilla, on the upper arms, the breast and the buttocks. However, this differentiation may be difficult in individual cases. The pathogenesis of red striae is explained in both instances by stretching of the skin, increased subcutaneous adipose tissue, and simultaneous involution of the elastic fibers due to the increased amount of cortisol. As a rule, obesity with striae can be differentiated from true Cushing's syndrome by the following laboratory tests:

1. the increased excretion of urinary 17-hydroxycorticosteroids is suppressible by dexamethasone in a dose of 2 mg per day (see p. 389) in obesity but not in Cushing's syndrome;
2. in obesity, there is a circadian rhythm of plasma corticosteroids, in Cushing's syndrome, there is a plateau;
3. excretion of free urinary cortisol is very low in obese as well as in healthy subjects, but is elevated in Cushing's syndrome.

The "diabète des femmes à barbe" of ACHARD and THIERES is, in our opinion, not a clinical entity, but a random coincidence of simple hirsutism and vegetative glycosuria caused by an accident in a 69-year-old woman. This suggestive term has since been used to describe several cases of Cushing's syndrome.

Virilization with normal or only insignificantly elevated urinary 17-ketosteroids is suggestive of an ovarian tumor (see p. 634).

The differentiation of Cushing's syndrome from Stein-Leventhal syndrome (see p. 609) can be difficult. The latter diagnosis can only be confirmed by the finding of specific ovarian alterations, whereas Cushing's syndrome is diagnosed from the increased corticoid excretion and the metabolic disorders.

For the differentiation from adrenogenital syndrome compare p. 358.

g) Course, Prognosis and Cause of Death

The course of untreated Cushing's syndrome is deleterious, although a few cases of spontaneous remission have been described (see p. 353). This occurs too rarely to justify any delay in

therapy. The course of the disease is extremely variable. The illness can lead from full health to death within 6 months or it can last for many years. There are known cases in which the illness lasted for over 20 years; this was, however, at least partly due to remissions induced by pituitary X-ray irradiation. In general, a patient with untreated Cushing's syndrome has a life expectancy of 3 to 10 years, on average of 5 years. The major cause of death is now hypertension and its complications. Before the era of antibiotics, death was due predominantly to infections. Resistance to infection is reduced in Cushing's syndrome, and staphylococcal and streptococcal infections are especially common; the incidence of fatal tuberculosis, however, is not higher than in the normal population, but tuberculosis does tend to have a malignant course in preexisting Cushing's syndrome. The third major cause of death is carcinoma. The earlier assumption of any increased predisposition to carcinoma has now been explained by the relative frequency of paraneoplastic Cushing's syndrome. In this condition, the life expectancy ranges from 30 days to 2 years with an average of 9 months. Complete cure through removal of the primary tumor has only been described once. The prognosis of adrenocortical carcinoma is poor. Only half the cases survive for more than 2 years and only an isolated few survive for over 5 years in spite of o,p'-DDD therapy.

h) Therapy

When an adrenal tumor has been diagnosed from X-rays or an adrenocortical function test with corticosteroid determinations, the only possible course of action is surgery. When preoperative findings favor a diagnosis of bilateral adrenal hyperplasia, there are three possible therapeutic approaches:

1. medical treatment with anabolic hormones or adrenostatic drugs;
2. pituitary irradiation;
3. surgery: adrenalectomy, hypophysectomy.

α) Anabolic Hormones

Testosterone or other anabolic steroids, which – at least in theory – can normalize the negative nitrogen balance, have at the most a palliative effect and can only be used for preoperative preparation. Estrogens, which should theoretically act by promoting cortisol binding to transcortin, are not sufficiently active to influence the course of the illness.

β) Adrenostatic Drugs

Amphenone-B can totally block adrenal cortical hormone production, but cannot be administered for long periods because of its toxicity.

Methopyrapone, an inhibitor of 11β-hydroxylation, inhibits the production of cortisol, but leads to excessive production of compound S and deoxycorticosterone, resulting in hypertension or edema.

o,p'-DDD (2,2-[4-chlorophenyl, 2-chlorophenyl] 1,1-dichloroethane) is beneficial for patients with inoperable adrenocortical carcinoma, although it is not free of toxic side effects such as anorexia, diarrhea, vomiting, and depression. Before administration of o,p'-DDD, as much as possible of the tumor tissue should be surgically removed. When a radical operation is not possible and the urinary excretion of 17-ketosteroids and 17-hydroxysteroids remains elevated or increases again with the formation of metastases, o,p'-DDD must be given continuously or intermittently in a daily dose of up to 10 mg. It has been ineffective in 20 to 25% of cases so far, but in two-thirds of the cases regression of the hormone production by the adrenal cortex has been achieved, associated with disappearance of the symptoms of Cushing's syndrome; in some cases substitution therapy has even become necessary. In one third of cases, mainly juvenile patients, primary tumor and occasionally even the metastases completely regress. Some patients have been successfully treated for up to two years with this drug. A few became refractory; permanent recovery has not yet been observed. Formation of metastases was not avoided by prophylactic postoperative treatment. The production of the biologically active corticosteroids and androgens is suppressed within the adrenals by inhibition of several enzymes, mainly of 3β-hydroxydehydrogenase, but the drug also affects the peripheral metabolism of steroid hormones.

Trial therapy with triparanol, an inhibitor of cholesterol biosynthesis which is not completely free of side effects, has been only partially successful.

Aminoglutethimide. This substance was developed as an antiepileptic drug under the trade name of Elipten. Animal experiments have shown that it inhibits the conversion of cholesterol to pregnenolone, and thus the biosynthesis of cortisol and corticosterone, by blocking adrenal desmolase (DEXTER, 1967). Results of the first clinical trials indicate that aminoglutethimide is suitable for the suppression of excessive steroid production by autonomous

adrenal tumors (Cushing's syndrome due to adrenal adenoma or carcinoma, primary aldosteronism), whereas the drug diminishes cortisol secretion rate only slightly in patients with Cushing's syndrome with bilateral adrenal hyperplasia. In healthy subjects, it does not induce a decrease in cortisol secretion rate, because its action is compensated by an increased ACTH production, but it does cause a decrease in aldosterone secretion rate (FISHMAN, 1967). Suppression of thyroid function (see p. 193) has been described and has to be treated by substitution therapy. Side effects such as allergic skin reactions or nausea are relatively frequent (HORKY, 1968).

The search for new, more effective and less toxic adrenostatic drugs, however, appears very promising.

γ) Radiotherapy

X-ray irradiation of the adrenals has been ineffective, whereas intensive radiation of the pituitary gland has been really successful in a few cases. The chance of success with conventional X-ray radiation is estimated at 10 to 25%; recurrences are frequent. The X-ray dose is limited to 3000 r because of the risk of damage to the surrounding organs. The application of strongly accelerated alpha particles or protons, which is possible in centers with special accelerators, appears to be considerably more promising according to the first reports of success. The incidence of recurrences with this new radiation method is not yet known. The success of pituitary irradiation can only be assessed after a waiting period of 6 months.

Although pituitary irradiation has been almost completely abandoned because total adrenalectomy is more reliable, it is gaining renewed importance in view of the occurrence of pituitary adenomas in a certain percentage of patients with Cushing's syndrome who have been treated by total adrenalectomy.

Pituitary irradiation may be tried first in mild cases of Cushing's syndrome with a chronic course and when a pituitary tumor has been clinically or radiologically detected. However, when the course is severe and progressive, no time must be lost and total adrenalectomy is the treatment of choice.

Transsphenoidal implantation of ^{90}Yt or ^{198}Au, possibly combined with ^{192}Ir, wich has recently been improved by a stereotactical method (MUNDINGER, 1967) destroys 70 to 90% or 30 to 50% of the pituitary gland respectively, and may cure Cushing's syndrome. On the positive side, it does not involve severe stress to the patient, but dosage is difficult, loss of the other pituitary hormones is possible, and the surrounding organs may be damaged, in particular the optic nerve with loss of visual fields, paralysis of the ocular muscles, and injury to the blood vessels. When the more effective ^{90}Yt is used, cerebrospinal fluid fistulas occur sooner or later in 20 to 30% of the cases. Better results are obtained when the puncture opening is closed with a screw. Isotope implantation is beginning to be replaced by stereotactic high-frequency electrocoagulation of the pituitary gland, which is associated with less complications (ZERRAS, 1965) or by the microsurgical transnasal-transsphenoidal operation according to HARDY (see Chap. V, p. 115). For the time being, isotope implantation appears to be justified only where adrenalectomy and hypophysectomy are contraindicated.

δ) Operations

1. Adrenalectomy. Total bilateral adrenalectomy is still the only reliable way of treating Cushing's syndrome with bilateral adrenal hyperplasia, and is thus the therapy of choice. Since it has become known that a pituitary tumor can develop and that the growth of a preexisting pituitary tumor can be accelerated after adrenalectomy, misgivings have come up about this form of treatment. After removal of the hyperplastic adrenals, plasma ACTH rises to high levels, and apparently there is a positive correlation between this increase and the probability of a pituitary tumor developing later on (NELSON, 1966). Nevertheless, we still consider total adrenalectomy the treatment with the best chance of success and with least risks. Up to 1963, 28 reactive pituitary tumors growing after adrenalectomy had been reported. Twelve of these were already known to be present before surgery (KRACHT, 1963). It is difficult to assess the incidence of these reactive pituitary tumors among all cases of total adrenalectomy, because this operation is often performed and not always reported in the literature. In a series reported by the Mayo Clinic, the incidence of reactive pituitary tumors growing after adrenalectomy was found to be 7%. Growth of these pituitary tumors proceeds slowly and can be detected at an early stage if frequent check-ups are performed. Treatment is necessary in only about half the cases. Radiotherapy is the treatment of choice.

When total adrenalectomy is performed, the treatment of Cushing's syndrome is purchased at the price of Addison's disease, and the patient is then dependent on substitution therapy for the rest of his life. In spite of these disadvan-

tages, i.e. the small risk of a reactive pituitary tumor and the necessity of substitution therapy, we still consider total adrenalectomy as the only reliable way currently available of converting a life not worth living and with an average life expectancy of 5 years into a symptom-free life with full activity and practically normal life expectancy. The development of more effective and harmless adrenostatic drugs or radiotherapeutic methods may alter the situation in the future.

Subtotal adrenalectomy should no longer be performed; it is only effective when 90 to 95% of the adrenal tissue is resected, which necessitates a substitution therapy in any case in almost half the patients, and the risk of recurrence is very high (25%). Since the realization of how high the plasma ACTH concentration can rise after adrenalectomy in patients with Cushing's syndrome, it has become apparent that it is only a matter of time before the residual tissue regenerates and resumes production of excessive amounts of cortisol. Finally, the risk of acute adrenocortical insufficiency is considerably higher after subtotal adrenalectomy without substitution therapy than in substituted and well-instructed Addisonian patients. The residual tissue is under maximum ACTH stimulation and cannot fulfill increased demands due to additional stress. The risk of the development of a reactive pituitary tumor is presumably the same after an effective subtotal adrenalectomy and after total adrenalectomy with substitution therapy.

At present, the following procedure is recommended: when the sella is normal, total adrenalectomy is performed. In mild cases only, a trial with radiotherapy may be considered. It must be remembered that a preoperative diagnosis of hyperplasia is never unequivocal and that an adenoma or carcinoma can be definitely excluded only by surgical revision. When the sella is enlarged, irradiation of the pituitary gland is recommended, before or after adrenalectomy. Again, only in the mild cases is there time to wait for the effects of irradiation. In severe cases of Cushing's syndrome, total adrenalectomy must immediately follow irradiation. We consider a neurosurgical or transethmoidal resection only when a pituitary tumor causes neurological complications, in particular a loss of visual fields.

Removal of both adrenals at the same operation is preferable to the previous two-stage method. It is unrealistic to expect a remission after the removal of only one adrenal. It occurs only in very rare instances. The disadvantage of the greater surgical stress is outweighed by the considerable advantage of terminating the illness at once instead of over weeks or months, and of avoiding a repetition of general anesthesia and surgical trauma.

Adrenalectomy has to be carried out in a medical center where a team of experienced surgeons, clinical endocrinologists and anesthesiologists is available. The operation is complicated technically by the obesity of the patients, their low resistance and their increased bleeding tendency. Small residues of adrenal tissue lead to recurrence, so that success is merely a temporary illusion; a second operation is generally impeded by the formation of scar tissue. Medical pre- and postoperative treatment and supervision are essential to the success of the operation. The mortality is less than 5%.

At present, the transdiaphragmatic, extrapleural approach is usually chosen for adrenalectomy, necessitating a bilateral incision along the 11th rib. In thin patients only, a transabdominal approach with a wide incision for both adrenals is feasible.

The following procedure is recommended during operation: if exploration on the right reveals an atrophic adrenal, in all probability there is a tumor on the left side. The atrophic adrenal is left intact and the tumor on the other side is removed. When a tumor is found on the first side, it is removed and the other side is left intact. However, when the right adrenal is found to be normal or hyperplastic, it is totally removed. The left adrenal is then also removed. See Table 8 for substitution during and after operation.

2. Hypophysectomy. In theory, hypophysectomy may also be considered in Cushing's syndrome with adrenal hyperplasia. Several approaches are possible: the neurosurgical transfrontal or better paranasal transethmoidosphenoidal, the microsurgical transnasal-transsphenoidal method (HARDY, 1969), stereotactic implantation of β- and γ-emittors (MUNDINGER, 1967) or stereotactic electrocoagulation (ZERRAS, 1965) (see p. 115). Advantages are a lesser surgical stress and the removal or prophylaxis of a pituitary tumor, but these are offset by the disadvantages of possible thyroid or gonadal failure and of the development of mild diabetes insipidus. Radical hypophysectomy is difficult, and after partial removal there is a tendency for regeneration and recurrence, particularly in Cushing's syndrome, in which the pituitary is under neurohumoral stimulation by the hypothalamus. Moreover, adrenocortical tumors cannot be excluded with absolute certainty, even with the most perfect diagnostic technique, except by surgical revision. We therefore recommend hypophysectomy only when the patient's con-

dition precludes adrenalectomy, when reactive pituitary tumors grow to dangerous proportions in spite of irradiation, or in the extremely rare cases of primary enlargement of the sella, particularly when associated with loss of visual fields.

3. Postoperative Course. The operation and postoperative course can be well controlled, initially by intravenous, later by oral administration of cortisone. However, the cortisone dosage must not be reduced too quickly. Rapid reconstruction of tissues may lead to the post-adrenalectomy syndrome, which is characterized by restlessness, tachycardia, and other vegetative circulatory disorders, anorexia, nausea, vomiting, and abdominal pains. In most cases, these symptoms can be corrected by temporarily increasing the dose of cortisone. Occasionally, there is a fall in blood pressure due to hypovolemia or tachycardia with pale, cold, moist extremities and nausea necessitating treatment with infusions of plasma or dextrane mixtures. Occasionally, often only after a few months, subacute hemorrhagic pancreatitis of unknown pathogenesis may develop. There may be hypercalcemia in the presence of normal serum phosphate levels. When these signs are observed, the patient must immediately be treated again with cortisone, with a daily dose up to 200 mg. The patients go through a critical phase between the 10th and the 20th postoperative days. They must definitely be kept under hospital supervision for at least that period. When, in cases of adrenal tumors, atrophy of the contralateral adrenal is suspected, synthetic long-acting ACTH, 1 mg twice daily, can be given i.m. for a few days even before the operation. Postoperatively, the same dose is continued for about a week; thereafter, it can be reduced to 1 mg once daily for another week. Sometimes, however, the atrophic adrenal recovers only after some months or not at all. In a few cases, persistent failure of ACTH secretion has been observed, lasting for years and necessitating continuous substitution therapy with cortisone.

The first signs of success appear within a few weeks, as soon as the daily dose of cortisone is reduced to 50 mg. The premorbid condition is not generally recovered for 3 to 6 months, and the patients must be well supervised during this period. The blood pressure falls to the original values, unless it is fixed by irreversible vascular changes. The diabetes almost always disappears. Excessive fat deposits are broken down, and the pendulous folds of abdominal fat must sometimes be corrected by plastic surgery. The skin usually peels after 6 to 8 weeks, as after scarlet fever. There is often loss of hair, which is immediately replaced by new hair, occasionally different in quality and color. Pigmentation of the skin can be of varying severity. Menstruation recommences after 2 to 3 months, and the chances of pregnancy after successful treatment of Cushing's syndrome are good. Mental changes usually regress after successful treatment. Individual symptoms, such as loss of libido, may persist. In the woman, this can be treated with small doses of androgens.

4. The Adrenogenital Syndrome

A. PRADER and M. ZACHMANN

The term adrenogenital syndrome describes the clinical states induced by overproduction of

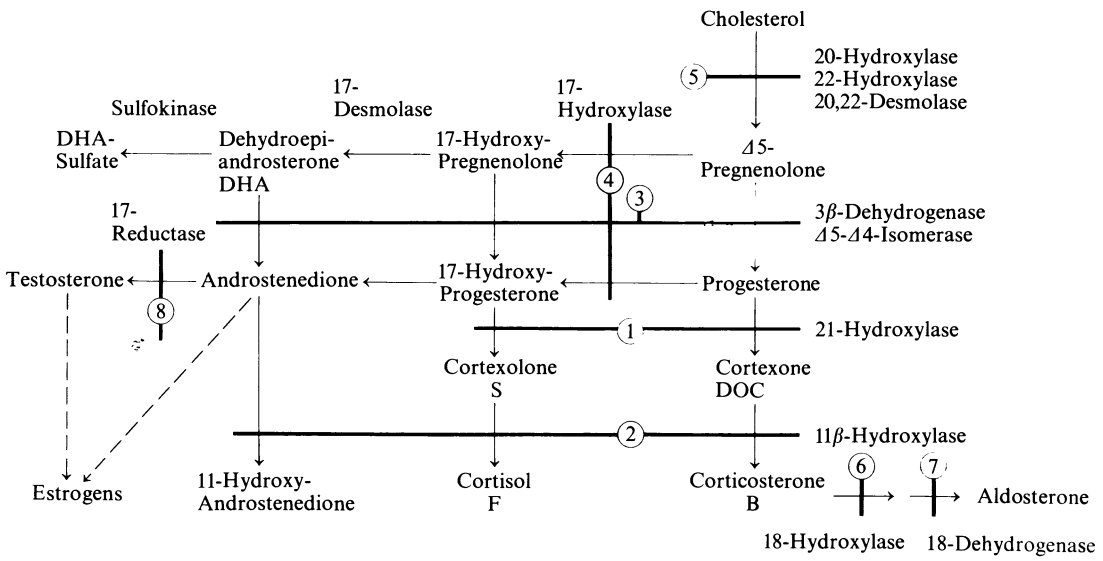

Fig. 27. Known hereditary enzyme deficiencies in the biosynthesis of adrenocortical and gonadal steroids

Table 16. Hereditary disturbances of steroid biosynthesis (enzyme deficiencies and clinical pictures)

Enzyme deficiency	Gonads	Adrenal cortex				Clinical picture
	Intersexual genitalia in boys	Intersexual genitalia in girls	Progressive virilization	Salt loss	Hypertension	
With adrenal hyperplasia

5. 20,22-desmolase						Lipoid hyperplasia of the adrenals (p. 323)
Without adrenal hyperplasia						
6. 18-Hydroxylase	−	−	−	+	−	Hypoaldosteronism (p. 325)
7. 18-Dehydrogenase						
8. 17-Reductase	+	−	−	−	−	Atypical (partial) testicular feminization (p. 725)
9. 17,20-Desmolase	+	−	−	−	−	

androgenic steroids by the adrenal cortex. This group is well characterized clinically. In the last few years, increasing knowledge about the mechanisms involved in steroid synthesis has led to the discovery of clinical conditions which are closely connected with the congenital forms (see below) of the adrenogenital syndrome biochemically but are clinically quite different. They are not associated with overproduction of androgens and only some are associated with hyperplasia of the adrenal cortex. Fig. 27 and Table 16 give a survey of the congenital disorders of steroid biosynthesis currently known. Only the various forms of the true adrenogenital syndrome are discussed in this section. Since the other disorders in the biosynthesis of adrenocortical steroids become clinically manifest in different ways, they are dealt with in the appropriate chapters (lipoid hyperplasia, p. 323; 17-hydroxylase defect, p. 371; 17,20-desmolase deficiency, p. 726; 17-reductase deficiency, p. 726; hypoaldosteronism, p. 325).

a) Classification, Definition

The adrenogenital syndrome does not always have the same etiology and pathogenesis. Overproduction of androgenic steroids of the adrenal cortex is, however, common to all forms. Three main forms are differentiated on the basis of pathogenetic and therapeutic features: 1. the hereditary adrenogenital syndrome due to congenital adrenocortical hyperplasia (see below for the different forms), 2. the adrenogenital syndrome with acquired adrenocortical hyperplasia, and 3. the adrenogenital syndrome resulting from an adrenocortical tumor.

The symptomatology of the overproduction of androgenic steroids is, of course, much more striking in the female than in the male, regardless of whether the androgens arise from the adrenal cortex or from the gonads. The symptomatology is referred to as virilization in the female sex, whereas in the male sex no special term is available as there is no characteristic set of symptoms. Unfortunately, the terms virilization, hirsutism, and hypertrichosis are generally used rather inaccurately. This results in obscurity and confusion, so that definition of these terms seems indicated before discussion of the individual syndromes. The term *virilization* is used in girls or women when 1. the secondary sexual characteristics are predominantly masculine, 2. female secondary sexual characteristics are absent or are undergoing regression, and 3. the clitoris is hypertrophic. This triad of symptoms only occurs during treatment with high doses of testosterone or in association with an increased androgen production due to either an adrenogenital syndrome or an androgen-producing tumor.

Hirsutism signifies a male type of hair distribution in women – increased sexual, body, and facial hair. It is sometimes accompanied by acne without the development of other androgenic symptoms such as hypertrophy of the clitoris or deep masculine voice. Hirsutism is usually idiopathic (p. 377), but may arise with ovarian disorders (Stein-Leventhal syn-

drome, p. 593) or adrenal disorders (Cushing's syndrome, p. 345).

Hypertrichosis implies increased body hair without accentuation of the sexual hair. It can, therefore, arise in children before development of the secondary sexual characteristics and has nothing to do with androgens.

b) Hereditary Congenital Adrenogenital Syndrome (Congenital Virilizing Hyperplasia of the Adrenal Cortex)

These conditions are classic examples of "inborn errors of metabolism" due to enzyme defects. The large number of specific enzymes required for the synthesis of cortisol from cholesterol (see p. 358, Fig. 27) explains the multiplicity of the clinical symptoms. There is one factor common to all enzyme defects so far known and associated with adrenocortical hyperplasia: cortisol synthesis or rate of production is diminished, and there is an accumulation of intermediary metabolic products due to the absence or reduced activity of enzymes required for their further processing. Depending on type, amount, and biological activity of these intermediate metabolic products, clinical features such as virilization, hypertension, salt loss, and (due to a decrease in cortisol) even Addisonian crises, poor resistance and hypoglycemia can arise.

α) Frequency

Statistics on the frequency vary from about 1 : 500 (Eskimos) to 1 : 67000. In Switzerland, the frequency is found to be 1 : 5000 (PRADER, 1962). It is approximately the same in both sexes. In the past it was assumed that the frequency was higher in the female sex, but this can be explained by the more difficult diagnosis in male patients and the fact that male patients with milder forms do not consult their doctors.

β) Heredity

The condition very frequently occurs in siblings. Consanguinity between parents is uncommon or lies many generations back and is thus insignificant. Statistical investigations indicate an autosomal recessive inheritance. Affected siblings also demonstrate the same enzyme defect, but not always to the same extent (ROSENBLOOM, 1966). Heterozygotes are common. If the rather low frequency of 1 : 40000 for homozygotes is accepted, at least 1% of the population must be heterozygous. Other authors accept a gene frequency of 1 : 16 (ROSENBLOOM, 1966) or 1 : 35 (PRADER, 1962). The ability to recognize heterozygotes would have a decisive effect on genetic counselling, but no satisfactory method has yet been found. Pregnanetriol excretion increases more in response to ACTH in heterozygotes for the 21-hydroxylase defect than in normal controls (see below), but this is not a safe way of identifying individual heterozygotes. As in the healthy, no pregnanetriolone is found in the urine of heterozygotes (see below). It may be possible later to detect heterozygotes for the 21-hydroxylase defect by estimation of 17α-hydroxyprogesterone or testosterone in the plasma after stimulation with ACTH.

γ) Pathogenesis

Theories on the pathogenesis of congenital hyperplasia of the adrenal cortex have changed with development of specific methods of steroid analysis. Originally, overproduction of androgens was claimed to be the primary pathogenic factor. It only became obvious after the introduction of specific methods that not only are certain steroids present in increased amounts but the production of other steroids is reduced. The idea that the reduced production of cortisol must be considered as the primary pathogenic factor became prevalent. Furthermore, it has also been shown that the cause of the diminished cortisol production is not the same in all cases but that synthesis is interrupted at different stages (Fig. 27). Deficiency of 3β-dehydrogenase, 21-hydroxylase and 11β-hydroxylase can cause a reduction in cortisol production and an adrenogenital syndrome.

Since cortisol is the chief regulator of ACTH secretion, a decrease in the amount of circulating cortisol can lead to the release of CRH (corticotropin releasing hormone) from the hypothalamus and thus to the liberation of increased amounts of ACTH from the anterior pituitary. The concentration of ACTH demonstrated by radioimmunological methods is thus found to be elevated in all forms of congenital hyperplasia of the adrenal cortex. The increase in ACTH secretion results in increased production of only those intermediary steroids formed before the particular enzyme block. The block, however, causes little or no increase in cortisol production, and ACTH secretion is not inhibited. Thus, hyperplasia of the adrenal cortex can be interpreted as a result of continuous overproduction of ACTH. The reason for the increased skin pigmentation found in some cases is the same as for that in ADDISON'S disease (see p. 317).

The enzyme deficiency is not absolute in the majority of cases of congenital hyperplasia of the adrenal cortex, i.e. the minimum vital

amount of cortisol is practically always produced. The degree of the cortisol deficit varies from case to case, and with a few exceptions (hypoglycemia, poor resistance) is not sufficient to become clinically obvious. In contrast, the deficient response of glucocorticoid production to ACTH is definitely perceptible. Steroid anomalies associated with adrenocortical hyperplasia have two common characteristics – they are accentuated by ACTH and normalized by glucocorticoids which inhibit ACTH.

δ) Pathologic Anatomy

R. E. Siebenmann

The reader is referred to the description of the clinical features (p. 364) for a discussion of the effects of androgen excess on the genital organs and on the organism as a whole. The effects of salt loss and hypertension in the special forms of the virilizing syndrome are described in the same section. The only other important pathologic changes are those found in the adrenals, the gonads and the pituitary gland (Dhom, 1965; Symington, 1969; Siebenmann, 1973).

The only observations so far recorded on the *uncomplicated, simple virilizing syndrome* (21-hydroxylase deficiency without salt-losing syndrome) are autopsy and biopsy findings in children and adults. A latent terminally decompensated salt-losing syndrome cannot always be excluded in children dying from the condition.

A fairly characteristic bilateral *hyperplasia of the adrenal cortex* is found in all confirmed cases (Fig. 28). In children the glands may be 4–10 times larger than normal, and in adults 6–8 times larger. The increase in cortical mass parallels to a certain degree the severity of the genital masculinization and the virilization. The cortical hyperplasia is initially diffuse, but always becomes irregularly nodular with advancing age. The surface, slightly folded at first, becomes increasingly knotted. Even in children the cut surface is intense brown in color, turning to dark brown with advancing age. Narrow zones of yellowish cortex may be found only in the subcapsular peripheral or in the central cortical area.

The histological structure of the cortex can only be studied as long as the hyperplasia is diffuse and not distorted by nodular growth, i.e. during childhood. The *zona glomerulosa* is then found to be definitely wider than normal. This layer is followed by a narrow *zona fasciculata*, built up of lipid-containing spongiocytes. In autopsy cases this zone is usually also lipid-depleted. The thickness of the zone varies and there is no definite border between it and the inner *zona fasciculo-reticularis*, which forms the main mass of the cortex. It consists of lipid-free "compact" cells. They are definitely enlarged and exhibit all signs of intensive activity. Intensive activity of phosphatases, succinic dehydrogenase and diaphorase can be demonstrated by enzyme-histochemical means. The activity of 3-β-hydroxysteroid-dehydrogenase, the only histochemically demonstrable enzyme of the biosynthetic steroid pathway, is marked. The 21-hydroxylase-deficiency has been demonstrated in incubation studies on slices of such glands, but cannot be shown by enzyme-histochemical means. In addition, the cells of this hyperplastic layer are loaded with an extraordinary amount of *lipofuscin* responsible for the deep brown color of the cortex. The pigment does not differ from that normally found in the adrenal cortex, but the reason for its excessive accumulation is not known. The outer layer of this zone still shows a fascicular structure, while further in toward the medulla the structure is predominantly reticular. It is this zone which forms more and more nodular and even adenomatous masses with advancing age. They extend right up to the capsule, often perforating it in a hernia-like manner, or break up the medullary tissue internally. Separated, distorted or flattened remnants of fasciculata or glomerulosa are always found. Whereas encapsulated and probably autonomous adenomas have frequently been observed anatomically, only two cases of cortical *carcinoma* have been described in this type of cortical hyperplasia.

Not only the normally situated tissue is found to be hyperplastic, but also *ectopic adrenocortical tissue*. Thus, in the female uni- or bilateral cortical nodules, which are sometimes tumorous, arise in the mesovarium and broad ligament. In the male, nodular proliferations occur in the epididymis and testis and may almost completely replace testicular tissue, although they probably always arise from the aberrant cortical tissue which commonly occurs in the hilar region of the testis. The nature of these testicular nodules, however, is still a matter of debate, since they cannot be distinguished from interstitial cell tumors by either morphologic or biochemical means. On the other hand, the question arises as to whether the cases of bilateral interstitial cell tumors are not in fact cases of unrecognized congenital adrenogenital syndrome. Regression in size of such testicular masses during cortisone treatment suggests that they are of adrenocortical origin.

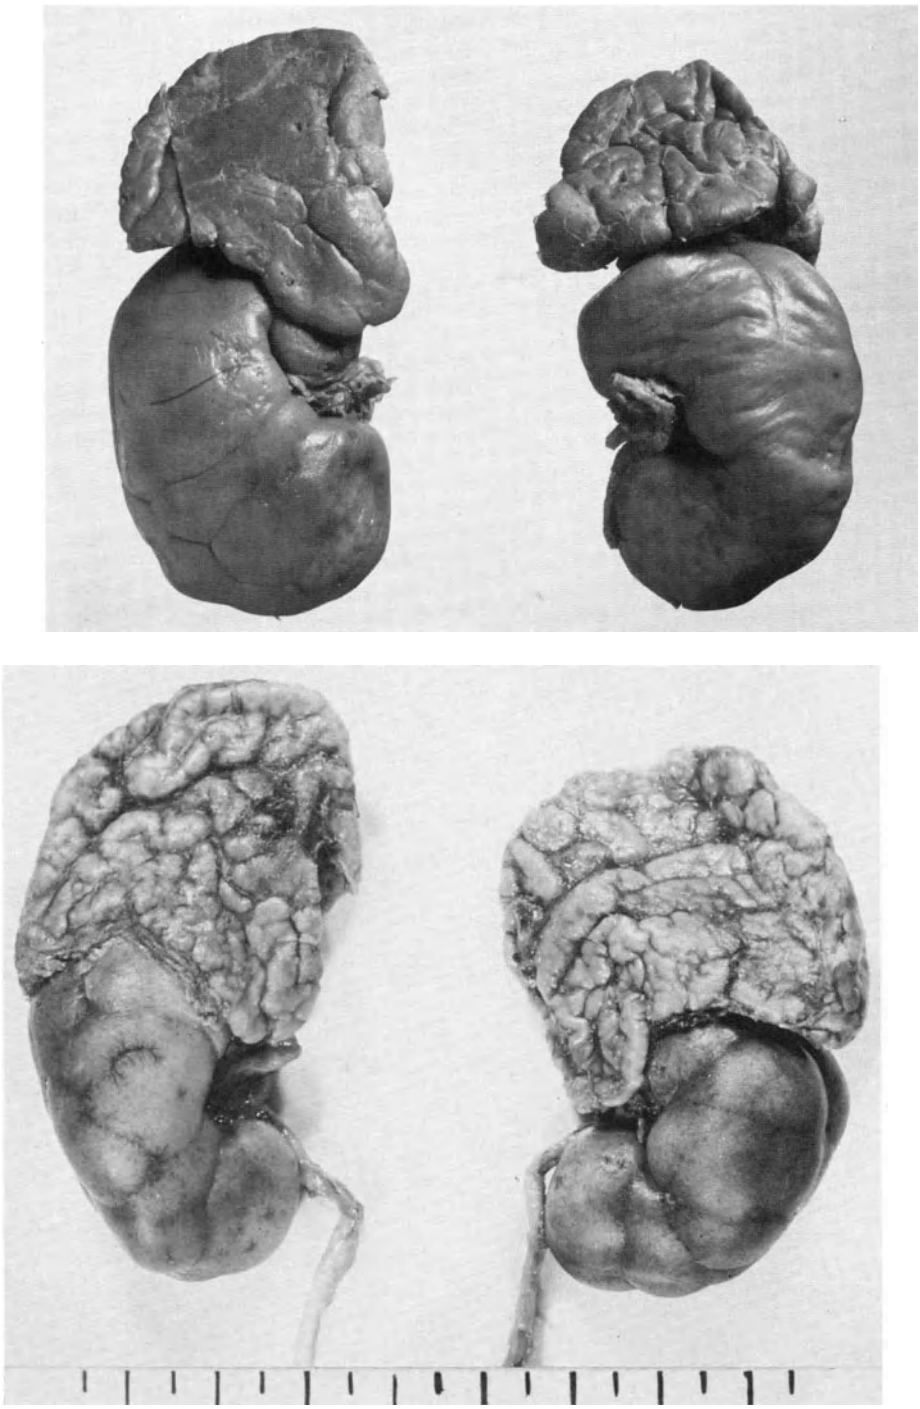

Fig. 28. Above: bilateral diffuse adrenocortical hyperplasia with moderate folding and segmentation of the surface in a 5-year-old girl with congenital adrenogenital syndrome (MB 2302/63). Below: cerebriform adrenocortical hyperplasia in an 18-day-old infant with congenital adrenogenital salt losing syndrome (SN 969/55)

The *testes* are definitely abnormal in all severer forms. During childhood there is some acceleration of tubular maturation up to the spermatocyte I, but the glands remain small, thus contrasting with the true precocious puberty, especially as no Leydig cells are found. They remain small also in the adult. The tubules show some incomplete spermatogenesis up to the spermatocyte I, fibrosis develops and no Leydig cells are found. Milder forms of the

syndrome may be responsible for some of the cases of spermatogenic arrest without further endocrine disorders. Exceptionally, intact spermatogenesis and fertility are observed even in untreated males.

The *ovaries* are usually normal in girls, but pubertal growth and maturation fail to occur in the fullblown syndrome, follicular development does not continue beyond the antrum stage, and ovulation and corpus luteum formation do not occur. The number of primordial and primary follicles diminishes rapidly, so that at the age of 30 years no more are found. In adults the number of usually small, but sometimes even large follicular cysts is increased and the result is the "*small sclerocystic ovary*". In contrast to the Stein-Leventhal ovary there is no stromal hyperplasia and no hyperthecosis. The ovaries have not been studied in milder cases with aberration of ovarian function only.

The *pituitary* does not show characteristic changes in the anterior lobe. An increase of the sparsely granulated mucoid cells cannot be distinguished from that observed in any stress situation. No Crooke cells are found.

In the *salt-losing form* of 21-hydroxylase deficiency the endocrine organs show quite a different morphology. The *adrenals* of these infants are huge, their relative weight being increased to 6 to 10 times above the normal. Their surface is very characteristically folded and reminiscent of a cerebral cortex, so that the term "cerebriform hyperplasia" has been coined (Fig. 28).

The cortex is several times thicker than normal even in an infant of 2–4 weeks, and is thrown up in high folds. They often form secondary folds, become superimposed and tightly packed together. The bulk of this cortex shows a *fascicular* structure. There is no zona glomerulosa and only the innermost layers, at the junction with the degenerating remnants of fetal cortex, exhibit some reticular arrangement of their cells. As a rule, all cortical cells are enlarged as well as their nuclei and mitoses are often found in the outer cortical layer. The cytoplasm is usually quite devoid of lipids, and granular; it contains vacuoles of hydropic degeneration, but never any lipofuscin. Accordingly this cortical tissue is of dirty gray color. The typical folding is the result of two parallel processes: The inner, fetal cortex, which is still present a few days after birth in the youngest patients examined, undergoes complete involution as in the normal subject, although this process is somewhat delayed. It is the definite "adult" outer cortex which builds up the typical folded cortex by intensive hyperplasia after birth. From observations in very young infants it can be assumed that the fetal cortex was definitely hyperplastic before birth. Accessory adrenocortical tissue shows the same type of hyperplasia. It is therefore more easily detected at the usual sites.

The *gonads* are found to be normal in both sexes. The *pituitary*, in contrast, always shows marked changes of the anterior lobe cells. The total number of sparsely and fully granulated mucoid cells and of large chromophobes is significantly increased at the expense of the acidophils. In addition to the cellular pattern consistent with an increased production and secretion of ACTH in cortisol deficiency, the fully granulated mucoid cells – formerly the basophils – are also increased for some unknown reason. This increase, however, is also a reaction to the adrenocortical disorder, and is reversible by corticosteroid treatment.

In summary the pathologic findings in both these forms of 21-hydroxylase deficiency are consistent with the present theory on their pathogenesis. They suggest a primary disorder of adrenocortical secretion. In the *uncomplicated* form a not very marked, but constant increase in ACTH stimulation causes not only lipid depletion and broadening of the inner fasciculo-reticular layer of "compact cells", but also a massive proliferation of this "functional" layer until a quantity of cortisol compatible with life is produced by these deficient cells. The hypertrophy of the zona glomerulosa reflects the secondary hyperaldosteronism compensating the latent salt loss in these patients, as is borne out by the hypertrophy of the *juxtaglomerular* apparatus found in these cases. In the *salt-losing form* the cortex is found to be under maximal stimulation, in keeping with the more severe cortisol deficiency, and the anterior pituitary reflects this situation. The absence of a zona glomerulosa corresponds to the equally deficient production of aldosterone. Juxtaglomerular cells are also increased in number, although to a lesser degree.

Biopsy and autopsy in cases of the rare *11-β-hydroxylase-deficiency* have so far revealed the same hyperplasia of the fasciculo-reticularis as is seen in the simple virilizing form. In addition, hypertrophy of the zona glomerulosa has been found, which seems to be integral to the disorder of cortical secretion and not due to secondary hyperaldosteronism. There is usually no salt loss in these patients and no hypertrophy of the juxtaglomerular apparatus has yet been found.

In the patients dying of *3-β-hydroxysteroid-dehydrogenase* deficiency the *adrenal* changes very much resemble those of the virilizing form

with severe salt loss. The hyperplasia is more marked in the fatal cases so far examined.

In the two studied cases, there was no detectable histochemical activity of 3-β-hydroxysteroid-dehydrogenase, whereas the other enzymes of the adrenal cortex were active (SIEBENMANN, 1973). The enzyme activity of Leydig cells could not been investigated, since they had already been involuted in the infants examined up to now.

ε) Laboratory Data

The analysis of three particular steroid groups is important for precise differentiation of the different types of the congenital adrenogenital syndrome. These three groups are: androgens, pregnane (and pregnene) derivatives, and cortisol and its metabolites. Group estimation of 17-ketosteroids (see p. 381) is often not sufficient for differentiation. The individual 17-ketosteroids can be assayed by gas chromatography. This is especially important in differentiation between a 21-hydroxylase and an 11β-hydroxylase defect. Estimation of testosterone in the plasma or urine is also of significance (see below). Among the *pregnane derivatives*, pregnanetriol and particularly pregnanetriolone have become important since only small amounts of pregnanetriol and no pregnanetriolone at all appear in the urine of normal subjects. Increased amounts excreted in the urine are therefore of pathognomonic significance. *Pregnene derivatives* such as Δ5-pregnenediol, Δ5-pregnenetriol and Δ5-16-α-hydroxypregnenolone (in infants) are also of significance, although they are more difficult to identify. Estimation of cortisol and corticosterone precursors tetrahydro-S and tetrahydro-DOC is also important in differentiation between different forms of congenital hyperplasia of the adrenal cortex (see below). The reader is referred to p. 379 for further details about the methods of estimating steroid hormones. Apart from the methods described in that section, *gas-chromatographic* methods have proved particularly suitable for the measurement of testosterone, pregnane derivatives and individual 17-ketosteroids.

ζ) Clinical Features

This section presents the clinical pictures and steroid findings in the three main forms of congenital hyperplasia. Since the clinical picture can vary considerably depending on the type of enzyme defect, a generalized account of the clinical picture in the adrenogenital syndrome is not given.

η) 21-Hydroxylase Deficiency

This is the most common type of congenital hyperplasia of the adrenal cortex, accounting for about 90% of cases. Cases with *salt loss* and those where there is no salt loss differ pathogenically only in the degree of the enzyme defect. However, a few authors postulate that there are two different 21-hydroxylases (see

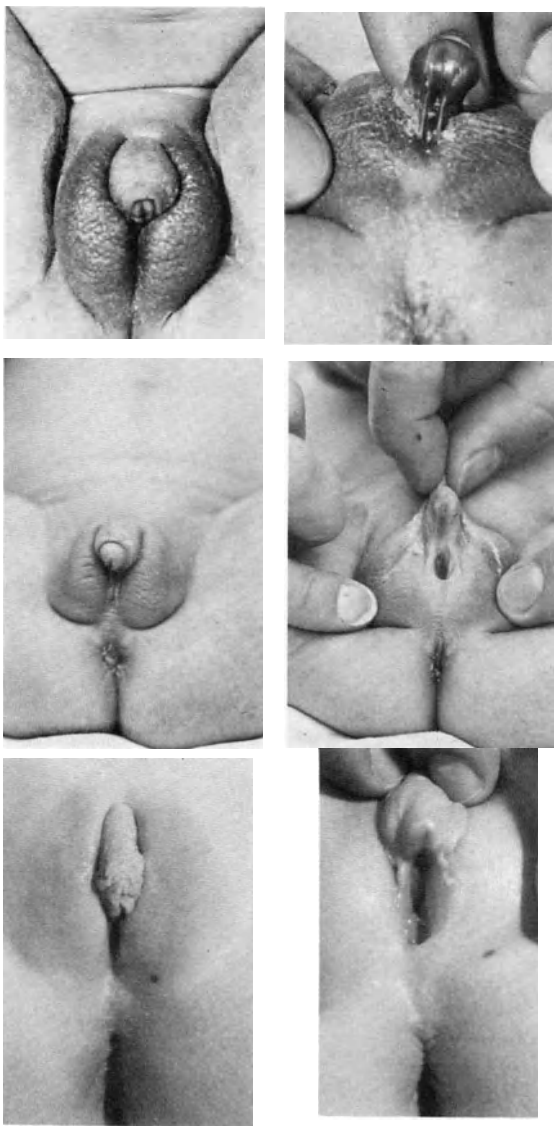

Fig. 29. External genitalia of 3 girls with congenital adrenogenital syndrome. Different degrees of virilization. Above: markedly enlarged clitoris with open urethral groove at the ventral side of the clitoris, small urogenital orifice (sinus urogenitalis) on the ventral basis of the clitoris and scrotum-like labia majora, corresponding to genital type IV in the scheme, p. 710. Middle: identical findings but larger urogenital orifice (sinus urogenitalis), corresponding to genital type III. Below: moderately enlarged clitoris with almost normal vulva with separate urethral and vaginal orifices, corresponding to genital type I

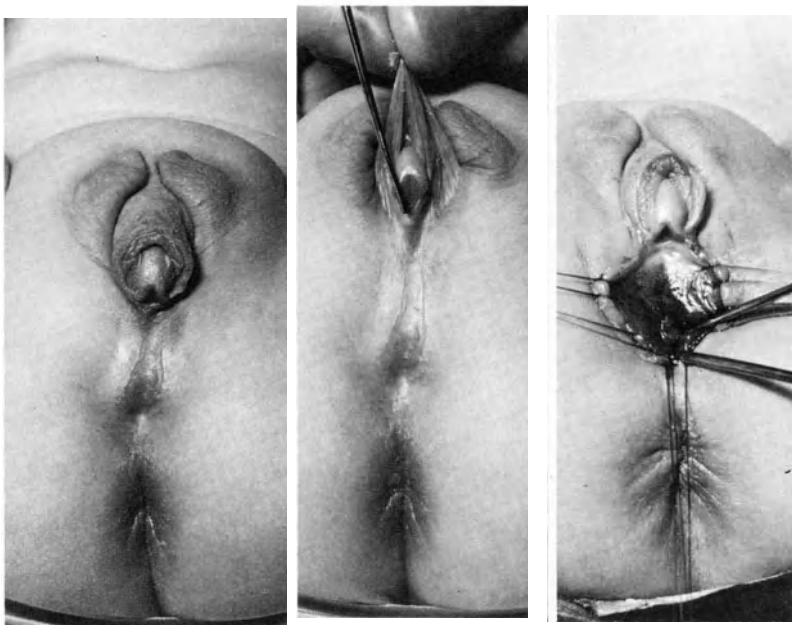

Fig. 30. Genitalia of a 3-year-old girl with congenital adrenogenital syndrome. Genital type IV according to scheme, p. 710. The superficial sinus urogenitalis can be recognized from an external flat groove. The internal urethral orifice (thin probe) and the vaginal orifice (thick probe) are localized where it ends in a pit (left side and middle)

below). In the *form without salt loss* (simple virilizing adrenal hyperplasia), *androgenic symptoms* are predominant. *Developmental anomalies of the external genitalia in girls* are the only effects caused by androgen overproduction in the fetus (PRADER, 1954). While the internal genitalia are unaffected, the external genitalia show masculine features under the pathologic action of androgens between the 12th and 16th weeks of pregnancy. The genitalia therefore have a more or less ambiguous appearance even in the newborn, and the term female *pseudohermaphroditism* is then applied. The clitoris is enlarged like a penis, is erectile, and continues to grow in later years if left untreated. An urogenital groove can often be seen on the ventral side (Fig. 29). The labia majora develop to be scrotum-like and fusion may even occur. The labia minora are usually completely absent. Instead of separate orifices for the urethra and vagina, usually only a single funnel-shaped or urethra-like urogenital opening is found on the ventral basis of the clitoris (Figs. 29 and 30). In addition to these classic findings, which are the most frequent, there are also all intermediary forms, ranging from slight enlargement of the clitoris with a normal vulva and distinct labia minora, to complete masculinization of the external genitalia (STOLECKE, 1970). A prostate anlage is frequently found, but otherwise the *internal genitalia* are always feminine. Urethroscopy and retrograde urethrography with contrast medium show how the urethra-like urogenital sinus divides into vagina and urethra (Fig. 30). The urogenital sinus is situated quite superficially, and can be recognized on external examination by a flat groove. This groove runs towards the anus and terminates in a small depression behind which the internal urethral and vaginal openings lie (Fig. 30). The genital changes can no longer be influenced even if treatment is instituted early. In contrast to the female genitalia, the *male genitalia*

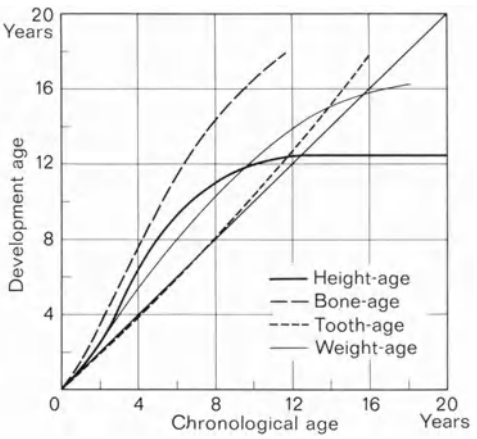

Fig. 31. Mean course of length, weight, bone and tooth development in congenital adrenogenital syndrome. Note the growth acceleration, the precocious arrest of growth and the discrepancies between the accelerated bone development and the normal tooth development

develop in an absolutely normal manner. The penis alone may be strikingly enlarged even at birth, but it is more common for enlargement to occur during the first few years of life. The enlargement increases rapidly in untreated patients in subsequent years, whereas the testes usually remain small. The genital region is often strikingly pigmented.

Accelerated increase in height and bone maturation are the next androgenic symptoms to occur in untreated patients. Weight, height and bone development are normal in these patients at birth. Towards the end of the first year or later, acceleration in bone maturation can be recognized radiologically. This is rapidly followed by a striking acceleration in height. Within the next few years, height and bone age are considerably ahead of chronological age (Fig. 31), bone age in turn being strikingly in advance of height. This results in premature fusion of the epiphyses at the age of about 10. Growth thus comes to a stop before normal adult height is reached. The patients are therefore of normal height in the first year, unusually tall between the 3rd and 10th years, and unusually short after the 13th year. The height of adult untreated patients is usually between 135 and 155 cm, and they are usually disproportioned (Fig. 34). Correctly treated patients are usually of normal height and their bone maturation (Fig. 35) is also normal.

Shortly after acceleration of growth and bone maturation become recognizable, the *secondary sexual characteristics* develop in untreated patients. Pubic hair appears between the 2nd and 5th year and axillary hair and gradually increasing body hair between the 4th and 7th years. The voice breaks at about the age of 10, when pubic and body hair become more masculine in appearance and facial hair increases (Figs. 32 and 33). Baldness may occur in the adult woman (Fig. 33).

Standstill of gonadal development contrasts with the premature appearance of the secondary sex characteristics. This developmental failure can be interpreted as hypogonadotropic hypogonadism since secretion of the pituitary gonadotropins is inhibited by the androgens (p. 452). In the girl, this causes failure of breast development and primary amenorrhea, and in the boy the testes remain strikingly small, contrasting with the marked development of the penis. Occasionally, however, normal testicular growth is observed, or the testis shows tumor-like enlargement. Biopsy may reveal hyperplastic adrenocortical tissue situated intratesticularly in these cases (HEDINGER, 1955; PIYARATN, 1957; EARLL, 1969). Boys with normal spermato-

Note the difference between the virilized untreated patients and the completely female development in body build and breast formation of the treated girl. (PRADER, 1956)

Fig. 35. Untreated 27-year-old woman, 145 cm tall, with congenital adrenogenital syndrome due to a 21-hydroxylase deficiency

genesis and girls with some slight development of the breasts and sporadic genital bleeding have also exceptionally been observed.

Thus, the premature physical development in untreated patients is not caused by true precocious puberty but rather by *precocious pseudopuberty* (see Chapter XIX). Since the precocity is of a masculine type in both sexes, it is described as isosexual in the boy and heterosexual in the girl. Normal gonadal development and normal spontaneous puberty are possible with treatment (Figs. 33 and 34).

Whereas the acceleration in growth and premature appearance of the male secondary sexual characteristics become obvious early in untreated cases, the *male stature* and *increased muscular development* usually appear later on and are more conspicuous in girls. The strong skeletal structure, wide shoulders, rather narrow hips and strong athletic musculature are particularly striking. The adult female patient looks like a small, thick-set but very strong man. This impression is further accentuated by the voice, facial features, growth of beard and baldness which occasionally arise (Fig. 35). The *skin* is not only more hairy but also thicker and coarser than that of a healthy woman. Acne occasionally occurs but is usually not as severe as in some healthy subjects during puberty. Brownish spots or a diffuse Addison-like pigmentation (see p. 316f.) are seen on the skin and less frequently on the mucosa in a few untreated cases.

In contrast to somatic development, intellectual, *psychic and psychosexual development* is not usually accelerated in untreated patients. The psychological picture is nonspecific and fits in with the general patterns of BLEULER's endocrine psychosyndrome.

The physical *efficiency* is usually not impaired. Most patients survive illnesses and surgery without complications. The *life expectancy* is hardly reduced. However, there are frequent reports of patients dying suddenly in a state of shock during mild infectious diseases such as measles or following an operation. Death in these cases is due to the inability to react to stress with increased glucocorticoid production.

The *steroid findings* can be deduced from Fig. 27. Increased amounts of steroids not hydroxylated in position 21 and their catabolites are found in the plasma and urine. Levels of 21-hydroxylated steroids are lowered. The total 17-ketosteroids increase steadily from an approximate mean value of 2–3 mg/24 h in the young infant up to a mean of about 40–50 mg/24 h or more at the age of about 15 in untreated patients. There are wide individual variations, and values can rise even higher in conditions of stress. Fractionation of the 17-ketosteroids shows that it is predominantly catabolites of androstenedione and dehydroepiandrosterone, namely androsterone and etiocholanolone which are excreted in the urine. Since 11β-hydroxylation is uninhibited in 21-hydroxylase deficiency, increased amounts of the corresponding 11-hydroxy-, and 11-keto-17 ketosteroids (11-hydroxyandrosterone, 11-hydroxy-etiocholanolone, 11-ketoandrosterone and 11-keto-etiocholanolone) are also excreted. 11-Hydroxylation of these 17-ketosteroids competes with 11-hydroxylation of the small amounts of substance S which are formed in spite of the deficiency (see Fig. 27). This leads to a further reduction in cortisol synthesis. Therefore, more tetrahydro-S (catabolite of S, see Fig. 27) is excreted in patients with 21-hydroxylase deficiency than in normal subjects, although significantly less than in patients with 11β-hydroxylase deficiency (see below). Excretion of dehydroepiandrosterone (principally as sulfate) is also elevated, but to a lesser degree. *Testosterone* arising in the adrenal cortex and periphery from androstendione and dehydroepiandrosterone, is also found to be raised in the plasma and urine (as glucuronide). This fact must be held primarily responsible for the clinical symptoms of the virilization (DEGENHART, 1965). Further,

estrogens (estrone and estradiol) arise from androstenedione or testosterone, and are also excreted in increased amounts (BONATI, 1968). Estriol has an exceptional position among the estrogens, since it is a 16-hydroxylated compound and develops mainly from 16α-hydroxy-pregnenolone.

Although the clinical symptoms are predominantly due to the androgens, the increase in progesterone and 17α-hydroxyprogesterone and their catabolites (steroids just "before" the block) is even more impressive. The plasma progesterone level is 6 to 10 times higher in children with 21-hydroxylase defect than in adult men, and plasma 17α-hydroxy-progesterone 50–200 times as high (STROTT, 1969). *Pregnanetriol* mainly arises directly from 17α-hydroxy-progesterone (HALPERIN, 1967). Its rate of secretion can be increased almost 100-fold (240–280 mg/24 h, normal: 3 mg/24 h) in cases of 21-hydroxylase deficiency. *Pregnanetriolone* differs from pregnanetriol in having an additional keto-group in position 11, and is not normally found in urine even after ACTH stimulation (FINKELSTEIN, 1962). Several mg are, however, excreted daily. In most cases, more pregnanetriol than pregnanetriolone is excreted, but there are cases where the situation is reversed, especially in young infants. This appears to be connected with a predisposition to 11-hydroxylation in early life. Other steroids found to be elevated are: Δ5-pregnenediol (from pregnenolone, see Fig. 27), Δ5-pregnenetriol (from 17α-hydroxy-pregnenolone) and 16α-hydroxy-pregnenolone (from pregnenolone) which can be further metabolized into estriol (REYNOLDS, 1965; JANOSKI, 1969). Reduction in the excretion of 17-hydroxycorticosteroids (Porter-Silber chromogens) can reflect the fall in the rate of cortisol production. However, cortisol production is frequently normal but does not rise or rises only slightly in response to ACTH. Individual cortisol metabolites and plasma 11-hydroxy-corticoids behave in a similar manner. However, it must be remembered at this point that increased amounts of 11-hydroxyandrostenedione and 21-desoxycortisol (which are measured at the same time by the nonspecific fluorometric method; see p. 380) can simulate a normal or even a raised cortisol concentration, while cortisol itself is in fact reduced. *Aldosterone* secretion is normal or even raised in patients with 21-hydroxylase deficiency without salt loss (PRADER, 1955; BLIZZARD, 1959; BONGIOVANNI 1968; GODARD, 1968). BARTTER (1968) has concluded from this that 21-hydroxylation is intact in compounds not hydroxylated in position 17 (see Fig. 27), thus permitting normal aldosterone production. If this is so it must be assumed that two different 21-hydroxylases exist in the human adrenal cortex (DEGENHART, 1965). The increased aldosterone secretion would then have to be interpreted as compensation for the increased production of natriuretic steroids in patients without the salt-losing syndrome (see below).

The typical steroid changes are sometimes only found after stimulation with ACTH in newborns and young infants with 21-hydroxylase deficiency (p. 372).

The most important steroid findings in 21-hydroxylase deficiency are summarized in Table 17.

Azoospermia is found in the untreated male, and testicular biopsy reveals immature tubules and only immature Leydig cells or none at all. These findings may be due to hypogonadotropic hypogonadism, but they are not constant and cases with normal spermiogenesis have been reported. Surprisingly, the vaginal smear of an untreated female shows no signs of estrogen activity, although chemical methods of measuring urinary estrogens show that elevated amounts are excreted in both sexes.

9) 21-Hydroxylase Deficiency with Salt Loss

This may be due to a deficiency of the same enzyme as simple 21-hydroxylase deficiency in a more pronounced form. It is, however, possible that 21-hydroxylase, which is responsible for the conversion of progesterone into DOC (see Fig. 27), is intact in the simple form and absent in the form with the salt-losing syndrome (see above).

A clinically manifest *electrolyte disturbance* similar to that in Addison's disease is found in some patients with 21-hydroxylase deficiency. This is characterized particularly by renal loss of sodium. It is common during infancy, less frequent during late childhood, and rare during adulthood. This age distribution may very well be due to the fact that patients instinctively learn to eat more salt. In addition, however, there is probably a tendency for the salt-losing syndrome to improve with increasing age. It is doubtful whether there are any geographic differences in the incidence of the salt-losing syndrome. HIRSCHFELD (1969) found an accumulation in Alaskan Eskimoes, MARKS (1969) found more cases than CHILDS (1956) in Maryland. It must be remembered, however, that more recent work cannot be compared to earlier statistics without certain reservations. More sophisticated methods of diagnosis also detect more cases of the salt-losing syndrome.

The symptoms of salt loss usually arise during the first few days or weeks of life. They usually

[a] Often increased due to non-specific cross-reaction with 21-deoxycortisol and 11-hydroxyandrostenedione.
[b] Often slightly increased (p. 369).

arise gradually but occasionally develop suddenly. The most common symptoms are anorexia, lethargy, inadequate weight gain, vomiting and frequent mild diarrhea. Vomiting is almost always present, usually occurring in a single stream, sometimes spastic in nature with visible gastric peristalsis. These symptoms of chronic salt loss are often followed by true crises, usually in association with an infection (stress). Without correct treatment, death may result. These crises are characterized by acute loss of weight, severe dehydration, and shock. If these patients survive, whether spontaneously or as a result of treatment, they often demonstrate a pronounced craving for salt towards the end of the first year or often even before. The symptoms disappear completely in some patients after 1–3 years, but the salt-losing syndrome can become manifest again at any time during intercurrent illnesses in early infancy.

Apart from symptoms due to salt loss, all other symptoms of 21-hydroxylase deficiency without salt loss can also occur in these patients. The only difference is that growth and bone development are retarded during the first year or two years due to the severely impaired electrolyte metabolism, and the characteristic acceleration does not occur until later.

Pathogenesis of the salt-losing syndrome can be explained in part by a relative aldosterone deficiency. In patients with severe salt loss, aldosterone and its metabolites are excreted in reduced amounts and the aldosterone production rate is decreased (BRYAN, 1965). Limitation of the sodium intake almost always induces a poor aldosterone increment in the salt-losing syndrome (BONGIOVANNI, 1967). Thus, apparently due to the enzyme deficiency, not enough aldosterone can be synthesized. This interpretation is also supported by the elevated plasma renin activity (IMAI, 1968) and the hypertrophic juxtaglomerular cells in patients with the salt-losing syndrome. The fact that infections and ACTH promote sodium loss and glucocorticoids inhibit it suggest that there are other pathogenic factors. In fact, there is evidence that progesterone and 17α-hydroxyprogesterone as well as other unknown steroids exert an antagonistic effect on the action of mineralocorticoids on the renal tubules; in other words, these steroids have a natriuretic action. This would explain why a compensatory increase in aldosterone excretion is sometimes found in patients with simple 21-hydroxylase deficiency without the salt-losing syndrome (see p. 369). It has recently been shown that 16α-hydroxy-progesterone has a natriuretic action. Since 16-hydroxylated compounds are found mainly in infants, this may explain the tendency towards spontaneous regression of the salt-losing syndrome with increasing age (JACOBS, 1969).

ι) 11-Hydroxylase Deficiency

There are few cases of congenital hyperplasia of the adrenal cortex in which an increase in blood pressure is the dominant clinical feature arising in association with other symptoms due to androgens. These symptoms may be as severe as or less pronounced than in cases with 21-hydroxylase deficiency. A salt-losing syndrome never arises. As in the other forms, the disorder is uniformly present or uniformly absent in siblings of the patient affected. The hypertension, like the salt-losing syndrome, is worsened by ACTH and improved by glucocorticoids. These cases are due to deficiency of 11β-hydroxylase, which converts substance S into cortisol and DOC into substance B (corticosterone) (Fig. 27). The steroid findings are therefore different from those found with 21-hydroxylase deficiency: androgens are similarly raised but to a lesser extent. On the other hand, 11-hydroxy-17 ketosteroids are absent or their excretion is greatly reduced. The excretion of *pregnanetriol* is also raised in this condition, but not as strikingly as in 21-hydroxylase deficiency. *Pregnanetriolone* is absent or present only in small amounts. In contrast, more substance S and DOC are produced and this is reflected in a greatly increased excretion of their metabolites tetrahydro-S and tetrahydro-DOC. Accumulation of the mineralocorticoid DOC (which is, however, less active than aldosterone) explains the hypertension and absence of a salt-wasting syndrome. Cases without hypertension have, however, been reported, as have cases with hypertension but no increase in tetrahydro-DOC excretion. Nevertheless, it must be remembered that in young infants, S and DOC are not only metabolized into the corresponding tetrahydro compounds but can also be excreted directly. Thus, low levels of tetrahydro-S and DOC in the urine of a baby in the first month of life does not exclude the diagnosis of an 11β-hydroxylase defect. The concentrations of plasma 11-hydroxycorticoids and urinary 17-hydroxycorticoids are greatly increased provided they are measured by nonspecific methods (p. 380). This increase is, however, not due to a rise in cortisol but to substance S. The rate of secretion of aldosterone is reduced (KOWARSKI, 1968). Plasma renin is also lowered (probably suppressed by DOC; IMAI, 1968).

Recently, a case of this deficiency has been described where only the 11β-hydroxylation of S to cortisol, but not that of DOC to corticosterone was impaired (ZACHMANN, 1971). This suggests that two 11β-hydroxylating systems exist in the human adrenal.

Metyrapone represents a model of 11β-hydroxylase deficiency. This substance, which is used in examination of the ACTH reserves of the anterior pituitary lobe (see p. 387), temporarily blocks 11β-hydroxylase.

κ) 3β-Hydroxysteroid-Dehydrogenase Deficiency

This form of congenital hyperplasia of the adrenal cortex differs from the forms described above in that there is only a slight production of biologically active androgens, so that virilization may be absent or only mild. In the rare cases of deficiency of 3β-hydroxysteroid-dehydrogenase, steroid synthesis is blocked at the stage of the Δ5 compounds (pregnenolone, 17-hydroxypregnenolone and dehydroepiandrosterone; see Fig. 27) (BONGIOVANNI, 1961, 1962). Thus dehydroepiandrosterone is the only androgen produced in excess. All the other steroids excreted in increased amounts are also Δ5 compounds, namely Δ5-pregnenediol (from pregnenolone), Δ5-pregnenetriol (from 17α-hydroxypregnenolone) and, depending on age, also 16α-hydroxy-pregnenolone. Since 21-hydroxylase is intact in these cases, Δ5-pregnenetriol, for example, can still be hydroxylated in position 21, resulting in Δ5-pregnenetetrol, a substance which BONGIOVANNI (1962) has demonstrated in a few cases. Pregnanetriol is absent or, with partial enzyme deficiencies, reduced or normal, but is not increased. Pregnanetriolone, testosterone and tetrahydro-S are absent. Since dehydroepiandrosterone is not very active biologically and cannot be converted into androstendione or testosterone (Fig. 27), only mild virilization arises in this syndrome if any at all. Male patients have incompletely masculinized genitalia (various degrees of hypospadia or phenotypic female genitalia). This can be explained by the absence of 3β-dehydrogenase in the testes as well and by their failure to form the testosterone necessary for normal development of the male genitalia during organogenesis. In contrast to the situation in 21- and 11β-hydroxylase deficiencies, the genitalia in female patients are normal or virilization is only slight, much less pronounced than in the other types. In most of the known cases there is also a severe salt-losing syndrome (p. 369f.). 3β-Dehydrogenase deficiency usually appears to be more complete than the other enzyme defects described. In the majority of cases, no cortisol metabolites at all are found in the urine. This would explain why patients with this syndrome almost always suffer from Addison-like crises and why most of them die in the first months of life despite adequate treatment. *Lipoid hyper-*

plasia of the adrenals (20, 22 desmolase defect, Fig. 27) is described in another section (p. 323).

17-Hydroxylase deficiency (Fig. 27) is connected with overproduction of corticosterone and desoxycorticosterone and is therefore also described in another section (p. 339).

λ) Diagnosis and Differential Diagnosis

Diagnosis of the different forms of the congenital adrenogenital syndrome is based on the family and personal histories, typical clinical features and characteristic steroid findings.

There is often a family history of sisters with intersexual genitalia or prematurely developed brothers. The differential diagnosis includes male pseudohermaphroditism in girls (p. 724) and true precocious puberty in boys (p. 1046).

In taking the *personal case history*, it is important to establish in girls whether the ambiguous genitalia were present at birth or whether they became obvious only later. In boys, the time at which penis enlargement was first noticed must be determined.

Clinical examination reveals the typical findings described above. Obesity and other symptoms of CUSHING'S disease do not belong to the classic picture but rather suggest a tumor of the adrenal cortex. In addition to the steroid findings, the genital findings and the degree of development of the secondary sexual characteristics are decisive for the diagnosis, although the possibilities in the differential diagnosis vary with the sex. A raised specific steroid excretion is characteristic of each type of enzyme defect. This steroid excretion can be normalized by glucocorticoids. This contrasts with the situation in the adrenogenital syndrome due to a tumor of the adrenal cortex, where the greatly increased excretion of 17-ketosteroids (dehydroepiandrosterone in particular) is unaffected by glucocorticoids (e.g. dexamethasone, see p. 389).

In *female patients* with a 21- or 11β-hydroxylase defect, the overproduction of androgen can be recognized immediately, suggesting a disorder in the adrenals or ovaries. The genital changes with the typical urogenital sinus permit the exclusion of "premature pubarche" (p. 1040) and prove the congenital nature of the disorder. The other types of intersexuality to be considered can be excluded during the first years of life by demonstration of chromosomal female sex and the presence of increased amounts of androgens. A case with hypertrophy of the clitoris without a urogenital sinus can be differentiated from androgenic tumors of the adrenal cortex and ovary by the steroid findings. A normal female fetus has been exposed to androgens. This occurs when the mother receives gestagens containing androgens or steroids which can be metabolized into androgens during pregnancy. In rare cases, virilization of the fetus (or even complete masculinization) has been observed due to an ovarian tumor (arrhenoblastoma) or a virilizing adrenocortical adenoma in the mother. Steroid findings, however, are normal in the children in all these cases and virilization does not progress after birth. Finally, forms of female pseudohermaphroditism associated with malformations (particularly of the kidneys) and probably not due to hormonal factors must also be considered in the differential diagnosis.

Isosexual development in the *male sex* (with the exception of 3β-hydroxysteroid-dehydrogenase deficiency) makes diagnosis very difficult. In the newborn, the penis is often of normal size or only slightly enlarged and the scrotum is sometimes only slightly pigmented. The testes are usually small in comparison to the general somatic development. They are seldom of normal size and are sometimes enlarged into tumor masses (p. 366). In true precocious puberty, the tests are usually of normal size. In contrast to 21- and 11β-hydroxylase deficiencies, the biopsy in a case of precocious puberty reveals Leydig cells and spermatogenesis, and the total 17-ketosteroids are not raised or only slightly. The same is true of "premature adrenarche" (p. 1040), where acceleration of somatic development is also absent. In cases with tumor-like enlargement of the testes, it is often difficult to differentiate congenital adrenocortical hyperplasia from a Leydig cell tumor, on the basis of a testicular biopsy. Differentiation is, however, possible on the basis of these findings: the tumor can only decrease in size and steroid excretion can only be normalized in a case of adrenocortical hyperplasia treated with glucocorticoids.

The symptoms are usually insignificant in the *adult man*. Mild forms of 21-hydroxylase deficiency can only be detected by taking an exact case history and performing routine steroid estimations in every case where the testes are unusually small, in cases with testicular tumors, sterility, and azoospermia, and in cases of small stature with full development of the secondary sexual characteristics.

An early diagnosis is of utmost prognostic importance, since treatment started early enough can bring about absolutely normal physical development and prevent salt-losing crises. Characteristic steroid findings may be absent in the young baby. If there is clinical suspicion of an adrenogenital syndrome or the total 17-ketosteroids are even only slightly elevated,

a provocation test with ACTH should be performed. As a rule, 1 mg/m^2 body surface of a synthetic depot ACTH is sufficient to produce the typical steroid findings. The 24-hour urine is collected the day before the test, the day the injection is given, and the following day. In the presence of 21-hydroxylase deficiency with the salt-losing syndrome or 3β-hydroxysteroid-dehydrogenase deficiency, this test is dangerous, since it may induce a potentially fatal salt-losing crisis. Glucocorticoids, mineralocorticoids and saline should be kept ready for intravenous administration.

When a congenital adrenogenital syndrome is suspected (affection of siblings) it may be possible to make the diagnosis *in utero* (CATHRO, 1969). The *estriol* excretion is raised in the urine of pregnant women from the 20th week of pregnancy when the fetus has 21-hydroxylase deficiency. This phenomenon is due to the fact that the excessive amount, of 16α-hydroxypregnenolone (p. 369) produced by the fetus are metabolized by the mother and the placenta into estriol. Theoretically, an even higher estriol excretion is to be expected in cases with a 3β-hydroxysteroid-dehydrogenase deficiency.

The differential diagnosis of *21-hydroxylase deficiency with the salt-losing syndrome* is particularly important in newborns. The free interval during the first few days or weeks, the weight loss, vomiting and the often visible gastric peristalsis usually suggest the much more common condition, pyloric stenosis. This diagnosis is contradicted by the rapid emptying of the stomach in the radiological investigations, frequent mild attacks of diarrhea, and the electrolyte findings. Occasionally the syndrome can also be mistaken for infectious gastroenteritis. A history stating that siblings were of indeterminate sex as babies, and that they suffered from pyloric stenosis or diarrhea before death occurred is very suggestive. The diagnosis is, however, confirmed by the steroid findings and electrolyte investigations: serum sodium and potassium are reduced in pyloric stenosis, whereas hyponatremia and hyperkalemia are found in 21-hydroxylase deficiency.

μ) Treatment

The only satisfactory basic treatment of all forms of congenital hyperplasia of the adrenal cortex is life-long *treatment with cortisol* or some other glucocorticoid. Cortisol acts in two ways: it inhibits the increased ACTH secretion, causing a reduction of the steroids accumulated "before" the enzyme defect, and it compensates for the inadequate endogenous production of cortisol. Treatment is thus both inhibitory and substitutive. It is also assumed that the treatment removes any possible inhibition of gonadotropin secretion. In any case, normal gonadal maturation is possible with adequate treatment.

In principle, the *lowest doses* resulting in the disappearance of symptoms should be chosen. This is important for the following reasons: Cushing's syndrome arises only after massive over-dosage, but a dose which is even very slightly too high and causes no other external clinical signs can lead to definite retardation of growth (BERGSTRAND, 1966; RAPPAPORT, 1968). This inhibitory action of cortisol on growth has also been observed in other conditions (e.g. asthmatics treated with steroids, or patients with rheumatoid arthritis or in pituitary dwarfism, see p. 98). This effect is due primarily on a peripheral antagonism between cortisol and growth hormone, but also to inhibition of the release of growth hormone from the anterior pituitary. On the other hand it has to be considered that patients with congenital hyperplasia of the adrenal cortex cannot react to stress with an increase in endogenous cortisol production, or only inadequately. For this reason the dose sometimes has to be massively increased during periods of stress. The treatment, although simple in principle, places considerable demands on the physician, who should keep the dose as low possible while recognizing the requirements for increased doses of cortisol during periods of stress.

Since the active physiological steroid absent is cortisol and treatment is partly substitutive, cortisol is generally chosen in preference to other glucocorticoids. Prednisone, prednisolone and the long-acting methyl prednisolone are sometimes used. Even in small doses, however, these compounds seem to exert an inhibitory effect on growth. It is best to refrain from using other synthetic glucocorticoids (especially the fluoridized), since they offer no advantages and sometimes produce unpleasant side effects.

The rate of production of cortisol in normal children is about 12 ± 3 mg/m^2/24 h in both sexes, and the basic dose for long-term treatment should correspond roughly to this figure. An intramuscular dose of about 12 mg/m^2/24 h is therefore sufficient. With oral treatment it must be remembered that not all the cortisol taken is completely absorbed. If the dose is regulated according to the normal rate of production, the oral dose of cortisol must be somewhat higher (approximately 15–25 mg/m^2/24 h) (MIGEON, 1968). This dose is lower than that recommended so far by most authors. They suggest a dose of about 35 mg/m^2/24 h. When prednisone is used, a quarter of this dose is

sufficient. Division of the daily dose over the day also seems to be of importance, but this point has not been thoroughly investigated. Theoretically, an effort should be made to imitate the physiological daily variations in the plasma level of cortisol (p. 300). It would therefore be better not to divide the recommended dose equally throughout the day, but to give three-quarters of the daily dose early in the morning and the remaining quarter in the afternoon.

The doses given are for long-term therapy. Initially, more (about twice as much) must be given for a few days or weeks.

It seems to be important to keep the dosage low during the period of growth, and particularly during the first two years of life. This is essential since only the optimal dose and early onset of treatment can ensure completely normal physical development. For this reason, *regular follow-up* examinations with monitoring of steroid excretion and any necessary correction of the dose of cortisol are important. Total 17-ketosteroids should be measured every few days in the first few weeks and later at intervals of a few weeks. The other steroids (particularly pregnanetriol and pregnanetriolone (in cases of 21-hydroxylase deficiency) should be checked every few months. It must be kept in mind during this procedure that not all steroid findings become normalized even with adequate treatment: in 21-hydroxylase deficiency, the total 17-ketosteroids and their fractions return completely to within normal ranges, whereas urinary pregnanetriol usually remains slightly elevated and pregnanetriolone continues to be demonstrable in the urine. A minimal excretion of pregnanetriolone is if anything desirable, as an indicator that the cortisol dose is not too high.

In addition to steroid excretion, body weight, blood pressure, growth, bone age and the secondary sex characteristics must be checked regularly, and menstruation should be exactly charted.

Once treatment has been stabilized, the dose can usually remain the same for years in adult patients. During the phase of growth, however, the dose must be adjusted to the increasing body surface.

Therapeutic success varies with the age and severity of symptoms at the onset of treatment and with the type of enzyme deficiency. Completely normal development can be attained in the *baby* with 21-hydroxylase deficiency (Fig. 33). In the *infant* and *school-age child*, acceleration of growth and bone development already in progress can be brought to a stop and physical development can be at least partly normalized. Masculine secondary sexual characteristics remain stationary until bone age reaches normal pubertal age (in girls at about 11, in boys at 13 years, p. 1024). At this point, cortisol treatment results in gonadal maturation and normal development of the isosexual secondary sexual characteristics before normal pubertal age is reached. In this way, breast development and menarche can take place in girls even before the 7th year, and testicular development and spermatogenesis in boys. Tumor-like enlargements of the testes can be reduced in size soon after the onset of treatment regardless of the age of the patient. This is due to the action of cortisol, which causes atrophy of the intratesticular adrenocortical tissue.

Without treatment the epiphyses fuse after the *10th year* of life, so that it is then impossible to influence growth, and the masculine stature, enlargement of the clitoris and the masculine voice in female patients can be affected only to a slight degree. Gonadal maturation and regression of body hair can still be expected in female patients, however. The breasts develop within a few months and menarche occurs. Facial and body hair usually regress only several months later. In male patients, the external characteristics remain unchanged apart from maturation of the testes.

Menstruation induced by treatment is more or less regular and usually due to a true ovulatory cycle. Frequency and duration of the bleeding are often the best indications of correct cortisol dosage. Spermatogenesis and pregnancy confirm the *fertility* arising in response to treatment.

During long-term cortisol treatment, *ACTH* stimulation and *intercurrent infections* induce a rise in steroid excretion in the urine. Thus, the adrenals remain capable of reacting in spite of partial atrophy, even if not to the same extent as before treatment. Since regular cortisol intake cannot cover a sudden increase in glucocorticoid requirements, it is advisable to increase the cortisol dose temporarily during any serious intercurrent illness, and particularly for any surgical intervention. There is now more reluctance to increase the dose, since mild infections with slightly raised temperature do not necessarily require an increase in dosage. The dose must be temporarily doubled in severe stress. The dose given should only be tripled in cases of severe infection and for operations.

Discontinuation of the long-term treatment is hardly ever indicated. If it were discontinued, temporary adrenocortical insufficiency and a gradual return of symptoms would be expected.

Malformation of the external genitalia is the only symptom which can no longer be

influenced by cortisol at any age. At the most, cortisol can inhibit further growth of the clitoris in the small girl. *Surgical correction of the external female genitalia* is therefore always indicated except in cases where the changes are minimal. Whenever possible, the procedure should be undertaken during babyhood or early infancy, before the child becomes aware of her genital anomalies and this has an untoward psychological effect. The operation should only be carried out under increased doses of cortisol and, in patients with the salt-losing syndrome, only when the serum electrolytes are normal. The clitoris can be excised or merely amputated. The latter procedure is adequate in most cases. An incision can be made into the superficial urogenital sinus, and the sinus can be exposed as far as the junction of urethra and vagina. A thorough genital check-up is necessary shortly before puberty so that a too-narrow vagina can be surgically corrected.

Success with the treatment mentioned is especially satisfactory in 21- and 11β-hydroxylase deficiency. Stabilization is more difficult in 3β-hydroxysteroid-dehydrogenase deficiency and crises due to salt loss can also arise frequently even during treatment.

There are basically two possible *treatments for the salt-losing syndrome*. 1. Covering sodium loss by increased sodium intake. 2. Administration of sodium-retaining steroids. In addition, cortisol may also inhibit the production of natriuretic steroids. As soon as the diagnosis has been made, the first and most important measure is the immediate administration of *salt and fluid* in adequate amounts. If the condition of the baby is alarming, 500–800 ml physiological saline and 250–400 ml glucose solution are given intravenously in the first few days. As soon as the baby can drink, this form of treatment is replaced by adding about 3–5 g of salt to the usual daily food. During the subsequent days and weeks, the maintenance dose, which is lower than the initial dose, must be ascertained individually in each case on the basis of serum electrolytes and weight gain. The maintenance dose depends on the patient and lies between 1 and 6 g of salt daily. Children usually respond excellently to this therapy, even though steroid excretion remains elevated and serum potassium is often not normalized.

Administration of desoxycorticosterone acetate (DOCA, in a daily dose of 2–6 mg in oily solution i.m.) or aldosterone (20–300 γ daily) is also indicated during salt-losing crises and in severe cases. Instead of these two compounds, fluorohydrocortisone can be given (dose adjusted to individual, approximately 50–200 γ/m^2 daily). The salt augmentation decreases with this procedure. If salt administration is adequate and cortisol treatment is correct, long-term treatment with mineralocorticoids is hardly ever necessary before the 2nd or 3rd year of life. Long-term treatment with DOC may be necessary in the first years of life. Microcrystalline injections are then given every 3–4 weeks.

In addition to the treatment described above, cortisol treatment based on the principles given is also instituted in patients with the salt-losing syndrome. Salt requirements decline as a result of treatment with cortisol, due either to the reduction of natriuretic steroids or to the sodium-retaining effect of cortisol itself (though this is slight).

As has already been mentioned, salt and fluid requirements increase during *intercurrent infections*, even during common colds. Experienced mothers give their children salted tea during these periods, and the children usually accept it readily.

After 1 to 3 years, a cautious attempt can be made to reduce the dose of mineralocorticoids and the daily salt supplement. Ultimately, treatment can be discontinued. More intensive treatment of longer duration is usually required in cases of salt-losing syndrome in 3β-hydroxysteroid-dehydrogenase deficiency than in cases with 21-hydroxylase deficiency.

Hypertension in patients with 11β-hydroxylase deficiency requires no special treatment as a rule since it disappears with adequate cortisol treatment. It may be necessary to give an antihypertensive drug as well at the onset of treatment in severe cases.

c) Acquired Adrenogenital Syndrome during Infancy

The majority of cases of the adrenogenital syndrome during infancy are due to congenital hyperplasia of the adrenal cortex (p. 360) with a deficiency of 21- or 11β-hydroxylase. It is debatable whether congenital hyperplasia of the adrenal cortex can be latent, causing no symptoms at first and become apparent later in infancy as an acquired adrenogenital syndrome. Some authors support this view (Brooks, 1960; Mahesh, 1968). In general, however, the acquired adrenogenital syndrome is due to an *androgen-producing adrenocortical tumor*. This form of the adrenogenital syndrome is uncommon, but nevertheless more common in children than in adults.

The macroscopic and microscopic appearance of androgen-producing adrenocortical tumors is indistinguishable from that of tumors causing Cushing's syndrome, feminization or

no endocrine effects. Conclusions about the endocrine activity can, however, be drawn from the secondary symptoms, from the behavior of the cortex of the other adrenal gland and from the steroid findings. Thus, cortical atrophy of the other adrenal occurs considerably less frequently in cases of the adrenogenital syndrome due to an adrenocortical tumor than in Cushing's syndrome. The tumors appear to be morphologically identical. The data on cortical tumors in the section on Cushing's syndrome (p. 330 and 357) is thus also applicable to androgen-active tumors. Carcinomas are more common than adenomas in this group, but they too are difficult to differentiate and occasionally they can only be definitely confirmed by the formation of metastases.

Broadly speaking, the androgenic symptoms are similar to those found in congenital hyperplasia of the adrenal cortex with 21- or 11β-hydroxylase deficiency (p. 371). It is of therapeutic importance to differentiate between these forms and an adrenogenital syndrome due to adrenocortical tumors. The former group is treated with glucocorticoids, whereas surgery is necessary when tumors are present. Differentiation on purely clinical grounds is often difficult. The same disorder in siblings and enlargement of the clitoris or penis at birth are only possible in congenital hyperplasia. In tumor cases the female genital findings are normal except for enlargement of the clitoris. In congenital hyperplasia a urogenital sinus is formed except in cases of 3β-hydroxysteroid-dehydrogenase deficiency and mild 21-hydroxylase deficiency. The salt-losing syndrome only occurs in certain forms of congenital hyperplasia (p. 369). In contrast to congenital hyperplasia, where glucocorticoid synthesis is reduced, *the adrenogenital syndrome is often associated with Cushing's syndrome* in cases with tumors.

Detailed steroid analysis is important for the differentiation. Estimation of the total 17-ketosteroids does not allow any distinction. Measurement of the pregnane derivatives and fractionation of the 17-ketosteroids (p. 370) are useful in the differentiation. Characteristic steroid findings (Table 17, pp. 368 and 370) are detected in the different forms of congenital hyperplasia. In cases of adrenocortical tumors resulting in acquired adrenogenital syndrome, pregnanetriol is almost never excreted in increased amounts and pregnanetriolone (p. 369) does not appear in the urine. On the other hand, the major part (about 90%) of the 17-ketosteroids excreted consists of dehydroepiandrosterone, which normally accounts for only a small part of the total 17-ketosteroids. Thus, the steroid findings in a tumor case are similar to those in congenital hyperplasia with 3β-hydroxysteroid dehydrogenase deficiency (p. 371). Cortisol or another glucocorticoid (dexamethasone, p. 389) promptly causes a fall in the elevated amounts of steroids excreted in congenital hyperplasia, whereas no effect or merely a slight one is produced in tumor cases, since hormone production is autonomous and largely independent of ACTH. As in Cushing's syndrome, pyelography, retropneumoperitoneum with tomography and oblique pictures, and possibly the aortography and renography can be employed for direct demonstration and localization of the tumor.

Surgical removal of the adrenocortical tumor is the only possible therapeutic measure. Since androgens do not inhibit ACTH, the adrenal cortex theoretically does not undergo atrophy in a case with an androgen-producing tumor. This means there should be no fear of a postoperative adrenocortical insufficiency such as is encountered in cases of adrenocortical tumors with Cushing's syndrome. Unfortunately, in practice this is not always the case since tumors often produce not only androgens but also glucocorticoids. Thus, the same measures as in Cushing's syndrome are instituted for the removal of any hormone-active adrenocortical tumor as a precaution (p. 330 and 357).

Results are excellent if no metastases are present and the tumor can be removed easily. However, metastases occasionally arise 2–3 years later. The postoperative course of somatic development is normal in these children, but prematurely developed secondary sexual characteristics usually only partly regress. If bone development is greatly advanced, small stature in adulthood is inevitable. If bone development before the operation corresponds to normal pubertal age, sudden gonadal maturation can be expected after the operation, even if the chronological age does not yet correspond to normal pubertal age. Cortisol treatment has the same effect in cases of congenital hyperplasia.

d) Acquired Adrenogenital Syndrome in the Adult

This syndrome is due to acquired hyperplasia of the adrenal cortex or to an adrenocortical tumor. It occurs predominantly in women. Virilization is as the dominant clinical feature. In contrast to congenital hyperplasia of the adrenal cortex, the genitalia, with the exception of the hypertrophic clitoris, are normally developed. Body configuration is feminine and breast development is normal. Pubic, body and facial hair are masculine in type. Secondary amenorrhea arises only if virilization advances. Ovulatory cycles and fertility can, however, also remain

intact. The total 17-ketosteroids in the urine are increased in cases of acquired adrenocortical hyperplasia and tumors. As in the acquired adrenogenital syndrome in infancy, dehydroepiandrosterone is the predominant steroid in the urine. Testosterone concentrations in the plasma and urine are also elevated. Pregnanetriol excretion is normal and pregnanetriolone cannot be detected. This excludes congenital hyperplasia of the adrenal cortex with 21-hydroxylase deficiency (p. 369). The differential diagnosis includes the different forms of hirsutism (p. 377) (although these are not usually accompanied by hypertrophy of the clitoris), ovarian tumors (arrhenoblastomas, p. 638) and the Stein-Leventhal syndrome (p. 609). In virilizing ovarian tumors, testosterone production is also increased, but excretion of 17-ketosteroids is normal or only slightly raised. If testosterone and dehydroepiandrosterone are elevated in the plasma or urine an adrenal tumor must be sought first by the methods described (p. 376). If testosterone alone is raised an ovarian tumor is more likely. In some circumstances, a laparoscopy or laparotomy to inspect the ovaries or surgical exploration of the adrenals may be necessary before diagnosis is possible. Unnecessary laparotomies in cases of idiopathic hirsutism must, however, be avoided.

If an adrenal tumor is found it must be removed surgically. The same precautions must be taken as for the removal of an adrenal tumor in Cushing's syndrome (p. 330 and 357).

Pathologic anatomy: these tumors are more commonly carcinomas than adenomas. Morphological details and difficulties in histological differentiation between adenoma and carcinoma are described on p. 342.

Some cases are not true acquired adrenogenital syndromes but a mild form of congenital 21-hydroxylase deficiency. These cases are easily recognized from the steroid findings (pregnanetriol raised, pregnanetriolone present). Congenital 11β-hydroxylase deficiency can become manifest for the first time during adulthood (GABRILOVE, 1965). It becomes apparent in a much increased excretion of tetrahydro-S and tetrahydro-DOC. In addition, 17-hydroxycorticoids rise in the urine in response to ACTH in acquired hyperplasia or in tumor cases, whereas there is only a slight rise or none at all in congenital cases.

Substitution with glucocorticoids may be indicated after surgical removal.

e) Idiopathic Hirsutism

Hirsutism (p. 359) signifies an increase in sexual, body, and facial hair in women with no concomitant signs of virilization. There is no hypertrophy of the clitoris and the voice does not become deeper, or only to a slight extent. Some patients have menstrual disorders (oligomenorrhea, anovulatory cycles, secondary amenorrhea). Others menstruate normally and remain fertile.

Hirsutism in women is extremely common. Conditions to be excluded are: congenital hyperplasia of the adrenal cortex (p. 359), acquired adrenocortical hyperplasia or an adrenocortical tumor (p. 376), Stein-Leventhal syndrome and a virilizing ovarian tumor (p. 638). The case history, thorough gynecological examination, and steroid tests are useful in the investigation. If obesity is present as well, Cushing's syndrome must also be considered. Only when all these have been excluded can idiopathic hirsutism (i.e. caused by adrenal hyperactivity) be diagnosed.

Excretion of the 17-ketosteroids in the urine and the concentration of testosterone in the plasma are slightly raised in idiopathic hirsutism and in hirsutism due to ovarian production of androgens. Differentiation is often possible if urinary 17-ketosteroids and the plasma concentration of testosterone are examined after administration of ACTH (p. 385) and chorionic gonadotropin (during simultaneous treatment with dexamethasone (p. 389)). In idiopathic hirsutism, excretion of the 17-ketosteroids and the concentration of plasma testosterone increase more than is normal after ACTH. Dexamethasone has an inhibitory effect. Chorionic gonadotropin has only a slight effect or none at all. In contrast, in cases of hirsutism due to ovarian factors, urinary 17-ketosteroids and plasma testosterone rise most after chorionic gonadotropin, whereas ACTH and dexamethasone only have a weak effect.

Glucocorticoids often produce therapeutic success in idiopathic (adrenal) hirsutism. If, for example, cortisol is given in a dose which reduces urinary 17-ketosteroids to normal values (5–10 mg/24 h), menstruation is normalized and the hair gradually becomes less. Hirsutism due to androgens produced by the ovaries is not influenced by glucocorticoids but may decrease under estrogens and gestagens.

5. Adrenal Feminization

The term adrenogenital syndrome really includes all adrenal disorders causing overproduction of sexual hormones. It is customary, however, to use this term only in connection with the syndrome with overproduction of androgen, i.e. with virilization. Disorders with overproduction of estrogens are much more

uncommon and are described as adrenal feminization. The most common cause of this syndrome is a *feminizing adrenocortical tumor in the male.* About 70 cases have been reported up to now (GABRILOVE, 1965). Clinical and hormonal findings vary considerably. Often, carcinoma of the adrenal cortex is the cause. In Gabrilove's series, 41 of 52 patients had carcinomas, 7 had adenomas and in 4 cases the diagnosis was doubtful. Gynecomastia and testicular atrophy are the presenting clinical features. Increased amounts of estrogens are excreted. Other steroid findings vary. All possible causes of gynecomastia must be considered in the differential diagnosis (p. 487). As with other tumors of the adrenal cortex (p. 351), radiological demonstration of the tumor is of great importance.

G. Assessment of Adrenocortical Function

J. MÜLLER

For the exact methodology required for the determination of individual adrenocortical hormones and their metabolites and of the peptide and protein hormones which regulate their secretion, the reader is referred to review articles and original publications. In this section only the principles and normal values of hormone assays which are of diagnostic importance – mainly the practically important group determinations – are mentioned, but exact procedures for adrenal function tests will be described.

1. Determination of Plasma ACTH

The most sensitive *biological methods* for determination of ACTH are based on the bioassay of LIPSCOMB and NELSON (1962), and can reliably detect concentrations of 0.1 mU/100 ml (1 ng/100 ml) and more. In the method according to NEY (1963), the ACTH of 100 ml of blood is concentrated 20-fold with a carboxyl exchange resin. The extract is administered to hypophysectomized rats by i.v. injection, and corticosterone is determined fluorimetrically in blood taken from the left adrenal vein. Suppression by dexamethasone instead of hypophysectomy considerably decreases the sensitivity of the assay.

Normal values

Morning:	0.1–0.5 mU/100 ml;
Evening:	0.1–0.15 mU/100 ml;
Stress (surgery):	0.5–2 mU/100 ml.

Elevated values are found in untreated Addison's disease, Cushing's syndrome of pituitary-hypothalamic origin after adrenalectomy and substitution therapy, ACTH-secreting carcinoma, and the congenital adrenogenital syndrome (see Fig. 8, p. 298).

Minute amounts of ACTH can also be detected by radioimmunology. Guinea pigs produce antibodies against porcine ACTH, which cross-react with human ACTH. A mixture of plasma with unknown ACTH content, ACTH anti-serum, and ACTH labeled with ^{131}I of high specific activity is separated by electrophoresis. The concentration of ACTH in the plasma can be calculated from the ratio of free ^{131}I-labeled ACTH to antibody-bound ^{131}I-labeled ACTH.

Normal values

Morning: 0.4–0.9 mU/100 ml (YALOW, 1964);
0.3–0.7 mU/100 ml (DEMURA, 1966).

At present, both biological and radioimmunological ACTH assays are technically very difficult and are thus unsuitable for general diagnostic purposes.

2. Determination of Plasma MSH

MSH is estimated *biologically in vitro* or *in vivo*, with frog's skin by assessing an increase in pigmentation by eye, by microscopy, or by reflex spectrophotometry. Without chromatographic separation this method cannot, however, differentiate plasma activity due to α-MSH from that due to β-MSH or ACTH. Elevated values of total MSH activity are found in Addison's disease and in advanced pregnancy; decreased values in pituitary insufficiency.

Radioimmunological methods have been developed for the determination of both forms of MSH (ABE, 1967a and b). Up to now, however, only β-MSH has been unequivocally demonstrated in peripheral human plasma. α-MSH, can be found in extracts of human pituitary gland and of ectopic ACTH-producing tumors.

β-MSH

Normal values:	9 ng/100 ml;
Elevated values*:	50–600 ng/100 ml.

3. Plasma Renin and Angiotensin Assays

Since the concentrations of renin and angiotensin II in the blood are dependent, among other factors, on the effective plasma volume, estima-

* Addison's disease; Cushing's syndrome of pituitary-hypothalamic origin after bilateral adrenalectomy; ectopic ACTH-producing tumor.

tions must be carried out in subjects on a normal salt intake (6 to 10 g daily) in the fasting state and after 12 hours in a recumbent posture.

a) Bioassay of Plasma Renin

Most methods currently in use for the estimation of human plasma renin are based on one of the two following methods:

BOUCHER (1964) described a method in which plasma is incubated at 37 °C with no additional substrate. The angiotensin II formed from endogenous substrate during incubation is extracted with Dowex-50 and eluted. Its blood pressure-increasing activity is measured in a nephrectomized anesthesized rat. *Renin activity* is expressed in ng of angiotensin II per 100 ml of plasma.

Normal values

0–570 ng/100 ml (VEYRAT, 1964).

In the method used by BROWN (1964), renin is extracted from plasma by adsorption onto DEAE cellulose. The purified renin is incubated for 30 min to 96 hours with a standard ox-serum substrate. The unknown renin activity is measured from the rate at which angiotensin is liberated from the substrate. Angiotensin is also estimated biologically by its blood pressure-increasing effect in rats. The *renin concentration* is expressed in renin units.

Normal values

2–19 renin units per liter.

b) Radioimmunological Determination of Plasma Angiotensin II

In 1967, three different laboratories succeeded in developing sensitive and specific radioimmunological methods for the estimation of angiotensin II in plasma (VALLOTTON, BOYD, CATT). These methods appear to be better suited than bioassays to the determination of angiotensin and renin for purposes of clinical diagnoses.

Normal values

Plasma >0.8–5.6 ng/100 ml (BOYD);
Blood 2.1 ± 1.4 ng/100 ml (CATT).

c) Plasma Renin Assay by Radioimmunological Determination of Angiotensin I

The determination of angiotensin I has the advantage that the addition of converting enzyme and the difficult inhibition of the angiotensinases can be avoided and that antibodies to angiotensin I show less cross reactivity towards peptide fragments (HABER, 1969).

Normal values:

Plasma: intake of 110 mEq Na/d:
1.02–1.75 ng angiotensin I/ml/h
intake of 10 mEq Na/d:
2.16–5.92 ng angiotensin I/ml/h

4. Determination of Steroid Hormones

a) General Methodology

Clear identification and quantitative measurement of all the known steroid hormones and their most important metabolites in plasma and urine are now theoretically possible, but such analyses are technically very difficult, costly, and time-consuming, and they are only exceptionally used in clinical diagnosis. The relatively simple chemical group determinations of urinary and plasma steroids are usually adequate for the laboratory diagnosis of adrenal cortical function. Biological assay methods of steroid hormones are no longer used in clinical diagnosis.

Group determinations of steroids generally consist of the following steps: hydrolysis (when conjugated steroids are to be estimated), extraction with a suitable organic solvent, purification of the extracts, group-specific color or fluorescence reaction, and spectrophotometric or spectrofluorometric measurement. Most of these estimations can be carried out without difficulty in any reasonably large clinical chemical laboratory. When used in function tests they permit a reliable diagnosis of the most important adrenocortical diseases. On the other hand, a single steroid determination in urine or plasma only exceptionally allows definite exclusion or confirmation of a diagnosis of adrenocortical disorder. Because many drugs (e.g. psychotropic agents) can impair or distort chemical steroid estimations due to false color reactions, it is always advisable to discontinue all drugs not absolutely necessary for a few days before a steroid analysis.

Numerous *chromatographic methods* (adsorption or partition chromatography on columns, paper, thin-layer, or gas chromatography) permit perfect separation and identification of individual steroids in most cases. However, a single chromatography is hardly ever adequate for the isolation of a pure steroid fraction from biological material; this is only possible if chromatography is repeated in different solvent systems and often only if it is combined with chemical modifications of the steroid molecule. Losses which might cause quantitative inaccuracies can be avoided by *isotope methods*. In simple isotope dilution methods, a tracer dose of tritiated or ^{14}C-labeled steroid is added to

the plasma or urine sample at the beginning of the analysis in order to check losses of material occurring during purification. Quantitative determination of the steroid isolated and purified by chromatography can be performed by a colorimetric, fluorometric or gas chromatographic method or by competitive binding to a specific carrier protein or antibody (DICZFALUSY, 1970; MURPHY, 1969). In double isotope dilution derivative assays, the unknown steroid concentration is also quantitatively determined by a radiochemical method, e.g. esterification of the steroid with labeled acetic anhydride. These methods, which are qualitatively and quantitatively very reliable but technically demanding, are used in clinical diagnosis, e.g. for the determination of plasma testosterone or urinary aldosterone, where simpler methods such as are used for the determination of cortisol and its metabolites are not available. Radioimmunoassays have been developed for the determination of steroid hormones, such as testosterone, aldosterone, corticosterone, deoxycorticosterone, and progesterone. These methods are somewhat simpler than double isotope dilution derivative assays, but generally still require at least one chromatography and the use of an internal radioactive standard for checking procedural losses.

Methods of estimating *steroid secretion rates or production rates* are also based on the principle of isotope dilution; the mixing between unlabeled and radioactive-labeled steroid occurs within the organism.

b) Plasma Steroid Determinations

α) Fluorometric Determination of Plasma Corticosteroids

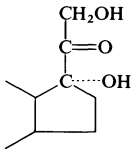
The two 11β-hydroxycorticosteroids cortisol and corticosterone can be determined by the fluorometric methods introduced by SWEAT (1952) and SILBER (1958). Since the fluorescence reaction due to corticosterone is three times more intense than that due to cortisol and the ratio of cortisol to corticosterone in the plasma is approximately 10 : 1, values obtained are 30% higher than when the Porter-Silber method (see below) is used, which measures almost exclusively cortisol. Moreover, every plasma extract produces a minor nonspecific fluorescence reaction. Single values must thus be carefully interpreted, because there is no definite limit between normal and decreased values. However, the method is very useful for repeated determinations in function tests. It is considerably more sensitive than the Porter-Silber reaction and yields precise and reproducible results even when the plasma cortisol concentration is in the normal or lower range. The technical procedure is very simple and results are available within a short time. We use a method described by SILBER (1966). Similar methods which are frequently used have been described by DE MOOR (1960) and MATTINGLY (1962).

Normal values

10–30 μg/100 ml depending on the time of day;
false high values during spironolactone medication.

β) Plasma 17-Hydroxycorticosteroids (Porter-Silber Chromogens)

The 17α,21-dihydroxy-20-ketone side chain of cortisol and its most important metabolites



react with phenylhydrazine in the presence of alcohol and sulfuric acid to produce a yellow color which can be measured by spectrophotometry. This so-called Porter-Silber reaction is used in the method of PETERSON for the relatively specific determination of cortisol (free cortisol and protein-bound cortisol, but not conjugated cortisol metabolites) in 5 ml of heparinized plasma. The method can be used for the metopyrapone test, because in contrast to the fluorometric methods it also measures cortexolone (compound S). It does, however, have the disadvantage that low normal plasma cortisol concentrations are at the lower limit of sensitivity of the Porter-Silber reaction.

Normal values

6–25 μg/100 ml, depending on the time of day;
false high values: ketone bodies, quinine, psychotropic drugs.

γ) Plasma Aldosterone

By using a modification of the original double-isotope method developed by KLIMAN (1960) for the determination of aldosterone in urine and in adrenal venous blood, PETERSON (1964) succeeded in measuring aldosterone in 20 to 30 ml of peripheral plasma. However, this method involved the use of ^{14}C-labeled acetic anhydride with a high specific activity and was too costly for purposes of clinical diagnosis. More recently, two similar methods have been developed in which aldosterone is esterified

with tritiated acetic anhydride (BRODIE, 1967; COGHLAN, 1967). Although these methods are also technically difficult and time-consuming, they are at least financially acceptable. They may later be replaced by radioimmunoassays.

Normal values

2–15 ng/100 ml;
primary aldosteronism:
23–88 ng/100 ml (during normal sodium intake).

δ) Plasma Androgens

Estimation of the plasma 17-ketosteroids is of no clinical importance. They consist mainly of the biologically inactive sulfates of dehydroepiandrosterone and androsterone. The determination of single biologically active androgens in the plasma is of greater significance and can be carried out in small amounts of plasma by means of a double isotope dilution derivative method (RIONDEL, 1963; HUDSON, 1963), a simple isotope-dilution method with gas chromatography with a highly sensitive electron-capture detector (BROWNIE, 1964), competitive binding to a carrier protein, or radioimmunoassay.

Normal values (according to GANDY, 1965)

Testosterone
Men: 0.38–1.19 μg/100 ml;
Women: 0.01–0.08 μg/100 ml.
Androstendione
Men: 0.05–0.06 μg/100 ml;
Women: 0.03–0.33 μg/100 ml.
Dehydroepiandrosterone
Men: 0.13–1.4 μg/100 ml;
Women: 0.14–1.06 μg/100 ml.

c) Determination of Urinary Steroids

Determinations of single steroids or a group of steroids in the 24-hour urine are frequently used in clinical diagnosis. The daily secretion rate of steroid hormones can be estimated from the excretion of representative urinary metabolites, which is not possible from the determination of plasma steroids. Group determinations of urinary steroids are also frequently used for stimulation and suppression tests.

The most common source of error in the determination of urinary steroids is the incorrect collection of a 24-hour urine specimen. In many cases it is advisable to monitor the daily urine output by means of the relatively constant creatinine excretion. The urine is best stored without the addition of a preservative under refrigeration at 2 to 4 °C for a few days at the most. When the analysis has to be postponed for a longer period, the urine must be frozen and stored in the deep freeze.

α) Urinary 17-Hydroxycorticosteroids (Porter-Silber Chromogens)

The urinary 17-hydroxycorticosteroids (17-OH-CS), which we determine by the reliable method of PETERSON (PETERSON, 1955; FIEDLER-BEHRENDT, 1962), account for 30 to 40% of the cortisol secreted in 24 hours and include all compounds with an intact 17,21-dihydroxy-20-ketone side chain. Metabolites of corticosterone and aldosterone are not determined, but tetrahydro-S, the most important metabolite of cortexolone, is. 20 ml of urine is incubated with β-glucuronidase at 37 °C for 24 hours and extracted with methylene chloride. The extract is washed with sodium hydroxide and treated with the phenylhydrazine reagent of Porter-Silber. This leads to the formation of a yellow pigment which can be measured spectrophotometrically. The unknown steroid concentration can be calculated from the optic density at 410 nm after subtraction of a sulfuric acid blank of the urine extract.

Normal values

3–13 mg/24 h, or
1.7–7.2 mg/m^2 for children.

Low Values. Low values are characteristic in Addison's disease and hypopituitarism but are not adequate for diagnosis of these conditions. A low excretion rate is also found in cirrhosis of the liver, myxedema, and old age.

Elevated Values. Elevation of the 17-OH-CS in the urine is characteristic in Cushing's syndrome, but may also be due to thyrotoxicosis or fever. The 17-OH-CS excretion is not proportional to the body weight, but in obesity a moderate increase in 17-OH-CS excretion up to 18 mg per day is often observed (see p. 354). In equivocal cases, obesity can best be differentiated from Cushing's syndrome by a dexamethasone suppression test (2 mg per day; see p. 389).

False High Values. Ketosis; quinine, meprobamate, phenothiazines (and other psychotropic drugs), and antiepileptic agents.

β) 17-Ketogenic Steroids According to NORYMBERSKI and "Total 17-Hydroxycorticoids" According to APPLEBY

The C_{21}-steroids which are hydroxylated in position 17 can be converted to 17-ketosteroids

Table 18. Color reactions and reactive groups of the side chain used in the determination of urinary steroids

Side chain	 Dihydroxy-acetone	 Glycerol	 17-20-glycol	 17-20-ketol	 17-ketone
Examples	Cortisol Cortisone TH-cortisol TH-cortisone Cortexolone TH-S	Cortol Cortolone	Pregnanetriol	17α-OH-pro-gesterone	Dehydroepiandrosterone Androstenedione Androsterone
Porter-Silber reaction (17-OH-CS)	+	−	−	−	−
17-ketogenic steroids according to NORYMBERSKI	+	+	+	−	−
17-ketogenic steroids according to APPLEBY	+	+	+	+	−
Zimmermann reaction (17-ketosteroids)	−	−	−	−	+

(17-KS) by oxidation with sodium or potassium bismuthate and then measured by Zimmermann's reaction. In this method, enzymatic hydrolysis is not necessary because the 17-KS are relatively stable compounds which can be hydrolyzed by heating with acid. In Norymberski's procedure, the 17-ketogenic steroids (17-KGS) are calculated from the difference in the 17-KS measured before and after oxidation. Recently, sodium periodate has been used in place of sodium bismuthate for the oxidation.

According to Appleby's modification, the steroids are first reduced with sodium borohydride. This eliminates the 17-ketosteroids and allows the determination of the 17-KGS by only one colorimetric reaction. The simultaneous reduction of the 20-keto group to 20-hydroxy groups also causes the steroids 17-hydroxyprogesterone and 17-hydroxypregnenolone to become ketogenic (see Table 18). The term "total 17-hydroxycorticoids" has become accepted in England and Sweden for 17-KGS as estimated by Appleby's method; this can lead to confusion with the Porter-Silber chromogens.

The 17-KGS include more cortisol metabolites than the Porter-Silber chromogens, since cortol and cortolone are estimated in addition to the tetrahydro derivatives. On the other hand, steroids which are not derived from cortisol, such as pregnanetriol are also estimated. Thus, there are advantages and disadvantages to the assessment of cortisol production as against the Porter-Silber chromogens.

Normal values according to BORTH (1957) (total 17-hydroxycorticoids)

Men: 6–21 mg/24 h;
Women: 4.5–16 mg/24 h.

γ) Free Urinary Cortisol and Corticosteroids

Determination of free, unmetabolized and unconjugated urinary cortisol is a valuable index of the concentration of free, non-protein-bound cortisol in the plasma providing renal function is normal (see p. 292). In contrast to the urinary 17-hydroxycorticoids, free urinary cortisol is only indirectly dependent on the cortisol secretion rate and metabolic clearance by the liver. It actually represents the amount of cortisol which has been at the disposal of the tissue cells during one day and it correlates with the functional state of the adrenal cortex more closely than any other parameter. The determination is not simple, however, and can therefore only be employed for clinical diagnosis in special cases (BROOKS, 1963; ROSNER, 1963).

Normal values

< 200 μg/24 h.

Substantial elevations are observed in Cushing's syndrome.

Direct fluorometric estimation of "cortisol" in urine extracts, in analogy to the estimation of plasma corticoids, leads to average values 3 times higher than those obtained by quantitatively and qualitatively exact analysis with isotope dilution and paper chromatography (ESPINER, 1965). Because the cortisol fraction of the total fluorogenic free urinary corticoids varies between 10 and 80% a determination of this kind cannot replace an exact analysis of free urinary cortisol. Nevertheless, MATTINGLY (1964) found very good correlation between the results of a simple assay like this and cortisol secretion rates as measured by isotope dilution in normal and ACTH-treated subjects, as well as in patients with Cushing's syndrome. The simple and quick fluorometric assay of free urinary corticoids can therefore partially replace the technically more difficult and time-consuming determinations of 17-hydroxycorticoids or 17-ketogenic steroids.

Normal values

78–372 μg/24 h (MATTINGLY, 1964).

δ) Urinary Aldosterone Metabolites. Determination of Aldosterone Secretion Rate

Since the introduction of the double-isotope derivative assay of urinary aldosterone-18-glucuronide by KLIMAN and PETERSON (1960), the previously used method of NEHER and WETTSTEIN (1956) has been abandoned. Various modifications have also been made to the double-isotope method. In our laboratory, we have found the procedure described by NEW (1966) to be very reliable. The principle of the method is as follows: A tracer dose of ^{14}C-labeled aldosterone is added to a urine sample. For hydrolysis of aldosterone-18-glucuronide the urine is acidified to pH 1 and kept at room temperature for 24 hours. The aldosterone liberated is extracted with methylene chloride and a preliminary purification by solvent partition and paper chromatography is performed. Esterification with tritium-labeled acetic anhydride leads to the formation of aldosterone-^{3}H-diacetate. This is followed by paper chromatography in three different solvent systems. Tritium and ^{14}C activities are measured in the purified samples by liquid scintillation counting. The amount of aldosterone in the counting vial can be calculated from the tritium activity and the known specific activity of the ^{3}H-acetic anhydride. The ^{14}C activity indicates which fraction of the original amount of aldosterone in the urine sample is still present in the counting vial and thus allows correction of any procedural losses.

Aldosterone secretion is dependent on sodium and potassium balance. Therefore, a patient in whom an aldosterone analysis is to be performed must be maintained on a liberal sodium (at least 100 mEq per day = 6 g of salt) and fluid intake; diuretics and potassium tablets must be discontinued for a few days.

Normal values

Adults: 5–20 μg/24 h;
Children: 3–13 μg/24 h per m^2 of body surface.

Because in liver diseases and pregnancy a relatively high proportion of secreted aldosterone is excreted as aldosterone-18-glucuronide, in certain cases it is also advisable to measure urinary tetrahydroaldosterone-3-glucuronide. A double-isotope procedure for measuring this metabolite has been described by NEW (1966).

Determination of the aldosterone secretion rate permits exact assessment of aldosterone production. Tritium-labeled aldosterone is injected intravenously and the specific activity of urinary aldosterone-18-glucuronide is determined by a method analogous to that of KLIMAN and PETERSON (1960) (using ^{14}C-acetic anhydride). The specific activity of urinary tetrahydroaldosterone-glucuronide can also be measured (ULICK, 1958). Because aldosterone-18-glucuronide is excreted more quickly than tetrahydroaldosterone-3-glucuronide (SIEGENTHALER, 1964), the collection of a 24-hour urine sample is sufficient for the first method, whereas a 48-hour urine sample has to be collected when tetrahydroaldosterone-glucuronide is measured.

Normal values

Adults: 50–200 μg/24 h.

ε) Urinary 17-Ketosteroids

We have found the procedure of PETERSON and PIERCE (1960) very reliable for the classic estimation of urinary 17-ketosteroids by Zimmermann's reaction. The 17-ketosteroids (17-KS) include the metabolites of adrenal and testicular androgens, which are inactive or only slightly active. Cortisol metabolites account for only a low proportion. Major 17-ketosteroids are androsterone, etiocholanolone, their 11-keto- and 11-hydroxy derivatives, and dehydroepiandrosterone. Although androsterone is the most important metabolite of testosterone, neither total 17-ketosteroid nor androsterone excretion can be considered as being representative of testosterone secretion. In normal conditions, 60% of the 17-KS in the male and

almost all the 17-KS in the female originates from the adrenal cortex. Practically all the urinary 17-KS are conjugated with sulfuric acid or glucuronic acid.

A 5 ml sample of the 24-hour urine is hydrolyzed by boiling with acid, and is then extracted with a mixture of petroleum ether and benzene; the extract is purified by washing with alkali. The 17-keto group (see Table 18) produces a purple color with *m*-dinitrobenzene in the presence of alkali (Zimmermann's reaction). This purple derivative can then be extracted with methylene chloride and measured spectrophotometrically.

Normal values are dependent on sex and age (Fig. 36, BORTH, 1957, see also Chap. XIX)

Adults

Men:	10–25 mg/24 h;
Women:	5–15 mg/24 h.

Children

First days of life:	up to 1.5 mg/24 h;
First year:	less than 0.5 mg/24 h;
2nd to 5th years:	less than 1 mg/24 h;
6 th to 9th years:	less than 2 mg/24 h;
10th to 15th years:	less than 10 mg/24 h.

Decreased Values. Addison's disease, pituitary insufficiency, cirrhosis of the liver, cachexia, advanced age.

Elevated Values. Very high values of up to more than 100 mg/24 h are found in adrenocortical carcinoma; high values in congenital adrenogenital syndrome, in the presence of Leydig cell tumors and virilizing adrenal cortical adenomas; elevated or normal values in Stein-Leventhal syndrome, arrhenoblastoma and simple hirsutism. A moderate increase is usually but not always found in Cushing's syndrome. Very high values in Cushing's syndrome are suggestive of an adrenocortical carcinoma.

ζ) Determination of Individual Urinary Androgen Metabolites. Androgen Production Rates

The numerous procedures developed for the fractionation and chromatography of urinary 17-ketosteroids have provided valuable information on human androgen metabolism but are of little importance in clinical diagnosis. No definite conclusions about the gonadal or adrenal origin of 17-ketosteroids or the malignancy of an adrenal tumor are possible from the percentage of individual 17-ketosteroid fractions.

Although dehydroepiandrosterone, 11-hydroxy- and 11-keto-17-KS are derived mainly from the adrenals, they can also be produced by a mixed embryonic tumor of the testis. The same enzyme defect may be present in congenital adrenogenital syndrome, as well as in malignant adrenocortical tumors. In contrast to an earlier opinion, there are probably no specific adrenal cortical androgens leading to hirsutism and not to virilization. Elevated plasma levels of testosterone in women with simple hirsutism rather indicate that the hirsutogenic activity of individual androgens parallels their virilizing activity.

In contrast to the 17-KS, urinary testosterone-glucuronide is only derived from testosterone. The determination of this metabolite in 24-hour urine allows certain conclusions about the endocrine function of the testis in man. However, only 0.15 to 1.9% of the testosterone secreted is excreted as testosterone-glucuronide in the urine (CAMACHO, 1964). The determination is of a similar degree of technical

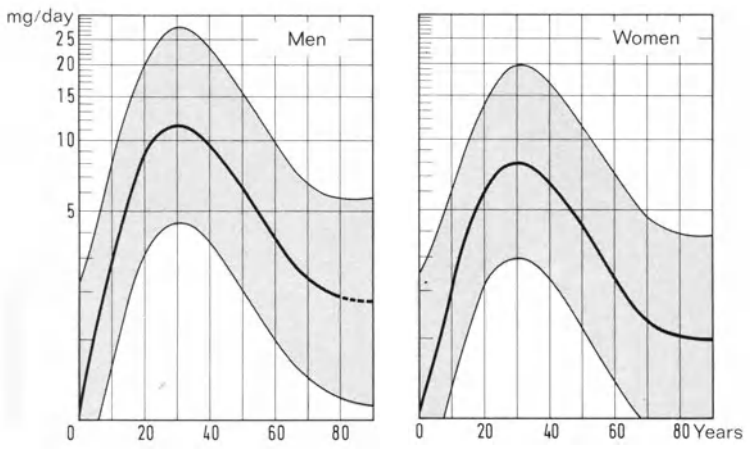


Fig. 36. Mean values of urinary 17-ketosteroids for normal individuals with average body weight and average length. Mean = solid line; limits of confidence = stippled area (P = 0.05). (From BORTH, LINDER, and RIONDEL, 1957)

difficulty to the measurement of plasma testosterone (see p. 381).

Normal values

Men: 15–520 μg/24 h (DULMANIS, 1964).

In women, most of the urinary testosterone-glucuronide is derived from androstenedione, which is secreted by the adrenal cortex and converted to testosterone by the liver. Since most of the testosterone is immediately conjugated by the liver and secreted into the blood stream as the glucuronide, the determination of urinary testosterone-glucuronide in women does not permit valid conclusions about the amount of testosterone secreted by endocrine glands or the amount of testosterone secreted into the blood stream during one day. This leads to wide differences between "blood production rates" and "urine production rates" of testosterone in women. The blood production rate is calculated by multiplication of the plasma testosterone concentration with the metabolic clearance rate. The urine production rate is calculated from the specific activity of testosterone-glucuronide in the 24-hour urine after intravenous administration of radiolabeled testosterone.

In men, determination of the testosterone urine production rate permits valid conclusions about the secretion of this hormone by the testes.

Normal values

Men: 4–12 mg/24 h (KORENMAN, 1963).

5. Stimulation Tests

a) ACTH Tests (Thorn Test) for the Assessment of Adrenal Cortical Function and Functional Reserve

The ACTH test, i.e. the determination of urinary or plasma steroids before and after stimulation of the adrenals with an ACTH preparation, is the most important test of adrenocortical function and is essential for the diagnosis of adrenal insufficiency.

There are numerous modifications of the ACTH test. ACTH may be given intravenously, either by injection or by infusion, or intramuscularly; determinations of various steroid fractions in plasma and urine and blood eosinophil counts can be performed at different times. For a review of the many original procedures with their normal values see PRUNTY. However, new modifications of this test are recommended almost every week. A critical evaluation of all these variations of the test is impossible. We can deal only with a few basic principles and a few modifications of the tests which we have found most reliable in 20 years of experience.

In agreement with RENOLD (1952), we have observed maximal stimulation of the adrenal cortex with a dose of 25 IU of a water-soluble natural or synthetic (0.25 mg) ACTH preparation administered by intravenous infusion over 8 hours. In all persons with a normal adrenocortical function, this causes the plasma corticoids as measured by fluorometry to rise to a value at least twice as high, in some instances three or four times as high, as the initial value. The 24-hour value of urinary 17-hydroxycorticoids as measured by the Porter-Silber reaction after enzymatic hydrolysis (see p. 381) also increased to 2 or 3 times the baseline value in all normal subjects on the day such an ACTH infusion was given. Intramuscular administration of 120 IU of a natural or 1 mg of a synthetic long-acting ACTH preparation leads to a similar optimal stimulation, which is characterized, however, by a later onset and a longer duration. Failure of the urinary or plasma corticoids to respond to ACTH in this dosage definitely indicates adrenal insufficiency. When the test is repeated on two or three consecutive days with no response, the diagnosis of Addison's disease is confirmed.

The assessment of an ACTH test by the fall in blood eosinophils is only permissible in emergencies or as an additional check. Only a positive result indicates an intact adrenal function, whereas false negative results are obtained in 30% of all tests. When a reliable assay for plasma or urinary corticoids is available, a simultaneous eosinophil count is pointless since it makes it impossible to carry out the ACTH test under steroid cover (see below). Determination of the plasma corticoids by a fluorometric method is no more difficult or time-consuming than an eosinophil count.

The response of urinary 17-ketosteroids to ACTH is less distinct and is often delayed by 24 hours. When a reliable assay of urinary 17-hydroxycorticoids or 17-ketogenic steroids is available, simultaneous estimation of the 17-ketosteroids is not necessary.

The ACTH test is also often used in the differential diagnosis of adrenal hyperfunction. In Cushing's syndrome with bilateral adrenal hyperplasia, there is a pronounced or even excessive rise in the urinary and plasma corticoids, whereas in cases of adrenal tumors the response is reduced or absent. The ACTH test does not, however, permit definite differentiation between Cushing's syndrome and normal adrenal function. It is therefore not advisable to perform an ACTH test to differentiate between

hyperplasia and a tumor until a diagnosis of Cushing's syndrome has been established by a low-dose dexamethasone suppression test.

Although different authors have suggested that the ACTH test also be subjected to quantitative evaluation (JENKINS, 1955; BIRKE, 1958) and that partial or relative adrenocortical insufficiency can be deduced from a less pronounced rise in corticosteroids, we think the result can only be positive or negative, showing whether the adrenals are responsive or not. In doubtful cases we repeat the test.

Side effects of ACTH are uncommon. Hypersensitivy reactions, however, can occur particularly in adrenal insufficiency and after repeated administration of ACTH. Immediate reactions of the anaphylactic type are pruritus, urticaria, exanthema, or asthma, which respond to antihistamines. A delayed reaction may occur a few hours after an ACTH infusion is started in the form of fever and vomiting and can be very dangerous in adrenocortical insufficiency. It is therefore advisable to perform all ACTH tests under cover of dexamethasone in a dosage of 0.5 mg p.o. twice daily. This does not interfere with the steroid analysis used for assessing the adrenocortical response to ACTH, and undesired side effects are avoided. Interpretation of the reduced eosinophil count is not possible during corticosteroid medication.

α) Eosinophil Count

Capillary or venous blood is used for the eosinophil count; calculation from the percentages obtained in blood smears is not sufficiently precise. The direct eosinophil count according to RANDOLPH is very reliable. Either capillary blood from the finger tip or venous blood can be used. In the latter case, 5 ml of blood are taken from the cubital vein and mixed at once with a weighed amount of an oxalate mixture. The oxalate-and-blood mixture can be stored in the refrigerator for up to 6 hours.

The composition of the oxalate mixture is: Ammonium oxalate 1.2 g, potassium oxalate 1.8 g, distilled water to give 100 ml. A pipette is used to transfer 0.5 ml of this mixture to each tube to be used for blood collection, where it is evaporated.

Randolph's solution has proved successful for selective staining of the eosinophils: phloxine 0.1, propylene glycol 50 ml, distilled water 50 ml. The solution can be kept indefinitely.

Capillary or venous blood is drawn up into a leukocyte pipette to the 0.5 mark, and then diluted with Randolph's solution up to the 11 mark. The pipette can then be left for up to 12 hours. It must be vigorously shaken for at least 2 min, and 3 to 5 min must elapse between filling the counting chamber and counting. The eosinophils are counted in 2 or preferably 4 Fuchs-Rosenthal cerebrospinal fluid counting chambers 0.2 mm in depth. The following formula is used for the calculation:

$$\text{Eosinophils per mm}^3 = \frac{\text{eosinophils per chamber} \times 100}{16} = \text{eosinophils per chamber} \times 6.25.$$

The staining method of DUNGER is useful when many estimations have to be performed, but the determination must be completed at once. Other methods of selective staining have been described by HENNEMANN and HINKELMANN.

β) Rapid ACTH Test (8-Hour Intramuscular Long-Acting ACTH Test)

The plasma corticoids are measured fluorometrically or colorimetrically (Porter-Silber reaction), or the blood eosinophils are counted before and 8 hours after an i.m. injection of long-acting ACTH (ACTH-Zn). Alternatively, the 24-hour urinary output of 17-hydroxycorticoids or 17-ketogenic steroids is determined on the day before the test and on the day the injection of ACTH is given. A blood sample is taken at 8 a.m., after which 120 IU of a natural or 1 mg of a synthetic long-acting ACTH preparation is given by i.m. injection to adults. The dose for children is 75 IU or 0.6 mg per m^2. A second blood sample is taken at 4 p.m.

When the plasma or urinary corticoids increase by 100% or more, or when the eosinophils decrease by 50% with a base-line value of more than 100 per mm^3, primary adrenocortical insufficiency can be definitely excluded. However, a negative result of the eosinophil test is no proof of adrenocortical insufficiency. When the result of a rapid ACTH test is negative, a prolonged ACTH test (with long-acting ACTH or repeated intravenous ACTH infusions) should be performed.

The rapid ACTH test is very suitable for ambulant patients.

γ) Prolonged ACTH Test

An i.m. injection of 120 IU, or 1 mg of a long-acting ACTH preparation, is given once or twice (with an interval of 8 to 12 hours) daily, depending on the duration of action of the preparation used. In patients with secondary adrenocortical insufficiency, a distinct increase

of urinary or plasma corticosteroids can be observed on the second or third day of ACTH treatment in most instances. However, an unequivocal increase may not be seen until after a week of treatment.

δ) 8-Hour Intravenous ACTH Test

ACTH given by intravenous infusion stimulates the adrenal cortex to the greatest possible extent and is therefore the most sensitive test for assessment of its functional reserve. It makes it possible to evaluate not only the immediate secretory increase (actual functional reserve) but, when administered for several days, also the maximum hormone production possible after development of adrenocortical hyperplasia, i.e. the "potential functional reserve" according to RENOLD (1952). An additional advantage is that an ACTH infusion can be interrupted at any time if a patient shows signs of a hypersensitivity reaction.

As a standard procedure, intravenous administration of ACTH over 8 hours on two consecutive days has proved very reliable. On the first day of the test the 24-hour urinary output of 17-hydroxycorticoids and 17-ketosteroids is measured (base-line). On the second day a blood sample is taken at 8 a.m. in the fasting state for the measurement of plasma corticoids and the eosinophil count. This is immediately followed by an intravenous infusion of 25 IU or 0.25 mg (children 12 IU or 0.12 mg per m^2) of ACTH in 500 ml (300 ml per m^2) of physiological saline solution over 8 hours. A second blood sample is taken at 4 p.m. Urine is collected from 8 a.m. on the second day to 8 a.m. on the third day of the test for determination of 17-hydroxycorticoids. The same procedure is followed on the third day of the test.

A fall of more than 85% (average 94%) in the blood eosinophils, an increase of the plasma corticoids to at least 40 μg/100 ml and to 100% above the base-line value, or an increase of 10 to 15 mg per 24 hours or 100% in the urinary 17-hydroxycorticoids indicates normal adrenocortical function and definitely excludes Addison's disease. An inadequate fall in eosinophils and failure of the corticosteroids to rise indicate adrenal insufficiency. In normal subjects, the rise in plasma corticoids and the fall in the eosinophils in response to the first and the second ACTH infusion are the same. In secondary adrenocortical insufficiency the ACTH effects is more pronounced on the third day of the test. In contrast, the urinary corticoids increase further on the third day of the test in normal subjects also. In the normal subject, the increase above the base-line value is between 4.5 and 30 mg per 24 hours on the second day of the test and between 5 and 41 mg per 24 hours on the third. In Cushing's syndrome with bilateral adrenal hyperplasia the increase of the 17-hydroxycorticoids can be as high as 50 to 80 mg per day. When Cushing's syndrome is due to an adrenal cortical adenoma, the response is variable. A definite increase of corticosteroid output is not common in adrenocortical carcinoma.

Cortisone-resistant eosinophilia can be recognized by the failure to respond to exogenous cortisone. The blood eosinophils are counted before and after the oral administration of cortisone acetate (adults 100 mg, children 60 mg per m^2). Alternatively, the eosinophils can be counted before and three hours after an intravenous infusion of cortisol hemisuccinate in a dose of 20 mg in 100 ml of physiological saline for adults or 12 mg per m^2 in 60 ml per m^2 for children, given over one hour. Constitutional aneosinophilia is not related to any adrenocortical disorder.

ε) Repeated Intravenous ACTH Test

A repeated intravenous ACTH test can be used in the same way as the prolonged intramuscular ACTH test for the differentiation between primary and secondary adrenocortical insufficiency. Secondary adrenal atrophy can be relieved by repeated intravenous stimulation in most instances, whereas primarily atrophic or damaged adrenals fail to react. A fall in the eosinophils can be examined on successive days as the eosinophils return to their original level overnight after an intravenous ACTH infusion.

b) Methopyrapone Test (Metopirone Test)

Principle. The adrenostatic drug methopyrapone inhibits the 11β-hydroxylase of the adrenal cortex and therefore blocks the synthesis of cortisol, corticosterone, and aldosterone without impairing production of their precursors cortexolone (compound S) and deoxycorticosterone. The failure of the negative feedback effect of cortisol on the hypothalamus results in a maximum output of ACTH, which elicits an increase in plasma and urinary 17-hydroxycorticoids and 17-ketogenic steroids corresponding to an increased formation of cortexolone (Fig. 37), providing the adrenal cortex responds normally to ACTH. When the adrenal glands are normal, the methopyrapone test allows assessment of the pituitary ACTH reserve.

Method. The test should be only carried out when the urinary 17-hydroxycorticoids are normal or have shown a normal response to ACTH. Any type of corticosteroid therapy must be discontinued during the test.

Day 1: determination of urinary 17-hydroxycorticoids (base-line value);
Days 2 and 3: 750 mg (or 30 mg per kg body weight) of methopyrapone are given orally every four hours after meals or with a glass of milk;
Day 4: no medication but collection of a 24-hour urine sample.

Urinary excretion of 17-hydroxycorticoids is measured on days 1, 3, and 4.

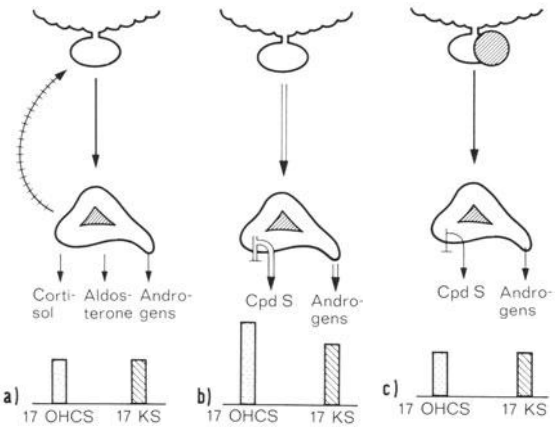

Fig. 37a–c. Methopyrapone test. a) Normal person before methopyrapone. b) Normal person under treatment with methopyrapone: suppression of 11-hydroxylase, production of cortisol blocked, instead cortexolone (compound S) is produced, which does not suppress ACTH secretion: increase in urinary corticosteroids. c) Patient with partial pituitary insufficiency treated with methopyrapone: cortexolone is secreted in place of cortisol. No increase in urinary corticoids because ACTH reserve is decreased

Interpretation. When the hypothalamic-pituitary-adrenocortical system is functionally intact, urinary 17-hydroxycorticoids increase by 100% or 10 mg per 24 hours above the base-line value on day 3 or 4 of the test. When the urinary 17-hydroxycorticoids respond to ACTH but not at all to methopyrapone a disturbance of ACTH secretion must be assumed. An inadequate rise with a normal base-line value is indicative of a limited ACTH reserve which can occur, for instance, after pituitary irradiation or in Cushing's syndrome due to an autonomous adrenocortical adenoma. The methopyrapone test is particularly suited for the assessment of a decreased ACTH reserve due to therapy with high doses of a cortisone derivative. However, cortisol secretion may respond normally to stress such as surgery in patients in whom the response to the methopyrapone test was pathologic, which can be explained by the different mechanisms of stimulation of ACTH secretion (see p. 299). Occasionally the test is also performed to differentiate between adrenocortical hyperplasia and tumor in CUSHING's syndrome. As a rule, the increase of 17-hydroxycorticoids is excessive in Cushing's syndrome with adrenocortical hyperplasia. In adrenocortical adenoma there is usually no increase even when the adenoma responds to ACTH.

We prefer to carry out the test under hospital conditions, although it can also be performed in out-patients. Regular intake of the drug every 4 hours even during the night is often not possible at home. Nausea and vomiting may occur during the test. These symptoms can be partially explained by a toxic effect of the drug, but they may also indicate adrenocortical failure. In patients with impaired ACTH secretion, there is the risk of an acute adrenocortical crisis provoked by a methopyrapone test.

In our opinion, the intravenous administration of methopyrapone (1 to 2 g or 30 mg/kg in 1 liter of physiological saline solution infused over 4 hours) offers no advantages.

c) Vasopressin Test

When pituitary insufficiency is suspected and the ACTH test is normal, an attempt can be made to stimulate the endogenous ACTH secretion by the administration of synthetic lysin-vasopressin. It has not been definitely established whether vasopressin acts directly on the pituitary gland or promotes the secretion of endogenous CRF (see p. 300). Its site of action seems to be below the center of negative feedback regulation and the site of action of stress. When a methopyrapone, insulin, or pyrogen test is pathologic, a normal vasopressin test indicates a lesion in the hypothalamus. The vasopressin test can also be used for the differentiation of Cushing's syndrome with adrenal hyperplasia from Cushing's syndrome due to an adrenal adenoma; no response in plasma cortisol can be observed in patients with an adrenal adenoma (BETHGE, 1968; TUCCI, 1968).

A blood sample is taken at 8 a.m., after which an intravenous infusion of 6 to 10 pressor units (depending on body weight) of synthetic lysin-8-vasopressin in 500 ml of physiological saline solution is given within two hours. A second blood sample for the determination of plasma corticosteroids is taken at 10 a.m. Normally the plasma corticoids increase by at

least 10 μg/100 ml or 100% above the base-line value.

Side effects are mild and consist of pallor, abdominal discomfort, and tenesmus.

d) Insulin and Pyrogen Stimulation Tests of the Pituitary Adrenal System

The nonspecific stimulation of the pituitary adrenal system by insulin-induced hypoglycemia or fever provoked by pyrogen can be used for diagnostic purposes. Only when the total hypothalamic-pituitary-adrenocortical axis is functionally intact can a rise in plasma corticosteroids be elicited by these measures. A definite increase of the plasma corticosteroid concentration in response to an intravenous injection of insulin can only be expected when a marked decrease in blood sugar is maintained for at least 10 minutes and leads to hypoglycemic symptoms. Whereas in most healthy individuals an insulin dose of 0.1 to 0.15 units per kg is sufficient, a higher dose (0.3 units per kg) is required to provoke a fall in blood sugar in patients with acromegaly. A maximum increase of the plasma corticosteroids by 13 μg/100 ml (5.4 to 18.4 μg/100 ml, LANDON, 1963) above the base-line value can be observed between 30 and 90 min after the insulin injection. Special caution is necessary in patients with pituitary insufficiency because a severe hypoglycemic coma may result.

In the pyrogen test according to ENGEL (1960), the plasma corticosteroids are determined in the early afternoon; pyrexal is then given in a dose of 0.2 μg by the i.v. route. A maximum increase of an average of 22.1 μg/100 ml ± 8.9 μg per 100 ml in the plasma corticosteroids is reached after three hours in normal subjects. In the test according to JENKINS (1964), a dose of 0.005 μg/kg body weight of pyrogen (Organon) is given by i.v. injection; in the healthy subject, the plasma corticosteroids increase by an average of 15 μg/100 ml within three hours. The test is terminated by an i.v. injection of 100 mg of cortisol hemisuccinate.

6. ACTH Suppression Tests with Dexamethasone

Principle. Small amounts of very potent glucocorticosteroids, such as dexamethasone, suppress ACTH secretion while contributing to the urinary or plasma concentrations of 17-hydroxycorticosteroids only minimally. These tests are clinically important

1. for the evaluation of ACTH-dependence or autonomy of adrenocortical steroid production, i.e. for the differentiation of normal and hyperplastic adrenals from adrenal tumors;

2. for a quantitative assessment of the suppressibility of ACTH secretion and thus for the differentiation between normal and uncontrolled pathologic function of the hypothalamic pituitary adrenal axis.

Whereas in most instances a determination of urinary or plasma corticoids before and during suppression is sufficient, the urinary 17-ketosteroids are also measured when adrenogenital syndrome or a cortisol- and androgen-producing tumor is suspected.

a) Overnight Dexamethasone Suppression Test

This test is an excellent screening procedure for Cushing's syndrome in outpatients. On the first day, a blood sample is taken at 8 a.m. for the determination of the base-line value of plasma corticosteroids (fluorometric or Porter-Silber method). A dose of 1 mg of dexamethasone is taken orally between 11 p.m. and midnight. A second blood sample is taken at 8 a.m. the following day. In normal subjects the concentration of the plasma corticoids decreases to less than 10 μg/100 ml or less than half the base-line value on the second day. In CUSHING'S syndrome of any etiology no response or an inadequate fall in plasma corticosteroids is observed.

The time of dexamethasone intake is very critical, since the morning rise of ACTH secretion cannot be blocked after midnight. We have found the test very reliable. Although a single dose of 1 mg of dexamethasone induces a significant fall in the plasma corticoids even in very obese patients, we increase the dose to 2 mg when the body weight exceeds 100 kg. Plasma corticoids did not decrease in any of more than a dozen patients with Cushing's syndrome, even when the base-line values were normal or only slightly elevated.

b) Low-Dose Dexamethasone Test (2 mg per day)

This reliable test, which was introduced by LIDDLE (1960), differentiates Cushing's syndrome of every etiology from simple obesity or any other disease with a high degree of accuracy. The original method entailed administration of 2 mg of dexamethasone on each of two successive days. We have found that there are certain advantages when dexamethasone is given on three successive days instead.

Method

Day 1: 24-hour urine collection for the determination of base-line steroid values;

Days 2 to 4: dexamethasone, 0.5 mg every 6 hours orally. Determination of urinary 17-hydroxycorticoids, perhaps also 17-ketosteroids, on days 3 and 4.

Interpretation. When the hypothalamic-pituitary-adrenal system is normal both urinary steroid fractions fall to values below 4 mg per 24 hours or less than half the base-line values, even when the base-line values of the 17-hydroxycorticoids (in obesity) or 17-ketosteroids (in simple hirsutism) are elevated. In Cushing's syndrome, the decrease is absent or inadequate. In rare cases of Cushing's syndrome with bilateral adrenal hyperplasia, administration of 2 mg of dexamethasone may provoke a paradoxical increase of the 17-hydroxycorticoids and 17-ketosteroids (BROWN, 1973). In the congenital adrenogenital syndrome, this low dose of dexamethasone is sufficient to suppress the ACTH secretion and normalize the elevated urinary 17-ketosteroids.

c) High-Dose Dexamethasone Test (8 mg per day)

When the diagnosis of Cushing's syndrome has been confirmed (by a pathologic low-dose dexamethasone suppression test), this test can differentiate adrenal hyperplasia from an adrenal tumor in most instances. It is less reliable than the low-dose dexamethasone test, however, and a number of cases of Cushing's syndrome with bilateral adrenal hyperplasia have been described in which the elevated urinary 17-hydroxycorticoids were not suppressed by 8 mg of dexamethasone (SILVERMAN, 1963; KATZ, 1966; LINN, 1967). The test can also be negative in nodular dysplasia (see p. 353).

Method

Day 1: base-line values of urinary 17-hydroxycorticoids and 17-ketosteroids;

Days 2 and 3: dexamethasone, 2 mg, every 6 hours orally. Determination of urinary 17-hydroxycorticoids and perhaps also 17-ketosteroids on day 3.

Interpretation. The inappropriate ACTH secretion of Cushing's syndrome of hypothalamic pituitary origin is suppressed by this dose and the steroid excretion decreases by more than 50%. In contrast, in cases of adrenocortical adenoma or carcinoma, the steroid excretion is not usually affected. Nor is the ectopic formation of ACTH in tumors, which leads to adrenal hyperplasia (paraneoplastic Cushing's syndrome), suppressed by 8 mg of dexamethasone, or only in rare instances (STROTT, 1968). A paradoxical increase of urinary 17-hydroxycorticoids during a high-dose dexamethasone suppression test has been observed in two individuals with apparently normal adrenocortical function, in whom the 17-hydroxycorticoids were normally suppressed by 2 mg of dexamethasone (ROSE, 1969). Diphenylhydantoin enhances hepatic conjugation of dexamethasone and may cause false positive 2 mg, but no 8 mg dexamethasone tests (JUBIZ, 1970).

7. Function Tests for Detection of the Source of Androgens in Hirsutism and Virilization

In the normal male, more than 90% of the plasma testosterone is secreted by the testes, whereas in the normal female more than half the plasma testosterone indirectly originates from the adrenal cortex. The major part is secreted as androstenedione by the adrenals and is converted to testosterone in the periphery (HORTON, 1966). When the plasma testosterone is elevated in a hirsute or virilized woman, an attempt can be made to detect the organ of origin by suppression and stimulation tests. Theoretically, it can be assumed that plasma testosterone deriving from the adrenals is stimulated by ACTH and suppressed by dexamethasone, whereas testosterone deriving from the ovaries is stimulated by chorionic gonadotropin and suppressed by estrogens, unless there is a completely autonomous hormone production due to a tumor. However, these assumptions have been only partially confirmed and valid procedures for androgen suppression and stimulation tests in the woman have not yet been established. Administration of ACTH did not stimulate the testosterone production in normal women, but had a stimulatory effect in a girl with congenital adrenogenital syndrome (KORENMAN, 1965). Prednisone significantly decreases plasma testosterone in normal women. Whereas in the normal male the plasma testosterone increases in response to treatment with chorionic gonadotropin (5000 units daily i.m. for five days) (LIPSETT, 1966), the same treatment led to a distinct rise in plasma testosterone in normal women only after pretreatment with human FSH (KORENMAN, 1965; LAMB, 1964). In contrast, the plasma testosterone rose in response to chorionic gonadotropin even without FSH pretreatment in women with the Stein-Leventhal syndrome (DIGNAM, 1964; KORENMAN, 1965). Whereas in the normal man the production and plasma concentration of testosterone can be significantly suppressed by treatment with a synthetic androgen such

as 2α-methyldihydrotestosterone-proprionate, 15 mg daily (DAVIS, 1965) or 9α-fluoro-11β-hydroxy-17α-methyltestosterone, 40 mg daily (LIPSETT, 1966) or an estrogen such as ethinyl-estradiol, 1 mg daily, corresponding results have not yet been found in the woman.

Because in most instances, virilization and endocrine hirsutism of the woman appear to be directly due to a pathologically high plasma testosterone level, and since the excretion of urinary 17-ketosteroids does not correlate with the plasma level or the production rate of testosterone, combined adrenal and ovarian function tests based on urinary 17-ketosteroid determinations such as have been proposed by SEGRE (1967) appear to be of doubtful value. Nevertheless, determination of the 17-ketosteroids is useful for establishing the organ of origin of elevated androgens in the woman. Whenever a pathologically elevated plasma testosterone is of adrenal origin, elevated levels of urinary 17-ketosteroids are found. When these are not clearly suppressible by dexamethasone, 2 mg daily, an adrenal cortical tumor must be suspected. On the other hand, even considerably increased testosterone production by the ovaries does not lead to elevated levels of 17-ketosteroids. However, an exception is found in the Stein-Leventhal syndrome, in which a relatively high proportion of the urinary 17-ketosteroids is of ovarian origin and can be stimulated by chorionic gonadotropin when the adrenal cortex is blocked by dexamethasone (MAHESH, 1964).

8. Indirect Evaluation of Adrenocortical Function

Direct assessment of adrenocortical function is now possible by determination of urinary or plasma corticosteroids in stimulation and suppression tests, so that the indirect function tests have lost a great deal of their importance.

An exact determination of aldosterone is so time-consuming, however, that the aldosterone production rate is often indirectly assessed by sodium and potassium balance studies or by determination of salivary or sweat electrolytes as screening procedures.

An estimation of mineralocorticoid production is also possible by the determination of fecal electrolytes. The unpleasant analysis of stool aliquots can be avoided by a simple *in-vivo* dialysis procedure (RICHARDS, 1969). Mineralocorticoid production can also be evaluated by the determination of the difference in electric potential between the rectal mucosa and the perianal skin (EDMONDS, 1970).

Sodium restriction, potassium loading, and insulin tolerance tests are dangerous and unnecessary screening procedures for adrenocortical insufficiency. The insulin tolerance test may lead to normal results in untreated Addisonian patients in whom some glycogen stores are still available and the blood sugar may spontaneously return to normal values.

Instead of the straining Robinson-Power-Kepler tests, we prefer to assess the single parameters, i.e. the capacity of diuresis and clearances, to a combined index. A simple water tolerance test is occasionally justified with due consideration for the risk of hypotonic hydration and with appropriate precautions.

a) Water Tolerance Test According to VOLHARD, *as Modified by* SOFFER *(1952)*

Method: No fluid or food is allowed after the evening meal the day before the test.

At 7 a.m. on the day of the test, urine is voided and discarded. The patient then drinks 1.5 liters of water or of tea with lemon and saccharine within 15 to 45 min. Urine is collected from 7 a.m. to 12 noon and the volume is measured. The patient is lying down or sitting when not voiding urine.

Interpretation. Normally, at least 800 ml are excreted in five hours. In adrenal or pituitary insufficiency, the urine volume excreted is less than 800 ml. A pathologic result of the test can be due to dehydration, tendency to edema or to cardiac or liver diseases or hypothyroidism.

b) Salivary Electrolytes

The sodium and potassium concentrations in the saliva are controlled among other factors by the adrenal cortex. Valid conclusions about mineralocorticoid activity can be drawn from these values when the other influences (time of day, duration of stimulation, secretion rate, salt content of the food) are taken into account. The test allows indirect estimation of the aldosterone production rate.

Method and Calculation (PRADER, 1955). An essential condition is a normal salt intake (10 g of NaCl per day) on the preceding days. A piece of unbreakable paraffin, the size of a hazel nut, is chewed for 10 min between 6 and 8 a.m. in the fasting state and before brushing the teeth. The patient is told not to swallow and to collect all the saliva in a glass container. The saliva of the first and second five-minute periods is collected separately, and only the saliva from the second period is examined. The volume (ml per 5 min) and the sodium and potassium concentrations are determined. The

sodium and potassium concentration and the sodium-potassium ratio are then corrected to a standard secretion rate (10 ml per 5 min = 2 ml per min) by the following formulas:

Na_k = Na + 1.6 (10–vol/5 min),
K_k = K,
$(Na/K)_k$ = Na/K + 0.1 (10–vol/5 min).

The normal values for adults and children are (mean ± 2 standard deviations):

Na_k = 20–36 mEq/l,
K = 11–27 mEq/l,
$(Na/K)_k$ = 0.6–2.1.

In pathologic conditions, the sodium values are changed more than the potassium values and the two ions usually move in opposite directions. Increased sodium and sodium/potassium values are indicative of adrenocortical failure, decreased values indicate mineralocorticoid excess. The test is not reliable when the serum electrolytes are conspicuously altered. A sodium/potassium ratio of less than 0.25 strongly indicates a primary or secondary aldosteronism. An excessive aldosterone production is unlikely when the value is above 0.5.

c) Evaluation of Sodium and Potassium Excretion in the Sweat

Like the sodium and potassium excretion in saliva, the secretion rate of sodium and potassium in sweat provides valid information on the production of mineralocorticoid hormones. With due consideration of the sweat secretion rate, the determination of sweat electrolytes can be used as a screening procedure for primary or secondary aldosteronism and is of value for mass screening of hypertensives. A reliable procedure has been developed by GRANDCHAMP (1968, 1969) and has been evaluated as a diagnostic tool for the various types of hypermineralocorticoidism.

Principle. After 5 min of pilocarpin iontophoresis on the forearm (GIBSON, 1959), sweat is collected for 20 min under a flat cover and drawn up into glass capillaries. The sweat secretion rate is determined by weighing the capillaries, and sodium and potassium concentrations are measured by flame spectrophotometry.

Results:

x = sweat secretion rate in µg/20 min/13.8 cm^2.
y = sodium/potassium ratio.

Normals:

$y = 0.03x + 1.81$
(± 2 standard deviations =) ± 2.60.

Experimental secondary aldosteronism:

$y = 0.02x + 0.5 \pm 1.3$.

Experimental primary aldosteronism:

$y = 0.004x + 1.37 \pm 0.62$.

In two cases of primary aldosteronism and in one case of renovascular hypertension, the sodium/potassium values were clearly in the range of results observed in experimental aldosteronism.

d) Determination of Total Body Potassium and Sodium

α) Determination of Potassium^{40} by Whole Body Counting

Natural potassium contains up to 0.0119% the radioactive isotope ^{40}K, a β- and γ-emitter with a half-life of 1.4×10^9 years. Determination of this isotope by whole-body counting is a relatively reliable index of total body potassium. Counting with the apparatus of JOYET (1968), which allows an optimum in couting geometry, takes 45 min. The instrumental measuring error is ±3.5–5%. Values determined in the same subject after intervals of several weeks vary by ±7%. Individual sex- and age-dependent variations appear to be mainly due to the variable portion of adipose tissue in the whole body mass. Adipose tissue has a very low potassium content.

Normal values according to JOYET (1968):

Men:
Age 20 years: 2.14 ± 0.02 g of K/kg
25–34 years: 1.89 ± 0.07 g of K/kg;
35–44 years: 1.94 ± 0.10 g of K/kg;
Above 45 years: 1.82 ± 0.06 g of K/kg;
Women:
Age 20 years: 1.58 ± 0.02 g of K/kg:

In patients with primary aldosteronism, the whole-body potassium was decreased by 20–50%.

β) Determination of Exchangeable Potassium and Sodium

For this determination two artificial short-life isotopes, ^{42}K and ^{24}Na, are used. By the determination of the potassium which is exchangeable with ^{42}K, 90 to 95% of the whole-body potassium is measured, whereas the sodium exchangeable with ^{24}Na is about 80

to 85% of the total body sodium. The specific activity of potassium or sodium in body fluids reaches a maximum 18 to 24 hours after the injection of a tracer dose of ^{42}KCl or $^{24}NaCl$ and remains constant for approximately 24 hours.

Exchangeable Potassium. According to the procedure of CORSA (1950), approximately 100 μCi of ^{42}KCl are given by i.v. injection. Urine is collected for 24 hours for the determination of ^{42}K-excretion. After 23, 24 and 25 hours, potassium (^{39}K) is measured in a fresh urine portion by flame photometry and the ^{42}K-activity is counted; the specific activity of urinary potassium is calculated from these two values. The exchangeable potassium can be calculated from this specific activity and from the radioactivity remaining in the body by the following formula:

$$\text{exchangeable potassium} = (^{42}K \text{ injected} - ^{42}K \text{ excreted}) \times \frac{^{39}K}{^{42}K}.$$

Normal values according to DEMANET (1958):

Men: 53 ± 5 mEq/kg;
Women: 42 ± 7 mEq/kg.

Exchangeable Sodium. According to FORBES (1951), the determination is performed by practically the same procedure as the one used for the determination of exchangeable potassium. About 100 μc of $^{24}NaCl$ are injected and the excretion in the 24-hour urine is determined. After 24 hours, the sodium concentration (^{23}Na) is determined by flame photometry and ^{24}Na is counted not in the urine, but in the serum.

Normal values according to DEMANET (1958):

Men: 43 ± 5 mEq/kg;
Women: 39 ± 5 mEq/kg.
