VIII. The Adrenal Medulla

A. LABHART

With Contributions by
CHR. HEDINGER, G. KISTLER, G. TÖNDURY, and W. ZIEGLER

A. Historical Dates

1805 CUVIER differentiated medulla and cortex of the adrenal gland.
1868 FRÄNKEL described the case of an adrenal tumor with pressor crises.
1892 BERDEZ discovered a chromaffin tumor of the adrenal.
1894 Two groups, OLIVER and SCHÄFER and SYZMONOWICZ and CYBULSKI, independently discovered the existence of pressor substances in adrenal extracts.
1898–1905 FÜRTH and ABEL, TAKAMINE and ALDRICH, and STOLZ and DAKIN isolated adrenaline, established its structural formula and synthesized it.
1901 BLUM described adrenal diabetes.
1922 First detailed clinical report of a pheochromocytoma by LABBÉ, TINELLE, and DOUMER.
1927 First successful surgical removal of a pheochromocytoma by MAYO.
1945 HOLTZ, CREDNER, and KRONENBERG discovered noradrenaline.
1957 ARMSTRONG detected vanilmandelic acid as a metabolite of catecholamines.
1957 AXELROD described the inactivation of catecholamines by O-methylation.

B. Embryology and Histology

G. TÖNDURY and G. KISTLER

Embryology. In the human embryo about 11–12 mm in length (early 6th week), neuroblasts which have separated from the primitive ganglia of the celiac plexus come into contact with the medial portions of the adrenocortical primordium (see also Chap. VII, p. 285). At the end of the 6th week, (embryonic length about 14 mm), these sympathetic cells begin to invade the primitive adrenal cortex. As early as the 12th week, they are found to contain small amounts of norepinephrine, and at about 22 weeks the chromaffin reaction (see below) becomes positive. By this time, most of the sympathetic neuroblasts have accumulated in the central portions of the developing gland where they become grouped in cords and clusters of varying size. Immigration of neuroectodermal elements into the fetal adrenal gland continues, however, throughout the prenatal period. The majority of them differentiate into *specific medullary cells*; a small number, however, develop into *sympathetic ganglion cells*, which are scattered singly or in small groups throughout the adrenal medulla.

Histology. The medullary tissue is usually not well preserved in routine necropsy material. When it has been fixed under favorable conditions, however, it is found to be composed of polymorphic epitheloid cells with a clear, rounded nucleus and a large number of minute cytoplasmic granules. In specimens fixed in solutions containing chromium salts, these granules stain specifically brownish yellow. This *chromaffin or pheochromic reaction* is thought to be due to oxidation and polymerization of the *catecholamines* epinephrine and norepinephrine (adrenaline and noradrenaline) within the granules. Since these cytoplasmic organelles disrupt rapidly after death, the cytoplasm of the medullary cells of routine specimens is usually stained diffusely.

The *chromaffin cells* can be histochemically divided into two distinct classes. Those producing *epinephrine* contain large amounts of acid phosphatase and stain intensely with azocarmine. However, these cells do not react with silver salts and are not autofluorescent. In contrast, the medullary cells which synthesize *norepinephrine* are argyrophilic and autofluorescent. They are less well stained with azocarmine and the reaction for acid phosphatase is negative. After double fixation with glutaraldehyde and osmium tetroxide, these two types of pheochromic cells can also be distinguished by electron microscopy. The main mass of the medullary parenchyma consists of cells with moderately electron-dense specific granules. In the rat, these membrane-bound granules have an average diameter of 210 nm and contain epinephrine.

Small clusters of cells, whose granules display a stronger affinity for osmium, are scattered throughout the adrenal medulla, mainly at the periphery of the epitheloid cords. These "dark" cells are thought to synthesize exclusively or predominantly norepinephrine. Their granules are larger than those of the "clear" cells (average diameter in rat 260 nm). In both cell types, the Golgi complex is located in a juxtanuclear position. Its vesicles and cisternae frequently contain electron-dense material which is thought to represent a precursor of the content of the granules. The short cisternae of the rough endoplasmic reticulum are often found to accumulate at the periphery of the cell, together with numerous elongated mitochondria.

The medulla receives blood which has traversed the cortex of the adrenal gland. A network of variably sized capillaries is intimately associated with the chromaffin cells from which it is separated by the corresponding basal laminae and a narrow interstitial space. In their thinnest parts, the endothelial cells display numerous fenestrae. Within the framework of reticular fibers between the epitheloid medullary cords, *sympathetic ganglion cells* occur singly or in small groups. Their pericarya contain moderate amounts of Nissl substance. Numerous preganglionic, sympathetic nerve fibers originating in the celiac plexus penetrate the connective tissue capsule of the adrenal gland and reach the medullary tissue by traversing the cortex. According to STÖHR (1951), every chromaffin cell is in direct contact with nerve endings. When stimulated, the medullary cells seem first to release the content of the granules into the cytoplasmic substance, and the catecholamines then reach the inner surface of the cell membrane by some unexplained pathway, where they can be recognized as small, strongly osmiophilic masses. They are thought to pass through the cell membrane partly in the form of small, cell membrane-bound vesicles (ELFVIN, 1968). In rat, the release of epinephrine from the clear medullary cells can be stimulated by subcutaneous administration of insulin. Six hours after the injection, the granules of the epinephrine-producing cells are found to have increased in size and their content is reduced to a small, electron-dense residual body. In contrast, no morphological changes are observed in the norepinephrine-synthesizing dark cells (MOPPERT, 1966a). In hamster, thirty minutes after an injection of H^3-dopa the concentration of radioactivity in the clear cells is significantly higher than that in the dark cells. Four hours later, however, the activity appears to be evenly distributed over both cell types. The epinephrine-producing cells thus seem to have a more rapid turnover rate, despite the extra methylation step which is necessary to convert norepinephrine to epinephrine. This observation also indicates that the clear cells which store epinephrine are able to perform the whole of the synthesis process of this hormone and that the norepinephrine produced in the dark cells is not transferred to the clear cells for further methylation (ELFVIN, APPELGREN, and ULLBERG, 1966).

C. Biochemistry

1. Chemistry, Site of Formation, Synthesis and Metabolism

Epinephrine and norepinephrine are the hormones of the adrenal medulla. They are called catecholamines because of the pyrocatechol in their basic structure. Dopamine, their immediate precursor, is also a catecholamine and is probably of physiological importance in the metabolism of the brain stem. Norepinephrine is the transmitter substance of the sympathetic system and probably also acts as a transmitter at the synapses of the central nervous system. Catecholamines are formed in the brain, chromaffin tissues, adrenal medulla, and also in the nerve endings of the sympathetic nervous system which are present in almost all tissues. Epinephrine is formed only in chromaffin tissue. Apart from the adrenal medulla, epinephrine is also found in groups of cells lying in the paraganglia scattered in the retroperitoneal tissues. These groups of cells decrease in numbers with increasing age. Catecholamines are formed from tyrosine, the basic amino acid, which circulates in the blood in a concentration of 1–1.5 mg/100 ml and which is taken up by brain, sympathetic and chromaffin cells by an active transport mechanism (Figs. 1 and 2). Tyrosine hydroxylase catalyzes the formation of dopa from tyrosine in the presence of different cofactors and is most probably located in the mitochondria. Amino acid decarboxylase, a nonspecific enzyme found in the free form in the cytoplasm converts dopa into dopamine which is itself oxidized into norepinephrine in the chromaffin granules by the copper-containing enzyme, dopamine-β-oxydase. In the adrenal medulla, most of the norepinephrine leaves the granules again and passes into the cytoplasm. There it is methylated at the N-atom with a methyl group from S-adenosyl methionine by the action of phenyl-ethanol-amine-N-methyltransferase, and is stored again in the granules in the form of epinephrine. The topography of the medulla within the adrenal cortex suggests

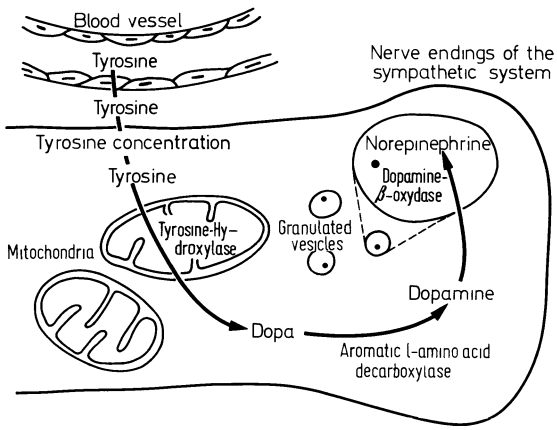

Fig. 1. Intracellular movements of substrates during the biosynthesis of norepinephrine. (After WURTMANN, 1965)

that the enzyme activity of phenyl-ethanolamine-N-methyl-transferase is regulated by dexamethasone or cortisol (WURTMANN, 1966; HARRISON, 1968). The action of glucocorticoids is blocked by puromycin and actinomycin D.

It is improbable that catecholamines other than epinephrine and norepinephrine (isopropyladrenaline, sympathol) play any role as medullary hormones and that the traces of dopamine in the medulla are of any significance. Tyrosine-hydroxylase, and perhaps dopamine-beta-oxydase, regulate the limiting steps in the formation of catecholamines. Dopamine and norepinephrine are formed throughout the sympathetic nervous system. Norepinephrine is also produced in organs with extensive sympathetic innervation, such as the heart. Less epinephrine is excreted in Addison's disease and after bilateral adrenalectomy, whereas norepinephrine excretion remains unchanged. In the human, epinephrine secretion is renormalized years after total adrenalectomy, indicating that inactive chromaffin tissue must be capable of being reactivated (HENKING, 1965). Norepinephrine excretion diminishes after sympathectomy. From this it can be concluded that norepinephrine is formed both in the sympathetic nervous system and in the adrenal medulla, whereas epinephrine is produced only in the medulla and in paraganglia.

2. Storage

Catecholamines are stored within the cells of the adrenal medulla in granules bound to the membrane. These granules are smaller than mitochondria and can be separated from them by centrifugation. About a third of the granules are accounted for by catecholamines, another third by adenosine triphosphate (ATP), and the last third by protein. The molar ratio of catecholamines to ATP is 4 : 1. Catecholamines appear to be bound within the granules in a chemically unaltered but inactive form. Granules similar in appearance but considerably smaller in size and containing only norepinephrine and neither epinephrine nor dopamine are found throughout the entire sympathetic nervous system. The granules form norepinephrine from dopamine, store it, and, in addition, can absorb and inactivate circulating norepinephrine.

3. Release

Catecholamines are inactive as long as they are within the granules. They can be released from the granules by physical, chemical, and neural means. The sympathetic nervous system continuously secretes a small amount of norepinephrine into the blood. Stimulation of the sympathetic nervous system results in the release of much increased amounts. The loss of ATP from the granules is increased by the same factor at the same time. There seem to be two pools of catecholamines in the granules. In one pool, there is a rapid turnover (half-life 2 hours); its catecholamines content is released by the action of tyramine or other sympathomimetic amines and nerve stimulation and can be inactivated by O-methylation. The turnover in the second pool is slow (half-life 24 hours); these catecholamines are not easily mobilized; they are stored in the pool and metabolized by monoamine oxydase (MAO). The adrenal medulla can be regarded as a special type of synapse which conducts the post-ganglionic transmitter substance to the end organ via a humoral instead of a neural route. The liberation of catecholamines which can be induced by insulin hypoglycemia occurs via the central nervous system. In addition, sympathomimetic amines, such as ephedrine and tyramine, cause direct displacement while ATP remains in the granules. Reserpine finally breaks down the granules (see p. 422).

Epinephrine and norepinephrine are not released in direct response to neural impluses in chromaffin tissue and in post-ganglionic fibers of the sympathetic system. Acetylcholine is liberated, which makes the membrane of the fiber permeable to calcium ions. Calcium ions enter the fiber and release noradrenaline from the granule (BURN, 1967). Nicotine and histamine probably also act in the same way as acetylcholine. In the sympathetic nervous system, only norepinephrine is liberated, whereas the medulla releases both epinephrine and norepinephrine into the adrenal vein. It is not known whether the medulla secretes more of

one or the other of the two hormones according to the releasing stimulus. In the human, the adrenal medulla contains between 70 and 90% epinephrine, whereas only traces of dopamine are present.

Certain organs with extensive sympathetic innervation, such as the spleen and myocardium, can absorb considerable amounts of norepinephrine from the blood and store them in the sympathetic nerve endings. Denervation reduces the storage ability and increases the sensitivity of these organs to norepinephrine. The uterus, where catecholamines can be stored outside the nerve-endings, is an exception. Norepinephrine is also formed in the brain and is found in higher concentrations particularly in the region of the brain stem. Parkinson's syndrome is associated with a deficiency of dopamine in the corpus striatum.

4. Transport

It is not yet certain whether catecholamines always circulate in the free form or are also present in the plasma in the bound form. Norepinephrine is stored by thrombocytes *in vitro*, but circulating thrombocytes contain only traces of norepinephrine. The half-life of catecholamines in the blood is about 10 min.

5. Breakdown and Excretion

Inactivation of catecholamines occurs mainly through reabsorption into the granules of the sympathetic nerve endings or breakdown. Catecholamines from the rapid-turnover pool can be inactivated to a minor extent by O-methylation by the enzyme catecholamine-O-methyltransferase, which is found mainly in the liver and kidneys. Normetanephrine and metanephrine are thus produced. These compounds are partly excreted unchanged and partly metabolized by monoamine oxidase to vanilmandelic acid and excreted in this form. Only traces of conjugated catecholamines are excreted. Catecholamines in the slow-turnover pool are first deaminated, and then excreted partly as dihydroxy-mandelic acid and dihydroxyphenyl glycol; the rest are O-methylated and excreted as vanilmandelic acid (VMA).

Only a small percentage of catecholamines (3–7%) appears unchanged in the urine. About 40% is excreted as vanilmandelic acid, and another 40% as normetanephrine or metanephrine, most of these two latter compounds appearing as the glucuronide or the sulfate in the urine. A further 5% is excreted as 3-methoxy-4-hydroxyphenyl glycol. 1% of free and 1% of conjugated 3,4-dihydroxy mandelic acid are excreted as a direct non-methylated product of monoamine oxidase (Fig. 2). 95% of radioactive catecholamines is excreted in the urine within 72 hours. Thus, the VMA excretion is a direct reflection of the total production of catecholamines but is no measure of the norepinephrine and epinephrine acting at the receptors.

D. Pharmacological Influence on Storage, Release, and Inactivation of Catecholamines

Cocaine, *imipramine* and *chlorpromazine* block uptake and binding in the sympathetic nerve endings and thus greatly potentiate the actions of epinephrine and norepinephrine. Release from the active pool is promoted by certain sympathomimetics (*ephedrine*, *amphetamine*). Others act at the same time on α-receptors (phenylephrine, epinine); *tyramine* probably acts via the oxidation product octopamine, a substance which displaces norepinephrine from the active pool.

Reserpine causes mobilization by dissolving the storage granules. Both pools are emptied in the brain and in organs with sympathetic innervation. The catecholamines, however, are deaminated at the same time and thus become inactive.

Release from tissue stores is blocked by bretylium, guanethidine and ganglionic blocking

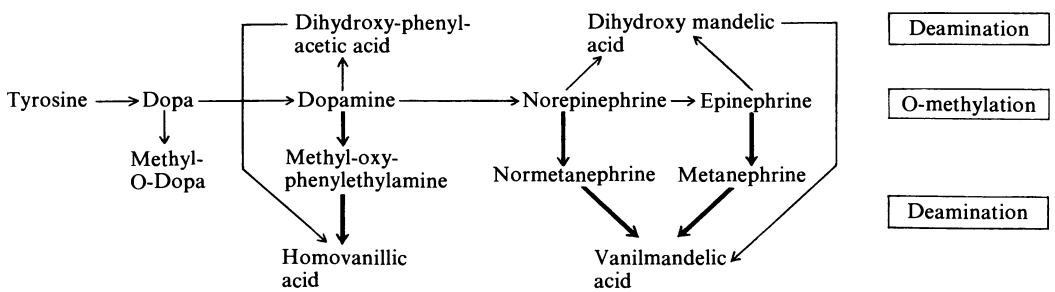

Fig. 2. Biosynthesis and breakdown of catecholamines in man

agents (nicotine), which inhibit particularly the nervously induced liberation. Monoamine oxidase inhibitors interfere with release by their effect on the metabolism of norepinephrine in the nerve cells. False transmitter substances such as metaraminol, α-methyl-dopa, and α-methyl metatyrosine competitively occupy the storage sites in the granules, reducing the norepinephrine content of the tissue. The activity of the sympathetic nervous system is thus diminished. Amino acids cross the blood-brain barrier whereas amines cannot. MAO inhibitors cause accumulation of octopamine formed from tyramine; the former substance can be stored in the granules as a false transmitter and be released by appropriate stimuli.

E. Physiology of the Adrenal Medullary Hormones

1. Actions on Organic Systems

Epinephrine and norepinephrine in physiologic doses have some similar and some antagonistic effects. Unphysiologic overdosage can change these actions.

a) Circulation

Epinephrine increases the pulse rate and cardiac output and thus the systolic blood pressure, whereas it decreases peripheral resistance. Norepinephrine has no effect on the cardiac output, induces bradycardia, and increases peripheral resistance with a rise in systolic and diastolic blood pressure. Unphysiologic doses of epinephrine are required before a rise in peripheral resistance and diastolic blood pressure is produced.

The circulation in the organs is influenced in different ways by the two hormones. Circulation in the skeletal muscle is promoted by epinephrine and inhibited by norepinephrine. Both catecholamines inhibit the blood supply of the splanchnic area and mucosa. Both medullary hormones dilate coronary vessels. The increase in the oxygen demand of the heart caused by epinephrine is greater than would be expected from the increase in pulse rate. The β-receptors of the myocardium (see p. 424) assume positive inotropic actions regulating the ability of the heart to respond to increased functional demands (EPSTEIN, 1966).

b) Musculature

Epinephrine enhances or inhibits the contraction of smooth muscle depending on the location. Epinephrine has a constrictor effect on the dilator muscle of the pupil, on the uterus in the human and cat, and on the erectores pilorum. In contrast, bronchial muscles relax and bronchi dilate; gastrointestinal function is arrested, and the bladder is usually relaxed.

c) Nervous System

Epinephrine, in contrast to norepinephrine, acts on the central nervous system, producing restlessness and a feeling of "uneasy expectancy".

d) Renal Function

Epinephrine and norepinephrine have similar actions on the kidneys. They affect renal hemodynamics and are thus probably an indirect cause of changes in renal function. (Review by WESSON [1961], with tabulated summary of the literature on investigations in man.)

Administration of small doses of norepinephrine (2–4 μg/min) leads to constriction of the vas efferens and reduces renal plasma circulation, whereas filtration initially remains unaltered or even increases slightly due to the rise in pressure (WESSON, 1961). Filtration remaining unchanged in the presence of a decreased plasma flow results in an increase of the filtration fraction. Larger doses (10–14 and 15–44 μg/min) also constrict the vasa afferentia so that filtration is also diminished (PULMAN, 1952; KING, 1956). Total renal vascular resistance increases, particularly that of the afferent part (KING, 1956). Certain influences on electrolyte excretion observed in both man and animals are probably due to hemodynamic changes. Thus, a diminished renal circulation always results in a rise in the reabsorption of sodium (WHITE, 1950; MUELLER, 1951). This is substantiated by the fact that epinephrine and norepinephrine produce a reduction in sodium excretion. Infusion of norepinephrine always gives rise to albuminuria which is due either to the increased hydrostatic pressure in the glomerula or to the ischemia (KING, 1956). The flow of urine remains unchanged with hydration (NICKEL, 1954), but usually decreases with hydropenia (KING, 1956). Diuresis always arises when norepinephrine ceases to act.

2. Action on Carbohydrate and Fat Metabolism

Epinephrine mobilizes energy reserves in the liver, muscle, and adipose tissue. Norepinephrine has this effect only in adipose tissue.

Epinephrine exerts a glycogenolytic action in the liver and muscle by activating phos-

phorylase by the formation of cyclic adenyl monophosphate (see p. 11).

Whereas glucose-6-phosphate liberated in the liver can leave the liver as glucose, it is broken down in the muscle by glycolysis to lactic acid, which is used or released into the blood stream.

Epinephrine and norepinephrine have a lipolytic action on adipose tissue, mobilizing fatty acids and glycerine.

Release of epinephrine or an injection of epinephrine results in a rise in blood sugar, lactic acid, and free fatty acids. Epinephrine and norepinephrine inhibit the release of insulin in response to glucose (see p. 748). Insulin release increases during α-receptor blockade (ILLIG, 1971).

3. General Action on the Organism

During rest and normal activity only norepinephrine is secreted as a transmitter substance in the sympathetic nervous system and for the regulation of blood pressure.

In emergency situations, it is predominantly epinephrine which is released from the adrenal medulla, converting the trophotropic phase into the ergotropic phase, and preparing the organism for immediate action (HESS, 1948). The divergent effects of epinephrine on various organs make sense when BRUECKES' "Notfallreaktion" or CANNON'S "emergency reaction" is kept in mind. The function of organs essential for rapid defense is promoted (eyes, lungs, heart, central nervous system), while the function of organs associated with building (gastrointestinal tract) is arrested. At the same time, necessary fuel, glucose and free fatty acids are set ready for the forthcoming function of the muscles – fight or flight.

4. Regulation of the Secretion of Catecholamines

It is probable but still disputable that the adrenal medulla releases a constant basic amount of catecholamines which cannot be suppressed; denervated adrenal medulla can still secrete small amounts of epinephrine.

In addition, there is a feedback control for catecholamine secretion, which works by neural and humoral routes. Every rise in blood pressure leads to suppression of catecholamine release via the carotid sinus, aortic arch reflex, and the central nervous system. But also, a rise of the epinephrine concentration in the region of the carotid sinus or in the CNS without a rise in blood pressure to a certain level inhibits the secretion of epinephrine. The secretion of catecholamines varies within certain limits in physiologic conditions. In states of shock or hypoglycemia, the inhibitory action can only come into effect with higher concentrations (MALMEJAC, 1964). This mechanism is also controlled by a regulating circle with negative feedback and variable adjustment.

The reader is referred to p. 150 for a discussion on the connection between the adrenal medulla and thyroid function, and for information on the connection between adrenal cortex and medulla to HARRISON (1968), and WURTMAN (1971).

5. Mode of Action and Pharmacological Influence on the Actions

It is assumed that the biological activity of catecholamines is due to interaction of the catecholamine molecules and specific receptors of the end organ. The morphology of these receptors has not yet been defined, nor have they been isolated. The concept is based on indirect pharmacological evidence.

On the basis of pharmacological experience we distinguish between α- and β-receptors. α-Receptors receive mainly the stimulatory actions of the catecholamines (vascular constriction [skin, kidney], conduction in the myocardium, uterine contraction, contraction of the iris dilator) and are inhibited by ergotamine and its derivatives as well as by phentolamine and phenoxybenzamine. Inhibitory actions of catecholamines affect predominantly the β-receptors (vascular dilatation in muscle, uterine relaxation, relaxation of bronchial muscle). They are competitively blocked by propanolol, practolol, alprenolol and oxprenolol (Tables 1 and 2). Propranolol and newer compounds are suitable for clinical use. Blocking of the receptors leads to increased concentrations of catecholamines in the circulation. Thus, β-blockers intensify the action of α-receptors, and α-blockers that of the β-receptors. The chemical structure of β-blocking agents is similar to that of the catecholamines. The action of iso-propylnorepinephrine on β-receptors is particularly marked, and the action of epinephrine is more pronounced than that of norepinephrine.

The receptors of the metabolic processes of glycogenolysis and lipolysis vary to some extent in different species. Lipolysis fails to occur after β-blockade in man. Glycogenolysis in the myocardium and skeletal muscle is always suppressed by β-blocking agents.

As in many other hormone actions, the receptors seem to act via the "second messenger", cyclic AMP. Catecholamines react with the adenylcyclase system, a part of the cell membrane, to form cyclic AMP, which releases

Table 1. Classification and reactions of various end organs to adrenergic stimuli. (After EPSTEIN, 1966)

End organ	Type of receptor	Response
Heart:		
Sinoauricular node	β	Increase in pulserate
Atrioventricular node	β	Increase in conduction velocity and shortening of the functionary, refractory time
Atrium	β	Increased contractability
Ventricle	β	Increased contractability
Smooth muscle:		
Blood vessels of skeletal muscle	1. α 2. β	1. Contraction (constriction) 2. Relaxation (dilatation)
Blood vessels of the skin and mucosa	α	Contraction
Bronchial muscle	β	Relaxation
Gastro-intestinal tract:		
Motility:		
Stomach	β	Decrease
Gut	α and β	Decrease
Sphincters:		
Stomach	α	Contraction
Gut	α	Contraction
Bladder:		
Detrusor	β	Relaxation
Trigonum and sphincter	α	Contraction
Eyes:		
Radial muscle of the iris	α	Contraction (mydriasis)
Ciliary muscle	β	Relaxation (negative accommodation)

Table 2. Functions connected with adrenergic receptors. (From LANGEMANN, after R. P. AHLQUIST, p. 380, Tab. 27-1; in V. A. DRILL: Pharmacology in Medicine, 2nd ed., New York: McGraw-Hill 1958)

α-Receptor; stimulatory actions	β-Receptor; principally inhibitory actions
Vascular constriction (skin, kidney etc.)	Vascular dilatation (skeletal muscle etc.)
Ectopic myocardial excitation	Increase in heart rate and cardiac output
Contraction of splenic capsule	Uterine relaxation (rat, non-gravid cat, human)
Uterine contraction (rabbit, dog, man etc.)	Relaxation of bronchial muscle
Contraction of iris dilator (mydriasis)	
Contraction of nictitating membrane	
Intestinal relaxation	
Pilomotor contraction	
Glycogenolysis, fat mobilization	
? Formation of adrenocorticotropin	
? Ganglionic blocking	
Blocked by usual adrenergic blocking agents	Blocked by dichlorisoproterenol

specific reactions in the cell (SUTHERLAND, 1965, 1968). It has been demonstrated that catecholamines cause an increase in cyclic AMP in the heart, liver, skeletal muscle, and adipose tissue. Cyclic AMP can produce some effects similar to those of the catecholamines. We are now advancing some way towards an understanding of the principles of molecular biology (BELLEAU, 1966).

Although the physiological significance of dopamine is not fully explained, it also exerts pharmacological actions independent of the α- and β-receptors. Thus, the vasodilatatory action of dopamine on mesenteric and renal blood vessels is not inhibited by α- or β-blockers.

α-Adrenergic substances increase peripheral resistance, whereas β-adrenergic substances can be dangerous in shock – in spite of positive inotropic cardiac action – due to the fall in blood pressure. Dopamine in a dosage of 0.5 to 10 μg/min, however, increases cardiac output, renal blood supply, and sodium excretion in healthy subjects and in patients with cardiac insufficiency (MACCANNELL, 1966; MCDONALD, 1964).

F. Hypofunction

Failure of the adrenal medulla has no clinical consequences. Even after adrenalectomy, epinephrine excretion is only temporarily suspended and norepinephrine excretion is not significantly reduced. This suggests that epinephrine must be formed by paraganglionic tissue as well. The reactions of Addisonian patients with primary cortical atrophy are no different than those of patients with Addison's disease due to tuberculosis or after adrenalectomy.

After adrenalectomy, insulin hypoglycemia still results in a rise in plasma epinephrine, albeit delayed and attenuated. Providing there is an adequate glycogen reserve in the liver, the blood sugar shows the same response to insulin in patients with Addison's disease as in healthy subjects.

However two clinical functional disorders are known, one affecting the adrenal medulla and the other the autonomic nervous system.

1. Idiopathic Hypoglycemia in Children (McQuarrie, Zetterström)

Hypoglycemic states with disturbed consciousness and fits arise in children up to the age of 6 years. There are no signs of epinephrine release and the condition is often associated with defects in intelligence and growth. Familial incidence has been described. Epinephrine excretion lies within normal ranges but there is no rise in response to insulin hypoglycemia as in the normal subject, and cortisol levels in the plasma do not usually rise either, whereas the level of growth hormone does (Tietze, 1972). The condition is probably not due to impaired synthesis of epinephrine or a defect in the medulla, but rather to a failure of the hypothalamus to register the hypoglycemia, so that there is no neurally-induced release of epinephrine or neurohormonal release of cortisol. The condition resolves spontaneously after the 6th year of life.

ACTH, glucocorticoids or ephedrine are recommended for treatment. They result in the liberation of epinephrine, but the success of this form of treatment is equivocal.

2. Idiopathic Postural Hypotension (Orthostatic Hypotension, Autonomic Insufficiency)

This condition affects elderly men more than any other group, and consists in the progressive fall of systolic and diastolic blood pressure on rising from the horizontal to the upright position. Sometimes hypoglycemia is an additional symptom, but there is no tachycardia, pallor, or sweating. Other disorders of the sympathetic nervous system, such as anhidrosis and impotence, are often present. These patients become invalids since they become unconscious in the upright position and can only move around in a stooping posture.

In the healthy subject getting up from the horizontal position, norepinephrine is liberated to maintain the blood pressure by counteracting the stagnation of blood in the lower half of the body by constriction of the arterioles and veins. This reflex mechanism is disturbed in idiopathic postural hypotension. The excretion of catecholamines in the urine is sometimes reduced but there is never, as in the normal subject, a distinct rise in plasma norepinephrine on rising from the horizontal to the upright position. The reflex release of epinephrine to hypoglycemia is also absent in these patients. The response to exogenous norepinephrine is not reduced but is even elevated in some cases. The disturbance probably lies in the hypothalamus, in spinal sympathetic centers or in efferent peripheral sympathetic fibers. Recent investigations suggest a connection with degenerative olivo-ponto-cerebellar atrophy (Mark, 1969).

Aldosterone excretion is reduced in these patients, and is only inadequately stimulated by salt withdrawal, ACTH, or angiotensin II. Loss of salt contributes to the circulatory symptoms. This reduction in aldosterone production is more probably a result of chronic hypostimulation than of a disturbance in synthesis in the adrenal cortex (Slaton, 1967).

The differential diagnosis includes vasovagal syncope in which the norepinephrine release is not diminished, but arteriolar constriction is overwhelmed by the strong vagal influence. A *secondary* type of postural hypotension, in contrast to the idiopathic form, is found in association with diabetic neuropathy and other neurological disorders, and with pharmacological blocking of the sympathetic nervous system (guanethidine, ganglion blockers, neuroplegics, monoamine oxidase inhibitors). The secondary form is also found in amyloidosis, adrenocortical insufficiency and hypokalemia, where there is no vasomotor response to norepinephrine. Treatment of idopathic postural hypotension consists of mechanical measures (bandages, elastic stockings, pressure suits of elastic material made to measure). Drugs with vasoconstrictory actions can be used, but they are usually only effective for a short time. Large doses of mineralocorticoids such as 9-α-fluorocortisol appear to work by producing temporary hypervolemia and sensitization of the arterioles.

3. Familial Dysautonomia

(Riley-Day Syndrome)

This is an inherited disorder of the sensory nervous system occurring in the Jewish race. It is also associated with a disturbance in the liberation of catecholamines, but only certain stimuli seem to be involved.

The disorder becomes noticeable during infancy, presenting as dysphagia and recurrent bronchopneumonia. Defective secretion of tears and disturbed motor coordination later become obvious. Orthostatic hypotension is sometimes the predominant feature, but hypertensive crisis and hyperhidrosis can also occur. At the same time, there is hyposensitivity to hypercapnia and hypoxia, and hypalgesia in some parts of the body.

The best way of diagnosing the condition is to inspect the tongue: there are no taste buds and the absence of fundiform papillae is obvious at first sight (DANCIS, 1966).

The orthostatic test reveals that the release of norepinephrine is inadequate in these children. The reaction to insulin is normal since epinephrine release is normal. The adrenal medulla contains an excessive quantity of catecholamines. Excretion of homovanillic acid is increased, whereas excretion of vanilmandelic acid is reduced, suggesting a deficiency of dopamine-β-hydroxylase. In one study, plasma dopamine-β-hydroxylase was in fact found to be decreased, and in one subgroup there was no dopamine-β-hydroxylase at all (WEINSHILBOUM, 1971). Recently, a decrease in norepinephrine synthesis and a shift towards dopamine metabolism has been proved (GOODALL, 1971).

4. Adrenal Medullary Insufficiency in Severe Stress

After exposure to severe stress, such as extensive burns or γ-radiation of the whole body, the excretion of epinephrine and the content of epinephrine in the adrenal medulla may be found to be decreased. It is not known whether these findings are significant within the grave clinical state.

G. Hyperfunction: Pheochromocytoma

1. Incidence

Pheochromocytomas are considered rather uncommon, but data vary widely. Thus, the incidence is variously given as between 1 in 3000 and 1 in 40000 autopsies. The incidence, however, is definitely much higher. The 25274 postmortems performed between 1945 and 1958 at the Pathology Institute of the University of Zurich revealed 23 pheochromocytomas. This gives an incidence of about 0.1% (Table 3). Pheochromocytomas were found in 66 of 12713 patients tested at the Mayo Clinic.

Table 3. Frequency of various tumors arising from the adrenal medulla, obtained in the Pathology Institute of the University of Zurich between 1948 and 1952

Total number of postmortems	8413
Sympathogoniomas	10
Pheochromocytomas	8
Ganglioneuromas	2

Pheochromocytomas make up two-fifths of medullary tumors and are almost as common as sympathogoniomas. SMITHWICK (1950) found 6 pheochromocytomas in 1200 patients (i.e. in 0.5% of cases) in whom he performed sympathectomy for hypertension. Since these tumors appear to be quite common, the possibility of a pheochromocytoma must now be considered in every young patient with hypertension. Pheochromocytomas arise most frequently between the 20th and 50th year but are sometimes present even at birth or appear during advanced age. Women and men are roughly equally affected. Familial incidence has been observed; then pheochromocytomas are multiple in 50% of cases. Neurofibromatosis is also present in 10% of cases. The combination of this disease with hypertension in particular must therefore prompt specific investigation for a pheochromocytoma. Combination with cerebellar angiomas, Hippel-Lindau syndrome, tuberous sclerosis, Sturge-Weber syndrome, Sipple syndrome and brachymetacarpal dwarfism occurs (Chap. XIV, see p. 900). Mixed tumors of the adrenal medulla and cortex occur in few cases. The incidence is sometimes familial and symptoms of Cushing's syndrome may sometimes be associated with these mixed tumors (MATHISON, 1969).

2. Localization

Pheochromocytomas are most often situated in the adrenals (80%), the right adrenal being more commonly affected than the left. Thus, 45% of pheochromocytomas are found in the right and 35% in the left adrenal. In 10% of the cases pheochromocytomas are bilateral, and the remaining 10% involve ganglia outside the adrenals, particularly in the abdominal region and less commonly in the thorax. GRAHAM presents the different localizations on the basis of findings in 204 cases (Table 4).

Table 4. Localization of pheochromocytomas in 213 patients. (After GRAHAM)

The total number of cases mentioned in this summary by GRAHAM does not agree with the 207 observations reported in his text, but in spite of this inaccuracy, a rough picture of the most common localizations can be obtained.

Unilateral pheochromocytomas		Bilateral pheochromocytomas	
Right adrenal	92	Both adrenals	19
Left adrenal	70	2 extra-adrenal tumors	3
Right, lumbar paravertebral	7	1 adrenal tumor on one side and 1 paravertebral lumbar tumor on the other side	1
Left, lumbar paravertebral	5		
Anterior to large abdominal vessels	4	Unknown localization	4
Zuckerkandel's organ	4		
Left, thoracic paravertebral	2		
Celiac ganglion	1		

3. Pathologic Anatomy

In necropsies, *hyperplasia* of the adrenal medulla has been found in patients with chronic circulatory stress and corresponding cardiac changes. Apparently medullary hyperplasia can also be produced by particular strain and hypertension in animal experiments (LIEBEGOTT, 1947). There have also been isolated reports of patients with symptoms similar to those caused by a pheochromocytoma, in whom removal of the hyperplastic medulla brought about a definite cure (MONTALBANO, 1962).

Tumors. Cysts and mesodermal tumors characteristic of the adrenal have already been mentioned briefly under cortical tumors. From the endocrinological point of view, the pheochromocytoma is the most important medullary tumor. Other tumors occurring in the medulla are: neuroblastomas (sympathicogoniomas, sympathicoblastomas, pheochromoblastomas) and ganglioneuromas. These tumors sometimes secrete catecholamines without causing endocrine symptoms (see p. 435).

Sympathicogoniomas are composed of cells corresponding morphologically to the most primitive developmental phase of the series of cells giving rise to differentiated ganglionic cells of the autonomic nervous system and to pheochromocytes. The tumor cells are small, look like lymphocytes, and contain a very dense, chromatin-rich nucleus surrounded by quite a small fringe of cytoplasm. These tumors develop almost exclusively in the adrenals, and 80% of cases occur in children during the first $2^1/_2$ years of life (KARSNER, 1950). They metastasize very rapidly in the liver and skeleton.

Cells of the next developmental phase are termed as sympathoblasts or pheochromoblasts, according to whether they represent the developmental series of sympathetic ganglionic cells or pheochromocytes. Tumors are correspondingly interpreted as *sympathicoblastomas* (sympathoblastomas) or *pheochromoblastomas*. Often, however, tumors of this developmental stage are simply termed as *neuroblastomas*, although this term also covers sympathicogoniomas in English and American usage (SYMINGTON, 1969). Sympathicoblastomas are rather better encapsulated than sympathicogoniomas, and are therefore less malignant. Cell differentiation is further advanced.

Ganglioneuromas and *pheochromocytomas* correspond to the highest phase of development. Some ganglioneuromas are malignant, and are termed as malignant ganglioneuromas or ganglioneuroblastomas. The same is true of pheochromocytomas, but the single term malignant pheochromocytomas has been accepted for these tumors. The term paraganglioma is used for pheochromocytomas arising from extra-adrenal tissue. This term is not completely explicit, since it is also used for tumors of the chemoreceptive organs, which are now also called nonchromaffin paragangliomas or chemodectomas to allow better differentiation.

Pheochromocytomas which cause clinical symptoms are usually at least as large as a cherry. In some cases, however, they have a diameter of several centimeters, and they exceptionally reach a weight of more than 1 kg. Small tumors the size of a pea and a few millimeters at the most in diameter seem to produce no endocrine symptoms. The tumors are usually distinctly encapsulated, especially the larger types, and round in shape. Remains of adrenocortical tissue may also be contained within the capsule. The cut surfaces vary in color between gray and brown and are often darkly pigmented. Cysts containing a brown liquid are sometimes dispersed throughout the tumor. Necroses and hemorrhage are not uncommon. If pheochromocytomas are put in colorless fixatives, such as formalin, the fluid usually assumes a typical dark brown color within a few days, allowing a tentative diagnosis of pheochromocytoma.

Histological section of these tumors reveals cell nests embedded in fibrous tissue with a rich

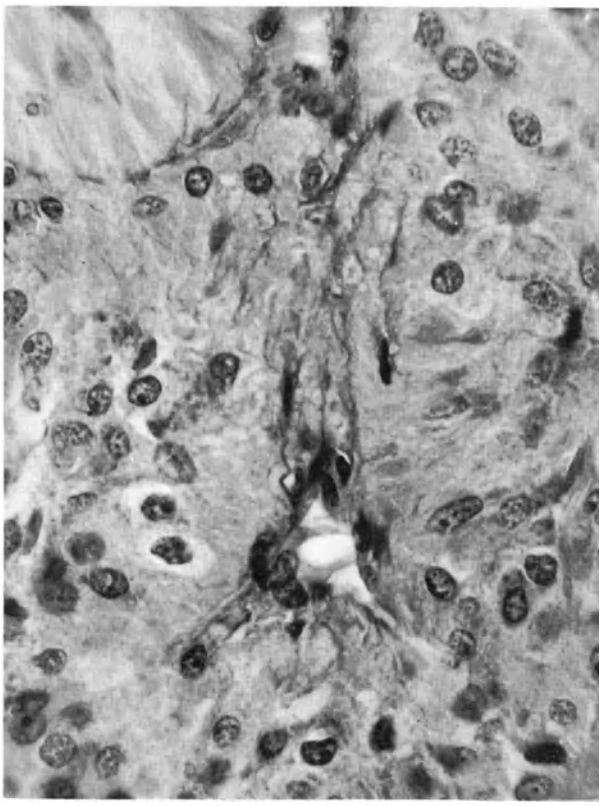

Fig. 3. Pheochromocytoma, MB 12871/55, 47-year-old man. H-E staining; × 450

capillary network, reminiscent of normal medullary tissue. The cells are usually large and polygonal. The outline is usually quite indistinct (Fig. 3). The cytoplasmic borders are acidophilic, slightly granulated, and contain pigment devoid of iron. Multinuclear cells are quite common, but mitoses are infrequent. Occasionally, the cells are better differentiated and possess clear cytoplasmic borders, producing a honeycomb effect, or quite large amounts of fatty substances are deposited in the cytoplasm. A variable number of tumor cells can be impregnated with chromium salts. The cytoplasm and granula take up the stain and turn brownish yellow in color. Often only the cells lying on the periphery of the cell's nests show an affinity for chromium. This affinity is associated with the catecholamine content of the cells.

The morphology of malignant pheochromoblastomas can hardly be differentiated from that of benign tumors, except in cases where metastases can be demonstrated. These malignant tumors are uncommon, their incidence being only one tenth that of the benign tumors at the most. Polymorphia of the tumor cells is not decisive proof of malignancy, because definite nuclear and cellular polymorphia is often found in benign pheochromocytomas. This may be predominantly of a degenerative nature, however. Demonstration of metastases is essential for the diagnosis of malignancy.

Cardiac and vascular changes are responsible for the most important *secondary patho-anatomical symptoms*. Thus, hypertension leads to such signs as cardiac hypertrophy, vascular changes such as arteriosclerosis, arteriolosclerosis, and even arteriolonecrosis. Other features worth mentioning are myocardial changes such as myocarditis and myocardial fibrosis, which are interpreted as direct results of the endocrine activity of the pheochromocytoma. Renal infarcts have been described as characteristic by ZOLLINGER (1959). For tumor combinations with neurofibromatosis or thyroid tumors see Chap. VI, p. 232.

4. Clinical Picture and Symptoms

The symptom complex of pheochromocytomas includes: 1. paroxysmal hypertension, 2. persistent hypertension, and 3. metabolic symptoms, such as hypermetabolism, hyperglycemia and

glucosuria, and occasionally diabetes mellitus and hyperlipolysis.

Symptoms can occur in any combination. They may arise singly or sometimes be completely absent. In some cases hypertension leads to cerebral vascular accidents and the elevated O_2 requirement of the heart to myocardial infarctions. Unusual symptoms due to the particular localization (ureteral occlusion, renal arterial stenosis, abdominal pains) have frequently been described.

The symptoms allow only limited conclusions about the nature of the hormones being produced to excess, although tachycardia, increased metabolic rate and glucosuria are characteristic of overproduction of epinephrine. Extreme overdosage of norepinephrine can also produce these symptoms, however.

a) Paroxysmal Hypertension

Pheochromocytoma with paroxysmal hypertension is characterized by typical attacks which allow a fairly definite diagnosis.

The sudden acute rise in systolic blood pressure to 200–300 mm Hg, which is sometimes preceded by a sort of aura with blacking out, nausea, and pains in the extremities, is associated with signs and symptoms caused by the release of epinephrine; tachycardia with thready pulse, pallor, outbreak of sweating, tremor, anxiety and palpitations, headache, visual disturbances, pain and pressure in the upper abdomen, nausea, vomiting and dyspnea, paresthesia, diarrhea occurs in some cases, and occasionally epileptic seizures.

During an attack, leukocytosis of between 10000 and 30000 with lymphocytosis, glucosuria, and hyperglycemia can be detected. Although the skin is cool to the touch, body temperature, particularly rectal temperature, is raised due to stagnation of heat. Peripheral cyanosis and a condition reminiscent of Raynaud's phenomenon sometimes develop. The thyroid gland may become swollen. In severe cases, circulatory failure with pulmonary edema finally arises, with advanced cyanosis and collapse. Rhythmic disturbances such as sinus arrhythmia, tachycardia and bradycardia, nodal rhythm, ventricular and supraventricular extrasystoles and ventricular fibrillation sometimes occur. Active "catechol myocarditis" characterized morphologically by myocardial necroses and histocytic and lymphocytic infiltrations are thought to be found at autopsy in 50% of patients with pheochromocytoma (VAN VLIET, 1966). At the end of the attack the blood pressure usually returns rapidly to the original value, the patient becomes flushed, and the profuse sweating and secretion of saliva may persist. Patients feel tired and spent for a long time afterwards. In contrast to the severely disturbed vascular system and carbohydrate and fat metabolism, the influence of the pheochromocytoma on the kidneys is usually discrete, though it is occasionally severe. Very often, neither functional nor morphological changes can be found in the kidneys (GREEN, 1946; SACK, 1963). Frequently, a discrete pathologic finding is noted at urinalysis, such as albuminuria, and occasionally microhematuria in association with paroxysmal or persistent hypertension. Albuminuria, microhematuria and cylindruria arise intermittently, and simulate nephritis (FERTIG, 1951). A pheochromocytoma must be suspected in every case of "paroxysmal" nephritis. Occasionally inhibition of diuresis with azotemia ranging to full anuria is seen during an attack (BAIRD, 1954; ZOLLINGER, 1959). It is partly explained by the constriction of the vasa afferentia and reduced renal plasma flow. Hyposthenuria has been observed. Termination of an attack is always followed by a flood of up to 5–7 liters of urine. Hyposthenuria and polyuria caused by the action of epinephrine may be due to the decreased renal medullary hypertonicity resulting from an elevated medullary blood flow, which, in contrast to cortical circulation, increases with a rise in arterial pressure (BUCHBORN, 1961). Electrolyte disorders associated with a pheochromocytoma are only rarely observed clinically, although from acute experiments the opposite would be expected.

Attacks are induced by exertion, postural changes causing compression of the adrenal area, straining on defecation and micturition, and also by excitement, fear, and anger, as well as by smoking. Iatrogenic attacks can be induced during general anesthesia and during the investigation of anacidity with histamine. Sudden collapse under such conditions should always suggest a pheochromocytoma. Attacks can, however, also arise spontaneously during absolute rest and even during sleep. The attacks usually last between 15 min and 2 hours, but can also be over in a few minutes or persist for a whole day. Initially, attacks can arise every few weeks or months. They usually become more frequent and severe until they finally occur daily. Sometimes there are intervals of several years between attacks.

b) Persistent Hypertension

Persistent hypertension is more common than paroxysmal hypertension in pheochromocytomas. The symptoms it causes are in no way

different from those of benign or malignant hypertension.

The signs and symptoms listed below can be regarded as indications for investigation of patients with hypertension for pheochromocytomas:

1. Attacks of headaches, palpitations, nervousness, thoracic or abdominal pains, tremor, hypertension, persistent or frequent excessive sweating.
2. Leanness with more than 10% underweight or a body weight of less than 48 kg.
3. Age of 35 years or less.
4. Basal metabolic rate 20% above normal in the absence of hyperthyroidism.
5. Duration of hypertension of less than 2 years.
6. Fundus changes, grade III or IV or severe forms of grade II.
7. Paradoxical reaction of blood pressure to ganglion blockers.
8. Blood pressure reaction at the onset of general anesthesia.

Pheochromocytomas must be suspected particularly in hypertension affecting young patients. About 100 cases of hypertension due to a pheochromocytoma have been reported in children. Hypertension in these cases was predominantly of the persistent type. Growth is arrested. Blood pressure is always considerably elevated, particularly the diastolic level (upper normal level of systolic pressure in children = 100 + twice age in years). Spastic changes are usually found in the ocular fundus, and papilledema or hemorrhage sometimes occurs.

In adults, the three cardinal symptoms of headaches, sweating, and palpitations are seldom absent. However, the suspicion of a pheochromocytoma can also be evoked by a considerably elevated basal metabolic rate or severe sweating and glycosuria in the presence of hypertension with concomitant bradycardia (so-called "H-triad" (HOWARD): hyperglycemia, hypertension, hypermetabolism without hyperthyroidism). Repeated estimations of the basal metabolic rate and blood glucose are indicated in such cases. Impotence due to impaired autonomic equilibrium can occur.

In cases of pheochromocytoma with persistent hypertension of long duration, the plasma volume can be considerably diminished due to persistent vasoconstriction (up to 20%), so that removal of the tumor may be followed by an immediate dangerous fall in blood pressure with oliguria, anuria and myocardial ischemia if preoperative treatment is inadequate (ZIEGLER, 1966; BRUNJES, 1960). Plasma renin is elevated accordingly (see Chap. XV). Vascular complications are also possible, with changes in the *fundus oculi*, impaired renal function, and renal infarct (see p. 429). The hypertension may be permanent in such cases, susceptible to reduction but no longer to correction by removal of the pheochromocytoma. In some patients, paroxysmal attacks are superimposed on the persistent form, and are associated with all the characteristic features. Not infrequently, the disorder begins with paroxysmal hypertension which progresses to the persistent form. As in essential hypertension, death results from apoplexy, cardiac failure, or uremia. Finally, in some cases the hypertension is extremely labile, varying from one minute to the next.

Table 5. Frequency of pheochromocytoma symptoms. [After GIFFORD: Mayo Clin. Proc. **39**, 281 (1964)]

Symptoms	Paroxysmal form (%)	Persistent form (%)
Headaches	92	72
Excessive sweating	65	70
Palpitations with or without tachycardia	73	51
Pallor, particularly in face	60	28
Nervousness or anxiety	60	28
Tremor	51	26
Nausea with or without vomiting	43	26
Weakness, exhaustion or tiredness	38	15
Thoracic pains	32	13
Abdominal pains	16	15
Visual disorders	3	21
Weight loss over 10%	14	15
Raynaud's phenomenon	8	3
Dyspnea	11	18
Constipation	0	13
Grand mal	5	3
Sensation of heat or hot flushes or both	11	8
Bradycardia, perceived by patients	8	3
Intolerance to heat	3	8
Giddiness or confusion	11	3
Paresthesia or pains in the arms	11	0

If the hypertension persists after removal of a pheochromocytoma the established hypertension shouldnt simply be accepted as a result of arteriolosclerotic changes. A careful search must first be made for a second pheochromocytoma. This is best done actually during the operation, by means of the phentolamine test. Secondly, renal infarcts and cortical atrophy are not uncommon after pheochromocytoma operations, due to lesions of the renal vessels (HARRISON, 1958; SACK, 1963). An infarcted kidney can lead to renal hypertension. In a few cases, pheochromocytomas have caused mechanical inhibition of renal blood supply, inducing a Goldblatt mechanism (ROSENHEIM, 1963; WEIDMANN, 1969).

In general, however, renal dysfunction is completely reversible after successful removal of the pheochromocytoma.

Table 6. Laboratory findings in pheochromocytoma. [After GIFFORD: Mayo Clin. Proc. **39**, 281 (1964)]

Findings	Paroxysmal form (%)	Persistent form (%)
Ocular fundus		
Negative	51	5
Hypertension I	26	16
Hypertension II	23	26
Hypertension III	0	16
Hypertension IV	0	37
Fasting blood sugar		
Below 90 mg% (autoanalyzer)	44	34
90–109 mg%	32	31
Over 109 mg%	24	35
Basal metabolic rate		
Below +10%	56	9
+10 to +19%	16	15
+20 to +49%	28	52
Over +50%	0	24
Albuminuria	35	64
Blood urea		
less than 40 mg%	81	76
40–59 mg%	16	19
60 mg%	3	5

In contrast to the situation in the paroxysmal form, clinical observation alone is no help, and the doctor is dependent on laboratory examinations. There is, however, one feature characteristic of patients with pheochromocytomas; they are said always to be thin due to the lipolytic action of catecholamines, and obesity is said to exclude the disease. Unusual clinical symptoms, such as paroxysmal abdominal pains and gastrointestinal hemorrhages, have been described. Circulatory disorders similar to those associated with Raynaud's disease also occur with the persistent hypertension.

An impaired metabolism of carbohydrates similar to that in diabetes mellitus is found in between one third and one quarter of patients with pheochromocytomas. This condition is characterized by reduced glucose tolerance, fasting hyperglycemia and glucosuria. Ketosis, however, is rare. This feature was previously explained by the increased glycogenolysis, but it is currently thought to be due primarily to the inhibiting effect of epinephrine and norepinephrine on the release of insulin in response to glucose (see p. 748). At the same time, there is also hyposensitivity to insulin. Free fatty acids and glycerine in the plasma are thought to be elevated, but we have not always been able to confirm this in our own investigations. Insulin release is normal again shortly after the operation; in contrast, glucose tolerance takes some months to return to normal (SPERGEL, 1968; WILBER, 1966).

c) Hypotension

Occasionally, the symptoms experienced are attacks of *hypotension* as low as 70/50 mm Hg, with tachycardia, pallor, sweating, leukocytosis, and glucosuria. It is possible that these attacks are preceded by rises in blood pressure of very short duration, which are completely overlooked. Low doses of epinephrine can have a hypotensive action, particularly if given repeatedly. Attacks can become manifest in tachycardia and outbreaks of sweating only, with no change in blood pressure.

In the type with persistent hypertension, there is sometimes a tendency to orthostatic fall in blood pressure, particularly if patients are being treated with phentolamine or phenoxybenzamine. The blood pressure falls to normal or hypotensive levels in the upright position. The additional release of norepinephrine, which normally occurs on standing, obviously no longer functions in such cases, or the adrenolytic drugs led to hypovolemia (see p. 436).

d) Special Forms and Combinations with Other Syndromes

α) Malignant Pheochromocytomas

The malignant pheochromocytoma with invasive growth and metastases is uncommon. Aberrant adrenal tissue in the retroperitoneal space must be excluded. Recurrences usually arise within one year following the primary operation. Life expectancy after malignancy has been confirmed is usually less than 3 years but can even be as long as 8 years. In cases where the course is slow, periodic operations to remove metastases may be worthwhile, since symptom-free intervals of several years may be achieved in this way. Local recurrences are particularly common. The incidence of metastases in the liver, lymph nodes, lungs, and skeleton is roughly the same. Forms where the course of the disorder is unusually slow – we are currently following a case which has extended over 40 years – indicate malignant degeneration of an originally benign pheochromocytoma. Elevated urinary excretion of dopamine and its metabolites is an indication of malignancy of a pheochromocytoma.

Palliative medical treatment is justified in inoperable cases (see p. 436). This form of treatment can at least abolish symptoms caused by the overproduction of catecholamines.

It is advisable to try cytostatics. Temporary success can be achieved with alkylated substances (cyclophosphamide).

A few types of tumors of neuroectodermal origin, such as neuroblastomas and chemodectomas, can be detected in the absence of endocrine symptoms from the increased excretion of catecholamines, and particularly from the presence of abnormal metabolites in the urine.

β) Familial Pheochromocytomas, Combinations with Other Syndromes
(see also Chap. XVIII, Pluriglandular Syndromes)

Familial pheochromocytomas are inherited on an autosomal dominant gene. They are often multiple and ectopic, and in children they are more common than nonfamilial pheochromocytomas. Pheochromocytomas also occur in association with RECKLINGHAUSEN'S neurofibromatosis (SCHLEGEL, 1960), with ganglioneuromas (STREIT, 1967), the Hippel-Lindau syndrome, and brachymetacarpal dwarfism (NAGANT DE DEUXCHAISNES, 1960) (see Chap. XIV).

γ) Association with Medullary Carcinoma of the Thyroid Gland

Over 30 cases of medullary carcinoma of the thyroid gland together with pheochromocytomas have been reported. The features of these patients are very characteristic, and they are all similar in appearance. The face with the pouting lips is reminiscent sometimes of acromegaly and sometimes of the Marfan syndrome. Neuromas of the eyelids and tongue are characteristic (see Chap. VI, p. 233). This disorder appears to have an autosomal dominant mode of inheritance. It is possible that the same gene is involved as causes familial pheochromocytomas. The combination with neurofibromatosis indicates an ectodermal disorder of the anlage, and the medullary carcinoma of the thyroid gland, like the chromaffin tissue, is regarded as a derivative of the ganglionic ridge ("familial chromaffinomatosis", LJUNGBERG, 1967). It is now known, however, that medullary carcinoma arises from parafollicular cells of the thyroid gland and that these cells originate ultimately in the neural crest. Combinations with parathyroid hyperplasia and Cushing's syndrome are discussed in Chap. XVIII (p. 1009).

5. Diagnosis of Pheochromocytoma

W. ZIEGLER

The diversity of the clinical picture is the main reason for the frequent long delays in arriving at the diagnosis. If a pheochromocytoma is suspected on clinical grounds the diagnosis must be confirmed by means of all diagnostic aids. Exploratory laparatomy, however, should never be considered for this purpose.

Case reviews from the Mayo Clinic show that the diagnosis is suspected on the basis of clinical observation in 9 out of 10 cases (GIFFORD, 1964).

Paroxysmal changes in blood pressure with all the accompanying features in a normotensive person are much more impressive and easier to detect than persistent hypertension, where the superimposed variations in blood pressure are often hardly measurable. In every case, however, the diagnosis must be confirmed before surgery by increased formation of catecholamines revealed by biochemical analyses of the urine and clinical pharmacological tests.

Pharmacological tests either provoke the release of catecholamines (induction of a blood pressure crisis) or block the effect of high plasma catecholamine levels (induction of a fall in blood pressure). They are valuable diagnostic aids which can be carried out without special laboratories if the doctor is prepared to spend an adequate amount of time on them, and observes certain precautions. The diagnosis, however, must always be confirmed by demonstration of an increase of catecholamines or their metabolites in the urine. The importance of previous pharmacological tests is decreasing with the widespread availability of simple methods of urinalysis. After confirmation of the diagnosis, the tumor must be localized as exactly as possible. It is advisable to measure blood volume with a view to the preoperative preparation.

a) Pharmacological Tests

The tests can only be carried out if the following conditions are fulfilled:

There should be no signs of renal or cardiac insufficiency. A history of myocardial infarction or apoplexy contraindicates these tests.

All drugs acting on the central nervous system, such as alcohol, hypnotics, sedatives, opiates, and psychotropic drugs, can distort results, as can drugs acting on synapses and nerve endings. All sympatho- and parasympathomimetics and their corresponding blocking agents, and other substances which stimulate or block the ganglia thus distort results.

Antihypertensives such as the veratrum alkaloids can also affect the test results. Reserpine (Serpasil) and α-methyl-Dopa (Aldomet) in particular must be withdrawn for at least 10 days before the test. If clinically possible, drug therapy should be completely withdrawn 48 hours before these tests are carried out.

A blocking test can be false-positive due to sedatives, for example, and antihypertensives can cause either false-negative or false-positive results.

The test itself should be performed in a separate room. It is essential that the patient rests in the supine position for at least 30 minutes before the test and that the blood pressure and pulse rate are measured until reliable base-line values are obtained.

α) Provocation Tests

These are based on depletion of the catecholamine stores of the tumor and the sympathetic nerve endings, thus inducing paroxysmal hypertension.

1. Cold Pressure Test. This test should always be performed immediately before the provocation tests, since conclusions are only possible when results of the two examinations are compared.

The cold pressure test is contraindicated in cases where the diastolic blood pressure is higher than 150 mm Hg. In the healthy subject, the short-acting stimulus usually produces a rise in blood pressure, the degree of this rise indicating the circulatory lability. In the patient with vegetative stigmata it will usually exceed the rise caused by histamine.

Method: The patient immerses one hand in a water bath with ice cubes (4 °C) for one minute. Pulse and blood pressure are measured after 30 and 60 seconds.

Interpretation: A considerable rise of the blood pressure indicates vegetative dystonia or possibly even labile essential hypertension.

2. Histamine Test. Depending on the age of the patients, this test should not be applied when blood pressure values exceed 150 or 170/110 mm Hg. Histamine leads initially to vasodilatation and a fall in blood pressure, followed immediately by a release of catecholamines from the stores.

Method: 0.05 mg (1/20 mg) of histamine in 0.5 ml physiological saline is given by rapid i.v. injection. The blood pressure is then measured every minute for the next 15 min. A first measurement after 30 sec detects the initial fall in blood pressure. Phentolamine (Regitin) and norepinephrine (Arterenol) should be prepared and be kept ready for immediate use to avert any threatened blood pressure crisis or hypotension. It is best to keep an intravenous route open throughout the test by maintaining a saline drip.

Interpretation: A rise in blood pressure to 60/40 mm Hg above the initial levels within 1 to 4 min after the injection, together with the appearance of symptoms typical of a hypertensive attack, is considered as a positive result. The blood pressure values obtained in the cold pressure test should be exceeded. If these conditions are fulfilled, the attack should be abolished by means of intravenous phentolamine. False-negative and false-positive results are obtained in 5% of tests.

3. Tyramine Test. Tyramine mobilizes catecholamines from the granules of the sympathetic nerve endings. It causes no unpleasant side effects like histamine does (headache, sensation of heat).

Method: At the onset, physiological saline is given by i.v. injection while blood pressure is monitored continuously. Tyramine is then injected in doses increasing from 250 to 500 to 1000 μg (1 mg). The blood pressure should be measured every minute. An interval of 15 min should elapse between injections.

Interpretation: A rise of the systolic pressure by at least 20 mm Hg within 1–2 min suggests a pheochromocytoma. False-positive results are obtained in 5% of the tests, whereas results are false-negative in 30%.

4. Glucagon Test. This test is also based on the release of catecholamines from the adrenal medulla and the tumor. As in the histamine test, it is advisable to compare the results with those obtained in the cold pressure test.

Method: At least 0.5 mg of glucagon, but usually 1.0 mg, is administered to the fasting patient by rapid i.v. injection. The blood pressure is subsequently measured every 30 sec for 5 min and then every minute for a further 10 min. Phentolamine and norepinephrine must be kept ready during this test also.

Interpretation: Criteria for a positive result are similar to those in the histamine test, although side effects are much more uncommon and less pronounced than with histamine. False-positive results have not been reported so far. False-negative results, however, have frequently been observed.

β) Blocking Tests

These tests are based on the inactivation of circulating catecholamines by means of α-

receptor blockade. The decrease in peripheral resistance causes a momentary fall in blood pressure. Phentolamine is the only α-blocking agent which has proved satisfactory.

Phentolamine (Regitin) Test. This test should not be performed when blood pressure is below 160/110 mm Hg.

Method: Access to an intravenous route of administration throughout the investigation is recommended, and is best achieved by setting up a saline drip. After i.v. injection of 5 mg Regitin (half an ampoule) (3 mg/m^2 in children) over 5–10 sec the blood pressure is measured every minute. There is a risk of inducing circulatory collapse, so that norepinephrine must always be kept ready for immediate injection.

Interpretation: A fall in blood pressure of 40/25 mm Hg below the initial levels within 5 minutes is considered a positive result. The initial levels should not be recovered until 5–15 min after the injection. False-positive results are obtained in 2–3% of the tests, and if the condition cited above is not observed 20% of the tests can be expected to give false-positive results. False-negative results are uncommon.

b) Biochemical Investigations

Demonstration of increased excretion of catecholamines and their metabolites in the urine is essential for confirmation of the diagnosis. Nonspecific quick tests should be avoided since they often give false-positive results.

Method of Urine Collection. The patient must refrain from consuming bananas, citrus fruits, nuts, tea, coffee, and vanilla for two days before collecting the urine. A 24-hour specimen of urine is then collected during the second day of diet. Acid is added to the urine (1 ml of concentrated perchloric acid to 100 ml of urine; concentrated hydrochloric acid may be used instead). The urine must be protected from heat and light. If the 24-hour specimen is correctly measured only 200 ml urine are required for the analysis.

Numerous drugs and their breakdown products in the urine can interfere with the analysis. They should be discontinued whenever possible, or the laboratory should be informed (salicylates, tetracyclines, sympathomimetic and anti-hypertensive drugs).

α) Vanilmandelic Acid

40% of the catecholamines (epinephrine and norepinephrine) are excreted as 3-methoxy-4-hydroxymandelic acid (VMA). PISANO'S method has proved to be the most suitable and is very reliable for routine examination. It involves extraction, oxidation and absorption measurement.

Interpretation: Healthy adults excrete between 1 and 7 mg vanilmandelic acid in 24 hours. In children these values are lower according to age.

The excretion is usually increased in cases of pheochromocytoma. Elevated values can also be detected in cases suffering from tumors of the sympathetic nerve tissue in which clinical symptoms due to overproduction of catecholamines are absent.

β) Metanephrine and Normetanephrine

Less than 1 mg of these metabolites of epinephrine and norepinephrine is normally excreted in a 24-hour urine sample. In exceptional cases, demonstration of these breakdown products is more reliable for diagnostic purposes than the estimation of VMA.

γ) Epinephrine, Norepinephrine, and Dopamine

Only 3–7% of epinephrine and norepinephrine are excreted unchanged in the urine. As the amounts lie in the μg range they can be estimated only by fluorometric methods.

Normal values: 10–30 μg of epinephrine in 24 hours, 20–60 μg of norepinephrine in 24 hours. Rule of thumb for normal values: free epinephrine plus norepinephrine below 100 μg in 24 hours. Increased values of dopamine, the precursor of epinephrine and norepinephrine, can indicate malignancy. This investigation is of particular importance in pediatrics for the detection of immature tumors of the sympathetic nerve tissue.

c) Localization of the Tumor

α) Catecholamine Excretion

A preponderance of epinephrine production suggests a tumor situated in the adrenal medulla. Excessive norepinephrine production is due to an extra-adrenal tumor in one third of cases.

β) Radiological Investigations

A chest X-ray and an intravenous pyelogram are routinely performed when a pheochromocytoma is suspected. On the other hand, aortography or a retropneumoperitoneum with tomography may involve serious risks of hypertensive crises and hemorrhage into the tumor with subsequent shock.

These investigations allow localization of the tumor in 60% of cases, but they demand meticulous supervision of the patient and immediate treatment of any complicating incidents. We perform venous catherization rather than retropneumoperitoneum and aortography. Brown fat ("Hibernoma") an immature form of adipose tissue, devellops occasionally in proximity to pheochromocytomas and may mimick a tumor by its extensive and irregular vascularisation (LEIPHART, 1970; FEYRTER, 1971).

γ) Catheterization of the Vena Cava

The catheter is introduced into the femoral vein and an X-ray monitor is used in guiding it along the inferior vena cava. Samples of blood are taken at different levels for the estimation of catecholamines. The highest values are found selectively in the vein draining the tumor or in the region of the venous inflow from the tumor. This method allows determination both of the level at which the tumor is situated and of which side is affected, which makes selection of the optimal surgical approach considerably easier (see Chap. VII, p. 352).

This procedure has proved not to be too strenuous for patients, but requires a special laboratory.

Estimation of catecholamines in the plasma by spectrofluorometric methods is very ambitious and detects plasma concentrations of 0.05 μg/l in the case of epinephrine, and of 0.45 μg/l in that of norepinephrine.

Biological methods of estimation have now been superseded by biochemical methods for clinical purposes.

6. Course and Prognosis

The prognosis depends on early recognition and treatment of the pheochromocytoma. Left untreated, the condition can continue for years and death can occur at any time due to apoplexy, pulmonary edema, myocardial infarction, or sequels of malignant hypertension. Spontaneous healing due to infarction of the tumor is possible but extremely rare. Patients are in constant danger of fatal shock induced by situations such as excitement, minor trauma, and surgery, which cause nervous stimulation of the adrenal medulla. As discussed above, attacks usually increase in frequency and intensity. No general life expectancy can be given. Successful surgery can bring about complete cure as long as the kidneys and circulatory organs are not irreversibly damaged. Pregnancy can lead to manifestation of the disorder. Immediate surgery is indicated since mother and child are both in danger (abortion).

7. Differential Diagnosis

Hypertension is the first condition to be considered in the differential diagnosis of the pheochromocytoma with persistent hypertension. Every hypertensive patient below the age of 40 should be investigated for a pheochromocytoma. Loss of weight and tachycardia can simulate hyperthyroidism. Lead poisoning with pallor, hypertension, and abdominal colic has certain similarities to the pheochromocytoma.

In the differential diagnosis of the paroxysmal form, the following conditions must be considered: headaches associated with encephalopathy, vasomotor crises, migraine (since nausea, headaches and scintillating scotoma can also arise with a pheochromocytoma), arteriosclerotic cerebral circulatory disturbances, hyperinsulinism, and carcinoid syndrome. The term "pseudopheochromocytoma" should be avoided for description of tumors in the region of the kidneys which are sometimes associated with blood pressure variations due to phentolamine and histamine but no evidence of increased catecholamine formation.

On the other hand, pheochromocytomas can be combined with renal hypertension due to renal ischemia caused by mechanical effects of the tumor (WEIDMANN, 1968).

Autonomous hyperreflexia in paraplegics with a transverse lesion of the spinal cord above thoracal 7 can lead to over-distension of the bladder, which in turn gives rise to the release of large amounts of norepinephrine accompanied by corresponding symptoms (GARNIER, 1964).

8. Treatment

Palliative medical treatment is an essential part of the presurgical preparation of patients. It is also indicated if the general condition of the patient does not premit surgical intervention and in cases of inoperable malignant pheochromocytoma. The α-receptor blocker phenoxybenzamine (Dibenyline) has proved suitable. It is given orally in high dosages ranging from 5 to 60 mg per day. The dose should be divided over the day, and the optimal dose must be determined individually. Hypovolemia is nearly always present and abates after 5–7 days of treatment, as is indicated by the fall in hemoglobin. Copious blood transfusions complete the preparation for surgery. This treatment improves the persistent hypertension at the same time and prevents hypertensive attacks.

Patients undergoing long-term treatment with high doses of dibenyline often suffer from orthostatic hypotension which can itself cause them to become completely bedridden.

α-Methyl-dopa (Aldomet), an antihypertensive drug, has not proved suitable for this treatment. α-Methyl-para-tyrosine promises to be effective although clinical experience is limited.

Guanethidine and ganglionic blocking agents are contraindicated in the treatment of pheochromocytomas since the sensitivity of end organs to norepinephrine rises under their influence.

Treatment must be aimed at surgical removal of the pheochromocytoma, which can bring about a complete cure.

If the diagnosis is confirmed and the tumor has been localized by radiography or venous catheterization, there is not great technical difficulty attached to the operation. Close teamwork is essential between surgeon, internist and anesthesiologist, who must all be very familiar with surgery of pheochromocytoma.

Pretreatment with phenoxybenzamine is now obligatory, since preoperative correction of the hypovolemia can prevent dangerous states of collapse immediately after surgical removal of the tumor. Propranolol (Inderal), a β-receptor blocking agent, should only be used (dosage: 15–45 mg/day) if there is tachycardia of more than 140.

Any narcotic agent, and particularly curare, can induce a blood pressure crisis even when ganglionic blockers have been avoided. Phentolamine must be kept ready for intravenous application in case of emergency. Continuous monitoring of blood pressure and ECG is advisable. A certain amount of risk due to anesthesia cannot be overcome in older patients, and anesthesia should only be used for the operation and not for diagnostic procedures such as aortography.

Although pheochromocytomas occur bilaterally in about one tenth of cases, so that revision of both sides is desirable, the less drastic dorsolumbar approach can be chosen for surgery if the tumor has been localized with certainty; if the tumor is found, exploration of the other side is avoided. Other authors prefer the transabdominal route via a transverse or longitudinal incision which permits inspection of both adrenals and their surroundings.

Cortisol hemisuccinate must be at hand in cases of bilateral pheochromocytomas where bilateral total adrenalectomy is essential. Doses (see p. 330) are the same as for adrenalectomy.

When the pheochromocytoma is located, it should be palpated and squeezed as little as possible to minimize the risk of inducing a hypertensive attack. The blood supply must be ligated as quickly as possible and the tumor removed intact. The whole of the adrenal involved must be removed because of the risk of recurrences. This principle can be disregarded in cases where the pheochromocytoma is topographically completely separated from the adrenal gland. Only in cases of bilateral pheochromocytomas should functioning adrenal tissue be left behind where possible.

Surgical treatment of pheochromocytoma is extremely rewarding, except in cases of malignancy or permanent hypertension. Patients can be completely cured. If the blood pressure does not fall immediately after the operation, it is possible that a second active tumor is present. This sign, however, is no longer entirely reliable because of the premedication with phenoxybenzamine. These cases must be explored with particular care. On the other hand, it has been known for hypertension to persist after removal of the tumor and the blood pressure to return to normal values only after some weeks or months. Hypertension can, however, become permanent in cases of long duration.

IX. Testis

A. LABHART

With Contributions by

CHR. HEDINGER, G. KISTLER, J. MÜLLER,
A. PRADER, G. TÖNDURY, and M. ZACHMANN

A. Historical Dates

1677 HAM and v. LEUWENHOEK discover the spermatozoa.
1849 BERTHOLD shows that the capon recovers the feathers of a cockerel after reimplantation of the testicles, thus proving a humoral effect of the gonads.
1889 BROWN-SÉQUARD, experimenting on himself, demonstrates the rejuvenating effect of testicular extracts, thereby generating interest in endocrinology.
1911 PÉZARD succeeds in producing an effective testicular extract.
1931 Androsterone, the first crystallized compound with an androgenic effect, is extracted by BUTENANDT from male urine and
1934 clarified in its chemical constitution.
1935 LAQUER isolates testosterone from testicular tissue. Clarification of the constitution and partial synthesis of testosterone by RUZIČKA and WETTSTEIN and by BUTENANDT.
1942 KLINEFELTER, REIFENSTEIN and ALBRIGHT describe the syndrome called after the first author.
1958 FORD, JACOBS, and LAJTHA discover that this syndrome is caused by an anomaly of the chromosomes.
1968 BRUCHOVSKY and WILSON discover the conversion of testosterone to 5α-dihydrotestosterone (i.e. a more active androgen) by target organs. At the same time, ANDERSON and LIAO discover selective nuclear receptors for 5α-dihydrotestosterone in the prostate.

B. Embryology, Gross Anatomy and Histology

G. TÖNDURY and G. KISTLER

Embryology. In the human embryo about 2.5 mm in length, the primordial germ cells (gonocytes) are situated in the wall of the yolk sac, close to the root of the allantoic diverticulum. Whether they originate in the yolk sac endoderm in the pre-somite stage, or are derivates of the overlying splanchnopleuric mesoderm is still a matter of dispute. From the wall of the yolk sac, the gonocytes, which contain a large, vesicular nucleus and abundant cytoplasm, migrate through the mesenchyme of the dorsal mesentery into the epithelium and the mesenchyme of the gonadal anlagen. The primordia of the sex glands become light microscopically recognizable, in the embryo about 4–5 mm in length, as thickenings of the coelomic epithelium (= genital ridges) on the medial aspect of the anlagen of the mesonephros. The genital ridges extend first from the 6th thoracic to the 2nd sacral segment. The cranial and caudal portions regress rapidly and only the parts belonging to the upper three lumbar segments develop further. In this region, the coelomic epithelium becomes first highly columnar and then stratified. Its basement membrane disappears and cords of epithelial cells (= primitive sex cords) invade the underlying mesenchyme (Fig. 1). At this developmental stage, the primordial germ cells, which stain selectively with the naphthyl alkaline phosphatase reaction, are already present in both the sex cords and the mesenchyme surrounding them. The gonadal primordia are thus formed from cells of three different sources, the coelomic epithelium with its underlying mesenchyme, which are both of mesodermal origin, and the primordial germ cells, which migrate secondarily into the primordia. In the first six embryonic weeks, the gonadal anlagen of both sexes are morphologically indistinguishable (sexo-neutral stage) and mesonephric and paramesonephric ducts are both intact.

During the 7th week of development (length of embryo about 18–20 mm), the *testis* becomes identifiable as such. Proliferating mesenchymal cells separate the outgrowing, still compact sex cords from each other. At about 25 mm, a layer of fibrous connective tissue, the *tunica albuginea*, forms peripherally, just beneath the

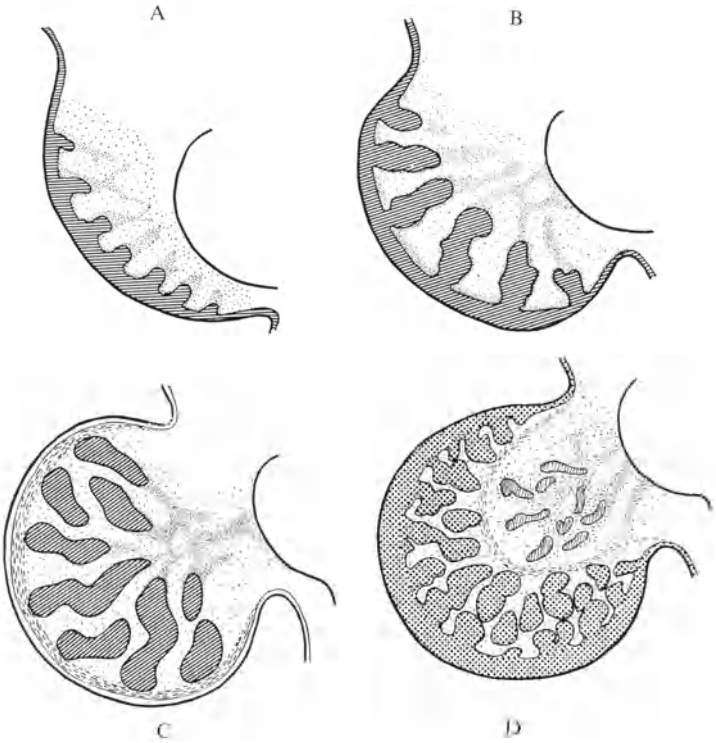

Fig. 1A–D. Diagrammatic representation of gonadal development. A) Proliferation of the coelomic epithelium in the region of the gonadal ridge. B) Development of the primitive sex cords, sexo-neutral stage. C) Development of the testis: Peripherally, the tunica albuginea develops and separates the medullary cords from the coelomic epithelium. Centrally, the outgrowing cords form the epithelium of the rete testis. D) Development of the ovary: Proliferation of secondary cords from the coelomic epithelium. A rudimentary tunica albuginea separates the cortex from the medullary portions of the anlage, which contain the rete ovarii. (Modified after R. K. BURNS, 1955)

germinal epithelium. The sex cords are thus separated from their original matrix. All primordial germ cells are successively taken up into the epithelial cords. Outgrowth of the cords leads to the formation of the *rete testis* in the gonadal mesentery (= the mesorchium). Finally, canalization of the cords gives rise to the *seminiferous tubules*. Their walls are formed by *sustentacular cells* (Sertoli cells), among which the primordial germ cells are dispersed.

The central parts of the epithelial cords, which form the rete testis, differentiate rather late into tubules (when fetuses are about 60–90 mm long). Some of these tubules contact mesonephric tubules which lose their glomeruli and become the *ductuli efferentes*. These ductules connect the rete testis to the mesonephric duct, which later becomes the *vas deferens*. The paramesonephric duct degenerates.

The *interstitial cells* (Leydig cells) differentiate from mesenchymal elements of the testicular stroma. In the early fetal stages (3rd to 5th month) these cells increase rapidly in number and display marked metabolic activity (production of fetal sex hormones).

Although the *chromosomal* sex of an individual is already determined at the stage of the fertilized ovum, the sexual differences in the gonads become morphologically detectable only after the 7th embryonic week. This still poorly understood differentiation, which is apparently not determined by the chromosomal sex of the immigrating primordial germ cells, establishes the *gonadal* sex of an embryo. *Genital* sex, finally, is highly influenced by hormones. It is established during the third month of gestation, when the sex ducts and external genitalia assume their specific masculine or feminine character.

The sex-specific differentiation of the gonads is a gradual process. In most mammalian species, the development of the testis seems to be determined as soon as the stage of the morphologically undifferentiated primordium, whereas that of the ovary is not. When a gonad at the sexo-neutral stage is transplanted from an experimental animal into the kidney of an adult specimen the genetically male gonad continues to develop normally. The differentiation of the genetically female sex gland, however, varies

considerably. Thus, in the rat embryo, the anlage of the testis is definitely determined by the 12th day, whereas the primitive ovary reaches a similar developmental stage only on the 15th to 16th day. From the 17th day onwards both male and female transplants develop typically (TORREY, 1950).

The androgenic *hormones* produced by the embryonic, differentiating testis are morphogenetically much more potent than the embryonic sex hormones formed in the ovary. Thus, in ovariectomized female rabbit fetuses, the genital ducts and the external genitalia develop more or less normally. However, in male rabbit fetuses castrated at the sexo-neutral stage, the mesonephric ducts degenerate and the paramesonephric ducts persist. In addition, the external genitalia assume a feminine appearance. The fetal testicular hormones seem, therefore, to stimulate the development of the mesonephric duct system and to inhibit the paramesonephric ducts.

The influence of the fetal *pituitary gland* on the differentiation of the gonads in humans is still poorly understood. The gonads and external genitalia of anencephalic newborn males, who usually have no pituitary gland, are normally not affected. It would thus appear that the hypophyseal gland does not play any major role in the development of the human sex glands.

Gross Anatomy. In the young adult, each testis weighs 10 to 16 g and measures approximately 4 × 2.5 × 3 cm. It is suspended in the scrotum at the end of the *spermatic cord* which comprises, besides connective tissue, the *ductus deferens*, (the excretory duct of the gland) and the blood vessels and nerves supplying the organ. The left testis usually hangs rather lower than the right one. The *epididymis* is closely applied to the posterior margin of the testis. It overlaps the lateral surface and the upper pole of the gland.

The testis is enclosed in a thick capsule of inelastic connective tissue, the *tunica albuginea*. On the posterior aspect of the gland, connective tissue of the tunica extends into the testis as the *mediastinum testis*. From here, incomplete septa project radially towards the tunica albuginea, thus dividing the testicular parenchyma into about 200–300 pyramidal lobules, the *lobuli testis*. Their apices converge upon the mediastinum. The innermost layer of the tunica albuginea, the *tunica vasculosa*, is rich in blood vessels. It is continuous with the loose connective tissue which forms the interstitium of the testicular lobules.

During its descent from the peritoneal cavity into the scrotum, each testis is accompanied by an outpocketing of the peritoneum, the *tunica vaginalis propria testis*, which consists of two layers. On the anterior and lateral surfaces of the testis, the inner, *visceral* layer is closely applied to the tunica albuginea. On the posterior aspect of the gland, the visceral layer is reflected and continuous with the outer, *parietal* layer. A cleft-like, serous cavity between the two layers, the *cavum serosum testis*, surrounds the gland except for the mediastinum testis and widens at its upper pole to form the sinus epididymidis.

The testis is supplied by a branch of the abdominal aorta, the internal spermatic artery. Some of its branches ramify in the tunica vasculosa, while others traverse the mediastinum testis and form the capillary plexus surrounding the seminiferous tubules. Other branches reach the epididymis, where they anastomose with the artery accompanying the ductus deferens. A number of veins emerge from the posterior aspect of the testis. Together with venous branches from the epididymis, they unite to form the *plexus pampiniformis*, which ascends along the spermatic cord. The lymph vessels of the testis supply the lateral and pre-aortic lymph nodes. The nerves accompanying the testicular vessels are derived from the 10th thoracic segment of the spinal cord. The sympathetic nerve fibers reaching the gland are probably vasomotor.

The *epididymis* is C-shaped. Its head lies on the superior pole of the testis, whereas its body is closely applied to the posterior margin of the gland. The lower, smaller part, the tail, contains the epididymal duct which increases in diameter to become the ductus deferens.

Histology. The histological appearence of the testis differs considerably according to the age of an individual. In the testicular lobules of a human fetus of about 60 mm CRL, canalized seminiferous tubules are still intermingled with some compact epithelial sex cords. Besides the supporting Sertoli cells, both contain large rounded *spermatogonia*, the successors of the primordial germ cells. The loose connective tissue surrounding the seminiferous epithelia contains numerous clusters and rows of polygonal cells with a large, spherical nucleus, the Leydig cells. The tubuli contorti of the testis of a 4-year-old boy (Fig. 2) contain supporting cells and spermatogenic cells at various stages of development. Only a very few immature sperms can be detected at this age, and the richly vascularized interstitium is completely devoid of typical Leydig cells.

In the adult, the lobuli testis consist of one to four convoluted seminiferous tubules, the *tubuli contorti*, which may reach a length of

60 to 70 cm. At the apices of the lobules, the tubules assume a straight course and unite to form 20 to 30 ducts about 0.5 mm in diameter, the *tubuli recti*, which open into the *rete testis*. This complex system of spaces in the connective tissue of the mediastinum testis is lined by a cuboidal epithelium. From the rete arise up to 20 convoluted, *efferent ductules* measuring about 5 mm in length and 0.6 to 0.8 mm in diameter. Together with the loose connective tissue surrounding them, they constitute the head of the epididymis. The ductuli efferentes gradually fuse into the highly tortuous ductus epididymis which is 4 to 6 meters long and forms the major constituent of the body and the tail of the epididymis.

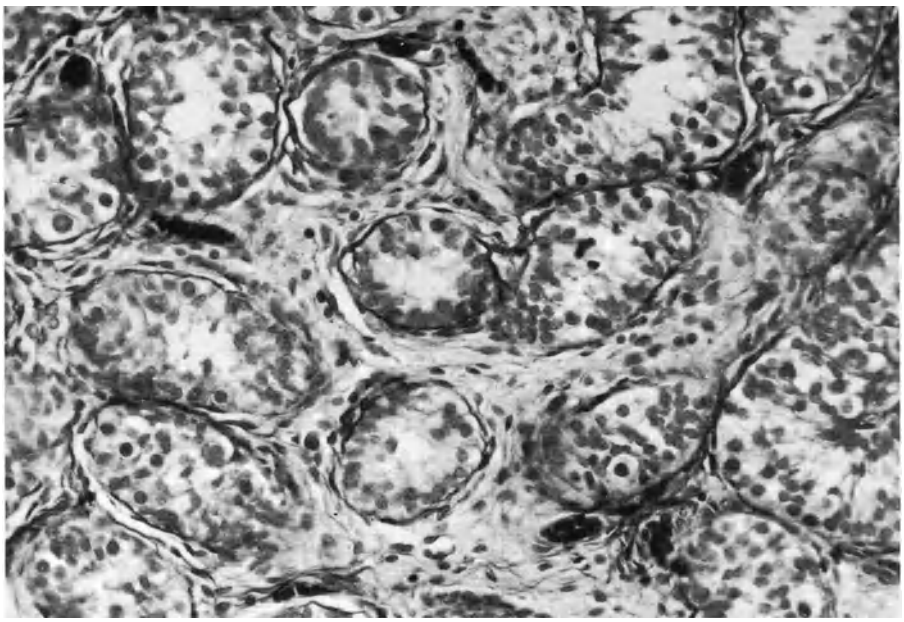

Fig. 2. Testis of a 4-year-old boy. Immature seminiferous tubules are surrounded by richly vascularized connective tissue. Note the complete absence of Leydig cells

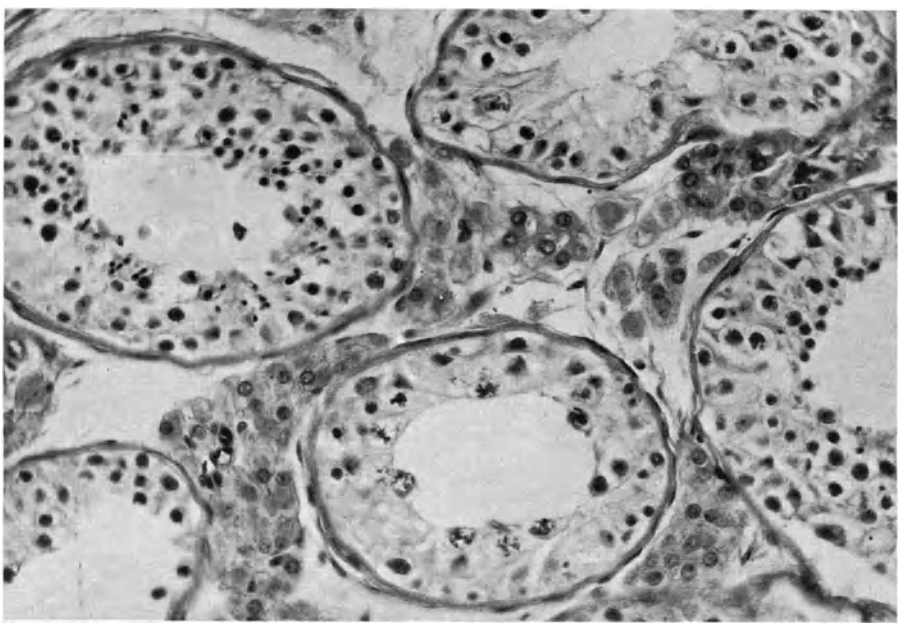

Fig. 3. Testis of a young adult. Seminiferous tubules with germ cells at various stages of development. The loose connective tissue between the tubules displays large clusters of Leydig cells

The tubuli contorti are lined by a stratified epithelium composed of sustentacular and spermatogenic cells. Each supporting or *Sertoli cell* rests on the basement membrane of the seminiferous epithelium. Its radially oriented, elongated nucleus contains a conspicuously large nucleolus. Numerous cytoplasmic, finger-like processes, whose outlines cannot be detected by light microscopy, extend upwards to the free surface of the epithelium. They are closely applied to those of neighboring Sertoli cells and to the spermatogenic cells. It is assumed that these cells, which usually contain lipid droplets and crystalloid inclusions (Charcot-Böttcher crystals), do not only support and protect the differentiating germ cells, but also play a role in their nutrition. Electron microscopically, the Sertoli cells are characterized by the presence of elongated mitochondria, often oriented parallel to the long axis of the cell, and by a moderately extensive rough- and smooth-surfaced endoplasmic reticulum. The cytoplasmic matrix also contains large numbers of microtubules and filaments. Beside lipid droplets and crystalloids, lipofuscin pigment granules are other typical paraplasmatic inclusions. The earlier opinion that the sperm cells are "embedded" in a syncytium of Sertoli cells has been found to be incorrect. Individual supporting cells are clearly separated by plasma membranes not only from each other, but also from the germ cells.

The sequence of events leading to the production of mature spermatozoa within the seminiferous epithelium is usually referred to as *spermatogenesis*. It can be divided into three phases, the first of which, the spermatocytogenesis, comprises the proliferation of the spermatogonia and the formation of the still diploid spermatocytes. In the second phase, meiosis, the spermatocytes undergo two maturation divisions. The resulting spermatids are haploid. In the third stage, spermiohistogenesis or spermiogenesis, the spermatids differentiate into the mature spermatozoa. The rounded or ovoid spermatogonia rest on the basement membrane of the convoluted tubules (compare Fig. 3). They display a spherical nucleus containing one to several nucleoli within a regularly dispersed chromatin substance. Their cytoplasm stains only faintly. The *primary* spermatocytes which arise from dividing spermatogonia first resemble their parent cell in size and affinity for dyes. After entering the first maturation division, however, their chromatin becomes condensed. The *secondary*, haploid spermatocytes resulting after the telophase of this division are definitively smaller than the primary ones. They rapidly enter the second maturation division, which leads to formation of the spermatids. Their differentiation into mature sperms is a very complex process involving the production of the acrosomal cap, the condensation of the nucleoplasm and the formation of the flagellum. A schematic representation of the mature spermatozoon is given in Fig. 4. In man, one complete cycle of spermatogenesis is estimated to be about two months.

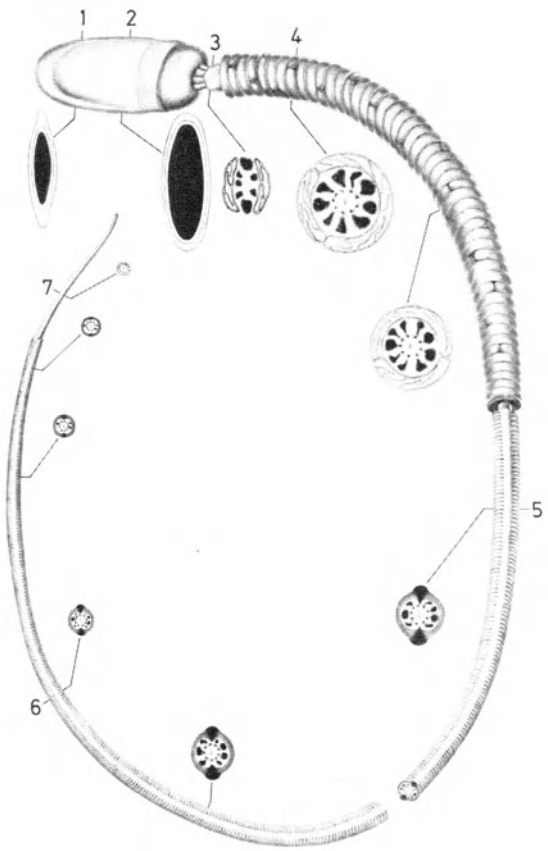

Fig. 4. Diagrammatic representation of a mature human spermatozoon. *1* acrosomal cap, *2* nucleus, *3* neck, *4* middle piece, *5* and *6* principal piece, *7* end piece. (Courtesy of Prof. D. W. FAWCETT, Boston)

The loose connective tissue surrounding the seminiferous tubules contains fibroblasts, mast cells and usually also a few macrophages and leukocytes. In addition, there are variously sized clusters and rows of epitheloid *interstitial cells*, the Leydig cells. They are diffusely dispersed throughout the lobules, often along the smaller blood vessels. The individual Leydig cells are polyhedral in shape and measure up to 25 µm in diameter. They usually have one large, spherical pale nucleus containing one or several deeply staining nucleoli. Binucleate cells are, however, also common. In most adult

human testes, the acidophilic cytoplasm of the interstitial cells contains faintly staining cristalloids which measure up to 20 µm in length and 1–3 µm in thickness. These so-called *crystals of Reinke* are protein in nature and their number varies considerably not only among different individuals, but also among the cells of the clusters. Electron microscopy reveals an abundant smooth-surfaced endoplasmic reticulum occupying the major portion of the cytoplasm in the Leydig cells, as well as a large Golgi complex. In contrast, only a few profiles of rough endoplasmic reticulum are usually seen. They are mainly situated close to the nucleus. Small lipid droplets and some lipofuscin pigment granules are regularly present. The mitochondria are large and similar to those present in the cells of the suprarenal glands, e.g. their cristae are vesicular or tubular in shape.

The sex hormone produced by the Leydig cells, *testosterone*, is not stored within incretory vesicles. It is assumed that the membranes of the smooth endoplasmic reticulum and of the Golgi apparatus contain the various enzymes needed by the cell for the synthesis of the hormone. The mechanism of its release into the capillaries surrounding the interstitial cells is still poorly understood.

C. Biochemistry

J. MÜLLER

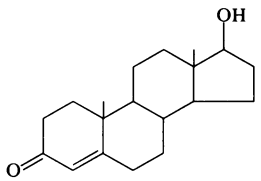
The testis is a gland with incretory and secretory functions. The interstitial Leydig cells produce androgens and estrogens; the spermatozoa arise from the seminiferous tubules.

1. Androgens

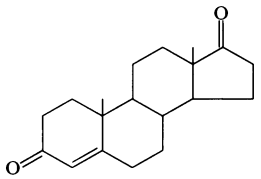
a) Human Androgenic Hormones

Androgens, i.e., the "man-makers", is a biological collective term for all substances which promote development of the male sexual characteristics. Almost all the known androgens are steroids and are therefore structural derivatives of cyclopentano-perhydro-phenanthrene (see p. 287 for the general chemistry of steroids). Natural androgens are C_{19} steroids without a side chain at C-17, but with two angular methyl groups. Androgenic activity is usually dependent on a double bond (between C-4 and C-5 or between C-5 and C-6) or on trans-linkage of rings A and B (H in the α-position at C-5). The type of substitution at C-3 and C-17 determines the androgenic potency.

Among the human androgens so far discovered, *testosterone* shows the greatest activity in numerous bioassays and in the human, as far as can be assessed from clinical experience. In the nuclei of its target organs (prostate, skin) testosterone is enzymatically converted to di-



Testosterone



Androstenedione
(Androst-4-ene-3,17-dione)

hydrotestosterone (5α-androstan-17β-ol-3-one), which is a more active androgen than testosterone. Apparently, this activation in the target organ has to precede the biological action of testosterone (BRUCHOWSKY, 1968; WILSON, 1969). However, testosterone is the most important *circulating* androgenic hormone in man. Androstenedione, dehydroepiandrosterone and androsterone are 5 to 20 times less active than testosterone. Epiandrosterone possesses only a very low activity, and etiocholanolone none at all (DORFMAN and SHIPLEY, 1956). In contrast to testosterone, its metabolite, androsterone, causes a fall in cholesterol, phospholipid and triglyceride levels in the blood. Etiocholanolone causes fever and leukocytosis when injected intramuscularly in the free form. Impaired conjugation of this substance may be involved in the genesis of a special form of periodic fever, so-called "etiocholanolone fever" (BONDY, 1956).

Table 1. Normal values of human androgens. (Mean values after NEHER, 1968)

	Concentration in the peripheral plasma (μg/100 ml)	Blood production rate ("secretion" mg/24 h)
Men (20–80 years)		
Testosterone	0.65–0.81	6.1–7.8
Androstenedione	0.04–0.15	0.5–1.4
Dehydroepiandrosterone	1.3	3
Dehydroepiandrosterone sulfate	70–150	6
Women		
Testosterone	0.035–0.18	0.14–0.8
Androstenedione	0.1–0.3	3.4
Dehydroepiandrosterone	1.0	2
Dehydroepiandrosterone sulfate	50–100	6
Boys (4–9 years)		
Testosterone	0.04–0.06	
Androstenedione	0.12	
Girls (3–9 years)		
Testosterone	0.02	
Androstenedione	0.03	

As shown in Table 1, the concentration of *dehydroepiandrosterone sulfate* in the plasma in both male and female is much higher than that of the other androgens. This substance is secreted by the adrenal glands in the conjugated form (BAULIEU, 1965). Its functional significance is not yet known. It possesses no androgenic activity, but it is possible, at least in theory, that it may be a potential precursor of active androgens.

Androgenic activity in the plasma of the male is due almost entirely to its content of *testosterone*. The plasma testosterone level is about 20 times lower in the normal woman than in the man, the level of androstendione is somewhat higher and that of dehydroepiandrosterone about the same, so that these two weaker androgens are relatively more significant. It can be definitely assumed from concentration differences between peripheral plasma and plasma from the spermatic, ovarian and adrenal veins, that all three hormones are formed in the testes, ovaries and adrenal cortex (HOLLANDER, 1958; GANDY, 1965; HUDSON, 1967). It is, however, very difficult to assess the contribution of the individual glands to androgen production, since the androgens are converted into each other in the periphery (see below). In the normal man, at least 90% of plasma testosterone reaches the blood as testosterone (HORTON, 1966). Plasma testosterone is about 7 times lower in the castrated than in the normal man (COPPAGE, 1965). We can therefore assume with certainty that in the healthy man the majority of testosterone originates directly from the testes. The mean normal level of total plasma testosterone for the adult male is in the range of 700 ng/ml (see Table 1, p. 449) with a diurnal variation due to variation in production rate. There is a morning peak which is connected with fluctuations during sleep and rises in the testosterone level associated with periods of REM or paradoxical sleep (EVANS, 1971).

b) Biosynthesis and Production

The biosynthesis of androgens and estrogens in the testes proceeds in the same way as in the adrenal cortex (see p. 290 and Fig. 3). Cholesterol, which can also be fully synthesized from acetyl-coenzyme A in the testes, is probably an obligatory intermediate. A possible route of synthesis is via pregnenolone-progesterone-17α-hydroxyprogesterone to androstendione and testosterone. A second process involves conversion through 17α-hydroxypregnenolone to dehydroepiandrosterone and from there to androstendione. Numerous experiments *in vitro* and *in vivo* show that both biosynthetic pathways are possible in the gonads and adrenals, and it has never been ascertained that one process is more important than the other. Nevertheless, the 17α-hydroxypregnenolone-dehydroepiandrosterone route seems to predominate during fetal life. Synthesis of dehydroepiandrosterone sulfate from cholesterol sulfate and its possible conversion into active free androgens are probably only of secondary biological importance.

Assessment of the secretion of androgens from the gonads and adrenals is handicapped

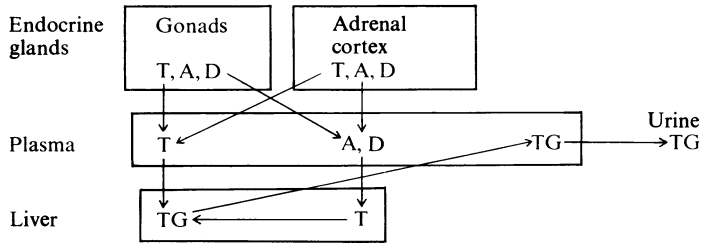

Fig. 6. Origin of testosterone in plasma and urine. (After LIPSETT and KOREMAN, 1964.) (T = testosterone, TG = testosterone glucuronide, A = androstenedione, D = dehydroepianandrosterone)

by the fact that circulating androgens can be converted into each other in the periphery. Thus, reversible conversion of testosterone into androstendione, and of dehydroepiandrosterone sulfate into dehydroepiandrosterone is possible, while dehydroepiandrosterone can be peripherally converted into androstenedione (VAN DE WIELE, 1963). According to HORTON (1966), 60% of the circulating testosterone in the woman, and less than 10% in the man, originates from circulating androstenedione. Conversely, 40% of the plasma androstenedione in the man arises from the circulating testosterone. It is still not known which organs are involved in these conversion processes. The role of the liver, in particular, is very obscure. All the reactions described above can occur in the liver, but the majority of testosterone formed in the liver is immediately and irreversibly further metabolized and conjugated. Labeled androstenedione given orally is therefore converted largely into testosterone, but only 2% of it is released into the peripheral circulation as free testosterone (HORTON, 1966). This explains why the so-called testosterone-urine production rates in the woman (estimated from the specific activity of testosterone glucuronide in the 24-hour urinary output after an intravenous injection of tracer doses of radioactive-labeled testosterone) are many times higher than testosterone-blood production rates (calculated by multiplying the metabolic clearance rate of infused labeled testosterone by the plasma testosterone concentration). In the man, however, this difference is insignificant.

c) Transport

Like glucocorticoids (see p. 291), the majority of unconjugated androgens also circulates loosely bound to plasma proteins. In man, 1.4% of testorone, 4.8% of androstenedione, and 2% of dehydroepiandrosterone are in a free, dialyzable from (RIVAROLA, 1968). The precentages of the free forms of these three androgens in the woman are 0.9, 2.7 and 2 respectively. They are partially bound to albumin, which shows a greater affinity for androgens than for glucocorticoids (DAUGHADAY, 1960) and has a practically unlimited binding capacity. It also appears that testosterone, and possibly also dehydroepiandrosterone, can also combine with a special β-globulin (MERCIER, 1966; VERMEULEN, 1969). In advanced pregnancy, the concentration of this testosterone-binding protein is raised, causing the proportion of free testosterone to fall to 0.2% (RIVAROLA, 1968), thereby preventing virilization despite increased plasma testosterone (MECKER, 1966).

d) Breakdown and Excretion

Testosterone circulating in the blood is very rapidly broken down and conjugated. The half-life as measured by the extractable radioactivity of the plasma after an intravenous injection of ^{14}C-labeled testosterone is on average 11 min during the first hour, and 100 min later on (SANDBERG, 1956). Only a slight amount of unchanged testosterone (less than 0.01% of the testosterone produced) is excreted in the urine (CAMACHO, 1964). About 1% of the circulating testosterone appears in the urine as testosterone glucuronide and 0.03% as testosterone sulfate. The greater part of testosterone is thus converted before it is conjugated and excreted.

It is impossible for us to discuss all the theoretically possible processes for the breakdown of testosterone, since, judging from their structure, there are about 60 different known substances which could be metabolites of testosterone (MOSEBACH, 1968). The following reactions are predominant in the catabolism of testosterone:

1. Isomerization or dehydrogenation of the 17β-hydroxy group;
2. α- or β-reduction of the double bond in ring A;
3. α- or β-reduction of the 3 keto-group.

In addition, there are numerous possible hydroxylations at different C atoms. Almost all the metabolites are conjugated with sulfuric acid or with glucuronic acid. Conjugated 17-

ketosteroids androsterone, etiocholanolone, and epiandrosterone are the quantitatively important metabolites of testosterone in the urine. About 40% of testosterone leaves the organism in this form (SANDBERG, 1956; WEST, 1951; SLAUNWHITE, 1957). The liver probably plays an important part in the catabolism of testosterone, but metabolism and conjugation are also possible in other organs.

The peripheral interconversion reactions of adrenal and gonadal androgens are described in section b. Because of these reactions it is impossible to draw valid conclusions about the type of androgen secretion and the organ from which it arises in healthy and diseased subjects from estimations of single 17-ketosteroid fractions. Even testosterone glucuronide is not exclusively derived from circulating testosterone; it can also originate from androstenedione (CAMACHO, 1964). This metabolite is therefore representative of testicular testosterone secretion only in the normal man. Since the portion of the testosterone produced which is excreted in the urine as testosterone glucuronide can vary between 0.15 and 1.88%, these figures are only of very limited value.

2. Estrogens

On average a man excretes about 10 μg estrogens in the urine in 24 hours, which is less than the woman does. The average daily production of estradiol in normal young men was calculated to be 70 μg (LIPSETT, 1966) according to the specific activity of estradiol glucuronide and estrone glucuronide in the urine collected after intravenous injection of ^{3}H-labeled estradiol. According to BAIRD (1968), the average so-called blood production rate (see p. 450) of estradiol in normal men is 39 μg/d and that of estrone 165 μg/d. Mean plasma concentrations are: estradiol 2 ng/100 ml; estrone 6 ng/100 ml. Treatment with HCG causes estradiol production to increase to twice or four times the original values. Estrogen excretion decreases after castration. We can therefore assume that most of man's plasma estrogens are directly or indirectly derived from the testicles. In a case of testicular feminization, estradiol concentration was found to be 10 times higher in spermatic vein plasma than in peripheral plasma (FRENCH, 1965). However, according to BAIRD (1968, 1969), less than 5% of total circulating estradiol is secreted directly into the bloodstream. More than 80% are produced by peripheral conversion of secreted testosterone, and approximately 15% by conversion of secreted estrone. On the other hand, 80% of circulating estrone is directly secreted into the blood stream, probably largely by the testicles (KELCH, 1972) and to a lesser extent by the adrenal cortex.

D. Physiology

1. Site of Production of Testicular Hormones

In man, testosterone is produced by the Leydig cells and to a slight extent by the adrenal cortex or by peripheral conversion of androgen precursors (see p. 449). In isolated damage to the tubular apparatus (bilateral cryptorchism, X-ray radiation), androgen production by the testes is maintained. Tumors of the Leydig cells cause a great increase in estrogen and androgen production. Stimulation with LH or with chorionic gonadotropin (HCG) causes an increase in the number and size of the Leydig cells as well as in testosterone and estrogen production. Leydig cells are present in the fetus, disappear a few weeks after birth and reappear during puberty. Excretion of testosterone varies accordingly. Chorionic gonadotropin increases estrogen excretion at the same time as it causes hypertrophy of the Leydig cells. The increase in estrogens exceeds that in testosterone so that the increased estrogen excretion cannot be due solely to the conversion of testosterone into estrogens.

2. Pituitary Control

The testes are controlled by the anterior pituitary. The pituitary has a two-fold control over the gonads in both male and female, and there is now little doubt that these two gonadotropic hormones, FSH (follicle-stimulating hormone) and LH (luteinizing hormone) or ICSH (interstitial cell-stimulating hormone) are identical in both sexes. In the female FSH acts on the follicle, and LH controls development of the corpus luteum. In the male, the Leydig cells are clearly under the control of LH, whereas the precise role of FSH and LH in regulating the tubular apparatus is not yet clear. Fluorescein-labeled FSH has been shown to localize in Sertoli cells and labeled LH in Leydig cells. LH exerts a stimulating effect on the seminiferous tubules by increasing the local concentration of testosterone. The mean concentrations in the adult male have been found to be between 4.1 – 16.0 μIU/ml for FSH and 10.9 to 24.2 μIU/ml for LH (2nd IRP units), both determined by bioassay or immunoassay. These values tend to rise with age (for review see BURGER, 1972). Clinical research now has biological as well as radioimmunological meth-

ods at its disposal for the separation of FSH and LH (see p. 563, Chap. X). They are, however, used for research purposes only. For clinical evaluation of single cases the bioassay of the total gonadotropins in the 24-hour urine is usually used. The rule that the hormone of the secondary controlled endocrine gland inhibits release of the stimulating hormone in the hypothalamus or in the hypophysis ("feedback" mechanism) (see p. 29, Chap. X), applies to the testes, as to all glands regulated by the anterior pituitary. Recently direct proof that LH secretion is inhibited by androgens has been obtained. A decrease of about 90% in the testosterone production rate can be demonstrated following oral administration of androgens and can be prevented by administering HCG at the same time (LIPSETT, 1966). On the other hand, most authors have not observed suppression of FSH due to androgens; at least their influence on FSH is controversial. Estrogens, however, inhibit LH and FSH only in pharmacological doses. They might also exert a direct effect on the Leydig cells, in certain dosages diminishing testosterone production with no decrease in gonadotropins. The formation of a second testicular hormone, "inhibin" or "x-hormone" in the tubules has been postulated, however, as gonadotropin levels are increased not only after castration or failure of the Leydig cells, but also in clinical syndromes with apparently isolated damage to the tubules (e.g. Klinefelter's syndrome). FSH is invariably elevated, while LH may be normal and is related to the testosterone level. The nature of this tubular substance, however, remains obscure. Although FSH levels may be elevated in severe oligospermia or azoospermia, it is still controversial whether there is any correlation between sperm count or the number of germinal cells and FSH level. It has been proposed that germinal elements, their breakdown products, or a yet unidentified "independent testicular station" (LEONARD, 1972), possibly located in the Sertoli cells, is responsible for FSH secretion in the male (THIEL, 1972).

On the other hand, in hypergonadotropic diseases with mainly tubular damage Leydig cells may also be functionally inferior. It is unlikely that estrogens formed in the Leydig cells or arising from testosterone conversion produce inhibition, since blockade of the hypothalamic receptors with the anti-androgen cyproterone (see p. 473), leads to a rise in the gonadotropins.

A diurnal rhythm for LH and FSH has not yet been conclusively demonstrated. It cannot, however, be excluded, although a diurnal rhythm in plasma testosterone levels and testosterone production rates might be due to variation in liver clearance for testosterone with vascular supply and physical activity (LIPSETT, 1966). The observation of seasonal fluctuations requires further investigation.

Human chorionic gonadotropin (HCG) obtained from the urine of pregnant women or from the placenta is chemically similar to human LH (see p. 670) and has almost the same biological activity. Its half-life, however, is considerably longer.

HCG causes plasma testosterone and testosterone and estradiol production rates to rise several-fold in normal males. There is a rise not only of testosterone in the spermatic vein of the dog, but also of dehydroepitestosterone, progesterone, and androstendione, precursors of testosterone (EIK-NES, 1967).

The reader is referred to the reviews by EIK-NES (1964) and BUTT (1967) for the influence of HCG, LH, and FSH on the testis in animal experiments, and to the book edited by SAXENA *et al.* (1972) for their effects in the human.

LH has a central role in the regulation of androgen biosynthesis and secretion by the testis, similar to that of ACTH in the regulation of the adrenal cortex. Like ACTH, LH stimulates the steroidal secretion increasing the biosynthesis of steroids. It acts at an early stage, probably before pregnenolone. The main action is the splitting of the cholesterol side chain. Furthermore, it stimulates the incorporation of labeled acetate into the androgens and so favors *de-novo* steroidsynthesis. Cyclic AMP seems to be the intracellular transmitter for ACTH and also for LH.

The exact mode of action, however, is still relatively unknown.

It is not sure to what extent LH acts by effecting changes of carbohydrate metabolism and protein synthesis, which have been observed *in vitro* in slides of testis tissue under the influence of HCG. As for ACTH, there may be different, and in part independent, sites of action at rate-limiting points in the biosynthesis. Active centers for the gonadotropin molecule are also unknown. Disulfide linkages and the carbohydrate of glycoproteins appear to be essential for the activity (BUTT, 1967). Like ACTH, HCG acts on intact cells only and not on tissue homogenates. For hormonal control of spermatogenesis see p. 455.

3. Action of Testosterone

The total effect of testosterone can be deduced from the difference between boy and man.

Testosterone promotes development of the genitalia, the secondary sexual characteristics, the larynx, the musculature, growth and skeletal maturation. It has a formative effect on the psyche.

a) Effect on the Genital System

Growth and function of the penis, epididymis, seminal vesicles, prostate, and Cowper's and Littre's glands are dependent on testosterone, as are growth and pigmentation of the scrotum. Testosterone acts via the seminal vesicles and the prostate to increase the seminal fluid and its fructose, citrate and acidic phosphatase content. Receptors for androgens have been found in the cytosol as well as in the nucleus of cells from the rat prostate (FANG, 1969). Testosterone is selectively accumulated in the prostate and seminal vesicles and is converted there to 5α-dihydrotestosterone (TVETER, 1968; BRUCHOVSKY, 1968). It has, however, yet to be confirmed whether dihydrotestosterone has a predominantly hyperplasiogenic effect on the prostate and its metabolite, androstane-3β,17β-diol, stimulates its secretion (BAULIEU, 1968; TAMM, 1972). In addition, it has to be proven, whether the hypertrophic prostate contains 4 to 5 times more dihydrotestosterone than normal (SIITERI, 1970).

The influence of testosterone on the testes themselves is complex. Testosterone has a trophic influence on the tubules. In hypogonadotropic hypogonadism the tubules do not develop under the influence of HMG alone but only when it is combined with HCG (see p. 474), i.e. after pretreatment with testosterone. Tubular atrophy and decreased spermatogenesis after hypophysectomy can be avoided to a great extent, though not entirely, by testosterone administration. Hormonal regulation of spermatogenesis has not yet been definitively explained (see p. 447). Testosterone is at least essential for the normal amount of spermatozoa and for the seminal fluid. On the other hand, large doses of testosterone lead to reversible atrophy of the testes and to azoospermia in the normal male. The seminal tubules become smaller, spermatogenesis decreases and finally ceases completely, the germinal epithelium becomes partly necrotic and diminished, the tunica propria thickens, and the Leydig cells disappear. After treatment is discontinued testicular tissue is completely restored (testosterone rebound, see p. 486). This action of high doses of testosterone is due to pituitary inhibition since it can be prevented by administering gonadotropin at the same time.

b) Effects on the Secondary Sexual Characteristics

The thickness of the skin, its circulation, and its ability to produce pigment increase under the influence of testosterone. The pubic hair assumes the characteristic male rhomboid form reaching up to the umbilicus only under testosterone influence, whereas in the woman and castrated male, it has a horizontal upper limit. Body hair can develop under the influence of testosterone, but only if the end-organs are sensitive, which varies widely individually. In most races, there is growth of beard and moustache in the male. North American Indians, however, remain beardless in spite of normal testosterone production, and in mongolian races the beard is scanty. The hair above the forehead recedes on both sides in the fully mature male at the peak of testosterone production. Baldness can only occur in the presence of testosterone. Eunuchs never develop baldness. Castration, however, does not bring about regression of baldness. Secretion of the sebaceous glands increases under the effect of testosterone. Its quantitative estimation indicates the degree of androgen production (STRAUSS, 1963). Overproduction leads to acne. Apocrine sweat glands (odoriferous glands) in the axillae and genital region begin to function. The larynx grows under the influence of testosterone, and the Adam's apple is formed. The voice breaks.

Testosterone promotes longitudinal and periostal growth of bones giving the male skeleton its characteristic form. The shoulders become broad and the pelvis narrow and long. The male development of the musculature is also due to testosterone.

In the woman, and especially in the child, testosterone has a "virilizing" effect, i.e., male sexual characteristics appear: beard and moustache, body hair, growth of the clitoris, deepening of the voice, forhead baldness, and in the child early skeletal maturation. Libido usually increases. The minimum dose leading to definite signs of virilization shows very great individual variations. On average, intramuscular injections of 150–300 mg testosterone propionate within one month produce signs of virilization in women. Contrary to popular opinion, hypertrichosis and hirsutism can appear with considerably lower doses of different androgens and also with so-called "anabolics" (see Chap. XX).

c) Metabolic Effects

Testosterone promotes protein synthesis. This "anabolic" action is always connected with a certain androgenic activity. Synthetic steroids

with an anabolic effect equal to or stronger than that of testosterone but with less virilizing effects have been successfully produced. Sensitivity to the virilizing properties of anabolic steroids varies with age and species. Children in particular are very sensitive, but no direct conclusions can be made from animal experiments about virilizing effects in the human.

The anabolic action of androgens promoting protein synthesis can be demonstrated *in vivo* in the human and in intact animals. The retention of nitrogen, electrolytes, phosphate and sulfate increases under the influence of the anabolically active hormones. They are retained in the same proportion in which they occur in the protoplasm. Raised amounts of protein are deposited in the accessory sexual organs and in the liver, kidneys, and musculature. Here too there are wide species-specific differences related to the same tissue among mammals. In addition, the same type of tissue responds differently to the anabolic action in various parts of the body (KOCHAKIAN, 1957). Estimation of ribonucleic acids at the same time shows that sometimes hypertrophy and hyperplasia occur together and sometimes hypertrophy alone.

Increased protein synthesis due to testosterone can be demonstrated *in vitro* in tissue sections from the liver and kidneys. Incorporation of labeled amino acids is increased, especially in the tissue of the seminal vesicles, and increased absorption of sulfate into cartilaginous tissue can also be shown.

However, we are only just beginning to understand the mechanism of anabolic activity. Labeled testosterone is rapidly stored in the accessory sexual organs, and later in the liver and musculature where it is converted to dihydrotestosterone. The anabolic action, however, only comes into effect when the labeled testosterone is uniformly mixed with endogenous testosterone. There may be two stages in protein construction, enzyme synthesis followed by protein synthesis. Testosterone increases different enzyme activities of protein metabolism such as β-glucuronidase, d-aminoacidoxydase, arginase, zymohexase and the phosphatases. Glutamicacid dehydrogenase, which is crucial in the metabolism of amino acids, is inhibited by testosterone and other steroids, probably due to alteration of its tertiary structure. The connection between the changes in these enzymatic activities and protein synthesis has not yet been explained. Finally, it has been shown in sections of the seminal vesicles of infantile rats that testosterone promotes neither the transport of amino acids through the cell membrane nor their synthesis during different stages of protein synthesis. Its effect is rather to enhance the combination of soluble ribonucleic acid-amino acid complexes to microsomal ribonucleoproteinates; this may be a remote result of a released chain of reactions (WILSON, 1962). Testosterone administered *in vivo* promotes the capacity of the ribosomes isolated from the prostate to incorporate amino acids into proteins. This effect seems to occur via an increase in the template RNA or their connection with the ribosomes (WILLIAMS-ASHMAN, 1964). Testosterone facilitates the attachment of RNA to ribosomes in some way which has still not been adequately explained (MANN, 1964). RNA synthesis in the seminal vesicles is promoted, and this also influences growth (VILLEE, 1967).

As for most hormonal activities, the molecular-biological bases are still at the hypothetical stage.

The influence of testosterone on muscular metabolism is indicated by a decrease in creatine excretion and by an increase in creatinine excretion. Creatine excretion, and creatinine excretion in particular, are increased due to the excessive synthesis caused by oral methyl testosterone.

The weight of the liver, heart, kidneys, and in particular, the accessory sexual organs decreases after castration. Testosterone produces the opposite effect. The effect on the kidneys, the so-called "renotrophic" action, does not appear to differ from the general anabolic action of testosterone. Renal blood supply is promoted by testosterone propionate in the healthy human. The fact that testosterone or anabolic steroids can cause a temporary standstill in uremia, in acute renal failure with oliguria, and in isolated cases of chronic renal failure is not due to the renotrophic effect, but to the anabolic effect and decreased production of protein metabolites.

In rats, testosterone and other anabolically active steroids can prevent adrenal atrophy after ACTH failure (see p. 300). The mechanism of action is unexplained.

It has still not been decided whether and in what way testosterone influences carbohydrate metabolism.

Testosterone, like many other steroid hormones, possesses the property of retaining sodium and therefore water. This effect is, however, considerably weaker than that of adrenocortical hormones, but edema may be an untoward side effect during sexual hormone therapy in older patients.

Effect on Fat Metabolism. The well-known clinical fact that eunuchs are less predisposed to coronary heart disease and that men under 40

years develop this disease 10 to 20 times more frequently than women of the same age is in keeping with experimental observations that estrogens inhibit experimental atherosclerosis and that androgens elevate low-density lipoproteins in the plasma.

Effect on the Blood. In the sexually mature male the hemoglobin level is on average 20% higher than in women and in eunuchs. The hematocrit and erythrocyte counts show corresponding differences, while the precursors in the bone marrow are not increased. The granulocytes and thrombocytes are unaffected by androgens. In rats, thymus and bone marrow are partially depleted of short-lived lymphocytes by high dosages of testosterone (FREY, 1970). High doses of androgens over a fairly long period promote normal or disturbed erythropoiesis in the human and may even lead to abnormally high hemoglobin values and erythrocyte counts. Slightly hypochromic macrocytes appear in the blood, and erythoid hyperplasia develops in the marrow. The mechanism of this effect is not clear. Inhibition of the erythropoietin-neutralizing effect of estrogens is being discussed.

Testosterone is capable of neutralizing some effects of estrogens. This antagonism also occurs directly at the reacting organ without involving the pituitary. See Chap. XIX, p. 1021) for the influence of androgens on development.

d) Psychic Effects

Small amounts of testosterone (e.g. testosteronepropionate, i.m., 5 mg every other day) cause no demonstrable effects in endocrinologically healthy women and men. On the other hand, treatment with high doses of testosterone (more than 500 mg per month) such as are used in carcinoma of the breast and in osteoporosis, usually causes an increase in the sexual drive of the endocrinologically healthy mature woman, but great quantitative and qualitative variations are observed in the individual reaction. Usually the increase in libido is found to be unnatural and pathologic. Emotional changes of short duration, often presenting as euphoria, may also occur.

For the psychic effect of testosterone and adrenal androgens in hypogonadism see pp. 459 and 309 respectively.

4. Semen

The morphology and biochemistry of the semen, a suspension of spermatozoa and other elements in the seminal fluid, have been extensively examined, particularly from the aspects of physiology and veterinary medicine. Origin, regulation of the formation, purpose, and function of its constituents have been extensively reviewed (MANN, 1964).

a) Spermatozoa

The cellular component of semen consists almost exclusively of spermatozoa, single cells of spermatogenesis and a few epithelial cells from the seminal ducts and their related glands. The morphology of the spermatozoa is discussed on pp. 447 and 494. Hormonal regulation of the formation and maturation of spermatozoa is still not clear. FSH and testosterone, or normally functioning Leydig cells induced by LH are necessary for the production of a qualitatively and quantitatively fully normal semen.

From individual experiments on hypophysectomized men, it has been deduced that HMG or FSH is essential either for maturation from the stage of spermatids to spermatozoa (GEMZELL, 1964) or for total maturation of spermatogonia (MCLEOD, 1966). Testosterone or LH and normal function of the Leydig cells are also necessary for quantitatively normal semen production. The entire process of spermatogenesis is still possible, albeit in a restricted way, even in the absence of testosterone (JOHNSEN, 1967; MCLEOD, 1966). Blockade of testosterone with cyproterone leads to inhibition of maturation at the spermatid stage (NEUMANN, 1968). Finally, experiments on testicular tissue cultures from different species have shown that differentiation of the germ cells right up to the late pachytic stage of meiosis is possible without hormones (STEINBERGER, 1967 a) and that FSH must be administered *in vivo* for completion of maturation (STEINBERGER, 1967 b). Spermatozoa are motile and produce the energy necessary for movement by fructolysis of fructose from the medium. Glycolysis is usually an anaerobic process. Entrance of air inhibits the use of the substrate via the Pasteur effect and with it the energy production and mobility of the spermatozoa.

Aerobic breakdown of phospholipids may be another source of energy. Spermatozoa are passively conveyed into the conducting system of the epididymis, where they mature further and are stored. Spontaneous movement does not arise until the surrounding medium provides oxidizable sugar or oxygen, or secretions of the prostate and seminal vesicles have a specific or nonspecific activating effect (MANN, 1964).

b) Seminal Fluid

The seminal fluid, with an average volume of 3.5 ml makes up the major part of the semen

in man; according to the species, the volume of semen varies between 1 ml (ram) and 250 ml (bear) per ejaculation, with corresponding differences in concentration (MANN, 1964). It is produced mainly by the seminal vesicles and prostate. The contribution of Cowper's and Littrè's glands and of the seminal ducts to the volume is only slight. Seminal fluid is a means of transport for the spermatozoa, providing a nutritional reservoir for them at the same time.

Seminal fluid contains proteins, peptones, amino acids, cholesterol, lactic acid, citric acid, pyruvic acid, inositol and sorbitol, which arise mainly from the prostate. In addition to Na, K, Cl and phosphate ions, traces of ascorbic acid and glucose are present. There are also 1 000–4 500 µg/100 ml of fructose, produced in the seminal vesicles from glucose through sorbitol. The normal amount of seminal fluid and its fructose and citrate content are dependent on testosterone activity (MANN, 1964; MCLEOD, 1966). Refer to MANN (1964) for the other organic and inorganic components. The high zinc content is worth mentioning. The polyamine, spermin, stems from the prostate and is responsible for the characteristic odor; it forms crystals in the cooled semen. Prostaglandins E and F, unsaturated dihydroxymonoketo acids are formed in the human prostate and lungs. They stimulate contraction of smooth muscle and have an antilipolytic action. Their physiological significance is not known (see Chap. XV, p. 990). Apart from this, proteolytic and other enzymes are found in the seminal fluid. These include fibrinolysin and fibrinogenase, which are important for coagulation and liquefaction of the semen. Acid and alkaline phosphatases are also present (MANN, 1964). Hyaluronidase is an intracellular enzyme, whose content seems to be proportional to the sperm count. The function of these enzymatic systems is unknown. It is possible that hyaluronidase is of importance in dissolving and penetrating the cervical mucus. The number of sperm may affect the fertility of a semen because of the content of hyaluronidase in the sperm. The importance of the seminal fluid in fertility is still very little understood. Ringer's solution with glucose is just as favorable a medium for maintaining motility of the spermatozoa. The buffer systems in the seminal fluid may be of significance.

Semen coagulates after ejaculation into a thick fluid mass with tapioca-like granules and reliquefies in 10–30 min after contact with air. The importance of this reliquefication is not clear, although it appears to be connected with the activation of sperm motility. Clotting impedes the loss of semen from the vagina. Perhaps, however, the only explanation for this phenomenon is a phylogenetic one.

E. Hypogonadism in the Male

1. Definition

The term male hypogonadism implies all states of testicular hypofunction, including incretory as well as secretory forms of insufficiency. Hypogenitalism means under-development of the external genital organs. Eunuchism [from εὐνή (bed) and ἔχειν (hold), εὐνοῦχος (the "bed-protector")] usually implies the condition after castration, whereas eunuchoidism means a congenital or acquired gonadal insufficiency. We also apply the term in this sense. Others use eunuchism for severe forms of hypogonadism and eunuchoidism for milder forms.

2. General Symptoms of Androgenic Failure

Only androgenic failure becomes clinically apparent, whereas impaired spermatogenesis does not affect the configuration of the body. The type is largely dependent on whether androgen production by the testes has been absent from birth, whether puberty has not occurred, or whether androgens have failed subsequent to puberty (see Fig. 7). The full picture of eunuchism and eunuchoidism arises after early castration or in congenital anorchia. The detailed description of the types of eunuchism can be found in the classical literature about castrates (PELIKAN, 1876; KOCH, 1921; WAGENSEIL, 1953; WOLF, 1934; PITTARD, 1934).

The physical stature of a man castrated early in life lacks male sexual characteristics, but female features are not pronounced (Fig. 8). The character is therefore neutral and childlike. The penis retains its infantile size even in the full-grown man, the scrotum is small, flat and not shaped like a sack, and is unpigmented; the prostate is not palpable or is only the size of a hazel nut, and the seminal vesicles are not palpable.

The skin is delicate, thin, and of a waxy pallor due partly to diminished blood circulation right up to advanced age. Normal male pigment formation is impaired in the absence of testosterone. In hypogonadism, ultraviolet radiation produces a reddening, but no browning. This may, however, develop subsequently under the influence of administered testosterone. In old age, the skin of the eunuch becomes very wrinkled, and old eunuchs are characterized by their wrinkled appearance. The cutaneous appendage organs remain underdeveloped. Pubic and ax-

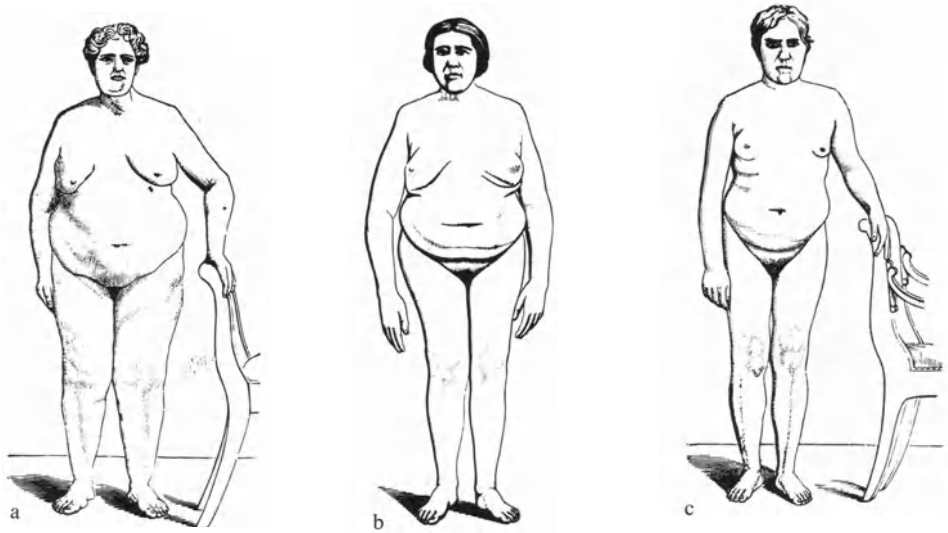

Fig. 7a–c. Influence of the timing of castration on the body build. a) Skopts who lost his genitalia at the age of 13: narrow shoulders, broad pelvis. b) Skopts castrated in his 6th year: broad pelvis. c) Skopts castrated at the age of 22: broad shoulders but narrow pelvis as in the normal man. (After PELIKAN, 1876)

illary hair may be completely absent, but scanty pubic hair of the feminine type is usually present due to the influence of adrenal androgens. Any other body hair is absent or remains at the lanugo stage. Beard and moustache may fail to develop, or there may be only a thin layer of lanugo on the cheeks and upper lip. In advanced age, as in the woman, a scanty beard is sometimes seen. The hair on the head is plentiful, fine in texture, and does not recede from the forehead on both sides. Eunuchs do not become bald, a fact which was already known to Aristoteles. The larynx in the castrated man is infantile and small; there is no Adam's apple, and it is not ossified. The voice therefore remains unbroken, and maintains its childish character. It is a childish soprano, not a woman's voice. It may become deeper with age.

There is a widespread opinion that castration leads to obesity. Statistical investigations, however, show that on average castrates and men with hypogonadism are no heavier than normal men. Nevertheless, fat deposition in eunuchs is prone to occur in characteristic parts of the body, such as the lower abdomen, hips, buttocks and mons pubis. Small fatty pads over the lateral parts of the eyelids are characteristic and lend a peculiar tired and sleepy appearance (BIEDL). The leptosomatic and pyknic habitus are otherwise no more peculiar to eunuchs than to the normal population. There is a thin tall type and a fat thickset type.

Growth of the bones and skeletal maturation are much influenced by testosterone. Failure of this hormone therefore causes both the eunuchoid stature and structural changes in the bones. The epiphyseal cartilages of the long bones fuse late, so that growth may continue to the 40th year. The epiphyses of the iliac bone may remain open for life. Delayed fusion of the

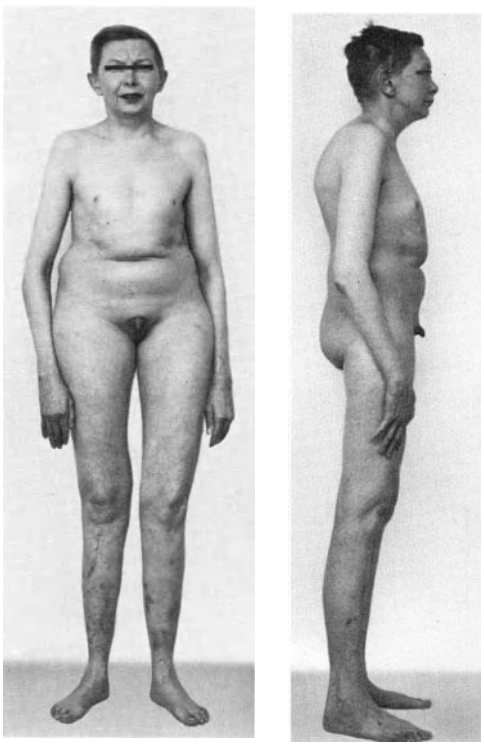

Fig. 8. 47-year-old man with congenital anorchia. Characteristic eunuchoid body shape. Upper body length : lower body length : half the extended arm length = 73 : 103 : 93. Small biacromial, wide bitrochanteric diameter. (Prof. A. SCHÜPBACH, Inselspital Berne)

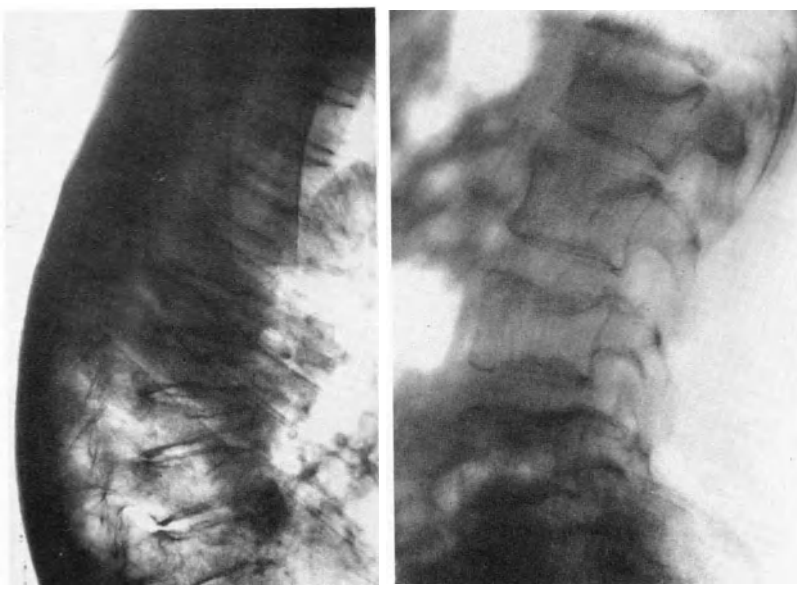
epiphyseal cartilages of the long bones results in the eunuchoid height. The length of the lower part of the body and that of half the arm span exceed the length of the upper part of the body. The hypogonadal patient is a standing giant and a sitting dwarf (Fig. 8). The average height of eunuchs lies a little above the normal height of the corresponding population groups. The height is not parallel to the testicular insufficiency. Apart from the over-dimensional extremities, the skull and pelvis also demonstrate peculiarities. The three diameters of the skull are smaller, and the face is broader at the level of the orbits (Fig. 9). Protruding cheek bones give the hypogonadal patient the appearance of a mongoloid type and are reminiscent of the face of an Eskimo or an American Indian. The pelvis assumes a form varying between the narrow male and the broad female form. The bitrochanteric diameter is enlarged, whereas the biacromial diameter is decreased. Thus, the V-form of the trunk typical of the male is absent (Fig. 8).

Fig. 9. 47-year-old man with congenital anorchia. Facial expression in extreme eunuchoidism: protruding cheek bones, fat pads over the lateral part of the eyelid. (Prof. A. SCHÜPBACH, Inselspital Berne)

Table 2. Symptoms of hypogonadism

Eunuchoid stature length of the lower part of the body and $^1/_2$ arm span > length of upper body (see Chap. XIX, p. 1022)
Underdeveloped, hypotonic musculature
Unbroken voice
Moustache, beard, body and axillary and pubic hair scanty or absent
Infantile genitalia small penis, testes, and scrotum

Failure of testosterone with loss of its anabolic action can lead to osteoporosis. Severe osteoporosis, with wedge-shaped vertebra and "fish vertebra" with vertebral infractions, is sometimes found in hypogonadal men after the 40th year (Fig. 10). According to Prokopius, the Byzantine



a b

Fig. 10. a) Extreme osteoporosis with anteriorly wedged vertebrae of the thoracic spine in a 55-year-old patient with idiopathic eunuchoidism. b) Osteoporosis with cod-fish vertebrae in a 46-year-old patient with congenital anorchia. (Prof. ZUPPINGER, Radiological Institute of the Inselspital Berne)

Field Marshall Narses was a eunuch with a hunchback. However, not all eunuchs develop osteoporosis. Only 2/3 of Chinese eunuchs have kyphoses (WAGENSEIL, 1953). NOVAKOWSKI (1952) found osteoporosis in 10 out of 26 cases of hypogonadism. Osteochondrosis appears to occur as frequently as osteoporosis and to present particularly frequently as Scheuermann's disease (juvenile kyphosis) with Schmorl's nodules on the vertebral column or the formation of wedge-shaped vertebra. Marginal ridges not yet fused with the vertebral bodies thereby become detached and so-called "apophysitis" develops.

Weakness of the connective tissue gives rise to flat feet and knock knees in male hypogonadism (Fig. 8). The joints are loose and are prone to arthrosis. Varicosis and hemorrhoids are common due to the yielding venous walls.

The male development of the musculature is absent even in hypogonadal males who do strenuous manual work. Increased creatine and creatinine excretions indicate impaired muscle metabolism.

Diminished protein metabolism leads to a slight fall in the basal metabolic rate. This is hypometabolism without concomitant hypothyroidism, although thyroid function may be reduced in a few cases (see p. 466). Castration does affect certain laboratory tests; hemoglobin, hematocrit, and erythrocytes are reduced by 10%, osmotic resistance is decreased, and the sedimentation rate is increased.

Although loss of testosterone after castration is compensated to a slight extent by the adrenal cortex, the gonadotropins are definitely elevated. FSH is increased to a greater extent, so that the FSH : LH ratio increases from 1.3 to 7 (BECKER, 1965).

Psyche. Postpubertal failure of androgens almost always results in a rapid loss of potency and sexual drive. Sometimes the drive is merely abated or recedes over the course of years. It seldom (in 1%) remains unchanged. The earlier castration is carried out the more pronounced is its effect on the psyche. It is mainly the physical drive which is influenced, and psychological sexuality may be retained as a need for love.

In congenital or prepubertal hypogonadism, there is psychic infantilism with impaired psychosexuality, inadequate character maturation, and to a lesser degree, impaired intellect, often associated with frequent primitive reactions and obstinacy – anxiety reactions and dependence on others. There is, however, also a physical "constitutional" form of infantilism, usually related to psychic infantilism, in which no endocrine disorder is demonstrable (BLEULER, 1964; LINDBERG, 1953).

Symptoms of the endocrine psychosyndrome are present: depression, moodiness, and passivity. Depression seems to be related to the preoperative personality and the social consequences of castration (BLEULER, 1955). The man castrated early in life and hypogonadal before puberty does not feel the loss of his sexual function for which he has never had any need. Male hypogonadism is therefore more often an incidental finding than a presenting symptom. In Albright's clinic this fact was known under the slogan "Forbes law": if a man complains of impaired sexual function, he is not suffering from a true endocrine disease but from a functional disorder. But even when a man castrated early does not suffer from his lack of sexuality, the high voice and eunuchoid appearance may cause social difficulties leading the patient to seek medical advice.

In contrast to early castration, later castration leads to little deviation from normal in appearance. Axillary and body hair and the beard, however, become sparser. The pubic hair seldom changes. Only the prostate invariably decreases in size. The later castration is performed, the less apparent are the physical changes (Fig. 7). See BLEULER (1964) for the psychiatric indications for and results of castration.

3. Investigation and Classification

The symptoms described above are more or less common to all forms of hypogonadism. However, only clinical examination and differentiation can reveal the etiology and pathogenesis. This is also of importance for the treatment.

Table 3 gives a survey of the full examination such as is possible in a hospital with laboratories and methods of endocrinological investigations at its disposal. Steps 1–3, inspection and palpation, simple X-rays and the simple semen examination, can, however, be undertaken by the general practitioner. It is possible to decide whether hypogonadism is present from these investigations alone. Sometimes their results may suggest classification into a sub-group. The differential diagnosis can, however, only be made with the aid of estimation of the gonadotropins, sex chromatin, and testis biopsy. Secondary sexual characteristics usually allow a good estimation of the 17-ketosteroid excretion, particularly of plasma testosterone. Estimation of 17-ketosteroid is only of importance in differentiating panhypopituitarism, in which the values are very low. Plasma testosterone gives more information than urinary testosterone, which

reflects only a small percentage of the total testosterone production.

Table 3. Clinical investigation for male hypogonadism

1. *Inspection and palpation*
   - Genitalia:
     - Length of the penis and its circumference (see Chap. XIX), hypospadia, epispadia
     - Size of testes (see Chap. XIX), consistency, tenderness
     - Size of the prostate and seminal vesicles
   - Stature:
     - Height, weight, upper body length, lower body length, arm span, constitution, fat pads
   - Hair distribution:
     - Pubic and axillary hair, moustache and beard growth body hair, hair on the head
   - Skin:
     - Texture, pigmentation, sweat and sebaceous secretion
   - Larynx:
     - Adam's apple, voice, pitch
2. *X-rays of the skeleton*
   - Skeletal maturation:
     - Hand and pelvis X-rays
   - Osteoporosis:
     - Thoracic and lumbar vertebra, lateral view
   - Pituitary size:
     - Sella turcica
3. *Examination of the semen*
   - Volume, viscosity, fructose content
   - Sperm count, motility
   - Morphological differentiation
4. *Sex chromatin, possibly karyogram* (see Chap. XII)
5. *Hormone determinations*
   - 17-ketosteroids
   - Gonadotropins in the urine
   - Testosterone in plasma and perhaps in the urine
6. *Testis biopsy*
7. *Tests for extra-gonadal pituitary functions* (see p. 122)
8. *Chorionic gonadotropin test for functional reserve of the Leydig cells* (see p. 474)

4. Different Forms of Male Hypogonadism

According to HOWARD (1950), there are two main groups: primary hypergonadotropic and secondary hypogonadotropic testicular insufficiency. We differentiate tubular, interstitial, and combined testicular insufficiency within each of the main groups (Table 4, Fig. 11).

The diagram is based on the assumption that the tubules are dependent on FSH, and the Leydig cells on LH. Testosterone probably has a local effect on maturation of the sperms, so that LH is also indirectly associated with spermatogenesis. The accuracy of the diagram has been largely confirmed since estimations of FSH and LH have been possible. For clinical purposes, when only the total gonadotropins can be clinically measured, isolated FSH or LH insufficiency has usually been recognized at testis biopsy.

Table 4. Classification of male hypogonadism

I. *Primary testicular insufficiency* (hypergonadotropic hypogonadism)
- A. Tubular and interstitial insufficiency
  1. Castration syndrome
     a) early
     b) late
  2. Congenital anorchia ("vanishing testis")
  3. Total atrophy
  4. Hereditary disorders and degenerative syndromes
  5. Anti-androgens ("chemical castration")
- B. Tubular insufficiency
  1. Exogenous damage
     a) Inflammation
     b) Heat (fever, injury to the spinal cord, bilateral cryptorchidism)
     c) α, β, γ rays
     d) Pressure
     e) Toxins
  2. Germinal aplasia (del Castillo syndrome), possibly identical to 1
  3. XXY trisomia, true chromatin-positive Klinefelter's syndrome and other chromosomal aberrations
  4. Chromatin-negative, "false" Klinefelter's syndrome
- C. Interstitial insufficiency
  1. Male climacteric

II. *Secondary testicular insufficiency* (hypogonadotropic hypogonadism)
- A. Tubular and interstitial insufficiency
  1. Isolated gonadotropin failure:
     "Idiopathic eunuchoidism" with low FSH
     Kallmann's syndrome
     Delayed puberty
     Hypothalamic damage
     Functional gonadotropin failure in starvation, cachexia, myxedema
  2. Panhypopituitarism, idiopathic or through pituitary destruction
  3. Adrenogenital syndrome
  4. Inhibition of FSH/LH by estrogen therapy or via impaired breakdown of estrogens in liver cirrhosis
- B. Tubular insufficiency
  Pubertas praecox
- C. Interstitial-cell insufficiency
  Testosterone therapy "Fertile eunuchs"?

a) Primary Testicular Insufficiency (Hypergonadotropic Hypogonadism)

In primary hypogonadism, gonadotropin excretion is raised to more than 3 mg/RP_2 per 24 hours. Normal values lie between 0.3 and 2 mg/24 hours, i.e. >4–10 IU FSH and >2 IU LH.

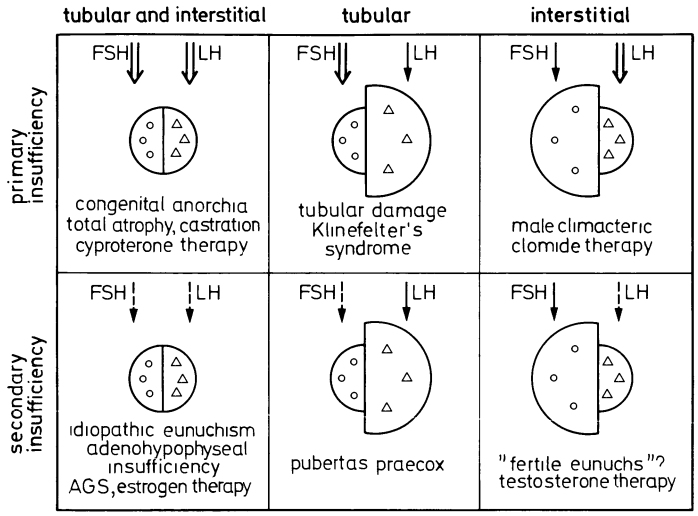


Fig. 11. Diagram of primary and secondary, tubular and interstitial testicular insufficiency

1 mg of the 2nd international reference preparation of HPG (1964) corresponds to 20–25 mouse units.

α) Tubular and Interstitial Insufficiency

1. Castration. The practice of castration was widespread in ancient times among the oriental peoples and has only fallen out of favor since the beginning of this century. The Greeks rejected the practice and it was only accepted in Rome during imperial times due to oriental influence. Castration was carried out to obtain harmless guards for harems, to tame war prisoners, to maintain the soprano voice in boys, and finally for religious reasons, in the Kybele cult, by the early Christians, and by the Skopts in Russia in the middle of the 18th century, on the authority of references in the New Testament (Matthew 19; Luke 23, 29). Although it is generally believed that loss of the male hormone leads to deprivation of energy and activity, eunuchs have achieved extremely high military, political, and religious honors (Narses, as Justinian's Field Marshall, Posides in imperial Rome, the patriarch Origenes).

Castration performed before puberty leads to the fullblown picture of eunuchism. The prostate and seminal vesicles atrophy, the thymus is hyperplastic, and characteristic changes occur in the anterior pituitary. The basophil and large chromophobe cells increase in number, and vacuoles and colloid appear in the basophil cells (the so-called castration or signet ring cells). Occasionally it even leads to tumor formation with enlargement of the sella (Bower, 1968). The 17-ketosteroid excretion is on average 7 mg/24 hours, corresponding to that produced by the adrenal cortex. It can be reduced to zero by 2 mg dexamethasone in the inhibition test.

Urinary excretion of testosterone-glucuronide decreases after castration, but by less than 90%, so that a compensatory increase in adrenal testosterone production is thought to be possible (Tamm, 1968).

Total gonadotropins are increased. It remains unexplained why FSH rises more, so that the FSH/LH ratio changes from 1 to 3–4 (Keller, 1968; Johnsen, 1972).

2. Congenital Anorchia, "Vanishing Testis". This diagnosis can be suspected when the scrotum is empty and the inguinal canal is free. The diagnosis can be confirmed and differentiated from bilateral cryptorchism only by surgical means. When the body shows signs of male sexual characteristics, there must have been a testis anlage which was destroyed during embryonic life. We therefore find "congenital anorchia" a more suitable term than "testis aplasia". "Prenatal castration" is no more explicit. The "vanishing testis" implies the pathogenesis better than "anorchia" (Abeyaratne, 1969). Complete absence of the gonads always leads to female sexual characteristics, regardless of the chromosomal sex. Stimulation with HCG does not effect any rise in plasma or urinary testosterone. Persistent extra-adrenal production of testosterone of unknown origin has been observed in patients with anorchia (Kirschner, 1970).

3. Total Atrophy. Total atrophy without differentiated cells can be the final stage of different pathological processes, such as orchitis, trauma, testicular torsion in particular, and impairment of vascular supply (defective orchidopexy, herniotomies). It may, however, also occur in the presence of positive sex chromatin and be an extreme form of Klinefelter's syndrome. Usually the etiology is unknown.

A small number of functioning Leydig cells often seems to be present, however; patients with testicular atrophy usually react to stimulation with HCG with a slight increase in testosterone excretion.

4. Hypogonadism in Hereditary Disorders and Degenerative Syndromes. In these cases there is predominantly primary damage to the testes, usually with involvement of the secretory and hormonal sections.

Steinert's Atrophic Myotonia. In this disease, which is inherited through a dominant autosomal gene, protein metabolism is impaired. In 80% of cases, the testes are atrophic in advanced age, whereas 70% of patients are fertile during early adulthood. Gonadotropins can generally be found in normal concentrations and are rarely elevated. The main feature revealed by testis biopsy is sclerosis of the tubules, and histological findings are remarkably similar to those in Klinefelter's syndrome, though the atrophy of the tubules is more homogeneous. Hypoplastic tubules such as occur in Klinefelter's syndrome are not seen. Leydig cell hypertrophy is also more homogeneous than in Klinefelter's syndrome. Differentiation is possible by the negative sex chromatin. Gonadotropin excretion is usually normal and plasma testosterone only seldom reduced, but HCG produces an inappropriate response (LIPSETT, 1966). Symptoms due to androgenic deficiency, gynecomastia and eunuchoid tallness are uncommon, in contrast to Klinefelter's syndrome.

Werner's Syndrome. This recessive sex-linked hereditary disorder first presents in later adulthood with premature baldness, if non obligatory small stature is not present. Other symptoms such as atrophy of subcutaneous fatty tissue, sensibility disturbances with cutaneous ulcers, cataracts, diabetes, arteriosclerosis and non obligatory primary secretory and incretory hypogonadism may develop. The high crowing voice is characteristic and cannot be explained by hormone failure. Incomplete forms of the illness may occur.

Rothmund's Syndrome. Poikilodermia, alopecia and cataract formation are usually associated with hypogonadism. The lack of pubic and axillary hair is probably cutaneous in origin and not due to androgen failure.

Laurence-Moon-Biedl Syndrome. This degenerative syndrome, which is only partly familial, consists of obesity, retinitis pigmentosa, debility, poly- and syndactylia. Primary or secondary hypogonadism can sometimes present as a facultative symptom.

Prader-Labhart-Willi Syndrome (Flour-Bag Dwarfs, HHMD-Syndrome, Myatonic Diabetes). Myatonia in very early infancy, small stature, obesity, imbecility, and diabetes of the stable adult type occurring at puberty are often associated with bilateral cryptorchism or anorchia and hypogonadism in boys. It has not yet been decided whether the hypogonadism is of the primary or secondary type. The definite, though inadequate increase in testosterone excretion in response to stimulation with HCG makes a purely primary hypogonadism appear unlikely (ZACHMANN, 1970). Secondary sexual characteristics are poorly developed in the adult. Beard and moustache are missing, pubic hair is of the female configuration, and the penis is infantile. Testes biopsies in the 3rd and 5th year of life show no germinal cells. Post-mortem findings in a 28-year-old included absence of spermiogenesis with slight tubular sclerosis and Leydig cells curiously rich in lipoid.

Hypogenitalism is present even in the male fetus. The scrotum is never definable from the perineal skin; it may be completely absent, or there may be a rudimentary suggestion of a scrotum in the form of coarse transverse folds in the skin with a median raphe. Often scoliosis, strabismus, and other degenerative symptoms are also present (Fig. 12).

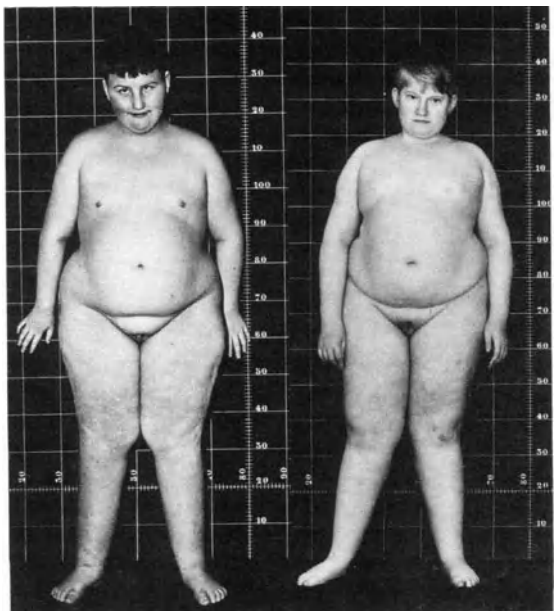
Cystic Fibrosis of the Pancreas. Males affected by this hereditary disease now sometimes reach adulthood. They are practically without exception sterile. The vas deferens is usually absent; the epididymis is malformed, the testes are often smaller than normal, and the germinal epithelium is diminished (KAPLAN, 1968).

The syndrome described by WEINSTEIN (1969), in which blind and deaf patients have small testes with hyaline tubuli and proliferating Leydig cells is also a form of primary hypogonadism, the gonadotropins being clearly increased. Hyperuricemia and hyperlipidemia seem to be constant symptoms in this syndrome. Plasma testosterone is in the lower normal range, and the secondary sexual characteristics are normally developed. The Leydig cells, however, are refractory to stimulation with HCG.

SOHVAL (1953) described cases of familial hypogonadism with gynecomastia, skeletal malformations, diabetes, and debility, which can probably also be classified into this syndrome. Histological findings of tubular changes are similar to those in Klinefelter's syndrome. There is tubular fibrosis and germinal aplasia,

the Leydig cells being proliferative in some parts and scanty in others.

See Chap. XII, p. 729 for other forms of more or less pronounced primary hypogonadism where male pseudohermaphroditism is the predominant clinical feature (testicular feminization; incomplete testicular virilization; Gilbert-Dreyfus syndrome; hereditary, vulviform or perineal hypospadia).



a b

Fig. 12a and b. 2 boys with the Prader-Labhart-Willi syndrome. a) 9-year-old. Oligophrenia, extreme obesity (76 kg with a heigth of 143 cm) especially in the region of the abdomen, the buttocks and the thighs of X-shaped legs, strabismus, acromicria, hypogenitalism. Occurrence of diabetes mellitus of the adult type at the age of 11. b) 17-year-old patient with oligophrenia, acromicria and subclinical diabetes, scoliosis, flabby obesity and dwarfism (140.5 cm at 67.5 kg), whose non-identical twin brother has a height of 176 cm and a weight of 54.5 kg, is normally built, of normal intelligence, and has a normal glucose tolerance (KspZ)

β) Tubular Insufficiency

1. Exogenous Damage to the Tubules. The tubules, and the germinal cells in particular, are more sensitive to exogenous noxious agents than is interstitial tissue. All degrees of tubular damage can occur, ranging from isolated failure of the germinal cells to complete fibrosis of the seminiferous tubules. Patients with tubular insufficiency appear normal since the androgenic action is intact, but the testes are usually too small. Apart from sterility, sexual function need not be impaired. The 17-ketosteroids and testosterone are normal or slightly reduced. On the other hand, gonadotropin and especially FSH excretion is nearly always elevated.

Inflammation. General infections spread to the testes relatively often. The first inflammatory reactions in the form of edema, hyperemia and small foci of inflammatory cells, possibly with abscess formation, usually arise in the interstitial tissue. The tubules are also involved at an early stage. In severe infections, such as smallpox, typhoid fever, and mumps, extensive necroses may develop. Fields of scar tissue with completely fibrotic tubules remain as a result from such types of orchitis.

These sequels are most commonly seen in association with mumps. The testes are not necessarily reduced in size. One or all tubules may be sclerosed. The interstitial tissue is penetrated by scars but usually contains well-maintained Leydig cells, in contrast to those found in Klinefelter's syndrome, in which the Leydig cells are abnormal and interstitial tissue contains less collagenous fibers. Mumps causes orchitis in one fifth of adult cases. This seldom occurs in childhood. Both testes are involved in only one sixth of cases. Atrophy follows in 40–60% of cases of orchitis due to mumps. Hypogonadism due to orchitis following mumps is therefore relatively uncommon. Since the mumps virus does not affect the immature testis there has been an attempt to use stilbestrol to produce reversible atrophy in adults with mumps. Control series, however, did not show any prophylactic effect. Cortisone, 300–200 mg, or prednisone, 60–40 mg per day, does not influence the course of the illness, as controls showed (KOCEN, 1961). The painful phase is, however, shortened. Only gamma globulins from convalescents have some prophylactic action (KABAL, 1963). Other viral infections which sometimes lead to orchitis with atrophy are chickenpox, dengue, phlebotomous fever, mononucleosis infectiosa, ECHO and Coxsackie-B viruses (CRAIGHEAD, 1962).

On the other hand, the incidence of luetic orchitis and luetic testicular scars has certainly been overestimated. Syphilis of the testis arises in two main forms: as interstitial and intratubular orchitis and as a gummatous inflammation. Although this can lead to total destruction of testicular tissue, diffuse orchitis can result in testicular fibrosis with predisposition for the tubules. The important clinical fact is that such cases of orchitis may progress undetected.

So-called granulomatous orchitis of unknown etiology is seen more often. It usually affects only one testicle and is characterized histologically by inflammatory foci of a granulomatous,

tuberculoid nature. There may be some connection with malakoplakia (BÜNZLI, 1968).

Tuberculous orchitis occurs in foci, hardly ever involves the whole testis and very seldom leads to hypogonadism without castration.

Thermogenic Damage. The destructive effect of heat has been observed in patients with pneumonia. It has been demonstrated experimentally that induced fever reduces the sperm count substantially in young men (STEINBERGER, 1959). Damage was seen in the rat testes at temperatures above 43° C.

The pathogenesis of tubular insufficiency in injuries of the spinal cord has not yet been explained. All degrees of damage to the germinal cells are found, often associated with gynecomastia. Since impairment of autonomic innervations can usually be demonstrated at the same time, it is possible that damage due to heat results from vasodilatation. On the other hand, the disturbance can be attributed to group IIB (Table 4).

Damage in bilateral cryptorchism is also due to the effect of the intra-abdominal temperature, which is 4° C higher than that in the scrotum. The tubules can show every degree of destruction. Often the Leydig cells are entirely spared (see p. 478). Frequently, however, undescended testes show primordial disorders in the germinal cells. Cryptorchism may also be caused by gonadotropin deficiency and can thus be classified as secondary testicular insufficiency.

It has been claimed that oligospermia may result from wearing tight underpants. Loose-fitting pants will at best contribute to an improvement.

Ionizing Radiation. α, β, and γ rays can lead to all degrees of damage to the tubular apparatus, depending on their intensity and the duration of exposure. Damage due to irradiation typically starts in the most sensitive elements, the spermatogonia, whereas the other stages of development are initially undamaged but cannot be regenerated. In contrast, the usual atrophy of the seminal epithelium affects the highly developed stages first. Radiation damage after atomic bomb explosions and radioactive exposure presents primarily as severe destruction ranging from minor to complete loss of germinal epithelium. From a few long-term investigations it can be concluded that the regenerative capacity, which takes some years to develop, is surprisingly great (HEMPELMANN, 1952).

Pressure Damage due to varicoceles and hydroceles leads to reversible azoospermia. Elevation of temperature may also have some effect. Pressure damage resulting from hematomas due to birth trauma can lead to permanent destruction (NOWAKOWSKI, 1956). Torsion of the testes, which is characterized by the persistence of pain on elevation of the testes, may result in infarction of the total testicular tissue and in extensive necrosis if the blood supply is not restored by surgery within a few hours.

Hypoxemia. Reversible oligospermia resulting from staying at extremely high altitudes is due to hypoxemia.

Germinal Aplasia (Del Castillo Syndrome, Sertoli-Cells-Only Syndrome). Patients with this syndrome seek medical advice because of sterility. Complete azoospermia is found and the physical findings are otherwise unremarkable, as is sexual function. Gonadotropin levels are usually elevated, but may also be normal. The testis biopsy shows typical findings: smaller tubules with fully mature Sertoli cells, with no cells of spermiogenesis.

DEL CASTILLO (1947) assumed that there was an embryonic developmental disorder in which gonocytes failed to migrate into the medulla. Occasionally, impaired growth and malformations such as occur in the Ullrich-Turner syndrome have suggested some connection with gonadal dysgenesis.

However, the histological findings resulting from injuries, X-rays, exposure to atomic bomb explosions (HEMPELMANN, 1952), as well as after treatment with cytostatics such as Myleran (BOLLAG, 1954), are the same.

Finally, autoimmunological reactions against testicular tissue produce a similar picture (MANCINI, 1964) (see p. 482). It is not yet known whether germinal cell aplasia is a single syndrome, or whether different causes can lead to the same condition.

2. Klinefelter's Syndrome (True, Chromatin-Positive Klinefelter's Syndrome, XXY Trisomia). Demonstration of the positive sex chromatin in 1956 and of XXY trisomia in 1958 showed, surprisingly, that the clinical picture of hypogonadism defined by KLINEFELTER and coworkers (1942) was due to a chromosomal aberration.

Klinefelter's syndrome is much more common than was assumed before it was possible to estimate the sex chromatin. Investigations of male newborns for sex chromatin gave an incidence of 1:1000, possibly even 1:400, among a population with lower intelligence. In schools for mental deficients the incidence is 1:42. Patho-anatomical findings of mixed post

mortems gave an incidence of 3.1:1000 (PASI, 1965).

Etiology and Pathogenesis. In contrast to the normal man with 46 chromosomes, the Klinefelter patient with a double X sex chromosome has 47 chromosomes. It is assumed that the disturbance usually arises in the mother during the first meiotic reduction due to nondisjunction of the sex chromosome, so that the ovum contains two X chromosomes instead of the haploid set of chromosomes with one X chromosome. It is possible that in a few cases of Klinefelter's syndrome the XXY trisomia is derived from the union of a normal ovum with an XY sperm resulting from non-disjunction in the father, in analogy to red-green color blindness, which is linked to the Y chromosome. Mosaic structures, i.e. cells with an XXY set of chromosomes in addition to cells with normal or XYY sets can occur in Klinefelter's syndrome. It is not yet possible to give the incidence of these.

As in mongolism, the other common condition caused by a non-disjunctional chromosomal aberration, the maternal age at the time of birth of Klinefelter patients is usually significantly higher than the average. It is conceivable that non-disjunction increases with the aging of maternal ova. On the other hand, there is no relation to paternal age. There is no familial incidence. However, other chromosomal aberrations, such as malformations of different types, occur more frequently among siblings of Klinefelter patients. The presence of the Y chromosome in mammals leads to the development of a male phenotype, but it is still unexplained why excess Y chromosomes can cause deviations in the development of the testes, degeneration of the tubular apparatus, disappearance of the germinal epithelium, inferior Leydig cells, and frequently gynecomastia as well.

KLINEFELTER'S original hypothesis that a second testicular hormone formed in the tubules, "X-hormone" or "inhibin", inhibiting FSH and development of the breasts in the normal man, has never been substantiated.

On the other hand, it has been shown that function of the Leydig cells is disturbed. Chorionic gonadotropin tests with estimation of estrogens (DECOURT, 1962), testosterone production rates, and plasma testosterone measurements (LIPSETT, 1966) show that testosterone production is in the lower normal range or reduced, and that it cannot be stimulated by HCG or only insufficiently. Testosterone synthesis is not blocked, but the abnormal Leydig cells need an increased LH stimulation to produce plasma testosterone levels approaching normal. LH is found to be elevated (BECKER, 1965), and the Leydig cells, which are already under maximum LH stimulation, cannot be further stimulated. Hyaline degeneration in the tubules is thought to be due to dysfunction of the Leydig cells (JOHNSEN, 1967).

Clinical Features. Before puberty, Klinefelter's syndrome can be clinically suspected only from the patient's lack of intelligence. The diagnosis, however, can be confirmed at any age by a positive sex chromatin finding, or the karyogram. The onset of puberty is delayed, and the testes maintain their infantile size of 2 cm^3.

Testis biopsies shortly before puberty show shrinkage of the germinal cells and developing tubular sclerosis (SIEBENMANN, 1958). During puberty, the size of the testis usually increases to about 4–6 cm^3 and decreases later with advancing tubular sclerosis.

In adults the testes are extremely small; their cut surfaces are intensively brown colored. The histological picture is characterized by an irregular sclerosis of the tubules with loss of the spermiogenesis and a relative increase of the Leydig cells (Fig. 13). The seminiferous tubules are atrophic; all stages of atrophy up to complete hyalinization of the tubules with total loss of the epithelium are found. However, especially in young patients, hypoplastic tubules and their remains can also be seen. The atrophic tubules may completely disappear so that finally only nests of Leydig cells remain. The Leydig cells show marked focal proliferation which manifests itself grossly in the intense brown discoloration of the cut surface. The polymorphism of the Leydig cells is very typical. Often they are markedly enlarged and possess a vacuolated cytoplasm. The nuclei also vary very markedly in size. With Feulgen's or hematoxylin stains the sex chromatin may be easily demonstrated. Gynecomastia is histologically characterized by an intense development of connective tissue whereas an epithelial proliferation is less conspicuous.

In adulthood, testicular atrophy is the one constant clinical finding. The body stature and secondary sexual characteristics can vary between the most severe eunuchoidism and a completely normal virile appearance (Figs. 14 and 15). As a rule, there are deviations in the body proportions, and the length of the lower half of the body is definitely greater than that of the upper body and half the arm span. Tallness and long legs appear before puberty and are thus not due to lack of androgens (SCHIBLER, 1971). There is often cubitus valgus and clinodactyly (ZUPPINGER, 1967). The pubic hair may be scanty or quite well developed, but

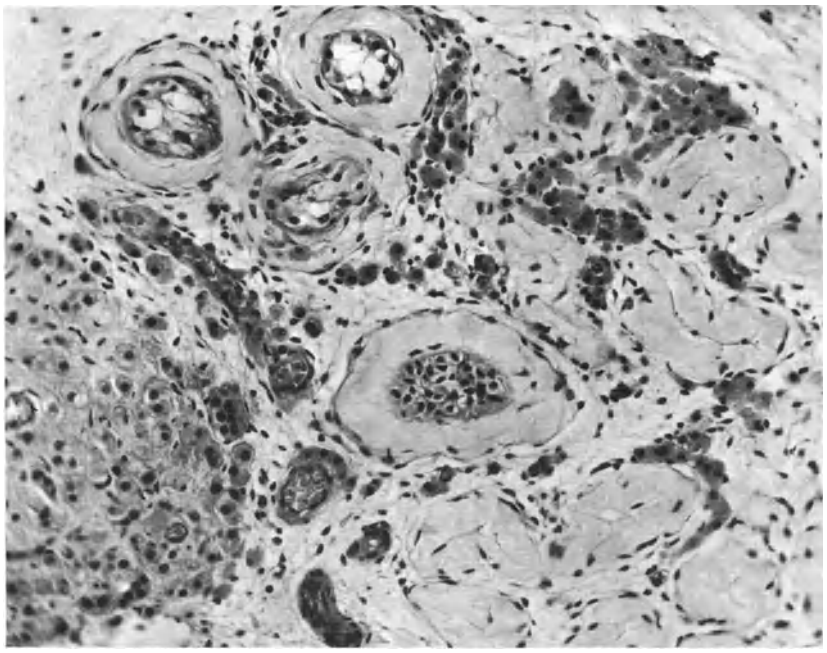


Fig. 13. MB 2996/53, 25-year-old man. Testes in Klinefelter's syndrome. Severe sclerosis of the tubules and focal hyperplasia of Leydig cells. HE staining, 180 : 1

it is of the feminine configuration with the horizontal upper border. The beard is usually thin, baldness seldom occurs, and the voice is masculine but rather high-pitched. The testes are almost always smaller than 5 cm^3, of normal or sometimes of reduced consistency. The prostate is of normal size or slightly smaller.

Two thirds of Klinefelter patients have gynecomastia which causes them to consult their doctor. It begins during or soon after puberty with development of pigmentation and swelling of the areolae. Hard glandular tissue surrounded by much fatty tissue then becomes palpable. In the majority of cases it is possible to differentiate the glandular from the adipose tissue by palpation with no difficulty. The gynecomastia can vary widely in degree, from the size of a hazel nut, with nonvisible, only palpable glands, to the size of the breast of a young woman.

Sexual function of Klinefelter patients is normal to begin with. Erection and ejaculation are unaffected. Sexual intercourse is usually entirely normal during early adulthood. Sterility is present almost without exception. A single case of a highly probable fertile Klinefelter patient has been reported. There was a sperm count of 200 000 cm^3 and the testes were as large as cherries (Warburg, 1963). Signs of involution, however, appear very early, often after the 35th year, obviously due to the inferior Leydig cells. Potency tends to decrease. Loss of androgens often results in a striking early osteoporosis. Thyroid hypofunction has been observed several times with no clinical manifestations and is probably of the primary type (Koller, 1955; Davis, 1963; Zuppinger, 1967). Diabetes, hyperlipidemia and obesity apparently occur more frequently than in the normal population (Zuppinger, 1967).

The majority of Klinefelter patients are slightly oligophrenic. Only a few cases are highly imbecile. On the other hand, not many are of average or above average intelligence. Pathologic EEG findings are common. In addition to the lack of intelligence, there is a certain psychological infantilism with an increased incidence of infantile deviations of sexual drive such as exhibitionism, transvestitism and homosexuality. Sexuality is, however, not very pronounced and decreases after puberty over the course of years and often disappears completely in the adult. Most of the patients show an endocrine psycho-syndrome with increased irritability and mood lability.

There may be an increased incidence of carcinoma (Lubs, 1962). This has been confirmed in the case of carcinoma of the breast, which occurs 70 times more frequently in Klinefelter patients than in normal males and about as frequently as in women (Jackson, 1965).

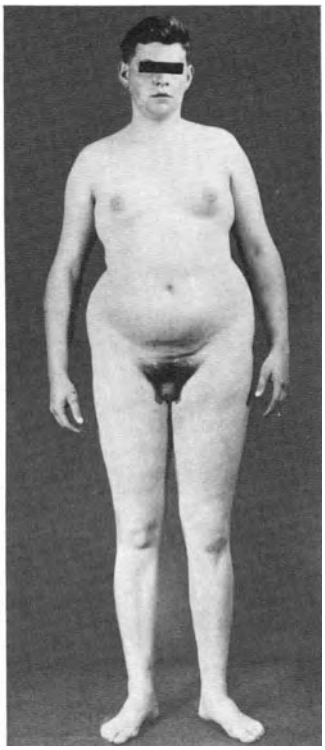

Fig. 14. 19-year-old, Klinefelter's syndrome, obese type with pronounced gynecomastia

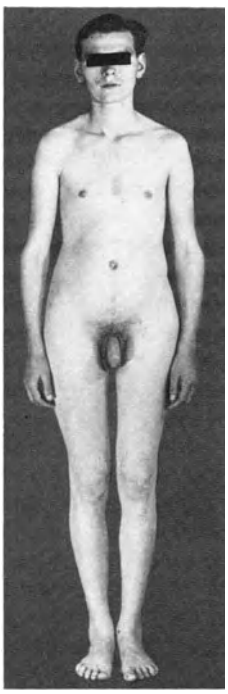

Fig. 15. 25-year-old, Klinefelter's syndrome, slender type, slight gynecomastia

Laboratory Findings. The sex chromatin in the buccal mucosal smear and the root of the hair is positive. Somewhat lower average values are found than in women, but there is no overlap with normal male values. Sex chromatin estimation from the nuclei of granulocytes is less suitable for the diagnosis of Klinefelter's syndrome since the drumstick appendage is found more frequently than in men, but less than in women. Examination of the ejaculate shows a reduction in semen volume. The fructose content is normal. There is azoospermia, and only very occasionally can single spermatozoa with impaired motility be seen.

The 17-ketosteroids may vary considerably. They are usually slightly reduced. Pregnanediol, pregnanetriol, estrone and estradiol are also decreased (GIORGIO, 1963). However the estrogen production rates are, increased (GABRILOVE, 1970). This suggests impaired conversion of androgens to estrogens. The rise due to puberty is retarded, while the fall due to age sets in soon after the 30th year. The low normal testosterone production can be stimulated by HCG only slowly and to a small degree, indicating a limited reserve of Leydig cells (LIPSETT, 1965; PAULSEN, 1968). Gonadotropin excretion is increased from puberty onwards and is usually over 4 mg IRP in 24 hours. FSH is almost always elevated; LH is increased or normal according to the plasma testosterone level (FRANCHIMONT, 1969; BECKER, 1965; KELLER, 1968). Normal values of gonadotropin have, however, been described in a few cases of confirmed Klinefelter's syndrome. Gonadotropin estimation is now superfluous for diagnosis when the sex chromatin is positive. The testis biopsy is characteristic (see p. 466) and, as a rule, can differentiate the true chromatin-positive Klinefelter's syndrome from other primary tubular testicular insufficiencies. It is no longer necessary to the diagnosis.

Differential Diagnosis. The true chromatin-positive Klinefelter's syndrome must be differentiated from other clinically and histologically similar forms with negative sex chromatin findings and different etiologies (so-called "false" Klinefelter's syndromes). Among others, hypogonadism in Steinert's dystrophic myatonia belongs to this group.

Multiple marginal chromatin bodies may suggest more serious irregularities in the set of sex chromosomes, such as XXXY, XXXXY, or XXYY, especially when combined with severe oligophrenia. These diagnoses can only be substantiated by a complete karyogram. Finally, the rare diagnosis of true hermaphroditism must also be considered, especially

when genital malformations or even hypospadia are present. Testicular biopsy is recommended in such cases.

Therapy. If the gynecomastia is severe it can only be corrected surgically. Only a small, hardly visible scar at the lower areolar margin remains when an experienced surgeon is available. When there are signs of androgen failure, substitution therapy with testosterone is indicated. Intramuscular injections of 250 mg testosterone-ester compound at 3-weekly intervals can improve waning potency, can prevent metabolic disturbances such as osteoporosis, and may cause deficient secondary sexual characteristics to develop. Substitution therapy may not be essential in early adulthood, but may become necessary with early involution in the fourth decade.

3. Hypogonadism with Tubular Fibrosis (So-Called "False" Chromatin-Negative Klinefelter's Syndrome). Primary hypogonadism with tubular fibrosis and negative sex chromatin is found somewhat less frequently. Disproportion of body stature, eunuchoid features and gynecomastia can be variably pronounced. The histological findings in the testes are characterized by less pronounced hyalinosis, and less impaired spermatogenesis than in true Klinefelter's syndrome, and diffuse instead of focal hyperplasia of the Leydig cells.

The etiology seems to vary. Familial occurrence has been described on different occasions.

Familial hypospadia with hypogonadism, as described by REIFENSTEIN (1947) and BOWEN (1965), also belongs in this group of syndromes. There is an external resemblance to Klinefelter's syndrome in addition to the hypospadia. In both syndromes the secondary sexual characteristics, i.e. eunuchoidism, are variably pronounced. Gynecomastia may also be pronounced or may be absent. The karyogram, however, is always normal, and the Y chromosome seems to be intact. The testes are less atrophic, and histologically there are atrophic tubuli with incomplete hyalinization and partly preserved elastics fibers, single Sertoli and germinal cells up to the spermatocytes. There are no morphologic alterations in the Leydig cells. There is azoospermia and sterility. The gonadotropin levels are usually raised though occasionally normal. Inheritance is either autosomal dominant with restriction to the male, or recessive and bound to the X chromosome.

The functional prepubertal castration in males described by HELLER, NELSON, and ROTH includes cases of primary hypogonadism of various etiologies.

4. The XYY Trisomia. The incidence of this syndrome is estimated at between 1 : 250 and 1 : 1000 male newborns (PFEIFFER, 1969; SERGOVICH, 1969). Alterations of the personality with aggressiveness and a tendency to criminal behavior, which were observed in the first cases examined (JACOBS, 1965), are not obligatory symptoms. Extreme height is characteristic of all these individuals. Up to now about 140 cases have been observed, 30 of them children. Differentiation into 4 subgroups might be possible; an additional Y chromosome can be found in normal, tall males, in tall criminal males, in tall males with hypogonadism or malformations of the external genitalia, and in tall males with malformations of other organs (HIENZ, 1969). Radioulnar synostosis seems to occur especially often (CLEVELAND, 1969).

There are no hormonal disorders in these patients: urinary and plasma testosterone is normal (ISMAIL, 1968; RUDD, 1968).

Growth hormone levels, fasting and after glucose load, are also normal. Tallness is not due to overproduction of growth hormone (NIELSEN, 1969). The chromosomes of parents and children of these patients are normal. The age of the parents is not different from that in the normal population. Chromosomal mosaics can occur.

γ) Interstitial Insufficiency

1. Male Climacteric. The menopause develops without exception in the woman, whereas the diagnosis of a climacteric is only seldom justified in the male. Strict criteria must be applied, and the diagnosis must not be made merely from age and subjective symptoms. In the woman, hormone production ceases abruptly. In the male, on the other hand, testicular function fails only gradually, if at all. Even in subjects over 90 years, the morphology of the testicular tissue may be completely normal (BÜRGI, 1959; DRY, 1967; NOWAKOWSKI, 1959). As testicular hormone production decreases, the body first tries to compensate by increased stimulation through gonadotropins. Whereas this compensatory stage is always of short duration in the female, the compensated state is the rule in the man, and manifestations of failure seldom appear. Climacteric failure shows a predisposition for men between 45 and 60, but it has been claimed to occur after the 25th year. Climacteric complaints in the male correspond to the typical symptoms in the woman: increased autonomic lability with hot flushes, sweating, palpitations, precordial pain, paresthesia, easy fatigability, nervousness, inability

to concentrate and depressive tendencies. The main complaint, however, is decrease in potency and sometimes in libido as well. All these complaints can, however, occur as a neurasthenic symptom complex without hormone loss. A definite rise in gonadotropin excretion is the only sure criterion. This corresponds to the findings in the female. The diagnosis ex juvantibus is simpler: climacteric complaints regress in response to a daily intramuscular injection of 25 mg testosterone propionate for 2 weeks, and they reappear when placebo injections are used instead of testosterone. The levels of 17-ketosteroids may be normal or slightly lowered. Their estimation is not conclusive. Estimation of plasma testosterone may be usefull for clinical purposes. Histological examination reveals a decrease in the number of Leydig cells and degenerative changes. The tubules are not affected, with the exception of occasional peritubular fibrosis. Spermatogenesis is only infrequently reduced (HELLER, 1944). Other authors have not observed histological changes despite elevated gonadotropin levels. See p. 475 for treatment.
for bioassay, <0.1 mg IRP/24 h. Urinary and

b) Secondary Testicular Insufficiency (Hypogonadotropic Hypogonadism)

The second main group, secondary hypogonadism, is recognized by the reduction or absence of gonadotropins. With prepubertal onset, the eunuchoid body stature is usually especially pronounced clinically.

α) Tubular and Interstitial Insufficiency

1. Hypogonadotropic Eunuchism (HELLER and NELSON), *Idiopathic Eunuchoidism with Decreased FSH* (HOWARD), *Isolated Gonadotropic Failure.* This disease is due to an isolated gonadotropin failure. The appearance of the patients differs little from that due to fully developed primary hypogonadism (see p. 476) (Fig. 18a). The size and consistency of the testes are the same in both conditions. They correspond to the testes of a boy before puberty, and have a volume of 1–5 cm^3.

The histological picture is similar to that of a boy's testis before puberty in different stages of development. In severe forms the seminiferous tubules form completely lumenless strands which enclose inactive germinal cells and undifferentiated Sertoli cells (Fig. 19a). The tunica propria is not thickened. Leydig cells are absent. In a somewhat advanced stage of development, the tunica propria may be thickened and contains only a small amount of elastic fibers. There are numerous spermatogonia in the tubules, and occasionally spermatocytes and differentiated Sertoli cells can also be recognized. Development of the Leydig cells is, however, deficient in these cases also. A thickening of the tunica propria can but does not always represent atrophy. It also arises in primary hypoplastic tubules and, in addition, with different hormone treatments (see p. 471). A thickened tunica propria can be indicative of many things; the etiologies are not yet satisfactorily explained. On the other hand, demonstration of elastic fibers permits certain conclusions to be made about the time of developmental standstill, since elastic fibers in the tunica propria do not appear until puberty. They may, however, disappear again with complete tubular sclerosis.

Hormonal Findings. The 17-ketosteroids vary between low (2 mg/24 h) to subnormal values (9 mg/24 h). Gonadotropin excretion is too low for bioassay, <0.1 mg IRP/24 h. Urinary and plasma testosterone rises quickly on stimulation with HCG.

Delayed puberty is of utmost importance in the *differential diagnosis.* It cannot be distinguished clinically from hypogonadotropic eunuchism, and therefore cannot be diagnosed with certainty before the 18th year (see Chap. XIX).

BARTTER and his team (1952) distinguished different forms of hypogonadotropic eunuchism, depending on results of treatment with chorionic gonadotropin.

In the first type the releasing mechanism of puberty is impaired. Development, once initiated with chorionic gonadotropin, continues spontaneously and the anterior pituitary produces gonadotropins from then onwards.

In the other form, function of the Leydig cells, and therefore development of the sexual characteristics, are only maintained as long as chorionic gonadotropin is administered. After withdrawal of treatment, the sexual characteristics regress again, but a higher degree of maturation is nevertheless often achieved by means of the treatment. Hypogonadotropic eunuchism is therefore due to complete inability of the adenohypophysis to produce gonadotropin, to a lack of the releasing hormones LRH and FSHRH, or to the absence of a mechanism for releasing hormone secretion. The etiology is unknown. Familial incidence has been reported. The pathogenesis of gonadotropin failure is largely obscure. Clinically, *hypothalamic hypogonadism* can only be diagnosed when other manifestations of hypothalamic failure, such as diabetes insipidus, are present at the same

time (see p. 32). Today, LHRH application can be of help in differentiating between pituitary and hypothalamic gonadotropic insufficiency (MARSHALL, 1972).

ROSEWATER (1965) described a type of hypogonadotropic hypogonadism with gynecomastia, descreased numbers of Leydig cells, and impaired maturation in the sperm. It is inherited recessively with the X chromosome or dominant autosomally and restricted to males.

2. Hypogonadotropic Eunuchism with Anosmia (Kallmann Syndrome). The combination of anosmia or hyposmia with eunuchism forms a special syndrome within hypogonadotropic hypogonadism. The syndrome was described by MAESTRE DE SAN JUAN over a hundred years ago and has only recently been recalled by KALLMANN (1944), DE MORSIER (1954), and NOWAKOWSKI (1961).

In addition to severe eunuchism including gynecomastia, as described in the previous section, the patient's sense of smell is usually completely absent or sometimes severely impaired from the time of birth.

Aromatic smelling substances, such as coffee, anis, asa foetida, are not recognized, whereas patients can identify substances such as ammonia, which stimulate sensory nerve endings of the trigeminal nerve in the nasal mucosa.

The sense of smell must be tested in every case of eunuchism. Patients pay no attention to this disorder and do not mention it spontaneously. Patho-anatomical findings include agenesis or defects of the olfactory nerves. Usually the anterior parts of the central olfactory system, i.e. bulbus, olfactory tract, and olfactory trigone, are involved, whereas the posterior parts (the anterior perforated area, parolfactory area and subcallosal gyrus) are not affected.

Atrophy of the hypothalamic nuclei tuberis is sometimes found, while in other cases it is not found despite serial sections.

LH and FSH excretion is similar to that in normal children and hypopituitary patients. Clomiphene does not usually stimulate LH excretion. HCG may or may not raise the low plasma testosterone levels, so that unresponsiveness of the Leydig cells has been described as a further factor of hypogonadism in this syndrome (BARDIN, 1969; SANTEN, 1973). LRF may increase slightly plasma LH, suggesting a hypothalamic disorder (NAFTOLIN, 1971).

The association of anosmia and gonadotropin deficiency can be plausibly explained as a developmental disturbance because of the close embryonic connections between pharyngeal and nasal mucosa, hypophysis, rhinencephalon and hypothalamus (see p. 27). The sex chromatin is negative and the karyogram is normal. The familial incidence of the syndrome suggests an autosomal dominant inheritance with incomplete expressivity (SANTEN, 1973). The gene leads in the female only to anosmia or hyposmia and cases with hypogonadotropic hypogonadism have been sporadic (TAGATZ, 1970).

The reader is referred to NOWAKOWSKI and LENZ (1961) for other forms of familial hypogonadism which are rather difficult to classify.

3. Hypogonadism in Malnutrition and in Hypothyroidism. The hypophysis, being an organ of adaptation in combination with the hypothalamus, limits production of certain hormones in hunger states and in severe illnesses. Gonadotropins fail, testosterone production decreases, and spermatogenesis regresses. In the undernourished calf, sexual maturation is delayed, the testes contain little testosterone, the seminal vesicles produce less fructose and citrate, but semen formation is less affected. These are most probably results of gonadotropin deficiency. However, the seminal vesicles of the undernourished animal show little response to testosterone (MANN, 1967). Long-lasting starvation states can lead to tubular and interstitial atrophy in the human (UEHLINGER, 1948). The syndrome of hypogonadism with gynecomastia has been observed in prisoners of war in Japan as well as in German concentration camps, and developed when feeding was restarted after a long period of malnutrition. Its pathogenesis is unexplained (see p. 488).

A special form of secondary hypogonadism of varying severity with normally large or enlarged testes, and with predominantly tubular insufficiency has been described in myxedema (DE LA BALZE, 1962). The gonadotropin-producing cells may be compressed and damaged by the hypertrophied TSH-producing cells. In contrast, an overproduction of gonadotropins was explained in hypothyroidism through feedback overlap, which leads to pubertal precocity (see Chaps. VI and XIX, p. 175, 1050).

4. Panhypopituitarism, Partial Pituitary Insufficiency. The clinical findings in this sub-group have been dealt with in the chapter on the hypophysis (see p. 97). The findings in the testes correspond to those in congenital pituitary dwarfism and in acquired pituitary insufficiency, as described above.

Hypogonadism in the true Babinski-Froehlich syndrome, so-called "dystrophia adiposogenitalis" (see p. 98), also belongs to this group. A gonadotropin deficit is usually also assumed to be present in the Laurence-Moon-

Biedl syndrome, although cases of primary testicular failure have also been known to occur.

5. Adrenogenital Syndrome (see p. 367). The AGS causes hypogonadism in both sexes. Paradoxically, hypogonadism due to atrophy or hypoplasia of both parts of the gonads develops in association with hypergenitalism, i.e., excessive development of the sexual characteristics. This is due to inhibition of the gonadotropins by the adrenocortical androgens and estrogens (see p. 366). When there is ectopic adrenal cortical tissue in the testes, these may appear to be enlarged and a mistaken diagnosis of carcinoma may be made (HEDINGER, 1954).

The histology of the testes is very similar to that in hypogonadotropic eunuchism: Leydig cells are absent, the lumens of the tubules are small, and only Sertoli cells and spermatogonia are demonstrable (NOWAKOWSKI, 1952). In children with AGS testicular development parallels the bone age following the initiation of treatment. True precocious testicular maturation may occur in such cases.

6. Estrogen Therapy. Estrogens in pharmacological doses inhibit the release and production of gonadotropins. The ratio of FSH to LH is not altered. There is first an acute fall in LH, FSH, and testosterone. A steady and slow decline in gonadotropins, testosterone and testicular volume follows. Even after months of therapy, testosterone levels are somewhat higher than in females and gonadotropins lie in the range seen before puberty. After withdrawal of estrogens gonadotropins rise first, followed slowly by a rise of testosterone levels. Physiological doses of estrogens seem to have no effect on gonadotropins. The observation that testosterone levels may be decreased during estrogen treatment despite normal levels of LH – seen especially with TACE – has led to the suggestion of an additional direct inhibitory effect of the estrogens on the testis (BURGER, 1972). Estrogens lead to testicular atrophy, azoospermia, and manifestations of androgen failure and gynecomastia in the man. As used in the treatment of diseases of the prostate, they usually lead to gynecomastia. Sensitivity of the glandular epithelium of the male breast varies widely. Response of the gland can be prevented by X-ray irradiation. Libido decreases, ejaculation becomes impossible, pubic and axillary hair may regress, and the appearance of these patients differs little from that of subjects who have undergone castration late in life. Gonadotropin excretion is no longer measurable, even with relatively low doses of estrogens. The 17-ketosteroids are usually reduced, the testes become smaller, and the histological picture is similar to that of the testes in pituitary failure (see p. 476, Fig. 19a). Testicular damage is reversible after short-term estrogen treatment over some weeks or months. LH deficiency causes atrophy of the Leydig cells.

The same pathogenesis is assumed for *hypogonadism of liver cirrhosis* and of hepatitis. Clearance and inactivation of estrogens may be disturbed due to the liver damage, but increased estrogen production, decreased disposal and elevated levels of binding proteins have also been discussed (BURGER, 1972). This may result in a lower level of unbound testosterone (GALVÃO, 1973). The changes in the testes in liver cirrhosis can be of varying severity. Severe testicular atrophy has also been observed as a concomitant symptom, especially in hemochromatosis. This situation is less clear.

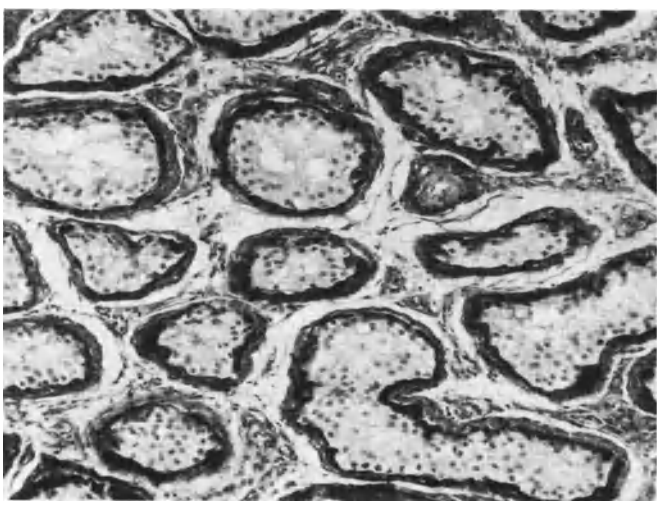

Fig. 16. MB 8819/55, 58-year-old man. Testicular atrophy after treatment with estrogens. Van Gieson, 140:1

Gonadotropin levels have been found to be reduced in some cases and normal or even elevated in others. There is no direct connection between the degree of testicular atrophy and the intensity of the iron deposition in the anterior pituitary lobe. Impaired breakdown of estrogens cannot, however, always be proved in liver cirrhosis. There may also be primary testicular damage due to deposition of iron (GILBERT-DREYFUS, 1967). There is a possibility that the same noxious agents cause liver cirrhosis and damage to the testes.

β) Tubular Insufficiency

It is not yet certain whether isolated FSH failure can also occur in the adult male. This constellation (no FSH, normal adult values for LH) is present in boys with pubertas praecox (KELLER, 1968). These findings have to be proved by immunological gonadotropin determinations.

γ) Interstitial Insufficiency

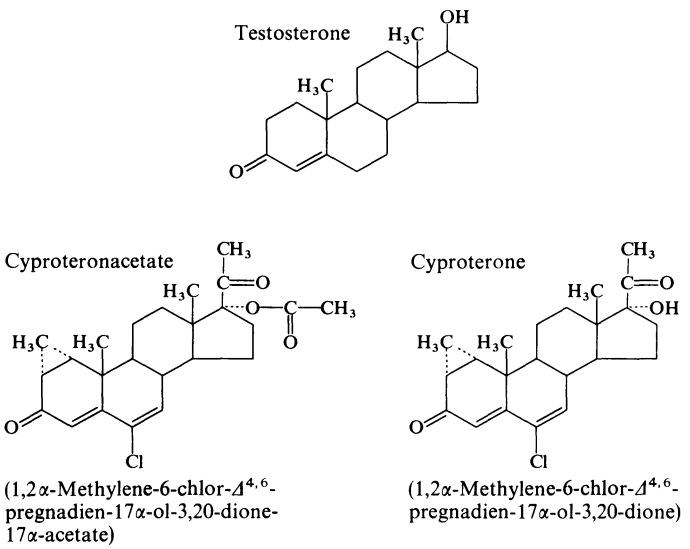
The syndrome of the "fertile eunuch", in which hormone formation is impaired in the presence of normal or almost normal semen production, is due to isolated LH failure (MCCULLAGH, 1953). Subjects with this syndrome have underdeveloped sexual characteristics, almost always with testes of normal size, and normal or slightly disturbed spermatogenesis, but there is hypoplasia or complete absence of Leydig cells. The semen volume is reduced, and the sperm count is normal or slightly diminished due to androgen deficiency. Complete aspermia may occur. FSH excretion is normal, but in contrast, LH excretion has been found to be reduced in a few cases. With improved methods, however, even elevated LH has recently been found. So the syndrome may be one of primary hypogonadism and be caused by damaged Leydig cells. The 17-ketosteroid excretion is in the lower normal limits or is reduced. Secondary sexual characteristics develop under chorionic gonadotropin as well as under testosterone.

5. Anti-Androgens ("Chemical Castration")

Anti-androgens are substances which competitively inhibit or block androgenic effects of other substances and of testosterone at the peripheral receptors.

A large number of steroids which inhibit or abolish androgenic effects have been examined (LERNER, 1964; DORFMANN, 1968; NEUMANN, 1968). However, up to now, the only compounds of theoretical and clinical importance are danazol, an ethinyl testosterone analogue (SHERINS, 1971) and cyproteron and cyproteron acetate. The former is biologically inactive, and the latter has a strong gestagenic effect and inhibits the complex formation between 5α-dihydrotestosterone and the intracellular receptors (FANG, 1969).

The pure anti-androgens, such as cyproteron, block the receptors of the negative feedback system. An uninhibited secretion of the releasing factors and an increased production of gonadotropins results, so that the inhibitory effect on the endorgans may finally be overcome by overproduction of testosterone (NEUMANN, 1971). Cyproteron acetate, however, with its



(1,2α-Methylene-6-chlor-$\Delta^{4,6}$-pregnadien-17α-ol-3,20-dione-17α-acetate)

(1,2α-Methylene-6-chlor-$\Delta^{4,6}$-pregnadien-17α-ol-3,20-dione)

marked progestational effect, inhibits the release of LH and FSH at the same time and thus has a lasting anti-androgenic effect (NEUMANN, 1970). Thus, cyproteron leads to an increase in LH, whereas cyproteron acetate inhibits both LH and FSH.

Cyproteron given to pregnant animals has an irreversible effect on fetal sexual differentiation. Cyproteron acetate inhibits spermatogenesis and causes histological alterations in the germinal epithelium. These effects are, however, entirely reversible after 3 to 20 months (OTT, 1972). Inhibitory effects normally exerted by androgens are abolished, but the processes induced by androgens are also retarded. The actual formation of the gonads themselves is not influenced, but the Wolffian ducts are suppressed. The Müller's ducts are unaffected, insofar as they are not regulated by factors independent of androgens. In the male fetus the gonaducts and prostate are absent, while a vagina but no uterus is formed. External sexual organs remain feminine since no hormonal effect is necessary for their formation. In the male rat mammary glands are formed as in the female animal, and they can be stimulated by estrogens and progesterone. The picture of testicular feminization is reproduced in the fetus (see p. 726). This supports the hypothesis that peripheral resistance to androgens is the cause of this hereditary disorder. In the adult man castration or the "fertile eunuch" syndrome or the male climacteric is simulated.

Libido and potency decrease, but the secondary sexual characteristics regress only slightly in the adult. Spermatogenesis is greatly impaired, and gonocytes mature only at the stage of the spermatids, whereas the Leydig cells become rather hypertrophied. Growth and function of androgen-dependent glands, such as the prostate, the preputial glands, and particularly the cutaneous sebaceous glands, are inhibited. The hypothalamic-pituitary inhibition of the gonadotropins is abolished by cyproteron even in the presence of exogenous testosterone. Castration cells arise in the anterior pituitary (NEUMANN, 1967). The hypothalamus becomes readjusted to the rhythmic regulation of the ovaries in the hirsute and amenorrheic woman. In the human, as in animals, total excretion of the gonadotropins rises (VOIGT, 1967). Apart from this, cyproteron might also act as a false transmitter in the synthesis and metabolism of testosterone. Changes in the amounts of precursors and metabolites of testosterone have been found (APOSTOLAKIS, 1967; BREUER, 1968). Enzymes stimulated by testosterone, such as LDH and acid phosphatase, decrease. A further central action demonstrated beyond doubt in animal experiments as well as in the human is the decrease in libido.

Cyproteron and cyproteron acetate have already proved clinically satisfactory in psychiatry, when used for excessive sexual drive which has caused subjective suffering to the patient or led to legal conflicts. The advantage of this therapy over estrogen therapy is obvious, the latter leading to gonadotropin inhibition and thus to testicular atrophy and to gynecomastia. Its effect against acne and hirsutism has also been tried in the human. The usage of cyproteron in women of childbearing age carries the danger of a male child being feminized, if a patient is unaware of her pregnancy. Local use against seborrhea and acne might be tried. Use in certain types of amenorrhea, in pubertas praecox in boys, and in the congenital adrogenital syndrome to prevent premature fusion of the epiphyses is under examination. In the proper dosage it could also be considered as a male contraceptive agent without side effects. Carcinoma of the prostate gland would be another valuable indication, if the castration and feminizing effects of estrogens could be thus avoided. However, very high doses are necessary, and the cost is very high.

The daily dose of cyproteron acetate varies between 50 and 150 mg, depending on the indication. The action of 0.5 mg testosterone on the sebaceous glands can be inhibited by 1 mg cyproton acetate. The relation to testosterone in other organs is still unknown. Clinical trial of cyproteron is not contraindicated in any of these patients, with the exception of women of child-bearing age, since it is biologically inert and has no known toxic effects.

Soldactona, an aldosterone antagonist, causes a decreased secretion of testosterone from the testes (DYMLING, 1972). DIMP, a non steroidal antiandrogen, blocks the effect of ketosterone and other androgens on their target organs (BORIS, 1973).

6. Differential Diagnosis of Male Hypogonadism

Panhypopituitarism is of prime importance in the differential diagnosis of male hypogonadism (see p. 93). In addition to eunuchoid signs, in panhypopituitarism there are clinical features of hypothyroidism, which can be best seen from the tired, puffy facial expression (Chap. V, Fig. 3b). In contrast, adrenocortical insufficiency, which is present at the same time, is less apparent apart from pallor of the skin. It is detected from the decreased physical capacity. Thyroid and adrenal function tests differentiate pituitary insufficiency from hypogonadism with certainty.

The constitutional anomaly, "pseudo-eunuchism", can be distinguished without difficulty from true hypogonadism by the normal size of the testes and intact sexual function. The boy-like face, childish voice, poor growth of the beard, and scanty axillary and pubic hair may, however, suggest eunuchism at first. This constitutional anomaly must be due to an inadequate response of the tissues to testosterone.

On the other hand, differential diagnosis between hypogonadotropic hypogonadism in youth and delayed puberty can be difficult. It may sometimes be impossible before the 18th year (see Chap. XIX). Laboratory tests can be useful: in delayed puberty, plasma testosterone is within normal adult levels even before the appearance of secondary sexual characteristics, and it can be stimulated by HCG.

Hormone estimations and testis biopsies are generally necessary for the differential diagnosis of the sub-groups. The following principles sometimes facilitate classification, even without hormone estimations or biopsies.

1. Disorders of the tubular system lead to azoospermia and, in general, to small testes. Masculine sexual characteristics are not affected in isolated tubular failure.

2. In contrast, insufficiency of the Leydig cells can be recognized by the absence of secondary sexual characteristics (beard, moustache, pubic and axillary hair, prostate). The testes need not be reduced in size.

3. In differentiating between primary and secondary insufficiency, gonadotropin estimation can be replaced by the HCG test to estimate the functional reserve of the Leydig cells. Leydig cells respond to chorionic gonadotropin in secondary insufficiency, whereas they are uninfluenced in primary insufficiency. A normal response is indicated by the increase in plasma testosterone, 17-ketosteroid and estrogen excretions, and by the appearance of secondary sexual characteristics.

4. Positive sex chromatin indicates Klinefelter's syndrome.

7. Therapy (for age-dependent indications see Chap. XIX)

There are two main methods of treating male hypogonadism: substitution and stimulation of testicular maturation with chorionic gonadotropin. Only substitution can be considered in primary testicular insufficiency. In contrast, in secondary insufficiency, there is the theoretical possibility of using gonadotropins to stimulate endogenous production of testosterone. The preparation obtained from pregnant mare's serum (PMG), which contains FSH, causes antibodies to be formed in the human, and thus cannot be used therapeutically. Human gonadotropin obtained from the pituitary is available in limited amounts only for research.

Preparations containing predominantly FSH can be gained from urine of menopausal women (human menopausal gonadotropin, HMG). They are still very expensive but are available commercially (Pergonal, Humegon). On the other hand, chorionic gonadotropin extracted from the urine of pregnant women (human chorionic gonadotropin, HCG), is available. The action of this preparation is similar to that of LH. Chorionic gonadotropin is suitable for short courses of treatment but not for long-term treatment, where testosterone is preferable. The indications for chorionic gonadotropin are therefore limited to specially selected cases of hypogonadotropic eunuchism and to cryptorchidism (see p. 469, 477). Re-establishment of spermatogenesis and fertility with HMG and HCG is now theoretically possible in men with no pituitary gland (see p. 485).

Table 5. Synopsis and differential diagnosis between primary and secondary, tubular and interstitial insufficiency

	Total gonadotropin excretion	Spermatozoa	Secondary sexual characteristics 17-ketosteroids	Reaction to chorionic gonadotropin
Primary insufficiency				
Tubular and interstitial	+ +	0	−	0
Tubular	+ + or n	0	n	n or 0
Interstitial	+ +	n or −	n or −	0
Secondary insufficiency				
Tubular and interstitial	− or 0	0	−	n
Tubular	n	−	n	n
Interstitial	n or −	n or −	−	n

n = normal; + = increased; 0 = missing; − = decreased.

a) Substitution

The genuine testicular hormone, testosterone, and its ester are used particularly for substitution therapy. The dosage is adjusted to the severity of the manifestations of failure and to individual response. Estimation of plasma testosterone is expensive for the individual case, but it demonstrates that normal values of plasma testosterone are achieved in the adult man with complete substitution. Initial therapy should be as intensive as possible in cases of complete failure. A dose of 25 mg of testosterone propionate daily or 50 mg 2 to 3 times weekly should be given intramuscularly. The onset of action of this therapy is rapid, and it may be apparent within hours. Erection is possible after a few days. Pubic and axillary hair begin to grow after 1–2 weeks. A change is noted in the voice after 3–6 weeks. As in puberty, acne may develop on the face and trunk. A mild, often painful gynecomastia becomes apparent, such as occurs quite frequently in puberty. The beard and moustache are the last to appear, but they hardly ever attain normal growth. Patients with prepuberal hypogonadism need hardly shave more than twice weekly after successful treatment (Fig. 9). Failure to completely normalize secondary sexual characteristics (JOHNSEN, 1967) is obviously due to the fact that treatment was not begun early enough.

After full development of secondary sexual characteristics in 2–4 months, a maintenance dose of 25 mg testosterone propionate 2 to 3 times weekly is usually sufficient. The use of depot preparations is advantageous. Subcutaneous implantation of pellets of free testosterone is no longer used.

It is now convenient to give a monthly injection of the slowly dissolvable ester or ester compound, such as undecylenate or valerianate, caprinoylacetate, enanthate. Numerous commercial preparations combine rapid- and prolonged-action testosterone esters. They are given intramuscularly in an oily solution in a dose of 250 mg (150–300) once a month or once every three weeks in order to compensate complete testicular failure adequately. Higher long-term doses are only indicated in the treatment of cancer, to obtain anabolic effects, or to prevent abnormal height. Overdosage must be avoided, as it can lead to too frequent ejaculations, to priapism, or to polycathemia.

These ester compounds can be used right from the start of the substitution therapy since their onset of action is rapid. They must, however, then be given in higher doses, e.g. 250–500 mg once a fortnight. The effect of testosterone, however, is variable according to the disease, a fact that has to be considered. In particular, the sensitivity to testosterone is diminished in growth-hormone deficiency (ZACHMANN, 1969).

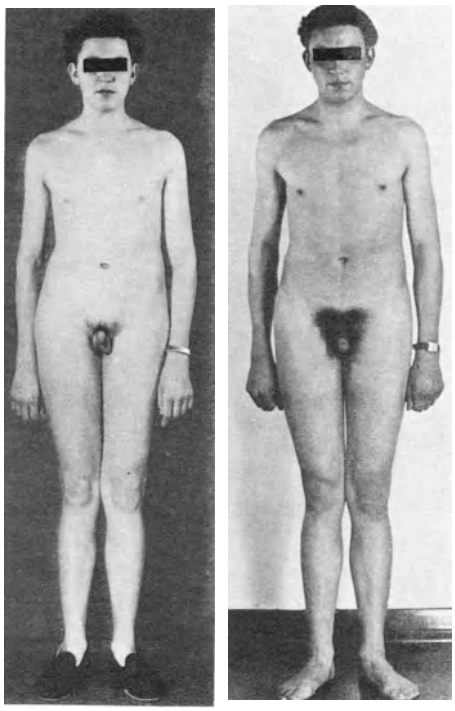
Smaller doses are adequate for the treatment of the male climacteric. Doses of 10–25 mg testosterone propionate can be given intramuscularly twice weekly, or 50 mg of a depot preparation every 4 weeks.

Oral testosterone therapy has the advantage of reducing the patient's dependence on the doctor, but it has the drawback of being less effective, more costly, and of involving the risk of cholestatic icterus. The methyl derivate of testosterone is used for oral administration. It is thought to reach the circulation by passing along the lymphatics and bypassing the portal circulation. Daily doses of 25 – 150 mg are necessary for replacement treatment. A halogenated testosterone derivative, fluoxymesterone, is a more effective oral preparation. A dosage of 5–20 mg daily permits appropriate substitution, which is not, however, equivalent to that achieved with preparations for injection. Mesterolone, 1α-methyl-5α-androstane-17β-ol-30, can be used orally withouth the risk of biliary stasis, since is does not possess a methyl group at atom 17. It is not converted into estrogens. The preparation has undergone extensive clinical trial, and it appeared that the effect in the human does not differ from that in animals, i.e. that effective doses will not inhibit gonadotropins (PETRY, 1968; LUDVIK, 1970).

Testosterone, like numerous other steroids, has a slight sodium-retaining effect. Edema may therefore arise with high doses, especially in elderly patients. This can be prevented by giving a low-sodium diet. See p. 455 for the effect of testosterone on spermatogenesis.

b) Stimulation of Hormone Production

In isolated gonadotropin failure, a trial with chorionic gonadotropin (HCG) might be indicated to promote maturation of the testes and hormone production. Substitution with testosterone must be continued for the rest of the patient's life. This treatment can prevent the absence of secondary sexual characteristics and metabolic disorders as well as psychic effects, but the patients remain sterile. HCG, on the other hand, can bring about maturation of the testes. They become larger and Leydig cells develop. HMG is needed in addition to produce spermatogenesis. HCG must be injected in high doses over a long period of time, at least 3 months. Many failures are due to inappropriate dosage. In our experience, a weekly or twice



a b

Fig. 18a and b. 23-year-old. Idiopathic eunuchoidism. a) Before treatment. b) 5 months after the first treatment with chorionic gonadotropin (120000 IU in 3 months)

weekly injection of 5000 units is very effective. Others advise 300–2500 units daily.

The testes respond rapidly to this therapy. The first signs of development are visible after only one week, and the whole process to complete development takes place within 3 months, in comparison to the 3–4 years needed for the physiological course (Fig. 18). Repeated testicular biopsies during treatment with chorionic gonadotropin show rapid growth of Leydig cells at first, followed by hypertrophy. At the same time, the tubular tunica propria thickens, which, however, does not signify degeneration but is merely an effect of testosterone (BARTTER, 1952). Sertoli cells mature, a lumen develops in the tubules, and the cells show signs of spermatogenesis (Fig. 19). Semen with numerous spermatozoa can be attained after 3 months of treatment even in a case of complete tubular immaturity. Plasma testosterone, 17-ketosteroid, and estrogen levels rise and may reach normal or higher values in a short time.

Initial treatment lasting for 3–6 months is followed by a pause of 3–6 months. As discussed in the description of hypogonadotropic eunuchism, success will be lasting in some patients, in whom the disorder is due only to failure of the normal mechanism to release puberty. In other patients, secondary sexual characteristics will

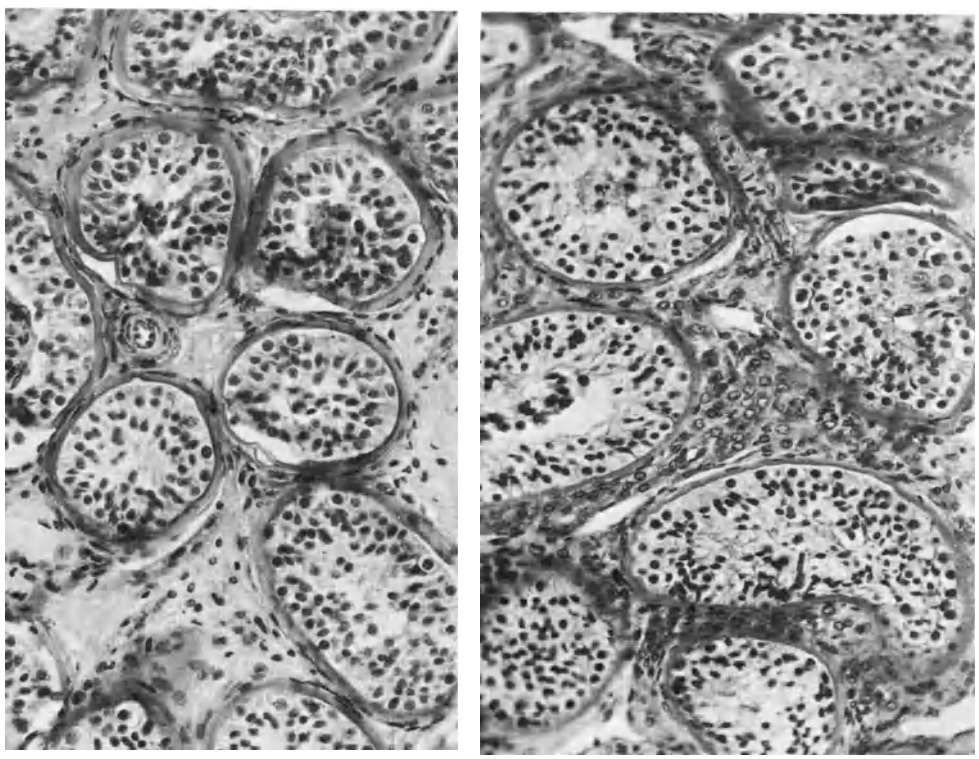


Fig. 19a and b. MB 268/53 and 4837/53, 23-year-old man. Testis in hypogonadotropic hypogonadism. a) Before treatment. b) After treatment with gonadotropins. Tubules somewhat better developed. Tunica propria narrower. Foci of Leydig cells. HE, 180:1

disappear gradually over the course of 2–5 months. Often a higher degree of maturation is retained after treatment. In these cases, a second and third course of HCG is indicated. The best possible degree of maturation is achieved after the third course, and any disturbing androgen deficiency remaining after this must be compensated with long-term testosterone substitution therapy. According to BARTTER, cases with a more mature histological picture have more hope of lasting success than the completely immature forms.

The course of HCG injections is tedious for both patient and doctor, and although a partial lasting success may be attained, life-long substitution with testosterone cannot usually be avoided. It is therefore often preferable to start with testosterone substitution, even in cases of secondary hypogonadism. Testosterone substitution can be withdrawn at least for a limited period when fertility is to be achieved. HCG, later combined with HMG, can then be given (see p. 485).

F. Cryptorchidism (Undescended Testes)

A. PRADER

With Contributions by
CHR. HEDINGER

1. Definition and Incidence

In German-speaking countries, the term cryptorchidism is used only for testes retained in the abdomen. In this chapter, however, as in Anglo-Saxon terminology, *cryptorchidism* or *undescended testes* generally refers to the incompletely descended testes. In contrast to this, the term "*ectopic testis*" is used when the testis lies in some position which never occurs under normal conditions. A normal variety is the testis lying partly inguinally and partly within the scrotum. This variety is still incorrectly looked upon as cryptorchidism (migratory testis, pendulous testis).

Descent normally occurs during the fetal peroid and is usually complete by the time of birth. The factors responsible for descent have not been fully identified. Chorionic gonadotropin probably plays a significant role.

The incidence of cryptorchidism is 2–3% in newborns born at full term (SCORER, 1964; VILLUMSEN, 1966), and higher in premature infants. Delayed descent commonly occurs during the first few weeks or months of life, so that the incidence is merely 0.8% at school age (COUR-PALAIS, 1966). Higher incidences are due to poor examination techniques (COUR-PALAIS, 1966). Contrary to previous assumptions, spontaneous descent appears to occur only during the first few months of life and occasionally during puberty. The figures for the incidence in adults vary between 0.2 and 0.9%. Cryptorchidism is bilateral in 10–20% of all cases. Ectopia is about ten times less common than retention.

2. Etiology

An endocrine disorder, anatomical obstruction, and inferior testicular anlage are etiological factors to be considered. Occasionally, it is a simple hereditary characteristic due to an irregular dominant inheritance (KLEIN, 1963).

Nothing definite is known about the *endocrine causes* of cryptorchidism. There is no doubt that descent is promoted during fetal life by adequate amounts of chorionic gonadotropin and by the development of hypophyseal gonadotropins during puberty. However, it is not known whether cryptorchidism can be related to a gonadotropin deficiency during the fetal period. In most cases of cryptorchidism no endocrine disorder apart from secondary gonadal atrophy can be demonstrated. Cryptorchidism is a common but not obligatory feature of hypogonadism (p. 464), pituitary dwarfism (p. 98), and some types of male pseudohermaphroditism (see Chap. XII), but it is not known whether the cryptorchidism is caused by the pituitary or gonadal deficiency or by the disorder underlying the pseudohermaphroditism.

Anatomical obstructions can lead to ectopia as well as to cryptorchidism. The inguinal canal is not patent enough, or the spermatic artery is short, or a congenital hernia is present (persistence of the processus vaginalis). The hernia prevents descent or results in adhesions and fixation of the testis in the wrong position. An anatomical obstruction causing cryptorchidism can only be revealed by surgery in the majority of cases.

It appears that about 50% of testes still undescended after puberty were already inferior in the anlage stage. In other words, *testicular dysplasia* or *testicular hypoplasia* is present. It is, however, only possible to prove this by histological examination. In one third of cases of unilateral cryptorchidism, both testes are primarily abnormal (HECKER, 1967). In isolated cases it is one symptom among multiple malformations or a symptom of a dysmorphic syndrome (male Turner's syndrome, Prader-Labhart-Willi syndrome, persistent oviduct, etc.).

3. Consequences of Cryptorchidism

The consequences of cryptorchidism are multiple. Testes situated in the inguinal canal are much more prone to *traumatic* injuries than scrotal testes. In addition, *testicular torsion* is thought to be more common. Pains are not infrequent in the region of the undescended testis, and an *incarcerated hernia* and *testicular torsion* must be considered in such cases. During adulthood, but not during childhood, *malignant tumors* are more common in undescended testes (10 to 50 times more common, depending on the author) than in scrotal testes. However, even after an undescended testis has been transferred into the scrotum, it appears to have a predisposition to developing tumors (GILBERT, 1941). Thus, it would appear that not the maldescent but rather the testicular hypoplasia or atrophy must be considered the cause of the increased frequency of tumors.

The *psychological complications* of cryptorchidism have also been stressed by various authors. There is no doubt that disadvantageous psychological reactions arise in boys and men with cryptorchidism, who are aware of "inadequately developed manhood".

Testicular atrophy is by far the most important consequence of cryptorchidism. This is apparently due to the fact that the temperature of the surroundings of undescended testes is 1.5–4° C higher than in the scrotum. Tubular development and spermatogenesis are very much affected by this, whereas development of the Leydig cells and their endocrine function are little influenced.

4. Morbid Anatomy

CHR. HEDINGER

Undescended testes are usually underdeveloped and are definitely reduced in size in the adult. The microscopic picture is determined primarily by the age of the patient but there is no proven relationship to the degree of alterations of retention, i.e. to the localization of the retained testis. No pathologic processes can be detected immediately after birth unless testicular dysplasia is present. However, pronounced changes arise during the first months and years of life, appearing mainly as a marked reduction in the number of spermatogonia and a usually rather discrete decrease in the diameter of the tubules compared with normally situated testes. Because of this, tubules devoid of spermatogonia are not uncommon even during the first few years of life (SALLE, 1968). As far as this question can be answered at present, in the majority of cases it appears that this is an acquired and not a congenital disorder (HEDINGER, 1971). All these changes become even more marked with the onset of puberty. The tubules continue to develop but remain smaller than normal. The tunica propria is thickened and hyalinized, Sertoli cells mature but the germinal epithelium is usually already absent or undergoes degeneration. The histological picture of the undescended testis in the adult is thus characterized by the combination of incomplete tubular development with simultaneous tubular atrophy advancing to complete tubular sclerosis. In contrast, the Leydig cells are usually well maintained, and are not uncommonly densely packed with increased amounts of lipids, which lend a peculiar golden yellow color to the cut surface of the testis on macroscopic examination. In about half the cases, so-called hypoplastic zones are recognizable (Fig. 20). They are composed of proliferations of peculiar tubules which contain only undifferentiated epithelia and no spermatogonia. These zones look similar to adenomas and may be mistaken for Pick's tubular adenoma, which also occurs particularly often in undescended testes. Concretions or so-called ring tubules appear to be somewhat more common in undescended testes than in normally situated testes (SCHEIBLI, 1968; HUBER, 1968).

5. Incretory and Secretory Function of Undescended Testes

Clinically, no differentiation is usually possible between primary hypoplastic testes and secondary atrophic testes. In both forms the testes are unobtrusive before puberty and strikingly small after puberty. Spermatogenesis is equally impaired in both forms. No mature sperms or only a few can be found in the ejaculate, and the patient is usually sterile. This is understandable in bilateral cryptorchidism, but surprisingly, the same features are often found in cases of unilateral cryptorchidism. In such cases, presumably bilateral testicular hypoplasia is present and the testes are not atrophic. In other cases, compensatory enlargement of the healthy testis can be observed (LARON, 1969).

In contrast to spermatogenesis, androgen production is not reduced or only slightly reduced. Secondary sexual characteristics are fairly to very well developed. Excretion of 17-ketosteroids and testosterone is normal or slightly reduced and is not as strongly stimulated by chorionic gonadotropin as in healthy subjects. Gonadotropin excretion is usually elevated due to tubular insufficiency. Thus, primary hypergonadotropic hypogonadism arises with

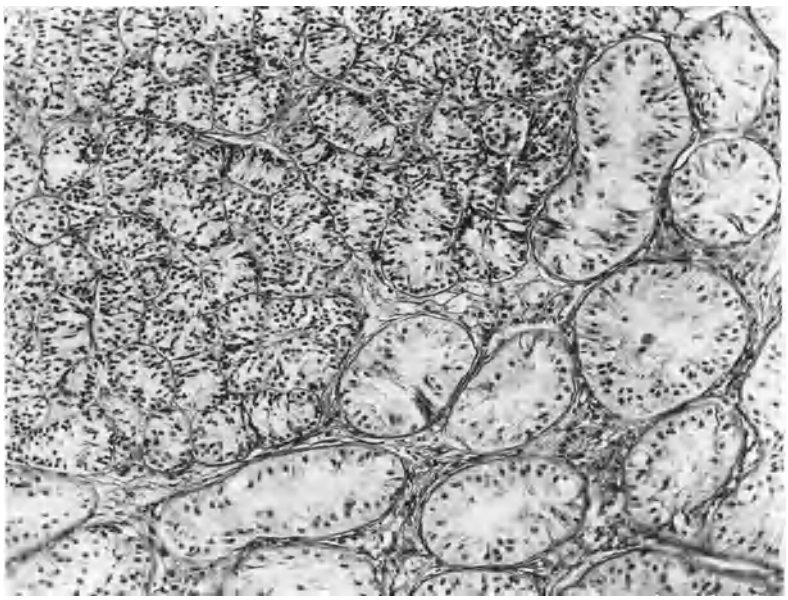

Fig. 20. MB 8853/51, 24-year-old man. Cryptorchidism with defined hypoplastic zone (upper left half of the picture reminiscent of a tubular adenoma). In the rest of the testicular tissue atropic tubules which are lined almost exclusively with Sertoli cells. Leydig cells recognizable in small groups. HE, 140:1.

secretory insufficiency and incretory function is just about adequate (p. 463). *In-vitro* experiments suggest some degree of 3β-dehydrogenase deficiency in the biosynthesis of testosterone (HAMILTON, 1970).

6. Examination Technique and Classification

There are numerous cases where a diagnosis of cryptorchidism has been wrongly made and the patient unnecessarily treated for this condition due to poor examination technique. Careful and correct examination is therefore of greatest importance. The patient should be examined in the standing and lying positions. The examination room must be warm since a cold stimulus promotes retraction of the testes. Bimanual examination is most suitable. One hand squeezes the inguinal canal and the subcutaneous pocket lying between the inguinal canal and scrotum against the other hand palpating away from the scrotum. If no testes are palpated at first, success can occasionally be achieved by making the patient cough or shout or by examining him in a warm bath.

Palpation findings permit a certain degree of diagnostic differentiation and classification into the various forms of cryptorchidism. The primary factor is to determine whether testes are palpable or not.

If the testes are not detectable by careful examination, they are lying in the inguinal canal (canalicular inguinal retention), or in the retroperitoneal space (abdominal retention), or are completely absent (anorchia). Anorchia can be recognized by the failure of development of secondary sexual characteristics, by the lack of response of the excretions of 17-ketosteroids and testosterone to stimulation with chorionic gonadotropin, and by failure to find the testes on surgical exploration although the ductus deferens is present. Among 748 children admitted to the surgical wards of the Children's Hospital in Zurich and operated on for cryptorchidism, bilateral anorchia was confirmed in 6 cases and unilateral anorchia in nine cases on the basis of the ductus deferens ending freely.

Palpable testes are practically always situated subcutaneously. Testes palpable in the inguinal region which can be easily pulled into the scrotum are a normal variety, as has already been mentioned (*migratory or pendulous testes*), and must not be looked upon as cryptorchidism. Very often, testes can just barely be pulled into the scrotum and rebound at once when released (retractile testes). This is the mildest form of cryptorchidism; it has a good spontaneous prognosis, and usually responds immediately to chorionic gonadotropin.

Testes palpable in the inguinal region (inguinal testes, inguinal retention) are less mobile, and an anatomical obstruction or inguinal ectopia cannot be excluded. The other forms of ectopia (ectopia femoralis, perinealis, penilis) are easily recognized from the abnormal position of the testes.

7. Treatment

There are only two therapeutic possibilities: treatment with chorionic gonadotropin and surgery (orchidopexy). Whereas it is unanimously agreed that the onset of puberty is the latest point for starting treatment, since testicular atrophy is otherwise inevitable, opinions differ as to the optimal age to start treatment. The fact that the tubular diameter and sperm count are lower than normal even in the 5th or 6th year (HECKER, 1967; SALLE, 1968) has led to the recommendation that treatment be started as early as possible. The question cannot be answered definitely since it is not clear at present whether these changes are due to the abnormal site of the testes or are a primary disturbance, and assuming there is a secondary disorder due to the abnormal position, whether this secondary disorder is reversible and if so, for how long. We therefore recommend starting treatment with chorionic gonadotropin as early as possible, i.e. from the 5th year, adjusting the doses to produce increased erections and mild penis enlargement but no pubic hair if possible. This side effect disappears after treatment is stopped. Between the ages of 5 and 10 years, 6–8 injections of 1500 U are given in 3–4 weeks; between the 10th and 13th years, 10 injections of 1500 U in five weeks or 3 injections of 5000 U in 3 weeks. Urinary excretion of testosterone rises significantly. Absence of the clinical reaction mentioned above and failure of testosterone to rise confirm the presence of true anorchia. The degree of success cannot be predicted in the individual case and is presumably dependent on the unknown causes of cryptorchidism. Success is achieved in 90 to 100% of cases of retractile testes, and the therapeutic indication is questionable here. Success is obtained in about 40% of cases of inguinal retention and in 20–30% of cases of abdominal retention (BIERICH, 1967; KNORR, 1970). Results are somewhat poorer in unilateral than in bilateral cryptorchidism. It may be assumed that in successful cases the testes would have descended spontaneously later on in puberty under the influence of endogenous gonadotropins, but there is some fear that this delay affects later fertitity. This form of treatment involves no risk. Descent of the inguinal and abdominal testes does not ensure fertility. The testes often remain smaller than normal, and normal spermatogenesis is probably only possible in half the cases at most. Failure to respond is an indication for surgery. Hardly any result is to be expected from the second course of chorionic gonadotropin.

In contrast to treatment with gonadotropin, orchidopexy is almost always successful as far as the position of the testes is concerned. It is the only form of treatment in the presence of anatomical obstruction, incarcerated hernia, testicular torsion and ectopia. Surgery results in just as little functional success as gonadotropin treatment in the presence of testicular hypoplasia. By and large, surgery using suitable methods can be described as harmless. However, subsequent testicular atrophy is almost inevitable if the testis can only be transferred to the scrotum under tension due to short vessels or an unsuitable surgical method. For reasons already discussed, the testes often remain abnormally small after the operation. Nor are the chances of fertility very good, particularly when the case is referred to the surgeon after failure to respond to chorionic gonadotropin. In summary, there is still a considerable amount of uncertainty as to the optimal treatment of cryptorchidism with the present-day state of knowledge. For the time being, the following principles for treatment of uni- and bilateral cryptorchidism in endocrinologically healthy boys can be recommended:

1. First exclude the migratory or pendulous testes which can be mistaken for true cryptorchidism. Migratory testes, in contrast to undescended testes, can easily be manipulated into the scrotum and require no treatment.

2. Every case of ectopic testes diagnosed clinically (position outside the normal path of descent) and of cryptorchidism with a manifest hernia should be operated on during babyhood or early infancy.

3. Treatment is urgently indicated in uncomplicated cases of undescended testes, and should begin as soon as possible after the 5th year of life and definitely before the onset of puberty.

4. If treatment with chorionic gonadotropin is decided upon, then a course of injections of 1500–5000 U over three to five weeks, making a total dose of 9000–15000 U, can be recommended.

5. If surgical treatment is decided upon because of failure to respond to treatment with gonadotropin or because of anatomical complications, careful orchidolysis and funicolysis with subsequent orchidopexy by fixation in the scrotum itself (between tunica dartos and scrotal skin or penetration of the septum) is indicated. Temporary fixation to the thigh gives poor results.

6. Retractile testes, which can just be pulled into the scrotum and recoil immediately, are an indication for treatment. Gonadotropin treatment is nearly always successful.

7. Chances of success with gonadotropins are lower but still fairly good in cases of testes retained in the inguinal region.

8. If the testes are not palpable, therapeutic possibilities are limited. Orchidopexy of abdominal testes can often be performed without difficulty, but occasionally only with great tension on the vessels, with consequent testicular atrophy. A previous attempt at treatment with gonadotropin is thus advisable, especially since even partial succes improves the prognosis of subsequent orchidopexy. A pronounced rise in 17-ketosteroid and testosterone levels during this treatment indicates the presence of testes, whereas absence of this rise suggests anorchia.

Treatment of cryptorchidism in adulthood also presents a difficult problem. Normal spermatogenesis cannot be achieved either with chorionic gonadotropin or by orchidopexy. The danger of increased predisposition to tumors must also be considered in this age group. Certain authors recommended castration for this reason, but then loss of function of the Leydig cells must be taken into account and compensated by substitution with testosterone.

G. Sterility

The incidence of sterile marriages has been estimated at 10%. In 30–50% of cases, the cause is found to lie with the man. The figures have remained more or less the same for the past three generations, and sterility affects all social groups to the same extent. There are different grades of fertility. The marriage will be fertile when a person of inferior fertility combines with a very fertile partner, whereas the combination of two partners whose fertility is low will remain childless. It is probable, but also difficult to prove, that inferior or incompatible sperms are the cause of frequent abortions.

1. Etiology and Pathogenesis

a) Functional and Anatomical Disorders of the External Genital Organs

History and clinical examination will quickly disclose impotence, hypospadia, and other anatomical abnormalities which will impede the normal course of coitus.

b) Urological Causes

Obstruction of the spermatic ducts is responsible for 25% of cases of azoospermia in the presence of normally large testes. The condition most often arises after gonococcal or tuberculous epididymitis. It is important to recognize the obstruction, since some of these cases are suitable for correction. The testes biopsy is therefore necessary in a case of azoospermia with normally large testes. It usually shows a normal picture in obstruction of the spermatic ducts, but spermatogenesis is slightly diminished in 20% of cases. The success rate for latero-lateral vasoepididymostomy performed by an experienced surgeon is variously quoted as 20 to 70%. Although the percentage of curable cases of azoospermia with normally large testes is relatively small, it is still worth trying. The patients should be informed in advance about the low chance of success.

Oligospermia or reduced motility of the sperms is infrequently due to changes in the spermatic and urinary tracts and in their appendage organs (prostatitis, vesiculitis).

"Pseudo-oligospermia praecedens" denotes impaired mobilization of the spermatozoa. In this condition, only a few spermatozoa are obtained from the first ejaculation, whereas ejaculation after 2 hours yields a normal number of spermatozoa.

Azoospermia may occasionally be due to retrograde ejaculation into the bladder.

Finally, congenital malformations of the spermatic ducts may cause azoospermia in the presence of testes of normal size (failure of the epididymal head and body to communicate, cystadenomas of the epididymis).

The spermatic ducts and the epididymis are nearly always absent or have malformations in mucoviscidosis. There is nearly always azoospermia (KAPLAN, 1968; VALMAN, 1969) (see p. 462).

Cases of loss of the seminal fluid, aspermia ("aspermatism"), in the presence of otherwise normal sexual function have been reported after treatment of hypertension with the sympathetic inhibitor, guanethidine. Secretions of the prostate and seminal vesicles appear to be inhibited.

c) Impaired Spermatogenesis

See p. 462 for spermatogenic disturbances in hypogonadism. All disorders of the tubular apparatus are associated with azoospermia or oligospermia. Isolated disorders in formation and maturation of the germ cells have been termed as hypospermatogenesis or as spermatogenic arrest (see p. 465). There is usually no certain morphological correlation in the testis biopsy with oligospermia, however, and the etiology of azoospermia or oligospermia re-

mains unknown in the majority of cases despite all the modern investigations. Chromosomal aberrations are responsible for 7.5% of cases of male sterility. They are recognized only by the karyogram and are mostly XY/XXY, XO/XY or other mosaics (KJESSLER, 1966).

Auto-immunological processes may be involved. Autologous and homologous immunization to testicular tissue have been used to produce cellular and weak circulating antibodies, clumping and desquamation of the germinal epithelium and vacuolar degeneration of the Sertoli cells in animal and man before orchidectomy for carcinoma of the prostate (MANCINI, 1965). The phenomenon of spermatozoal agglutination can be found in sterile men, sometimes after contusion of the testes. Antisperma-antibodies in the serum can also be demonstrated in some cases (FJÄLLBRANT, 1965). Antigens can be found in the acrosome of the head of the spermatozoon. They can arise from the accessory organs and can enclose the spermatozoa. These antigens can evoke production of antibodies bound to the vaginal cells and uterus in the woman and thus cause sterility. The antibodies may disappear and the woman become fertile again after a year of abstinence or coitus condomatus.

d) Sterility with Normospermia (So-Called "Biological Sterility")

α) Immunological Causes, Incompatibility of the AB0 Blood Groups
(BEHRMAN, 1960; MACHER, 1964)

Natural, not acquired anti-A and anti-B antibodies (agglutinins) have been found in the cervical mucus of women of group 0. It is assumed that spermatozoa with the antigens A and B can be immobilized by antibodies in the cervical mucus. Direct agglutination has, however, not yet been demonstrated. Some men in the A and B blood groups excrete the A and B substances in the saliva and semen, and it is possible that these substances neutralize the anti-A or anti-B in the cervical mucus. It is also possible that this immunological A-B-0 incompatibility is in some way involved in the diminished fertility of A-B-0 married couples, since incompatible blood group constellations were found more frequently among "biologically" sterile couples than in a control group. Therapeutic measures to overcome this incompatibility are still at the speculative stage (homologous intra-uterine artificial insemination, neutralization of antibodies in the cervical mucus). Antibodies against sperms can also be acquired.

Agglutination of Sperms. The sperms of a small percentage of sterile men agglutinate before or after ejaculation. High titers of spermatozoa agglutinins can be detected in these cases, suggesting autoimmunological processes (RÜMKE, 1965).

β) Nucleic Acid Deficiency of the Spermatozoa

Nucleinic acid in the head of the spermatozoon can be quantitatively estimated by ultraviolet or Feulgen microspectrophotometry. A decrease in the nucleinic acid content in the heads of the sperms has been successfully demonstrated in a few cases of sterility with normospermia. Connections between this and habitual abortion are currently being discussed (LEUCHTENBERGER, 1957; MEYHÖFER, 1963; JOEL, 1962).

Finally, a morphologically, chemically, and immunologically normal semen may also be inferior.

γ) Capacitation and Decapacitation
(see also Chap. X, p. 623)

Capacitation is a process which enables the sperm to invade the ovum inside the uterus, passing through the matrix of the cumulus oophorus and the zona pellucida (AUSTIN, 1970). Capacitation and decapacitation are not yet completely understood. The sperms seem to be coated with a protective layer, the decapacitation factor, while passing along the seminal ducts (CHANG, 1970). This factor is dissolved inside the uterus near the ovum. It has been isolated to a fairly high degree (WILLIAMS, 1970). Capacitated and decapacitated sperms cannot be differentiated, either by light or by electron microscopy. The outer membrane of the head of capacitated sperms is, however, dissolved in the neighborhood of the ovum, and the enzyme-containing acrosome fuses with the ovum, forming a vesicle (BEDFORD, 1970). Male and female hormones have some influence on these processes. Estrogens, LH and HCG seem to promote capacitation while progesterone inhibits it. Capacitation and decapacitation have been proven in many mammals, including the human. Recently, indirect methods, as tetracycline incubation, to investigate the first phase of capacitation, have been developed (DUKELOW, 1971).

2. Diagnosis

When the history is taken, special attention must be paid to the following: frequency of sexual intercourse, number of siblings, number of their children, previous illnesses, particularly

mumps, tuberculosis, venereal diseases, malnutrition, cryptorchidism and the time of descent, age at onset of puberty, indulgence in alcohol and tobacco, mental stress, professional overexertion, exposure to heat, type of dress, particularly whether close-fitting underpants are worn.

Signs of hypo- or hyperthyroidism, diabetes mellitus, vascular diseases and neurological disorders must be looked for in the general examination. Secondary sexual characteristics must be investigated.

Careful examination of the male genitalia is most important. The size of the testes must be noted. This is best measured with the orchidometer giving the volume of the testis (see p. 1036). The epididymis and vas deferens must be palpated, and a rectal examination performed to examine the prostate and seminal vesicles. Attention must be paid to varicoceles, open hernial orifices, and to the possibility of the testes sliding back into the inguinal canal.

Examination of the semen is the first and most important special test. For the methods see p. 493. Any doctor can come to the simple conclusion of whether the semen contains actively motile spermatozoa, but the differential morphological assessment needs special experience.

Normal semen after 3–5 days of abstinence contains 40–250 million sperms/ml, at least 60% of which must be motile, and 60% normally formed (McLeod, 1965). The sperm count falls if the period of abstinence is shorter, and motility is reduced if it is longer. Fertility is reduced when the sperm count is below 40 million/ml (oligospermia). The possibility of fertility is very slight if the count is less than 20 million/ml. The fall in the sperm count is usually accompanied by impaired motility and morphology. Sterility, however, can only be assumed to exist when spermatozoa are completely absent (azoospermia). If conditions are unfavorable in the woman, a high sperm count is needed for conception to occur. Aspermia is described as the inability to ejaculate semen. We use the nomenclature recommended by the Commitee for Male Infertility in Amsterdam in 1959. In German-speaking countries azoospermia is usually used for the absence of spermatozoa in the presence of cells of spermiogenesis; aspermia is applied to the absence of both, and aspermatism indicates the inability to produce semen. Other terms, such as cryptospermia and astheno-teratospermia are unnecessary and are best avoided. Necrospermia indicates that the sperms are immotile and not revivable. Fertility is also thought to be reduced with sperm counts over 250 million/ml.

Table 6. Examination of the male

A. *History*
1. General: venerea, tuberculosis, mumps-induced orchitis, testicular torsion, mechanical trauma of the genitals, genital surgery: orchidopexia, operation of hydroceles or varicoceles, hernia inguinalis operations. Exogenous damage: alcohol, nicotine, heat, X-rays.
2. Genital: coital frequency, timing and technique, ejaculatio praecox (duration of coitus), possibility of impotence.
3. Psychological: wish for children? Reason for wanting children, attitude to wife, professional aims and interests.

B. *Physical examination*
1. General: state of health, blood pressure, sedimentation rate, red and white blood count and blood smear, serological reactions for lues, urinalysis.
2. Genital: cryptorchidism, hypospadia, genital hypoplasia, orchidometry (testicular size), varicocele, hydrocele, inflammation

C. *Sperm examination*
Quantity and quality (see p. 493)

In case of pathological sperm:

D. 1. Endocrinological examination: gonadotropins, 17-ketosteroids and 17-hydroxysteroids, plasma or urinary testosterone, thyroxine, basal metabolic rate and serum cholesterol.
2. Examination of prostatic secretion (massage of the prostate gland).
3. Testicular biopsy, examination of the clear passage of the sperm ducts, rinsing, vesiculography, urethrography).
4. Sex chromatin or karyogram in case of abnormalities of the external genitalia, underdevelopment of the secondary sexual characteristics, small testicles with azoospermia.

It is not certain how much significance can be attached to biochemical investigations in the practical assessment of fertility. The content of fructose (normal 1200–4500 µg/ml) and that of citric acid (normal 30–420 mg/100 ml) in the semen are dependent on the production of testosterone by the Leydig cells. Fructolysis (fructose consumption in 5 hours) and hyaluronidase activity are parallel to the number of motile sperms.

The testis biopsy is indispensible for an exact diagnosis in hypogonadism and in azoospermia. It is sometimes justified for therapeutic reasons, although only a small percentage of hypogonadal men have any hope of their sterility being cured.

On the other hand, the use and indication of the testis biopsy in oligospermia is disputable. No therapeutic conclusions can be derived from it; however, the chance of success can be better assessed from the biopsy and can spare married couples years of disappointing waiting. In cases where the secondary sexual charac-

teristics are present it can definitely exclude an idiopathic eunuchism. In cases where the testes are particularly small (less than 10 cm^3), fertility is almost impossible, and patients can be spared this tiresome investigation.

It is possible that although the testis biopsy is of no use in some cases, all patients in this group can profit from it since it can provide a basis for future therapy.

The so-called Sims or Huhner's test involves microscopical examination of sperm taken from the cervix post coitum. This test is supposed to indicate individual incompatibility between the sperm and the cervical mucus.

3. Therapy

We still have no certain means of improving the quality and number of spermatozoa except in hypogonadotropic hypogonadism. All reports of success with hormones and vitamins apply to subfertile patients with sperm counts between 20–40 million/ml, which would have allowed conception even without treatment. Therapeutic successes of this kind can be fallacious. The hopes of improving oligospermia with HMG outside of pituitary insufficiency have not materialized (McLeod, 1967).

In Zurich we have never observed any improvement of the semen quality during treatment with HMG, 500 U every day and HCG, 5000 U weekly for 3 months in selected patients with a sperm count of less than 20 million/ml and spermatogonia in the testicular biopsy. Other series have shown comparable results (Polishuk, 1967; Mroueh, 1967).

Azoospermia in the presence of normal-sized testes can be due to obstruction of the spermatic ducts. The testis biopsy shows normal histological findings or only slightly reduced spermatogenesis. Patency of the vas deferens is best tested by lavage with lukewarm physiological saline. Vasography with X-ray contrast medium is thought to cause epithelial lesions.

Biopsy from testes of normal size, however, also reveals disorders of information or maturation, such as spermatogenic arrest, hypospermatogenesis, or germinal aplasia. Treatment is hopeless in all three conditions.

The diagnosis of oligospermia can only be made by repeatedly finding lowered sperm counts. Temporary reductions in the sperm count are not uncommon. In oligospermia without signs of hypogonadism, urological causes such as prostatitis must be investigated and cured. Inflammatory components in the secretory product can impair motility of the sperms and thus their fertility. The varicocele may cause sterility (see p. 464) (Tulloch, 1955; Scott, 1962). Operative treatment with ligation of the vena spermatica can improve the quality of the semen in 60–70% (McLeod, 1967). Improvement of the motility was the most constant result. Although 37% of the patients in one series had sperm counts of less than 20 million/ml, pregnancies were achieved in 30–50% (McLeod, 1967). Similar observations were recorded in patients with hydrocele. Spermiogenesis may be impaired either by changes in temperature or by hypoxia (Brown, 1967).

It is doubtful whether advice to limit sexual intercourse to the fertile days of the woman's cycle is of any value. It is true that the sperm count increases with sustained abstinence, but motility decreases at the same time. The chances with frequent intercourse are better than with infrequent intercourse (McLeod, 1967). General advice usually given is the following: The patient should relax, have sufficient sleep, avoid becoming overweight, and have some physical exercise. Close-fitting underwear is thought to be unfavorable since it increases the temperature in the testes.

Table 7. Treatment of male sterility

Cause	Sperm count	Size of testes	Testis biopsy	Therapy
1. Azoospermia in the presence of obstructed spermatic ducts	0	Normal	Normal or slightly decreased spermatogenesis	Surgical
2. Hypogonadism	Decreased or 0	Smaller	Pathologic	HCG, HMG in selected cases
3. Oligospermia	Decreased	Normal	Normal or slightly pathologic	Homologous artificial insemination in selected cases
4. Unknown	Normal	Normal	Normal	None

Postcoital loss of semen can be prevented by the woman's adoption of a suitable position with the thighs drawn up and apart.

When these measures are unsuccessful, mechanical means of concentrating the semen can be considered. Homologous artifical insemination, i.e. insemination with the husband's semen, makes it possible to place semen in the concentrated form in the cervix or in the uterine cavity. The first half of the ejaculate usually contains the majority of the more motile sperms. This fact can be exploited by using a "fractionated ejaculate" for artificial insemination. The semen is obtained by masturbation and is collected in sterile containers. It can be concentrated by centrifugation. Semen from repeated masturbations is collected and stored in the deep freeze. It is then allowed to thaw out and is centrifuged. The semen thus obtained for homologous artificial insemination has a normal sperm count. The sperms may, however, be damaged by highspeed centrifugation. Whereas the chances with homologous insemination are high in sterility due to mechanical causes, the success in oligospermia is uncertain. Some authors disclaim any success. Statistics of the success range between 0 and 100% and are not comparable because of the different material (ZANARTU, 1960; SCHELLEN, 1957). In Zurich the procedure has been abandoned. In any case the physician will do well to undertake this tiresome procedure, which is a great strain to the married couple, only if the couple expressly requests it.

In *hypogonadism*, it is only possible to achieve fertility by hormone therapy in the case of hypogonadotropic hypogonadism.

Secondary hypogonadotropic hypogonadism can at present be treated with human gonadotropin until normal incretory *and* excretory functions of the testes are restored. Only a few well-examined cases have so far been described.

In a hypophysectomized man with partial pituitary insufficiency and receiving cortisone and androgen substitution, in whom azoospermia developed 2 years after the operation and spermatogenesis was arrested at the spermatid stage, treatment with a weekly dose of 5 mg of human FSH derived from pituitaries for 13 weeks resulted in restoration of normospermia and a sperm count of 61 million/ml (GEMZELL, 1964). A diabetic with a total hypophysectomy whose sperm count fell from 480 million to 0 within 3 months, and whose testis biopsy showed only Sertoli cells and a few remaining spermatogonia responded well to HMG. After 65 daily injections of 5 mg HMG, active spermatogenesis with primary spermatocytes and spermatozoa was demonstrable (MCLEOD, 1966). A probably less purified preparation (Pergonal) obtained from human menopausal urine was used at that time. Recently, clear-cut morphological differences between the immature Sertoli cell of hypogonadotropic hypogonadism and the adult Sertoli cell after treatment with HMG was demonstrated by electron microscopy (DE KRETSER, 1972). Whereas in gonadotropin deficiency inter-Sertoli cell junctions are absent, they appear in the adult Sertoli cells, suggesting that the Sertoli cells have a crucial role in the development of spermatogenesis.

HMG alone has no success on undeveloped testes in congenital secondary hypogonadism (idiopathic eunuchism). On the other hand, preliminary treatment for 6 months with HCG (2000 U three times weekly) resulted in normal development to slight hypertrophy of the Leydig cells and in spermatogenesis to the spermatid stage. Administration of HMG at this point, in addition to HCG (12.5 U of HMG i.m. three times weekly with continuation of HCG in the previous dosage), achieved at least focally complete spermatogenesis with mature spermatozoa in the testis biopsy after 8 weeks (LYTTON, 1966). Complete maturation of the spermatozoa takes about 70 days. Androgens alone or normally functioning Leydig cells can maintain the early stages of spermatogenesis, whereas FSH is necessary for the terminal phases of maturation.

Normal spermatozoa were demonstrated in the ejaculate of 12 of 38 patients with azoospermia and low or absent gonadotropins; in these 12, the testis biopsy showed only Sertoli cells, spermatogonia and some spermatocytes before treatment. Pregnancy occurred in 4 cases. No success was achieved in those where there were no spermatogonia in the testis biopsy. A dose of 75 IU HMG* i.m. every other day is recommended; only if the semen volume is less than 1.5 ml does the treatment, which lasts 80–120 days, have to be combined with HCG, 2500 IU i.m. every other day (LUNENFELD, 1967). Neither the optimal dosage nor the chances of success are known yet. Large amounts of FSH are necessary to initiate spermatogenesis, but maintenance can be achieved by much lower FSH levels, which HCG might also possess (MCLEOD, 1972).

On the other hand, no success can be achieved with HMG and HCG in cases of oligospermia where there is no evidence of reduced gonadotropins (MROUEH, 1967; MCLEOD, 1967).

The very expensive combined replacement therapy with HMG and HCG for hypopitui-

* One ampoule Pergonal or Humegon containing 75 IU FSH and 75 IU LH.

tarism or for hypogonadotropic hypogonadism is only justified when fertility can be achieved, at least temporarily, in the patient. Development of the technique for storing human semen in the deep freeze will increase the chances for hypophysectomized patients to produce children.

In other forms of hypogonadism, hormone therapy can correct signs of failure and metabolic disorders, but not sterility. The use of HCG, and probably also of HMG, is not justified in infertility with oligospermia or normospermia. Gonadotropin from animal serum (PMS, pregnant mare serum) leads to the formation of antibodies within 2 months, and suppresses FSH and LH effects. The testosterone rebound, meaning an attempt to influence oligospermia favorably by producing azoospermia with temporary high doses of testosterone (150 mg weekly) is useless or even harmful. The first critical reports recently published about therapeutic trials with human FSH (HMG) show negative results. Treatment with clomiphene, which increases the gonadotropins, has not been successful in the male either.

Two of the numerous other therapeutic propositions are mentioned here: desiccated thyroid, in a daily dose of 0.2 g, has been considered a means of overcoming sterility for many years. Re-examination, however, has shown that it is only of use in hypothyroidism. Vitamins B_1, E, and A in particular have been recommended. Apart from the fact that avitaminosis occurs only rarely in the human in Western countries, careful studies have shown no effect of vitamin A on oligospermia.

This is not the place for discussing the ethics and psychological problems of heterologous insemination, i.e. insemination with semen of a donor known only to the physician and not to the married couple. The legal principles are manifold and still not fully explained. The legal problems in the European countries and in the USA have been reviewed by SCHELLEN (1957). This procedure is more widely accepted in the United States and in the Scandinavian countries, and is performed by recognized clinics.

Heterologous artificial insemination has not been approved by the Churches. In Switzerland, general opinion is reserved. All the problems have recently been reviewed by GLATTHAAR (1971).

Although the treatment of sterility is so seldom succesful, thorough investigation and consideration of the therapeutic possibilities are to be encouraged. If the physician merely adopts the vague attitude that not much can be done for the patient this produces worrying uncertainty in the patients and drives them into the hands of medical and non-medical quacks. In addition, the childless married couple can be greatly helped by the declaration that investigational possibilities are exhausted and a diagnosis of untreatable sterility has to be made, as they can readjust to the possibility of adopting a child.

4. Induced Reversible Sterility

Induced reversible sterility in the man as a means of birth control is still in the experimental stages. Auto-immunization of the man with testicular tissue inhibits spermatogenesis for just a few weeks (MANCINI, 1965). Substances with an alkylating and cytostatic action do not work specifically enough on spermatogenesis. Hexamethyl phosphoramide has been used in insects and results in long-lasting sterility. Derivatives of hydrazine act very slowly (JACKSON, 1966). The action of a dinitropyrrol on the different stages of maturation have been thoroughly investigated, and the late stages have been found to be the most sensitive. Intermittent administration of the substance in the rat produces reversible sterility (PATANELLI, 1964). Substances acting on different phases of maturation of the sperm are in the first stage of investigation (JACKSON, 1970). Progesterone and other natural steroid hormones can inhibit the capacitation (see p. 482) of sperms and lead to a reversible sterility, an effect which has been observed in animals (SEGAL, 1968). Progesterone influences the uterine mucosa, which prevents the sperms from becoming fertile (see p. 482 and Chap. X, p. 623).

H. Impotence, Satyrism, Perversion

Impotence usually signifies impotentia coeundi, whereas impotentia generandi implies sterility, which is a better term. Impotence is most often due to psychogenic disorders. It is rarely due to vascular diseases, neurological or endocrine factors. Impotence can result from lipiodol arachnoiditis and is an early sign of Buerger's disease. Antihypertensive drugs, especially ganglion-blocking substances such as guanethidine and psychotropic drugs such as phenothiazines may cause impotence.

True endocrine impotence can occur in all forms of hypogonadism with androgen deficiency. However the hypogonadal man is, usually quite unaware of his functional loss since he has no need for it. However, even without manifestations of failure, impotence is a common disorder in advanced age, in hypo-

and hyperfunctional states of the thyroid gland and adrenal cortex, and finally in diabetes mellitus where, as in paraplegics, androgen function is not impaired but neurological disturbances can be detected (FAERMAN, 1972). There have been attempts to differentiate between "constitutional" and "psychogenic" impotence by the urinary excretion of testosterone (COOPER, 1970).

The conflict causing psychogenic impotence can be concealed and may also occur in a person with no neurotic tendencies. It is often astounding what can be achieved with common sense and a brief course of psychotherapy. A treatment with testosterone (25 – 50 mg daily) for 1 – 2 weeks is permissible for the diagnosis ex juvantibus between impotence due to endocrine factors and psychogenic impotence. Stimulation of the libido over a long period can be detrimental if the conflict is not resolved, since the drive is increased but cannot function normally without removal of the inhibition. Testosterone propionate is sometimes useful as an adjuvant. High doses must be used (25–50 mg, 2–3 times weekly, or 250–500 mg depot testosterone i.m. every other week.

Ejaculatio praecox is due to psychological factors and is not an endocrinopathy. Psychotherapy is recommended in the first place. Often the simple means of more frequent sexual intercourse or the application of a cream with a local anesthetic action on the gland can help.

Treatment with 1 mg stilbestrol daily is advocated for excessive sexual drive which is socially unacceptable (satyrism, perversion). The anti-androgen, cyproteron acetate, is also effective in a daily oral dose of 100–200 mg, and it has the advantage of not producing unpleasant side-effects such as gynecomastia and testicular atrophy (see p. 472) (LASCHET, 1968; OTT, 1968).

I. Gynecomastia

Gynecomastia, i.e. increase in male mammary tissue, is a symptom which occurs most frequently in hypogonadism but does also arise in other endocrinopathies and in non-endocrine diseases. HALL (1959) has compiled a thorough and critical monograph on gynecomastia. It occurs frequently in a mild form, and is thought to be histologically demonstrable in 40% of men.

Hormonal regulation of growth of the mammae is discussed in Chap. XI (see p. 694). In addition to estrogens, progesterone, prolactin, growth hormone, and other substances also promote growth of the mamma. These include testosterone, (see p. 475), adrenocortical hormones (desoxycorticosterone, total adrenocortical extracts), and even steroids related to the digitalis compounds. The possibility of conversion of individual steroids and substances within the body must be considered. Chorionic gonadotropin can lead to gynecomastia through stimulation of estrogen production in the testes. Nervous factors also influence growth of the mammae. Drugs which inhibit the hypothalamus (chlorpromazine, reserpine) can result in the release of prolactin and thus cause gynecomastia, probably by inhibiting PIF (see Chap. II, p. 30). Elevated serum prolactin levels have been detected only in patients with gynecomastia due to tranquilizers or reserpine (TURKINGTON, 1972). Finally, sensitivity of the end-organs to hormonal influences must be taken into account, as unilateral gynecomastia or idiopathic gynecomastia could not otherwise be explained. The fact that the factory workers concerned with the production of estrogens and are exposed to them do not all develop gynecomastia, and not all to the same degree, indicates that sensitivity of the end-organ has a decisive effect on the pathogenesis of gynecomastia. An increase in estrogen excretion is found in only one third of patients with gynecomastia. The initiating factor in pubertal gynecomastia seems to be associated with the growth hormone. The patho-anatomical changes in gynecomastia are due to proliferation of the efferent ducts and a simultaneous increase in the surrounding connective tissue. The efferent ducts are not only lengthened and branched, but are also increased in number. True glandular lobules, on the other hand, develop only in rare cases, such as in the presence of endocrine active teratomas (see p. 490f.). The epithelium of the excretory ducts often consists of many layers, and papillary-like protrusions may develop. Proliferation of the basket cells may also occur. Treatment with estrogens leads to pronounced epithelial proliferation. Histologically, the epithelia occasionally show signs of secretion. On the other hand, milk or colostrum which can be expressed are only exceptionally produced. Two types of gynecomastia can be differentiated according to the connective tissue surrounding the excretory ducts. In one form, the excretory ducts are enclosed by coats of loose connective tissue which is surrounded by a tissue rich in collagen fibers. In the second form, the excretory ducts are embedded directly in a connective tissue with a very high content of collagenous fibers with no loose tissue. These two types are probably different stages of development, the type with loose sheaths of connective tissue depicting the active phase, and the type with collagen-rich connective tissue only being the inactive phase. Small inflammatory infiltrations

consisting of lymphocytes, plasma cells, histiocytes and occasionally leukocytes as well can almost always be demonstrated.

Table 8. Occurrence of gynecomastia. (Modified after BRONSTEIN, 1950; and HALL, 1959)

A. Physiological gynecomastia (see Chap. XIX)
1. Gynecomastia in the newborn
2. Pubertal gynecomastia, transitory and persistent forms
B. Gynecomastia in endocrinopathies
1. Hypogonadism (castration, Klinefelter's syndrome, liver diseases, malnutrition, involution)
2. Testicular tumors (p. 490)
3. Feminizing adrenal tumors (p. 387)
4. Hyperthyroidism
5. Tumors of the anterior pituitary: acromegaly, chromophobe adenoma, craniopharyngeoma
6. Hermaphroditism
C. Drug-induced gynecomastia
1. Gonadotropins
2. Estrogens
3. Testosterone (p. 475)
4. Desoxycorticosterone
5. Digitalis
6. Isoniazid, alpha-methyl dopa, amphetamine, reserpine, chlorpromazine, certain anti-androgens.
D. Gynecomastia in non-endocrine diseases
1. Leprosy
2. Leukemia
3. Diseases of the nervous system (injuries to the spinal cord and intercostal nerves, syringomyelia, Friedreich's ataxia)
4. Bronchial carcinoma
5. Osteoarthropathy
6. Uremia
7. Chronic hemodialysis
E. Familial
F. Idiopathic

The differential diagnosis includes pseudogynecomastia or lipomastia, which arise from hypertrophy of fatty tissues. It also includes inflammatory processes and true tumors which may arise spontaneously or after hormone therapy. Palpation is essential for the diagnosis since pseudo-gynecomastia cannot always be differentiated from true gynecomastia by mere observation. Palpation will always reveal firm glandular tissue in true gynecomastia, and glandular enlargement can vary from the size of a pea to that of a fist. After the history has been obtained, with special reference to any drugs taken, examination must then be directed to the testes and pituitary. The testes must be carefully palpated. Even in the absence of a palpable testicular tumor, it is advisable to perform a simple pregnancy test on the urine to exclude chorial carcinoma. In every case of gynecomastia, a lateral X-ray of the sella must be taken, liver and thyroid must be investigated, and thorax screening should be performed to exclude a bronchial carcinoma.

1. Pubertal Gynecomastia

Refer to Chap. XIX, p. 1041.

2. Gynecomastia in Endocrinopathies

Gynecomastia in hypogonadism occurring after starvation and involution and in the presence of testicular tumors has been discussed on p. 490. Gynecomastia occurring with rare feminizing adrenal cortical tumors is dealt with on p. 378. Gynecomastia is occasionally seen in hyperthyroidism, sometimes arising only with the remission after ^{131}I therapy. There may be some connection between gynecomastia and renourishment after starvation.

3. Gynecomastia Produced by Drugs

Gynecomastia can arise temporarily during treatment of cryptorchidism and hypogonadotropic eunuchoidism with chorionic gonadotropin. Estrogens used therapeutically in men (carcinoma of the prostate, satyrism) almost always result in gynecomastia. It can be prevented by prophylactic X-ray irradiation (HAURI, 1971). Testosterone propionate, and more frequently methyl testosterone, may produce gynecomastia during treatment of primary hypogonadism. Conversion of testosterone into estrogens within the body has been considered the cause. Development of gynecomastia after administration of desoxycorticosterone and total adrenocortical extracts has not been explained. Digitalis glycosides, spironolactones, isoniazid, alpha-methyl dopa, amphetamine, reserpine, and chlorpromazine (see p. 558) may occasionally cause gynecomastia.

4. Gynecomastia in Nonendocrine Diseases

Gynecomastia is thought to occur commonly and in severe forms in leprosy. Leprosy does, however, cause hypogonadism at the same time, so that this may also be involved in the etiology of the gynecomastia. Estrogen excretion does not appear to be increased. Gynecomastia has been described in paraplegics after traumatic damage to the spinal cord. It has also been observed after injury to the intercostal nerves during thoracoplastic operations and in bronchial carcinoma. Half of all patients with osteoarthropathy have gynecomastia. The clubbed fingers and the gynecomastia may regress after vagotomy. There have been isolated reports of gynecomastia occurring in other diseases, such

as ulcerative colitis, erythrodermia, and lymphogranuloma. Coincidental occurrence cannot be excluded for the time being. A curious observation is the frequent occurrence of gynecomastia in chronic hemodialysis (one third to one half of all cases). It is explained as a form induced by renourishment, such as was seen in the Second World War, due to the restoration of gonadotropin secretion. Increased FSH and LH secretion is assumed (FREEMAN, 1968; SCHMITT, 1968; SAWIN, 1973).

5. Familial Gynecomastia

Familial occurrence has been reported. It is probably inherited through a recessive or autosomal dominant gene with sex-linkage and slight hypogonadotropic hypogonadism (ROSEWATER, 1965) (see p. 470).

6. Therapy

Any known cause must be removed. Surgical removal is indicated when the gynecomastia is conspicuous or painful. This, however, should not be done until 1 or 2 years after puberty, i.e. not before the 18–19th year. Spontaneous regression is still possible during this time. Local application of testosterone can help against pain. Regression of the gynecomastia is not to be expected with testosterone therapy. X-rays before estrogen therapy can prevent gynecomastia. Intensive radiotherapy may be tried therapeutically (HAURI, 1971).

K. Syndromes of Testicular Hormonal Overproduction

The overproduction of testicular hormones occurs only in tumors with the exception of one well studied case (GOLDFINE, 1971). Besides this, compensatory hyperplasia of one testis is seen in semicastration or underdevelopment of the other testis (LARON, 1969). Total testosterone secretion remains unchanged. For increased testosterone secretion relative to age see pubertas praecox, Chap. XIX, p. 1047.

1. Neoplasms of the Testis

Neoplasms of the testis account for about 0.5 to 1% of malignant tumors in the male. They can arise from the testis itself or from its coats and appendages. True tumors of the testis are not uncommonly endocrine active. On the other hand, tumors of the testicular coats and appendages, in particular the so-called adenomatoid tumors of the epididymis, paratesticular fibromas, fibrosarcomas, liposarcomas and rhabdomyosarcomas, produce no endocrine symptoms (SCHRÖDER, 1970). We are therefore limiting our discussion to true testicular neoplasms.

In the classification of these tumors, there are certain differences between the American (DIXON, 1952) and European nomenclature (V. ALBERTINI, 1955; COLLINS, 1964) most commonly in use. We prefer the classification recommended by COLLINS as it offers the advantage of being especially simple, while permitting a clear classification of teratomas (Table 9). The whole group of malignant teratomas corresponds to so-called chorial carcinomas (V. ALBERTINI), whereas the anaplastic malignant teratoma corresponds to the embryonal carcinoma of DIXON.

Table 9. Classification of tumors of the testis, epididymis and neighboring structures. (After COLLINS and PUGH, 1964)

1. *Tumors of the testis*
Seminomas
Teratomas:
Teratomas, differentiated forms (TD)
Malignant teratomas, intermediary form (MTI)
A: with differentiated or organoid areas (MTI A)
B: without differentiated or organoid areas (MTI B)
Malignant teratomas, anaplastic forms (MTA)
Malignant teratomas, trophoblastic forms (MTT)
Combination tumors:
seminoma and teratoma in the same testis
Sertoli-cell tumors
Interstitial-cell tumors
Orchioblastomas
Malignant lymphomas
Metastases
Various types and unclassifiable tumors
2. *Tumors of the epididymis, testicular coats and spermatic cord*
Adenomatoid tumor
Tumor of connective tissue and muscle;
Benign: fibroma, leiomyoma, lipoma, etc.
Malignant: embryonal sarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, etc.
Metastases
Various types and unclassifiable tumors

The relative frequency of the individual tumors of the testis is indicated in Table 10, which has been derived from 995 tumors of the testis (COLLINS, 1964). Seminomas, teratomas and combination tumors consisting of seminomas and teratomas, which are almost without exception malignant, together constitute 86% of tumors of the testis. The other group, however, also includes predominantly malignant tumors, such as orchioblastomas, malignant lymphomas and metastases, and these together

make up a further 8% of the total number of testicular tumors. Thus, benign tumors of the testis are exceptionally uncommon.

a) Seminomas

Seminomas are the most common tumors of the testis. They occur most often in men between the 30th and 50th year. They are more common on the right side. Furthermore, they occur more frequently in imperfectly descended testes than in normally descended testes. On rare occasions, both testes are involved. Seminomas combined with a teratoma are not uncommon (see combination tumors). Histologically, they consist of clusters of cells, loosely arranged. These clusters vary in size and are separated by narrow septa in which groups of small lymphocyte-like round cells are embedded. The tumor cells themselves are fairly large, possessing ill-defined clear cytoplasmic edges and rather large, roundish nuclei. The tumor cells thus appear similar to germ cells, from which they also arise. According to the degree of differentiation of the tumor cells banal seminomas, which are more frequent, are separated from the less common spermatocytic forms. Giant cells are not infrequently found in seminomas. Occasionally a tuberculoid reaction is seen in the interstitial and surrounding tissues. Seminomas metastasize relatively late. They are very radiosensitive and have a good prognosis. As a rule, metastases first arise in the iliac and paraaortal abdominal lymph nodes. They may also occur in the inguinal lymph nodes.

Seminomas may cause a slight rise in urinary gonadotropin levels. This rise, however, is not so pronounced as with teratomas. SYMINGTON and WALLACE (1964) found an average rise from 20 units HPG/day in the healthy subject to 36 units HPG/day in patients with seminomas. These values can temporarily increase even further after surgery. The rise is attributed to a loss of normal testicular tissue, and thus to inadequate inhibition of the pituitary.

b) Teratomas

True teratomas are somewhat less common than seminomas. They occur in younger age groups than seminomas, and are particularly common in men in the third decade. Teratomas are also more frequently found on the right side. Bilateral teratomas are extremely rare.

Teratomas of the testis are almost without exception malignant, in contrast to the corresponding ovarian tumors. Thus, mature testicular tumors which may appear to be benign must be examined carefully for undifferentiated, malignant areas. COLLINS and PUGH (1964) found only 13 benign lesions among 322 true teratomas (4%).

Table 10. Frequency of the different types of tumors among a total of 995 testicular tumors. (After COLLINS and PUGH, 1964)

	Number of cases	%
Seminomas	400	40
Teratomas	322	32
Combination tumors (seminoma + teratoma)	136	14
Sertoli-cell tumors	6	2
Interstitial-cell tumors	14	
Orchioblastomas	8	8
Malignant lymphomas	66	
Metastases	6	
Various types and unclassifiable tumors	37	4
Total	995	100

The frequency of different malignant forms can be seen in Table 10. Since quite undifferentiated areas can be demonstrated in practically all malignant testicular tumors, COLLINS and PUGH (1964) classify teratomas according to their most highly differentiated areas, even when these are only localized. In the intermediate form (MTI), more or less differentiated tissue can be demonstrated. Fully mature tissue or organoid structures can be found in intermediate form A (MTI A), and immature tissue only and no organoid structures can be seen in intermediary form B (MTI B). An anaplastic teratoma (MTA) can only be referred to in the presence of undifferentiated, mainly cancerous cell masses, a picture corresponding to so-called embryonal carcinomas. A trophoblastic malignant teratoma (MTT) can only be assumed to be present when villous-like structures can be recognized. Syncytial giant cells alone are not sufficient to justify this diagnosis since isolated giant cells can be found in almost all forms of malignant teratomas and even in seminomas.

Malignant teratomas have a considerably worse prognosis than seminomas. Metastases were confirmed at surgical removal of testicular tumors in almost one sixth of the patients in the COLLINS and PUGH series (1964). Half of the 322 patients with teratomas died within the next 4 years, 62% of them in the first postoperative year.

In contrast to seminomas, teratomas are often endocrine-active. Like placental tissue, they produce mainly chorionic gonadotropin (HCG). They also produce estrogens and progesterone. Large amounts of chorionic gonadotropin may be produced and may cause a positive result in immunological pregnancy reactions

even in a dilution of 1:10 (Gravindex) or for 20–40000 IU/l (Pregnosticon). HCG, progesterone and estrogens together cause gynecomastia associated with character changes in the patient, with awakening of maternal instincts. Pregnandiol, a derivative of progesterone, is excreted. Estrogen excretion is also elevated. Demonstration of a massive urinary excretion of chorionic gonadotropin confirms the diagnosis of a malignant teratoma. It is also of importance in the follow-up of the patient.

Table 11. Frequency of the different types of teratomas among 322 teratomas. (After COLLINS and PUGH, 1964)

	Cases	%
Differentiated teratomas (TD)	13	4
Malignant teratomas		
Intermediate form A (MTI A)	181	56
Intermediate form B (MTI B)	101	31.5
Anaplastic form (MTA)	16	5
Trophoblastic form (MTT)	11	3.5
Total	322	100

c) Combination Tumors (Teratomas and Seminomas)

Tumors consisting of teratomas and seminomas are relatively common, as is shown in Table 2. Combinations are possible with all forms of teratomas, and their frequency corresponds roughly to that of the teratomas without seminomas. At present there is no definite explanation for this tumor combination. v. ALBERTINI (1943) speaks of reactive seminomas in teratomas, but this reaction cannot be explained merely by abnormal hormonal stimulation. The prognosis of such combined tumors is somewhat more favorable than that of teratomas without seminomas. The endocrine activity corresponds to the type of the teratoma.

d) Sertoli-Cell Tumors (Androblastomas)

Sertoli-cell tumors are some of the least well-defined testicular tumors. They are rare in the human, and large investigation series are therefore not available. The tumors vary widely in the histological picture. Typical Sertoli-cell tumors are relatively small and are sharply defined. Microscopy shows strands of cells and gland-like formations, their epithelia being reminiscent of Sertoli cells. Such tumors occur in both normally situated and undescended testes. They only rarely metastasize.

In addition to these tumors with more or less typical Sertoli formations, other tumors also arise with proliferation of the interstitial tissue. For this reason, DIXON and MOORE (1952) subdivided these tumors, which were collectively described as androblastomas by TEILUM (1946), into 3 forms, namely diffuse stromal forms, mixed stromal and glandular forms, and true tubular forms. MORRIS and SCULLY (1958) refer to the corresponding ovarian tumors simply as Sertoli-Leydig cell tumors since the combination of a proliferation of glandular tubes and stromal constituents is very typical. Such tumors are a rarity in man, whereas they are the most common form of testicular tumor in dog.

Sertoli-cell tumors may be endocrine-active, forming estrogens or androgens. Gynecomastia may occur. COLLINS and SYMINGTON (1964) found elevated gonadotropin urinary excretion in one case. They themselves, however, also raised the question of whether this tumor might be a teratoma and not a Sertoli-cell tumor.

Besides the Sertoli-cell tumors tumor-like proliferations of hypoplastic tubules occur. Single hypoplastic tubules may be found in normally developed and descended testes, at least in young adults (HEDINGER, 1968). In undescended testes, however, such tubules may form whole fields, the so-called hypoplastic zones. In the syndrome of testicular feminization transitions to the so-called *tubular adenoma* PICK are found.

Furthermore, tumors of dysgenetic gonads, the so-called *gonadoblastomas*, are a special group (SCULLY, 1953; SIEBENMANN, 1961). The same applies to similar tumors, which can be seen in the gonadal crest and in testicular tissue on the opposite side in the mixed testicular dysgenesis where there is a chromosome mosaic (SALLE, 1969) (see also Chap. XII, p. 722).

e) Interstitial Cell Tumors

These tumors also occur only rarely. In large statistical series they account for about 1–2% of testicular tumors. A total of rather more than 100 cases has so far been reported in the medical literature. It is probable that some of these cases are not true tumors but rather hyperplasias of Leydig cells or of Leydig-like cells of adrenocortical tissue in the congenital adrenogenital syndrome. This is especially true of the few observations of so-called "bilateral Leydig-cell tumors" and of the "unilateral tumors" in children with pseudopubertas praecox, in whom the clinical symptoms do not regress after orchidectomy but may even worsen (see p. 366).

α) True Leydig-Cell Tumors

Tumors of the Leydig cells are usually small, attaining the size of a walnut or a hen's egg at

the most. They are encapsulated. Their cut surface is yellowish-brown. The tumors are composed of cells very similar to Leydig cells. They may enclose brown pigment and crystals in addition to fatty substances. Cells and nuclei are very polymorphous, which suggests malignancy. The tumors are, however, generally benign. Only very few cases of confirmed malignant Leydig-cell tumors with formation of metastases have been observed. The histological picture, however, hardly differs from that of the benign tumor.

Leydig-cells can produce testosterone and estradiol (see p. 451). Leydig-cell tumors can result in an enormous increase in 17-ketosteroid excretion. Amounts of 1 g/day have been measured. Biologically active steroids (androgens), on the other hand, are increased to a lesser degree. Nevertheless, 470 µg/day testosterone glucuronide and 345 µg/day testosterone sulfate have been measured. The latter substance is assumed to originate directly from the tumor. Testosterone production is estimated to be 50 mg/day with a plasma testosterone concentration of 1.9 µg/100 ml, and dehydro-epitestosterone sulfate production to be 2.27 g/day (LIPSETT, 1966). Androgen overproduction does not become clinically manifest in the mature man. In contrast, in infancy it results in pseudopubertas praecox with disproportional stunted stature and extremely pronounced male sexual characteristics.

Increased amounts of estrogens may also be excreted in the presence of Leydig-cell tumors. Increased production becomes clinically manifest with the development of gynecomastia. Natural and synthetic estrogens can cause Leydig-cell tumors in certain breeds of mice. The mechanism of this process is not clear.

β) Adrenocortical-Like Interstitial Cell Tumors

These tumors are histologically quite similar to adrenocortical tissue, and a few authors have therefore stated that they are due to proliferation of ectopic components of the adrenal cortex frequently demonstrated in the testis of the newborn. The picture may often vary in the same tumor. Such tumors may lead to pseudopubertas praecox in the child and to gynecomastia in the adult. Formation of estrogens has been chemically demonstrated. In infantile cases with pseudopubertas praecox, the possibility of a congenital adrenogenital syndrome with hyperplasia of ectopic adrenocortical tissue must always be considered v. ALBERTINI concluded that these adrenocortical-like tumors are large-cell hypernephroid varieties of true Leydig-cell tumors, since this type of hypernephroid picture can often also be observed in tumors of other endocrine organs. THEILUM considers all Leydig cell-like tumors, as well as Sertoli-cell adenomas or so-called tubular adenomas as various differentiation forms of tumors of a single common parent cell, the androblast. He calls all these tumors androblastomas.

As long as large numbers of individual observations continue to be unavailable and our knowledge of the histogenesis and endocrine activity of these tumors remains inadequate, it is advisable to classify such neoplasms by purely morphological criteria. Thorough hormonal investigations are indicated in all cases before removal of the tumor. It is possible that the nature of these tumors may become more apparent following treatment with hormones. Thus, response to HCG, LH, or ACTH, i.e. regression with estrogens or cortisone due to inhibition of the adenotropic hormone, may perhaps throw some light on the type of tumor.

f) Orchioblastoma (Adenocarcinoma of infancy, yolk sac tumor, endodermal sinus tumor)

Orchioblastomas occur only in infants. The histological picture is very uniform. It shows a partly papillary and partly trabecular structure of a clear-cell adenocarcinoma. Some authors consider orchioblastomas to belong to the teratoma group. The orchioblastoma is an exceptionally typical tumor with no signs of endocrine activity. The tumors are malignant, but the prognosis appears to be somewhat more favorable than that of the corresponding teratoma (KARLY, 1968; THEILUM, 1971).

g) Malignant Lymphomas

Malignant lymphomas, lymphosarcomas and reticulosarcomas can occur in the testis as in most organs. However, primary forms are uncommon. The possibility of metastases or primary generalized forms must always be recognized.

h) Metastases

The frequency given in Table 2 refers entirely to surgical material. In postmortems, metastases in the testis are not so uncommon and are found especially in cases of leukemia and malignant lymphoma. However, other tumors, e.g. small-cell bronchus carcinoma, also metastasize to the testis occasionally. Endocrine symptoms can hardly be expected since the basic malignant disease is usually predominant.

L. Methods of Investigation

1. Clinical Signs

The history and clinical examination alone can show whether hypogonadism is present or not because no other hormone influences features to such an extent as the male sexual hormones. Fertility in all likelyhood excludes hypogonadism.

Attention must be paid to the development of the male sexual characteristics, to the type of voice, pubic and axillary hair, skeletal maturation and body stature. If the size of the testes is normal, i.e. >15 cm^3, then hypogonadism is highly improbable, even if the external masculine appearance is not impressive. It must be remembered that the testes first increase in size with the onset of puberty and are infantile prior to this (see Chap. XIX, p.1035).

2. Examination of the Semen

In contrast to incretory testicular function, spermatogenesis can only be assessed by examining the semen or testicular biopsy if the ability to reproduce does not already indicate a normal state. In the presence of small testes, especially if they are greatly reduced in size, spermatogenesis is always severely impaired or completely absent. Milder degrees of infertility, however, can only be recognized through examination of the semen.

The simplest form of semen examination can be performed by the general practitioner, whereas more detailed morphological and physiochemical assessment requires special laboratories. Examination of the semen is essential to the investigation of hypogonadism and every case of sterility. For psychological reasons it is usually not possible before early adulthood.

Procedure. Abstinence from sexual intercourse is required for 3–5 days prior to the test (see p. 483). Semen can be obtained either by masturbation or by coitus interruptus, and should be collected in a clean dry glass vessel. Condoms are not suitable for collecting the semen since the substances contained in the rubber and powder can damage the spermatozoa. If possible semen should be examined 30–60 minutes after ejaculation. The time of collection must be indicated in every case as the time since ejaculation is important in the assessment of motility. Assessment of fertility is also possible from material sent by post to special laboratories.

Macroscopic Examination. Volume in ml, appearance and viscosity (measured by immersing a platinum loop), must be noted. When the viscosity is normal, semen drops from the loop, whereas pathological semen sticks to the loop or forms threads.

Microscopic Investigation. Motility: after thorough shaking, a few drops of the semen are put on a glass slide and covered with a cover slip. The motility is assessed under high magnification, focusing on the uppermost layer. The motile and immotile spermatozoa should be counted in a quarter of the total field so that the motility can be evaluated as a precentage. The degree of motility can also be indicated by 1–4 crosses. Special laboratories employ so-called revival methods with special solutions for assessing motility. This distinguishes between apparently dead spermatozoa and true necrospermia.

Sperm Count. After thorough mixing, semen is aspirated into a leukocyte pipette up to the 0.5 mark. A diluting solution is then aspirated to the 11 mark. HOTCHKISS employs a 4% sodium bicarbonate solution with 1% phenol as a diluting solution. According to JOEL, it is an advantage to use physiological saline with 1% ZIEHL'S carbol fuchsin, which stains the spermatozoa and allows them to be easily detected. After 2 min of mixing, a counting chamber for counting erythrocytes is filled. Five large squares with 16 small squares, each i.e. 80 small squares in all, are counted. The number of spermatozoa counted in the 5 large squares is multiplied by a million. This gives the sperm count per cubic centimeter. The mean of 2–3 counts must be taken.

Morphology. Assessment of the percentage of pathological forms of spermatozoa requires special knowledge. Whereas there is no difficulty in differentiating between normal forms and obviously pathological forms such as double formations, giant head types, and amorphous forms, it is difficult to recognize certain intermediate forms (Fig. 21). According to HOTCHKISS, a smear must be prepared for morphological assessment. It is then fixed in 95% methyl alcohol for 5 min and stained with hematoxylin-eosin or special stains.

Other Investigations. Numerous other investigations such as measurement of pH, revival tests, resistence tests, estimation of fructose, citrate, and different enzymatic activities are performed in specialized laboratories.

The clinical significance of these tests is not yet certain. It is, however, still maintained that the fertility of a sperm is not conclusively proven, even if all the methods of investigation show it to be normal.

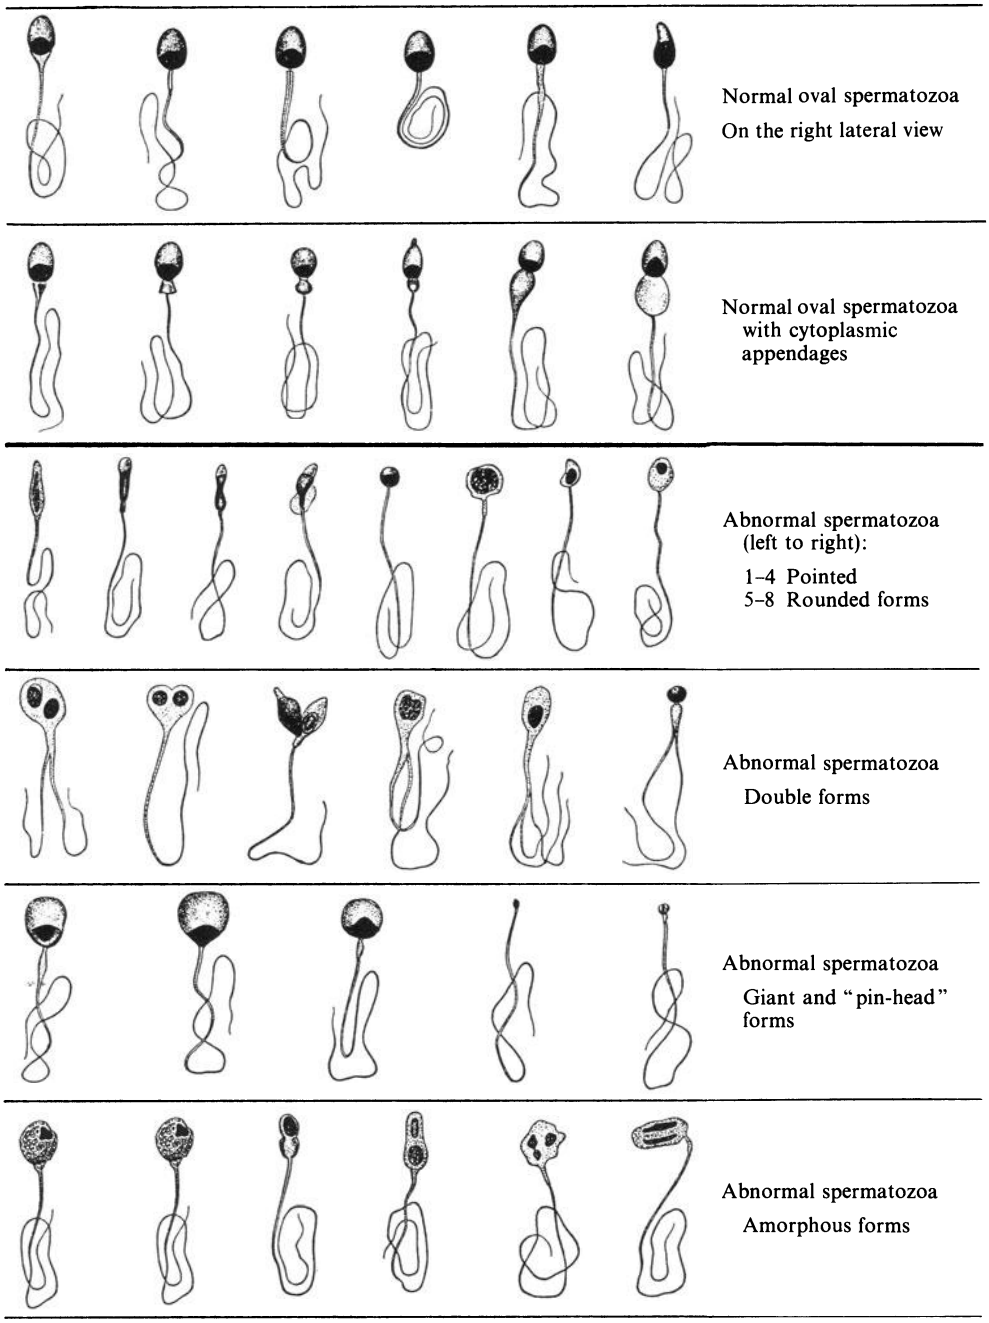

Fig. 21. Morphology of spermatozoa. (After R. S. HOTCHKISS, Infertility in Men, Springfield: Ch. C. Thomas 1952)

Evaluation. The volume of semen, sperm count, motility and morphology of spermatozoa are important in assessment of the fertility of the patient.

The volume normally lies between 2.5 and 3.5 cm^3. Deviations to 0 and as high as 10 or 15 cm^3 are possible. Too large a volume is unfavorable for fertility since the concentration of spermatozoa falls. The normal sperm count is considered to be 40–120 million per cm^3. Fertility is reduced with counts below 40 million. Fertility is highly improbable with values under 20 million. It cannot be emphasized strongly enough that a single assessment of the sperm count is no indication of the degree of fertility. The sperm count can vary by several. 100 % within a week even in healthy men. Repeated assessments must be made and at least 3 are required before fertility can be assessed.

Normal fertility necessitates at least 40% motile spermatozoa, counted 30–60 min after ejaculation.

Furthermore, at least 60% of the spermatozoa should be morphologically normal, and in all, not more than 2% of other cells, such as leukocytes, epithelial cells or cells of spermatogenesis, should be present (see also p. 455).

3. Testis Biopsy

Indication. Testis biopsy is absolutely essential for the exact diagnosis of male hypogonadism (see p. 460). Azoospermia in the presence of testes of normal size is an absolute indication for a biopsy since it is necessary for the detection of obstructions of the seminiferous ducts which can be corrected by surgical means. The biopsy indicates the prognosis in cases of oligospermia and saves costly and useless attempts of treatment in therapeutically hopeless cases (HEDINGER, 1971). In contrast to semen investigation, it can also be performed during childhood.

Procedure. Biopsy of the testis is only a minor surgical procedure and can be performed on outpatients. Strict asepsis is of course essential. We prefer to hand over our patients to the surgeon in spite of the technical simplicity of this minor procedure. The physician should not take the responsibility for postoperative hemorrhages, which do occasionally arise. Admission to hospital for 2 days is advisable for anxious patients.

We usually do unilateral biopsies. American authors recommend bilateral biopsies as a precaution, although divergences are seldom found.

Operative Technique. The skin between the umbilicus and middle of the thigh is shaven and disinfected. The scrotum is held so that the skin is stretched above the testis to be examined. The testis should not be rotated and the incision should be made along the ventral side. Local anesthesia with nerve block of the funiculus at the level of the site of exit from the external inguinal ring ensures complete freedom from pain. With local anesthesia alone, slight pain may be felt on incision of the albuginea, which cannot be infiltrated because of the risk of damaging the testicular tissue lying below.

After nerve block and local anesthesia of the skin and subcutaneous tissue, a longitudinal incision of approximatively 1.5 cm is made in the skin at the base of the scrotum. Such an incision causes much less discomfort than the more distal transverse incision. The scrotal skin can then be spread with a selfholding eye retractor. The tunica vaginalis is also anesthesized. After a cut of 3 to 5 mm through the tunica albuginea, a small amount of testicular tissue can be made to emerge by slight pressure on the testis, and a $4 \times 3 \times 2$ mm piece of tissue can be easily excised. Care must be taken that this piece of tissue is not compressed, torn or shaken. Therefore we prefer to excise with a scalpel rather than with scissors. The biopsy is immediately placed into the fixing solution, because evaluation is impossible if it becomes dried out. We suture the tunica albuginea with the finest cotton thread to avoid any oozing of blood, while the tunica vaginalis is not sutured to permit any drainage to occur. Some authors suggest the albuginea not to be sutured to avoid subsequent pain.

The scrotal skin is closed with one or two catgut sutures. A collodium bandage is applied and a suspensory is worn over the bandage for a week. On the day of operation one should stay quietly at home and on the following day there should be very little discomfort.

Handling of the Testicular Tissue. For histological examination tissues of 2 mm in diameter are sufficient. Amerişan authors recommend Zenker's fluid with a 5% addition of glacial acetic acid, Helly's fluid, or Bouin's fluid (ROULET, 1948) for fixation. We had good results with Stieve's mixture.

Stieve's mixture:	
Saturated aqueous sublimate solution	76 ml
Formaldehyde (40 %)	20 ml
Acetic acid, glacial	4 ml

After 24 hours at the latest, the biopsies have to be put into 70% alcohol where they can remain for a longer period of time without damage. The fixation in Stieve's solution occurs quickly and thoroughly and prevents the washout of cells, especially from the seminiferous tubules. This frequently happens when biopsies are fixed in the usual 4% aqueous formalin solution.

Interpretation. Histological examination enables reliable assessment of the state of development, of any degenerative process, of germinal epithelium, and of the Leydig cells. On the other hand, however, it is not always possible to differentiate between primary testicular damage and secondary changes on the basis of the histology alone. Biopsy must therefore be complemented by appropriate hormone estimations. Although the biopsy provides information from only a very small section of the whole testis, results obtained are very informative, as has been shown in various testicular changes (CLAVADETSCHER, 1970; HEDINGER, 1971).

4. Testosterone Estimations and Functional Evaluation of the Hypothalamus-Pituitary-Gonadal-Axis

M. ZACHMANN

Since only about 1% of the produced testosterone is excreted as unmetabolised testosterone glucuronide, the quantities of testosterone in urine are low even in mature males. Nevertheless urinary testosterone determinations are useful in special cases or for research studies because very specific gaschromatographic techniques (CURTIUS, 1970) are available. Normal values in adult males range from 30 to 160 µg/24 h with a mean value of 72 µg/24 h (age 18–38 years), with other methods normal values have even a range between 15–520 µg/24 h (see p. 379). Above the age of 40 years, urinary testosterone tends to decrease gradually. In prepubertal boys, urinary testosterone remains undetectable (below 0,5 µg/24 h) up to a bone age of about 8 years. Thereafter, it gradually increases and reaches adult levels at a bone age of about 16 years. In adult females, urinary testosterone is about 12 µg/24 h or less.

For clinical purposes, the gaschromatographic techniques for testosterone determination in urine are too time consuming and the less specific estimations of plasma testosterone are more practical. Among others, various competitive protein binding techniques (FISCH, 1973) and radioimmunoassay methods (FOREST, 1973) are useful for the estimation of testosterone in plasma. Normal plasma testosterone values in adult males are 612 ± 172 ng/100 ml (range 300–1000 ng/100 ml). In women, the levels are much lower (35 ± 22 ng/100 ml, range 10–60 ng/100 ml). The same is true in prepubertal children where extremely low values (6.6 ng/100 ml, boys and girls) are found up to a bone age of about 8 years. Only in newborns and infants up to about 3 months there is a sex difference, the values in boys being considerably higher than in girls (FOREST, 1973).

The Leydig-cell function may be evaluated by determining testosterone in urine or plasma after stimulation with human chorionic gonadotropin. In this respect, various test procedures have been proposed and most frequently, HCG has been given repeatedly and plasma testosterone determined before and after several days or weeks of HCG administration. When 800–5000 units of HCG were given for 5 days in prepubertal boys, plasma testosterone increased from 26 to 431 ng/100 ml (RIVAROLA, 1970). In adult males, the post HCG values are accordingly higher and may reach levels up to 2000 ng/100 ml.

Especially during prepuberty, a more specific evaluation according to the biological age of the subject studied may be obtained by giving only a single dose of HCG (5000 units/m^2 of bodysurface area) and determining urinary or plasma testosterone 2, 4 and 6 days after injection (ZACHMANN, 1972). With this procedure urinary testosterone increases logarithmicly with bone age from birth to maturity.

Recently luteinizing hormone releasing hormone (LHRH), a decapeptide elaborated by the hypothalamus, has been synthesized and has become available for testing the gonadotropin secreting capacity of the anterior pituitary (BENER, 1972; KASTIN, 1972; REBAR, 1973; ROTH, 1972; TAMM, 1973).

The combined analysis of HCG, LHRH and possibly also clomiphene (see p. 599) test results presently allows a differentiated evalutation of the hypothalamus-pituitary-gonadal axis and makes a localization of the disorder possible.

For other hormone determinations refer to Chaps. VII, X and XI.

X. The Ovary

W. E. SCHREINER

A. Historical Dates

1668 N. STENSEN described the ovary as the organ in which ova are formed.

1672 R. DE GRAAF and TH. KERCKRING observed the presence of the graafian follicle and yellow body in the ovary of the woman.

1686 M. MALPIGHI coined the term "corpus luteum" and suggested that this structure had characteristics of a gland.

1778 A. VON HALLER described the conversion of the follicle into the corpus luteum.

1827 K. E. VON BAER discovered the human ovum.

1871 R. SIGISMUND, a general practitioner, showed that there was mucosal destruction during menstruation, and deduced that menstruation resulted when fertilization failed to occur.

1873 H. KUNDRAT and G. J. ENGELMANN discovered the cyclic changes in the endometrium.

1893 E. RÉGIS used ovarian extracts injected subcutaneously to demonstrate that the ovary produced internal secretions.

1896 E. KNAUER and HALBAN (1900) showed the endocrine action of the ovary on the genital organs in animal experiments by implanting ovaries in castrated rabbits.

1898 L. A. PRENANT and BORN (1900) suspected a connection between the corpus luteum and pregnancy, since the corpus luteum inhibits ovulation.

1902 L. FRAENKEL showed that excision of the corpus luteum in the early stages of pregnancy led to abortion in rabbits.

1905 F. H. A. MARSHALL and W. A. JOLLY discovered that ovarian extracts produced estrus in castrated animals.

1911 L. FRAENKEL observed that there was a time relation between ovulation and menstruation.

1910–1913 L. ADLER (1910) and O. FELLNER (1912, 1913) succeeded in obtaining extracts from the ovary and placenta, which caused estrus in castrated animals.

1913–1915 L. FELLNER (1913) and E. HERMANN (1915) produced extracts from the corpus luteum and placenta.

1913–1915 R. MEYER and R. SCHRÖDER recognized the morphological connection between ovarian function and endometrium.

1917 C. R. STOCKARD and G. N. PAPANICOLAOU described the cyclic changes in the vagina of guinea pig.

1921 H. M. EVANS and J. A. LONG found the first indication of a gonadotropic principle of the anterior pituitary lobe in rats.

1923 E. ALLAN and E. A. DOISY recognized that signs of estrus were dependent on ovarian function in mice and rats. They obtained a relatively purified crystalline substance from bovine and porcine follicular fluid, and were able to induce estrus in rats with this substance. They elaborated this observation to produce a test, which was named after them, and thus derived the first exact hormone estimation.

1926–1927 R. T. FRANK demonstrated the estrus-inducing hormone in the blood by means of the Allen and Doisy test. S. ASCHHEIM and B. ZONDEK showed the presence of the same substance in the urine of pregnant animals.

S. ASCHHEIM, B. ZONDEK, and P. E. SMITH obtained proof from animal experiments with transplantation after hypophysectomy that ovarian function was dependent on the anterior pituitary lobe. The hypothesis of two different gonadotropins was then developed. B. ZONDEK and S. ASCHHEIM (1928) demonstrated successfully that there was a follicular-stimulating principle in the urine of menopausal women.

1929 E. A. DOISY and A. BUTENANDT reported almost at the same time on the isolation of an estrogen-active substance in crystalline form the urine of pregnant women. N. K. ADAM suggested that this substance be named estrone because of the C-17-ketone group present (1933).

Chemical research on the estrogen hormones began at this time. G. W. CORNER and W. M. ALLEN noticed that termination of pregnancy at an early stage in rabbits due to destruction of the corpus luteum failed to occur if extracts of corpus luteum were injected (porcine).

1929/30 H. KNAUS (Graz/Prag) reported that follicular maturation was inhibited by extracts of corpus luteum, and that sensitivity of uterine muscle to extracts of the posterior pituitary was also reduced.

1930 A. BUTENANDT *et al.* determined the structural formula of estrone. G. F. MARRIAN and E. A. DOISY extracted estradiol in crystalline form from the urine of pregnant women.

C. CLAUBERG showed that progesterone produced no proliferative action on the endometrium but an entirely differentiating effect, and that it is only effective on endometrium undergoing proliferation due to estrogens.

E. PHILIPP showed experimentally that progesterone was produced in large amounts in the syncytium of the chorion during pregnancy. G. T. POPA and U. FIELDING described the portal vascular system connecting hypothalamus and hypophysis.

1931 P. E. CLAUS and H. E. FEVOLD and their teams produced potent extracts from anterior pituitaries.

1932 A. BUTENANDT showed that esters of estrone had prolonged activity. Treatment with estrogens commenced at this stage.

C. KAUFMANN referred knowledge gained from experiments in rabbits to the castrated woman.

W. HOHLWEG and K. JUNKMANN postulated that there was a higher "sexual center" in the hypothalamus.

1934 S. L. COHEN and G. F. MARRIAN described a chemical method based on KOBER's method for estimation of estrogens in the urine.

W. SLOTTA, W. RUSCHNIG, and W. FELS succeeded in purifying the hormone of the corpus luteum. A. BUTENANDT and U. WESTPHAL successfully determined the structure of this hormone. It was officially named *progesterone* because of its protective action during pregnancy.

1935 MCCORQUODALE and his team isolated estradiol from the ovaries of pigs.

1938 H. H. INHOFFEN and W. HOHLWEG produced the first highly potent oral estrogen (ethinyl estradiol) from estrone. At the same time they succeeded in synthesizing an orally effective gestagen (ethinyl testosterone = pregneninolone).

1940 H. H. INHOFFEN succeeded in partially synthesizing estradiol from cholesterol. Pure progesterone was produced from cholesterol.

1946 J. E. MARKEE and his team demonstrated experimentally the humoral control of the hypophysis through hypothalamic "action substances" (so-called neurovascular chain).

1954 C. DJERASSI and his team synthesized 19-norsteroids which were then introduced therapeutically as orally effective progestines by R. HERTZ and his team.

1958 J. ZANDER discovered another natural gestagen, 20α,β-hydroxypregn-4-ene-3-one, in the placenta, corpus luteum and mature follicle.

From 1955 G. F. MARRIAN and his team described a series of other natural estrogens representing metabolites.

1955 G. W. HARRIS and his team and R. GUILLEMIN, S. M. MCCANN, M. SAFFRAN, and A. V. SCHALLY showed in animal experiments that hypothalamic extracts caused release of gonadotropins from the anterior pituitary.

1971 A. V. SCHALLY and his team isolated LRH and determined its chemical structure.

B. Anatomy

1. Macroscopic Anatomy

There are changes in position, size, form, color and superficial structure of the ovaries during the different phases of life. In the newborn, they are found on the posterior surface of the uterus above the linea innominata. During childhood they migrate into the small pelvis and come to lie on the lateral wall of the small pelvis at the beginning of puberty. They become almond-shaped at the stage at which increase in height occurs. The ovary of the newborn is pink and shiny and the surface is smooth. At puberty it is grey in color and shows cystic protrusions corresponding to tertiary follicles which measure 3–8 mm in diameter. The ovary reaches its full size in the 25th year. It is then 2.5–5 cm long, 1.5–3 cm wide, 0.6–1.5 cm thick and weighs 7.2–14.6 g (WATZKA, 1957).

During pregnancy the ovaries are displaced from the small pelvis by the enlarging uterus and have a reddish felt-like covering at the end

Fig. 1. Section of an ovary from a prepubertal girl. Numerous primordial follicles can be seen in the corticalis (zona parenchymatosa), as can a primary follicle in the process of developing into a secondary follicle and two tertiary follicles at different stages of development, neither of which has attained full maturity

of pregnancy. This covering is due to the reaction of the "germinal epithelium" to stimulation by estrogens and gestagens. The ovary shrinks to about one third its original size during the post menopause, when it is white in color and has numerous scarred depressions on its surface.

There are two ovaries. The flattened ventral border of each ovary is bound by the mesovarium to the posterior surface of the ligamentum latum. The mesovarium ends on the ovarian surface at the level of the border between the hilus and medulla, at the so-called *Farré-Waldeyer's line*, which forms the boundary between the ovarian surface covered with peritoneum and that free of peritoneum. The free surface is covered by the so-called germinal epithelium, consisting of one layer of cuboid to cylindrical epithelial cells. Peritoneum and germinal epithelium are of the same origin. They both arise from the mesodermal coat of the embryonal coelom (mesothelium). It appear, however, that the prospective potency of the so-called germinal epithelium remains considerably higher than that of the rest of the peritoneum. It is currently assumed that the majority of ovarian tumors, such as serous and pseudo-mucinous cystomas and endometrioid tumors, arise from the germinal epithelium.

In the adult the ovary is kept in the vertical position by the mesovarium, the fibromuscular utero-ovarian cord and the infundibulopelvic ligament.

As a rule, the right ovary, which is phylogenetically older, is somewhat larger than the left.

Supernumerary ovaries are extremely uncommon (6 cases in the world literature) (VALDES-DAPENA, 1967). They may lie in the ligamentum latum, in the infundibulopelvic ligament or retroperitoneally. There is usually an associated uterine malformation.

These ovaries must be differentiated from *accessory ovaries*, which are more common and usually lie in the immediate vicinity of an ovary, and occasionally even connected with it. Uterine malformation is exceptional in these cases.

Absence of one ovary is almost without exception associated with developmental disturbances of Müller's tube giving rise to homolateral aplasia of the tube and uterine cornus. Bilateral aplasia, so-called *gonadal agenesis* is a rarity (ERSKINE, 1946; OVERZIER, 1961). Rudimentary gonads consisting of stroma and with no sex cells are found considerably more frequently (gonadal dysgenesis). Clinically, a differentiation is made between different syndromes with gonadal dysgenesis, depending on the associated growth disorder and malformations:

Gonadal dysgenesis + normal growth
= pure gonadal dysgenesis or Swyer's syndrome

Gonadal dysgenesis + small stature
= Rössle's syndrome

Gonadal dysgenesis + small stature + malformation
= Turner's syndrome.

Gonadal dysgenesis must also be differentiated from *ovarian hypoplasia*, where the small ovaries are also often cyclindrical in shape. A few primordial follicles can, however, be found in normal ovarian stroma (STAEMMLER, 1964) (p. 46).

In true hermaphroditism, ovaries and testes are present together, either separately or as ovotestes.

Exceptionally, the ovary fails to descend on one side or on both sides. The ovary may then lie under the liver. The ovary occasionally lies in the inguinal canal or in the labium majus (congenital hernia). It cannot be placed back since the mesosalpinx changes immediately into the hernial sack.

The density of the fibrous tissue structures increases from the inside out. The *medulla* of the ovary consists of loose, vascular and nervous structures (zona vasculosa). *The cortex* is denser and contains many cells (zona parenchymatosa) and the *tunica albuginea* is tough (Figs. 1–4). The medulla contains the rete

Fig. 2. Section of an ovary from a woman of 19 or 20. Primordial, primary and secondary follicles and a graafian follicle are seen in the corticalis, and a tertiary follicle is beginning to form. A corpus luteum and a corpus atreticum are also present

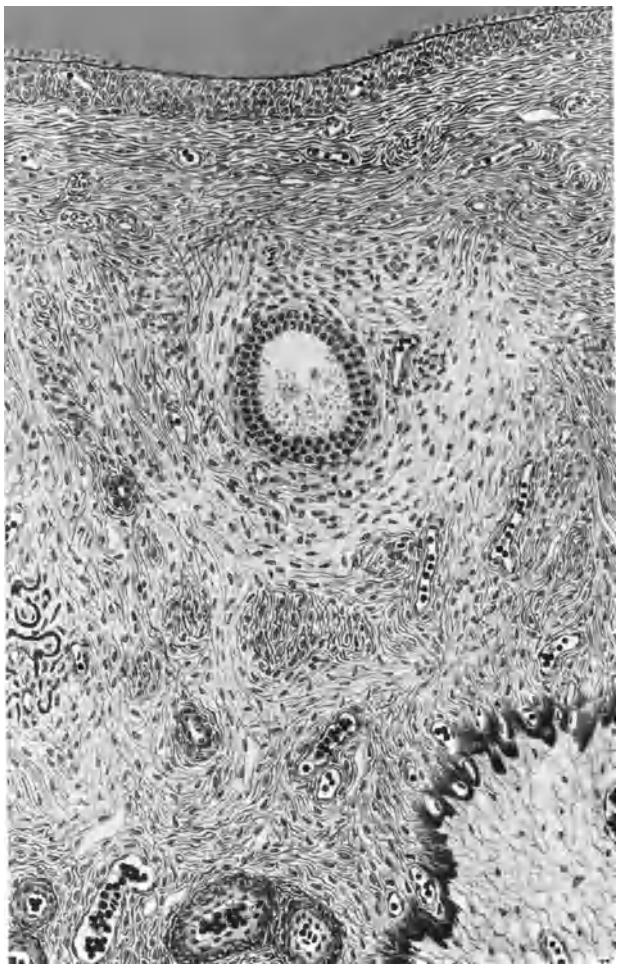

Fig. 3. Section of an ovary from a premenopausal woman. The corticalis contains only isolated primordial follicles or none at all; one tertiary follicle is seen to be disintegrating (pyknosis, disintegration of the ovum, dissociation). One corpus luteum is at the stage of conversion to a corpus albicans

ovarii, consisting of a few degenerated and functionless tubules, whereas the cortex contains the ova which form the germinal parenchyma. The tunica albuginea possesses a dense frame of collagen fibers running parallel to the ovarian surface and fixed with ramifications from the surface to the underlying mesenchyme. On the other side, delicate argyrophilic fibers surrounding the individual follicles radiate into the tunica albuginea.

Blood, lymph vessels, and nerves leave and enter the ovary at the ovarian hilus situated on the ventral border of the ovary. It contains about 80% of all the large ovarian polyhedral eosinophilic cells. These cells store lipochrome, and correspond morphologically and probably also functionally to the Leydig cells of the testis. These cells are arranged in groups and are closely connected topographically to unmedullated nerve fibers, blood and lymph vessels. They are described as *hilus cells*. Since hyperplasia of these cells and tumors arising from these cells are associated with virilization, it has been assumed that they produce androgens (MERRILL, 1959). They are found in increased amounts in anencephalic fetuses. It is possible that this hilus-cell hyperplasia is a compensytory process due to the adrenal atrophy present with anencephaly.

The changing vascular demand of the functioning ovary is insured by balanced vascularization, which self-regulates blood pressure and blood distribution. Thus for example, the anti-clockwise arterial vessels are stretched during follicular maturation in this region. This causes vascular resistence to be reduced and circulation increased. Local blood supply is also regulated by arteriovenous anastomoses and barrier arteries (WATZKA, 1957). The great abundance of lymph vessels is probably connected with the formation of follicular fluid.

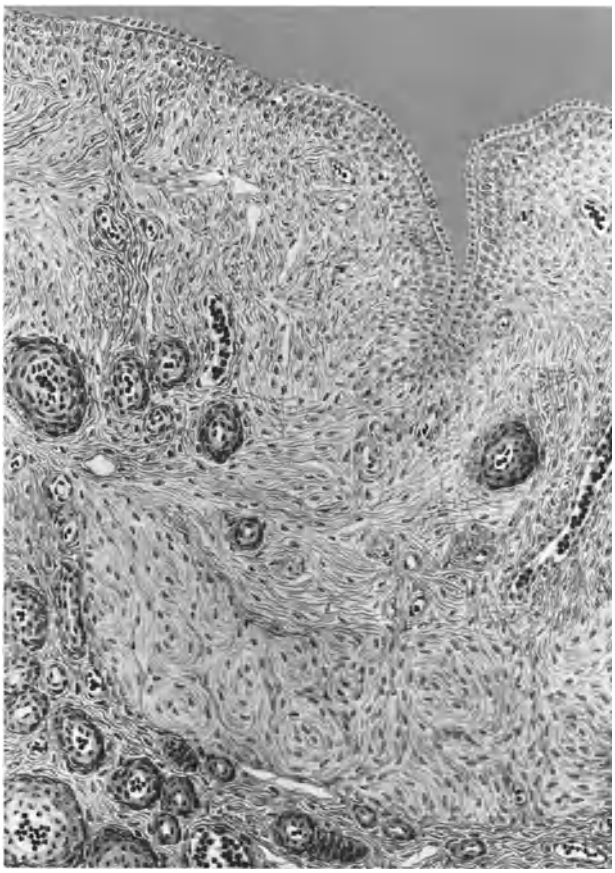

Fig. 4. Section of an ovary from an elderly woman. Follicles are no longer present in the corticalis, and only corpora albicantia in the medulla (zona vasculosa). Intense proliferation of the intima has caused thickening of the walls of small and medium-sized arteries and hyalin degeneration of some vessel walls

2. Embryology and Histology

The germinal cells can be recognized in the region of the allantois in the 4-week human embryo. From this region, several hundred of these cells migrate by means of ameboid movements (so-called entodermal migrating cells) and are chemotactically conducted into the germinal ridge, which strictly speaking should be termed the genital ridge. The genital ridge develops as a thickening of coelomic epithelium near the mesonephros and the adrenocortical "anlage". Ovarian mesenchyme is thus mesodermal in origin.

Between the 7th and 8th weeks of pregnancy, the fetal gonads begin to undergo sexual differentiation. The ovary can be structurally distinguished from the testis at this stage, since it has quite a wide cortex separated from a small medulla. At the same time, the oogonia which have migrated via the germinal ridge begin to divide mitotically. The original few hundred cells develop into 5–6 million cells within 2–3 weeks.

The phases of multiplication and growth of the oogonia (STIEVE, 1943, 1952) appear to be concluded in the human in the 10th week of pregnancy (1st phase of growth). Nuclear maturation then begins, and oogonia are converted into oocytes (10th to 20th week of pregnancy). Oogonia can no longer increase in number after the 20th week of pregnancy. Postnatal oogenesis has been widely discussed, but it has never been proved to occur and it is therefore rejected by most authors (STIEVE, 1952; WATZKA, 1957; ZUCKERMANN, 1951, 1957). The *primary oocyte* developed from the oogonium is in the prophase of the first *reduction division* or *meiosis* at birth. It remains at this stage for many years, at least until sexual maturity (1st resting phase). The first meiosis is resumed during postnatal development of the follicle and is ended about the time ovulation occurs. This may take as long as 12–50 years after the onset of meiosis. Reduction division gives rise to the *secondary oocyte* and polar body. Each possesses 23 chromosomes. The *2nd meiosis* occurs immediately after the first

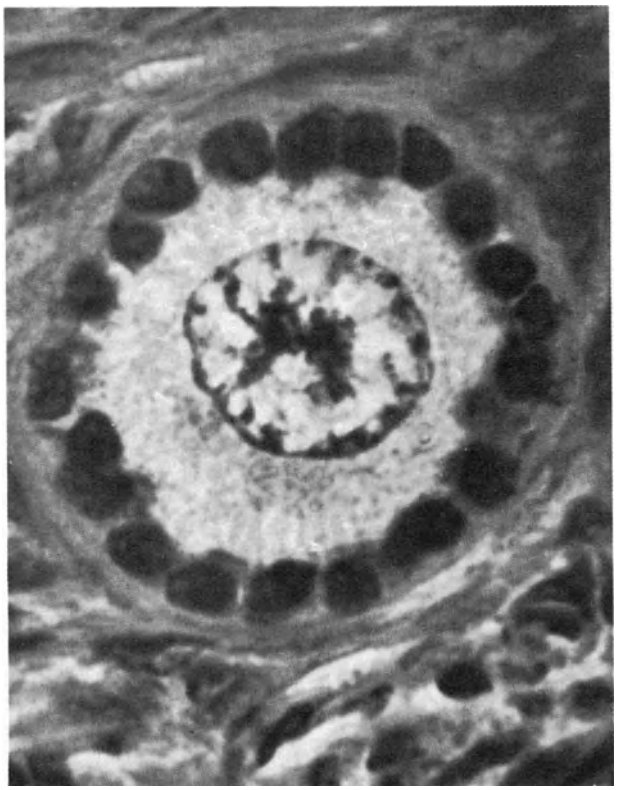

Fig. 5. Primordial follicle (human). (After SHETTLES, 1960)

and ends only after fertilization. It gives rise to the mature ovum and one polar body. From about the 20th week of pregnancy, the primary oocyte is surrounded by a single layer of cuboid cells, follicular or granulosa cells. It is currently assumed that these cells arise from the germinal epithelium. Oocyte and follicular cells together form the so-called primordial follicle (Fig. 5).

The two ovaries of the newborn contain about 500000–700000 primordial follicles which are closely packed together in the zona parenchymatosa. The majority undergo destruction due to atresia even during the intra-uterine phase. At menarche, there are still about 400000 primordial follicles, while at age 35, there are only about 80000 (Table 1). Only 300–400 primordial follicles develop into mature follicles with the potential possibility of becoming fertilized during sexual maturity. About 90% of the primordial follicles become atretic at all stages of development from the postnatal stage right up to the onset of the postmenopause. Both ovaries together contain less than 10000 primordial follicles at the onset of postmenopause. If these follicles are transplanted into ovaries of young sexually mature animals, they can grow into mature follicles.

Table 1. Quantities of follicles in the human ovaries as a function of age (BLOCK, 1952)

Age (years)	No. of cases examined	Average no. of primordial follicles in both ovaries	Average no. of growing follicles (up to and including 100 μm) in both ovaries	Average no. of graafian follicles in both ovaries
6– 9	5	484000 (258000–755000)	15400 (7700–34600)	13– 97
12–16	5	382000 (85000–591000)	7300 (3000–11200)	231
18–24	7	155000 (39000–290000)	6800 (1000–17300)	27–136
25–31	11	59000 (8100–228000)	3500 (680– 9200)	21–117
32–38	8	74000 (15000–208000)	6200 (1800–16500)	33–101
40–44	7	8300 (350– 28000)	2600 (900– 9400)	11– 81

In parentheses: minimum and maximum numbers.

Thus, the follicles do not grow old, but the stroma probably does, possibly due to vascular changes (p. 580). Generative ovarian function disappears with failure of the follicle to react to increased gonadotropic stimulation.

Ovarian Cycle. The primordial follicle has a diameter of 40–60 mμ and contains a primary oocyte measuring 18–24 mμ in diameter, which is surrounded by a layer of cuboid follicular cells (Fig. 5). Even during the fetal phase, childhood, and especially at the time of puberty, single primordial follicles lying deep in the cortical layers grow quickly into primary, secondary, and tertiary follicles (2nd phase of growth). They protrude into the superficial layers, and have a diameter of up to 3 mm (Fig. 2). They develop before the 5th year, probably without the influence of gonadotropins (cf. hypophyseal gonadotropins p. 559). They can remain at this stage for several months (2nd resting phase).

We do not know which factors induce the resting primordial follicle to grow, nor do we know whether the primary stimulus occurs in the oocyte or in the follicular cells. It appears that the second phase of growth is partly independent of the pituitary since a certain degree of follicular growth also occurs in hypophysectomized animals.

The cuboid follicular cells grow into cylindrical cells, and the oocyte enlarges at the same time to produce the *primary follicle*. The follicular cells increase in number and size to form the *secondary follicle*. A membrana granulosa of 3–4 layers, containing numerous mitoses, is formed. The secondary follicle has a maximum diameter of 0.3 mm. During this period, the ovum develops into the largest cell of the organism (90–130 μm diameter). After this stage is reached, only the follicle continues to grow.

Until the onset of sexual maturity, any tertiary follicles formed become atretic. Atresia begins in the granulosa cells. The tertiary follicle is characterized by the formation of an antrum, which develops through confluence of small single vesicles, and is filled with follicular liquor. This is probably due to active secretion of the granulosa cells. Labeled water appears first in the granulosa cells and then in the follicular fluid. It is possible that cellular degeneration and vascular transudation from the follicular veins, which become congested through growth of the follicle, also has some effect. The follicular fluid has a high content

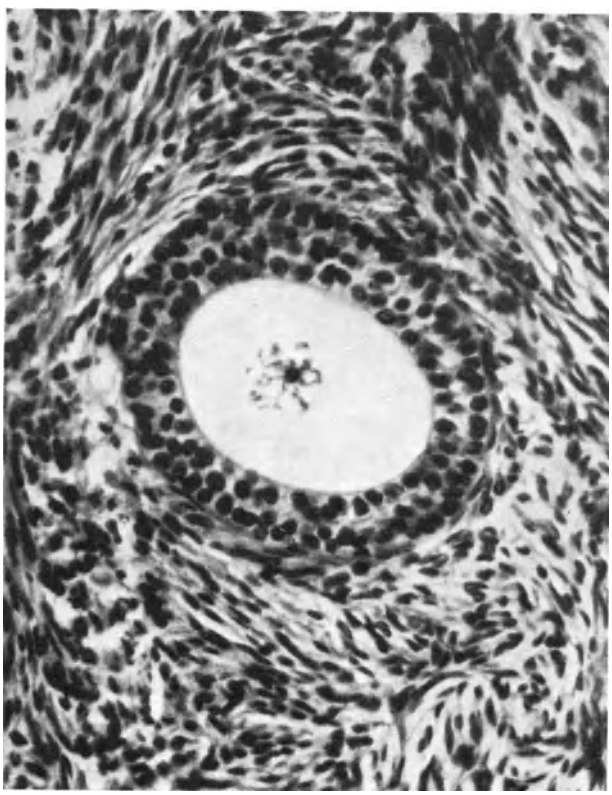

Fig. 6. Secondary follicle (human). (After SHETTLES, 1960)

of estrogens (estrone and estradiol), and also of progesterone from mid-cycle on. Microscopically small collections of fluid can be seen between the granulosa cells, and together with the neighboring follicular layer these form the so-called *Call-Exner body*. The cell margins of the granulosa cells become gradually indistinct, and 8–12 layers of these cells form the *membrana granulosa*. It is thickened at one point, where the ovum is contained *(cumulus oophorus, discus proligerus)*. The granulosa cells next to the oocyte form the *corona radiata*. Its cells are characterized by y chromatin-rich nucleus and granular cytoplasm. They become cylindrical and adopt a radial arrangement. They form a biological unit with the oocyte, and the hyaline *zona pellucida* of 5 mμ thickness surrounding the ovum is pierced by processes of the cells of the corona radiata. The intact membrana granulosa contains no vessels or nerves. Connective tissue structures appear for the first time in the tertiary follicle, in the form of the theca interna and externa. The theca interna is composed of delicate fibrils of connective tissue with a rich supply of capillaries and nonmedullated nerve fibers, and also contains spiral cells (fibrocytes) and clear, polygonal theca-lutein cells laden with fat. The latter cells are particularly well-developed in follicles reaching ovulation and in polycystic ovaries. They probably contain steroids which are precursors of estrogens and gestagens. They also show increased dehydrogenase activity (JKONEN, 1961). The theca-lutein cells arise from the mesenchyme, probably originating from the ovarian medulla.

The theca externa is composed of strong collagen fibers arranged concentrically, and contains blood and lymph vessels. It surrounds the tertiary follicle, which has a diameter of 3–8 mm at this stage. A fibrous membrane separates the vascular theca interna from the avascular membrane granulosa. During sexual maturity, single tertiary follicles grow from the 8th to 10th day of the cycle (CORNER, 1952) into *Graafian follicles* (Fig. 2), which have a diameter of 16–24 mm. Whereas there is a regular increase in the size of the follicle during the phase of follicular maturation, growth is greatly accelerated (Fig. 7) towards the ovarian surface (BLANDAU, 1966) 10–12 hours prior to ovulation (rats). The theca is pushed forward in the form of a wedge against the ovarian surface (thecal wedge), so that the follicle finally protrudes conically from the ovarian surface. Terminal growth is due mainly to an increase in follicular fluid, which becomes less viscous at the same time due to depolymerization (BLANDAU, 1966). The number of mitoses decreases in the membrana granulosa, which is still avascular and which at this stage has 16–20 layers of cells. The cells of the cumulus oopherus steadily dissociate, but the corona radiata remains intact. The gel of the ovum is released from the membrana granulosa. The theca interna becomes hyperemic and loose, and *K cells* arise which are eosinophilic and contain a dark nucleus. These cells are said to possess a special secretory function, but nothing definite is known about the nature of this function.

Nor are we fully orientated about the original physical and chemical factors involved in ovulation. It is very probable that follicular rupture is not only due to a rise in intrafollicular pressure, and that vascular and enzymatic processes are also very much involved (MORICARD, 1946; BLANDAU, 1966, 1967). Follicular fluid contains high concentrations of proteolytic enzymes. It is not yet known what effect gonadotropins exert in this process (JUNG, 1959). The *follicular stigma* is the thinnest spot of the Graafian follicle lying against the ovarian surface, and before ovulation consists of only 1–2 layers of granulosa and theca cells and diluted tunica albuginea. The stigma becomes anemic before ovulation and is pale yellow in color. Digestion by proteases together with a slight rise in intrafollicular pressure probably

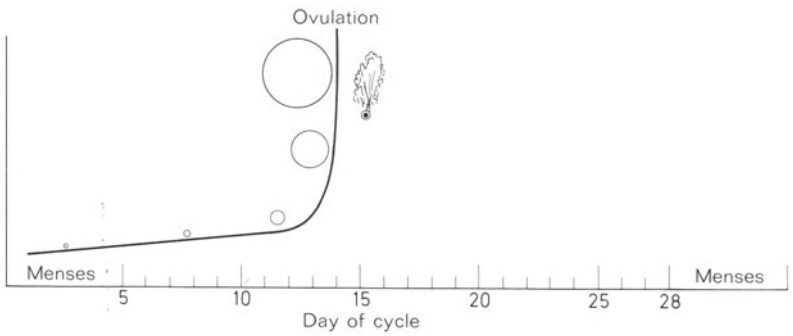

Fig. 7. Growth curve of the follicle, showing the spurt of growth beginning 10 hours before ovulation. (After HARTMAN, 1962)

then causes follicular rupture. Ovulation has been observed in rats and rabbits (WALTON, 1928; BLANDAU, 1955). This does not occur by explosive bursting of the mature follicle, but slowly through gradual release of a viscous fluid, which flows from the stigma of the follicle as from an hourglass. The ovum is finally flooded out together with the cumulus ovigerus. Fibrillary currents and tubal peristalsis convey the ovum to the tubal ampulla, where fertilization may occur. The second meiosis occurs during this sequence of events, but only comes to an end after fertilization. Bleeding connected with follicular rupture leads to closure of the site of rupture through formation of blood clots which also fill up the collapsed follicular lumen. The bleeding is usually very mild. It is questionable whether "mittelschmerz" is caused by slight peritoneal irritation due to this bleeding (ISRAEL, 1967).

The corpus luteum develops from the ruptured follicle (CORNER, 1956). According to MEYER'S (1911, 1913) classic description of the formation of the corpus luteum (which is still valid) 4 developmental stages can be differentiated. First, there is intensive growth of the granulosa, and of theca cells in particular. These cells contain large amounts of lipoids (proliferative stage). Vascularization of the membrana granulosa occurs after 3 to 4 days. Capillaries, connective tissue and K cells penetrate right into the center of the coagulum from the theca interna. Nearly every granulosa cell is thus directly connected with a vessel. Macroscopically, the dark red periphery is clearly distinguishable from the pink, gelatinous center. During the budding phase (from the 5th to about the 10th postovulatory day) the corpus luteum increases in size again; the granulosa cells grow and are now arranged in columns, forming a reddish yellow covering zone around the sanguine gelatinous center. The yellow color is due to carotin, and the various color tones are caused by the oxidation product of carotin. The granulosa cells are polygonal, have a clear bright cytoplasm and can be clearly differentiated from the smaller, even brighter cells of the theca interna interspersed among them. While connective tissue grows inwards, the central core steadily liquefies. This stage is reached after not more than 7 days. If fertilization does not occur the corpus luteum undergoes rapid regression 3–4 days before menstruation (about the 10th postovulatory day) due to the absence of the luteotropic action of chorionic gonadotropin. The center becomes fibrous, and then hyaline, as does the fibrous septa between the granulosa cells. The granulosa cells themselves become smaller, granular and vacuolized, and lose their columnar arrangement. The loosely arranged theca cells show a dark nucleus in pale cytoplasm. The theca interna becomes fibrotic and finally undergoes hyaline degeneration. The *corpus albicans* is formed by a process of shrinking within roughly 70 days. It contains cells with iron pigment, a residue of the central bleeding. A fibrous depression is produced through shrinking. This area is characterized by a broad hyaline zone which is sharply defined and undulated, and surrounds a fibrous nuclear zone (Fig. 3).

The majority of follicles regress long before reaching maturity *(follicular atresia)* (SLAVJANSKY). This regressive process even occurs in the ovary of the fetus during the second half of pregnancy, and is also particularly pronounced during pregnancy. An oocyte must be completely surrounded by follicular cells to prevent its becoming atretic. If this is not so, there is a hurried maturation process with subsequent atresia (OHNO, 1964; BLANDAU, 1965). Atresia probably starts in the oocyte, resulting in chromatolysis of the germinal vesicle with subsequent round-cell invasion of the degenerating ovum and dissociation of the cumulus oopherus. The liquor folliculi is absorbed, the peripheral cell layers fold, the basal membrane becomes thickened and hyaline, and the granulosa cells and some theca cells degenerate and are finally replaced by fibrous tissue. This gives rise to the *corpus fibrosum*. The scar formed in this way can persist for years as a corpus fibrosum or atreticum. This corpus have purely hyaline structure or can be an undulating hyaline "glass skin" surrounding a reticular fibrous tissue. Cells containing iron are also absent. Some of the cells of the theca interna of the atretic secondary and tertiary follicles remain intact and together form the so-called "interstitial gland" or the *theca gland* of the ovary (TONUTTI, 1961). This "gland" probably secretes small amounts of estrogens continuously (basal estrogen formation) (DEANE, 1952). The theca glands react to the luteinizing hormone, which is also termed the interstitial cell-stimulating hormone by increasing in size. It is thus not astonishing that the epitheliod theca lutein cells also increase in size during pregnancy (SCHRÖDER, 1930). This reaction is especially pronounced in polycystic ovaries and in the adrenogenital syndrome, and in the latter case is related to a rise in the production of androgens. Primary follicles disappear completely. During the post menopause the ovary shrinks to half or one third of its original size (WATZKA, 1957). The few follicles still present become atretic within 4–5 years

(LAURITZEN, 1968). During this time, follicular maturation and ovulation occasionally occur, with formation of a corpus luteum and uterine bleeding from a transformed endometrium.

C. Physiology of Ovarian Function

Ovarian Hormones (Natural and Synthetic)

1. Chemistry and Occurrence

Results obtained by isolating steroids from human ovaries (ZANDER, 1958, 1959; RYAN, 1967) and estimating their concentrations in ovarian veins and peripheral blood (MIKHAIL, 1967) have shown that the following steroid hormones are formed and secreted by the normal ovary of the woman (Fig. 8, Table 2): progesterone, 17α-hydroxyprogesterone, 20α,β-hydroxy-4-pregnen-3-one, dehydroepiandrosterone, androstenedione, testosterone, estrone, estradiol and estriol.

Chemically these hormones are steroids *(sexual steroids)*. The basic framework is the sterane or gonane, constisting of 3 hydrated benzol rings (A, B, C) and a cyclopentane ring (D). Structure and numbering of the C atoms is shown in Fig. 8 (cyclopentanoperhydrophenanthrene).

The biological action of the sexual steroids is very much dependent on their stereochemical structure. An exact description is therefore necessary (Chap. VII, p. 287). Three groups of ovarian steroids are differentiated according to their biological action (p. 532ff.): gestagens, androgens and estrogens (Fig. 8).

Table 2. Steroids isolated from normal human ovary (RYAN, 1967)

Follicular fluid	Corpera lutea
Estradiol	Progesterone
Estrone	20α-hydroxypregn-4-en-3-one
Estriol	17α-hydroxyprogesterone
Androstendione	Androstendione
17α-hydroxyprogesterone	Estradiol
20α-hydroxypregn-4-en-3-one	Estrone
Progesterone	

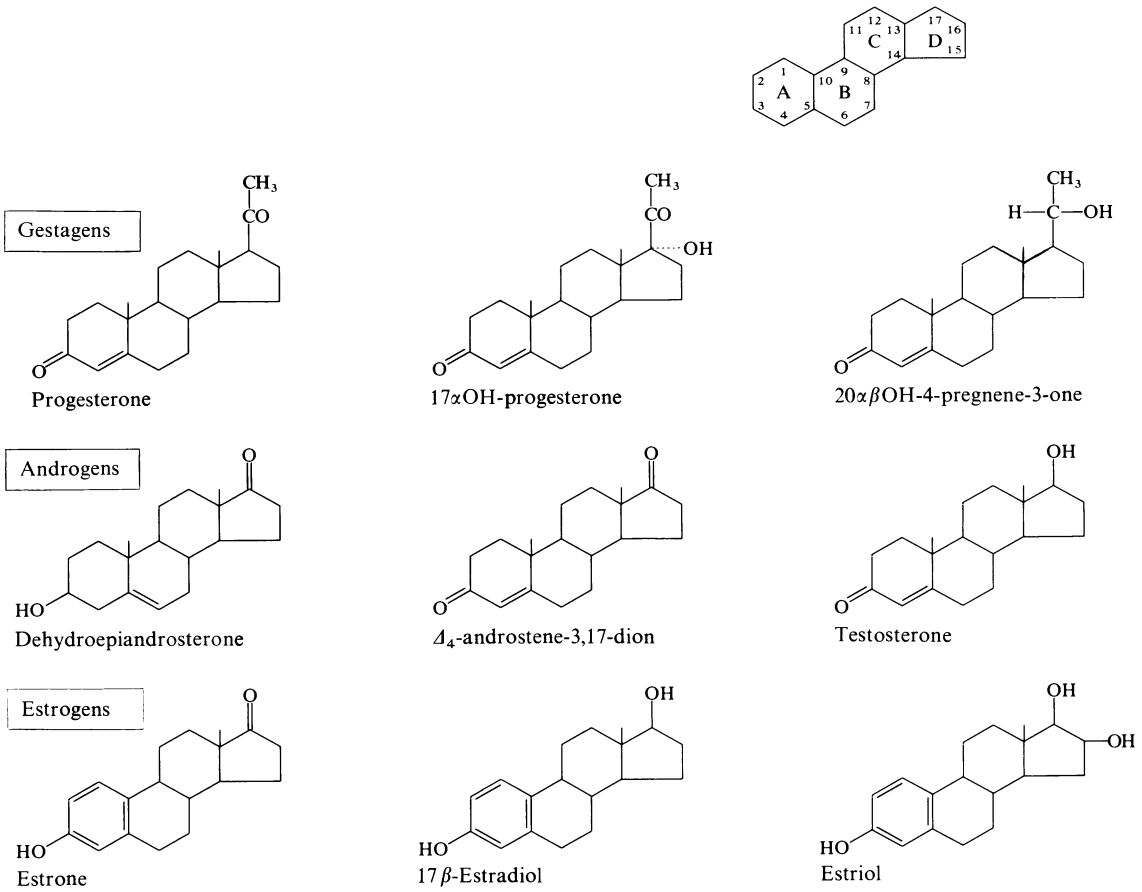

Fig. 8. Ovarian steroid hormones

Table 3. Progestagens

	Compound	Commercial preparation	Main effect
	17α-methyl-	Orgasteron	Androgenic and anabolic
	17α-ethyl-	Nilevar	Anabolic
	17α-ethinyl-	Primolut N; Norlutin	Inhibition of ovulation and gestagenic effect
	-acetate	Primolut Nor; Norlutat	
	-diacetate	with EEME: Metrulen; Ovulen	
	-3 desoxy-	Lynoestrenol	
	-$\Delta^{5,10}$-	with EEME: Enovid	
	-13-ethyl-	with EE: Eugynon, Stediril	
19-nortestosterone derivatives	17α-allyl-3 desoxy-	Gestanon	Protection of pregnancy
	6α-methyl	Provera	Inhibition of ovulation and gestagenic effect
	$\Delta^{6,7}$-6α-methyl-	with EE: Planovin; Volidan	
	$\Delta^{6,7}$-6α-chloro-	with EEME: Sequens	
	3 desoxy-6α-methyl-	with EEME: Neonovum	
17α-acetoxyprogesterone derivatives			
	9β,10α,Δ^4-pregnene-3,20-dione	Duphaston	Gestagenic
Retroprogesterone			

EE = ethinyl estradiol; EEME = mestranol.

Gestagens. Progesterone, 17α-hydroxyprogesterone and 20α,β-hydroxyprogesterone are structurally C_{21} steroids, with a methyl group at C_{10} and C_{13} and a $COCH_3$ side chain at C_{17}. They are fat-soluble and insoluble in diluted alcohol and petroleum ether.

Synthetic gestagens are termed as pre- or progestagens. Gestagens and pregestagens form the group of *progestins*. Progestagen is chemically a derivative of 19-nortestosterone, 17α-hydroxyprogesterone or retroprogesterone. Table 3 shows the progestagens which are currently most important but is by no means complete. The name of a commercial preparation may vary from country to country.

Androgens. Dehydro-epiandrosterone, androstenedione and testosterone have 19 C atoms, with methyl groups at C_{10} and C_{13}.

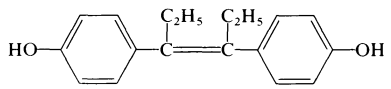
Estrogens. Estrogens are steroids with 18 C atoms and no methyl group at C_{10}. They possess an OH group at C_3, which has a weakly acidic reaction. They also all have a cyclic A ring. They are soluble in oil, alcohol, acetone, chloroform and other fat-soluble substances, and also in alkaline aqueous media. In addition to the three *classic estrogens* (Fig. 8) estrone (E_1), estradiol (E_2) and estriol (E_3) 16 other estrogenic substances have so far been demonstrated in the urine of nonpregnant women (Table 4).

Table 4. Estrogens demonstrable in the urine of woman

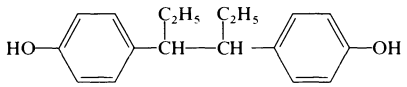
Estrone
16α-hydroxy-estrone, 16β-hydroxy-estrone, 16-keto-estrone, 6ξ-hydroxy-estrone, 2-methoxy-estrone, 18-hydroxy-estrone
17β-estradiol
16-keto-17β-estradiol, 2-methoxy-estradiol, 11β-hydroxy-17β-estradiol
Estriol
16-epiestriol, 16,17-epiestriol, 17-epiestriol, 2-methoxyestriol
Equilenin, estrandiol A and B

These are metabolites of the three genuine ovarian estrogens, estrone, estradiol and estriol.

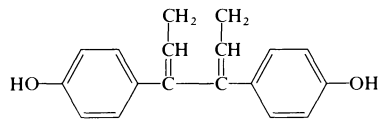
With the exception of 16-epiestriol, the amounts of these other substances are insignificant. We know nothing of their biological activity. In addition to the estrogens occurring naturally in man, animals and botanical organisms, there is a series of synthetic or "artificial" hormones with estrogen activity. The best-known synthetic estrogens are the *stilbenes*: diethylstilbestrol (stilbestrol), dihydroxystilbestrol (hexestrol), dienestrol and tri-p-anisylchlorethylene (Tace) (Fig. 9). These substances are not steroid hormones, and in contrast to natural estrogens are not decomposed in the liver. They are thus effective when taken orally. This is also true of the synthetic estrogen methallenestril (Vallestril).



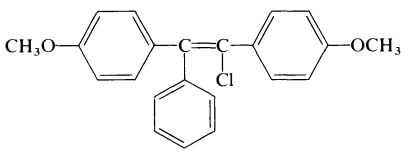
Diethylstilbestrol



Hexestrol



Dienestrol

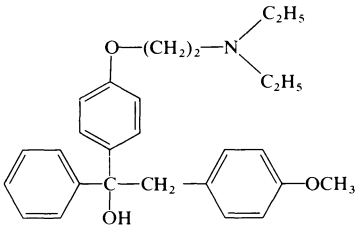


Chlorotrianisene (Tace)

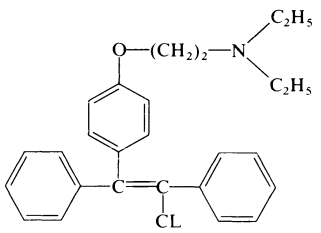
Fig. 9. Structure formulas of the stilbenes

Estrogen antagonists are chemically related to the stilbenes (CALLANTINE, 1967) (Fig. 10). These antagonists are compounds which inhibit certain actions of estrogens. However they also demonstrate a weak estrogenic effect. The most important estrogen antagonists are clomifene (MRL-41) and sexovid (F 6066) (p. 599, 630).

Antiprogestins are substances which prevent the biosynthesis or secretion of progesterone (F 6066, F 6060, methallibur), influence the transport or stability of progesterone in the



Ethamoxytriphetol (MER-25)



Clomiphene (MRL-41)

blood (α-1-acid gluco-protein), or interfere with the action of progesterone on the end-organ. The last group of compounds which interfere at the end-organ is large and includes, 17α-ethinyl-4-estren-3,17-diol and its derivatives since they inhibit uterine growth induced by exogenous progesterone. Large doses of estrogens also act as antiprogestins by inhibiting the release of gonadotropins.

2. Biosynthesis

(RICE, 1964, 1966; SAVARD, 1965; RYAN, 1965, 1967; ZANDER, 1963, 1969)

Steroid synthesis occurs in a similar manner in the ovary, testis and adrenal cortex. These glands all have the same embryonal origin from the germinal ridge. Estrogens and androgens are formed in these three endocrine organs, and gestagens in the ovary and adrenal cortex. There are only quantitative differences in the biosynthesis of these steroids in the individual organs, the qualitative nature being identical. The endocrine specificity of these organs is due to the quantitative distribution of the individual steroids secreted. The specificity is based ultimately on the specificity of the enzyme pattern and the ability of this pattern to react to a higher specific controlling mechanism. The "atypical" steroids of single endocrine glands only acquire clinical importance when organic disease leads to a displacement in the quantitative relation of the individual steroids. Typical examples of such cases are the Stein-Leventhal syndrome and adrenogenital syndrome (p. 609 ff.).

There are four morphologically and functionally different structures in the ovary which can react to gonadotropic stimulation and produce sexual steroids. These are the follicle, the corpus luteum, the stroma and hilus cells. The follicle and corpus luteum are predominantly dynamic structures whose activity and morphology change in relation to the age of the woman, the phase of sexual maturity and the development of pathologic processes. The reproductive and endocrine functions of the ovary are related to the morphological and functional integrity of the follicle and corpus luteum. Ascorbic acid is present in large quantities in the ovary and appears to exert a catalytic function there.

Insight into the biosynthesis of the ovarian steroids has been gained by incubation of ovarian homogenates and sections, and by perfusion of the ovaries with labeled precursors of the steroids and with the steroids themselves. Knowledge of the synthesis of ovarian steroids is essential for an understanding of the clinical features of certain endocrine disorders (Fig. 11).

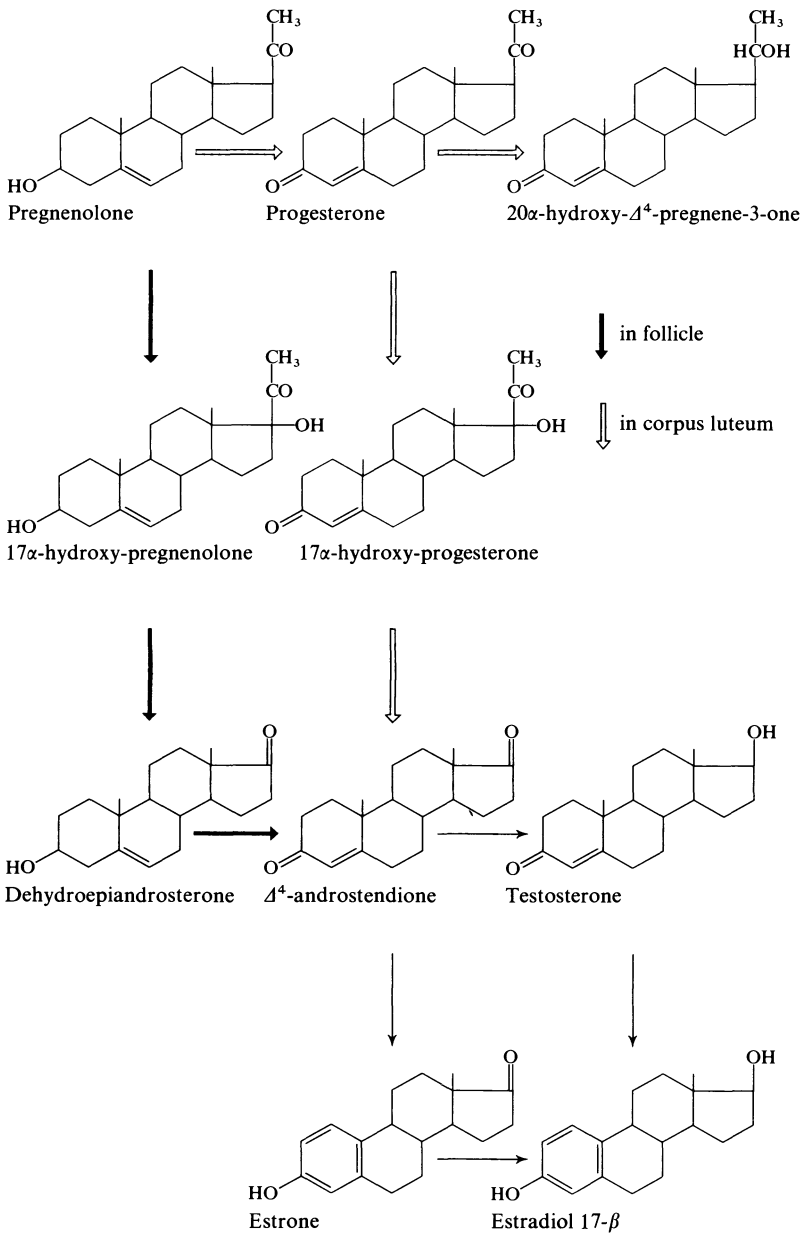

Fig. 11. Biosynthesis of ovarian steroids

a) Biosynthesis of Progesterone

Acetate is the basic material for the formation of steroids in the ovary. It is synthesized to cholesterol via squalene; cholesterol then provides the sterane ring and is converted into the biologically inactive Δ5-pregnenolone, by means of several oxidative intermediate products and by the splitting off of isocapronic acid. Luteinizing hormone and NADPH (reduced nicotineamide-dinucleotide phosphate) are essential for this process. Luteinizing hormone stimulates the 20 and 22 hydrolases and thus provides the stimulus for the splitting off of isocapronic acid. NADPH accelerates the formation of progesterone from pregnenolone by 8–10 times, even in the absence of gonadotropins. Gonadotropins are necessary for the synthesis of pregnenolone, and their absence results in inactivity and consequent atrophy of the ovaries.

It is not yet known whether pituitary gonadotropins still exert a direct influence from this stage on on the biosynthesis of ovarian steroids, or whether further synthesis is determined only by the enzyme pattern and supply of substrate. Oxidation at C 3 by 3β-hydroxy-dehydrogenase and displacement of the double bond to C 3 by $\Delta^{4,5}$-isomerase results in the formation of progesterone. It has been shown that progesterone can be formed from acetate and cholesterol in the follicular wall, corpus luteum and ovarian stroma.

Progesterone has a key position in steroid synthesis, since androgens, estrogens, and glucocorticoids can be formed from it. Because of this, the molecule is extremely labile; it can be rapidly inactivated and transformed (cf. Metabolism, p. 531).

b) Biosynthesis of Androgens
(JUNKMANN, 1960; ZANDER, 1963)

The activity of 17α-hydroxylase is very high in the ovary, and this leads to the oxidative splitting off of the side chain at C 17 via 17α-hydroxyprogesterone, and to the formation of Δ4-androstene-3,17-dione. This route is used predominantly in the corpus luteum.

Androstenedione is not a very potent androgen. Through 17β-hydroxydehydrogenase it is in reversible equilibrium with testosterone, the most potent androgen.

In contrast to the situation in the corpus luteum, in the follicle most of the androstenedione is formed without the intermediary formation of progesterone, via 17-OH-pregnenolone and dehydro-epiandrosterone. 17α-OH-pregnenolone and 17α-OH-progesterone in particular are partly metabolized to pregnanetriol (Fig. 11a) and are excreted in the urine (1–2 mg per day during a normal cycle).

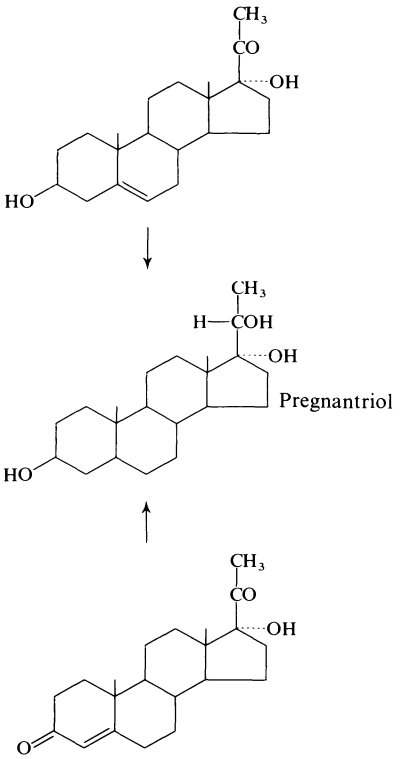

Fig. 11a. Pregnantriol synthesis

Pregnanetriol excretion is greatly increased in the adrenogenital syndrome, due to the failure of enzymatic conversion of 17α-OH-progesterone into 11-desoxy-17-OH-corticosterone.

The two androgens, dehydro-epiandrosterone and androstenedione are released into the blood of a normally menstruating woman, and are partly converted there into testosterone. Increased amounts of these two androgens are released with polycystic ovaries (p. 611).

In contrast to relations in the adrenal cortex, 11β- and 21α-hydroxylase are only weakly active in the ovary, and therefore only small amounts of desoxycorticosterone are formed in the ovary.

c) Biosynthesis of Estrogens

It has been shown that androgens are converted into estrogens in the follicle, corpus luteum, and ovarian stroma. This biosynthesis is similar to that occurring in the testis, adrenal cortex, placenta and liver. In contrast to the situation in the placenta, the androgens in the ovary do not originate from the adrenal cortex, but

are synthesized in the ovary itself. Conversion of the C_{19} steroids, androstenedione and testosterone, into C_{18} phenols probably occurs via their 19-OH and 19-oxy derivatives with subsequent aromatization of the A ring in the microsomes. Conversion of androgens into estrogens is characteristically disturbed in the polycystic ovary (p. 611).

It is assumed that all 3 classic estrogens are formed in the ovary, estradiol being the main estrogen found in follicular fluid and venous ovarian blood. Although it has been shown that there is 16-hydroxylase in the ovary, it is still not known whether estriol is formed via 16-hydroxylation of estradiol or estrone, or whether, as in the fetus, it is formed from hydroxylized androgens. Route and end product of the biosynthesis are dependent on the enzyme pattern of the ovarian structures involved. Absence or reduction of enzyme activity leads to accumulation of intermediary stages (see polycystic ovaries, p. 609).

3. Production and Plasma Content

The amount of sexual steroids produced by the ovary varies greatly in the different phases of life. In addition, it is dependent on the cycle during sexual maturity (Tables 5–9).

Estimations of steroids in venous ovarian blood by means of double-isotope dilution methods have provided interesting information on the secretory activity of the ovaries in relation to the cycle phase (RUNNEBAUM, 1965; MIKHAIL, 1967). A series of biologically active steroids can be isolated from venous blood from the ovary as well as from ovarian tissue (ZANDER, 1958, 1959). It was possible to show by these means that the ovary secretes mainly the steroid androstenedione in the pre-ovulatory phase, and that significant amounts of progesterone and 20α-OH-progesterone are secreted in the ovary even before ovulation. ZANDER (1958) was able to show that these two latter substances were formed before ovulation in the

Estriol (E 3)					Postmenstrual minimum 4.7 µg (1.9–11.4) Ovulation maximum 30.9 µg (8.1–119.0) Luteal maximum 21.1 µg (5.0–89.0)	
Progesterone	*After ovulation* 15–20 mg (OBER, 1957; CAREY, 1963)	~200 mg (OBER, 1954)	*Follicular phase* ~0.1 µg *Before ovulation* 0.4–0.5 µg *After ovulation* ~1.0 µg	Gas liquid chromatography, radioisotope methods (WOOLEVER, 1963; VAN DER MOLEN, 1965; RIONDEL, 1965; MIKHAIL, 1967; ZANDER, 1967, 1969)	**Pregnandiol** *Follicular phase* 1–2 mg *After ovulation* 3.0–7 mg (KLOPPER, 1957; OBER, 1961; FOTHERBY, 1962)	Colorimetry (KLOPPER, 1955)
20α-Hydroxy-progesterone			*Follicular phase* negative *Before and after ovulation* 0.25 µg	(RUNNEBAUM, 1965; MIKHAIL, 1967)	*After menopause* 0.6 mg (0.3–0.9) (LORAINE, 1958)	

mature Graafian follicle. It has also been shown that 17β-estradiol is the estrogen produced in the largest amounts by the ovary, and that the ovary containing the mature follicle produces significantly greater amounts of estradiol. On the other hand, estradiol secretion has not been definitely demonstrated in the ovaries of post-menopausal women (MIKHAIL, 1967).

Ovarian steroids are probably formed in all cellular structures of the ovary. There is a series of indications implying that the 3 natural gestagens, progesterone, 17α-hydroxyprogesterone and 20α,β-hydroxy-4-pregnene-3-one are synthesized predominantly in the granulosa lutein cells (SHORT, 1964), whereas ovarian androgens are synthesized in the hilus cells, and under normal conditions only to a slight extent (RYAN, 1967). Experiments have been performed with physically separated granulosa and theca cells in the anterior chamber of the eye in rabbits (RYAN, 1966). From the results obtained from these experiments it may be assumed that estriol, estrone and estradiol are formed mainly in the theca cells of the maturing follicle, in the theca-lutein cells of the corpus luteum, and in the theca formations of the stroma (Table 10). All other estrogens are metabolites of the 3 classic estrogens. 17β-estradiol is the main estrogen secreted and formed in the ovary. A continuous secretion of estrogens independent

on the cycle is attributed to the theca formations of the stroma *(basal estrogens)*. This secretion is extremely small in normal ovaries. During the postmenopause and in the case of non-endocrine ovarian tumors, there may be increased estrogen production caused by *cortical stroma- and theca-cell hyperplasia* (LAJOS, 1963).

Table 10. Conversion of pregnenolone and progesterone by the action of granulosa and theca cells isolated from the follicles of woman (RYAN, 1967)

Basic substance	Metabolite synthesized *in vitro*	
	Granulosa	Theca
Pregnenolone	Progesterone 17α-hydroxy-progesterone	Progesterone 17α-hydroxy-progesterone Androstendione Estrone Estradiol
Progesterone	17α-hydroxy-progesterone	17α-hydroxy-progesterone Androstendione Estrone Estradiol

Table 11. Steroids synthesized from acetate in the follicle of woman (RYAN, 1967)

Steroid synthesized	Amount synthesized as a percentage of amount of estradiol (= 100%)
Estradiol	100
Estrone	74
Androstendione	30
Dehydroepiandrosterone	29
Pregnenolone	16
17α-hydroxyprogesterone	8.3
17α-hydroxypregnenolone	3.9
Progesterone	1.5

Without the ovarian structures, small amounts of estrogens are also formed in the zona reticularis of the adrenal cortex *(residual estrogens)*, the Leydig cells of the testis and in great quantity in the syncytiotrophoblast of the placenta. As is to be expected, the secretion of residual estrogens increases in response to stimulation with ACTH.

The *daily secretion of estrogens* by the ovary is 50–340 μg, depending on the phase of the cycle (BROWN, 1957; ZANDER, 1959). The lowest amounts are secreted during menstruation. The maximum (ovulation maximum) is reached at the time of ovulation, and a second, somewhat lower but broader peak (luteal maximum) arises during the luteal phase (Fig. 12), which can, however, fail to occur in women even though ovulation has taken place. Because of the difficulty of the determining the exact time of ovulation (p. 565), the time relation between ovulation and the maximum estrogen secretion is still uncertain. A close connection between these two factors has been deduced from the fact that the time interval between the maximum estrogen production and menstruation is quite constant, is independent of the duration of the cycle and is on average 14 days.

Successful artificial inseminations at the time of the estrogen maximum also indicate a temporal concordance (BROWN, 1962). The total estrogen production during a normal cycle is estimated to be 4–8 mg (BROWN, 1957). It is thought that 10–40 μg of estrone are secreted daily by the adrenals. This amount is almost the same as the amount of estrogens formed during the postmenopause (residual estrogens) (Table 9, Fig. 13).

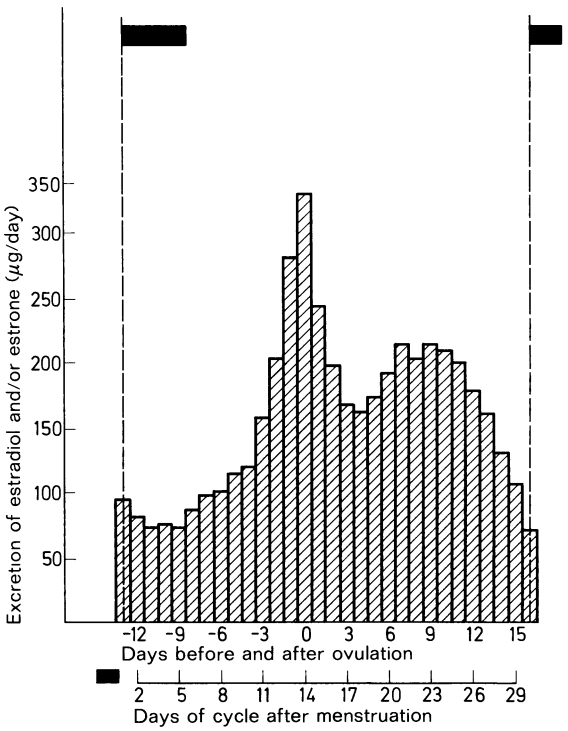

Fig. 12. Excretion of estrogens (estradiol and/or estrone) in an ovulatory cycle (BROWN, 1957). Calculated on the basis of average estrogen excretion from 11 normal cycles

The estrogen level in the plasma is very low, 0.01–0.12 μg per 100 ml plasma, depending on the phase of the cycle.

The formation and secretion of progesterone and 20α-hydroxyprogesterone are also cyclic (Figs. 14 and 15), and start 2–3 days before ovulation or the rise of the basal body temperature (ZANDER, 1958; RUNNEBAUM, 1965; MIKHAIL, 1967). The concentration of these two compounds is many times higher in ovarian

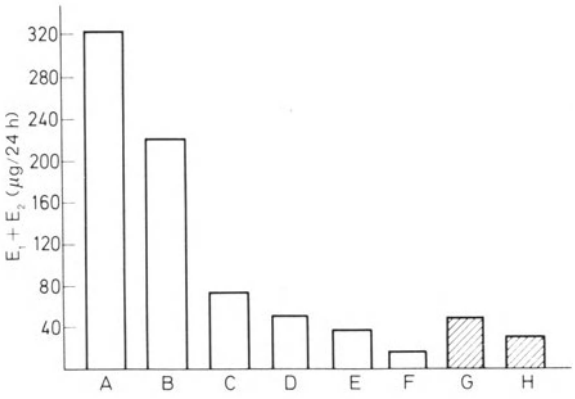

Fig. 13. Daily estrogen excretion in the nonpregnant woman under various conditions (after DICZFALUSY, 1961). *A* ovulation maximum, *B* luteal maximum, *C* menstruation minimum, *D* after X-ray induction of sterility (before the menopause), *E* after bilateral oophorectomy (before the menopause), *F* after bilateral oophorectomy and adrenalectomy, *G* after the menopause, *H* after cortisone medication after the menopause

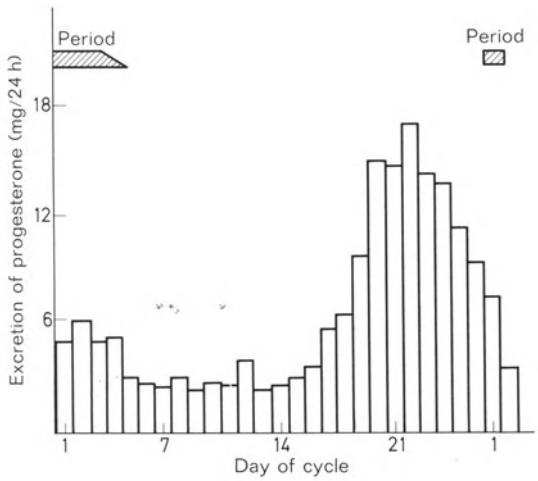

Fig. 14. Progesterone synthesis during the normal biphasic cycle. (After CAREY, 1963)

venous blood than in peripheral blood (Tables 5–7). This shows that they are secreted by the ovaries. The LH peak in the plasma seems to precede the progesterone rise (NEILL, 1967). The total amount of progesterone formed during a cycle is about 200 mg (OBER, 1954). Smaller amounts of 5–8 mg per day are secreted regardless of the stage of the cycle by the adrenals (so-called residual progesterone). The plasma concentration is about 0.1 µg/100 ml in the preovulatory phase, increases rapidly before ovulation and is about 1 µg/100 ml during the luteal phase (WOOLEVER, 1963; RIONDEL, 1965; VAN DER MOLEN, 1965; MIKHAIL, 1967; ZANDER, 1967, 1968). The second gestagen, 20α-hydroxyprogesterone, which is biologically considerably less active, is not demonstrable in the plasma during the follicular phase. Its concentration in the plasma rises rapidly shortly before ovulation and is about 0.25 µg% after ovulation (RUNNEBAUM, 1965; MIKHAIL, 1967). The plasma level of the biologically inactive 17α-hydroxyprogesterone is roughly the same before and after ovulation (MIKHAIL, 1967).

It is not known what amounts of androgens are normally formed in the woman. A small proportion is derived from the ovaries. Androstenedione and dehydro-epiandrosterone are normally secreted from the ovary into the blood and are excreted as 17-ketosteroids in the urine. Some parts is also converted to testosterone in the blood of the normal woman. The plasma level of testosterone is 0.036 ± 0.009 µg/100 ml in sexually mature women (LLOYD, 1966). The level of testosterone is decidedly higher in the plasma in cases of polycystic ovaries, which is in keeping with the increased formation of androstenedione (p. 613, Table 52). About two-thirds of the estrogens circulating in the plasma are bound to β-globulins. Only one-third is in free from in the blood, mainly esterized. The gestagens circulate loosely bound to albumins. We still do not know to

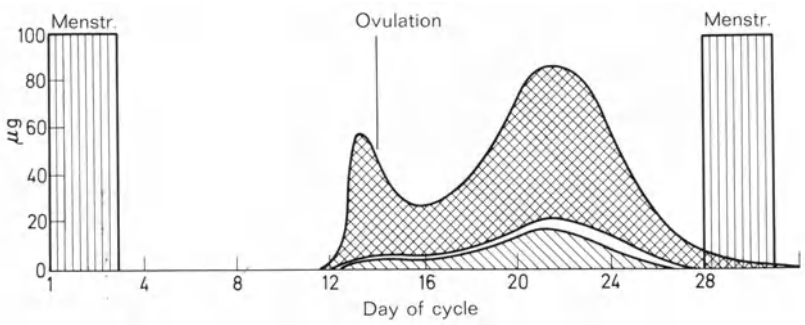

Fig. 15. Total amounts of progesterone (double cross-hatched area) and 20α,β-hydroxy-pregn-4-ene-3-one (single cross-hatched area) in 7 follicles and 32 corpora lutea during the cycle. (After ZANDER, 1958)

what extent the large amounts of enzymes present in the blood are involved in the conversion of estrogens. A conversion of this kind is likely, by analogy with androgens, where 39–54% of testosterone in the blood is derived from androstenedione.

4. Metabolism and Excretion

Valuable information on the metabolism of the ovarian hormones has been obtained by injection of radioactive-labeled sexual steroids.

Following a general principle of hormonal action, estrogens secreted into the blood rapidly disappear into the tissues or are inactivated by the kidneys and liver and excreted in the gut. The half-life of circulating estrogens is only 6 min (PEARLMAN, 1957). Only a small proportion of the estrogens become bound to the specific receptor molecule of organs sensitive to estrogens and produce their specific effect there. There is no accumulation in the end-organs. The highest concentrations are found in the sites of breakdown and excretion, the liver and kidneys.

As deduced from animal experiments, the ovaries and other reproductive organs have no effect on estrogen metabolism. Inactivation of estrogens secreted into the blood occurs by at least two routes: conjugation and oxidation. About half the estrogens secreted are made water-soluble in the liver by esterification with glucuronic and to a lesser degree with sulfuric acid (conjugation), and are then excreted as sodium salts through the kidneys. Another portion is converted into a biologically less active form through oxidation in the liver, is conjugated and also excreted in the urine. About 80% of the estrogens formed leave the organism via the kidneys (BEER, 1955). Investigations on patients with biliary fistula have shown that a fraction of the conjugated estrogens or metabolites reaches the gut with the bile, where it is partly reabsorbed.

This results in an *enterohepatic circulation of estrogens*. Only 7–10% of estrogens are excreted in the free form in the feces. This circulation is probably responsible for the relatively slow excretion of estrogen. The maximum excretion is reached after 24 hours. Only 80% of exogenous estrogens administered are excreted in the urine after 120 hours, while excretion through the gut takes place even more slowly; small amounts of estrogens leave the body in the expired air and sweat and by epithelial desquamation. It is still controversial whether, as in the cases of the synthetic estrogen, tri-p-chlorethylene (Tace), and progesterone, natural estrogens are also stored in adipose tissue. It is assumed that a certain amount of estrogens is stored in adipose tissue, and the greater incidence of carcinoma of the body of the uterus in overweight women has been related to a depot action (Twombly).

Liver cirrhosis, infectious hepatitis and chronic liver diseases can lead to hepatogenic hyperestrogenism (congestion of follicle hormones). This may then provoke dysfunctional bleeding in the woman and feminization (gynecomastia, "abdominal baldness") in the male.

Results of experiments with animals and of tissue analysis and excretion tests in the woman have contributed to our knowledge of the quantitative relations in production, metabolism, and excretion of the sexual hormones. These results, however, vary very widely according to the species and method used. For example, if labeled estradiol is injected 80% of the radioactive material can be regained from the urine. On the other hand, quantitative chemical estimations in the urine show an increase of only 30% of estrogens in the form of estrone, estriol and estradiol. Older methods give a yield of only 10%.

BROWN (1957) found a total of 9–23% (mean 16%) of the 17β-estradiol or estriol given intramuscularly in the urine, 6.8% in the form of estrone, 2% as estradiol and 7.2% as estriol. The estriol excretion was found to be somewhat delayed (so-called estriol lag).

Assuming that administered exogenous estrogens are excreted in the same way as those formed in the organism, the amounts of estrogens formed in the body can be roughly calculated from this excretion estimation by multiplying the amount excreted by 6 (= 100/16). The secretion rate of estrone, estradiol and estriol calculated in this way is 15–314 μg daily, depending on the phase of the cycle. The estrogen excretion in the 24-hour urine is less than 10 μg before sexual maturity is attained and after the menopause. The estrogens in these periods are mainly adrenal estrogens (residual estrogens). Excretion rises shortly before the onset of menarche and reaches adult values as soon as the biphasic cycle is established.

The estrogen excretion is subject to cyclic variations related to the ovarian secretion in sexually mature nonpregnant women (Table 9).

The mean value of the total estrogen excretion in the urine in 24 hours lies between 10 and 60 μg. The estriol, estrone + estradiol quotient is approx. 1 in sexually mature women and the ratio of estrone to estradiol excretion is about 2 : 1. Estrogen excretion is at its lowest during menstruation, beginning to rise on the 7th day of a 28-day cycle and reaching a maximum on the 13th day (ovulation maximum).

BROWN (1955) found an ovulation maximum of 28–99 µg in 24 hours on the 13th day of 10 normal 28-day cycles in eight women between the ages of 17 and 40 (average 56 µg/24 h). The excretion then falls steeply, and rises again parallel to the vascularization of the corpus luteum, reaching a 2nd maximum with the luteal phase (18th to 23rd day) (luteal maximum). There is another fall in excretion 2–3 days before the onset of menstruation (Fig. 16). Bleeding due to withdrawal of estrogens then occurs. The excretion peak of estriol lags 24 hours behind the secretion peak (estriol lag). In the absence of ovulation with endocrine-active ovaries, estrogen production and excretion can remain more or less constant over a long period of time but can also show periodic variations. The daily excretion values are over 10 µg and may even reach values between 80–100 µg/24 h when excretion fluctuates. The endometrium is subjected to the whole spectrum of estrogen stimulation, and corresponding to estrogen production demonstrates all stages, ranging from poor proliferation right up to glandular cystic hyperplasia. The duration of amenorrhea is dependent on the degree of estrogen secretion and the type of secretion increase. In general, the amenorrhea lasts longer as the level is lower and the rise occurs more slowly. It has been shown that the level of estrogen excretion is of prognostic value in amenorrhea (BROWN, 1959). If the total estrogen excretion is repeatedly found to be less than 5 µg/24 h ovarian function is deficient, and the patient will remain amenorrheic. It is uncertain whether a spontaneous cycle can be attained when values are between 5 and 10 µg in 24 hours. The prognosis of a spontaneous cycle is favorable only if the excretion is more than 10 µg/d.

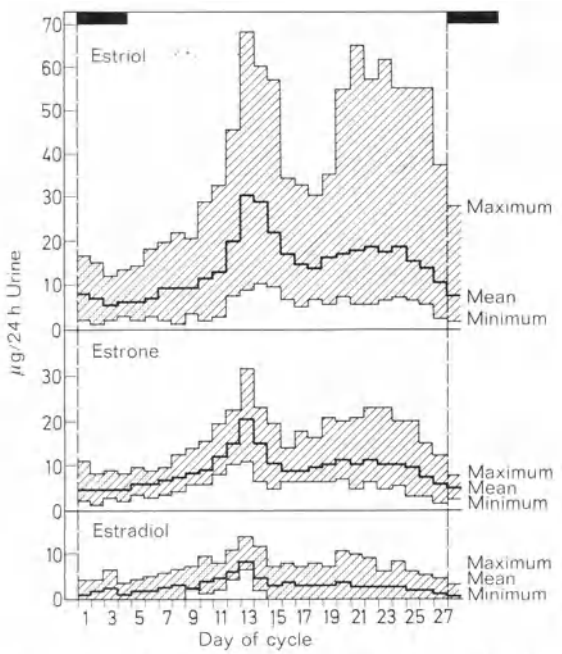

Fig. 16. Excretion of estrone, estradiol, and estriol during the cycle (BROWN, 1959). Mean, minimum and maximum during the cycle in 16 normally menstruating women aged 18–41

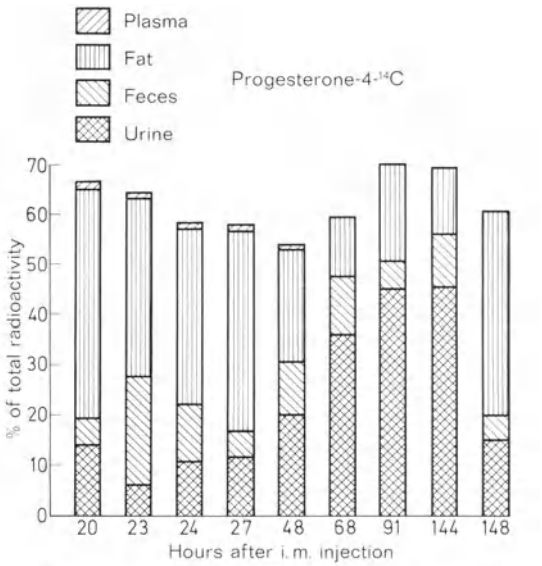

Fig. 17. Distribution of labeled progesterone in the organism. (After PLOTZ, 1959)

Like estrogens, progesterone also disappears rapidly from the blood. The half-life of progesterone circulating in the blood is only 2 min (PEARLMAN, 1957). When progesterone is given intravenously, only 2% of it is present in the blood in the free form after 25 min, and less than 6% in the inactivated conjugated form (PEARLMAN, 1957). If radioactive progesterone is injected intramuscularly, only 1.3% of the administered activity can be demonstrated in the blood at the most, but 80% of the activity is transmitted to the tissue within 3 hours (Fig. 17). Most of this is stored in adipose tissue, while as in the case of estrogens, only minute amounts are found in the end organs. Some of the progesterone secreted is reduced to pregnanediol (a mixture of pregnane-3α, 20α-diol and allopregnane-3α,20α-diol) in the liver, and is excreted in the form of glucuronides mainly via the kidneys and to a lesser extent through the gut and lungs. In the absence of pregnancy, 12–30% of the progesterone produced by the body appears in the urine as sodium pregnanediol glucuronide (KLOPPER, 1956; ZANDER, 1969). From this it can be

calculated that the daily secretion rate of progesterone is 15–20 mg during the luteal phase, and that a total of about 200 mg is excreted during the entire cycle (OBER, 1954). The pregnanediol excretion in the sexually mature woman is related to the cyclic ovarian secretion (Fig. 18). The excretion is 1–2 mg daily during the follicular phase (KLOPPER, 1957; OBER, 1961; FOTHERBY, 1962). This excretion is due to the adrenal progesterone (residual progesterone) and the insignificant amounts of cortexone. Two to three days before ovulation there is a rapid rise in pregnanediol excretion, due to the formation of ovarian progesterone, and 3–7 mg is excreted daily during the luteal phase (KLOPPER, 1957; FOTHERBY, 1962).

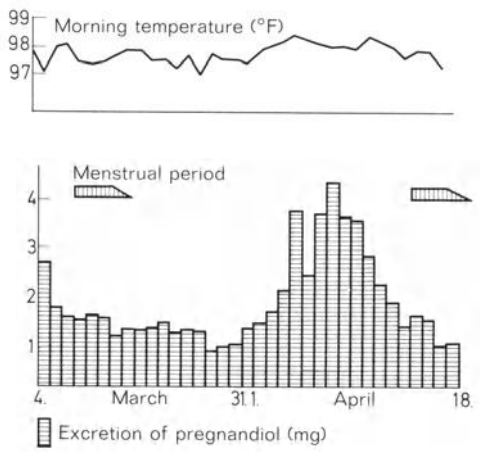

Fig. 18. Pregnandiol excretion and basal temperature curve recorded during a normal cycle. (After KLOPPER, 1957)

Some progesterone is also metabolized by hydroxylation at C_{17} and C_{20} (Fig. 19). The biological activity of progesterone is reduced by conversion to 20α,β-hydroxyprogesterone or 17α-hydroxyprogesterone. The latter substance is an intermediate product in the synthesis of estrogens and androgens, and normally only a small amount is converted to pregnanetriol and excreted as such in the urine in the characteristic cyclic manner. The excretion of this substance precedes that of pregnanediol by about 3 days (FOTHERBY, 1962).

5. Biological Action

The absence and onset of the formation of ovarian hormones, the cyclic secretion and finally their cessation determine the phases

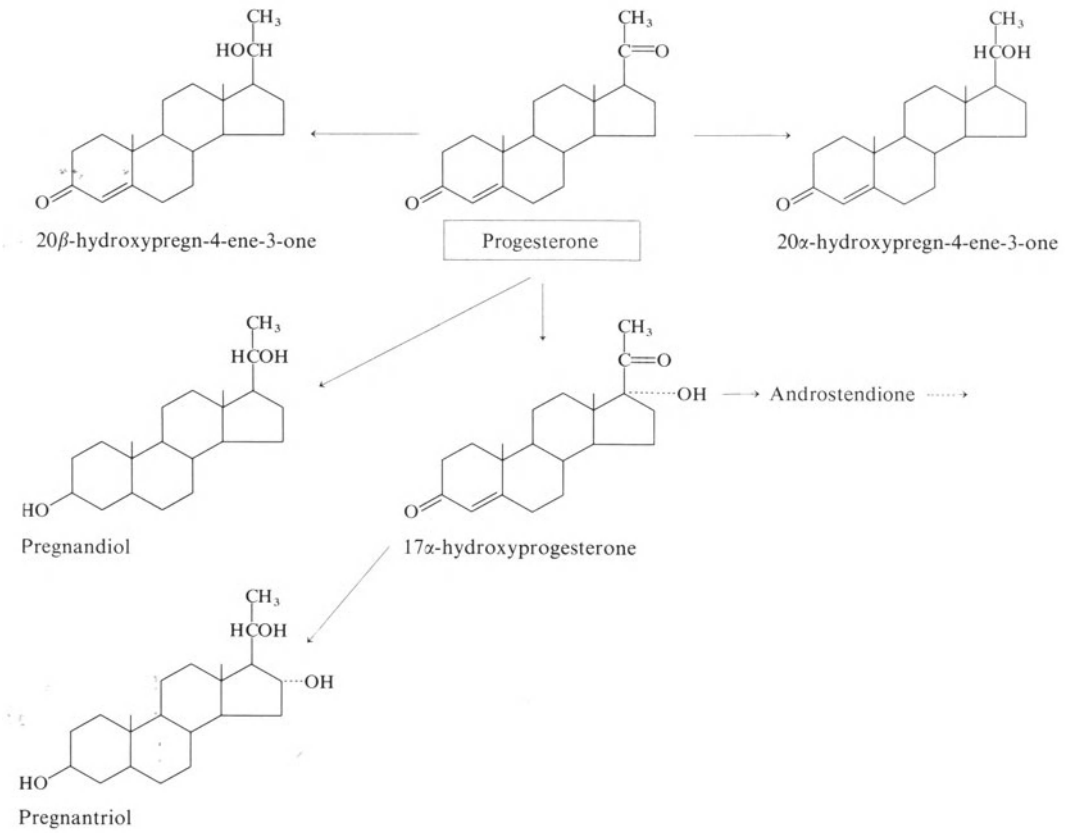

Fig. 19. Pathways of progesterone metabolism

of life in a woman (p. 576). Physical, intellectual and emotional maturity are reached under the action of ovarian hormones. The somatic effect becomes obvious primarily in the reproductive organs, whose development and function are dependent on the presence of estrogens and gestagens. They also cause the development of the secondary sexual characteristics and exert a series of other extragenital effects. In addition they are involved in regulating ovarian endocrine function by their action on gonadotropin secretion (p. 557).

Our knowledge of the physiology of estrogens and gestagens is derived from the state after castration and during ovarian dysfunction and the postmenopause, as well as from the effects of administration of ovarian steroids. Our knowledge about the actions in the woman is modest since in the human, real experimental conditions cannot be produced and there are always endocrine factors producing variable actions. Results from experiments performed mainly in rodents can only be referred with reservations to the conditions in the woman, and there are considerable differences even among the various animal species. Understanding the biological actions of these steroids is, however, essential to the explanation of the pathology and clinical endocrinological picture, as well as to therapeutic use of ovarian hormones.

Both groups of female sexual steroids can be characterized as follows:

Estrogens are substances which produce signs of heat and estrus in castrated female rodents (Allen-Doisy test). They are growth-promoting substances which act primarily on trophism and growth of the reproductive organs. Their action is associated with the presence of folic acid. They increase oxidative phosphorylation in some cells, causing ATP production to be doubled. More amino acids and phosphates are absorbed, and more proteins, ribonucleic acids, glycogen and lipids are synthesized. Thus, estrogens exert a trophotropic-endophylactic or anabolic action on their target organs.

Table 12. Some biological effects of estrogens and gestagens

	Estrogens	Gestagens
Metabolism	Trophotropic and endophylactic:	Ergotropic and dynamogenic:
	Circulation and cell permeability increased; increased deposits of amino acids, carbohydrates, lipids, and phosphates in the cell; increased cell oxidation, augmented synthesis of ATP	Activation of ATPase; increased release of energy
	Retention of sodium and water	Temporary increase in sodium and water excretion
	Growth	Differentiation
	Fall in temperature	Rise in temperature
Vagina	Increased numbers of superficial cells, rise in acidophil and pyknosis indexes; glycogen storage	Massive exfoliation of superficial and intermediary cells (crowding effect)
	pH 3.8–4.5	pH 4.5–5.0
Cervix	Dilatation of ostium uteri and cervical canal	Narrowing of ostium uteri and cervical canal
	Mucus: increased amount (cascade), clear, lower viscosity and increased elasticity (spinnbarkeit), alkaline (pH 7.5–8), penetrable to sperm (Sims-Huhner test)	Mucus: scanty, viscous, cloudy, less penetrable or impenetrable to sperm
	Formation of fern-leaf crystals, increased sugar content (Doyle test)	Test for fern-leaf phenomenon negative
Endometrium	Proliferation:	Secretory transformation:
	Abundant mitoses in glandular epithelia and stroma, multiple layers in glandular epithelia, pronounced increase in alkaline phosphatase	Secretion of glandular epithelia, development of spiral arteries, stromatic edema and pseudodecidual transformation of stroma cells
		Increase in acid phosphatase
		Increased oxygen consumption
Myometrium	Increased intensity and frequency of myometrial activity, increased isometric tension, rise in ATP and actomyosin contents	Relaxation (progesterone block)
	Increased responsiveness to oxytocin	Reduced responsiveness to oxytocin
	Increased circulation	
Ovary	Growth: sensitization to gonadotropins	Reduction of sensitivity to gonadotropins

Various anabolic cellular processes provide the necessary conditions for hypertrophy and hyperplasia of cells. These processes are increased circulation due to liberation of biogenic amines (acetylcholine, histamine, serotonin), increased cellular permeability, and increased cellular oxidation providing biological energy usable in the form of ATP. Apart from influencing the metabolism of proteins, carbohydrates and lipids, estrogens also cause elevated sodium and water retention in the extracellular space. Physiological doses of estrogens exert a permissive action on gestagens i.e. they are necessary for the action of gestagens on the target tissues.

Gestagens preserve pregnancy (implantation and development of gestation). They cause specific differentiation in target structures after the estrogenic growth impulse. They have ergotropic-dynamogenic effects in the reacting organs, and thus promote catabolic cell processes by increasing the release of usable energy by greater activation of ATPase. High doses can inhibit the estrogenic effects in the reacting organs (competitive action). The various actions of gestagens on the reacting organs are described as *progestative actions* (Table 12).

a) Action on the Reproductive Organs

Estrogens cause vascularization, circulation and turgidity to be increased in the *vulva*, and promote growth of the labia minora where the skin becomes thickened. They cause an increase in the secretion of Bartholin's, Skene's and sebaceous glands. Development of the clitoris, labia majora and the pubis are primarily influenced by androgens, and growth of the labial section of the pubis is stimulated partly by estrogens. The *vagina* increases in length and becomes more elastic under the influence of estrogens, and the vaginal vault becomes deeper. The *vaginal epithelium* is highly sensitive to estrogens, more so than the endometrium. It is therefore the classic biological organ for testing estrogens (p. 547). 40 μg daily for 10 days is sufficient to restore atrophic vaginal epithelium in a castrated or elderly woman (Fig. 10, OBER, 1957). Even after 24–48 hours there is an increase in the layers of cells with formation of prekeratin in the superficial layer (Fig. 11 a, OBER). At the same time glycogen is stored from the parabasal zone towards the lumen. This reaction has also been observed in the endometrium and myometrium. Gestagens and androgens, on the other hand, only build up vaginal epithelium to the intermediary layer (Fig. 20). Increased glycogen storage in the vagina of a castrated woman under the influence of progesterone is probably due to partial conversion of progesterone to estrogens. *Vaginal cytology* is used to detect carcinoma and to assess the state of ovarian function (endocrine cytodiagnostic methods, p. 566).

When carried out correctly it is a simple, quick, and reliable method of assessing the levels of estrogens in clinical cases.

It allows the assessment of ovarian function in simple amenorrhea, and a rough estimation of the time of ovulation (p. 566). It is also used to monitor hormone therapy (p. 601) and to examine the potency and duration of action of an estrogen compound (p. 551).

Results obtained by chemical estimation of estrogen excretion and vaginal cytological smears are largely consistent.

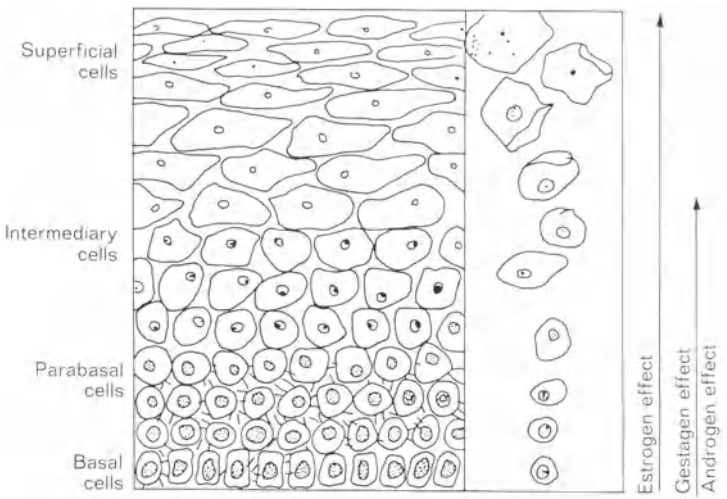

Fig. 20. Structure of the vaginal epithelium in the sexually mature woman, and corresponding exfoliative cells. (After BOSCHANN, 1960)

In order to obtain a perfect smear, a series of conditions are necessary. The cytological smear must be taken before a vaginal examination or treatment. We have found the following *technique for taking* the smear most satisfactory:

A dry self-supporting speculum is introduced and the os uteri is kept in view (Cusco, Trélat speculum). A wooden rod with a small amount of dry cotton wool wrapped round one end is used to take some material from the lateral aspect of the vaginal vault. The cotton wool is then rolled in the opposite direction to that in which it was rotated when the smear was taken to transfer the material to two dry, carefully cleaned microscopic slides. These must be fixed in ether alcohol (96%) for 20–30 min while the smear is still moist and subsequently stained. In children and virgins the smear is taken by means of a glass catheter with a suction balloon. Introduction of a speculum is unnecessary in such cases.

Staining technique (after PAPANICOLAOU, 1942)

1. 80% alcohol ($\frac{1}{2}$ min)
2. 70% alcohol ($\frac{1}{2}$ min)
3. 50% alcohol ($\frac{1}{2}$ min)
4. Distilled water ($\frac{1}{2}$ min)
5. Hemotoxyline (Harris) (3–6 min)
6. Distilled water ($\frac{1}{2}$ min)
7. 0.25% aqueous hydrochloric acid (immerse 6 times)
8. Top water (6 min)
9. Distilled water ($\frac{1}{2}$ min)
10. 50% alcohol ($\frac{1}{2}$ min)
11. 70% alcohol ($\frac{1}{2}$ min)
12. 80% alcohol ($\frac{1}{2}$ min)
13. 95% alcohol ($\frac{1}{2}$ min)
14. Orange G 6 ($1\frac{1}{2}$ min) } separate
16. 95% alcohol ($\frac{1}{2}$ min) } cuvettes
17. EA 50 ($1\frac{1}{2}$ min)
18. 95% alcohol ($1\frac{1}{2}$ min) } separate
19. 95% alcohol ($\frac{1}{2}$ min) } cuvettes
20. 95% alcohol ($\frac{1}{2}$ min) }
21. Absolute alcohol ($1\frac{1}{2}$ min)
22. Xylol alcohol ($\frac{1}{2}$ min)
23. Xylol ($\frac{1}{2}$ min)

If the smear shows inflammatory changes, it is advisable to insert a terramycin capsule (50 mg) deep into the vagina 2 to 3 days before the next smear is taken. Refer to the following authors for the endocrinological evaluation of vaginal cytological smears: PAPANICOLAOU (1033, 1946), SHORT (1940), ROTH (1950), WIED (1953), SCHMITT (1953) and textbooks of cytology by BOSCHANN (1960), KOOS (1961), DE NEEF (1967), PUNDEL (1952, 1957, 1966), SMOLKA (1965) and ZINSER (1957).

Rough quantitative assessments of the levels of estrogens and gestagens are possible with vaginal cytology (PAPANICOLAOU, 1933; PUNDEL, 1952). The *atrophic vaginal smear* encountered before menarche, after the menopause, and in vegetative ovarian insufficiency during sexual maturity shows a predominance of parabasal and basal cells. These cells are small and round, each containing a large, chromatin-rich vesicular nucleus in the basophilic cytoplasm (Fig. 21 colored cytological slides). In addition there are a few larger ovoid intermediary cells, as well as a varying number of leukocytes and bacteria (vaginitis senilis).

In the vaginal cytological picture, an increasing number of large-surfaced, polygonal superficial cells appears under the influence

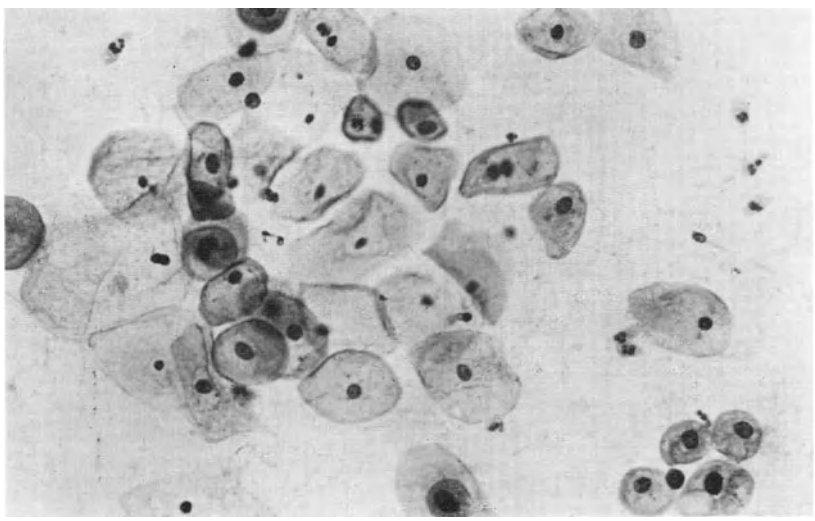

Fig. 21. Atrophic vaginal smear

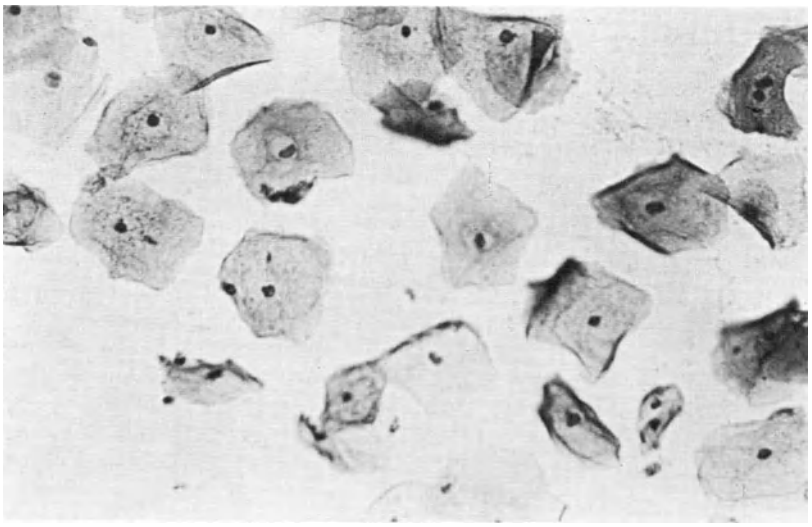

Fig. 22. Preovulatory vaginal smear

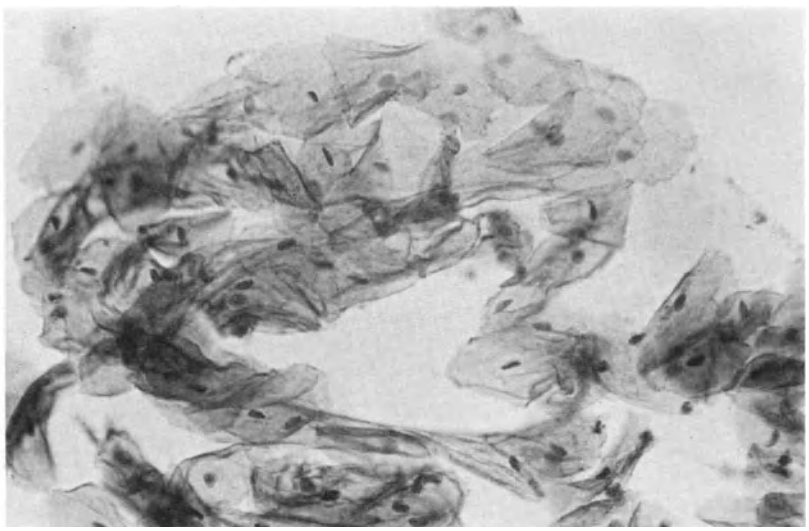

Fig. 23. Luteal vaginal smear

of estrogens. These cells have a pyknotic, structureless nucleus, often associated with a perinuclear chamber, and the cytoplasm is transparent and acidophilic. The cells lie separately and make up 40–80 % of the desquamated cells before ovulation (Fig. 22). Besides these cornified superficial cells, uncornified, karyopyknotic superficial cells are also found during the proliferative phase. These can be distinguished from the cornified cells only by the fact that their cytoplasm shows an affinity for basic stains and assumes a bluish violet color. Intermediary cells originating from the stratum spinosum are rarely seen. They are smaller and ovoid, the nucleus is vesicular and the cytoplasm is basophilic. Basal and parabasal cells do not normally arise in the smears of sexually mature women. The smear also reveals leukocytes, erythrocytes, Döderlein bacteria, fibrin and mucus in varying amounts depending on the cyclic phase.

The *pyknosis index* (= percentage of cells with pyknotic nuclei in the cytological smear) and to a lesser degree the *acidophil index* (= percentage of acidophilic cells) are of practical importance in assessment of the estrogen action in cases of dysfunctional bleeding or amenorrhea, and in the investigation of sterility (Fig. 24). The pyknosis index is simply and quickly determined, and is a reliable indicator of estrogen production. There is a significant relation between the pyknosis index

and the logarithm of estrogen excretion (JOHANNISSON, 1961). Continuous preparation of vaginal smears in association with assessment of the cervical factor permits an approximate estimate of the time of ovulation (p. 567). The pyknosis index is over 40% before ovulation and between 60–80% at the time of ovulation, when leukocytes and Döderlein bacteria almost completely disappear from the picture.

After ovulation progesterone acts on the fully developed vaginal epithelium, causing massive desquamation of the superficial and intermediary cells (so-called luteal effect in the vagina). In the smear (Fig. 23) group formations with superimposed cells in place are seen (crowding effect). There is a predominance of superficial cells and later of intermediary cells with basophilic cytoplasm, which is rolled in at the edges due to loss of cellular turgidity. Only a few superficial cells with karyopyknosis and acidophilia are still found. The pyknosis index falls below 30%.

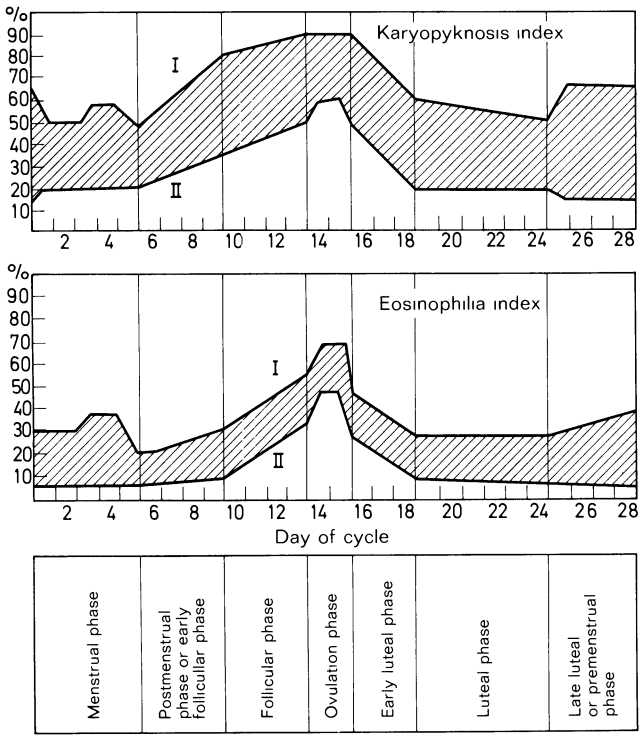

Fig. 24. Changes in the karyopyknosis index and the eosinophilia index over a normal 28-day cycle. Normal range: I = maximum, II = minimum. (After PUNDEL, 1952)

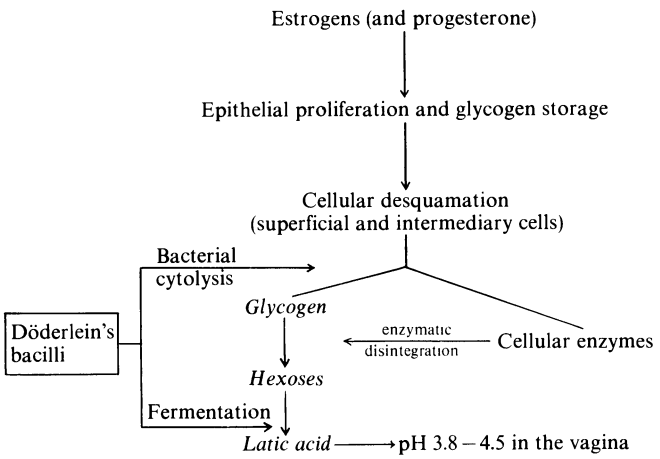

Fig. 25. Lactic acid synthesis (self-purification) in the vagina

Epithelial proliferation, glycogen storage and increased desquamation of the superficial and intermediary cells caused by the actions of estrogens and progesterone are physiological processes of basic importance to the so-called *self-purification of the vagina* (Fig. 25). The glycogen liberated by bacterial cytolysis is converted into hexoses by enzymes contained in the cells. The hexoses are then fermented to lactic acid by the gram-positive Döderlein bacteria, giving pH 3.8–4.5. Only Döderlein bacteria can thrive in these acidic surroundings. Growth of pathogenic organisms is prevented (with the exception of trichomonads).

Epithelial proliferation, glycogen storage and desquamation of vaginal epithelium reach their maximum at the time of ovulation and in the premenstrual phase. The time of these maxima depends on the maximal secretions of the sexual steroids. Thus, glycolysis and lactic acid formation due to Döderlein bacteria are most pronounced between ovulation and menstruation. pH values are lowest (3.8–4) at this time, rising to 5 during the other phases of the cycle. The lowest values are found in the anterior vaginal vault, the highest at the introitus. Vaginal acidity is of physiological importance since most pathogenic organisms cannot thrive at a pH between 4.1 and 4.9. Menstrual blood almost completely neutralizes the pH, and there is an increased risk of infection during menstruation. Similar conditions are found during the postmenopause and in prepuberty, when the pH is 7 and 6 respectively.

The infantile uterus increases in size (length increases from 4 to 8 cm), becomes more vascular and increases from 16 to 60 g in weight under the trophic influence of estrogens. The length of the cervix is greater than that of the body of the uterus during infancy. The final ratio of the fundus to the cervix in the sexually mature women is 2 : 1 because the cervix does not grow as quickly as the fundus (Fig. 26).

Estrogens cause a trophotrophic-endophylactic reaction in the muscle cells, together with a rise in the ATP concentration and contractile protein (actomyosin). Intensity and frequency of myometrial activity also increase. Progesterone in contrast lowers the frequency of contractions of myometrial cells and their ability to respond to oxytocin (KNAUS, 1953; CSAPO, 1966) (progesterone block after CSAPO, 1961, 1963) by diminishing the concentration of intracellular potassium (CSAPO, 1956).

Characteristic changes occur in the cervix factor in the preovulatory phase 3–4 days before ovulation, due to increased stimulation by estrogens (RAUSCHER, 1954; SABINE, 1941) (Fig. 27). The dilatation of the os uteri is increased (ASPLUND, 1952) (Fig. 28), as is the amount of cervical mucus displaying alkaline reaction (pH 7–8) (VIERGIVER, 1944). The transparency, elasticity, spinnbarkeit (PALMER, 1941; CLIFT, 1945) and penetration capacity of the mucus by sperms are also increased (p. 625, Sims-Huhner test) (SIMS, 1868; HUHNER, 1913). Viscosity (VIERGIVER, 1946) and the leukocytic and bacterial contents are diminished. In addition, characteristic crystallization occurs when the mucus is allowed to dry in the air on a microscope slide, due to the increase in NaCl content. This crystallization takes the form of fern-leaf crystals (fern test or arborization phenomenon) (Fig. 71).

For the *fern test*, a pipette is cleaned with distilled water and then dried; some mucus is then aspirated from the cervical canal with

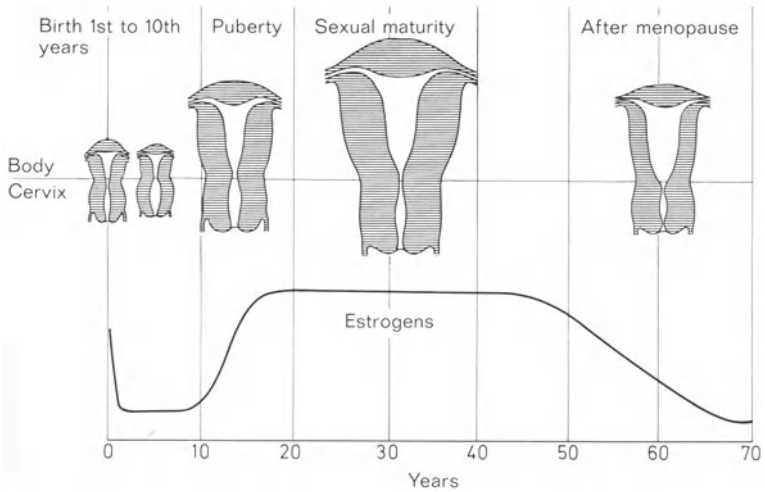

Fig. 26. Relative size of the uterus, body-cervix ratio, and estrogen excretion at different stages of development. (After Pschyrembel, 1968)

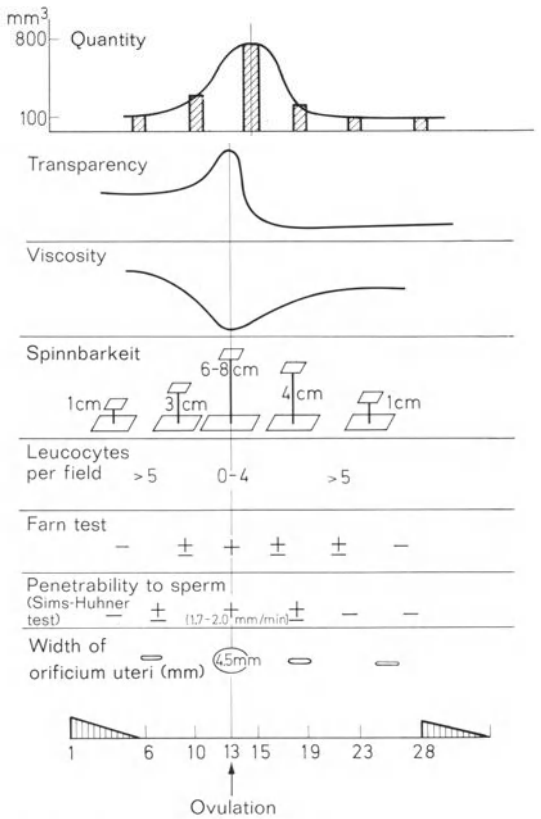

Fig. 27. Cyclic changes in the cervix factor

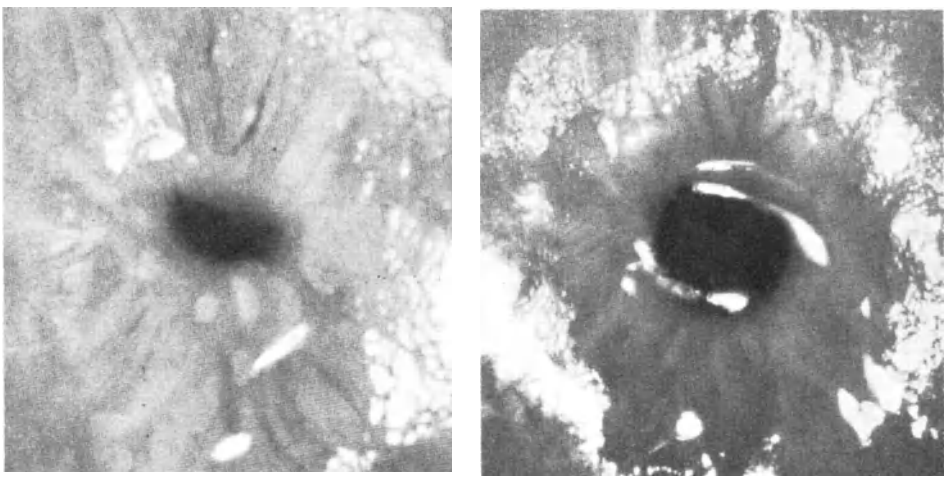
this pipette and blown out onto two microscope slides. Large amounts of glass-clear mucus (so-called cascade formation) are usually found around the time of ovulation, and fern leaf-like crystals of salt crystallize out from this mucus after 15–20 min (PAPANICOLAOU, 1946; RYDBERG, 1948; CAMPOS DA PAZ, 1953). Assessment is made under 100 times magnification. This phenomenon is quite nonspecific, and can also be observed before ovulation or when other body fluids, e.g. saliva, are allowed to dry up (ZONDEK, 1954). A reaction of this type always occurs when mucopolysaccharides and electrolytes come into contact. In the cervical mucus, it is a sign that estrogen influence is adequate. The fern test becomes positive 24–48 hours after administration of estrogens (PUCK, 1958), and becomes negative 10 days after ovulation has occurred. False-positive results are always obtained when the pipette used for aspiration or the slides are contaminated with salt, or when blood is present in the cervical mucus. The semi-quantitative method of colorimetric estimation of NaCl content in cervical mucus can also be helpful in determination of the time of ovulation (MCSWEENY, 1964). An applicator with a strip of filter paper soaked in silver nitrate and potassium chromate is used for this test. Due to metabolic changes produced in the cervical glands by the influence of estrogens, the glucose content is increased and the acid content reduced, parallel to the increased NaCl content. *Doyle's test* for colorimetric demonstration of glucose content can also be used to determine the time of ovulation (DOYLE, 1959). DOYLE's and the MCSWEENEY's test are of limited practical importance.

The spinnbarkeit of the cervical mucus is at its greatest at the time of ovulation (PALMER, 1941; COHEN, 1952), and is best examined as follows: a forceps is used to pull out a thread of mucus from the cervix and the length of the thread at its breaking point is estimated. Normally this length can reach 8–10 cm shortly before and during ovulation. Inadequate spinn-



a b

Fig. 28. a) Ostium uteri before ovulation (4 days before lowest point of temperature curve). b) Ostium uteri of the same woman in the same cycle at the time of ovulation (day corresponding to lowest point of temperature) (OBER, 1957)

barkeit at this time indicates estrogen deficiency. Progesterone reverses the cervical changes already described: the external os and uterine isthmus become narrower, the amount of cervical mucus decreases to between one eighth and one tenth of the ovulation maximum, the mucus becomes cloudy, yellowish and thick due to increased leukocytic invasion, and it is impenetrable to sperms. The spinnbarkeit progressively diminishes, and the fern-leaf phenomenon is no longer demonstrable 8–10 days after ovulation. The inhibitory effect of progesterone on the arborization phenomenon in the cervical mucus can be shown quantitatively: administration of 25 mg estradiol benzoate to the castrated woman results in the fern-leaf phenomenon, but this is prevented by giving an injection of 15 mg progesterone at the same time (ZONDEK, 1957). Increased function of the cervical glands at the time of ovulation can present clinically as intermenstrual discharge.

Cyclic changes in the endometrium occur at the same time as those in the ovary. The so-called *endometrial cycle* results from the influence of estrogens and gestagens, and the associated changes arise almost exclusively in the functionalis (HITSCHMAN, 1908; SCHRÖDER, 1928); NOYES, 1950; BEHRENS, 1953; BARTELMEZ, 1957; SCHMIDT-MATHIESSEN, 1963). Three functional and histological phases can be differentiated:

1. the proliferative, regenerative, estrogen or preovulatory phase;
2. the secretory, transformative, progesterone or postovulatory phase;
3. the menstrual or desquamation phase.

Glandular tubules and stroma with vessels react characteristically to estrogens and gestagens. The changes are so specific that it is possible to determine the stage of the ovarian cycle to 48 hours from the endometrial changes especially during the luteal phase (Fig. 29). In a normal cycle of 28 days, the menstrual phase lasts 1–4 days, the proliferative phase from days 5–13, and the secretory phase from days 14–28. The duration of the postovulatory phase is frequently constant and is usually 14 ± 2 days (ROCK, 1949), whereas the preovulatory phase is of unlimited duration.

Increasing estrogenic effect causes the *proliferative phase*. From day 5 of the cycle, new functionalis is formed from the basalis, and reaches a mean thickness of 3.5 mm at the time of ovulation. At the same time epithelialization of the uterine wound surface begins, with sprouting of the epithelia of the remaining glands.

The proliferative influence of estrogens can be recognized histologically from the increasing number of mitoses in the glandular epithelia and stroma.

Protein synthesis associated with the building up of the functionalis is reflected in the increased content of ribonucleic acids in the glandular epithelia and the increased mitotic activity by the raised desoxyribonucleic acid content. At the same time, the concentration of alkaline phosphatase increases considerably, reaching its maximum at the time of ovulation.

Three periods can be differentiated histologically: early, middle and late proliferative phases. The originally sparse, narrow, and stretched glandular tubules begin to branch, become wider and show definite meandering at the end of the proliferative phase. The nuclei originally situated basally come to lie at different levels in the cells due to increasing nuclear division. This leads to pseudo layers in the glandular epithelium, which disappear with the mitoses during the early secretory phase. The stroma usually has a dense cellular framework during the proliferative phase, and the initially small number of mitoses increases considerably up to ovulation. A transient edema, which varies widely, leads to a picture of "naked nuclei" in the stroma cells with little cytoplasm. This edema causes rapid thickening of the functionalis from day 10 onwards. Severe extensive stromal edema prevents secretory transformation.

After ovulation, the functionalis remains under the influence of estrogens, but is also affected by increasing amounts of gestagens secreted by the corpus luteum. *Secretory transformation* occurs in the endometrium "prepared" by the estrogens. In the first half of the secretory phase, the combined effect of both hormone groups becomes primarily obvious in the glandular tubules: formation of basal vacuoles due to storage of mucus and glycogen, secretion into the widened tubular lumen, increasing convolutions of the glandular tubules, which gives a saw-like structure to the histological picture during the secretory phase. In the second half of the transformative phase, the influence on the stroma is predominant: development of spiral arteries found only in menstruating primates, forming a subepithelial plexus, extensive stromal edema and pseudodecidual conversion of the stroma cells with formation of perivascular sheaths around the spiral arteries, and development of a superficial compacta and spongiosa lying next to the basalis. Acidic phosphatase and dehydrogenases replace the alkaline phosphatase after ovulation. At the same time, progesterone acts ergotropically and dynamically to increase the activity of adenosine triphosphase and oxygen requirements in the endometrium.

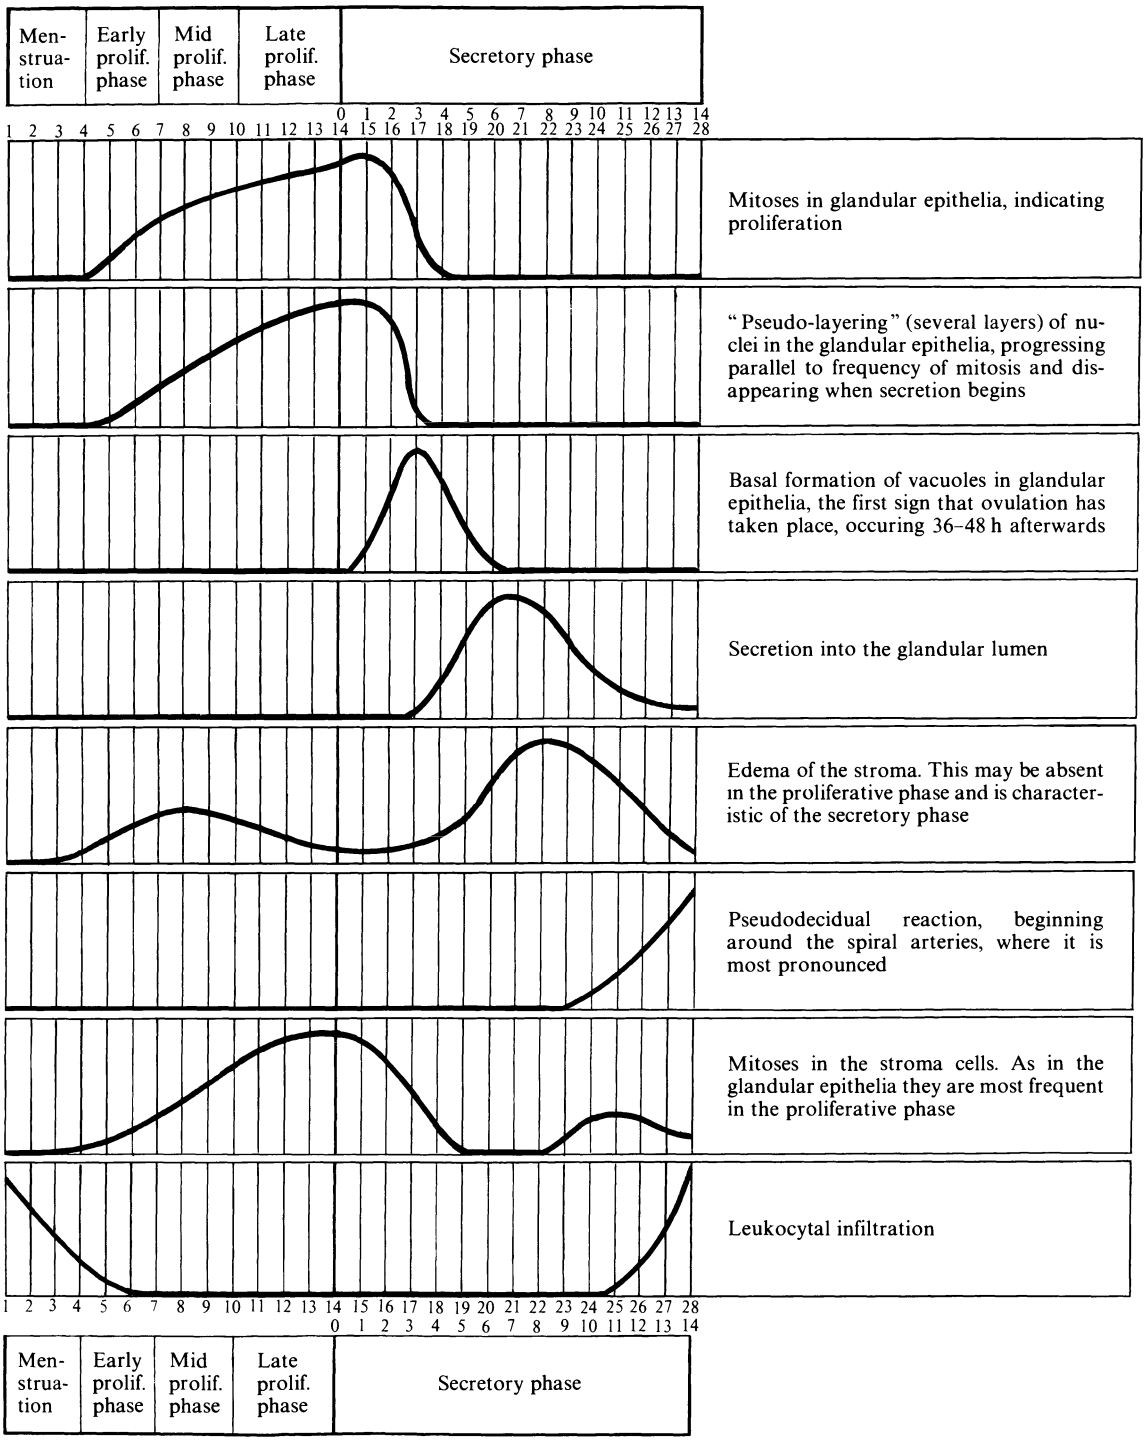


Fig. 29. Determination of the stage in the endometrial cycle. Course of characteristic morphologic signs in the endometrium during the cycle. (After R. W. NOYES, 1950)

The first signs of progesterone influence arise in the basal sections of the glandular epithelium. Vacuoles appear, and the cell nuclei become arranged at the same level in the middle of the cell. Pseudolayers disappear. Mucus and glycogen storage is demonstrable in the cell basis even only 24–48 hours after ovulation. Glycogen secretion into the lumen of the glandular tubules begins on day 4. Glandular tubules continue to become convoluted. At the same time, cell nuclei no longer undergoing mitosis are once more found at the cell basis. A stromal reaction which can be detected histologically arises from day 7 at the time when the blastocyste becomes implanted if fertilization

has occurred. The stroma becomes edematous and loose, mitotic activity of the stroma cells increases again, and some of the cells form a net due to water deposition, while some are converted into decidual cells due to storage of glycogen and lipids (so-called pseudodecidual reaction). Nuclei and cytoplasm become larger, and the pseudodecidual cells arrange themselves in layers of the functionalis. This distinguishes the superficially situated compacta from the spongiosa.

The temporal phases of the various histological changes in the functionalis are shown in Fig. 29 (NOYES, 1950).

If fertilization fails to occur, the corpus luteum regresses as early as 10 days after ovulation due to the absence of the action of chorionic gonadotropin produced by the zygote. The significance of chorionic gonadotropin for the preservation of the corpus luteum (so-called luteotropic action) can be shown experimentally: injections of 5000 IU chorionic gonadotropin on the 3rd, 5th and 7th postovulatory days converts the corpus luteum of menstruation into one of pseudopregnancy. Regression of the corpus luteum results in a fall of the levels of estrogens and gestagens in the blood, which in turn gives rise to regressive changes in the functionalis even from the 4th day before menstruation. There is first lymphocytic and then leukocytic infiltration of the stroma, which shrinks at the same time due to loss of water. As much as 90% of the mucosal volume can be lost through this shrinkage. This has been observed directly in women with visible endometriosis. (HOFFMANN, 1953).

The external course of the associated tissue changes can be observed directly when the technique introduced by MARKEE (1940) is used. Endometrial fragments of a Rhesus monkey are implanted into the anterior chamber of the eye of the same animal. The first sign that menstruation is about to occur is pallor of the vascular regions due to vasoconstriction of the individual spiral arteries. Necrotic foci arise in the compacta, accompanied by discrete hemorrhage. Pressure of the recirculating blood then results in rupture of the arterioles damaged by anoxia. A thin streak of blood is emitted from the opened vessel (bleeding per rhexin). This gives rise to massive hemorrhage into the tissue, causing destruction and desquamation of the tissue with the onset of menstruation. Thus menstruation is a hormone-withdrawal bleeding. It is different from breakthrough bleeding in the anovulatory cycle, in which the relative estrogen deficiency results in bleeding per diapedesim. In this case, the blood is coagulable, since the fibrinolytic enzymes liberated with massive destruction of the endometrium are absent.

The significance of estrogens for endometrial vascularization can be shown experimentally. Intravenous administration of 2 mg estrone or estradiol provokes extensive arterial hyperemia in the endometrium after 3 minutes, and secondary rhythmic vasoconstrictions result from the withdrawal (LOESER, 1948; BURGER, 1957). The original factor responsible for vasoconstriction of the spiral arteries is not known. It is possible that at the beginning of the process an unknown *bleeding factor* is liberated in the endometrium by estrogen and progesterone withdrawal. This factor may be identical to the potent vasoconstricting substance postulated by MARKEE (1950) or to the phytotoxic substance, "menotoxin", thought by MACHT and LUBIN (1924) to arise in damaged endometrium or to the "toxic endometrial euglobulin" of SMITH (1950). Changes in vascularization of the functionalis very probably have a great effect (BARTELMEZ, 1931, 1933, 1937; MARKEE, 1950; SCHLEGEL, 1945/46; DALGAARD, 1946), although the importance of this has not been fully accepted (KAISER, 1948). It is still a subject of controversy whether arteriovenous shunts with contractile elements under nervous control are also involved (SCHLEGEL, 1946). The importance of inadequate lymph drainage (REYNOLDS, 1947) with accumulation of toxic breakdown products of proteins is still open to discussion.

The periodic uterine bleeding is termed *menstruation* (period, monthly bleeding). It is accompanied by desquamation of the functionalis of the endometrium, with rejection of the major parts of the zona compacta and spongiosa. Since the normal endometrial cycle results in secretory transformation of the endometrium, menstruation is usually the result of bleeding from the secretory converted endometrium. It is, however, pointless to attach the clinical term "menstruation" to the presence of a certain histological change which is only exceptionally verified. Ovulation fails to occur in 4–8% of all regularly menstruating women (EFFKEMANN, 1939; ROCK, 1939; SIEGLER, 1951).

It is probable that occasional *anovulatory cycles* also arise during the "best" years of the reproductive period of a woman (Table 13). According to investigations, 3–10% of all cycles are anovular in women aged between

Table 13. Percentage of anovulatory cycles as a function of age in woman. (VOLLMAN in: HARTMAN, 1962)

	Gynecologic age					
	1–2	3–4	5–6	7–8	9–10	11–12
%	55.0	35.0	24.0	14.5	7.3	3.0
Average	17%					

20 and 40 (DÖRING, 1963; MATSUMOTO, 1962). Anovulation is physiological in the first few years after menarche, post partum and in the premenopause (VOLLMANN, Fig. 30, DÖRING), and causes relative sterility during these periods (ASHLEY-MONTAGU, 1946; COOPERMAN, 1949). Depending on the type of groups examined, 3–15% of cycles are anovulatory (FELDING, 1949; OVERSTREET, 1948; COLLETT, 1954; MATSUMOTO, 1962). This is observed much more frequently in patients attending sterility clinics than in other groups (ROCK, 1939). [The reader is also referred to the sections on dysfunctional bleeding, polycystic ovaries, transition periods in the woman.]

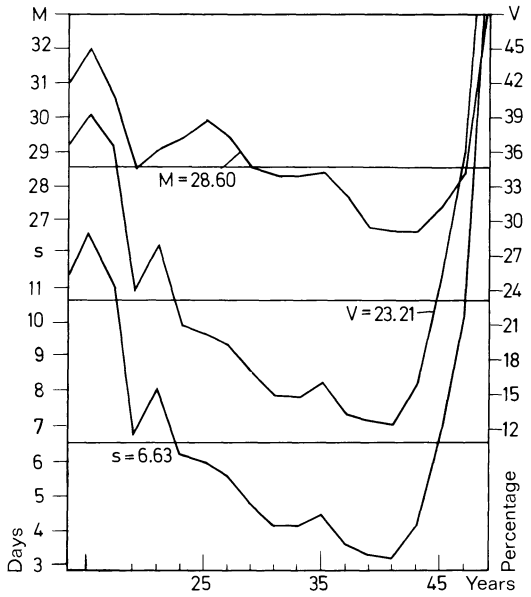

Fig. 30. Dependence of average length of cycle (M = mean = 28.60 days), its variability (V = 23.21 days), and standard deviation (s = 6.63) on age. (After VOLLMAN in HARTMAN, 1962)

Looked at biologically, the *menstrual cycle* begins with the proliferative phase and ends with the termination of menstruation. For practical reasons, however, it has become customary to consider the first day of menstruation as the beginning of the cycle, and the last day before the next menstruation as the end of the cycle. Thus, the *duration* of the cycle, is the interval from the first day of menstruation up to and including the day before the next period. Since ovulatory cycles are very rarely distinguished from anovulatory, WHO has suggested that it would be best to adopt the term "menstrual onset interval". In spite of the varying composition of the groups examined (age distribution, period of observation, race, ovulatory ± anovulatory cycles etc.), the statistical results of different authors about the duration of the cycle show only minor discrepancies. According to different investigations in large groups, this interval is 28.4–30.8 days (KING, 1933; FLUHMANN, 1934; LATZ, 1935; BJÖRNSSON, 1937; GUNN, 1937; AREY, 1939; HAMAN, 1942; VOLLMANN, 1956; MATSUMOTO, 1962). It has been found that 13–15% of all cycles in the adult woman last the "classic" 28 days (AREY, 1939; VOLLMAN, 1940), and that only 6% are of this duration during adolescence (ENGLE, 1934). The length of the cycle changes during the course of development: it decreases up to the 44th year and then rapidly increases again in the premenopause (Fig. 30). The cycle lasts 21–35 days in 90% of adult women (AREY, 1939; MATSUMOTO, 1962). (Fig. 31).

The menstrual interval is prone to variations even in the same woman (Fig. 31). Only 1%

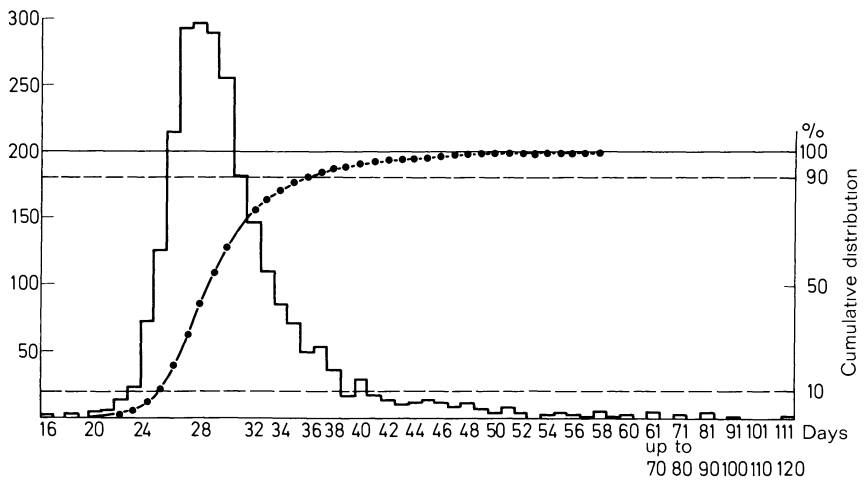

Fig. 31. Frequency and cumulative distribution of length of cycle in 2500 ovulatory cycles in 2500 women aged 20–30 (MATSUMOTO, 1962)

demonstrate a difference of not more than 2 days within a year (LATZ, 1935), whereas 20% show a difference of more than 7 days (LATZ, 1935; GUNN, 1937). FRÄNKEL's statement that irregularity is the only regular feature of the menstrual period (1911) is still true even today. Variations in the duration of the cycle are least common between the ages of 30 and 44 (VOLLMAN, 1956; MATSUMOTO, 1962). They are especially common at the beginning and end of sexual maturity, due to the higher number of anovulatory cycles at these times (Table 58).

More recent investigations (FLUHMANN, 1957; VOLLMAN, In: HARTMAN, 1962; MATSUMOTO, 1962; DÖRING, 1966) have confirmed that the corpus luteal phase lasts about 14 days. This was first determined by KNAUS (1929). The hyperthermal phase lasts 12.65 ± 1.63 days on average (MATSUMOTO, 1962) or 12.7 ± 1.7 days (DÖRING, 1966). VOLLMAN (in: HARTMAN, 1962), however, examined 2081 basal temperature curves and found that the hyperthermal phase lasted 14 ± 2 days in only 42.5% (Fig. 30). On the other hand, the preovulatory phase is much more subject to variation.

The *duration of menstruation* varies between 3 and 7 days in 80–90% of normally menstruating women (VASQUEZ-ROCHA, 1943; MATSUMOTO, 1962). FLUHMAN (1934) arrived at similar figures, finding a mean duration of 4.6 days. The duration of bleeding decreases slightly with increasing age (MATSUMOTO, 1962), although menstruation is prolonged with anovulatory cycles (MATSUMOTO, 1962) (Fig. 31).

Information obtained from women investigated about the *severity* of bleeding is very subjective. The number of tampons used gives only an inexact picture of the severity of bleeding, and 8–10 sanitary pads may very well be an average.

More reliable information on the loss of menstrual blood is gained from examination of the amount of iron in the menstrual blood collected (BARER, 1939) or the hemoglobin content of this blood (RYBO, 1966), or by using Fe 59 or erythrocytes labeled with Cr 51 as tracers (BALDWIN, 1961; GÖLTNER, 1964; PRICE, 1964; MATSUMOTO, 1962). The mean blood loss in the normally menstruating woman is 25–50 ml, but varies between 5–180 ml. Bleeding is usually at its maximum on the 2nd day (RYBO, 1966), and 79% of the blood is lost in the first two days (RYBO, 1966). Blood loss becomes less severe with increasing age (MATSUMOTO, 1962). It is slighter in nullipara than in multipara (RYBO, 1966). The monthly loss of iron is 3–30 mg, mean 12 mg (HYTTEN, 1964). The amount of iron (about 120 mg) saved during a pregnancy is thus rather small in comparison to the iron requirements (500 mg during pregnancy, after HYTTEN, 1964). The monthly loss of iron can, however, result in iron-deficiency anemia in poor nutritional states. Thus for example, about 13% women must be refused as blood donors because of anemia, in contrast to 1% of men (HERVEY, 1952).

Menstrual blood does not clot, because of the proteolytic and fibrinolytic enzymes liberated by the decomposing endometrium (PHILLIPS, 1956; ALBRECHSTEN, 1956; FUHRMANN, 1962; BELLER, 1964, 1968; WEISS, 1968). It does not contain fibrinogen, and most of the other factors are diminished. Concentrations of erythrocytes and thrombocytes are also reduced.

Estrogens prevent ovarian atrophy in adult hypophysectomized animals. Follicular atresia fails to occur. These "estrogen ovaries", however, have no follicles with antrum formation, and the interstitial tissue is reduced. Estrogens increase mitotic activity of granulosa cells in the follicles during the antrum phase, and thus cause follicular growth. They are also thought to increase follicular sensitivity to FSH at the same time, whereas progesterone inhibits follicular growth by a contrary action (DICZFALUSY, 1961). Estrogens promote the growth of the glandular tubules in the breasts and the nipples; progesterone and estrogens combine to produce development of the alveoli (FOLLEY, 1948).

b) Extragenital Actions

General effects of estrogens are: the female figure, fat distribution around the hips, development of the female-shaped pelvis, failure of laryngeal conversion, feminine distribution of pubic hair. High doses cause pigmentation of the nipples, labia minora and linea alba. Estrogens exert a mild anabolic effect on the whole body, particularly on the secondary sexual characteristics. Gestagens, in contrast, have a catabolic action. Sexual steroids influence the autonomic reactive state, presumably via autonomic centers in the posterior hypothalamus. There is a total autonomic switch-over during the course of a biphasic ovarian cycle, at ovulation and at menstruation (Fig. 32). (HOFF, 1944; HESS, 1948); during the follicular phase, the parasympathetic system (trophotropic-endophylactic system) becomes particularly reactive, whereas the sympathetic system (ergotropic-dynamogenic) is predominant during the corpus luteal phase (ARTNER, 1954, 1959, 1960; HAUSER, 1960).

Estrogens accelerate epiphyseal fusion and lead to increased calcium deposition in the

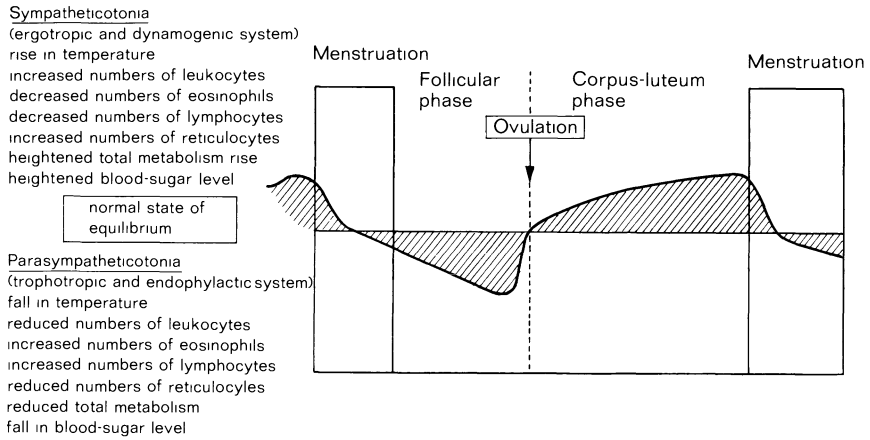

Fig. 32. Changes in the autonomic reaction situation during the biphasic cycle

bones by the stimulation of osteoblastic activity (LANDAU, 1955; GOLDZIEHER, 1956; JOWSEY, 1963; LAURITZEN, 1968). These effects have been observed in cases of gonadal dysgenis treated with estrogens. Gestagens appear to increase calcium mobilization from the bones.

Estrogens influence the composition of the blood by increasing the protein component (DANFORTH, 1946; DÖRING, 1951) and water content (ENGSTRÖM, 1952). The increase in transcortin causes elevated values of the total cortisol although the concentration of free cortisol is unchanged (LAIDLAW, 1962). The concentration of protein-bound iodine also increases (ENGBRING, 1954). Estrogens cause a fall in serum cholesterol levels and in the cholesterol-phospholipid quotient in the blood (KAUFMANN, 1928, 1930; OLIVER, 1953). Oxidative phosphorylation increases in the individual cells under the action of estrogens. ATP formation is doubled, and the uptake of amino acids and phosphates is increased. Protein and RNA synthesis is raised (VILLEE, 1963). Gestagens do not effect oxidative phosphorylation, but more energy for biological use is liberated by activation of adenosine triphosphatase per time unit (SCHREINER, 1965) and amino acid turnover is increased at least in the liver cells. Estrogens cause an increase in extracellular interstitial fluid. Estrogens are assumed to act directly on tissues, causing increased cell and capillary permeability (BUCHHOLZ, 1953) as well as depolymerization of tissue polysaccarides (FRIEDBERG, 1959). 15–20 mg estradiol benzoate causes a mean weight increase of 1 kg after 7–10 days (Fig. 33, LAURITZEN). Gestagens primarily have the opposite effect, since they temporarily increase sodium excretion in the urine. The water-retaining effect of estrogens is especially pronounced when combined with the action of gestagens, as is the case premenstrually (Fig. 34). This secondary synergistic action of estro-

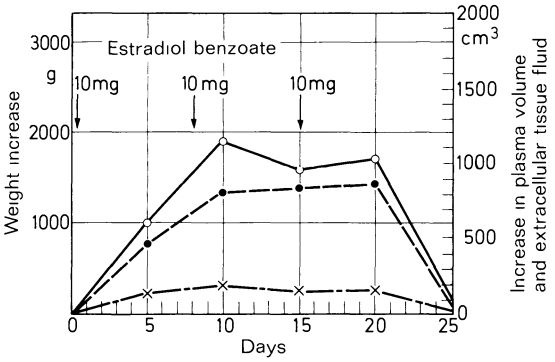

Fig. 33. Increase in weight (○ ——— ○), volume of plasma (× – – – ×) and interstitial tissue fluid (● ——— ●) after administration of 30 mg estradiol benzoate to a castrated woman. (After LAURITZEN, 1961)

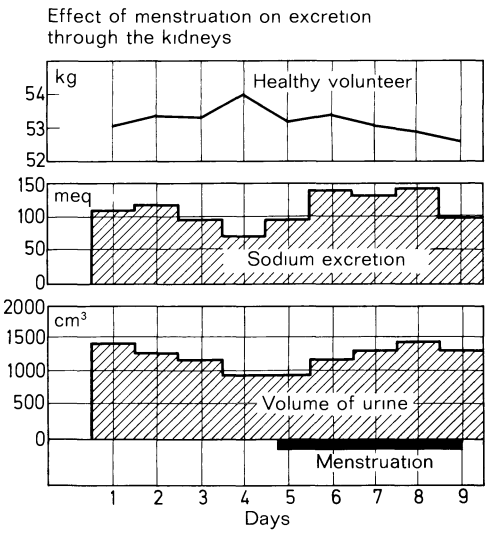

Fig. 34. Effect of menstruation on excretion through the kidneys

gens and gestagens on water retention may be due to the primary natriuretic action of progesterone causing an increase in the secretion of aldosterone and possibly also of desoxycorticosterone (LAIDLAW, 1962). The physiological interstitial water retention present premenstrually is about 700–1500 g (RÖTTGER, 1957) but can be very much more and reach pathologic amounts (up to 6 liters), giving rise clinically to the premenstrual syndrome (p. 616). The hyperemic effect of estrogens in the genital organs, skin, brain and myocardium is probably due to an increase in the amounts of acetylcholine released locally (REYNOLDS, 1931). Estrogens exert a definite hypothermal effect (Fig. 35),

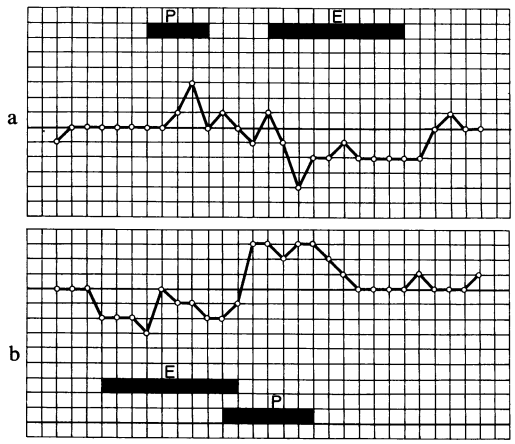

Fig. 35a and b. Effect of progesterone and estrogen on the basal temperature (after ISRAEL, 1950). a) In the castrated woman progesterone causes the basal temperature to rise, while estrogens cause it to fall. b) The same dose of progesterone causes a more pronounced rise in basal temperature after previous administration of estrogens. *P* progesterone, *E* estrogen

whereas gestagens have a thermogenic action causing a rise of 0.4–0.6 °C in temperature during the cycle (BUXTON, 1948; OBER, 1951) (Fig. 35). This is probably due to a central action (ELERT, 1951). The basal temperature curve has a biphasic course in a normal biphasic ovarian cycle (Fig. 69). The action of estrogens on the hypothalamus is dependent on the type and amount of the estrogen, and on the duration and time of onset of the action. Small doses of estradiol and estrone stimulate gonadotropin excretion (SMITH, 1955) (so-called positive feedback). Large doses also produce a temporary increase, probably by stimulating LH release (BROWN, 1947; VORYS, 1965). Short-term estrogen therapy is therefore thought to be successful in a few cases of hypophyseal-diencephalic amenorrhea (KUPPERMAN, 1958). High doses of estrogens for several days reduce gonadotropin excretion to practically nil (WERTH, 1955). The central inhibitory effect of progesterone is significantly less, and 100–400 mg progesterone is required daily to prevent gonadotropin excretion (BUCHHOLZ, 1959, 1964). The central antigonadotropic action of estrogens has gained practical importance in the field of ovulostatics.

Gonadotropin production, secretion and excretion may be increased after discontinuation of long-term estrogen treatment (so-called rebound phenomenon) (HELLER, 1944; HOHLWEG, 1952). This is a secondary effect of inhibition therapy with estrogens, which used to be commonly applied in cases of anovulatory cycles.

Progestagens and gestagens have different activity spectra (EDGREN, 1967) (Table 14). In addition, individual progestagens differ considerably in their biological activity (Fig. 36, SZONTAGH). It is therefore impossible simply to compare their progestative action, and the results obtained depend on the test used. Single progestative properties can be strengthened or diminished by changing the side chains of the steroid nucleus. Thus, for example, the central inhibitory action is particularly pronounced for derivatives of 19-nortestoids and 17α-hydroxy-progesterone, and is one of the three factors essential for the contraceptive action of the "pill" (p. 568). All progestagens have the ability to convert proliferative endometrium (due to estrogens) into secretory endometrium. With the exception of retroprogesterone, progestagens such as progesterone have a definite thermogenic action.

Table 14. Properties of progestins. (After KISTNER, 1964)

Test	Progesterone	17α-hydroxyprogesterone capronate	Medroxy progesterone	Norethisterone	Norethynodrel
Clauberg	+	+	+ + + + +	+	+ ($\frac{1}{4}$)
McGinty	+	+	+ (× 25)	−	−
Deciduoma	+	+	+	−	−
+ Pregnancy	+	+	+ +	−	−
↑ Seminal vesicle	−	−	+	+	+
♀–♂	−	−	+	+	+
↓ Gonadotropin	±	+	−	+ +	+ + +

Most progestagens given orally are many times more potent than progesterone. Their activity is measured in the endometrium and is connected with the stability of the molecule. Progesterone and the ground substances of progestagens, 17α-hydroxy-progesterone and 19-nortestosterone are all typical intermediate products of steroid biosynthesis and are extremely fragile molecules. The stability of these molecules can be increased by changing the molecular structure, by methylation or chlorination at C 6, and by esterification or ethylation at C 17. From these and other processes it has been found that a ketone group at C 3 is not essential for various progestive effects.

Because of these structural changes, progestagens are broken down differently from progesterone. Progestagens are not excreted as pregnanediol. As expected, only a small amount of 19-nortestoids is metabolized into estrogens. They therefore also exert a slight estrogenic effect in addition to their progestative and weak androgenic actions. Regulation of the cycle is therefore more effective than with derivatives of hydroxy-progesterone, which possess no estrogenic action. Breakthrough bleeding and amenorrhea due to atrophy of the endometrium occur less commonly. In contrast, the anti-estrogenic effect of hydroxy-progesterone derivatives is marked. The anti-estrogenic action due to inhibition of the production of endogenous estrogens is, however, not compensated (p. 575) by the amounts of estrogens used in ovulostatics (Table 37).

Progestagens with the $CO\text{-}CH_3$ group at C 17 in the β position and a ketone group at C 20 (derivatives of 17α-hydroxy progesterone) act catabolically, like progesterone, and temporarily increase the excretion of sodium chloride. Progestagens with the side chain at C 17 in the α position (derivates of 19-nortestosterone) have a salt-retaining effect, as do estrogens (LANDAU, 1958).

6. Methods of Estimation and Standards

a) Estrogens

Estrogenic substances can be demonstrated by biological, biochemical, physical and chemical means. The extreme sensitivity of vaginal epithelium to estrogen hormones is put to practical use in the *Allen-Doisy test* (1923) for biological semi-quantitative testing of estrogens. Castrated adult female mice or rats are used as experimental animals. A mouse unit (MU) or rat unit (RU) is the minimum amount of estrogens which produces the estrus phase in the vaginal epithelium in at least 50% of the experimental animals. In 1932, the MU and RU were replaced by the international unit (IU), whose potency corresponds to that of 0.1 μg estrone. It is that amount of test substance which when injected subcutaneously just results in a positive estrus phase in 50% of the castrated female mice. With the introduction of estrogen esters into the therapeutic field, a second standard (the international benzoate unit, IBU) was created for estradiol-3-monobenzoate in 1935. This unit corresponds to the estrogenic activity of 0.1 μg estradiol benzoate.

The following equation is valid:

$$1\ \text{MU} \cong 0.2\ \text{RU} \cong 1\ \text{IU} \cong 0.1\ \mu\text{g estrone.}$$

These equations are only valid for the Allen-Doisy vaginal keratization test, but the values can deviate by several hundred percent. The international unit was abolished as a comparative mass in 1950, since the most important estrogens

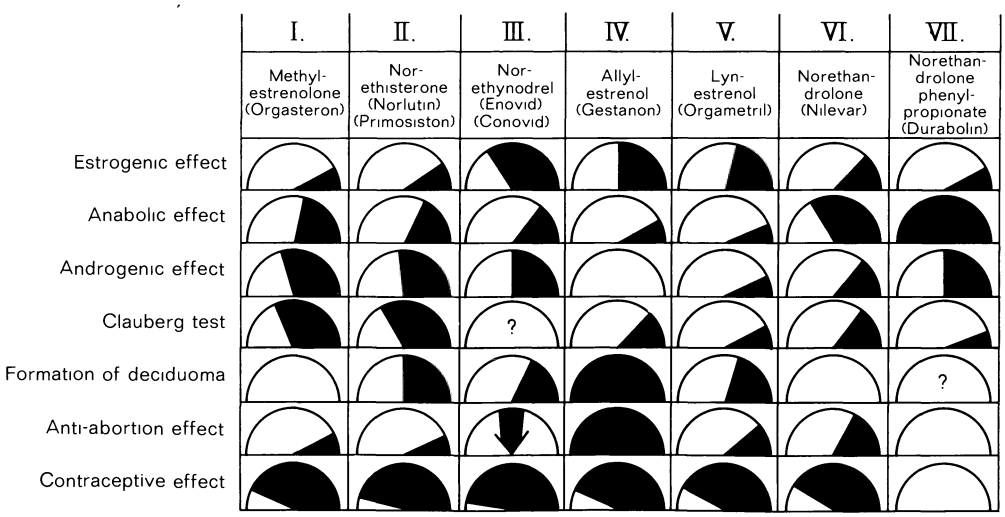

Fig. 36. Spectra of effects of various progestins (SZONTAGH, 1967)

were produced in the purified form and the weight unit could be given.

Instead of standardization in units, information is presented as the number of milligrams required to produce estrus in 50% of the experimental animals. A comparison of the approximate activity of the different estrogens measured in the vaginal epithelium or by uterine growth in the castrated adult mouse following s.c. administration gives to the following picture:

1 mg 17β-estradiol	120000 IU or MU
1 mg estrone	10000 IU or MU (by definition)
1 mg estriol	1500 IU or MU

Thus the potency of estradiol to estrone to estriol is roughly in the ratio 100 : 10 : 1.

1 mg estradiol benzoate	60000 IU or MU
1 mg di-ethylstilbestrol	50000 IU or MU

In comparison to this, the potency of 1 mg conjugated estrogen is equivalent to about 3500 IU of MU given orally.

Since 1955, reliable, quantitative chemical methods have become available for the measurement of estrogen excretion in the urine (BROWN, 1955, 1957; ITTRICH, 1958, 1960). They are based on colorimetric estimation of isolated urinary estrogens with the aid of the Kober reaction. This reaction is based on the fact that estrogens produce a red coloration under certain conditions with a mixture of phenols and sulfuric acid. In our experience, estimation of the excretion of the three classic estrogens for practical purposes is best by BROWN's modified method using 24-hour urine (BROWN, 1957). This test consists of: acidic hydrolysis of the conjugated steroids, several stages of extraction, purification of the ether extracts and separation of the phenol fraction, methylation, chromatographic separation of the different estrogen fractions in aluminium oxide, and quantitative estimation of these fractions as 3-methyl ether by colorimetric means using the Kober reaction. The sensitivity limits lie between 0.6 and 0.8 μg/24 h.

Quantitative demonstration of minute amounts of estrogens such as are found for example in the plasma can be performed by means of ultra-violet spectrophotometry, gas chromatography or radioisotope methods (SVENDSEN, 1960). These methods are, however, available only in a few special laboratories at present.

b) Gestagens

The endometrium of a rodent pretreated with estrogens is the classic substrate for testing the progestative action of a substance. The *Allen-Corner test* (1929) is performed in ovariectomized adult rabbits, and the *Clauberg test* (1930) in juvenile female rabbits.

The rabbit unit of ALLEN and CORNER and of CLAUBERG corresponds to the smallest amount of a test substance which causes complete secretory transformation in the proliferative endometrium when injected in 5 equal daily doses into the experimental animal.

A Clauberg unit corresponds to the progestative action of 0.6 mg progesterone, and the Allen-Corner rabbit unit to that of 1.2 mg progesterone.

The following approximate equation is valid:

1 Allen-Corner rabbit unit
≅ 2 Clauberg rabbit units
≅ 1 international unit
= 1 mg progesterone.

The Allen-Corner and Clauberg tests are not sensitive enough for clinical purposes. They have therefore been modified repeatedly (Table 15) by increasing the sensitivity by local intrauterine application of the test substance (McPhail test, McGinty test).

Table 15. Biological methods for estimation of progestational activity

1929	Corner-Allen test	Adult female rabbits castrated 18 h after mating
1930	Clauberg test	Young female rabbits pretreated with estrogen
1934	McPhail test	Modification of the Clauberg test
1939	McGinty test	Modification of the McPhail test; the test substance is given by the intra-uterine route
1947	Hooker-Forbes test	Ovariectomized mice, to which the test substance is administered by direct injection into the lumen of a ligated uterine segment (hypertrophy of stroma-cell nuclei in the endometrium)

The *Hooker-Forbes test* is the most sensitive biological test for gestagens (1947). 0.0002 μg progesterone is sufficient to produce hypertrophy of the nuclei of the stroma cells of the endometrium of the mouse. The Hooker-Forbes microunit corresponds to the progestative action of 0.0002 μg progesterone. This test is, however, not very specific.

The progestative action of a substance may vary considerably within one species. Reservation is therefore indicated when the results obtained from experiments with animals are

extrapolated to the woman. For example, 17α-hydroxy-progesterone is about 60 times more active than progesterone in the mouse, whereas it has no progestative effect in the human and rabbit (SALHANICK, 1957). Progesterone and 20α(β)-hydroxyprogesterone can be demonstrated reliably during the cycle by gas chromatography in the blood, urine, and tissue. This method is not suitable for routine work in the clinical laboratory, however, and is used for research into special scientific problems.

The methods used for practical clinical purposes rely on the pregnanediol excretion in the 24-hour urine for assessment of the production of endogenous progesterone. Since pregnanediol is derived almost entirely from progesterone, its concentration in the urine reflects the endogenous progesterone production. There are numerous methods of estimation, but the chromatographic method of KLOPPER, MITCHIE and BROWN (1955) has proved the most satisfactory for practical clinical requirements. It is specific and sensitive. The limits of sensitivity are 0.5–1.0 mg/liter. The method consists of: acidic hydrolysis, extraction and purification of the extracts, adsorption chromatography with aluminium oxide, acetylation, purification by oxidation with potassium permanganate, repeated adsorption chromatography and colorimetric estimation of pregnanediol acetate.

Since most pregnanediol is derived from ovarian progesterone, its measurement serves to assess the function of the corpus luteum. It must be remembered, however, that even in normal conditions quite a considerable amount of pregnanediol arises from the adrenals.

Pregnanediol can also be quantitatively estimated by thin-layer (SULIMOVICI, 1965) and gas chromatography (TURNER, 1963).

7. Modes of Administration and General Principles for Adjusting the Doses of Ovarian Hormones

The actions and side effects of ovarian hormones must be known for successful therapeutic results as precisely as possible. Modes of administration, dosage, time and duration of treatment all affect the result substantially. Together with the nature of the compound, they determine the time interval before onset of action, potency, duration of action and possible side effects. Examination of one compound therefore necessitates a considerable time and a necessary number of patients in the same initial condition. It is therefore also essential, even in a large clinic, to use a selection of the numerous drugs available, in order to obtain the necessary experience. Limitation to a few preparations does not necessarily qualify the remaining commercial compounds, since numerous excellent hormone compounds are now on the market.

The following conditions are essential in hormone treatment:

1. the treatment should take up as little as possible of the patient's and the doctor's time;
2. an exact dosage regime should be possible, and it should be possible to estimate the effect in advance;
3. treatment should be as economical as possible.

The results obtained with laboratory animals are only of limited value, and can be extrapolated to the woman only with serious reservations. Only results obtained from clinical trials in the woman can be appealed to in decisions on clinical treatment. The following factors must be considered:

a) the dose required to produce a certain clinical effect (potency);
b) time lapse before onset of action;
c) duration of action;
d) further specifically sexual and general side effects.

The activity threshold must be crossed before a reaction can occur. The threshold value depends on the receptor organ i.e. on the sensitivity of the receptor. The concentration at the site of action, the time lapse before onset of action, and duration of action of a given dose are dependent on the speed of absorption, conversion, and breakdown in the organism and the speed of excretion. They vary according to the mode of administration and the compound used. A series of tests have been developed, based on the numerous receptor organs and the activity qualities of an ovarian hormone. Every fact given about the activity qualities of a sexual steroid should be related to an appropriate test. As they are produced in purified forms steroids are dosed in milligrams. In earlier literature biological units were used since purification of the hormone concerned was not possible at that time. In the evaluation of results obtained from these tests in women, it must be remembered that these results are not statistically significant because it is simply not possible to test a large enough group of suitable women. These results are empirical, and increase in value as the number of women in comparable initial conditions subjected to the treatment under consideration rises.

We differentiate three principal forms of hormone treatment: stimulation, substitution and inhibition.

In cases where hypothalamo-hypophyseal function is absent or insufficient and the ovaries are intact, ovarian function can be successfully reestablished by *stimulation* with hypophyseal gonadotropins. If there is peripheral ovarian failure, the hormonal deficit can only be compensated for by appropriate *substitution* of the absent ovarian hormones.

High doses of ovarian hormones cause temporary ovarian failure by *inhibition* of gonadotropic function of the anterior pituitary. After discontinuation of hormone administration, gonadotropin secretion is rapidly resumed and the amount released may even be elevated (so-called rebound phenomenon). Previously inadequate ovarian function can be normalized in such cases.

Forms of Administration

Ovarian hormones are now available in pure crystallized form. They are either produced synthetically or gained from biological material.

They can be administered orally, parenterally or topically. Depending on the form of application, the same dose gives different absorption times and thus different clinical results (Fig. 37).

Oral administration is simple and economical and facilitates regular hormone intake over a definite time. The oral route is therefore the route of choice. Natural ovarian hormones are absorbed in the small intestine and are subsequently rapidly inactivated in the liver. Because of this, synthetic compounds with corresponding actions are used instead. These substances belong to different groups: 17α-alkylized steroids, such as 17α-ethinyl-estradiol (INHOFFEN, 1938) which is approximately 100 times more effective than estradiol, and synthetic progestagens (19-nortestoids, derivatives of 17α-acetoxyprogesterone) (Figs. 45, 46); when given orally stilbenes (p. 523), non-steroid substances, stilbestrol and chlorotrianisene (Tace), which are stored in adipose tissue and are slowly released, give rise to a depot action. Methallenestril (Vallestril) is also orally effective. Finally, conjugated estrogens must be mentioned. These are a mixture of esters of sulfuric and glucuronic acids of natural estrogens, particularly of estrone and its metabolites. They are fully effective orally since they are water-soluble. They have only a slight effect on the endometrium. Withdrawal and breakthrough bleeding seldom occurs and they are therefore termed as "soft" estrogens in contrast to the "hard" synthetic estrogens. Their effect on the vaginal epithelium is thought to be almost twice as great as that of nonesterized estrogens (GRANT, 1950).

Buccal (sublingual) administration of ovarian steroids to avoid the portal circulation of the liver is little used. Natural estrogens exert a definite although slight effect by this route. It is seldom necessary to give ovarian steroids parenterally. As lipoids they are easily soluble in oil, and can be given intramuscularly in the natural form or as the ester disolved in oil. Natural estrogens are rapidly absorbed; a peak is reached in the plasma on the first day, and a fall with loss of activity occurs after 2–3 days (Fig. 38). Thus, if a longer duration of action is required, administration should be repeated every second day. Esterification with a fatty acid causes a depot action resulting in retarded absorption (Fig. 38). Decomposition and excretion may also be delayed. The duration of action is dependent on the molecular weight of the ester and the dose (Table 16). An analogous depot action is achieved by intramuscular administration of microcrystals suspended in aqueous solution. The rate of absorption is

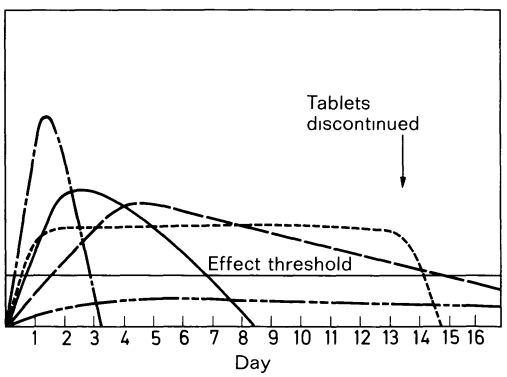

Fig. 37. Schematic comparison of the effectivity of various drug forms (UFER, 1966). ——— i.m. injection, – – – – – prolonged-action injection, ---—---—--- hormone implant, ---------- tablets, — - — - — i.v. injection

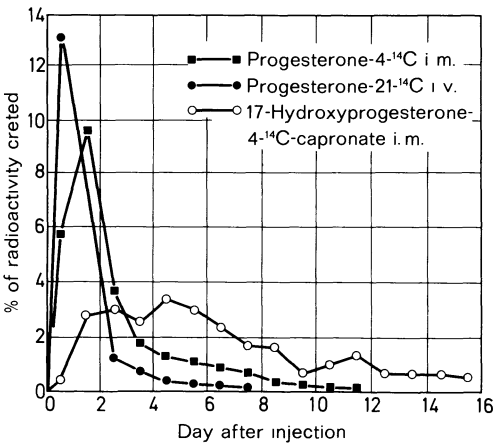

Fig. 38. Different speeds of excretion with radiolabeled gestagens. (After PLOTZ, 1960)

determined by the length of the edge of the crystals. It is, however, often dependent on tissue reaction and circulation variations which impair the desired clinical effect, so they are now seldom used.

Table 16. Examples of the varying duration of effect and saturation dose of ester compounds of estradiol. (After UFER, 1966)

Steroid	Single dose (mg)	Duration effect (days)	Saturation dose (mg)
Estradiol	10	2	40–60
Estradiol benzoate	5	6	25–35
Estradiol valerianate	10	10–14	20
Estradiol undecylate	10	40–60	–

The polymer of estradiol or estriol and phosphoric acid has an excellent depot action when given intramuscularly (polyestriol phosphate or polyestradiol phosphate) (Table 16). Phosphoric acid combines with the estrogen molecule at C 3 and C 17 to form a macromolecule. The compound is stored in the liver and spleen where the estrogen is steadily released by the splitting off of the phosphate portion due to the action of alkaline phosphatase.

Conjugated estrogens and polyestriol and estradiol phosphate can also be given intravenously in an aqueous solution. *Intravenous* administration of ovarian hormones offers no advantages, however, and therefore has no practical significance.

Implantation of crystal pellets into the tissue is now practically obsolete because of the danger of severe uncontrollable hemorrhage.

Ovarian hormones are used *topically* in the form of vaginal ovula and tablets, pessaries, creams and lotions. Rectal application to avoid the liver has gained no practical importance. The same is true of percutaneous administration, where addition of alcohol or menthol improves absorption.

a) Estrogens

The therapeutic importance of estrogens is connected with their specific action on the growth of the female genitalia and mammae, their controlling action on gonadotropic secretion and their influence on specific metabolic processes.

Estrogen treatment has proved satisfactory for the following indications:

1. promotion of development of primary and secondary sexual characteristics (gonadal dysgenesia, ovarian hypoplasia);
2. dysfunctional bleeding, including functional amenorrhea;
3. endometriosis, when used together with progestagens;
4. for improvement of the cervix factor in sterility;
5. suppression of laction;
6. inhibition of ovulation in functional dysmenorrhea and for contraception;
7. prevention of climacteric syndrome (vasomotor and psychological disorders, osteoporosis, atherosclerosis);
8. inhibition of excessive growth during female adolescence.

Undesirable *side effects* which may develop are gastric complaints with nausea when used orally, especially with stilbenes; cyclic disturbances through displacement of ovulation; painful swelling of the breasts, possibly mastopathia cystica; hemorrhage after implantation of crystal pellets or with too high doses during the post menopause; edema due to sodium retention.

There is no evidence of any causal connection between estrogen therapy and carcinoma of the uterus and the breast. A series of methods have been developed to test the *potency and duration of action* of estrogenic substances in the woman. These vary with the receptor organ, and it is essential to give the receptor organ when stating the action of an estrogen.

The vaginal epithelium is the most sensitive test organ reacting to estrogens. The test uses atrophic epithelium from an elderly or a castrated woman, from which hormonal cytological smears are made (p. 534). From these tests it has been deduced that a daily dose of less than 40 µg but more than 20 µg estradiol is necessary to build up the atrophic epithelium completely after 10 days (OBER, 1957). Generally, 10 mg of an estradiol ester given intramuscularly is sufficient (Fig. 39). Vaginal epithelium reacts slowly, and 3–6 days are required for a definite build-up to occur, and 5–10 days for full proliferation. Actual hormonal states and variations can therefore not be detected by this method. Vaginal cytology is particularly suitable for assessing the duration of action of an estrogen (WIED, 1954) (Fig. 39).

The dose of estrogens required to build up the resting endometrium to the full proliferative phase (so-called build-up dose) in the woman is of practical therapeutic interest (Table 16). KAUFMANN determined this dose in a trial with ovariectomized women with intact uterus or in woman with functional amenorrhea and with uterus of normal size (FERIN, 1952). According to KAUFMANN (1932), 25–30 mg estradiol benzoate given in divided doses over 3–4 weeks is required to convert

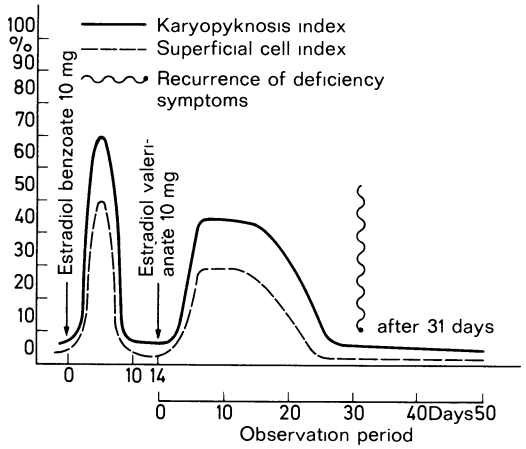

Fig. 39. Effect of 10 mg estradiol benzoate and 10 mg estradiol valerianate on atrophic vaginal epithelium in a 55-year-old woman. (After WIED, 1954)

the resting endometrium to its full proliferative phase. Lower doses are adequate if the estrogens are very potent, e.g. 3 mg over 4 weeks when estradiol crystals are implanted (GIESSEN, 1943). This corresponds roughly to the amount of estrogens produced per cycle (p. 527). 2 mg ethinylestradiol given orally over 3 weeks is sufficient to produce full proliferation. Too high doses of estrogens in the first half of the cycle prevent secretory transformation by causing stromal edema. BISHOP (1950) tested the potency of different oral estrogens by means of withdrawal bleeding in women with functional amenorrhea. If the activity of stilbestrol is set at 100, the potencies for other estrogens are:

Table 17. Efficacy of various estrogens in inhibiting ovulation. (After MARTINEZ-MANAUTOU, 1966)

Substance	Dose	Cases	Cycles	Ovulatory cycles
Ethinyl estradiol	20 µg	10	20	2
Ethinyl estradiol	50 µg	20	44	1[a]
Ethinyl estradiol-3-methyl-ether	20 µg	10	20	2
Ethinyl estradiol-3-methyl-ether	80 µg	18	60	1
Estradiol	1 mg	4	11	5
Estradiol	2 mg	10	18	7
Estradiol	5 mg	10	24	3
Estriol	5 mg	5	7	6
Premarin	1.25 mg	10	18	12
Premarin	3.75 mg	15	17	1
Stilbestrol	5 mg	6	12	1
Total		118	251	41

[a] Secretory endometrium in 12th cycle in one patient.

Stilbestrol	100	Ethinyl estradiol	2562
Dienestrol	26	Stilbestrol sulfate	44
Hexestrol	5	Estrone	5

The duration of administration before onset of withdrawal bleeding also permits comparison of the duration of action of different estrogen preparations (FERIN, 1952). Withdrawal bleeding occurs 4–6 days after discontinuation of orally administered estrogens. The bleeding threshold is exceeded by a daily dose of 50 µg ethinyl estradiol. Potency and duration of action of an estrogen preparation can be tested using the disappearance or reappearance of the post menopausal syndrome as an indicator. To exclude possible psychological influences, tests of this kind should always be performed as double blind trials against placebo.

The following duarations of action have been obtained with a single administration (WIED, 1954; LAURITZEN, 1968):

Table 18. Methods for experimental and clinical testing of gestagens

Animal experimentation	Clinical trials
	Kaufmann trial
	Withdrawal bleeding in secondary amenorrhea
	Manipulation of menstruation
Clauberg test Deciduoma test	Testing on the vaginal epithelium
Testing for local efficacy (MCGINTY, HOOKER-FORBES)	
Anti-oxytocin test on the pregnant rabbit (CSAPO)	Anti-oxytocin test in saline-induced abortion (BENGTSON)
Anticycle test	Quantitative estimation of gonadotropins in urine
Anti-ICSH-Test (reduction of weight of testes)	Determination of the dose inhibiting ovulation (PINCUS)
Androgenic effect on cockscomb and test on seminal vesicle	–
Fetal virilization	–
Estrogenic effectivity (Allen-Doisy test)	Testing on vaginal epithelium Estimation of estrogen metabolites
Anabolic efficacy (levator-ani test)	Metabolic equilibrium
Anti-ACTH effect (determination of weight of adrenal cortex)	Estimation of corticoid metabolites

10 mg estradiol valerianate ~ 1 month
50 mg polyestradiol phosphate ~ 1 month
50 mg polyestriol phosphate ~ 1 month
80 mg polyestriol phosphate ~ 2 months
25 mg estradiol undecylenate ~ $2\frac{1}{2}$ months
50 mg estradiol undecylenate ~ 3 months

The central antigonadotropic action of estrogenic substances is reflected in their efficacy as contraceptives. Ethinyl estradiol (EE) and its 3-methyl ester (mestranol = EEME) are orally much more effective than stilbestrol or conjugated estrogens (Table 17). Doses of as little as 0.05 mg EE or 0.08 mg mestranol daily have proved to be effective inhibitors of ovulation.

b) Progestins

The therapeutic use of progestins is based both on the action of gestagens and various progestagens in preserving pregnancy, and on the differentiating effect exerted on end structures made to proliferate under the influence of estrogens.

They are therefore indicated in the following circumstances (ROLAND, 1965; KISTNER, 1967):

1. threatened abortion;
2. dysfunctional bleeding and amenorrhea (usually combined with estrogens);
3. endometriosis;
4. for contraception and in combination with estrogens for functional dysmenorrhea;
5. inoperable carcinoma of the body of the uterus and the breast.

Even high doses of gestagens produce no undesirable side effects, but progestagens may have side effects because of the activity of the androgenic component. Thus, for example, 19-nortestoids are contraindicated during pregnancy because of the possible virilizing effect on the female fetus (p. 574).

There is a series of methods for testing the very variable spectrum of action of progestins (progestive, androgenic, estrogenicaction) (UFER), and the duration of progestative action and potency (Table 18).

If the ovaries of a sexually mature woman are removed premenstrually, withdrawal bleeding occurs on average 36 hours later. The time

Table 19. Relative efficacy of various progestins, assessed by the amounts needed to produce withdrawal bleeding (in patients with adequate endogenous estrogen or receiving appropriate amounts of exogenous estrogens). (After AYDAR, 1961)

Substance	Dose (mg/d for 5 days)	Total dose (mg)	Time-lapse before onset of withdrawal bleeding (h)
Progesterone	90 –100	450 –500	24–72
Medroxyprogesterone acetate	2.5– 5	12.5– 25	24–72
Ethisterone	20 – 30	100 –150	24–72
Dimethisterone	10 – 15	50 – 75	24–72

Allylestrenol	10 – 15	50 – 75	24–72

Table 20. Doses of different gestagens needed to obtain various effects. (After NEVINNY-STICKEL, 1964)

Compound	Inhibition of ovulation	Minimum doses (mg) necessary for:			
		Transformation of endometrium	Manipulation of menstruation	Arrest of functional bleeding	Withdrawal bleeding in amenorrhea
6-chloro-6-dehydro-17α-acetoxyprogesterone	1–3	20	4[a]	4[a]	2
1,2α-methylen-6-chloro-dehydro-17α-acetoxyprogesterone	2–3	20	3[a]	3[a]	2
9α-fluoro-11-hydroxy-16-methylen-17α-acetoxyprogesterone	1–4	30	20[a]	4[a]	2
17α-ethinyl-19-nortestosterone acetate	4[a]	40	10	8	4
17α-ethinyl estrenol	5	150	10	–	–
17α-hydroxy-19-norprogesteron-17-acetate	10[a]	100	25[a]	>20	20
17α-allyl estrenol	25	250	30[a]	20	40

[a] When estrogens are added.

interval between progestin administration and the development of withdrawal bleeding in a woman with functional amenorrhea but with a uterus of normal size is another test of the duration of action of a progestin, if the uterus is previously prepared with estrogens.

The potency can be deduced from the dose progestin needed to produce withdrawal bleeding (Table 19).

Displacement of menstruation in a normally menstruating woman is probably the most usual method for estimation of the potency of a progestin (GREENBLATT, 1958; SWYER, 1962) (Table 20).

The *transformation dose* is of therapeutic importance. This is the amount of a progestin necessary to transform the proliferative endometrium into the full secretory phase (Table 21). Awareness of the broad spectrum of activity of progestagens is essential since a compound is usually chosen for a single property while its other potential effects are unwanted.

Table 21. Transformation doses of various progestins (estrogens to day 20, progestin from day 15 onward). (Modification after UFER, 1966)

D. Regulation of Ovarian Function

1. Anatomical and Functional Structure of the Hypothalamo-Hypophyseal System

Vegetative and generative functions of the ovaries are regulated centrally. Reception, integration and modulation of proprioceptive and exteroceptive stimuli influencing ovarian function take place in the nuclear areas of the hypothalamus, where they are converted into neural and neurohumoral impulses, the latter being transmitted to the adenohypophysis via neurovascular routes. The anatomical structure is presented and discussed in another section (Chap. II, p. 27) and it will only be mentioned here when necessary to the explanation of central ovarian disorders.

Our knowledge of the functional segmentation of the hypothalamus and its influence on the pituitary and ovaries is obtained mainly from experiments on rat and rabbit, and also on guinea pig, cat and monkey. Results have been gained from section of the pituitary stalk, pituitary transplantations, selective stimulation or destruction of hypothalamic nuclear areas and their associated structures and from extracts of the eminentia mediana. Clinical features arising from tumors and traumatic lesions in the region of the hypothalamus in man are consistent, to a great extent, with the knowledge obtained from animal experiments and permit this to be referred, with caution, to the human.

The large-celled supraoptic and paraventricular nuclei are found in the anterior region of the hypothalamus. The ganglia of these nuclei produce the neurohormones vasopressin (adiuretin) and oxytocin. Their axons form the part of the hypophyseal tract consisting of thick fibers and ending in the infundibular process. The center responsible for the cyclic secretion of gonadotropins (secondary or cyclic inhibitory center/system) also lies immediately under the paraventricular nucleus in the rostral portion of the hypothalamus. In both sexes, the cyclic secretion of gonadotropins appears to be inborn. Castration of newly born male rats results in cyclic secretion. Administration of testosterone to female rats not more than 5 days old causes the loss of this ability and produces continuous estrus (BARRACLOUGH, 1954, 1955, 1966). The same phenomenon is also caused by the transplantation of ovaries to castrated male rats. The already "masculinized" inhibitory center for gonadotropins in these animals lacks the ability to function rhythmically. Polycystic ovaries are also formed in such cases, and they correspond histologically to the ovaries in Stein-Leventhal syndrome in the human. In addition to testosterone, HCG, estrogens and corticosteroids also have the same effect. Such influences must act during intrauterine life on the early development of these centers in man, and it is not known to what extent these influences are involved in the etiology of the Stein-Leventhal syndrome.

This rostral nuclear area is an inhibitory center, since its destruction also leads to continual FSH secretion and to loss of rhythmic LH release. It is assumed that the inhibitory action of estrogens and androgens on FSH

secretion is exerted by way of this nuclear region (FLERKO and SZENTAGOTHAI, 1957) since, for example, transplantation of the ovary to this region in the castrated rat has an effect analogous to that of substitution with estrogens. On the basis of animal experiments, it is assumed that the sensitivity of this center to sexual steroids is much greater before menarche than during sexual maturity. It is known that the pars distalis of the anterior pituitary already contains gonadotropins a few years before menarche (JOHNSON, 1959), and that prepuberal ovaries are sensitive to gonadotropins (PASCHKIS, 1955), but gonadotropins are not released at this stage. This suggests that the onset of cyclic ovarian function at the time of puberty is due to a decrease of the sensitivity of this inhibitory center to sexual steroids. Indeed, bilateral lesions in the anterior hypothalamus in the rat result in premature puberty. Similar observations have been made in boys with hypothalamic tumors, even though these tumors were situated in the posterior hypothalamic region. It is possible in these cases that there is a lesion of the fibers running from the amygdaloid nucleus to the mamillary body, since in rats precocious puberty can also be produced by bilateral destruction of the amygdaloid nucleus in the temporal lobes.

The limbic system (cingulate gyri, hippocampus, amygdaloid nucleus, mamillary body), which is connected with the hypothalamus by very well developed fiber systems, appears to modulate the integrating ability of the hypothalamus, producing a predominantly inhibitory effect (AKERT, 1964). It is now assumed that hypothalamus and hypothalamo-hypophyseal system receive the most important impulses from the limbic system. It represents centers of the endocrine and autonomic regulation systems directly above the hypothalamus. It receives its afferent signals via the reticular system, i.e. information from the surroundings and interior of the body are transmitted to the limbic system via the reticular formation (visceral brain). Increased inhibitory action of the limbic system on the hypothalamic "sexual center" causes loss of libido and impotence, as in psychomotor epilepsy. Conversely there is no motivated sexual behavior in animals with bilateral lesions of the amygdaloid nucleus. External stimuli lead to pointless motor activity and hypersexuality develops. Psychological and autonomic influences also act on the hypothalamus via the limbic system.

The rostral hypothalamic nuclear region acts via the basal tuberal nuclei (ventro- and dorsomedial nuclei, infundibular nucleus, arcuate nucleus) to inhibit gonadotropin release. These nuclei form the primary or tonic system or center. The axons of these nuclei form the tuberohypophyseal tract, which corresponds to the part of the hypophyseal tract consisting of fine fibers. It contains no Gomori-positive granules. These nerve fibers terminate in the region of the eminentia mediana, which forms the most anterior part of the tuber cinereum and the cranial portion of the neurohypophysis. This area shows a dense primary capillary plexus derived from the hypophyseal portal system (POPA, 1930).

2. Releasing (RH) and Inhibitor (IH) Hormones of the Hypothalamus

Impulses from the tuberal nuclear region are transmitted to the adenohypophysis by means of neurosecretions from the hypothalamic nerve endings in the eminentia mediana. These are extremely active substances which are effective *in vivo* and *in vitro* in doses of a few nanograms/gram pituitary tissue. A dose of one μg of the hormone releasing LH induces ovulation in sexually mature female rats (ARIMURA, 1967). These neurohormones are described as transmitter substances or hypophysiotropins and are classified as releasing (RF) and inhibitor factor (IF) or releasing hormones (RH) and inhibitor hormones (IH) according to the type of action. In addition to oxytocin and vasopressin, there are seven other known, well defined neurohormones in the hypothalamus. Five of these cause liberation of anterior pituitary hormones (RH), and two inhibit their release (IH).

It has been known for some years that extracts of animal hypothalamus demonstrate FRH and LRH activity (HARRIS, 1961, 1964; GUILLEMIN, 1955, 1964; MCCANN, 1960, 1962). In 1967 it was also possible to show these activities in extracts of human hypothalamus (SCHALLY, 1967). The highest concentration of LRH was found in the eminentia mediana, but this amount is still so small that only 6 mg LRH would be obtained from the eminentia mediana of 6000 sheep (JUTISZ, 1966). This is also true of FRH. MATSUO (1971) was the first to isolate LRF in a practically pure form and to determine its chemical structure. LRH is a decapeptide with the following sequence:

Pyrogly–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2.

Interestingly enough, this peptide releases not only LH, but also FSH. As different basic peptides (e.g. arginine vasopressin) have a releasing effect on FSH, it has been suggested that the FRH effect of this decapeptide is only

a side effect due to basic groups. There are observations of two principles in the course of isolation.

Methods of investigating FRH activity *in vivo* are based on depletion of the FSH content in the pituitary of male rats (DAVID, 1965). *In vitro*, the liberation of FSH from pituitary cultures is measured (MITTLER, 1964). *In-vitro* experiments have shown that FRH and LRH act directly on pituitary tissue (SCHALLY, 1964). From experiments in animals it can be concluded that RH and IH stored in the eminentia mediana are transmitted to the primary capillary plexus of the hypophyseal portal system and reach their site of action, the pars distalis of the adenohypophysis, via the bloodstream (so-called neurovascular chain). The presence of LRH in hypophyseal portal blood has been demonstrated in rats (FINK, 1967). There is no direct nervous connection between hypothalamus and adenohypophysis, so that active substances from the hypothalamus can only reach the adenohypophysis via the neurovascular chain. The integrity of the hypophyseal portal system is therefore essential for optimal function of the adenohypophysis (POPA, 1930). It is still not known whether RH merely cause the liberation of gonadotropins, or whether they are also necessary for their formation. It is generally assumed that the latter is true.

The content of FRH in the hypothalamus is increased in the castrated animal. It decreases after administration of estrogens. It has also been possible to show that sexual steroids and ovulostatics influence the content of FRH and LRH in the hypothalamus (MARTINI, 1968). This shows that the feedback mechanism regulating the release of FSH and LH passes through the hypothalamus.

Not only releasing elements, but also inhibitory factors are produced in the hypothalamus. Thus, transplantation of the hypophysis into the region of the temporal lobe, for example, leads to continuous secretion of LTH in female rats, and thus to persistent corpora lutea (EVERETT, 1956). It is presumed because of this that there is a hypothalamic LTH- or prolactin inhibitor factor (PRIH) which inhibits prolactin release (MEITES, 1963). In 1965, PRIH was shown to be present in hypothalamic extracts of sheep, cow and pig (SCHALLY, 1965). In addition, radioimmunological studies have shown that porcine hypothalamic extracts reduce the prolactin level in sheep (ARIMURA, 1969). PRIH withstands boiling, diffuses through semipermeable membranes and has a molecular weight between 1000 and 2000. In contrast to the anterior pituitary cells producing FSH and LH, in which secretion mainly occurs only after hypothalamic stimulation, formation and liberation of prolactin appear to be inherent abilities of these cells. In the presence of intact hypothalamo-hypophyseal connections, prolactin secretion is inhibited by the hypothalamic PRIH.

The amenorrhea with galactorrhea sometimes associated with low FSH values and observed in women with Chiari-Frommels' disease and Forbes-Albright syndrome, in pseudocyesis and during medication with chlorpromazine and reserpine etc. (p. 592) imply the loss of hypothalamic influence on the adenohypophysis. Hypothalamic stimulation of the pituitary cells producing FSH and LH and the central inhibitory action on prolactin production are absent at the same time.

Section of the pituitary stalk results in loss of ovarian function. The recovery of ovarian function is parallel to regeneration of the hypophyseal portal system. As soon as this has regenerated, ovarian cycles return and the animal becomes fertile again. If, however, regeneration of the hypophyseal portal system is definitely prevented, for example mechanically, ovarian atrophy occurs. Destruction of the eminantia mediana produces the same effect.

A small degree of FSH and LH secretion appears, however, to occur independently of the hypothalamus. This was deduced from animal experiments. If a large number of pituitaries are transplanted into a hypophysectomized animal, for example into the eye, the ovaries do not atrophy and ovarian function is restored (GITTES, 1965).

Pituitary transplants into hypophysectomized animals (HARRIS, 1957) have shown, further, that the function of the anterior pituitary is dependent on sexual differentiation and the state of maturation of the hypothalamus. If the hypophysis of a male is transplanted into a hypophysectomized female rat, it functions as a female hypophysis, meaning that it retains its pluripotential ability and functions according to female hypothalamic stimulus. If the hypophysis of a prepuberal animal is transplanted into a hypophysectomized, sexually mature animal, it functions like the hypophysis of a sexually mature animal.

To summarize, central ovarian regulation has the following anatomical-functional structure:

the adenohypophysis lacks the ability to form and secrete significant amounts of FSH and LH independently of the hypothalamus. On the other hand, it possesses an inherent capacity to produce and secrete prolactin.

Two regulatory systems are localized in the hypothalamus. They control the formation and release of pituitary gonadotropins:

a) A primary system which exerts a continuous stimulatory effect on formation and release of FSH and LH, and which has a continuous inhibitory action on formation and secretion of prolactin (tonic center). It is localized in the region of the periventricular area and eminentia mediana. Stimuli are transmitted via neurosecretions which are described as releasing hormones (RH). The route of transmission is neurovascular, and the "trade-center" is the eminentia mediana.

b) A secondary system which inhibits the primary center and induces cycles in the woman (cyclic center). Its functional state is influenced by proprioceptive and exteroceptive stimuli. It lies in the rostral hypothalamus just below the paraventricular nucleus.

3. Regulation Mechanism

Hypothalamus, hypophysis and ovaries form a neurohormonal *functional circle* which is self-regulating, adjusting hormone release to momentary needs. Regulation functions according to the feedback, push-and-pull principle also termed the so-called cybernetic principle (Fig. 40). The feedback mechanism is based on the reciprocal relation between sexual steroids and gonadotropins.

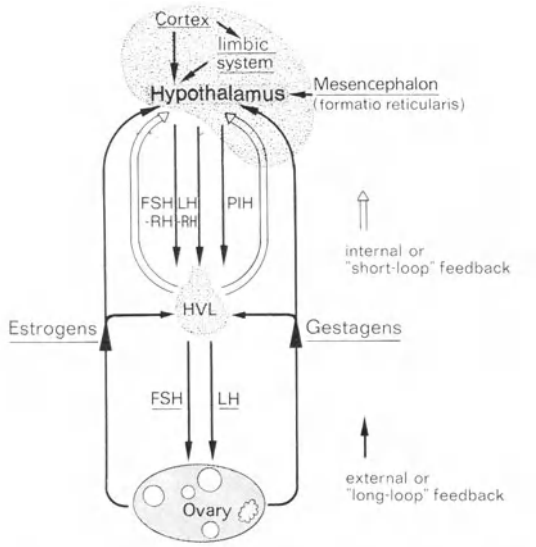

Fig. 40. Diagram of the neurohumeral function circuit: cortex-hypothalamus-hypophysis-ovary

The following main stages occur (ROTHCHILD, 1967): FSH leads to maturation of the follicle. Together with LH, it results in the formation of estrogens, particularly in the thecal cells of the developing follicle. The increasing estrogen secretion during the proliferative phase stimulates the secondary system situated in the anterior hypothalamus, so that the release of FRH is inhibited while LRH release is stimulated at the same time. This results in a reduction of FSH secretion and a simultaneous rapid rise in LH secretion. This then leads to terminal growth of the graafian follicle and to ovulation. The fall in the levels of estrogens after ovulation causes a new rise in FSH release due to the decreased stimulatory effect of estrogens on the hypothalamus. The ruptured follicle is luteinized by LH, whereby progesterone, acting as an antiestrogen, inhibits LH stimulation caused by the rising estrogen secretion. It has not been proved in the human whether the action of progesterone is analogous to that of estrogens, influencing LRH secretion centrally via the rostral hypothalamic inhibitory center. The same can be said of the direct influence of sexual steroids on the adenohypophysis. Regression of the corpus luteum menstruationis and the diminished estrogen production resulting from this together lead again to increased FSH secretion over both hypothalamic centers, and thus to a new ovarian cycle.

From the facts stated so far, it can be deduced that the influence exerted by sexual steroids on the hypothalamus is dependent on the chemical nature of these steroids, their dosage, and the duration of action, and also on the functional state of the hypothalamus ifself. Among the naturally occurring sexual steroids, estrogens exert the strongest central inhibitory effect, which surpasses the action of progesterone by far. In contrast, synthetic progestagens (19-nortestoid and 17α-acetoxy-progesterone) have a pronounced central inhibitory effect. This is exploited therapeutically to inhibit ovulation (p. 568). Estrogens in physiological doses can release ovulation, probably by causing short-term increases in LH secretion. In the same way, pre-ovulatory formation of progesterone is thought to favor ovulation in the human. These pre-ovulatory influences are of short duration. The long-lasting effect of estrogens (and androgens) is analogous to the action of higher doses causing the release of gonadotropins to be inhibited. The long-lasting action of progesterone prevents the liberation of LH in the pre-ovulatory phase. In rats treated with progesterone, ovulation only occurs after stimulation of the eminentia mediana. It is probable that treatment with progesterone results in an elevated LH concentration in the adenohypophysis due to inhibition of the release of LH.

High doses of estrogens and progesterone almost completely suppress secretion of pitui-

tary gonadotropins. A physiological suppression of this type is observed during pregnancy.

The reaction capacity of the hypothalamus is influenced by the functional state of the limbic system (p. 555). The inhibiting action of certain drugs on hypothalamic nuclei must also be mentioned. These drugs are morphine, reserpine, atropine, pentobarbital and chlorpromazine. Their site of action has not been confirmed. Interruption of endogenous stimuli from the reticular formation is under discussion. According to recent investigations (KELLER, 1968), clomide also exerts its anti-estrogenic action centrally in man. If estrogens are given to women with hypergonadotropic amenorrhea, there is a reduction of gonadotropin excretion (FSH and LH). On the other hand, if clomide is given together with estrogens, there is a significant rise in LH release.

In addition to the indirect, external feedback mechanism already described, there may be a direct internal feedback (the so-called short feedback mechanism) (DAVID, 1966), between pituitary and hypothalamus (SZONTAGH, 1964).

The peripheral regulatory system, the autonomic nervous system and the peripheral endocrine organs interfere with the centrally controlled cybernetic system. Loss of this intervention leads to equilibrium disorders. The peripheral regulatory system is composed of various parts – the ovaries as chief site of formation of estrogens, the liver as site of breakdown and conversion, kidneys and intestine as site of excretion, tissue as depot, and blood as transport agent. This peripheral system influences the blood level of sexual steroids considerably. Finally the autonomic nervous system determines circulation and course of

Table 22

International name	Synonyms	Chemistry and physical data (ODELL, 1964)	Origin (HERLANT, 1966)	Effect
Hypophyseal gonadotropins				
FSH	Follicle-ripening hormone, follicle-stimulating hormone, prolan A, gonadotropin I, thylacentrin, gametokinetic hormone, epithelial factor	Glycoproteid: protein + mannose. Mol. wt: 41000. Soluble in water, soluble in trichloroacetic acid	γ cells (amphophile = chromophobe cells)	Growth of secondary and tertiary follicles
LH = ICSH = luteinizing = interstitial cell stimulating hormone	Lutinizing hormone, corpus luteum-ripening hormone, metakentrin, ovulation hormone, prolan B, gonadotropin II	Glycoproteid: protein + mannose. Mol. wt: 30000. water-soluble, insoluble in trichloroacetic acid	δ cells (hypocyanophile cells)	With FSH: estrogen synthesis and release of ovum; formation of corpus luteum
LTH = LMTH = luteotropic hormone, luteomammatropic hormone	Luteotropic hormone, prolactin luteotropin, lactation hormone, lactogenic hormone, galactin, mammotropin, gonadotropin III	Simple protein. Mol. wt: 32000. hardly soluble in water, soluble in slightly acidic methyl and ethyl alcohol	α cells (eosinophilic cells)	In rodents: stimulates endocrine function of corpus luteum, preserves corpus luteum
HMG = human menopausal gonadotropin	Menopausal gonadotropin, castrate's gonadotropin	Glycoproteid: protein + hexose. Mol. wt: 36000. water-soluble	γ + δ cells	
Placental gonadotropins				
HCG = human chorionic gonadotropin	Chorionic gonadotropin, placental gonadotropin, pregnancy urine hormone (PU), anterior pituitary-like hormone (APL)	Glycoproteid: Mol. wt: 29000–30000. water-soluble	Trophoblast	Similar to LH
PMS = pregnant mare's serum gonadotropin	Serum gonadotropin, equine gonadotropin	Glycoproteid: protein + galactose. Mol. wt: 30000 water-soluble	Trophoblast or decidua	Similar to FSH

reaction attitude of the peripheral endocrine glands and their reacting organs by direction of the effect and tone.

4. The Pituitary Gonadotropins (Table 22)

The ovaries of a non-pregnant, sexually mature woman are controlled by pituitary gonadotropins, follicular stimulating hormone (FSH) and luteinizing hormone (LH), also known as the interstitial cell-stimulating hormone (ICSH). It has only recently been successfully proved, after numerous objections, that FSH and LH are two different pituitary gonadotropins. The activities of the two hormones can be more or less completely separated by chromatography (REICHERT, 1964; ALBERT, 1965), and they also show differences in metabolism (p. 560) (KELLER, 1966). Trypsin destroys 99% of LH, whereas FSH is not affected. There are still no FSH and LH preparations which are absolutely chemically and immunologically pure. Only highly purified pituitary or urinary FSH and LH are available (ROOS, 1964). Thus, NIH-FSH-S_1 contains only 0.6% LH (PARLOW, 1961). In contrast to the situation in the rodent, the luteotropic hormone (LTH) seems to have no effect on ovarian regulation in the human. FSH and LH are sufficient to produce a biphasic cycle with normally functioning corpus luteum in hypophysectomized women (GEMZELL, 1964). Nor is LTH identical to prolactin in the woman.

Structure. FSH and LH are glucoproteins (GÖSCHEL, 1960) containing the carbohydrate mannose. Apart from containing glucosamine, sialinic acid is bound terminally to the protein (Table 23). This forms an integral component of the biological potency of these two hormones. Enzymatic splitting of sialinic acid by neuramidase leads to a loss of at least 97% of the activity. Splitting off of mannose also results in a definite loss of activity. Although pituitary FSH and urinary FSH have the same qualitative composition and clinical action, they appear to differ in molecular weight (ROOS, 1967) (Table 23).

Table 23. Chemical and biological properties of human FSH in hypophysis and urine. (After P. ROOS, 1967)

	Hypophyseal FSH	Urinary FSH
Molecular weight	41000	28000
No. of amino acids	254	208
Residues per mol		
Hexose	39	14
Glucosamine	30	8
Sialinic acid	8	2
Biological activity IU/mg	14000	780
Yield	2 µg/hypophysis	1 µg/liter urine

a) Production and Plasma Content

Hypophyseal gonadotropins are formed in the anterior pituitary. It is still not clear what type of cells synthesize them (HERLANT, 1966). Whereas the fetal hypophysis appears to contain very small amounts of gonadotropins, there is none present in children before the 6th year (Table 24). On the other hand corticotropin and somatotropin are present in the infantile hypophysis in similar concentrations to those in the adult.

The lack of pituitary gonadotropins during infancy is substantiated by the observation that gonadotropins cannot be demonstrated in the urine until 3–4 years before menarche. The appearance of pituitary gonadotropins in the urine before the 9th year of life is described by JOHNSON (1959) as pathologic. They should, however, be present in the urine not later than the 13th year.

FSH and LH content in the hypophysis rises during the individual phases of life of the woman right into senility, except during pregnancy.

During pregnancy, the gonadotropin content in the pituitary is low, due to the high level of sexual steroids. Conversely, the pituitary contains the largest amounts of gonadotropins after the menopause (Tables 24, 25). Release and probably also formation of gonadotropins results from the influence of releasing hormones of the hypothalamus (p. 555).

Investigations on the *transport* of gonadotropins *in the blood* have yielded very variable results. It is possible that they are transported in Cohn fractions II and III, which include β-lipo-proteins and γ-globulins. In sexually mature women, plasma values of total gonado-

b) Metabolism and Excretion

Very little is known about the metabolism. The functional state of the liver does not seem to influence gonadotropin levels in the blood and urine. Gonadotropins are excreted through the kidneys, although these hormones are highly molecular glycoproteins. Comparative studies in plasma and urine have shown that the average renal clearance for total gonadotropic activity is 0.17 ml/min (APOSTOLAKIS, 1960), 0.58 ml/min for FSH, and 0.14 ml/min for LH (KELLER, 1966). It is 0.95 ml/min for HCG (LORAINE, 1950). Only a small proportion of plasma gonadotropins are excreted through the kidneys. Most of the secreted gonadotropins are probably inactivated in some still unknown manner. The obviously different excretion ratios for FSH and LH also add to the evidence that they are two different substances. These ratios also explain why urinary and plasma gonadotropins are qualitatively different in composition (Table 23). Gonadotropins are not demonstrable in the urine until 3–4 years before menarche. In adolescence there is an irregular excretion pattern with isolated FSH and LH peaks until regular biphasic cycles are established. Excretion values of gonadotropins exhibit a characteristic course in the sexually mature woman (ROSEMBERG, 1965; MCARTHUR, 1958; FUKUSHIMA, 1964). Both gonadotropins are demonstrable throughout the cycle, LH showing a higher peak than FSH at the time of ovulation (1st to 6th day and 1st to 2nd day respectively after fall in temperature). At mid-cycle, LH levels in the urine reach 40 IH/24 h (Fig. 41). The total gonadotropic activity (TGA) in the 24-hour urine specimen varies between 0.4–2 mg of the 2nd IRP-HMG (Table 27).

A considerable change in the FSH/LH quotient can arise in pathologic endocrine states (Table 28). These are only temporary values and other investigators have obtained different results. The normal LH titer and the almost absent FSH titer are striking findings in precocious puberty, and it can be assumed from this that premature stimulation of the

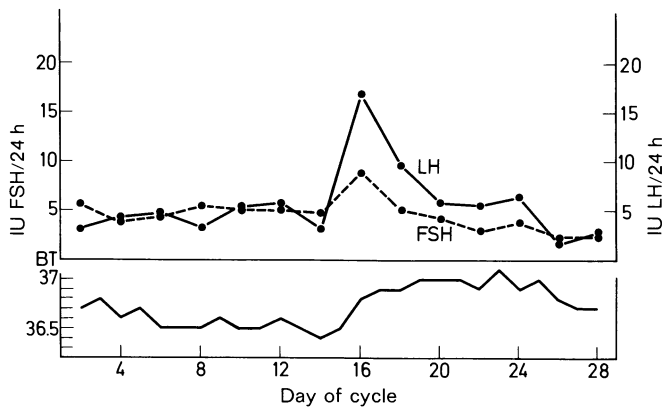

Fig. 41. Excretion curves for FSH and LH during the normal biphasic cycle (after KELLER, 1970). (Plotted from pooled values in 7 cycles)

Table 27. Normal gonadotropin excretion values in woman. (After KELLER, 1969)

Stage of life	TGA mg-eq./24 h	FSH IU/24 h	LH IU/24 h	Characteristics
Childhood	0.2	2	3	No gonadotropins demonstrable until 3–4 years before menarche
Adolescence	0.2–1.0	2–8	3–10	Irregular pattern of excretion with separate peaks for FSH and LH
Cycle	0.4–2.0	4–15	2–8	Mid-cycle rise in FSH and LH, LH up to 40 IU
Pregnancy	–	–	–	Not determinable due to presence of HCG, probably secretion of FSH and LH is copious
Lactation	0.4–2.0	4–10	2–8	Situation similar to that during cycle, isolated LH peaks possible
Premenopause	3.0–40	40–400	15–90	Rapid rise of FSH values, less pronounced rise in LH values
Postmenopause	3.0–15	40–200	10–60	High gonadotropin values persisting into senium in absence of cycles

Table 28. FSH and LH excretion in endocrine diseases (KELLER, 1968)

Clinical diagnosis	Cases	FSH excreted IU/24 h	LH excreted IU/24 h	FSH/LH
Pubertas praecox	3	1.3–2.0	1.8–3.7	0.5–0.8
Fertile eunuchs	3	2.4–8.3	5.9–9.5	0.4–0.9
Hypophyseal adenoma	1	2.5–3.5	4.3 4.5	0.6–0.8

48-h to 144-h aliquots urine. Extraction after ALBERT. Determination of FSH after STEELMAN and POHLEY. Determination of LH by ascorbic acid depletion test after PARLOW. Standard: 2 IRP HMG.

sexual steroids is due only to LH. The relatively high production of LH in fertile eunuchs indicates peripheral failure and not primary pituitary insufficiency. Whereas the activity of both FSH and LH is elevated in ovarian dysgenesia, it is predominantly FSH which is elevated in cases of male gonadal dysgenesia and in castrated women.

During the climacteric, FSH values rise rapidly and LH to a lesser extent. These values remain high right into senility when cycles disappear (Tables 26, 27). Both values fall again slightly after the 70th year.

c) Biological Action

One action of FSH is to stimulate follicular maturation. Estrogens are produced under the combined influence of FSH and LH, predominantly in the thecal cells of the growing follicle. LH also stimulates the 20- and 22-hydroxylation of cholesterol, producing pregnenolone in the process. (ISCHII, 1963; MASON, 1961). Increasing amounts of estrogen act on the hypothalamus and probably cause a decline in FSH secretion by means of the feedback mechanism. The increasing estrogen titer may stimulate the release of LH. The terminal spurt of growth of the Graafian follicle and ovulation are due to the rapid increase in LH liberation. The number of follicles which reach maturity and the rate of maturation seem to be constant for each species (GEMZELL, 1969). Administration of additional FSH increases the number of mature follicles, but the speed of maturation is unchanged. In order to produce the number of fertile ova specific to any one species, the amount of FSH secreted by the anterior pituitary must be constant. In the human, only one follicle of the original group of maturing follicles reaches full maturity and ovulation; the others become atretic. The mechanism of this selection is not known.

The ruptured follicle becomes luteinized under the increasing influence of LH. Synthesis of progesterone and estrogens is stimulated in the corpus luteum. Progesterone inhibits LH secretion, either by a direct central action or by its antiestrogenic effect. This leads to regression of the corpus luteum about 10 days after ovulation in the absence of a pregnancy. The fall in the estrogen levels causes the feedback mechanism to fail and there is a new

increase in FSH during menstruation. LH secretion, however, remains low, since the low estrogen production is insufficient for stimulation of LH secretion. Thus, a new cycle is started.

In recovery tests in young women with primary amenorrhea and low urinary excretion of FSH it was possible to recover 12.8–20.8% (average 17%) of the FSH administered from the urine (GEMZELL, 1969). During a normal 28-day cycle, about 360 IU FSH (2nd IRP-HMG) can be found in the urine. About 170 IU FSH are found during the first days of the cycle. The hypophysis of a normally ovulating woman secretes about 2000 IU FSH during a four-week cycle, about half of it before ovulation (GEMZELL, 1969).

d) Estimation

In contrast to the estimation of HCG, that of pituitary gonadotropins in the urine and plasma is still associated with considerable difficulty. Pituitary gonadotropins can be detected by

Table 29. Most usual biological methods for the estimation of gonadotropins. (After KELLER, 1971)

Test	Specificity	End point	Duration of test (days)	Sensitivity	Precision
Mouse uterus test (KLINEFELTER, 1943) (MU test)	TGA	Weight of uterus in infantile mice	3	0.03 mg-eq. 2nd IRP	0.06–0.15
Rat ovary test (RO test)	TGA	Weight of ovaries in infantile rats	3.5	0.2–0.4 mg-eq. 2nd IRP	0.10–0.24
Augmentation test after STEELMAN and POHLEY (1953)	FSH	Weight of ovaries in HCG-stimulated infantile rats	3.5	1–2 IU FSH	0.10–0.24
Augmentation test after BROWN (1955)	FSH	Weight of ovaries of HCG-stimulated infantile mice	3.5	0.5–1 IU FSH	0.20–0.50
Ventral prostata test (VRP test) (GREEP 1941)	LH (ICSH)	Weight of ventral flap of prostata of infantile, hypophysectomized rats	4.5	0.4–0.8 IU LH	0.15–0.40
Ovarian ascorbic acid depletion test after PARLOW (1958, 1960) (OAAD test)	LH (ICSH)	Fall in ascorbic acid in ovary of infantile pseudopregnant rats	1	0.3–0.6 IU LH[a]	0.10–0.28

[a] When NIH LH is used as the standard preparation the sensitivity is approximately 10–12 times higher.

Table 30. Most usual methods for extraction of gonadotropins from urine and plasma. (After KELLER, 1971)

Method	Principle	Processing time (hours)	Yield
1. Urine			
Kaolin and acetone method after ALBERT (1955)	Adsorption of gonadotropins onto kaolin at acid pH, elution with ammoniac and precipitation with acetone	1–1.5	50–200 mg/24 h
Kaolin and acetone method after LORAINE and BROWN (1954)	As above	2–3	150–500 mg/24 h
Tannic acid method after JOHNSON (1959)	Precipitation of gonadotropins in unacidulated urine with gallic acid with addition of Hyflo-Supercel, elution with ammoniacal alcohol, precipitation with alcohol	1–1.5	20–100 mg/24 h
2. Plasma			
Acetone precipitation after APOSTOLAKIS (1960)	Precipitation of total proteins with acetone, dialysis against physiological saline	1	60–80 mg/ml
Alcohol and ammonium acetate method after KELLER and ROSEMBERG (1965)	Precipitation of total proteins with alcohol, extraction with ammonium actetate and alcohol, reprecipitation with alcohol	1–1.5	5–12 mg/ml

biological, immunochemical or radioimmunological means.

Biological methods are now principally used for routine investigations (KELLER, 1963). They are based mainly on stimulation of the genital organs of rats and mice (Table 29) and involve two steps: concentration of gonadotropic substances from urine or plasma (Table 30), and biological testing of the extracts (Table 29). Since the concentration of pituitary gonadotropins is low in urine and even lower in plasma, accumulation is necessary for the biological estimation. We have found that among the numerous extraction methods (Table 30) from urine, the *kaolin-acetone method* after ALBERT (1955), modified after HEINRICHS and EULEFELD (1960), has proved most suitable for routine laboratory work (Table 31). The average recovery is 93.7%, and the method is quick, cheap and simple to carry out.

Immunochemical methods, in which gonadotropins are estimated with the aid of specific immune antibodies, are increasing in importance. This is especially applicable to estimations of HCG and LH, since there is a cross-reaction between HCG and LH. Indeed, the estimation of LH activity by means of an antiserum to highly purified pituitary LH gives practically identical values to those obtained when antiserum to HCG is used instead. Immunological measurement of LH in the urine is very sensitive, simple, and quick. It gives a reliable picture of the excretion pattern for LH (Fig. 42).

Table 31. Extraction of hypophyseal gonadotropins from urine after ALBERT. (After KELLER, 1971)

Acidulation of the 24-h urine to pH 4.5 with glacial acetic acid and addition of 20 g kaolin. Mix with magnetic stirrer for 3 min.
↓
Filter of the urine in automatic rapid filter (Spincraft) and was the residue with 2 liter water at pH 4.5.
↓
Elution of the gonadotropins with 100 ml 2 mol NH_4OH pressed through twice. Final wash with 30 ml distilled water.
↓
Adjust to pH 5.5 with glacial acetic acid and extract with 2 volumes acetone.
↓
Leave to standard at 4°C for 30 min, centrifuge, dry the precipitate.

However, there is still no proof that the reaction for LH is specific, and that augmentation factors are not determined at the same time. LH measured biologically is not identical to LH estimated immunologically. It is thus possible that the biological extraction necessary alters the biological action of the gonadotropins. Obtention of a genuinely pure preparation for the production of specific antibodies is the greatest problem in immunological methods.

Immunochemical assay of FSH in the urine has recently also become possible. In the serum,

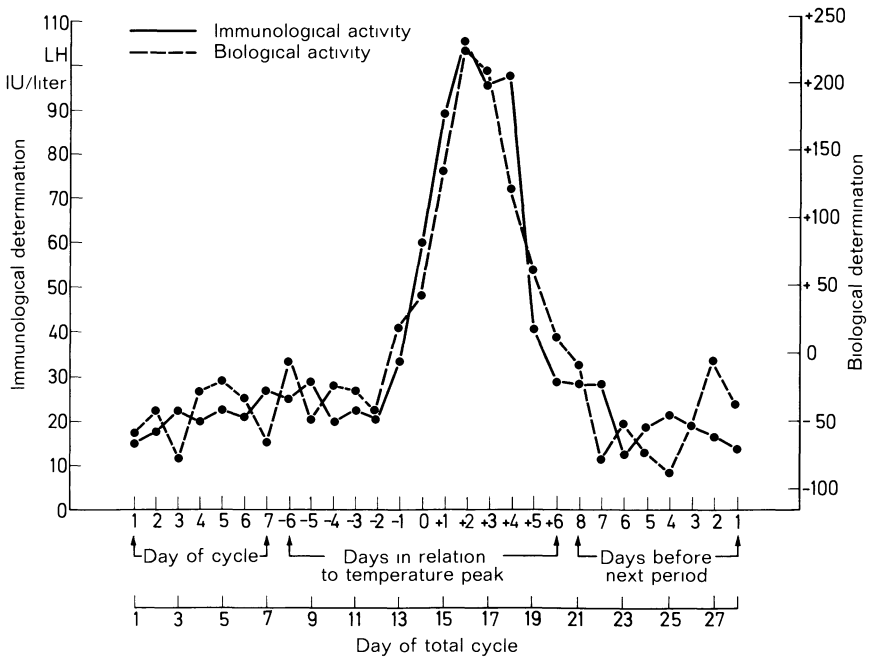

Fig. 42. Excretion curve for LH during a normal cycle, plotted from values determined by a biological (ventral prostate test) and an immunological method. (After WIDE, 1966; from MCARTHUR and INGERSOLL, 1958)

plasma, and in certain conditions in the urine, FSH and LH can be estimated by *radioimmunoassay*. As this is a rather sophisticated method it is still performed only in a few specialized laboratories.

Chemical methods, which are still based on the demonstration of glucoproteins, are not specific enough. Further progress is necessary before anything more can be learnt about the chemical structure of gonadotropins. Lack of a chemical method for the quantitative estimation of gonadotropins and of chemically pure gonadotropin are the main reasons why there is still no reliable, generally recognized weight unit for gonadotropins.

The standards in use for pituitary gonadotropins and the conversion factors are presented in Table 32. The 2nd international reference preparation (2nd IRP) is the standard preparation used at present. It is obtained from postmenopausal urine, and one ampoule contains 5 mg active material or 40 IU FSH or LH.

Table 32. Usual standards for hypophyseal gonadotropins. (After KELLER, 1971)

Preparation	Application	Unit	Conversion
HMG 24 (1st IRP)	TGA	mg-eq.	1 mg ~ 0.06 mg 2nd IRP
	FSH	mg-eq.	1 mg ~ 0.15 IU FSH
	LH	mg-eq.	1 mg ~ 0.50 IU LH
2nd IRP	TGA	mg-eq.	1 mg ~ 8 U ~19 mg HMG 24
	FSH	IU	1 IU FSH: ~0.045 mg NIH FSH S_1 ~7 mg HMG 24
	LH	IU	1 IU LH: ~0.015 mg NIH LH S_1 ~2 mg HMG 24
NIH FSH S_1	FSH	mg-eq.	1 mg ~ 22 IU ~150 mg HMG 24
NIH LH S_1	LH	mg-eq.	1 mg ~ 67 IU ~135 mg HMG 24

Conversions for LH are based on the ventral prostata test. Other factors must be considered if the OAAD is used.

e) Therapeutic Use

Due to their ability to stimulate follicular growth and to induce ovulation, pituitary gonadotropins are used in the treatment of anovulatory sterility. Originally, extracts from animal pituitaries and from the serum of pregnant mares (PMS = pregnant mare's serum) were used as FSH preparations. The results obtained with these extracts were, however, disappointing, since these heterologous gonadotropins showed an antigenic effect in man. So-called antihormones are formed, which weaken or inhibit gonadotropic activity. In addition, the action of these heterologous proteohormones is probably inconstant in man due to species-specificity. Quite often allergic reactions were produced. Ovulation was successfully induced in women with amenorrhea for the first time in 1958, by administration of FSH from human pituitaries with human chorionic gonadotropin (HCG) (GEMZELL, 1958).

It was shown subsequently, in 1960, that FSH obtained from the urine of postmenopausal women, was clinically active (LUNENFELD, 1960). This substance was given the name human menopausal gonadotropins (HMG) and came onto the market in the purified form in 1964, under the name Pergonal (75 IU FSH + 75 IU LH) (DONINI, 1964). Humegon (75 IU FSH) is also obtained from postmenopausal urine and is used for the same purpose.

Ovulation release due to human FSH and HCG is dependent on various factors (GEMZELL, 1969):

1. the ratio of FSH to LH in the preparation used;
2. the total dose of FSH/LH and HCG;
3. the time at which FSH/LH and HCG are given.

The ratio of FSH to LH can, seemingly, vary between 1 : 2 and 2 : 1 with no significant loss of activity. From recovery experiments with physiological doses it has been calculated that 75–100 IU of FSH must be administered daily for 8–10 days to produce ovulation (p. 562). If no reaction occurs, the daily dose can be increased to 250 IU, although the risk of overstimulation increases rapidly (p. 600, 630). There is no necessity to separate human LH for therapeutic purposes. Large amounts of chorionic gonadotropin (HCG) occur in pregnant urine, and the luteinizing effect of this HCG is adequate. HCG is usually given in single doses; as a rule, 5000 IU are given daily for 3 days, the first dose of HCG usually coinciding with the last of FSH. The results obtained with this method are very good with the right choice of patients (GEMZELL, 1958, 1963, 1966, 1967, 1969; TAYMOR, 1963; ROSEMBERG, 1964; BETTENDORF, 1964; VAN DE WIELE, 1965; KISTNER, 1966). (Refer to p. 600, 630 for more about treatment.)

E. Ovulation

Ovulation is the central event in a normal biphasic ovarian cycle. During this process, the fertile ovum leaves the ovary and reaches the tubal ampulla by way of the collecting mechanism.

The processes responsible for ovulation are the same in all spontaneously ovulating animals (e.g. mice, rats) and in women. The preovulatory increase in the ovarian secretion of progestin (EVERETT, 1944) causes the peak of preovulatory LH secretion due to increased LRH secretion (MCARTHUR, 1959). This peak in turn leads to the terminal spurt of growth of the Graafian follicle and to ovulation.

Anatomy, endocrinology, and central regulation of ovulation are discussed on p. 512ff., 544ff.

1. Influence of Thyroid Gland and Adrenal Cortex on Ovulation

A high percentage of female patients with thyroid dysfunction, whether hypothyroidism or hyperthyroidism, suffer from anovulatory cycles with oligomenorrhea or amenorrhea and from dysfunctional hemorrhage depending on the severity of the thyroid disorder (SCHNEEBERG, 1967). The pathophysiology underlying ovarian dysfunction in these conditions is, however, not exactly known at present. Experiments in rabbits, mice, rats and baboons show that thyroid hormones can intervene at various stages in the complex mechanism of ovulation. Thus the injection of thyroxine leads to an elevated concentration of thyroxine in the paraventricular nucleus and eminentia mediana (FORD, 1958). Surgical removal or medical inactivation of the thyroid gland causes FSH secretion to be increased and LH secretion to be reduced, resulting in follicular persistence and endometrial hyperplasia (CHU, 1945), and also in increased sensitivity of the ovaries to exogenous gonadotropins (FLUHMANN, 1934; MANDL, 1957). It is assumed that thyroxine stimulates LH secretion and inhibits formation of LH (CHU, 1945).

Whereas there is no doubt that there is an etiological connection between thyroid dysfunction and anovulation, it is doubtful whether there is any such connection in sterile women who are euthyroid. Much has been written about the value or otherwise of treating female infertility with thyroid hormones (ENGLE, 1959; KUPPERMANN, 1959; KOTZ, 1961; STARR, 1962, 1966; ROGERS, 1963; LLOYD, 1964; SCHNEEBERG, 1967). Although ovulation induction by thyroid hormones has not so far been statistically proved in sterile euthyroid patients, there are still people who support this form of treatment of female sterility (ENGLE, 1959; KUPPERMANN, 1959; STARR, 1962). However, since the introduction of human gonadotropins and antiestrogens into the treatment of anovulation, the empiric treatment with thyroid preparations for female sterility has not been considered so important. In our opinion this form of treatment is not justified in clinically euthyroid women in whom laboratory findings are normal. The objection that subclinical states of hypothyroidism may be overlooked is in our opinion not valid.

It has long been known that there is a functional relationship between *adrenal cortex and ovary*. Disturbances of adrenocortical function associated with increased production of sexual steroids, such as Cushing's syndrome and the adrenogenital syndrome, are connected with ovarian dysfunction particularly often. It can be shown experimentally that adrenalectomized rats have no ovarian reaction to injected gonadotropins. This observation is equivalent to the clinical finding of amenorrhea in female Addisonian patients.

Despite numerous studies (JEFFERIES, 1966) the exact nature of the mutual influence between adrenal cortex and ovary are still not clear. The increased androgen production in Cushing's syndrome and the adrenogenital syndrome suggests that this may interfere with ovarian function via the hypothalamus and pituitary. This conjecture is supported by the observation that numerous women with ovarian dysfunction show signs of acne, and hirsutism and have a slightly higher 17-ketosteroid excretion than normal. It is, however, true that women with abnormally high androgen production can be fertile, and also that even slightly higher androgen production than normal can lead to considerable ovarian dysfunction. It is possible that the increase in adrenal estrogen production which is often found at the same time is etiologically involved in the ovarian dysfunction.

Prolonged cortisone treatment can lead to normalization of ovarian function in some cases. JEFFERIES (1963) reported on 104 women with ovarian dysfunction, in whom gonadotropin excretion was normal or low and in whom there was no tumor or primary pituitary disturbance. These women received 10 to 20 mg cortisone daily for 6 months. Ovarian function improved in 4 out of 5 patients, and 2 of every 3 sterile women conceived when the husband's semen was normal.

2. Proof of Ovulation

Despite all efforts, there is still no reliable and simple method of estimating the exact time of ovulation. Even success of artificial insemination at the first attempt and pregnancy arising after a single act of intercourse permit only approximate dating of ovulation, since the lives of the ovum and sperms are of un-

certain duration. Exceptionally, ovulation can be visually observed during culdoscopy, culdotomy or laparotomy, but these methods are not suitable for practical purposes. Biopsy of the corpus luteum for the histological assessment of its age (HARTMANN, 1955) is only possible in special cases and hardly offers any more information than is obtained from the endometrial biopsy (p. 566).

The occurrence of ovulation can be shown by a number of other methods, some of which are indirect and not entirely reliable. Pregnancy is the only certain proof of ovulation. In all other cases, several indirect methods must be employed together to show that ovulation has occurred. Since none of them is fully reliable, the result of any single test is a mere indication. All the tests are based on the formation of progesterone in the corpus luteum.

a) Pregnanediol Excretion in the Urine (Fig. 43)

Less than 1.5 mg pregnanediol is excreted in 24 hours until shortly before the fall in urinary estrogens and shortly after the basal temperature rises (KLOPPER, 1957). This pregnanediol derives from adrenal progesterone (residual progesterone). On day 2 or 3 after the temperature has increased, progesterone excretion rises rapidly and reaches its peak 5–7 days before the onset of menstruation. A maximum of about 5 mg pregnanediol is excreted in 24 hours in the presence of one corpus luteum (KLOPPER, 1957), but GEMZELL and ROOS (1966) calculated significantly higher values in the cases of multiple pregnancies, indicating that several corpora lutea had developed at the same time. However, greatly increased pregnanediol values in the urine are no definite evidence that ovulation has occurred or that a corpus luteum has been formed. This fact has been confirmed by observation of cases in which a greatly elevated pregnanediol excretion was found to be due entirely to luteinization of the thecal cells of several follicular cysts (GARCIA, 1967).

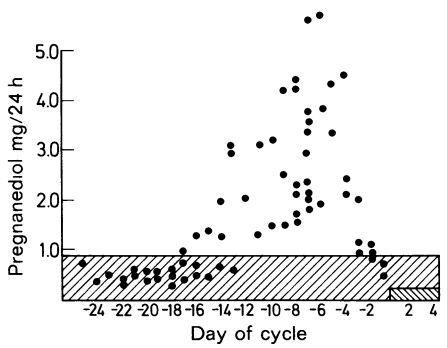

Fig. 43. Excretion of pregnanediol in 18 women during a biphasic cycle. The numeric values refer to the number of days before the beginning of the next period. (After GUAL, 1966)

b) Endometrial Biopsy (p. 625)

The study of so-called diagnostic smears from endometrial strips obtained from outpatients is a relatively reliable indirect method of determining histologically whether ovulation has occurred or not. This method is well suited for fixing the time of ovulation. It is best to take the biopsy from the fundus of the uterus on the 9th day of the hyperthermic phase. Errors of interpretation are reduced by these measures. In contrast to pregnanediol excretion, which can vary greatly from one person to another (Fig. 43), the histological picture of the endometrium changes uniformly and quite regularly under the influence of progesterone (ROCK, 1937; HERTIG, 1946; NOYES, 1950) (Fig. 29). An experienced investigator can determine the cyclic phase to within 48 hours from the degree of secretory transformation (p. 540), which allows the time of ovulation to be assessed quite accurately (NOYES, 1950). Reproducibility and accuracy are good with this method (NOYES, 1953), and endometrial maturation is fairly uniform in the different fundal sections (NOYES, 1956).

c) Vaginal Cytology (p. 534)

Daily preparation of a vaginal smear is a relatively simple and reliable method of roughly estimating the time of ovulation and assessing the state of ovarian function (RILEY, 1955). It is particularly suitable for the assessment of estrogen secretion during the follicular phase. It has been shown that during the follicular phase, the karyopyknotic index bears a significant relation to the logarithm of the total excretion of estrogens (JOHANNISON, 1961). In contrast to the situation in the endometrium, progesterone tends to have a nonspecific action on vaginal epithelium, and androgens, for example, can also produce the same effects. The vaginal smear at the time of ovulation has a characteristic "clean" appearance (p. 537 and Fig. 22). Results obtained are only reliable, however, when smears are taken continuously. Typical regressive changes occur in the individual cells within 1–2 days after ovulation (p. 537 and Fig. 23). These changes have been mentioned already and are not due to progesterone alone but can also be produced by a fall in the level of estrogens alone, by androgens or by corticosteroids.

Special practical importance is attached to exfoliative cytology when ovulation is stimulated by human gonadotropins and in the case of artificial insemination.

d) Cervix Factor (p. 538)

Examination of the cervical mucus, including assessment of the quantity, color, spinnbarkeit, crystallization (Fern test), penetrability to sperms (Sims-Huhner test) and the number of leukocytes contained, is another fairly simple method of determining the approximate time of ovulation and whether progesterone secretion has already started (Fig. 44). The width of the external os is also of practical use. There are also other methods of estimating the so-called cervix factor, such as measurement of the glucose content (BIRNBERG, 1958; DOYLE, 1959), the sodium chloride concentration, or the enzyme content (DONAYRE, 1965) or protein content (MOGHISSI, 1966). The cervix factor can also be assessed from its immunoelectrical behavior (HERVE, 1965). However, these additional methods are of no practical importance since they are unreliable and considerably more costly than assessment of the spinnbarkeit and the fern test.

e) Basal Body Temperature (BBT) (p. 546)

The simplest and most widely used method of estimating the time of ovulation and corpus luteum function is measurement of the temperature on wakening (VAN DE VELDE, 1905; VOLLMANN, 1942). The curve is based on the temperature-decreasing action of estrogens and the thermogenic effect of progesterone. It is believed that a plasma progesterone concentration of 25 ng/ml always results in a rise in BBT (ROSS, 1970). In order to obtain reliable results a number of conditions have to be observed (p. 624). In general, the temperature fall before the temperature rise is taken as the time of ovulation. Pregnancy occurring after one act of intercourse or a single artificial insemination has, however, shown that there is probably no strict relation between basal temperature and ovulation (ABARBANEL, 1958; HARTMANN, 1962). According to recent observations (JOHANSSON, 1972) a monophasic BBT is found in 12% of cycles even though other parameters investigated suggest that ovulation has occurred. It can therefore be supposed that the registration of a monophasic BBT during an otherwise seemingly biphasic menstrual cycle does not warrant the conclusion that the cycle is anovulatory.

f) Immunological Estimation of LH

The mid-cycle rise in LH secretion and excretion is taken as the immediate mechanism stimulating ovulation. Even biological assays of LH excretion have shown that increased LH secretion can already be determined before ovulation but that the peak of secretion is reached only after ovulation (FUKUSHIMA, 1964; MCARTHUR, 1958; ROSEMBERG, 1966). This has been confirmed by investigations with immunological estimations of LH (WIDE, 1962). Thus, it has become possible to determine the day on which ovulation will occur. The immunological method is simple and quick, but it is costly and not very precise.

Other tests for detecting ovulation, such as estimation of the action of oxytocin on myometrium contractibility (KNAUSS, 1935), pH changes in the vagina, electropotential changes between vagina and mons veneris (BURR, 1935)

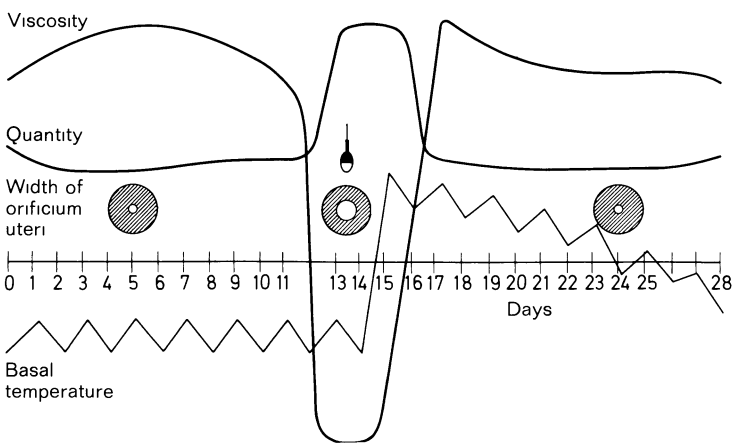

Fig. 44. Diagram showing the pattern of changes in mass and viscosity of the cervical mucus and the dilatation of the orificium uteri related to the basal temperature. (After BERNOTH, 1956)

composition of the blood and alveolar CO_2 tension (GOODLAND, 1952), have failed to gain practical importance for various reasons.

g) Clinical Symptoms

"Mittelschmerz" and mid-cycle bleeding (p. 608) are reliable signs of the time of ovulation, whereas intermenstrual discharge and changes in libido are of doubtful value.

h) Conclusions

Among the numerous methods available for detection of ovulation, the following investigations have proved to be quite reliable:

measurement of the basal body temperature;
endometrial biopsy;
pregnanediol excretion;
assessment of cervix factor;
vaginal cytology and immunological estimation of LH.

With the exception of the last method, none of the tests is reliable enough to be used as a single test. It is therefore necessary to use a combination of several (SÉGNY, 1933; BERGMANN, 1950; RAUSCHER, 1954, 1956, 1964; BELLER, 1962).

Stimulation of ovulation is discussed on p. 599, 630.

3. Inhibition of Ovulation

It has been deduced from the neuro-hormonal mechanism regulating the female cycle that the ovaries fail to function normally if the mid-cycle LH secretion can be successfully suppressed or if ovarian response to gonadotropins can be blocked.

Such a state of temporary physiological sterility occurs during pregnancy. This is a case of hormonal sterility, since the large amounts of estrogens and gestagens formed in the placenta almost completely suppress the secretion of pituitary gonadotropins.

HABERLANDT (1921) was the first to observe experimental hormonal sterility. He was able to show that ovaries of pregnant laboratory animals produced temporary sterility when transplanted into sexually mature female animals of the same species. Various investigators later showed (PAPANICOLAOU, 1926; PHILIPPS, 1937; MAKEPEACE, 1937) that progesterone inhibited estrus in rodents and produced temporary sterility in this way. BICKENBACH and PAULIKOVIVS (1944) found that intramuscular administration of 20 mg progesterone daily inhibits follicular maturation and ovulation in the female. Finally, Pincus and Chang investigated the mechanism of inhibition of ovulation in rabbit and rat by means of progesterone and its derivatives and metabolites. Oral progesterone has only a weak effect, and at least 300 mg must be taken orally every day to suppress ovulation in the woman (PINCUS, 1955). This prevents progesterone from being used as an ovulatory inhibitor in the woman.

In 1954, two groups of chemists reported the synthesis of 19-norsteroids (COLTON, ZAFFARONI). The progestive effect of these substances when given orally was described during the same year (HERTZ, 1954). Pincus and his team in particular deserve credit for examining the ovulostatic action of a large number of different steroids in rabbits and women (estrogens and other phenol steroids, androgens, progesterone derivatives and 19-nortestoids).

The first results on the contraceptive action of estrogen and progesterone mixtures in a large group of women appeared as long ago as 1957 (PINCUS, 1957; RICE-WRAY, 1957). From the large number of steroids so far investigated, various progestagens (p. 522, 546) and a few estrogens have proved to have an ovulostatic effect when given orally. The progestagens now in use as ovulatory inhibitors in the woman can be divided into two groups:

a) derivatives of 19-nortestosterone, the so-called 19-nortestoids (Fig. 45);

b) derivatives of 17α-acetoxy progesterone (Fig. 46).

Both groups were first tested by PINCUS and his team before being introduced therapeutically.

19-nortestoid is a chemical derivative of testosterone, the only difference between the compounds being the absence of the methyl group at C-19. Hence the name – 19-nor [no (r) = no methyl]. In addition, the 19-nortestoids now used as contraceptives have an ethinyl group at C-17, which stabilizes the molecule. These structural changes of the testosterone molecule result in a pronounced ovulostatic effect and the complete disappearance of androgenic action in the doses required for contraception.

Clinical investigations have shown that six 19-nortestoids are orally effective for contraceptive purposes in the woman (Fig. 45).

It has been shown that methylation and particularly chlorination at C 6 of 17α-acetoxy progesterone derivatives considerably increases the ovulostatic effect. Introduction of a double bond at C 5–6 also has this effect. The molecule becomes stabilized since breakdown of the progesterone molecule by hydroxylation at C 6 is impeded. All four derivatives of 17α-acetoxyprogesterone (Fig. 46) currently in use

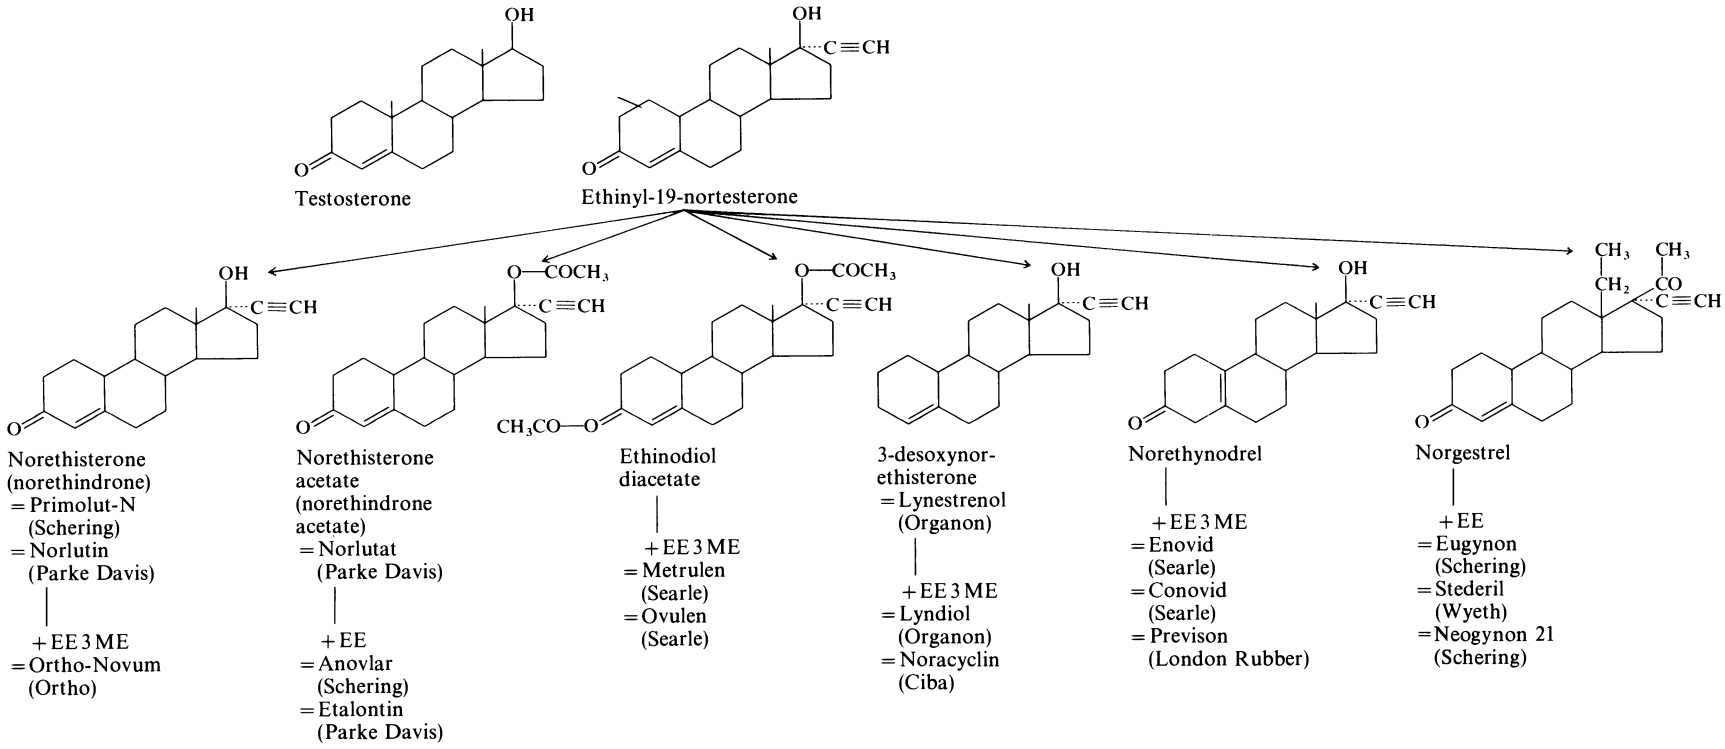

Fig. 45. Inhibitors of ovulation (19-nortestosterone derivatives) (SCHREINER, 1966)

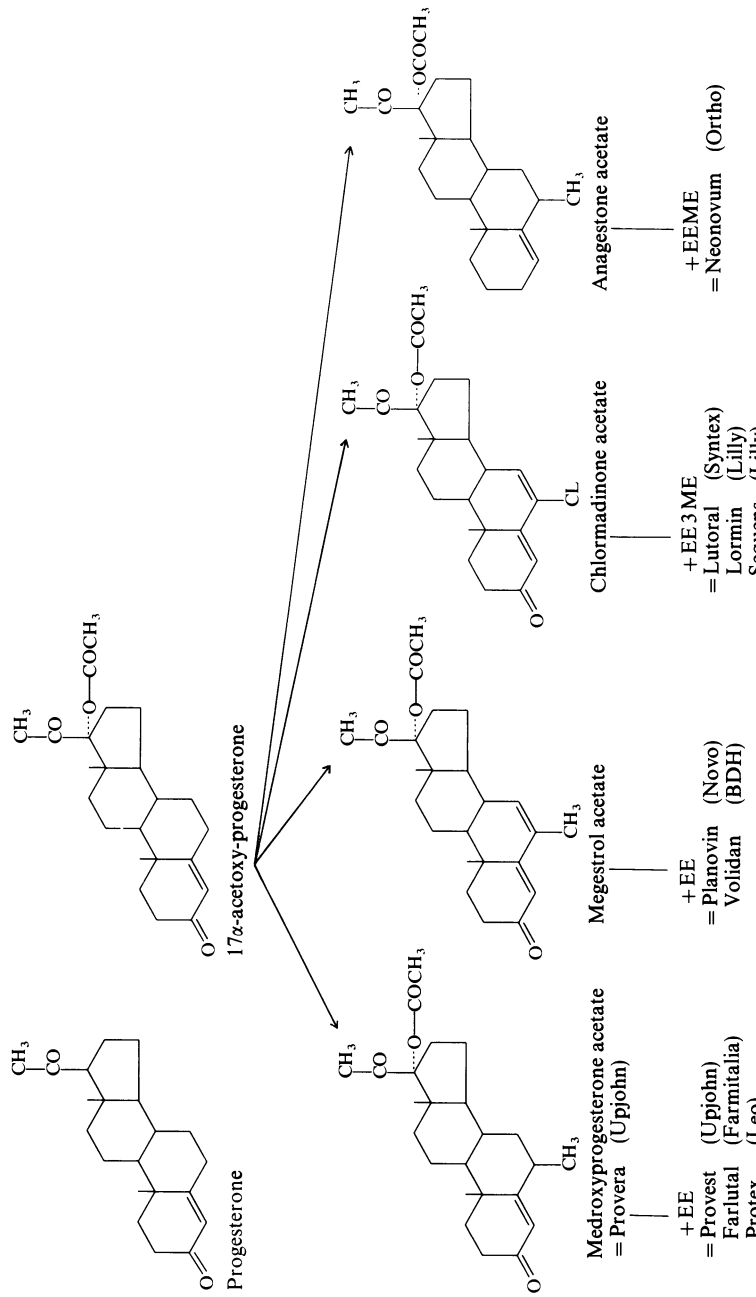

Fig. 46. Inhibitors of ovulation (17-acetoxy-progesterone derivatives) (SCHREINER, 1966)

for contraceptive purposes are therefore chlorinated or methylated at C 6. They are free of other hormone actions and cheaper to produce than 19-nortestoids. Since, unlike the nortestoids, they are not partly broken down into estrogens, the stabilizing effect on the endometrium is slighter. Breakthrough bleeding often occurs.

It is also known that estrogens and androgens in the correct doses can inhibit follicular growth (Fig. 46). The ovulostatic action of estrogens is now used in so-called sequential therapy (p. 573). Both groups of substances have significant disadvantages when used separately. Oral administration of estrogens often gives rise to gastrointestinal disturbances, painful swelling of the breasts, and severe breakthrough bleeding of long duration, due to endometrial hyperplasia. In addition, the onset of bleeding is uncertain. Androgenic substances in the doses necessary to suppress ovulation lead to virilization when administered for long periods.

All ovulostatic preparations contain 0.5–5 mg of a progestagen and 50–150 µg of an orally effective estrogen (Tables 33, 37). Either ethinyl estradiol (EE) or its 3-methyl ester (EE 3ME), the so-called mestranol, is used. When these substances are used, the dose of progestin can be reduced, since in the doses used they themselves have a central ovulostatic action. This also reduces the danger of unwanted side effects due to progestagens. The atrophic action of progestagens on the endometrium is reduced, so that breakthrough bleeding and amenorrhea seldom occur.

The contraceptive action of the estrogen-progestagen tablet is based primarily on inhibition of follicular maturation and ovulation. A hypothalamic inhibitory action is also involved, as well as a probably direct action on the ovaries (Fig. 47). The pre-ovulatory LH spurt (STEVENS, 1965) is suppressed due to inhibition of the LRH, and the response of ovarian enzymes to gonadotropins is also reduced (MATSUMOTO, 1960; LUNENFELD, 1963).

Table 33. Oral progestines and contraceptives. (Adapted from PINCUS, 1965)

	Progestagen		mg	Estrogen (µg)		Brand name
				EE3ME	EE

			3	100	–	Aconcen (Mark)
		Anagestone acetate	2	100	–	Neonovum (Ortho)

Reserpine and chlorpromazine also exert a similar inhibitory action on gonadotropin secretion via the hypothalamus (Fig. 47). Ovulation is successfully blocked but galactorrhea occurs due to simultaneous loss of prolactin inhibition (RATNER, 1964).

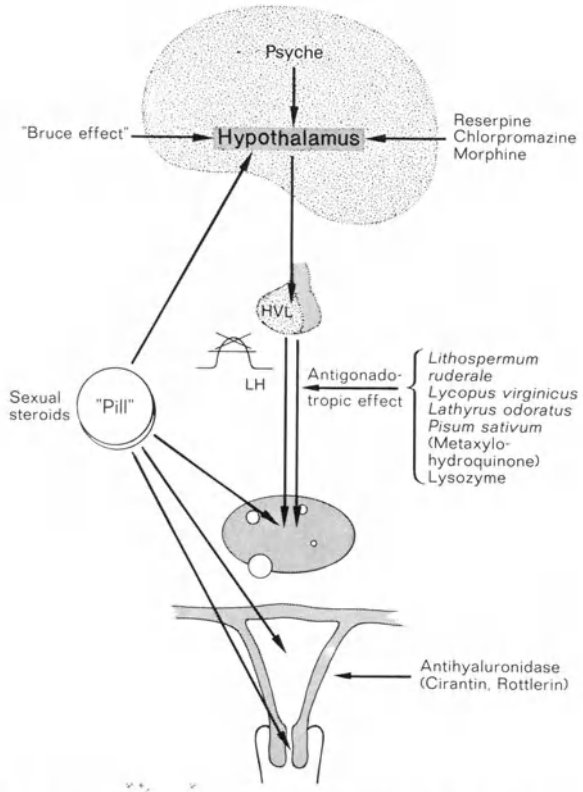

Fig. 47. Sites of action of various factors inhibiting fertility

The changes in the endometrium and cervical mucus caused by the progestagens also exert a contraceptive effect.

Chemical and physical changes occur in the cervical mucus. These changes are similar to those produced after ovulation due to the influence of gestagens and the cervical ascent of the sperms is impeded or made impossible (sperm barrier).

Fertility inhibition due entirely to corresponding changes in the cervical mucus is currently being intensively tested experimentally and clinically. This method has proved successful ("Minipill"). This represents considerable progress, since a contraceptive effect can be achieved with a minimal change in the reproductive system (p. 575).

The combination therapy (p. 573) also causes changes in the endometrium which impair blastocystic implantation (ROCK, 1956, 1957). Premature transformation with premature regression of the endometrial glands and endometrial atrophy arise after long-term treatment. These changes do not occur with the sequential therapy (p. 573) (Fig. 48).

During treatment with oral contraceptives, estrogen excretion in the urine is reduced, the values being lower than those at the time of ovulation or during the luteal phase (LORAINE, 1965; FLOWERS, 1966; WALLACH, 1968). Thus, there is a certain estrogen deficit during ovulostatic treatment. Prompt normalization of excretion values even after treatment lasting many years shows that this inhibition of estrogens is not irreversible (LORAINE, 1965; WALLACH, 1968).

During medication with estrogen-progestagen drugs, pregnanediol excretion is reduced to the values found during the follicular phase. However, different investigators have found pregnanediol values similar to those arising during the luteal phase (GOLDZIEHER, 1962, 1964; LIGGINS, 1967), but in the absence of pregnancy. Such values were found in 2.2 to 8.7% of the cycles produced with different compounds. The following explanations are under discussion:

1. formation of a corpus luteum during an "escape" ovulation, and
2. luteinization of the follicles.

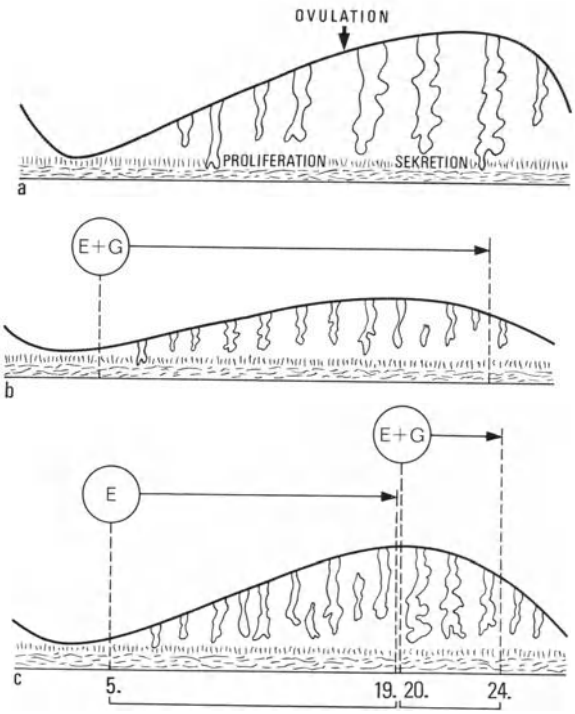

Fig. 48a–c. Diagram representing behavior of the endometrium a) in the natural biphasic cycle; b) during prolonged combined contraceptive treatment; and c) during sequential contraception (HALLER, 1968)

Table 34. Efficacy of various contraceptive methods. (Adapted from VENNING, 1965).

Method	Average number of pregnancies per 100 woman-years[a]
No contraception	115
Vaginal douching	31
"Safe period"	24
Vaginal jelly or cream	20
Coitus interruptus	18
Condom	14
Diaphragm (with or without jelly)	12
Intra-uterine contraceptive device	1–5.5
Ovulation inhibitors	0–3.1

[a] Pregnancies per 100 woman-years

$$= \frac{\text{No. of pregnancies}}{\text{No. of months in observation period}} \times 1200$$

The development of corpora lutea during conventional ovulostatic treatment has been reported (ERB, 1965).

Comparison with other contraceptive methods has shown that hormonal contraception is very effective (Table 34). The rate of pregnancy (= No. of pregnancies observed × 1200 divided by no. of observation months; Pearl Index), lies between 0 and 3, where failure is due partly to the fault of the patients and not to the drug. There are currently two methods of oral hormonal contraception in use:

Method I: combination therapy (PINCUS, 1955; ROCK, 1956)

Method II: biphasic or sequential therapy (GREENBLATT, 1961; GOLDZIEHER, 1963).

The original administration schedule introduced by Pincus (Pincus schedule) prescribes one estrogen-progestagen tablet daily from the 5th day for 20 to 22 days (combination tablet). The first day of the cycle is taken as the first day of menstruation. Withdrawal bleeding occurs 2–3 days after discontinuation of the tablets (i.e. on the 27th or 28th day of the cycle). Treatment is restarted on the 5th day after onset of bleeding. The following schedule is simpler: 3 weeks intake, 1 week tablet-free; when 21 tablets are used, treatment is always started on the same day of the week and there is a free interval of 7 days. If 22 tablets are used, the first and last tablets are taken on the same day of the week, and the free interval is only 6 days.

Sequential therapy is also started on the 5th day of the cycle. Pure estrogen tablets (80–100 µg EEME) are taken for the first 14–15 days, followed by conventional combination tablets for the next 5–7 days. The dose of estrogens selected is adequate to suppress ovulation, and progestagens are used only to achieve secretory transformation and limited withdrawal bleeding. The sequential therapy is considered to be less safe than the combination method, since it is based entirely on inhibiting ovulation. It does, however, have the advantages that endometrial atrophy with the associated danger of amenorrhea are removed, and that unwanted side effects are less common. The withdrawal bleeding is more severe.

With both forms of therapy, observation of two conditions is necessary to achieve a definite anti-fertile effect:

1. medication must be started before the 6th day of the cycle, and

2. the tablets must be taken regularly.

Corresponding investigations (MATSUMOTO, 1960) have shown that follicular maturation and ovulation can no longer be effectively suppressed if medication is started after the 5th day of the cycle. Steroids are quickly metabolized, so that a single dose exerts a reliable inhibitory action on the ovary for only about 36 hours. If a tablet is forgotten in the evening, it should be taken no later than the following morning. If the time interval is longer, it is pointless to double the dose. In order to maintain the intake schema, the patient should continue with the usual daily intake until the 24th day of the cycle. When a tablet has been omitted a conventional contraceptive method must be used in addition to the ovulation inhibitor for the remainder of the cycle. It has been shown statistically that the number of failures or pregnancies is related to the number of tablets omitted (PINCUS, 1965). The fact that an ovulostatic is only as reliable as the patient taking it is one of the main reasons why the failure rate is so high in the places where contraception is most needed, namely in the developing countries. Whereas in Holland, only 6% of women stop taking the tablets with in one year (SWAAB, 1964), 28% of women in Singapore (SAN, 1963) and 74% in Madras (MENON, 1964), stop within one year, and in Puerto Rico 82 to 92% no longer take the tablets for contraception after $2\frac{1}{2}$ years (PINCUS, 1965).

Doctors are often asked how quickly the contraceptive action develops after the beginning of tablet intake. Studies in a large number of women have shown that 6.3 of every 1000 ovulations occur during the first 7 days of the cycle (RICHTER, 1963). Premature ovulation occurs almost without exception in women with short cycles. In these uncommon cases, tablet intake started on the 5th day is too late. To ensure full protection it is therefore wise to advise the couple to use another conventional contraceptive method during the first

10 days of the first intake cycle, or to tell the patient to start taking the tablets from the first day of the cycle. This is only necessary during the first cycle.

To what age must contraception be practiced? Although the likelihood of conception decreases rapidly after the 30th year and is only 3% at 40 (MÜNZER, 1934), a few pregnancies have occurred at 51, and despite the increasing frequency of abortion, have been carried to term (WYLER, 1957). One third of all pregnancies in women of 45 or over end in miscarriages (JAVERT, 1957).

Table 35. Treatment with ovulation inhibitors (SCHREINER, 1966). (Available on prescription only)

Before commencement of a treatment

Case history, Assessment of general condition } see contraindications

Examination of genital organs including breasts: colposcopy, cytotest after PAPANICOLAOU, bimanual palpation.

During treatment

First check-up after 2 months, then annual check-ups, annual cytotest after PAPANICOLAOU.

Indications

a) Contraception, polymenorrhea, oligomenorrhea, hypermenorrhea, dysmenorrhea, premenstrual syndrome, functional sterility

b) Functional sterility, genital hypoplasia, endometriosis

c) Manipulation of menstruation

Treatment schedule

ad a) Cyclic treatment: 1 tablet daily on days 5–24 (25) of cycle.

ad b) Continuous treatment: 1st week 1 tablet daily, 2nd and 3nd weeks 2 tablets daily, increase daily dose by 1 tablet every 2 weeks to a maximum of 4–6 tablets daily as long-term treatment.
Duration in functional sterility 3–4 months, in genital hypoplasia 3–6 months, in endometriosis 9 months or longer.

ad c) 1 tablet daily for 4 days before the expected menstrual period. If time of period is to be changed by more than 1 week, increase dose to 2 or more tablets daily after 7 days.

Contraindications

Carcinoma of the reproductive organs including the breast. Tendency to thromboembolism: status varicosis, severe obesity, recent surgery or delivery. After cerebrovascular trauma; cholestasis, e.g. after jaundice in pregnancy. Pregnancy (nortestoid preparations).

To be used with caution during lactation, in the presence of uterine fibromyoma or tendency to water retention: cardiac insufficiency, bronchial asthma, migraine, epilepsy; diabetes mellitus.

No other substance has been so extensively examined for undesirable side effects as the estrogen-progestagen mixture in the "pill". The severity and type of the side effects are not only dependent on the dose of the single hormone fractions but also on psychological factors to a particular degree (PINCUS, 1965). About every 5th patient complains of side effects (HALLER, 1968). These may take the form of bleeding disturbances, or may be of a generalized nature (PINCUS, 1965; HALLER, 1968). The frequency usually decreases after the tablets have been taken for 2–3 months.

No form of organic damage or disturbances in the ova or regulation has been detected even after contraceptive tablets have been taken for years. There is no carcinogenic action (Table 36) though the growth of a hormone-dependent carcinoma (carcinoma of the breast and body of the uterus) already present can be accelerated by the estrogen components (Table 35). The only real risk associated with ovulostatic treatment, is the increased danger of thromboembolism (Royal College of General Practitioners) (VESSELS, 1968; INMAN, 1968). According to statistical investigations, the risk of a non-fatal lung embolus is 10 times higher (VESSELS, 1968). The risk of a fatal lung embolus or cerebral venous thrombosis is in any case very slight, but it is 7 times higher when ovulostatics are taken (INMAN, 1968). This risk, however, is no higher than during pregnancy and the danger is significantly less than the general risks encountered in pregnancy.

In addition to the unwanted side effects, ovulostatics also demonstrate a series of desirable secondary effects, so that the indications for use are not restricted to contraception. A number of gynecological disorders can be treated (Table 35):

Table 36. Incidence of cancer during long-term estrogen substitution (LAURITZEN, 1968)

Author	Patient-years	No. of patients	Duration of treatment (years)	Calculated incidence	Observed incidence
GORDON (1961)	1200	120	14	12–15	0
WILSON (1962)	2604	304	17	20	0
WALLACH and HENNEMAN (1959)	1480	292	25	22	5
SCHLEYER-SAUNDERS (1960)	–	500	15	30	0
GEIST (1941)	–	206	5.5	12	0
Total	–	1422	–	96	5

endometriosis (p. 553, 633);
dysfunctional bleeding: polymenorrhea, oligomenorrhea, hypermenorrhea, secondary amenorrhea (p. 585, 603);
functional dysmenorrhea, "mittelschmerz" (p. 618);
postponement of menstruation;
functional sterility (p. 623);
genital hypoplasia.

Contraindications. Carcinomas of the reproductory organs including the breasts;
tendency to thromboembolism: state after thromboembolism, varicosis, excessive obesity, after surgery or postpartum (6 weeks), after cerebovascular accidents;
during lactation;
cholostasis (not, however, liver cirrhosis or chronic hepatitis).
Caution is indicated in:
cardiac failure, bronchial asthma, migraine, epilepsy because of tendence to retain water;
diabetes mellitus (glucose tolerance is reduced by ovulostatics).

Since contraceptive tablets are not all the same and they are contraindicated in certain instances they are only available on prescription; thorough medical examination is essential before and during the treatment (Table 35).

In the last few years, the practical value of the contraceptive action of long-term treatment with small oral doses of progestagens (so-called "luteal supplementation"), has been examined (RUDEL, 1965; MARTINEZ-MANAUTOU, 1966) and proved effective.

This form of treatment is of special interest, since apart from its simplicity, it produces antifertile effects exclusively by altering the cervical mucus and the endometrium, hypothalamic-pituitary-ovarian function remaining intact. Experience obtained in the use of the so-called "minipill" in a daily dose of e.g. 500 mg chlormadinone acetate has shown that the rate of pregnancy is 3.7 per 100 women years, which is only slightly higher than that for other methods in use, although 70% of the women concerned ovulated. Disadvantages are frequent breakthrough bleeding (20% in the first cycle) and a tendency to oligomenorrhea (about 20% of the trial women showed a cycle lasting between 36 and 59 days).

GREENBLATT (1967) has developed a tablet which only has to be taken once every month. It has therefore been described as the "one-pill-a-month contraceptive". It contains an oral estrogen with a long-lasting effect (the 3 cyclopenthyl ester of ethinyl-estradiol 2–5 mg) and a short-acting progestagen, (chlormadinone acetate 5–8 mg). The tablet is taken on day 25 of the cycle. Ovulation inhibition throughout the month is achieved by the constant estrogen level. The investigations performed so far on its reliability have yielded a result of 1.5

Table 37. Hormonal contraceptives (inhibitors of ovulation)

pregnancies to 100 women years. This corresponds to that of the sequential therapy, and its chances of being accepted appear to be good.

The same effect is produced by intramuscular administration of an estrogen-progestagen preparation (the so-called "one-shot-a-month"), on the 8th day of the cycle (RICE-WRAY, 1965). A depot estrogen e.g. estradiol-valerianate is combined with a depot gestagen (16α,17α-dihydroxy-progesterone acetophenide). Dependence on the doctor, and frequent breakthrough bleeding are disadvantages of this method. Sometimes the bleeding is so severe that it necessitates a curettage.

According to experience gained so far the injection of 150 mg medroxy-progesterone-acetate every three months or 300 mg every 6 months can also prevent pregnancy with a high degree of certainty (TAYMOR, 1964). As with the combination tablet, a multi-locular anti-fertile effect is involved. Ovulation inhibition, atrophy of the endometrium and gestagenic alteration of the cervical mucus occur. Severe disadvantages are the recurrent breakthrough bleeding and amenorrhea, which may last for several months.

Finally, investigations with depot progestagens are currently in progress. Silicone tablets are injected into the tissue, and micro-doses are released through the capsule wall. Conception can possibly be prevented for a desired time by refilling the capsule. This method is still in the preliminary stages, so that nothing definite can be said about the dosage, effectiveness and side effects.

For the sake of completion, the so-called "morning-after pill" and "month-after pill" must be mentioned here. Neither is an ovulation inhibitor. The so-called "morning- or day-after pill" (MORRIS, 1966), consists of a large dose of estrogen (50 mg diethyl-stilbestrol or 2–5 mg ethinyl-estradiol daily) and is given for the first 5 days after possible conception. Presumably implantation is inhibited, and possibly tubal transport is also accelerated so that the ovum reaches the endometrium at a stage where it is still too immature for implantation. Failures are usually due to too low a dosage of estrogens.

Anti-metabolites such as 6-mercaptopurine or 5-fluorouracil can interfere with the development of a pregnancy during the first four months (month-after pill) (MORRIS, 1967). There is probably an inhibitory action on blastocystic mitosis.

There is a second group of substances which inhibit synthesis of progesterone so that withdrawal bleeding and expulsion of the fetus result, but clinical trials in Sweden have failed. The so-called "Bruce effect" (BRUCE, 1960; PARKES, 1961) must also be mentioned (Fig. 47). This effect is based on the observation that 80–90% of female mice do not become pregnant when they are brought into close contact with strange male mice or their urine shortly after copulation. LTH production is probably inhibited via the hypothalamus by a strong transient odorous substance.

F. Transition Periods in the Woman

1. Puberty and Menarche

(see also Chap. XIX, p. 1034)

In the life of a woman different stages of development can be differentiated: infancy, puberty, adolescence, sexual maturity, climacteric and senility (Fig. 49).

The boundaries of the different phases of life are indistinct and somewhat arbitrary.

Puberty begins with the development of the pubis (STUART, 1946). Pre-puberty is often termed as the time between the onset of the development of the breasts and that of pubic hair. The mechanism causing the development of puberty is still not clear. Hypothalamic maturity (see below) and normal thyroid and adrenocortical function seem to be essential, whereas the state of maturation of the hypophysis and ovaries (p. 554) is irrelevant (ABRAMS, 1967). The importance of the pineal body is not clear (Chap. IV, p. 73). From studies made in animal experiments, it is assumed that the inhibitory center in the anterior hypothalamus continuously loses its sensitivity to the sexual steroids, resulting in a decrease of its inhibitory effect on the eminentia mediana, which in turn causes the liberation of gonadotropin-releasing hormone already present (VAN DER WERFF TEN BOSCH, 1966). The increased androgen formation is probably responsible for the puberal spurt of growth. At this age (adrenarche) androgens are mainly produced in the rapidly growing zona reticularis of the adrenal cortex and perhaps also in the hilus cells of the ovaries. At the same time, the pelvis and breasts develop under the influence of the androgens. It is possible that androgens also have some important effect on maturation of the hypothalamic "sexual center", since maturation of this center is a decisive factor in the onset of vegetative ovarian function, the so-called *oophorarche*. Due to gonadotropic stimulation, estrogens are formed in the ovaries, and estrogen excretion in the urine soon exceeds 10 μg per 24 hours. The influence of estrogens brings about development of the primary and secondary sexual characteristics (p. 532ff. for the biological action of estrogens). So for example, after the

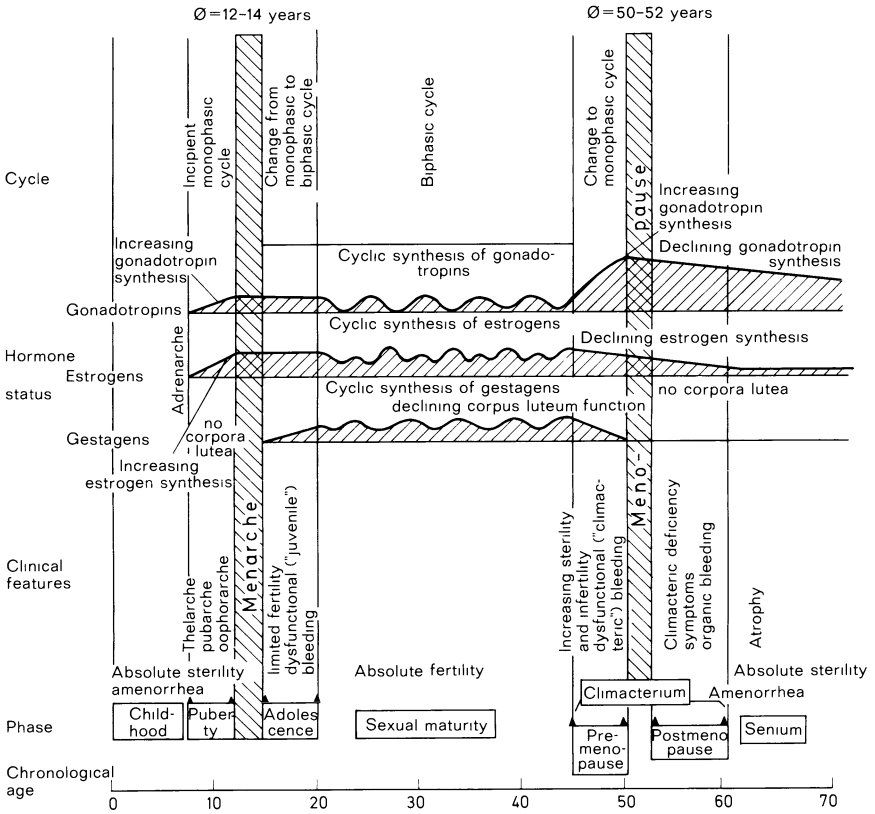

Fig. 49. Phases in the life of woman

10th year, the uterus rapidly increases in size (Fig. 26) and the original ratio of body to cervix of 1 : 2 is reversed (p. 538).

However, the ovaries can react to gonadotropic stimulation to form sexual steroids long before the oophorarche (PASCHKIS, 1955; ABRAMS, 1967). No gonadotropins are formed before the 5th year (BETTENDORF, 1962) and excretion begins only 3–4 years before menarche (JOHNSON, 1959). Hypophyses of juvenile animals implanted into hypophysectomized adult animals are capable of functioning fully as soon as the hypophyseal portal circulation has been re-established (HARRIS, 1952). This is proof that hypothalamic maturity is essential for the onset of formation of pituitary gonadotropins.

The influence of the androgens is predominantly responsible for the development of the pubic hair and causes the so-called *pubarche* and the formation of axillary hair shortly before menarche.

Androgens, somatotropin and estrogens in particular lead to the development of the puberal breasts, the so-called *thelarche*. The breasts, however, only undergo complete development under the additional influence of gestagens.

The most striking event at this time is *menarche*, which is an obvious manifestation of incipient cyclic ovarian function. This marks the onset of *adolescence* which lasts until regular biphasic ovarian cycles are established i.e. until the end of growth. The peak velocity of increase in height ends almost without exception with the onset of menarche (DEMING, 1957). Growth in height usually ends 3 years after menarche. The inhibiting influence of the increased estrogen secretion on height is indicated by the fact that an early menarche is frequently associated with a small, pyknic stature, and a later menarche with a large leptosomatic type. The average age at which menarche occurs varies from population to population. In Europe and North America it is currently between 12 and 14 years (Fig. 50), menarche arising between 11.8 and 16 years in 90% (GRIMM, 1948), and between 11 and 16 years in over 95% (STAEMMLER, 1964). When menarche occurs between 16 and 18 years, since these ages are taken to be outside normal limits (SOUTHAM, 1966) it is justifiable to speak of a *delayed menarche*. Menarche arises this late in less than 5% of young women (GRIMM, 1948). After completion of the 18th year, the

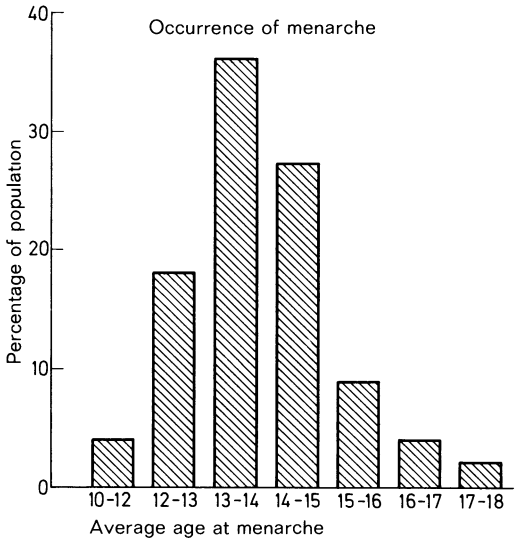

Fig. 50. Age at menarche in American girls. (After WELLENBACH, 1967)

first period arises spontaneously in only 0.3% of these women (GRIMM, 1948). The term *primary amenorrhea* is used when menstruation has failed to occur after completion of the 18th year. Precocious puberty is spoken of when menarche arises before the 9th year. The age at which menarche occurs is primarily genetically determined, and is almost always the same for mother and daughters and sisters (TANNER, 1962) and practically identical in monozygotic twins (PETRI, 1935). Distribution of the age at which menarche arises within a population group gives a gaussian binominal curve corresponding to genetic determination (Fig. 50). The onset of menarche is also influenced by environmental factors. Socio-economic factors in particular, and nutritional conditions (protein intake, vitamins) play a part as well. Menarche usually arises a few months earlier in the higher social classes than in girls of lower social level (TANNER, 1962). This is also illustrated by the fact that menarche arises earlier in urban than in rural populations. The influence of nutrition is particularly apparent in chronic nutritional disorders such as diabetes mellitus and ulcerative colitis. Menarche was also later during the war years. One of the most convincing arguments for the influence of nutrition is the observation made in Lapland. The average age at menarche was found to be constant at 16.5 years between 1870 and 1930 in the sections of the population which continued their nomadic life, whereas the age at menarche declined by two years during the same period in the neighboring settled farmers (TANNER, 1968). The higher incidence of disease and the greater exposure to stress situations in poorer population groups have an additional retarding effect on menarche (RENOLDS, 1947; MANDL, 1952; VARON, 1963). In contrast to results obtained with animals, light seems to exert an inhibiting influence on menarche in women; it is usually earlier in blind girls (ZACHARIAS, 1964). Climate and race seem to influence menarche much less than nutritional conditions (HENTON, 1958; LEE, 1963). Menarche occurs at the same age in Nigerian girls belonging to higher tribes and in Eskimo girls (ELLIS, 1950; LEVINE, 1953) whereas the first menstruation occurred $1\frac{1}{2}$ years earlier in Japanese girls born and brought up in California than in Japanese girls born in California but brought up in Japan (ITO, 1942). In these cases, nutritional conditions are probably the decisive factor again. On the other hand, in ancient days, menarche appeared to arise a year later in German girls than in Roman girls. This difference between south and north Europeans can still be observed (BACKMAN, 1948). The average age at menarche fluctuated considerably during the course of the centuries. It occurred at the age of 12 in Hindus 2500 years ago (BENERJEE, 1961), at 14 in Europe during the period of classical antiquity, and at 18 at the end of the 18th century (BACKMAN, 1948). Since then there has been a continuous decline of about 4 months per decade in age at menarche (PORTMANN, 1967) (Fig. 51). Increased stress to the individual due to urbanization (BENNHOLDT-THOMSON'S urbanization trauma, 1942), and various inherited factors are the basis of this mainly Western phenomenon (LENZ, 1965).

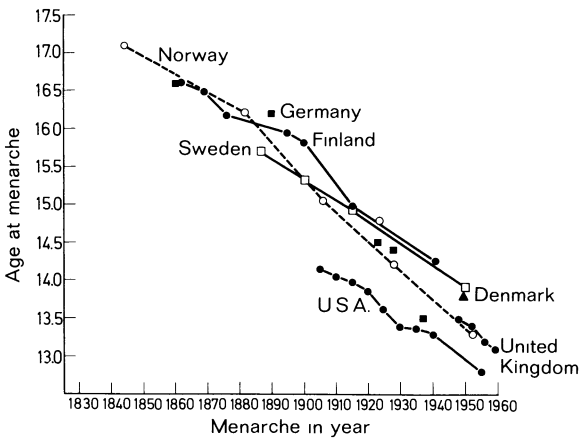

Fig. 51. The secular shift in age at menarche between 1830 and 1960. (After TANNER, 1962)

Certain prognostic conclusions about later sexual function can be deduced from the age of menarche. Labile or irregular cycles with

dysfunctional bleeding and sterility arise more frequently after a late or retarded menarche ($14\frac{1}{2}$–16 years) (p. 603) (STAEMMLER, 1964; SOUTHAM, 1966). The cause of delayed menarche or primary amenorrhea can be situated at one of the three functional levels: hypothalamus and hypophysis, ovary and thyroid or adrenal cortex, or uterus and vagina (see primary amenorrhea, p. 585ff.). In most cases only variations of the normal are present. Investigation of delayed menarche is similar to that of primary amenorrhea (p. 594ff.) (SOUTHAM, 1966).

2. Climacteric and Menopause

a) Definition

The terms "climacteric", "menopause", and "postclimacteric" are used differently in different countries and often appear as synonyms. In the following discussion, we use only the terminology recommended by the Nomenclature Committee of FIGO (Féderation internationale de gynécologie et d'obstétrique) (KAISER, 1956). This terminology is factually and etymologically correct (Fig. 49).

The *menopause* is the last menstruation or in retrospect, the time of the last menstrual period before one complete year of amenorrhea (TIETZE, 1952; BREWER, 1954; KAISER, 1965 etc.). Climacteric (the change of life) depicts the transition period from the time of full sexual maturity to the point at which ovarian function is lost. It includes a few years before and after the menopause and is followed by senility. The years prior to the menopause are termed as premenopause, and the years thereafter up to senility as postmenopause (WENNER, 1959; BÉCLÈRE, 1963).

The climacteric or premenopause begins about 2 to 3 years before the menopause with a resultant fall in estrogens and a rise in gonadotropins. The postmenopause ends when estrogen excretion reaches the values found in senility. This phase lasts on average 6–8 years after the menopause (KAISER, 1965).

An *early menopause* (precocious climacteric) is spoken of when the last menstruation occurs before the 40th year of life. The term *late menopause* (climacterium tarda) indicates that the last period did not occur until after completion of the 54th year. The incidence of early menopause has been variously quoted as 1.2% (GOECKE, 1959) and 8% (KEETEL, 1964). The menopause is late in 6.9% of women (GOECKE, 1959).

Like puberty and adolescence, the climacteric represents a normal, physiological transition period between sexual maturity and senility. It is not an illness in itself but the development of deficiency symptoms which may become pathologic may cause some women to look upon it as an illness (p. 582ff.). The climacteric is peculiar to the human so that it is impossible to investigate any associated processes in animals.

b) Age at Menopause

As the age at menarche has been declining, so climacteric and menopause have been occurring progressively later in the past 130 years. The proportions of these changes are about the same for menarche and menopause, and up to 1950 were approx. 3 years per 100 calendar years (BACKMAN, 1948).

Until the Middle Ages, the average age at menopause was around 40, while between 1500 and 1840 it was 45 years. Since then, there has been a rapid and progressive rise in the age at the onset of the menopause, so that in 1940 the average age at menopause was 48 years (BACKMAN, 1948). This continuous rise in the age at which menopause occurs shows a pronounced rhythm, with a phase duration of about 20 years (Fig. 52). Since 1940 there has been another acute rise. Whereas menopause occurred at the age of 49.5 (HAUSER, 1961) or 49.3 (DÖRING, 1959) in 1960, it was found that it occurred at 50.1 years (FROMMER, 1964) or $52\frac{2}{12}$ years (DE WAARD, 1964) in 1964. Menopause occurs between 45 and 55 years in about 50% of women (GOECKE, 1959) (Fig. 53). The tendency for menopause to arise later is supported by the decreased incidence of early menopause and the increased numbers of women with late menopause.

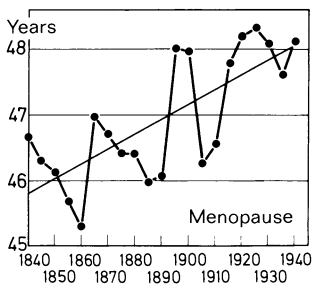

Fig. 52. Changes in mean age at menopause per decade and for every fifth year in Europe, 1840–1940. (After BACKMAN, 1948)

The long-term trend in the ages at which menarche and menopause arise, which is statistically significant, also appears to be valid for individual women. There is a connection between the age at menopause and that at menarche, in the sense that an early menarche generally

means that menopause will be late, and conversely a late menarche indicates an early menopause (BACKMAN, 1948; GOECKE, 1959). The duration of sexual maturity in the woman has increased during the course of the last 100 years (Fig. 54). This is also applicable to the average life expectancy. A few investigators doubt that there is any connection between duration of sexual maturity and life expectancy (SCHAEFFER, 1906, 1908; BENJAMIN, 1960).

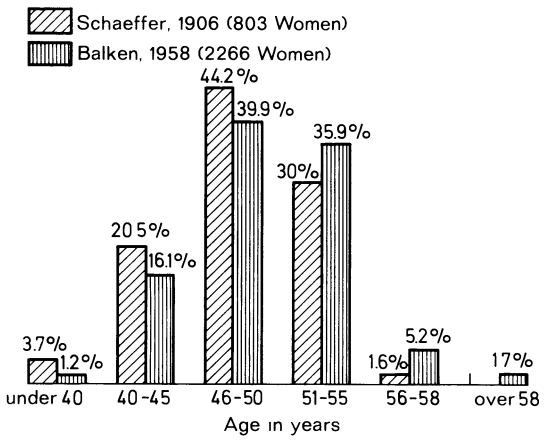

Fig. 53. Range of age at menopause. (After GOECKE, 1959)

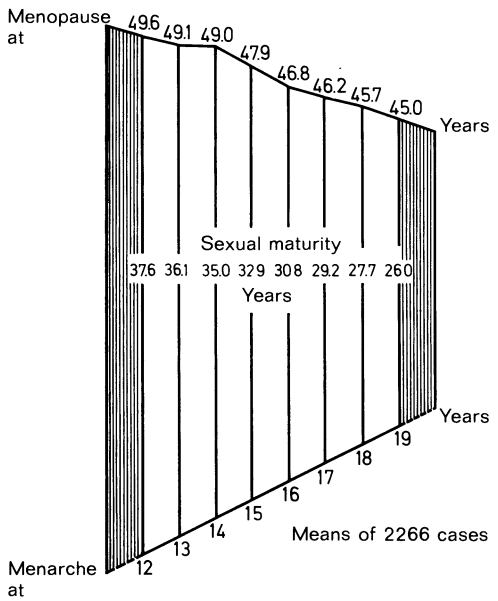

Fig. 54. Temporal dependence of the menopause on the menarche. (Balken in: GOECKE, 1969)

c) Causes of the Onset of Menopause

Present-day knowledge suggests that the cause of the onset of the climacteric and menopause lies within the ovary itself. It is not primarily due to the absence of primordial follicles ("burnt-out ovaries"), since a small number of these follicles is present even after the menopause (BLOCK, 1952) (p. 517) but results rather from the reduced response to gonadotropic stimulation. It is probable that the cause of this is not in the oocyte, but in the ovarian vascular system, which undergoes senile changes earlier than other vessels elsewhere in the body (SOHMA, 1908). The increased gonadotropin levels may accelerate this process, since administration of high doses of gonadotropins to animals has been observed to lead to sclerosis of the ovarian vessels (LAURITZEN, 1968). The ovary is the only endocrine gland which begins to decrease in weight from the 30th year (Fig. 26). The ovary may temporarily increase in size during the premenopause due to follicular persistence. In the postmenopause there is increasing shrinkage with fibrous tissue formation. The cortex in particular becomes narrower due to the disappearance of germinal parenchyma. Cortical granulomas consisting of large, polygonal cells with lipoid deposits arise in the hilus (HERTIG, 1944); they are similar to thecal cells, but may produce androgens (p. 527). Hilar vessels degenerate (SOHMA, 1908). The surface of the ovary becomes grooved like the brain, and becomes whitish-yellow in color. The weight of the ovary can decline to half or one third of its weight during sexual maturity (WATZKA, 1957).

Estrogen formation decreases due to the reduced response of the follicular apparatus to gonadotropic stimulation. FSH release is reduced to a lesser extent, and LH liberation is increased (p. 561). This causes the formation of tertiary follicles, but there is no terminal spurt of growth due to the disturbed feedback mechanism. Estimations of estrogen excretion have shown that the ovaries can be stimulated by the administration of exogenous gonadotropins in the presence of elevated HPG formation even 1–2 years (PAULSEN, 1958) or 3–5 years (depending on the investigator) (LAURITZEN, 1968) after the menopause and that a few ovulations can even occur spontaneously in the postmenopause, as is confirmed by occasional pregnancies arising at this phase (SHARMAN, 1962). Studies in monozygotic twins have shown that hereditary factors are of considerable importance in determining the age at menopause. In monozygotic twins, the average difference in age at menopause is two months, as against 19 months in dizygotic twins (GOECKE, 1959). The familial occurrence of climacterium praecox and tarda confirms the influence of genetic factors (MAYER, 1928). In addition, as in the menarche, environmental influences, particularly nutritional factors (MCBRIDGE, 1956) have some

effect on menopause. Wasting diseases and unknown endogenous influences also affect the organism so that menopause occurs later. This is also true of women with fibroids and carcinoma of the body of the uterus.

d) Hormonal Conditions

The first result of reduced response of the follicle to gonadotropins is a decrease in the amount of estrogens produced. A fall in estrogen excretion can sometimes be demonstrated even between the 40th and 45th year (KAISER, 1965), but in these cases there is no further significant fall during the premenopause (Table 38). Other investigators, however (FURUHJELM, 1966), have found no correlation between age and estrogen excretion between 40 and 50 years. We and a few other authors have observed that not infrequently the estrogen excretion is temporarily considerably increased during the premenopause (ZONDEK, 1947) while gonadotropin excretion is found to be increased at the same time (PAPANICOLAOU, 1969) (so-called polyfolliculine stage after ZONDEK, 1947). It appears that in these cases, the central "feeler system" no longer responds to the elevated estrogen titer (p. 557). If estrogen excretion is less than 7–10 µg/24 h for a long time no more bleeding occurs because endometrial stimulation is inadequate (BROWN, 1959). Estrogen excretion falls steadily during the postmenopause, and values between 5–18 µg/24 h have been reported (DICZFALUSY, 1961; PAPANICOLAOU, 1969). The senile level of 5µg/24 hours is attained after 7 years at the earliest. Excretion values of over 20 µg/24 h in late postmenopause and senility indicate a pathologic process (DICZFALUSY, 1961). It is interesting to note that cyclic variations in estrogen excretion may arise immediately after the menopause (BULBROOK, 1957) without bleeding. The reduced estrogen secretion during the climacteric is reflected in the *vaginal cytology smear*: the pyknosis index falls to an average value of 10% during the postmenopause (DICZFALUSY, 1961). In a few cases, the pyknosis index is as high as 30% even 30 years after the menopause in the absence of any kind of estrogen administration (SMOLKA, 1956; PUNDEL, 1957). One must, however, remember that apart from sexual steroids, nonhormonal substances such as digitalis, senna, cascara and tetracyclines can also exert a proliferative stimulus on vaginal epithelium. Intensive proliferation in the vaginal epithelium can be caused only by estrogens, and has been observed in 9.1% of women after the menopause, exceptionally as long as 14 years after the menopause (KAISER, 1965). It is probable that ovarian

Table 38. Excretion of gonadotropins and estrogens in women after the 41st year (KAISER, 1965)

Age	Gonadotropins in mg HMG 20 A/24 h	Total estrogens in µg/24 h
Normal cycles	13 ± 7 (12)[a] (maxima)	30.1 ± 6.7 (17)[b] (average)
41–45	30 ± 40 (12)	22.3 ± 5.9 (10)
46–50	53 ± 42 (13)	20.7 ± 14.0 (31)
51–55	82 ± 57 (10)	12.7 ± 8.7 (10)
56–60	63 ± 54 (6)	7.2 ± 2.0 (5)
61–65		6.8 ± 2.5 (6)
66–75	41 ± 30 (12)	5.9 ± 1.8 (5)

[a] No. of cycles examined.
[b] No. of cases.

estrogens are steadily replaced by adrenal estrogens in the urine to the same extent as germinal parenchyma disappears, so that the estrogens originate mainly from the adrenals during late postmenopause and in senility (residual estrogens) (DICZFALUSY, 1961). The estrogen excretion does not change after surgical castration during a normally occurring menopause (BULBROOK, 1958), whereas estrogen values in the urine fall to unmeasurable levels following adrenalectomy in the postmenopause (BULBROOK, 1957). On the other hand, vegetative symptoms due to loss are often intensified after ovariectomy during the postmenopause (HELLER, 1944). This may be due to the effect of castration in the early postmenopause when the basal estrogen secretion of the ovarian stroma still has a certain quantitative effect. It is also of interest that a slight estrogen excretion can still persist during the postmenopause even after ovariectomy and adrenalectomy (BULBROOK, 1957); its origin is uncertain. Incubation studies have shown that the ovaries produce mainly androgens during the postmenopause (PLOTZ, 1967; MATTINGLY, 1969), so that the ovarian stroma in aging ovaries functions as an endocrine gland (ENGLE, 1955; RICE, 1966).

During the premenopause the fall in estrogens leads to a diminished arrest of the hypothalamo-hypophyseal system, which leads in turn to a rapid rise in the amounts of FSH and LH excreted. The rise in LH excretion is somewhat less than that in FSH excretion. Particularly high values arise during the premenopause (Table 27, p. 561). These values lie between 40–400 IU/24 h for FSH and between 15–90 IU/24 h for LH where the total gonadotropin excretion is 3–40 mg Eq/24 h (KELLER, 1970). KAISER (1965) found a raised gonadotropin excretion even after the 40th year, but this observation has not been confirmed by other investigators (JOHNSON, 1959; KELLER, 1970).

During the postmenopause there is a steady decrease and any type of cycle is lost (Fig. 49). The variations in FSH and LH excretion during this phase of the postmenopause are not so great in the individual case (KELLER, 1968) as have been reported by some authors (ALBERT, 1966).

Even in senility, the gonadotropin excretion is many times higher than during sexual maturity (JOHNSON, 1959; KAISER, 1965). JOHNSON therefore speaks of the "eternal youth" of the pituitary. In contrast, 17-ketosteroid excretion in the woman decreases from the 20th year onward, there being a significant negative correlation between age and the quantities excreted (FURUHJELM, 1966). There is no "adrenopause", however.

e) Clinical Features

α) Premenopause

Progressive generative ovarian insufficiency arises during this phase of life. Corpus luteal function is deficient and cycles are often anovulatory. Clinically, bleeding disorders characteristic to the premenopause frequently arise. Only a little over a quarter (23.5%) of women enter the postmenopause with no cyclic disturbances. Disorders in rhythm (44.7%), and type (26.8%) are observed in 71.5% of cases (GOECKE, 1959). Twin studies have shown that hereditary factors play a considerable part in determining this course of events (MORETTI, 1953). Dysfunctional bleeding termed as "climacteric bleeding" is the predominant feature at this stage. It arises about 3 years before the onset of menopause (Fig. 55) with increasing frequency and especially often in the last year. It constitutes 70–80% of bleeding disorders during the premenopause, in the presence of an intact ostium uteri (KAISER, 1965). The characteristic climacteric bleeding is continuous, arises after a prolonged interval, and is associated with glandular-cystic hyperplasia due to follicular persistence (p. 607). The diagnosis "dysfunctional bleeding" should, however, be made only after organic causes have been excluded. This applies in particular to carcinomas of the cervix and of the body of the uterus, which, like polyps and fibroids, increase in incidence at this age (Fig. 55). Dysfunctional bleeding presents predominantly as disturbances in the bleeding rhythm.

Disorders in the type of bleeding, particularly metrorrhagia, are much more frequently caused by organic factors.

Functional sterility arising from progressive insufficiency of the corpus luteum, is of only little practical significance at this stage of life. The likelihood of pregnancy at 30 is thought to be 30% that at 20, only 11% at 35 years and 3% at the age of 40 (MÜNZER, 1934). Pregnancy can, however, occur up to the 51st year (WYLER, 1959), but every third pregnancy in women over 45 ends in abortion (JAVERT, 1957).

β) Postmenopause

Estrogen production finally falls below the physiological threshold (hypofolliculine stage) and is no longer adequate to stimulate endometrial bleeding. The postmenopause is reached at this stage. The amounts of estrogens produced are, however, still sufficient to cause significant proliferation of the endometrium. Dense endometrial proliferation, which has been described during the postmenopause, is probably due to delayed maturation of an ovum, which occasionally occurs. In so-called cystic atrophy, a few silent glandular tubes become cystically dilated. Ovulation can exceptionally arise several years after menopause, as has confirmed by the occurrence of pregnancies during the postmenopause (SHARMAN, 1962).

The clinical picture of the postmenopause is characterized by bleeding disorders, and by various types of psychological and somatic disturbances. Bleeding at this stage after 6 months of amenorrhea is dysfunctional in almost 50% of cases (KAISER, 1965; BÄTTIG, 1968). Later, organic causes are of primary importance, particularly carcinoma of the body of the uterus. Only about 20% of all types of bleeding at this phase of life are dysfunctional (Fig. 55), whereas 30–50% are due to malignant tumors (BÄTTIG, 1968; GOECKE, 1959).

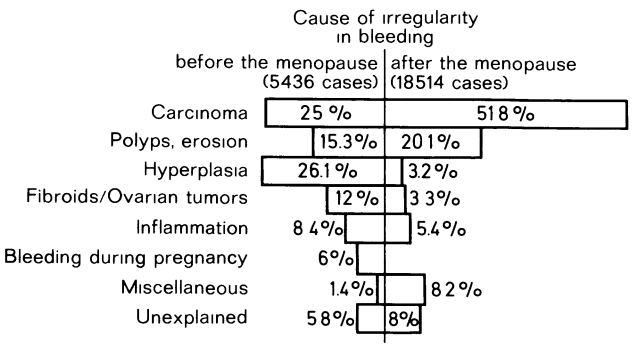

Fig. 55. Frequency of various causes of bleeding in the climacteric. (After HARBORT in GOECKE, 1959)

The climacteric syndrome (menopause syndrome), which includes vegetative (so-called climacteric vegetative syndrome) and psychological disorders during the climacteric, is the

presenting feature in the majority of cases. The data about type and frequency of disorders vary widely between 2% (MARANON, 1929) and 85% (ISRAEL, 1967) according to investigator and population group. There seems to have been an increase during the last decade. The climacteric features must be evaluated as a true illness in a quarter to a third of these women, and treatment is then necessary (BOSHANN, 1966; ISRAEL, 1967; LAURITZEN, 1968). The causal factor is the fall of estrogens. Castration leads to symptoms similar to those arising with the natural menopause (Fig. 56); substitution therapy with estrogens removes these symptoms. The level of the gonadotropin excretion is not, however, related to the severity of the symptoms. The poor adaptation of the organism to the fall in estrogens leads to diencephalic false regulation with vegetative dysfunction. A state of neurovegetative equilibrium usually arises after a few years, but sometimes only during senility. Disturbance of the functional circle consisting of diencephalon, hypophysis and ovary can result in false regulation of other functional circles, and can lead to hyperthyroidism, or less frequently hypothyroidism.

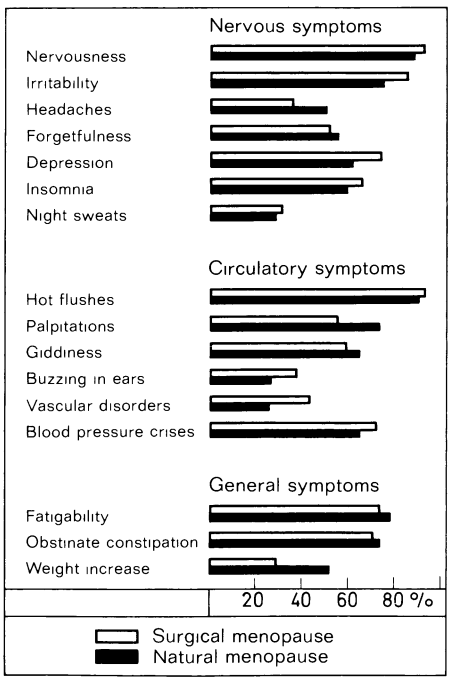

Fig. 56. Postmenopausal symptoms. (After LAURITZEN, 1968)

The climacteric symptoms are numerous (Fig. 56). Duration and severity vary with the individual, both being dependent on constitution and to a lesser extent on external environmental conditions. The woman "experiences the form of climacteric appropriate to her vegetative and psychological constitution" (WIESEL, 1924). Any woman who is already vegetatively and psychologically labile is predisposed to symptoms due to loss of function. Climacteric dysfunctional symptoms can precede the menopause by some years and usually disappear within a few years, although they do exceptionally persist into advanced age. The pathogenesis is not explained. It has never been shown that increased amounts of serotonin, adrenaline, noradrenaline or histamine are liberated. Hot flushes are the main clinical feature of the vegetative disturbances. As a rule these flushes are followed by an outbreak of sweating and this is probably the only symptom which is pathognomonic to the climacteric since it never arises otherwise. These hot flushes are ergotropic sympathetic attacks with hyperemia in the region supplied by the cervical sympathetic nerves (HAUSER, 1961), i.e. in the face, neck, thorax and hands, in those areas where erythema pudendum also arises. Often there is also a rise in blood pressure (HOFF, 1959). In diagnosis and treatment of the climacteric syndrome, it must be remembered that similar symptoms can also be due to organic cardiovascular changes.

Psychological disturbances during the climacteric are not a direct result of the endocrine adjustment, but are rather psychological reactions to the changed position in life. A conscious or unconscious fear of the loss of femininity moves into the foreground with the emotional lability. This fear is based on real changes: loss of the ability to bear children, decreased sexual capacity, loss of female charms, independence of the children, displacement at work by younger female colleagues etc. (DEUTSCH, 1948). The intelligent woman with a healthy psychological understanding usually disposes of these psychological factors without developing psychological disorders. Constitution, upbringing and particularly the situation in life have a considerable influence on the type of reaction.

Disorders due to organic factors arise more frequently after the menopause. Thus there is an increase in the incidence both of genital diseases such as kraurosis and pruritus vulvae, senile colpitis, urethro-cystitis, carcinomas of the fundus of the uterus, ovaries and breast, and of extragenital diseases; unstable blood pressure, hypertension, rise in cholesterol and lipoproteins in the blood, obesity, coronary sclerosis, myocardial infarction, osteoporosis and osteoarthrosis all increase in frequency. Some of these conditions are due directly to the reduction in estrogen production (dys-

pareunia, senile colpitis, urethro-cystitis). There is probably a causal relation between the loss of estrogens and osteoporosis and the syndrome of hypertension, obesity, coronary sclerosis and myocardial infarction (WEGELIN, 1944; HOFF, 1959; BERKSON, 1964; PRILL, 1966; THOMAS, 1966; PLOTZ, 1967; DAVIS, 1967; PSCHYREMBEL, 1968). The loss of ovarian function does predispose women to obesity (matron's fat, old woman's fat) (HOFF, 1959). The climacteric accounts in some way for 37% of cases of obesity in women (climacteric obesity) (SCHULZ, 1958). In castrated women there is an increase in weight of over 10 kg in 18% (TRIASSAC, 1956), 5% put on over 20 kg (BAHNER, 1955); after a natural menopause 22 to 39% of women put on weight (BARRET, 1933, 1931; WIRTZ, 1935). Large-scale statistical studies from American life insurances also show that "climacteric obesity" does exist. Metabolic changes, reduced physical activity and elevated calorie intake (worry fat) are causal factors. Constitutional factors are also of importance.

Senile osteoporosis in the woman is discussed in Chap. XIV (p. 867). This type of osteoporosis is about 5 times more common in the female than in the male (REIFENSTEIN, 1958).

f) Therapy

In 1900 the life expectancy of American and European women was 51 years. By 1960, it had already risen to 74 years (MENDUKE, 1967). This means that ovarian function is now absent for one third of a woman's life. Since the testes continue to function to an advanced age, there is no analogous phase of life in the male and no parallel in the animal kingdom. The question of a general continuous substitution during the postmenopause and senium is therefore under discussion. The following facts have now been established: although the theoretic advantages of general prophylaxis with estrogens cannot be disputed, until now there are no certain bases for assessing the value of long-term estrogen treatment, and the duration of treatment with estrogens such as is now being employed empirically during the postmenopause is still too short to permit any conclusions (PLOTZ, 1967).

Substitution treatment is indicated in cases where the symptoms due to loss of estrogens take the form of a true illness. Substitution is absolutely contraindicated in cases of carcinoma of the reproductive system, the breast included, and for five years following treatment of these cases. Caution is indicated in the presence of uterine fibroids, endometriosis, mastopathia cystica and particularly with any cholostatic hepatopathy, since 17-alkalized steroids promote stasis (p. 575). In general the doses prescribed are too high, particularly immediately after the menopause, so that iatrogenic bleeding occurs in about 10% of patients under treatment (LAURITZEN, 1968). The optimal dose is the lowest possible dose which leads to the disappearance of symptoms due to loss of estrogens. Treatment must be adjusted to the individual, and oral treatment is especially well suited for substitution. Yearly examination by a specialist is essential for women receiving substitution treatment. Metrorrhagia calls for investigation by a fractionated curettage. The cytotest is only 65% accurate in cases of carcinoma of the corpus uteri and is not adequate for investigation of these cases of metrorrhagia (HELD, 1955).

Assessment of the onset of action, the duration of action and the therapeutic value of a drug depend mainly on observations of the climacteric symptoms before and after treatment. Estimation of the so-called "climacteric index" has proved to be of practical value (KUPPERMAN, 1959). Double-blind trials against placebo are essential. The "Kupperman index" is a simple arbitrary system, in which 10 recognized climacteric symptoms are given a number from 1–4. The intensity of the symptoms is also given such a numeric factor (Code: symptom not present = 0, mild = 1, average = 2, pronounced = 3) (Table 39).

Table 39. Assessment of the severity of climacteric symptoms or the therapeutic value of a preparation in the climacteric index (KUPPERMAN, 1959)

Symptoms	Factor	Intensity	Numeric conversion
Vasomotor symptoms	4	M (2)	8
Paresthesia	2	+ (3)	6
Sleeplessness	2	+ (3)	6
Nervousness	2	M (2)	4
Depression	1	+ (3)	3
Giddiness	1	L (1)	1
Weakness (fatigue)	1	L (1)	1
Arthralgia and myalgia	1	M (2)	2
Headache	1	L (1)	1
Palpitations	1	+ (3)	3
Climacteric index (sum)			35

[a] 0 = no symptom = 0; L = mild = 1; M = moderate = 2; + = severe = 3.
[b] Numeric conversion = factor * intensity.

Multiplication of the symptom factor by the intensity factor gives the "numerical conversion". The "climacteric index" is obtained by adding the results for each of the 10 symptoms together. A "climacteric index" of 35 or more indicates severe climacteric dysfunctional symp-

toms. An index between 20 and 25 indicates an average case, whereas values of about 15 indicate mild cases. The "climacteric index" should fall to 15 or less if treatment is successful.

Good results are achieved with conjugated estrogens (p. 550). The risk of iatrogenic bleeding is reduced since their action on the endometrium is rather slight ("soft" estrogens). The following doses are usual:

Presomen, Oestrofeminal or Premarin, 1.25 mg daily for 3 weeks, followed by a break of one week.

Estradiol preparations can be used successfully instead of conjugated estrogens, e.g. Progynova (estradiol valerianate) 1 mg daily for 3 weeks, then a break of one week. In some cases a combined preparation of conjugated estrogens with a tranquilizer has the most favorable effects when psychological disorders are predominant: Menrium (conjugated estrogens with Valium) 3 × 1 tablet daily for 3 weeks, then a week's break, followed by 1–2 tablets daily for 3 weeks and a week's break and so on.

During the first two years after the menopause, there is an increased risk of hemorrhage during treatment with estrogens. On account of this, some authors recommend biphasic treatment with one of the modern oral contraceptives. We think the value of this is debatable, since the risk of breakthrough bleeding is merely replaced by the risk of withdrawal bleeding. Both types of bleeding indicate a curettage.

Higher doses of estrogens can of course be prescribed for hysterectomized women when indicated.

G. Ovarian Dysfunction

1. Amenorrhea

Menarche occurs between the 10th and 16th year in about 95% of all women in European countries (GRIMM, 1948; STAEMMLER, 1964; WELLENBACH, 1967), and it only arises spontaneously in approximately 0.3% of cases after completion of the 18th year (GRIMM, 1948). It is therefore reasonable to speak of a *primary amenorrhea* when menarche has failed to occur even after completion of the 18th year in a person of female phenotype.

The point at which secondary amenorrhea may be diagnosed is still somewhat arbitrary. According to most authors, secondary amenorrhea is present when three or more months have elapsed since the onset of the last menstrual period in a patient who previously menstruated more or less regularly. A pregnancy must of course be excluded (ROCK, 1945; BICKERS, 1948; JONES, 1954). Secondary amenorrhea may occur physiologically during lactation, in the post menarche and in the postmenopause. The physiological forms of amenorrhea, which also include amenorrhea during pregnancy, must be distinguished from pathologic amenorrhea.

In addition, *generative* amenorrhea (amenorrhea of the 1st stage) must be distinguished from *vegetative* amenorrhea (amenorrhea of the 2nd stage). In the first type, generative ovarian function is absent i.e. there is no follicular rupture and no corpus luteum is formed, while in the second type no estrogens are produced either. Classification into hypergonadotropic amenorrhea (where excretion of pituitary gonadotropins (HPG) is increased) and hypogonadotropic amenorrhea (where HPG excretion is reduced) is justified for prognostic reasons. Hypergonadotropic amenorrhea has a considerably worse prognosis.

Amenorrhea is merely a symptom and not a disease. The causes of the symptom amenorrhea are extremely varied and the connections are often complex and still partly unexplained. This fact is reflected in the large number of recommended classification principles. A classification system considering the individual links of the functional cycle: hypothalamus, hypophysis, ovary, and uterus, and based on the etiology and pathology, is of practical use for didactic, diagnostic, and therapeutic reasons (Table 40). Some arbitrary classifications are inevitable. Thus classification of the Stein-Leventhal syndrome under ovarian amenorrhea is at least debatable. This pluriglandular disorder could be classified with as much justification under amenorrhea due to hypothalamo-pituitary factors. This is also applicable to symptomatic ovarian insufficiency in extragenital endocrine disorders, which is classified under hypothalamic forms of amenorrhea.

a) Primary Amenorrhea (Table 41)

In the majority of these cases amenorrhea is due to congenital ovarian defects, often genetic in nature (gonadal dysgenesia, ovarian hypoplasia) or to congenital malformations (Mayer-Rokitansky-Küster syndrome, gynatresia). It is rarer for it to be due to pseudohermaphroditism (testicular feminization, congenital and prepubertal adrenogenital syndrome). Pathologic chromosomal idiograms are therefore often encountered (PHILIP, 1965; JACOBS, 1961). The pathogenesis is more frequently ovarian than uterine. Primary amenorrhea due to hypothalamo-hypophyseal failure or to dysfunction

Table 40. Classification schedule for amenorrhea

1. *Hypothalamic amenorrhea*

a) Organic	Inflammation (meningoencephalitis) Degeneration (Laurence-Moon-Biedl syndrome) Neoplasm Trauma
b) Psychogenic (exogenous, endogenous)	Psychoreactive (emotional amenorrhea) Anorexia nervosa (mentalis) Pseudocyesis (grossesse nerveuse, grossesse imaginaire) Genuine psychosis Simple, postpartum ovarian insufficiency Chiari-Frommel syndrome (sometimes Forbes-Albright syndrome)
c) Iatrogenic	Sexual steroids, especially progestagens, phenothiazines, reserpine
d) Nutritional	Chronic malnutrition
e) Symptomatic in dysfunction of correlating organs	
Adenohypophysis	M. Cushing
Ovary	Endocrine-active ovarian tumoras or non-neoplastic ovarian cyst
Adrenal cortex	Adrenogenital syndrome M. Addison
Thyroid	Hypo- or hyperthyreosis
Pancreas	Juvenile diabetes mellitus
f) Idiopathic (dysfunctional)	

2. *Pituitary amenorrhea (adenohypophyseal)*

a) Organic	M. Simmonds: Inflammation (TB, syphylis, actinomycosis, giant-cell granulomas, etc.) M. Simmonds: Degeneration: postpartum ischemic necrosis = M. Sheehan (Sheehan's syndrome) Neoplasm (adenoma, craniopharyngioma) Forbes-Albright syndrome = Ahumada-del Castillo syndrome = Argonz-del Castillo syndrome (chromophobic adenoma) Acromegaly (eosinophilic adenoma) Trauma
b) Idiopathic	

3. *Ovarian amenorrhea*

Gonadal dysgenesis (or agenesis)
Chromosome idiogram 45/XO, 46/XY, 46/XX and mosaic)
(Swyer's, Rössle's or Turner's syndrome)
Ovarian hypoplasia
Ovarian dysfunction; polycystic ovaries or Stein-Leventhal syndrome
Destruction of ovarian tissue (tumors, inflammation)

Ovarian hypofunction, e.g. physiologic amenorrhea post partum and post abortum, autonomic ovarian insufficiency, so-called burnt-out ovary in post menopause and old age)

4. *Uterine amenorrhea*

Mayer-Rokikansky-Küster syndrome (uterus bipartitus cum vagina solida)
Traumatic amenorrhea, uterine synechiae (*Asherman's* syndrome)
Métrose de réceptivité (Moricard's syndrome)
Silent menstruation

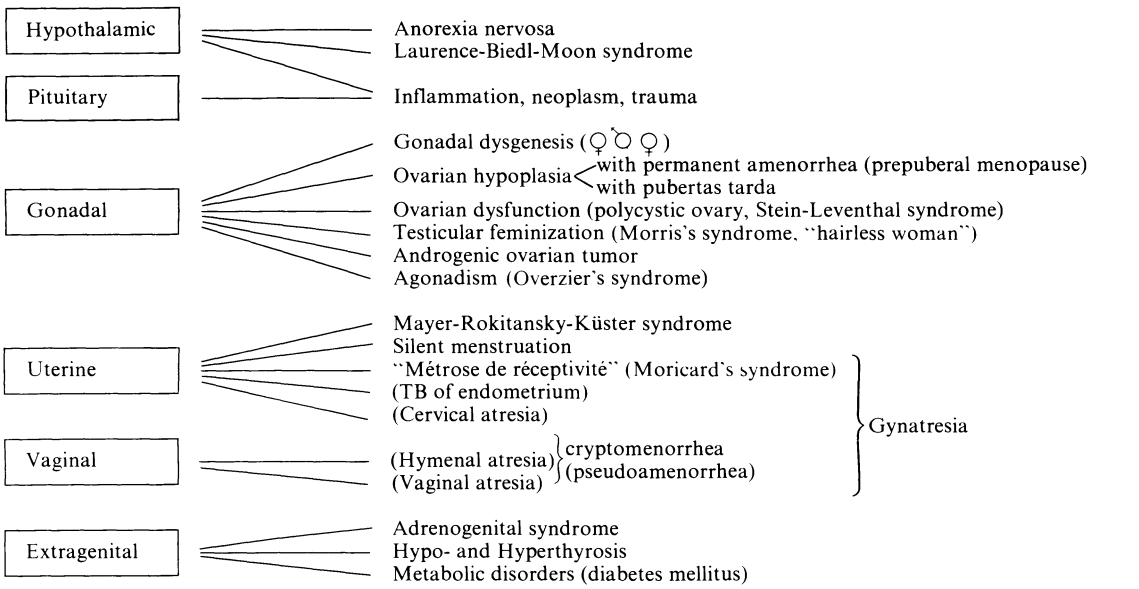
5. *Amenorrhea in hermaphroditismus verus and pseudohermaphroditismus masculinus with external feminization*

(testicular feminization)

Addendum

False amenorrhea in gynatresia (hymenal, vaginal, or cervical atresia)

Table 41. Primary amenorrhea: classification of primary amenorrhea by site and pathogenic aspects



of extragenital incretory organs and metabolic disorders is common (Fig. 57) (KUMSCHIK, 1966; PHILIP, 1965).

Patients with *ovarian primary amenorrhea* usually show hypogonadism. Genitalia and breasts are underdeveloped, pubic and axillary hair sparse. This type of amenorrhea occurs in individuals with gonadal dysgenesia and ovarian hypoplasia.

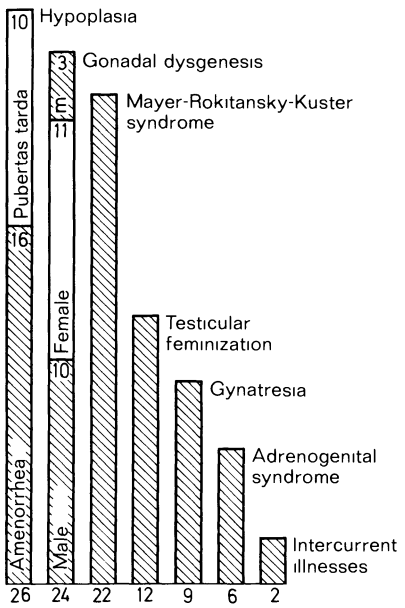


Fig. 57. Distribution of 101 cases of primary amenorrhea by type of disorder. (After KUMSCHIK, 1966)

In *gonadal dysgenesia*, there is a congenital disorder of the gonadal anlage due to a defect of the sex chromosomes. This has been discussed in detail in another section (PRADER, p. 713). In these cases, there is a gonadal rudiment with complete absence of the germinal cells. It is usually the malformations or the small stature and not the amenorrhea which cause the patient to consult the doctor, particularly the pediatrician. Primary amenorrhea with hypogonadism can be the first symptoms leading to further investigation in a case of gonadal dysgenesia where growth is normal (so-called Swyer's syndrome).

So-called *ovarian hypoplasia* is another quite common cause of primary amenorrhea (STAEMMLER, 1964). The etiology and phenology are very irregular in this group of patients, disorders of the menstrual cycle in the presence of hypoplasia, but typically formed or cylindrically formed ovaries being the only common features. The proportion of germinal parenchyma may be reduced (primary hypoplasia = *hypogenesia*) or may be abundant in comparison to the sparse ovarian stroma (secondary hypoplasia). Both forms of hypoplasia represent an anomaly of the anlage, probably due to a genetic defect (PASCHKIS, 1955). This signifies a developmental anomaly (Table 42). It is quite possible that a congenital defect in the ovarian enzyme system is present (STAEMMLER, 1963). Accelerated follicular atresia due to an unknown hypergonadotropic phase is under discussion (BÉCLÈRE,

Table 42

Ovarian hypoplasia

(After STAEMMLER, 1964)

Primary (hypogenesis)		*Secondary*
Deficient germinal parenchyma defective anlage?		Germinal parenchyma relatively abundant Underdevelopment
	Forms	
Basic form: small, cylindrical ovary	Marginal form: small, but typically-formed ovary	Basic form: small, cylindrical ovary
Bordering on *gonadal dysgenesis*		Bordering on *normal*
	Clinical picture	
Tall or short stature (45%)		Noncharacteristic
Underdeveloped primary and secondary sexual characteristics		Primary sexual characteristics hypoplastic, and secondary ones noncharacteristic
Possibility of prepuberal menopause		Possibility of pubertas tarda
HPG elevated (hypergonadotropic hypogonadism)		HPG often lowered (hypogonadotropic hypogonadism)

1963). It is probable that some of the disorders are of hypothalamo-hypophyseal nature, and still undetectable. Primary amenorrhea with primary hypoplastic ovaries is also described as *pre-pubertal menopause*. Secondary hypoplastic ovaries can lead to the clinical picture of *delayed puberty* (pubertas tarda).

Growth disorders in the form of exaggerated (>170 cm) or diminished growth (<155 cm) have been observed in almost 50% of all women with primary ovarian hypoplasia. Genital organs, breasts, pubic and axillary hair are poorly developed due to the primary estrogen deficiency. Elevated HPG activity in the urine is characteristic (hypergonadotropic hypogonadism) (KINCH, 1965). In contrast to this, there is no uniform phenotype for women with secondary ovarian hypoplasia, since the hypoplastic genital organs may be associated with infantile or normally developed secondary sexual characteristics. The urinary excretion of pituitary gonadotropins is often reduced (hypogonadotropic hypogonadism).

Primary amenorrhea may exceptionally arise in the syndrome of *polycystic ovaries* (p. 609).

Agonadism (Overzier syndrome) is rare. The external genitalia are of female type, but only the vaginal opening is present, the vagina itself being absent. Primitive Müller's and Wolffian ducts are the only internal genitalia present. Overzier's first two cases were siblings (OVERZIER, 1961). All patients so far described have had male chromosomes (XY).

Patients with a malformed uterus or without a uterus constitute a second large group with primary amenorrhea.

Inhibition malformations of the distal part of Müller's duct are quite common in the so-called *Mayer-Rokitansky-Küster-syndrome* (MRK syndrome) (bipartite solid uterus without vagina) (HAUSER, 1961). We observed this syndrome 12 times within 4 years. Other authors (KUMSCHIK, 1966) have reported that this syndrome accounted for as many as 22% of their cases of primary amenorrhea. The uterus usually consists of a solid muscular cord divided in two. Both uterine cornua with lateral club-like processes are immediately next to the ovaries, and extend medially in the form of a comma. They are connected by a retrovesical peritoneal structure (ligamentum latum). The malformation increases in the craniocaudal direction (Fig. 58). Genetically, a developmental inhibition of the distal section of the Müller's filaments during the second month of embryonal life, gives rise to the MRK syndrome, the causal genesis is unknown. These subjects have a 46/XX chromosomal configuration. Inheritance must be excluded on the basis of the cases reported so far.

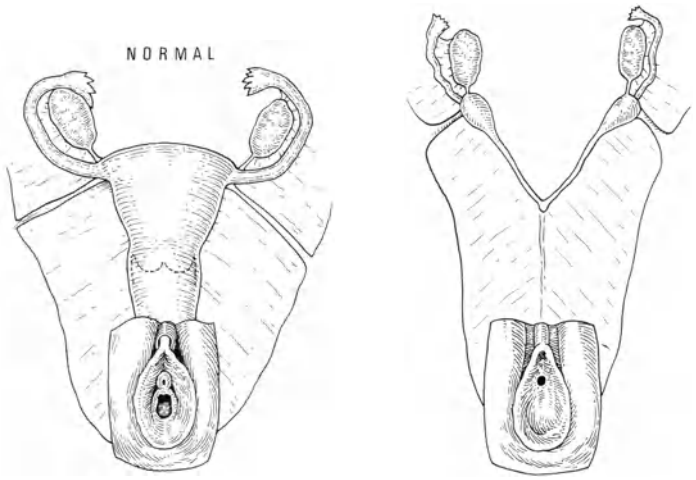

Fig. 58. Diagram showing normal female reproductive tract contrasted with Mayer-Rokitansky-Küster syndrome: no vagina, divided uterus, a single thread in the middle and club-shaped at the sides. The ovaries are placed higher than normal. (After HAUSER, 1961)

Symptoms: Primary amenorrhea and the inability to have intercourse are the most frequent reasons for consulting the doctor. The patients only rarely seek medical advice because of primary sterility.

Very rarely, primary amenorrhea is due to an *imperforate hymen*, *congenital vaginal closure* in the cranial third, or *closure of the cervix* (MCKUSICK, 1964). These defects lead to hematocolpos, or hematometra and hematosalpinx (false amenorrhea). The cramp recurring monthly in the lower abdomen, increasing in severity and radiating to the lumbar region, together with the demonstration of a retrohymenal, or uterine or parauterine (tubal) painful tumor rapidly leads to the right diagnosis.

Endometrial TB exceptionally leads to primary amenorrhea. The ovarian cycle is maintained in these patients. This can be shown by the biphasic basal body temperature and the colpocytogram. The estrogen test is negative.

Patients with primary amenorrhea very occasionally have normal ovarian and endometrial cycles and normal fertility (ISRAEL, 1967). Absence of cyclic withdrawal bleeding is attributed to the absence of the hypothetic uterine hemorrhagic factor (silent menstruation or amenorrhea spuria).

Testicular feminization must be mentioned as another form of primary amenorrhea (so-called Morris syndrome, "hairless woman") (MORRIS, 1953). This form of intersexuality has been described fully in another section (p. 726).

In contrast to secondary amenorrhea, primary amenorrhea is seldom due to functional disorders of the hypothalamo-hypophyseal system resulting from infections, circulatory disturbances (infarct, hemorrhage, internal hydrocephalus) tumors (neoplasms, aneurysms of the internal carotid artery), malnutrition or psychological factors. Organic changes in the region of the pituitary and hypothalamus always lead to primary amenorrhea together with disorders of growth and development as well as impaired metabolism, water balance and sleep.

Craniopharyngiomas affecting the hypothalamus are discussed on p. 120.

Primary amenorrhea due to *psychological* factors (BENEDEK, 1952; MICHEL-WOLFROMM, 1963; CONDRAU, 1967) arises in the absence of any psychosis in girls who are continuously under pressure at school and in the parental home. In addition, an acquired aversion towards everything sexual may also be an etiological factor. Often this is combined with obesity or emaciation (THOMÄ, 1961). These women are psychologically and psychosexually infantile. The estrogen secretion is decreased in the presence of normal gonadotropin excretion. Differentiation from primary ovarian amenorrhea, which is considerably more common, is achieved by careful psychiatric exploration and perhaps in retrospect after successful psychiatric therapy. Often, however, the situation can only be clarified by an ovarian biopsy.

Primary amenorrhea can also be due to *dysfunction of one of the endocrine organs* correlated with the hypothalamo-hypophyseal-ovarian axis. Hypothyroidism and hyperthyroidism, as well as severe metabolic disturbance in unstabilized juvenile diabetes, can lead to primary amenorrhea, probably due to ovarian insufficiency caused via the hypothalamus.

States of *hypercorticism* produce primary amenorrhea more frequently than the endocrine and metabolic disorders mentioned. Thus the *adrenogenital syndrome* in the congenital or acquired forms can lead to primary or secondary amenorrhea if untreated. As a rule, however, it is the intersexuality and not the amenorrhea which leads to further investigation. The syndrome has been discussed in detail elsewhere (p. 358, PRADER). When virilization arises only after the 2nd or 3rd year of life, the presence of an adrenocortical tumor must be considered.

According to present-day knowledge the so-called pre- and postpubertal forms of the adrenogenital syndrome are also congenital disorders of steroid metabolism in the adrenal cortex. Borderline adrenal hyperplasia usually results in secondary amenorrhea (p. 593).

Cushing's syndrome arising before the menarche leads to primary amenorrhea if not treated. This symptom, however, retreats into the background beside the basic symptoms.

Endocrine active ovarian tumors (arrhenoblastoma, hilus-cell tumor, adrenal-rest tumor, chorioepithelioma and perhaps also tumors of the granulosa-theca cells) can cause primary amenorrhea. This is especially true of arrhenoblastomas. More often however, these tumors cause secondary amenorrhea (p. 638).

Primary amenorrhea is a concomitant symptom in the *Laurence-Moon-Biedl syndrome* (BIEDL, 1922, 1933; KEIFER, 1950), giving way to retinitis pigmentosa (which can lead to amaurosis), imbecility, dwarfism and obesity. Polydactylia, which is often present, and the involvement of siblings are evidence of the occurrence of this incurable neurological disease.

b) Secondary Amenorrhea

Secondary amenorrhea is more common than primary. Before endocrinopathies are considered, pregnancy and its sequelae must be excluded in an amenorrheic patient of sexual maturity, whatever the patient may say.

Physiological amenorrhea during the puerperium lasts a maximum of 3 months in a woman who is not breast feeding, and 4 months in the nursing mother.

Physiological amenorrhea also occurs frequently in the postmenarchal period, and is probably a reflection of a certain lability in the functional chain between hypothalamus, hypophysis and ovaries. Treatment is only exceptionally necessary since normal rhythm often arises spontaneously. Disturbed primary cycles, however, occur more frequently in women who later suffer from ovarian dysfunction. Secondary amenorrhea arising during the climacteric is due to the gradual development of generative and vegetative ovarian insufficiency. Menopause before the 40th year of life, is referred to as an *early menopause* (precocious climacteric). The climacteric syndrome is due to the reduced estrogen secretion (p. 582). At the same time there is a rise in gonadotropins. The cause of premature ovarian insufficiency is often not clear. Cytogenetic investigations have shown that an early menopause arises for example in patients with an XXX set of chromosomes (GORDON, 1967). In contrast to other women with precocious climacteric, these women often have hypogonadism.

The largest group of patients with pathologic secondary amenorrhea includes young women of inconspicuous appearance in whom psychological influences produce menstrual disorders. This is a form of hypothalamic amenorrhea, described as *psychogenic or emotional amenorrhea* on the basis of its etiology. Conflicting factors are at the root of the disturbance: unsatisfactory matrimonial or familial conditions, psychosexual tension, exaggerated fear of pregnancy, desire for a child, fears about the future, financial problems etc., and frightening experiences such as accidents, sudden death of a relative, war experiences. Conflicts arise from disturbed living conditions. Severe psychological trauma such as occurs during wars leads to amenorrhea particularly frequently. Examples of this are amenorrhea occurring during states of emergency, internment in concentration camps and ghettos, and during flight (WHITEACRE, 1944; SYDENHAM, 1946; STROINK, 1947; HEYNEMANN, 1948; TIETZE, 1948; BASS, 1947; MAYER, 1948; KNEER, 1949; NOCHIMOWSKI, 1946; NETTER, 1962). Secondary amenorrhea due to psychological factors was observed in up to half the female members of prison camps. Rapid development of secondary amenorrhea resulting from psychological factors belies the causal influence of malnutrition. Malnutrition begins to act only after several months but also contributes to the fact that 90% of the women in prisoner camps were amenorrheic. A purposeful reaction underlies this emotional amenorrhea: preservation of the species is abandoned in favor of self-preservation. This is also applicable to *nutritive amenorrhea* due to chronic inanition (KEYS, 1950; ZUBIRAN, 1953). In some women, quite trivial psychological influences are sufficient to produce menstrual disorders. The occurrence of secondary amenorrhea in girls and young women during a change in environment (time spent abroad in another part of the country), is a good illustration of this. On the other hand, not all

women react to even very severe psychological factors with the development of amenorrhea. Some do not react at all or react in some other way. We therefore speak of labile-cycle and stable-cycle women (SEITZ, 1939), which is meant to indicate that constitutional factors are involved. We know nothing about the nature of these individual differences. Women suffering from emotional amenorrhea often have immature and infantile personalities and unexpected experiences cause erroneous hypothalamic regulation. The hormone values vary widely and are dependent on the duration of amenorrhea. Urinary excretion of pituitary gonadotropins is decreased in most of these women, and may be completely absent in some. Estrogens are correspondingly reduced. Hypogonadotropism is rarely associated with hypothyroidism or hypocorticism. The HPG activity in the urine is quite commonly normal in the presence of normal or even elevated estrogen levels. High HPG and low estrogen levels can be found in acute forms, and the women affected complain of climacteric symptoms (RAKOFF, 1962). Excretion of metabolites of adrenal corticoids may vary widely in certain forms (STURGIS, 1962), and the urine excretion of 17-keto steroids may be considerably raised.

The observation that gonadotropin excretion is often reduced at least initially led to the conclusion that the hypothalamus is the main seat of the disorder in these cases of emotional amenorrhea. Any estrogen deficit in these women may be due to the fact that LH excretion is disturbed in the presence of normal or even raised excretion of FSH (KLINEFELTER, 1943). Reduced LH excretion has been described in psychogenic amenorrhea (MCARTHUR, 1958).

Amenorrhea with *anorexia nervosa* must also be classified as a hypothalamic form of amenorrhea (LASÈGUE, 1873; GULL, 1874; NEMIAH, 1950; BLISS, 1960; THOMÄ, 1960). This condition is not an endocrinopathy but primarily a psychoneurosis which takes the form of an aversion to any form of food intake. These patients are psychologically immature, and are incompatible to changes in environment. Domineering parents are often involved initially. The discontinuation of nutrition, which can lead to cachexia, results secondarily in limited gonadotropic function. Animal experiments have revealed that the release but not the production of gonadotropins is reduced during inanition. The reduced formation or absence of estrogens leads to atrophy of the reproductive organs and secondary sexual characteristics in these cases too.

Pseudocyesis must be classified in the group of psychogenic amenorrhea (MOULTON, 1942; FRIED, 1951; BENEDEK, 1952). It is an excellent example of the psychological influence on reproductive processes. It is a psychoneurosis arising from an exaggerated wish for a child or from pathologic fear of pregnancy. A series of indefinite signs of pregnancy arise: nausea, vomiting, meteorism, increase in weight with formation of striae distensae, enlargement of the breasts with lactation. Rhythmic uterine contractions start at the "calculated date" of delivery. In contrast to the other psychogenic forms of amenorrhea, secondary ovarian insufficiency does not arise in this case. Estrogen production is normal and atrophy of the genitalia fails to occur. Secretory transformation of the endometrium may even be well developed.

Because of the functional structure of the hypothalamus, it is not surprising that hypothalamic amenorrhea can be associated with disorders of other functions regulated by the central nervous system. Examples of these functions are: fat and carbohydrate metabolism, water balance and wake-sleep regulation. Thus, secondary amenorrhea is often found in obese women. This is probably not due to the obesity; both are probably concomitant consequences of the same psychological influence. Normalization of weight is followed quickly by the return of menstruation, so that one is tempted to assume a direct causal connection. However, it is the removal of the psychological disturbance which probably leads to the conscious limitation of food intake and often to the release of gonadotropins at the same time.

The patients are often unaware of the psychological factors causing the amenorrhea, and quite often emphatically deny them. Wide experience and great patience and tact are required for the doctor to expose the connection, which is often complex.

If neither psychological nor organic causes can be found to explain hypothalamic amenorrhea, it is justifiable to refer to an *idiopathic disorder*. These cases are probably examples of emotional amenorrhea where no psychogenesis can be found. Obesity is often present at the same time (BAHNER, 1969).

Analogous clinical illnesses have also been observed with tumors in the region of the tuberal part of the hypothalamus. On the basis of animal experiments it is suspected that this area is responsible for regulation of body weight. However, in the majority of cases, there are hypothalamo-hypophyseal functional disorders of unknown etiology. The high familial incidence suggests the influence of hereditary factors. The fat distribution is typically feminine, fat deposition being mainly in the buttocks, thighs, lower abdomen, breasts and shoulder

girdle. The distal extremities on the other hand remain quite slim. The psychological structure of these women is in keeping with the somatic composition in that they are calm, well-balanced people. Although the patients are of normal height, the distal regions of the extremities are quite short. This irregularity in bone growth indicates a central dysfunction arising early. External and internal genitalia are hypoplastic (secondary hypogonadism). Menarche is not usually delayed, but the primary cycles are often abnormal, in the form of menorrhagia with oligomenorrhea. Amenorrhea finally develops. Hypertrichosis is often visible on the lower jaw, extremities and lower abdomen but is not very marked. Pituitary gonadotropin levels are diminished in the urine, in contrast to the elevated values in primary hypogonadism, and normal levels of the total gonadotropins in polycystic disease of the ovaries. Estrogens are reduced. The endometrium can show a certain degree of proliferation so that the progestin test gives a positive result. The endometrium is usually atrophic after amenorrhea of long duration.

In addition to these psychoneurotic forms of amenorrhea, hypothalamic amenorrhea has also been observed in association with *true psychoses*, especially those of depressive character (BLEULER, 1954). Secondary hypothalamic amenorrhea can also be *iatrogenic* for example after administration of sexual steroids, and particularly depot-progestins. Amenorrhea has also been reported during the administration of reserpine, chlorpromazine, barbiturates, morphine and dithiocarbamide (Fig. 47, p. 572).

A special form of hypothalamic dysfunction leads to the *Chiari-Frommel syndrome* (CHIARI, 1852; FROMMEL, 1882; GUMPEL, 1960; JAZMAN, 1963; KAISER, 1963; HASKINS, 1964; CHARD, 1964). This syndrome consists of postpartum amenorrhea with galactorrhea, often associated with moderate obesity. Gonadotropin and estrogen levels are reduced. The syndrome is due to increased prolactin secretion by the anterior pituitary, possibly resulting from the loss of the inhibitory factor in the hypothalamus, and associated with a reduction in the release of gonadotropins at the same time (CANFIELD, 1965). (The reader is referred to p. 556 for a discussion of the prolactin-inhibiting factor.) The uterus and ovaries atrophy due to the decrease in FSH and LH secretions. Secondary sexual characteristics are not affected by the estrogen deficit. The increased prolactin excretion has been demonstrated biologically with pigeon goiters. With the exception of the ovaries, function of the other endocrine organs is not altered.

The case histories of these women often show an exaggerated state of fear in connection with delivery so that psychological factors could very well be involved in the etiology of this syndrome (MÜLLER, 1962). This has been confirmed by the observation of a Chiari-Frommel syndrome arising after a pseudocyesis. The Chiari-Frommel syndrome together with special cases of Forbes-Albright syndrome (Ahumada-del Castillo or Argonz-del-Castillo syndrome) may form a group of hypothalamic forms of amenorrhea due to common psychogenic etiological factors, where no organic changes can be found in the region of the hypothalamus and pituitary. However, even in the puerperal form, the possibility of an intracranial neoplastic process must always be kept in mind (see below).

The Chiari-Frommel syndrome is too frequently diagnosed. The two mandatory symptoms of amenorrhea and galactorrhea can be caused by a series of drugs such as the "pill", reserpine, phenothiazine, α-methyl dopa and Tofranil (HOOPER, 1961; RABINOWITZ, 1961; KLEIN, 1964), in cases where the frequence of the galactorrhea is directly dependent on the amount of drug administered. Both symptoms have been observed together in cases of hypothalamic and hypophyseal neoplasms, hypothyroidism [sometimes combined with precocious puberty (VAN WYK, 1960; BROWN, 1965)], and after hysterectomy (SACHS, 1959).

The Chiari-Frommel syndrome must be differentiated from the considerably more common *uncomplicated postpartal ovarian insufficiency*, which is due simply to generative ovarian insufficiency. Estrogen excretion is normal and progesterone administration leads to bleeding from the secretory transformed mucosa. There are no features of failure. 17-Ketosteroids and 17-OH corticoids are often at the upper normal limits, particularly in obese women. Adrenal and thyroid functions are normal. The etiology and pathogenesis of this disorder are still not clear. It is possible that there is a refractory connection between the ovaries and gonadotropic stimulation, such as is present in lactating women (KELLER, 1968). There are no investigations about the gonadotropic activity in series of these women.

Secondary amenorrhea is often the first symptom of a pituitary adenoma and craniopharyngioma in the adult woman (ROGERS, 1963). At the onset of the illness, there is only a loss of gonadotropic function, but later the clinical picture of panhypopituitarism develops. Loss of hypothalamic function (loss of formation and release of the gonadotropin-releasing factor, and other hypophysiotropins) can arise due

to pressure on the centers lying between the supra-optic and paraventricular nuclei when the tumor is situated more anteriorly, or through compression of the eminentia mediana and tuber cinereum when the tumor is more posteriorly placed. The suprasellar tumor lying anteriorly causes pressure on the optic chiasma resulting in visual disturbances (homonymous hemianopsia).

The *Forbes-Albright syndrome* (Ahumada-del Castillo or Argonz-del Castillo syndrome) (p. 106, Chap. V), in contrast to the Chiari-Frommel syndrome, arises independently of a birth. It is often caused by a chromophobe adenoma of the pituitary. The clinical features are secondary amenorrhea with galactorrhea, low values of urinary HPG and an estrogen deficit (AHUMADA, 1932; ARGONZ, 1953; FORBES, 1954; BRICAIRE, 1958; JAGIELLO, 1960; BERCOVICI, 1963).

The less common, endocrine-active eosinophil and basophil pituitary adenomas can also lead to secondary amenorrhea. This, however, retreats clinically into the background against the disorders of growth and metabolism (acromegaly, Cushing's disease).

"Compensation neurosis" must be considered as the cause of a secondary amenorrhea occurring after cerebral concussion. Postpartum amenorrhea may be due to Sheehan's syndrome (p. 92, Chap. V).

Women with *primary ovarian insufficiency* account for only a small proportion of patients with secondary amenorrhea. Patients with secondary ovarian hypoplasia, and a small number of women with an XXX set of chromosomes belong to this group. This form of amenorrhea has already been mentioned under primary amenorrhea.

Patients with *polycystic disease of the ovaries* must also be discussed in this section (p. 609 ff.). Since this disease is a pluriglandular disorder of uncertain etiology and pathogenesis, classification under ovarian amenorrhea is entirely arbitrary. The form described originally by STEIN and LEVENTHAL (1935) referred often to obese young women with hirsutism, secondary amenorrhea or oligomenorrhea, sterility, and enlarged polycystic ovaries.

Epidemic parotitis may occasionally lead to *ovarian destruction* causing primary or secondary amenorrhea. On the other hand, the functional capacity of the ovaries is very impressive, since menstrual disturbances may be completely absent even in cases where bilateral ovarian tumors have caused almost complete pressure atrophy of the ovarian stroma. The one exception to this is the Krukenberg tumor, which commonly gives rise to secondary amenorrhea when present bilaterally.

Endocrine-Active Ovarian Tumors. Arrhenoblastomas, tumors of the hilus cells, adrenal remnant tumors, chorioepitheliomas, and less frequently tumors of the granulosa-theca cells can give rise to amenorrhea. This is especially true of the arrhenoblastoma (p. 638).

This tumor arises most frequently between the 15th and 30th years of life. Defeminization and masculinization are the predominant clinical features, and are due to prolonged action of the slightly increased testosterone production. Excretion of the 17-ketosteroids is usually at the upper normal limit or slightly increased, and never reaches values as high as those found with adrenocortical tumors. The excretion values are generally also below those in the adrenogenital syndrome. Estrogens are usually normal, while gonadotropin excretion is decreased.

Dysfunction of Related Endocrine Organs such as the adrenal cortex and thyroid gland can cause secondary amenorrhea. Thus, the *postpubertal* form of the adrenogenital syndrome is a further cause. The probability of an adrenocortical tumor increases with advancing age of onset of this syndrome. Like hyperfunction, hypofunction in Addison's disease can also lead to secondary amenorrhea. The same is true of hypo- and hyperthyroidism.

The borderline cases of adrenal hyperplasia are of more practical importance since the incidence is greater. Mild cases can lead simply to a shortened luteal phase, whereas severe cases can give rise to anovulatory cycles with secondary amenorrhea. These cases of adrenal hyperplasia are a type of postpubertal adrenogenital syndrome where there is only a slight or moderate increase in the excretion of 17-ketosteroids and where the pregnanetriol excretion is also only slightly elevated. These women usually present clinically with hirsutism. Enlargement of the clitoris may also be present. There is a mere generative ovarian insufficiency in most of these cases. Progesterone leads to withdrawal bleeding.

Traumatic or atretic amenorrhea is a rare form of secondary amenorrhea (*Fritsch-Asherman syndrome, métrose de réceptivité Moricard*, so-called uterine adhesions or synechia) (ASHERMAN, 1948; 1950; 1957). It is a uterine amenorrhea in which gonadotropins and ovarian sexual steroids are normally secreted and formed, in which the cyclic sexual processes run a normal course but menstruation fails to occur. It is usually due to a too radical curettage post partum or post abortum, if it was performed especially in the first 14 days after termination of a pregnancy. Less frequently, manual removal of the placenta with mechanical re-

moval of the basal stratum of the endometrium or chemical or radiogenic cauterization for severe hemorrhage may result in traumatic amenorrhea. Tuberculous endometritis may exceptionally cause this type of amenorrhea by causing partial or total adhesion of the two uterine walls.

Secondary amenorrhea has also been observed after postoperative adhesion of the cervical canal, e.g. after amputation of the cervix during a prolapse operation, a diagnostic or therapeutic conisation, or electrocauterization of an ectropion.

Adhesions of the vagina after cauterization giving rise to amenorrhea are rare.

False amenorrhea is caused by all these forms of secondary gynatresia. The molimina menstrualis quickly leads the patient to the doctor.

c) Diagnostic Procedure (Tables 43, 44)

Amenorrhea is not a disease but merely a symptom. It must therefore be investigated thoroughly before treatment can be started. Often, however, treatment is only symptomatic. Unscrupulous symptomatic therapy is very often not only useless, but associated with the danger of indirect damage, as it may mask the disease underlying the amenorrhea. As long as there is no obstruction (gynatresia) in the discharging genital organs, primary amenorrhea should not be investigated or treated before completion of the 18th year of life. Spontaneous menarche has only exceptionally been observed after this age [approximately 0.3% of cases of primary amenorrhea (GRIMM, 1968)]. An investigation should then be instituted as promptly as possible, since the woman's future depends to a considerable extent on the prognosis.

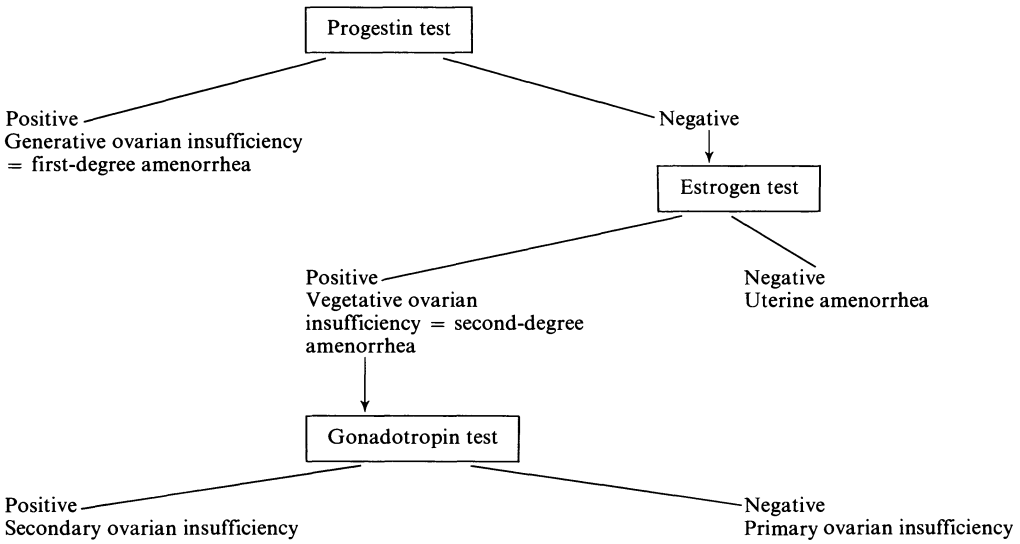
Physiological amenorrhea must be excluded before any form of treatment is started. Every amenorrheic sexually mature female must be considered pregnant until the opposite has been proved. A pregnancy can be diagnosed or be excluded with a high degree of certainty (96–98%) by means of the immunological pregnancy test as early as 14 days after the

Table 43. Diagnostic interpretation of amenorrhea

A. Case history
General and gynecological examination

B. Basal temperature, Shorr smears, cervical mucus,
HPG activity in 24-h urine

C. Hormone tests



D. Estrogens, pregnandiol, pregnantriol, 17-ketosteroids, 17-OH corticoids

Ocular fundus, perimetry
Idiogram
Endometrium biopsy, culdoscopy or laparotomy, ovarian biopsy
X-ray examinations: bone age, sella turcica, colpogram, hysterosalpingogram, urogram, etc.

Table 44. Diagnostic procedure in amenorrhea

Examination	Symptoms	Primary amenorrhea	Secondary amenorrhea
1. Case history	Familial incidence	Testicular feminization Laurence-Biedl-Moon syndrome (agonadism) Adrenogenital syndrome	Adrenogenital syndrome
	Postpartum occurrence (after collapse, mental trauma, curettage)		Sheehan's syndrome Chiari-Frommel syndrome Asherman's syndrome
	Previous infection (genital TB, parotitis epidemica)	MORICARD's syndrome (métrose de réceptivité)	
	Conflict situations shock	Emotional amenorrhea	
	Brain injury (cerebral concussion, contusion)	Postconcussion amenorrhea (compensation neurosis)	
	Slow-release progestagens, inhibitors of ovulation, reserpine, phenothiazines		Iatrogenic amenorrhea
2. General condition	Obesity, pronounced	Laurence-Biedl-Moon syndrome	Cushing's syndrome
	Obesity, moderate		Stein-Leventhal syndrome Chiari-Frommel syndrome
	Cachexia	Anorexia nervosa	
	Dwarfism	Adrenogenital syndrome Gonadal dysgenesis	
	Body hair as in man	Adrenogenital syndrome Virilizing ovarian tumor	
	Absence of pubic and axillary hair	Testicular feminization	
	Scanty growth of pubic hair, lateral portions of eyebrows scanty		Sheehan's syndrome
	Breasts Hypoplastic or atrophic	Primary and secondary ovarian insufficiency	
	Galactorrhea		Chiari-Frommel syndrome Ahumada-del-Castillo syndrome Iatrogenic: reserpine, phenothiazines (usually without amenorrhea) Hypothyreosis Acromegaly
	Inguinal hernia	Testicular feminization	
3. Genital status	No uterus present Vagina blind	Testicular feminization	
	No vagina present Uterus rudimentary	Mayer-Rokitansky-Küster syndrome	
	Vagina hypoplastic	Primary ovarian insufficiency	
	Clitoris hypertrophic	Adrenogenital syndrome Virilizing ovarian tumor Hermaphroditus verus Testicular feminization	
4. Hormonal status	HPG normal (LH lowered) Estrogens lowered Progesterone test negative Estrogen test positive	Hypothalamic amenorrhea (see Table 40) Exceptions: some forms of emotional and nutritional amenorrhea (Release blocked)	
	HPG lowered Estrogens lowered Progesterone test negative Estrogen test positive	Pituitary amenorrhea (see Table 40)	

Table 44 (continued)

Examination	Symptoms	Primary amenorrhea	Secondary amenorrhea
	HPG elevated Estrogens lowered Progesterone test negative Estrogen test positive	Ovarian amenorrhea (see Table 40)	
	HPG normal Estrogens normal Progesterone test negative Estrogen test negative	Uterine amenorrhea (see Table 40)	
	HPG normal Estrogens normal (occasionally lowered) Progesterone test positive	Polycystic ovary	
	HPG lowered Estrogens lowered Progesterone test positive	Adrenogenital syndrome	
	Urinary steroids lowered		Sheehan's syndrome Panhypopituitarism with pituitary tumors M. Addison
	17-ketosteroids elevated	Psychogenic amenorrhea Adrenogenital syndrome in adrenocortical hyperplasia Polycystic ovaries Virilizing ovarian tumors	
		Adrenogenital syndrome due to adrenocortical tumors	
	Estrogens lowered	Ovarian insufficiency (primary and secondary) Testicular feminization	
	Estrogens normal	Polycystic ovaries Adrenogenital syndrome Mayer-Rokitansky-Küster syndrome	
5. Vaginal cytology	Atrophic	Ovarian insufficiency (primary and secondary) Testicular feminization	
	Normal i.e. good estrogen effect	Polycystic ovary Traumatic amenorrhea (Asherman's syndrome) Métrose de réceptivité (Moricard's syndrome)	
6. Culdoscopy or Laparotomy	Uterus		
	None present	Testicular feminization	
	Rudimentary	Mayer-Rokitansky-Küster syndrome	
	Hypoplastic	Gonadal dysgenesis Ovarian hypoplasia	
	Ovaries		
	None present	Agonadism Testicular feminization	
	Hypoplastic or rudimentary		
	Threadlike	Gonadal dysgenesis (gonadal anlage, streak)	
	Cylindrical	Ovarian hypoplasia	
	Large, pale	Polycystic ovaries	
	Oystershell-like		
7. Radiographic examination	Urography		
	Malformations	Gonadal dysgenesis Mayer-Rokitansky-Küster syndrome	
	Colpohysterography		
	Synechiae	Gynetresia	Traumatic amenorrhea
	Sinus urogenitalis	Adrenogenital syndrome	
8. Chromosomal sex	Negative ("male")	Gonadal dysgenesis ♂ Testicular feminization Genuine hermaphroditism XX woman	

first missed period. Charting the basal body temperature is cheaper—a hyperthermal phase lasting for more than 16 days indicates a pregnancy with the same high probability as the immunological pregnancy test (BARTON, 1945).

Pathologic amenorrhea necessitates thorough investigation. A careful case history and the general and gynecological examinations usually provide valuable information on the etiology and pathogenesis (Table 44). Gynatresia and genital malformations, such as the Mayer-Rokitansky-Küster syndrome, can be detected or excluded (molimina menstrualis), and the presence of gonadal dysgenesia, testicular feminization or adrenogenital syndrome can further be indicated.

A biphasic basal body temperature in an amenorrheic patient indicates uterine amenorrhea, whereas the smear and cervical mucus show the degree of estrogen production.

The chromosome idiogram is often valuable in primary amenorrhea. Between 28–40% (JACOBS, 1961; PHILIP, 1965) of these patients have a chromosome anomaly. Estimation of gonadotropic activity (HPG) in the 24-hour urine permits differentiation between hypergonadotropic amenorrhea and hypo- or normogonadotropic amenorrhea. The hypergonadotropic form reflects primary ovarian insufficiency and allows substitution therapy at the most. Ovulation cannot be induced, and treatment of the sterility is thus hopeless.

The reactive capacity of the endometrium is examined by the *gestagen test* (Table 45), which should be performed before the *estrogen test* (Table 45). Both tests are negative in the presence of uterine amenorrhea. The result of the gestagen test permits generative ovarian insufficiency (Stage I or mild degree) to be differentiated from the severe form of vegetative ovarian insufficiency (Stage II or severe degree).

The use of progestagens in the gestagen test is not only simpler and cheaper, but also produces better defined withdrawal bleeding within 2–4 days after discontinuation due to the rapid fall in the hormone level. The development of withdrawal bleeding after withdrawal of the hormone (positive gestagen test) indicates estrogen formation in the ovaries and a certain degree of endometrial proliferation. Therefore only a generative ovarian insufficiency is present due to failure of ovulation. This disorder of the function of the hypophyseal-hypothalamic system may be caused by endogenous factors (i.e. through a dysfunction of a related endocrine organ).

If the gestagen test is negative, a subsequent estrogen test is a further means of investigation (Table 45).

Table 45. Testing the reactivity of endometrium or ovaries

A. Gestagen test
a) Oral Progestagen (Primolut-N; Gestanon, etc.) e.g. 3 × 2 5-mg tablets of Primolut-N daily for 5 days Withdrawal bleeding within 2–4 days
b) Parenteral Depot gestagen i.m. e.g. Proluton-Depot (250 mg) Lutocyclin M (200 mg) Withdrawal bleeding within 10 days Oily solution: 10 mg/day for 5 days i.m.
B. Estrogen test
a) Oral Ethinyl estradiol e.g. Progynon-C 3 × 1 0.02-mg tablet daily for 14 days Withdrawal bleeding after 2–4 days
b) Parenteral Depot estrogen i.m. e.g. Progynon-Depot 20 mg (2 ampoules) Ovocyclin M 20 mg (2 ampoules) Withdrawal bleeding after 4–5 weeks
C. Gonadotropin test 75 IU HMG/day for 10 days (HMG: Pergonal; Humegon) 5000 IU HCG/day on days 10, 11, and 12 (HCG: Pregnyl; Gonadex; Primogonyl) If negative, repeat with double these dosages

Uterine amenorrhea is present if withdrawal bleeding does not occur within 4–5 weeks after parenteral administration or after 8 days at the latest after discontinuation of the tablets (negative estrogen test). In such a case, the endometrium is not reacting. A positive estrogen test with a negative gestagen test shows the presence of an endometrium capable of reacting, associated with almost complete failure of the formation of ovarian estrogens (vegetative ovarian insufficiency, ovarian insufficiency grade II or severe degree). The question as to whether primary or secondary ovarian insufficiency is present can be answered by estimation of the urinary gonadotropins. Elevated levels (hypergonadotropic amenorrhea) are found in primary ovarian insufficiency. Nuclear sex, chromosome idiogram, laparotomy, and gonadal biopsy are further methods of investigation of the disorder. Secondary normogonadotropic or hypogonadotropic ovarian insufficiency requires further thorough investigation of the basic disease to detect any grave organic disorders in the hypophyseal-hypothalamic region (intracranial, particularly intrasellar tumors) or of other endocrine organs (Cushing's disease, Addison's disease, hypothyroidism, hyperthyroidism, diabetes mellitus). It is useful for neurologist, ophthalmologist, and endocrinologist to cooperate (Table 45).

The *gonadotropin test* (Table 45) is used to examine the reactive ability of the germinal parenchyma in the presence of secondary ovarian insufficiency. It is of prognostic significance only. If there is no ovarian reaction, there is no chance of normalizing the ovarian cycle. The test is expensive and necessitates daily checks of the size of the ovaries to avoid overstimulation. The amount of gonadotropin must be adjusted individually.

d) Prognosis and Therapy

The prognosis of amenorrhea is primarily dependent on the type of underlying disease. If the basic disorder can be removed cycles often arise spontaneously. This is not only applicable to organic disorders but also to psychogenic disturbances, which are much more common. In assessing the degree of success of treatment it must be remembered that a spontaneous cure not infrequently arises.

STAEMMLER (1964) found the following figures for normalization among his patients:
in hypothalamic dysfunction 49%, 25% of these spontaneously; in postpartum ovarian insufficiency 54%, about half spontaneously; with hypoplastic ovaries 23%, no spontaneous cures; with polycystic ovaries 46%, 8.5% of these spontaneously.

Whereas all other illnesses concerned in amenorrhea show approximately the same recovery rate, patients with hypoplastic ovaries have a definitely worse prognosis. The number of spontaneous cures is particularly high for postpartum amenorrhea, whereas a spontaneous recovery is not to be expected with hypoplastic ovaries, and the chances of such a cure are very slight with polycystic ovaries. The prognosis of the amenorrhea is dependent on the basic disorder and the duration of the amenorrhea. Thus, lasting success is estimated in a mean of 55% of cases of amenorrhea of 1 year's duration and less, in 49% in cases of 1–3 years' duration, and 29% where amenorrhea has lasted for more than 3 years (STAEMMLER, 1964). The prognosis improves with the extent of estrogen proliferation in the endometrium before the onset of treatment.

Often, the causal factor cannot be found or cannot be removed. Treatment in such cases is aimed at the production of an ovarian or an endometrial cycle, according to whether or not there is any desire for children. *Gynatresia* is treated surgically. The operation should be performed as early as possible, before fertility is permanently damaged. In the presence of hymenal atresia the hematocolpos only should be evacuated, and patients should be treated with antibiotics to reduce the high risk of infection. The uterus empties spontaneously.

Careful dilatation of the uterine cavity or of the cervix, together with parenteral estrogen and progesterone treatment, are sometimes sufficient in cases of *uterine synechia* or *cervical stenosis*. The curative effect of the hysterosalpingography (as has been described for traumatic amenorrhea) is due to the same mechanical action. Homotransplantation of mucosa through the intracavital autotransplantation of one tube (STRASSMANN, 1935) is reserved for special individual cases.

Treatment of *congenital vaginal aplasia* consists in surgical construction of a vagina allowing intercourse. Numerous methods are available. We find that the surgical construction of an artificial vaginal lumen lined with free epidermal flaps has proved satisfactory (modified method after KIRSCHNER, WAGNER and MCINDOE) (BÄBLER, 1967). The operation should only be done if regular sexual intercourse can occur subsequently. This factor among others also determines the results of the operation.

Patience and sympathetic listening alone can lead to success in cases of *psychogenic amenorrhea*. Consultations with the husband, parents or superior at work may be necessary. The cyclic employment of sexual steroids to produce withdrawal bleeding frequently cannot be avoided (Table 49b). General measures such as relief from work, sufficient sleep, physical exercise and reduction in weight can restore menstruation in some cases, but are of a supportive nature in all cases. Severe psychoneurosis such as anorexia nervosa requires treatment by a psychiatrist and hospitalization for treatment of the electrolyte disturbance often present.

Three principle forms of hormone treatment are available:

stimulation at the hypothalamic or ovarian level,

substitution at the uterine and vaginal levels, and

central inhibition with subsequent "rebound effect".

An ovarian cycle is achieved through ovarian stimulation with either gonadotropins or clomifene.

There may be a slight chance of producing a so-called rebound effect (increased release of pituitary gonadotropins) by hypophyseal-hypothalamic suppression by means of sexual steroids and their discontinuation.

An endometrial cycle is obtained by substitution treatment.

α) Stimulation Therapy

Ovarian stimulation can be achieved either indirectly with clomifene or directly with gonadotropins. This form of treatment is only indicated when ovulation is to be induced in cases where a child is wanted. Stimulation is thus the form of treatment for anovulatory sterility.

The quantitative HPG excretion is of prime importance in the prognosis and choice of treatment. The excretion pattern can be used for assessment of the LH peak. It is now possible to determine the excretion pattern without particular exertion by immunological estimation of LH. On the other hand, quantitative excretions can still only be determined by considerably more costly biological and radioimmunological tests. Treatment is adjusted primarily to the excretion type.

Table 46. Stimulant treatment with clomifene citrate. (See also p. 630ff.)

Special precaution:
Only to be used in the presence of a functional hypothalamo-hypophyseal system and ovarian tissue.

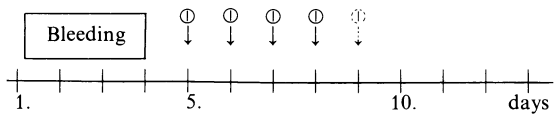
Endocrinological:
Normogonadotropic oligo-amenorrhea or anovulation; estrogens normal.

Standard therapy:
50–100 mg Clomid/day for 4–5 days.

Preparation:
Dyneric, Clomid (MERRELL)

Ovulation (in about 70% of patients):
On average 8–12 days after beginning of therapy.

50–100 mg/day



Risks (lower than with gonadotropins):
Overstimulation with formation of ovarian cysts with torsion of the pedicle, rupture and intra-abdominal hemorrhage, Meigs's syndrome, thromboembolism.
Multiple ovulation: multiple births (7.5%)

Implications:
Bimanual gynecological examination every other day during stimulation.
Discontinuation of the treatment if there is rapid growth of the ovaries.

Less dangerous than stimulation with gonadotropins, but also less effective.

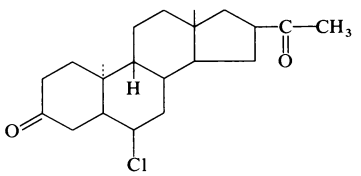
Treatment is less costly and time-consuming. No lasting success.

Four main gonadotropin excretion types have been demonstrated with anovulation:

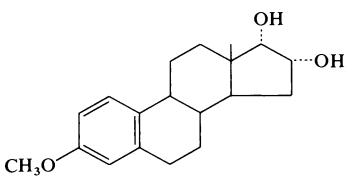
a) If the *anovulation* is *normogonadotropic* a trial of diencephalic stimulation with Dyneric (clomifene citrate) or Sexovid F 6066) is justified (Table 46). In order to reduce the risk of over-stimulation as much as possible, which however is lower than with gonadotropins, the initial dose of clomifene should not exceed 50 mg daily. If the ovarian stimulation obtained with this dose is inadequate, a daily dose of 100 mg for 4 to 5 days may induce ovulation. The danger of over-stimulation is especially great when treatment lasts for longer than 10 days or is repeated. A new cycle of treatment should only be started at the earliest after 4 weeks and after pregnancy and ovarian cysts have been excluded (GREENBLATT, 1966; SCHREINER, 1968).

The LH peak achieved with Dyneric may exceptionally be too low to produce ovulation. In such cases, additional administration of HCG can lead to success (Fig. 60). Determination of the excretion pattern is valuable in such cases. Recently steroids like Retroid (Roche), a weak progestagen, and Epimestrol (Organon), a weak estrogen, have been discussed for the induction of ovulation.

The former is 1,6-dehydro-6-chloro-retroprogesterone, the latter 3-methoxy-17-epiestriol (Fig. 59). Both steroids seem to act as a positive feedback by enhancing the LH secretion (KELLER, 1971).



Retroid



Epimestrol

Fig. 59. Symptoms of the menopause

We found a fairly good effect when 4–8 mg Retroid was given daily for 10 days beginning on day 15 of the cycle, or 5 mg Epimestrol daily for 10 days from the 5th day of the cycle onward (Table 46a).

In cases of secondary amenorrhea ovulation was found in 29% treated with Retroid and 26% treated with Epimestrol (KELLER, 1971).

Table 46a. Stimulant therapy with steroids. (See also p. 630)

Special precaution:
Only to be used in the presence of a functional hypothalamo-hypophyseal system and ovarian tissue.

Endocrinological:
Young women with normogonadotropic oligo-amenorrhea or anovulation: estrogens normal.

Standard therapy:
Retroid: 4–8 mg/day for 10 days, beginning on day 14–16 of bleeding.
Epimestrol: 5 mg/day for 10 days, beginning on day 5 of bleeding.

Preparations:
Retroid (Roche), Epimestrol (Organon).

Not dangerous, less effective than clomifene citrat.

Table 47. Stimulant therapy with human gonadotropins. (See also p. 629)

Special precaution:
Only to be used in the presence of functional ovarian tissue.

Endocrinological:
Hypo- or normogonadotropic oligo-amenorrhea or anovulation, estrogens normal or lowered.

Basis of treatment:
HMG + HCG

Preparations:
HMG: Pergonal (Istituto Serono, Rome)
Humegon (Organon, Oss)
HCG: Pregnyl (Organon)
Gonadex (Leo)
Primogonyl (Schering)

Ovulation:
On average 12–60 hours after beginning of HCG medication.

Risks:
Overstimulation of the ovaries: formation of cysts with torsion of pedicle, rupture and intra-abdominal hemorrhage, ascites, pseudo-Meigs's syndrome, thromboembolism.
Multiple ovulation: multiple births.

Implications:
1. Daily bimanual gynecological examination. Discontinuation of treatment if ovaries grow rapidly;
2. daily hormonal vaginal cytology (karyopyknotic index)
3. daily assessment of cervix factor:
Appearance and quantity of cervical mucus
Spinnbarkeit
Fern-leaf test
Possibly Sims-Huhner test;
4. Basal temperature

Advantage:
Most effective form of stimulant therapy

Disadvantages:
Dangerous, costly, time-consuming for patient and doctor; no lasting success.

b) The treatment of choice for induction of ovulation in cases of *hypogonadotropic anovulation* is direct stimulation with HMG/HCG. The ideal patient for treatment with human gonadotropins must fulfill the following conditions: sterility, age less than 35 years, normal nonfunctioning ovaries, no endogenous gonadotropin production and normally developed genitalia (GEMZELL, 1965). Normal or slightly reduced gonadotropin secretion in the presence of anovulation does not exclude treatment with human gonadotropins, but these cases are more difficult to treat since the reactive capacity of the ovaries varies widely. They generally react more sensitively to HMG. This is especially true of polycystic ovaries, and wedge resection or treatment with clomifene is therefore an adequate form of therapy in such cases. Pergonal: 75 IU FSH + 75 IU LH (Instituto Serano, Rome) and Humegon: 75 IU FSH (Organon, Oss) are HMG preparations. The simultaneous action of FSH and LH provided by Pergonal and Humegon is essential for follicular growth and the production and secretion of estrogens. Almost pure forms of FSH or LH have only a slight action on the follicle.

The "LH-spurt" required for releasing ovulation is achieved by giving HCG in addition (Pregnyl, Primogonyl, Gonadex).

We have found the *2-phase treatment* the most satisfactory *schedule for administration* (Fig. 60). The woman receives 75–150 IU HMG daily for 10–12 days, followed by HCG. Thus a total of 1000 IU FSH is administered on average. This roughly corresponds to the amount of FSH secreted by the anterior pituitary before ovulation (p. 562). HCG is given in three equal daily doses of 5000 IU (Fig. 60). Treatment with HCG can follow or overlap that with HMG. If the ovaries are enlarged and painful after the last injection of HMG, we refrain from giving HCG. HMG treatment is continued until a significant estrogen effect can be observed in the vagina and in the cervix in particular. This stage is usually reached after 8 to 10 days, and is also indicated by the estrogen excretion which must be estimated constantly (GEMZELL, 1969).

If the follicles do not respond to this form of stimulation the doses can be gradually increased.

Very often 150–225 IU HMG daily are needed for ovarian stimulation.

Ovulation usually occurs between 12 and 60 hours after the initiation of HCG treatment.

The form of administration advocated by CROOKE (1967) has not proved so satisfactory in our opinion (KELLER, 1969). This form of treatment consists of an initial single dose

of HMG, varying between 5 and 15 ampoules of Humegon or Pergonal. At the point when the estrogen effect is at its maximum, generally after 8 to 10 days, 5000 IU of HCG are given daily for 1–4 days (Fig. 60). BETTENDORF (1962) was able to induce ovulation with HPG alone.

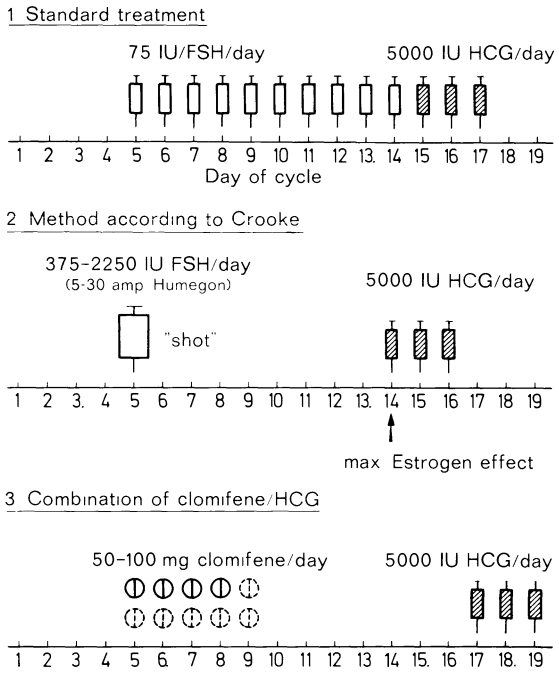


Fig. 60. Administration schedule for human gonadotropins

According to the results it is supposed that the effect of HMG on the growth of the follicle follows the "all-or-nothing" law. The range between the dose which is without effect and the one which provokes an overstimulation is very small. According to the excretion of estrogens there is always an overstimulation of the ovaries by the exogenous HMG (GEMZELL, 1969).

The results connected with the induction of a biphasic ovarian cycle are very good in correctly selected patients. Ovulation can almost always be induced by this method, and pregnancy occurs in 40–45% of these previously sterile women (VAN DE WIELE, 1965; GEMZELL, 1969). About a third of these pregnancies, however, terminate in abortion or in premature birth, mainly because of multiple pregnancies. About 25% of the children born alive are from multiple pregnancies (Table 48).

Patients must be subjected to a daily bimanual vaginal examination during treatment with human gonadotropins to avoid the development of large polycystic ovaries. GEMZELL (1969) has recommended daily estimation of urinary estrogens and pregnanediol and of progesterone in the blood, but this is expensive and only justified in the investigation of special scientific problems. It is unnecessary during treatment and the karyopycnotic index and cervix factor are sufficient for estimation of the estrogen effect (Table 48).

Table 48. Results obtained in 228 women with primary or secondary amenorrhea with human hypophyseal FSH and HCG over a period of 8 years (1960–1967). (After GEMZELL, 1969)

1960–1967	
No. of patients	228
No. of treatments	463
Pregnancies	101
Including: twins in	19
triplets in	5
Abortions or premature births	30

c) In cases of *hypergonadotropic anovulation* the prognosis is considerably less favorable (repeated finding of more than 2 mg in 24 hours). The ovaries in such cases are already under increased gonadotropic stimulation. As long as the values are not too high (over 3 mg IRP/24 h), an attempt can be made to induce ovulation by means of diencephalic stimulation with clomifene. Additional gonadotropic stimulation is not indicated.

d) When hormone levels are quantitatively normal, reduced follicular response to gonadotropic stimulation can be suspected. This state may be present postpartum (KELLER, 1968). Here too, an attempt to increase central ovarian stimulation with clomifene is permissible.

β) Substitution Therapy (Table 49)

Substitution therapy is indicated when induction of withdrawal bleeding by an effect at the endometrial level is desired or when an estrogenic and gestagenic effect is to be produced on the primary and secondary sexual characteristics.

Spontaneous cycles can be induced in exceptional cases where the hypothalamo-hypophyseal-ovarian axis is intact, by stimulation of the hypothalamo-hypophyseal system caused by rhythmic administration and withdrawal of estrogens and gestagens. Treatment must, however, be continued for at least 6 months. Estrogens and progesterone can be given orally or parenterally in injections. Oral administration of gestagens has the advantage that the fall in hormones occurs rapidly, thus allowing the onset and end of the withdrawal bleeding to be well defined and treatment to be short.

One effect of the administration of estrogens and gestagens is the suppression of gonadotropin secretion. Experiments with animals show that there is an excessive release of gonadotropins from the pituitary after the discontinuation of long-term administration of sexual steroids. This is described as the *rebound effect* (HOHLWEG, 1934). It causes increased ovarian stimulation. Although it has never been proved that gonadotropin release in the female is increased by this treatment, there have been frequent attempts to release ovulatory cycles by hormonal inhibition of the hypophysis (BUSCHBECK, 1957). Simultaneous administration of high doses of estrogens and gestagens over a period of weeks produces the most pronounced suppressant effects on hypothalamus and hypophysis (Table 49).

Table 49. Substitution therapy

A. If genital bleeding is desired
Only possible in the presence of a responsive endometrium
a) If some estrogen stimulation is still present and the amenorrhea is of only short duration (< 1 year):
Oral gestagen e.g. Primolut-N (120 mg)
3 × 2 tablets (30 mg) daily on days 21–24 of cycle, or Primosiston
3 × 1 tablet on days 17–26 of cycle,
or Duogynon
1 tablet daily for 2 days (24 and 25 of cycle).
b) Modified Kaufmann schedule:
3 × 1 tablet of Progynon C daily for 14 days, followed by
3 × 1 tablet of Primosiston daily, later from day 5 of cycle
3 × 1 tablet of Progynon C daily for 10 days, followed by
3 × 1 tablet of Primosiston daily for 10 days, or Sequens, Estirona for 20 days from day 5 of cycle.
c) To induce pseudocyesis
10 mg of a slow-release estradiol preparation on each of days 1, 10, 20, and 30 (Ovocyclin M; Progynon-Depot)
Oral Progestagen (e.g. Primolut-N)
days 11–20 1 tablet daily
days 21–30 2 tablets daily
days 31–40 3 tablets daily
B. If uterine bleeding is unnecessary, estrogens alone can be given:
0.25 mg stilbestrol/day
0.02 mg ethinyl estradiol/day
2.50 mg Premarin, Presomen, Progynova 1–2 mg/day
10 mg slow-release estrogen (1–2/month) (Ovocyclin M; Progynon-Depot)

Substitution therapy with estrogens in gonadal dysgenesia (rudimentary gonads) is aimed at preventing osteoporosis, stimulating skeletal growth and developing primary and secondary sexual characteristics. Complete growth compensation is, however, not achieved (OVERZIER, 1969). Whether cyclic genital bleeding is desired will depend on the woman's mentality. It is important that the patient is given to understand in the early stages that the sterility is permanent and not wait until she gets married. Normal ability to take part in sexual intercourse and a normal libido can be attained. Substitution should not be started before the 12th year (WILKINS, 1957). It corresponds to the long-term treatment presented in Table 49 under Form Ab or B.

There is no evidence, as has been claimed (STANGE, 1958), that dysgenetic gonads are more prone to tumors (HAUSER, 1961). Removal of such gondas is therefore unnecessary. Psychological instruction and advice are the important factors in these patients, since subsequent mental maturation often occurs with substitution treatment (POLLOCK, 1955).

A few authors recommend bilateral orchidectomy in cases of *testicular feminization* because of the alleged increased danger of malignant degeneration in retained testes (STANGE, 1958). Substitution therapy is absolutely essential in these castrated patients since severe symptoms of failure may arise. We were not convinced of the necessity of castration in our cases (SCHREINER, 1959); we leave the testes intact or remove one testis if a herniotomy is necessary.

Treatment of *ovarian hypoplasia* consists of stimulation with human gonadotropins where there is a desire for children (Table 47). Where children are not wanted, treatment consists of substitution (Table 49). Substitution with estrogens is adequate as long as uterine bleeding is not necessary for psychological reasons (Table 49).

Uterine hypoplasia can be favorably influenced by stimulation producing a pseudocyesis (Table 49).

The treatment of polycystic ovaries is discussed on p. 614ff. If a tumor can be excluded, prolactin release can be suppressed in the *Chiari-Frommel or Forbes-Albright syndrome* with high doses of estrogens or progestagens, over 3–4 months (HASKINS, 1964). Cyclic substitution with sexual steroids in normal doses leads to uterine bleeding but has no significant influence on the galactorrhea (MCDONALD, 1965). There have been reports of success with normal doses of clomifene (p. 599) giving rise to ovulatory cycles, and even of pregnancy (KAISER, 1963; LORAINE, 1966).

There is no causal treatment possible for Sheehan's syndrome, except if pregnancy occurs. Pregnancy causes physiological hypertrophy of the residual anterior pituitary, and since this hypertrophy does not usually regress postpartum, improvement is obtained. One must however be aware that this method of treatment is restricted and dangerous in these patients. A new sub- or postpartum complication to

which these patients are particularly liable can cause complete destruction of the residual anterior pituitary and thus lead to an extremely severe form of global insufficiency of the anterior pituitary lobe. Long-term treatment is usually purely symptomatic. Estrogens in doses which do not induce genital bleeding are adequate to prevent genital atrophy and osteoporosis (Table 49B). The production of cyclic bleeding is sometimes necessary for psychological reasons in young women (Table 49b). Substitution with human gonadotropins is only exceptionally considered as a form of treatment (p. 584). Knowledge of this can, however, be of psychological importance to younger patients, since this method provides at least a theoretical possibility of pregnancy.

2. Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding indicates abnormal functional endometrial bleeding resulting from primary or secondary ovarian dysfunction (synonyms: functional uterine bleeding, metropathia hemorrhagica).

The bleeding can be of various types. Cyclic bleeding disorders can be so-called temporal anomalies (= impaired bleeding rhythm) or type anomalies (= disorder of type of bleeding), or the bleeding may be acyclic (metrorrhagia) or a combination of different anomalies. Anovulatory bleeding is common.

The causal factor leading to bleeding disturbances is endocrine in nature and can lie anywhere on the cortex-limbic system-hypothalamus-hypophysis-ovary-endometrium axis or less commonly in the adrenal cortex or thyroid gland. Endocrinopathies are exceptionally the cause. Disturbed ovarian function however is always the core and presents mainly as anovulation. Investigations in experimental animals and observations in castrated women have yielded information on the pathogenesis of functional bleeding disturbances. Castration of a sexually mature female monkey leads to endometrial bleeding within 2–5 days, regardless of the point in the cycle at which castration was performed (E. ALLEN, *in* OBER, 1957). Thus estrogen withdrawal alone is sufficient to induce bleeding; but the endometrium is more sensitive to and reacts more quickly to withdrawal of progesterone, even after short-term, slight progesterone effects. Clinical observations in castrated women have confirmed these results (OBER, 1957). Furthermore, it has been deduced that increasingly high doses of estrogens are necessary to maintain endometrium proliferation and prevent breakthrough bleeding over a longer period of time. The picture of glandular cystic hyperplasia arises in the endometrium following the continuous action of estrogens alone for at least 4 weeks (p. 607). The quantitative estrogen influence is also essential in the determination of the histological picture and of the type of dysfunctional bleeding. Glandular cystic hyperplasia occurs only if the total estrogen excretion is more than 30 µg/24 h for at least 3–4 weeks, even in the presence of fluctuating estrogen production (Fig. 61). Amounts between 10–30 µg/24 h results in simple proliferation (Fig. 61). If estrogen administration is not increased after a certain time, a state of relative estrogen deficiency arises, resulting in constant bleeding termed as breakthrough bleeding (W. M. ALLEN, 1951), which occurs from the surface where the blood is coagulable.

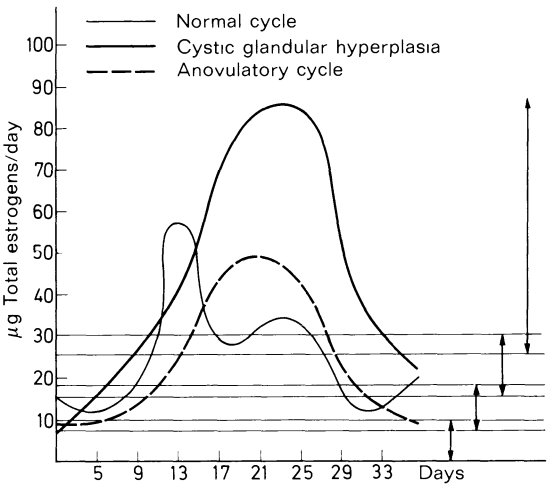

Fig. 61. Quantitative changes with fluctuating influence of estrogens on the endometrium. (After BROWN, 1959)

Increasing amounts of progesterone are also required to maintain the secretory transformed mucosa. This fact is illustrated by the hormone treatment of endometriosis (p. 633). Atrophy and shrinkage occur only under the influence of progestin, whereas relative progestin and estrogen deficiency does not give rise to a typical mucosal destruction but to superficial bleeding.

Further observations have shown that withdrawal of progesterone even after only one day results in withdrawal bleeding without histologically detectable endometrial changes. Destruction of the functionalis occurs characteristically only when progesterone acts for longer than 10 days together with estrogens. This is probably associated with the facts that destruction of menstrual mucosa necessitates the development of a characteristic vascular

system, consisting particularly of spiral arteries, and that the process of development requires at least 10 days.

All the investigations mentioned have shown that functional or dysfunctional endometrial bleeding occurs if the estrogens and progestins required for build-up are withdrawn or are present in inadequate amounts. This fact is of practical importance in the treatment of dysfunctional uterine bleeding.

Dysfunctional bleeding accounts for a considerable proportion of the female patients subjected to curettage for bleeding disorders. Dysfunctional bleeding is responsible for 60% of all diagnostic curettages performed in the Gynecological Department in Zurich. The disorder can arise at any age between menarche and early postmenopause, but is more frequent during the postmenarche and the premenopausal period. This is understandable, since luteal ovarian function is in a state of development or decline during these phases of life (DÖRING, 1963). Anovulatory cycles are also more frequent at these times (Table 58, DÖRING, p. 623). Of our patients with dysfunctional bleeding, 46% were over 40 years old. Other authors have found an incidence of about 66% (ISRAEL, 1967). In contrast, among our cases, only 1% of dysfunctional bleeding occurred in women under 20 years. This figure is consistent with those of other investigators (SUTHERLAND, 1953; ISRAEL, 1967). Incomplete abortion is the predominant reason for the bleeding in the majority of these young patients. Dysfunctional bleeding was present in only every fifth patient in this age group (SOUTHAM, 1960). These figures for young women are, however, misleading, since dysfunctional bleeding in this age group now only exceptionally requires curettage. Dysfunctional bleeding in young women, termed as "juvenile bleeding", can be very profuse, and if untreated can lead to severe anemia within a short time. The fertility of these patients is reduced even when the cycle later becomes normal (FRIES, 1947; SOUTHAM, 1966). However only 55% of these women later have a normal cycle, and normalization occurs in about half of them within 4 years (SOUTHAM, 1966). The risk of developing a carcinoma of the body of the uterus later seems to be greater in young women who suffer from dysfunctional bleeding (SOUTHAM, 1966). Dysfunctional bleeding is uncommon in women between 20 and 40 years, and the reasons are usually emotional. Bleeding due to disturbed gestation or neoplastic changes is predominant in this age group. Carcinoma of the uterus and dysfunctional bleeding top the list of conditions to be considered in the differential diagnosis of bleeding disturbances in the age group between 40 and 50. During the postmenarche and postmenopause, ovaries with numerous cysts 1–3 cm in diameter are the most frequent cause of dysfunctional uterine bleeding. The functional state of the ovaries is dependent on the state of the theca cells found in the cysts.

The histological picture of the endometrium is not only dependent on the age of the patient but also on the time at which the tissue is removed, i.e. the previous duration of bleeding. Mucosa in the phase after bleeding has occurred no longer indicates the original functional structure. Since anovulation is the principle reason for dysfunctional bleeding, the endometrium usually shows an exclusively estrogenic effect. All transition phases are observed, from weak proliferation through simple hyperplasia to glandular cystic hyperplasia and polyposis. A certain progesterone influence cannot be excluded in individual cases, since some glycogen and mucus are sometimes found in the endometrium. It is possible that the theca cells in the cystic cells become luteinized. When bleeding occurs from a fully secretory transformed endometrium, the possibility of an early abortion must be considered since about 40% of fertilized ova are unviable (HERTIG, 1948). Frequently no evidence of this can be obtained in the first two weeks of pregnancy, since the very small ovum can escape histological identification and the pregnancy test may still be negative. In a few cases, the endometrium shows secretory transformed areas together with regions purely proliferative in character (so-called irregular maturation, after TRAUT and KUDER, 1935), or the endometrium may show the picture of delayed regression of the corpus luteum (so-called irregular shedding). Atrophy of the endometrium is seen in only about 5% of cases (ZONDEK, 1954) (Table 50).

Before a diagnosis of dysfunctional bleeding can be made, neoplastic and inflammatory uterine changes and pregnancy must be excluded. The pretherapeutic investigation involves a fractional curettage first of all, which has a therapeutic effect in about 50% of cases. Curettage is essential in cases of bleeding in the premenopause. "Hormonal curettage" is of prime therapeutic and diagnostic importance particularly in younger patients (p. 607). If this procedure is unsuccessful dysfunctional bleeding is unlikely. Important aids to diagnosis are the basal temperature and pregnanediol excretion, which together with the pregnancy test help to clarify the question of a pregnancy. The case history often leads to a diagnosis, but differention from abortion may be difficult at times. A widely dilated os, clear cervical

Table 50. Histology of the endometrium in dysfunctional bleeding

Diagnosis	KISTNER (1964) (400 patients)	SUTHERLAND (1950) (861 patients)	Universitäts-Frauenklinik, Zurich (1968) (704 patients)
Hyperplasia	123	265	93
Atrophy	7	10	206
Irregular shedding	9	13	–
Devascularized mucus membrane	31	26	42
Simple proliferation	230	547	363

mucus that can be drawn into threads, and a positive fern-leaf phenomenon exclude a pregnancy. Disturbances of blood coagulation are of practically no importance in patients not receiving anti-coagulant treatment.

a) Disorders of the Bleeding Rhythm (Temporal Anomalies) (Figs. 62a and b)

These disorders present as oligomenorrhea or polymenorrhea. Since about 95% of all cycles last between 21–35 days between the ages of 20 and 40 (AREY, 1939), the term oligomenorrhea is applied when the cycle lasts for more than 35 days but less than 90 days (see amenorrhea, p. 585). Polymenorrhea occurs when the cycle last less than 21 days.

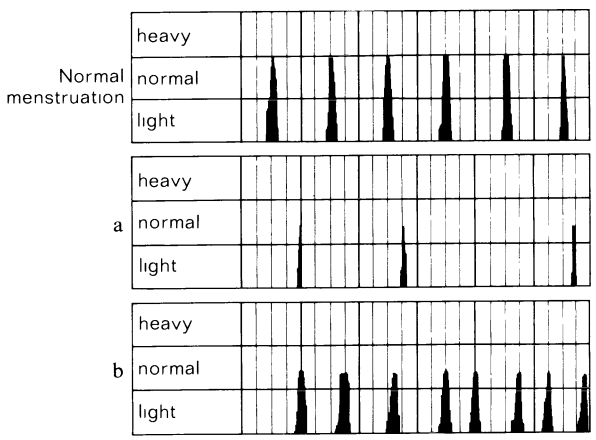

Fig. 62a and b. Dysfunctional bleeding. Anomalous rhythm (temporal anomalies). a) Oligomenorrhea = abnormally infrequent menstruation (interval >35 days, <90 days). b) Polymenorrhea = abnormally frequent menstruation (interval <21 days)

Most temporal anomalies result from hypothalamic dysregulation.

Oligomenorrhea is usually due to anovulation and less commonly to a biphasic cycle with a prolonged phase of follicular maturation. It can precede secondary amenorrhea. This is indicated in particular when the interval lasts longer than 45 days and hypomenorrhea arises at the same time. Menopause is often premature in women with oligomenorrhea, due to ovarian insufficiency.

Bleeding may occasionally be due to hypothalamic dysfunction such as occurs with severe psychological stress, malnutrition or obesity, dysfunctional states of related endocrine organs and in the syndrome of polycystic ovaries.

Oligomenorrhea is not important as long as there is no desire for children. Treatment is only necessary in unwanted functional sterility. The therapeutic procedure corresponds to that for secondary amenorrhea (p. 590). In cases of obesity, reduction in weight is often sufficient to normalize the cycle. Absence of ovulation and a shortened follicular maturation or luteal phase can also lead to polymenorrhea (KNAUS, 1950; MOSZKOWSKI, 1962). Experience has shown that functional sterility is present when the luteal phase is less than 10 days. The blastocyste, which is implanted around the 7th postovulatory day, produces too little HCG at this stage to prevent regression of the corpus luteum. Since ovulation occurs on the 8th day of the cycle at the earliest (HARTMAN, 1936; BREWER, 1947; HERTIG, 1956) the cycle of 18 days is the shortest fertile cycle.

Polymenorrhea arises commonly in the postmenarche and the premenopausal period, since luteal function of the ovaries is often absent or deficient in these phases. A shortened cycle may arise between the ages of 20 and 40 as a result of severe physical or psychological stress. As long as it does not produce anemia, treatment is not necessary during the postmenarche and the premenopausal period.

In the absence of ovulation, there are cycles with relatively regular follicular breakthrough bleeding of short duration (SCHRÖDER, 1928). It must be mentioned that 4–8% of all women who menstruate quite regularly have anovular cycles (EFFKEMANN, 1939; ROCK, 1939; SIEGLER, 1951).

Treatment is indicated when polymenorrhea arises secondarily during sexual maturity, and if there is sterility in the presence of a desire for children. Treatment is adjusted according to the basal body temperature and the endometrial

histology. The temperature on waking also permits the detection of pseudopolymenorrhea, which may exceptionally be due to extensive ovulation bleeding. A healthy way of life with sufficient sleep and relaxation are often enough to normalize the shortened cycle.

If the object of treatment is to prolong the interval without bleeding and possibly to reduce the severity of the bleeding, a mixture of estrogens and progestagens (ovulation inhibitors) can be given from days 5–25 of the cycle. If sterility associated with anovulatory cycles is the dominating feature, treatment with clomifene or human gonadotropin is indicated (p. 629).

The "displacing effect" of estrogens on ovulation due to inhibition of gonadotropin secretion can also be applied to cases with biphasic cycles with a reduced follicular phase: 10 mg estradiol benzoate or valerianate is given intramuscularly on day 5 of the cycle, or 0.05 mg ethinyl estradiol is given twice daily or 0.5 mg diethyl stilbestrol daily from day 3–10 of the cycle.

Finally, if the luteal phase is too short, the second phase of the cycle can be prolonged by substitution treatment, by giving for example Primosiston (ethinyl nortestosterone acetate 2 mg + 0.01 mg ethinyl estradiol) three times daily from day 21 to day 26 of the cycle.

Stimulation with chorionic gonadotropin is only justified in the treatment of sterility. HCG is given three times in a dose of 5000 IU between days 20–24 of the cycle.

b) Disorders of the Type of Bleeding (Type Anomalies) (Fig. 62c)

In contrast to the temporal anomalies, which are usually of a dysfunctional nature, type anomalies, with the exception of hypomenorrhea, mostly originate from organic causes.

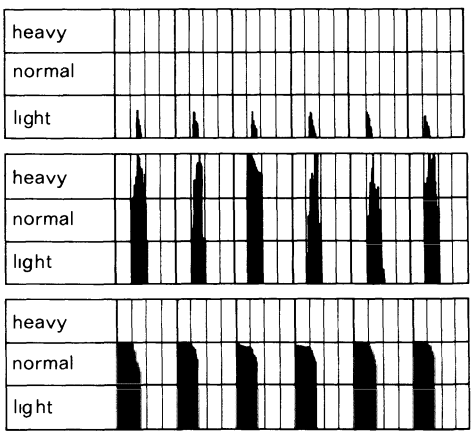

Fig. 62c. Anomalies in type of bleeding; hypomenorrhea = abnormally light menstrual bleeding; hypermenorrhea = abnormally heavy bleeding of normal duration; menorrhagia = abnormally prolonged menstrual bleeding (>7 days, <14 days)

In *hypomenorrhea* the bleeding is abnormally mild, and can present in the form of bleeding of short duration often lasting only a few hours or 1–2 days (LAX, 1939). Hypomenorrhea has been observed more frequently since ovulation inhibitors have been in use, and may precede amenorrhea. Like oligomenorrhea, with which it can be combined, hypomenorrhea may be due to hypothalamic primary ovarian dysfunction or to disorders of the correlated organs. It has also been observed in association with physiological stress, changes in surroundings and climate, obesity, the climacteric and in hypothyroidism and hyperthyroidism, Addison's disease, Cushing's syndrome and adrenogenital syndrome.

Treatment of hypomenorrhea is superfluous.

Hypermenorrhea is abnormally severe cyclic, uterine bleeding of 7 days' duration at the most. It is frequently characterized by the discharge of blood clots, since severe bleeding results in a relative deficiency of fibrinolytic enzymes in the decomposing endometrium. Hypochromic anemia develops with repeated episodes of hypermenorrhea. It is caused by organic changes in over 90% of cases. These changes cause a reduction in the contractility of the myometrium and an increase in the bleeding surface. Uterine hypoplasia, intramural or submucosal fibroids, polyps of the uterine mucosa, adenomyosis of the uterus and, exceptionally, bleeding diseases with clotting disorders may be involved. Psychological stress may occasionally give rise to hypermenorrhea.

Histology shows that the gestagenic influence on the endometrium is often inadequate and is removed during the bleeding.

Except during adolescence, a fractional curettage is indicated for diagnostic reasons. It is often of therapeutic value at the same time.

Hormonal treatment of dysfunctional hypermenorrhea is aimed at the improvement of secretory transformation, by giving, for example, 2 tablets Primolut-N 3 times daily between days 21 and 24 of the cycle, or at suppression of ovulation by giving an ovulostatic drug from day 5 to day 25 of the cycle.

Hemostasis of profuse dysfunctional bleeding is best achieved by giving Primosiston tablets in the following dosage: 5 tablets on the 1st day, 2 times 2 tablets on the 2nd day, 3 tablets daily from the 3rd to the 9th day (KAUFMANN). Withdrawal bleeding normally occurs 8 days after discontinuation of the treatment.

Menorrhagia indicates cyclic uterine bleeding lasting for more than 7 days but for less

than 14 days. The bleeding is often more severe than normal but can also be of normal severity; it is rarely diminished. If bleeding lasts for 14 days or more, then the term *meno-metrorrhagia* is used, since acyclic bleeding can be maintained in prolonged cyclic bleeding. Menorrhagia, and meno-metrorrhagia in particular, very frequently have organic causes. They can also arise as dysfunctional bleeding in combination with oligomenorrhea.

Endometrial hyperplasia occurs in the presence of a *persistent follicle* due to the prolonged action of estrogens (SCHRÖDER, 1928; 1954; BEHRENS, 1956). Follicular persistence may last a few days or several weeks but rarely longer than 8 weeks. A picture of *glandular cystic hyperplasia* develops in the endometrium when estrogenic influence lasts uninterrupted for more than 4 weeks (R. MEYER, 1913; SCHRÖDER, 1928). The histological picture is termed the "Swiss-cheese pattern" of the endometrium. Sooner or later, nutritional disorders arise in the endometrium due to the relative estrogen deficiency, and this in turn gives rise to metrorrhagia in the form of "spotting" or to true breakthrough bleeding in the form of metrorrhagia or meno-metrorrhagia. The amounts of estrogens produced by the ovaries are seldom above the bleeding threshold for longer than 8 weeks. Bleeding occurs from the surface, and the endometrial necrotic foci become progressively drained of blood over weeks in some cases. Severity and duration of the bleeding depend on the rate at which the estrogen level falls. Mucosa obtained from a curettage after several days of prolonged bleeding shows a "bled-out", poorly regenerating basalis.

Bleeding after follicular persistence is characteristic of the climacteric, due to the loss of generative ovarian function, and is termed as "juvenile bleeding" if between the 12th and 20th years. It arises during the postmenarche (FRIES, 1947; DEWHURST, 1963). The bleeding is often profuse in both cases and may lead to severe anemia. The prognosis for later normalization of the cycle and fertility is very poor (p. 604). The risk of the later development of carcinoma of the body of the uterus is elevated (SOUTHAM, 1966).

Oligomenorrhea and amenorrhea in the presence of follicular persistence are characteristic of patients with polycystic ovaries. Ovarian tumors producing estrogens (granulosa- and theca-cell tumor, occasionally Brenner tumors) can also lead to glandular cystic hyperplasia and breakthrough bleeding. The development of breakthrough bleeding in the late postmenopause should always suggest the presence of such a tumor.

The connection between glandular cystic hyperplasia and carcinoma of the body of the uterus is still not clear (TAYLOR, 1923; NOVAK, 1936; LARSON, 1954), and opinions are still divided in spite of numerous investigations (KISTNER, 1964). However, there is no doubt that there is a series of developmental stages, from glandular cystic hyperplasia to atypical adenomatous hyperplasia and carcinoma *in situ* of the endometrium. Thus, carcinoma of the body of the uterus has been observed to arise within 5 years in 12% of patients with atypical adenomatous hyperplasia (GUSBERG, 1958). Hypertension, obesity, diabetes and nulliparity (WEBER, 1961) are predisposing factors (so-called syndrome of carcinoma of the body of the uterus).

Delayed regression of the endometrium (so-called irregular shedding) produces dysfunctional bleeding. It is a special form of menorrhagia (SCHRÖDER, 1928; MCKELVEY, 1947; MCCLENNAN, 1952). This disorder is probably due to delayed regression of the corpus luteum. This is supported by persistent pregnanediol excretion, which maintains postovulatory values during the bleeding, and by the histology of the endometrium removed at the earliest 5 days after the onset of bleeding. The histology is characteristic: the endometrium shows signs of incomplete regeneration as well as secretory changes due to the prolonged progestative influence. This is in contrast with the situation in the normal cycle, where the regenerative phase has come to an end and the endometrium is beginning to show signs of proliferation by this stage.

In 9% of cases of meno-metrorrhagia arising between the ages of 10 and 20, and 20–30% of those occurring during the premenopause, there are organic changes (SUTHERLAND, 1953). The diagnosis should be confirmed by means of a fractional curettage before any therapeutic action is taken. The curettage may also have a therapeutic effect, since every type of dysfunctional bleeding is stopped at least temporarily. Juvenile bleeding in virgins is an exception. In these cases an attempt is made to stop the bleeding with hormone treatment. The same is applicable to recurrent dysfunctional bleeding occurring within 6 months after a curettage. Treatment consists of the administration of an orally effective estrogen-progestagen compound (e.g. Primosiston) in the following dosage (KAUFMANN):

1st day	5 tablets
2nd day	2 × 2 tablets
3rd to 9th day	3 × 1 tablet (total: 0.3 mg ethinyl estradiol + 60 mg ethinyl nortestosterone acetate).

The dysfunctional bleeding is stopped within 36 to 48 hours. Withdrawal bleeding from the secretory converted endometrium occurs 2–3 days after discontinuation of the tablets ("hormonal curettage"). Treatment with injections of an estrogen-progestagen compound (e.g. Primosiston) gives considerably worse results. The slow fall of the hormone level often leads to prolonged withdrawal bleeding.

About 50% of cases of juvenile bleeding and 60–75% of cases of glandular cystic hyperplasia recur during the premenopause (SOUTHAM, 1966; ISRAEL, 1967). Prophylaxis of recurrences necessitates plotting of the basal body temperature. If there is no rise in temperature within three weeks, there is a danger that the endometrium has become hyperplastic again. In this case, secretory transformation of the endometrium must be precipitated by the administration of exogenous progestin, because of the risk of recurrences. Oral progestagens are best used to produce transformation, for example in doses of 1 tablet of Primolut-N 3 times daily for 4 days (Table 21). Withdrawal bleeding occurs 2–3 days after discontinuation of the tablets. If bleeding does not occur, it can be assumed that the patient has reached the postmenopause (so-called progestin test, p. 597). Abdominal total hysterectomy and bilateral ovariectomy are indicated when glandular cystic hyperplasia arises during the postmenopause, since a minute hormone-active ovarian tumor may be present.

c) Acyclic Dysfunctional Uterine Bleeding (Fig. 62d)

Bleeding arising outside the cycle is termed as *metrorrhagia* or *additional bleeding*. It necessitates investigation by means of a curettage without exception since such bleeding is particularly likely to be due to organic changes. It can arise pre- or postmenstrually, and often leads to the clinical picture of menorrhagia. Dysfunctional premenstrual bleeding occurs in the presence of insufficiency of the corpus luteum due to a premature fall of the estrogen and progesterone levels. Insufficient secretory transformation of the endometrium, which is often associated with this condition, leads to functional sterility.

As has been mentioned already, the retarded regression of the corpus luteum and the delayed withdrawal of progesterone cause a delay in the menstrual rejection of the secretory transformed endometrium (irregular shedding), which may also present clinically as postmenstrual bleeding. The metrorrhagia is not really related to menstruation. It has recently become more

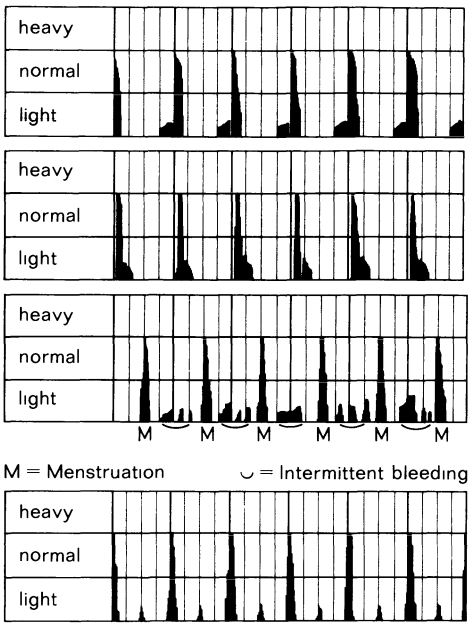

Fig. 62d. Acyclic uterine bleeding (metrorrhagia) = bleeding at times other than during the normal menstrual period: premenstrual bleeding, postmenstrual bleeding, intermenstrual bleeding = metrorrhagia, mid-cycle bleeding = ovulation bleeding = bleeding at the time of ovulation

frequent due to the use of ovulostatics (breakthrough bleeding).

Ovulation bleeding or *mid-cycle bleeding* is a special form of metrorrhagia. These terms should only be applied after organic causes have been excluded and the bleeding has been localized in the cycle by means of the basal body temperature and the possible development of mittelschmerz (DIDDLE, 1948). Ovulation bleeding lasting between a few hours and 2 days occurs in 20% of women with mittelschmerz. The benzidine test on cervical mucus is positive in as many as 94% of ovulating women at the time of ovulation (BROMBERG, 1956), so that very mild mid-cycle bleeding can be considered normal. If the bleeding is as heavy as during menstruation, it may simulate polymenorrhea (so-called pseudopolymenorrhea). It may exceptionally continue until the next menstrual period. It is believed to be a form of withdrawal bleeding due to the fall in estrogen secretion after ovulation.

Administration of 0.02 mg ethinyl estradiol daily from day 10–16 of the cycle in a 28-day cycle will compensate the postovulatory fall of estrogens, and thus prevent ovulation bleeding. If the bleeding still occurs, it is not ovulation bleeding. Premenstrual bleeding due to insufficiency of the corpus luteum is prevented by giving exogenous progestins: e.g. 1 tablet Primolut-N is given three times daily from

the 21st to 24th day of the cycle in a 28-day cycle. The rapid fall of progestin after intake of the tablets results in accelerated destruction of the secretory transformed endometrium, so that bleeding can be prevented even in cases of delayed regression of the corpus luteum. Frequently, only thorough curettage leads to arrest of the bleeding. Ovulostatics are used prophylactically against recurrence.

3. Polycystic Ovary

[Sclerocystic ovary, androgenic ovary (JEFFCOATE, 1964; SHORT, 1965), polycystic ovarian disease (GREENBLATT, 1960; GOLDZIEHER, 1963), Stein-Leventhal syndrome (STEIN & LEVENTHAL, 1935)].

In 1935 STEIN and LEVENTHAL described an apparently well-defined clinical syndrome consisting of sterility, amenorrhea and hirsutism in a group of young women, some of whom were obese, and all of whom had greatly enlarged cystic ovaries. Since then, numerous authors have reported almost identical cases, but more often similar clinical features with ovarian dysfunction. This makes the so-called Stein-Leventhal syndrome one of the most controversial syndromes in endocrinology, as far as its clinical features and pathophysiology are concerned. This syndrome now includes a spectrum of overlapping dysfunctions of the ovary and adrenal cortex, with clinical symptoms differing not only from one woman to the next, but also varying temporarily in the same woman. A few investigators have come to doubt the existence of this syndrome because of this extreme variability (NETTER, 1958; ROBERTS, 1960). The incidence of the syndrome differs greatly with different authors, depending on the criteria used to differentiate it from similar clinical syndromes. According to early reports it is rather rare. STEIN (1964) operated on only 108 cases within 34 years, and LEVENTHAL (1958) observed only 114 women with the so-called Stein-Leventhal syndrome in 29 years. Other authors report a considerably higher incidence (GOLDZIEHER, 1962; TAYMOR, 1963; PRUNTY, 1967).

Polycystic ovaries are found quite frequently, namely in 1.4% of a random sample of 12160 gynecological laparotomies (VARA, 1951), and in 3.5% of a consecutive series of 740 female autopsies (SOMMERS, 1956). Polycystic ovaries are encountered more frequently in sterile patients, as is to be expected (4.6%) (MCGOOGAN, 1954).

Thanks to improved methods of investigation which allow better understanding of the pathophysiology of the ovary it has been shown in the last ten years that quite a small fraction of patients suffer from the Stein-Leventhal syndrome, and that these patients can be definitely differentiated from a significantly larger group of women with polycystic changes in the ovaries (GOLDZIEHER, 1967).

Table 51. Symptomatology in 1079 published and confirmed cases with polycystic ovaries (GOLDZIEHER, 1962)

Symptom	Prevalence (%)	
	Mean	Range
Obesity	41	16–49
Hirsuties	69	17–83
Virilization	21	0–28
Amenorrhea	51	15–77
Sterility	74	35–94
Dysfunctional bleeding	29	6–65
Dysmenorrhea	23	–
Biphasic basal temperature	15	12–40
Corpus luteum found at laparotomy	22	0–71

Clinical symptoms vary. Consideration of 1079 surgically confirmed cases (Table 51) (GOLDZIEHER, 1962) suggests that *anovulation* is the most frequent symptom, arising on average in 85% of cases, but varying between 20% and 90% in the different series. Even ignoring the fact that the frequency of the diagnosis "anovulation" is partly dependent on the criteria used, the existence of this syndrome, which is characterized by a symptom which is often absent, is justifiably questionable. *Sterility* is found on average in about 75% of these women, and a previous pregnancy does not exclude the syndrome. Thus, for example, a woman can have two children with a short interval between after several years of anovulatory sterility and then become sterile again with oligomenorrhea or amenorrhea. *Secondary amenorrhea* is encountered in an average of 55% of patients, whereas primary amenorrhea is found only exceptionally. *Hirsutism* is quite common (70%) and is an important leading diagnostic symptom (GREENBLATT, 1968). *Virilization*, in contrast, is considerably less common, but occurs in 20% of patients. *Dysfunctional bleeding* can be very severe, and occurs in 29% of these women on average.

The typical patient is a young woman with hirsutism, in whom menarche arose at the right time (STEIN, 1964), but with a subsequent history of irregular bleeding at intervals of three to six months. The patient often seeks advice because of primary sterility.

The clinical findings connected with the development of the breasts, vaginal smears, cervical mucus, endometrial histology, and size of the uterus, are uncharacteristic, and can embrace the whole spectrum of clinical types of hypo- and hyperestrogenism.

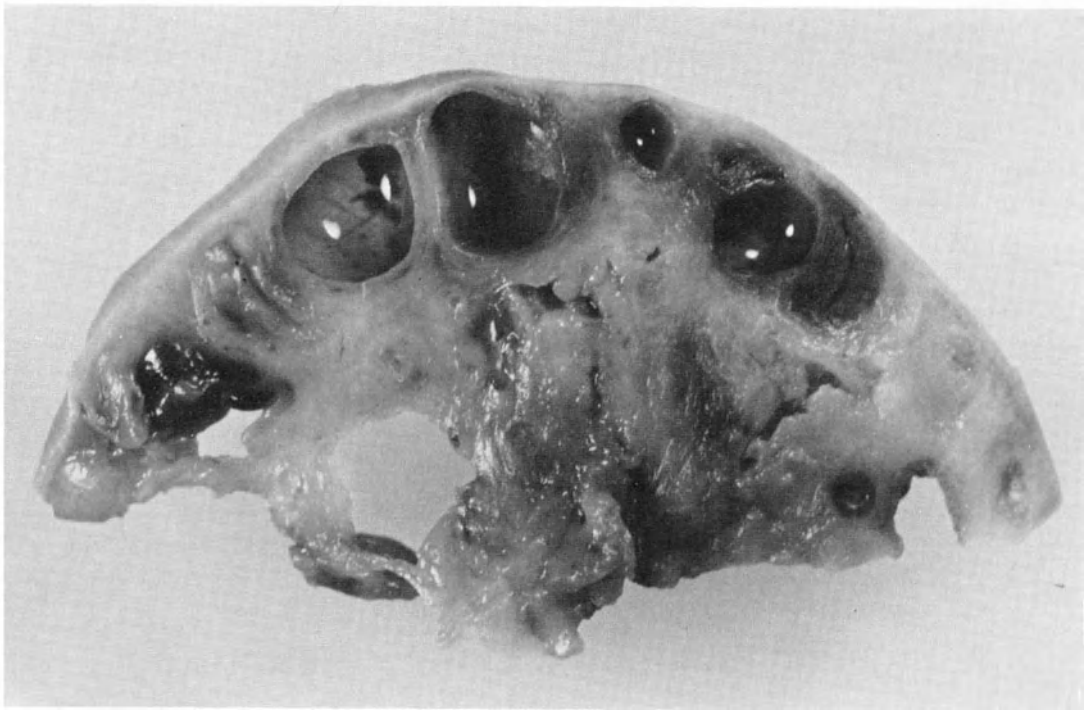

Fig. 63. Ovary taken from a patient with Stein-Leventhal syndrome. (After KRAUS, 1967)

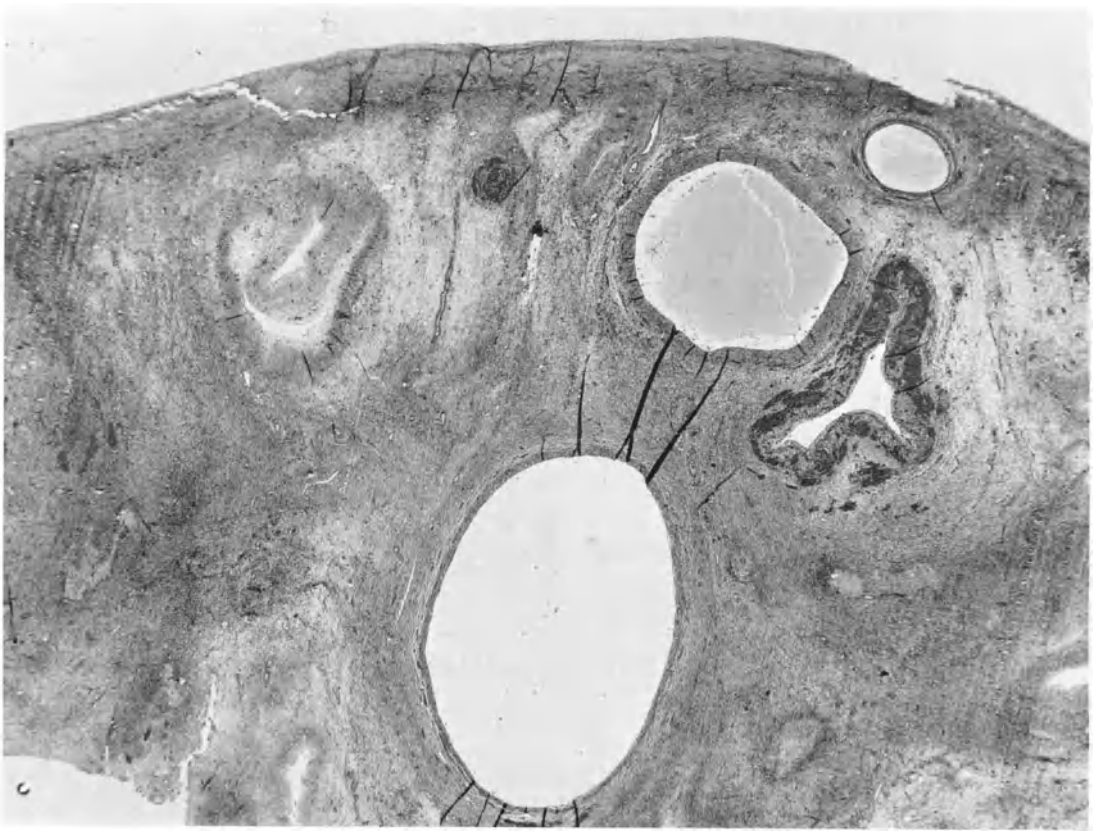

Fig. 64. Microscopic picture of ovary shown in Fig. 63. (After KRAUS, 1967)

The ovaries described originally by STEIN and LEVENTHAL (1935) were enlarged, with a maximum diameter of 4–6 cm. In some cases the ovaries were larger than the uterus. The same clinical picture is observed, however, in women with ovaries of normal size or with one enlarged ovary (EVANS, 1960; BENEDICT, 1962). Enlarged ovaries are found at operation in only 70–80% of the patients (GOLDZIEHER, 1962; TAYMOR, 1963; SMITH, 1965). The capsule is thickened and pearly-white in typical advanced cases (oyster shell-like ovaries), and the ovary is more vascularized than normal. The histological picture pathognomonic of the fully developed syndrome is characterized by fibrosis of the collagenous thickened capsule, which is a result of the influence of the androgens; there are numerous subcapsular follicular cysts and an increased number of atretic follicles; the follicular system shows a thickened and markedly vascularized theca interna with luteinized cells and frequent mitoses (PLATE, 1958; JONES, 1962; LEVENTHAL, 1963). It is generally assumed that the cells of the theca interna are the site where androgens are formed in normal or increased amounts (RICE, 1964). The histological picture thus indicates anovulation of long duration in the presence of strong and continuous gonadotropic stimulation. Like the clinical picture, the microscopical picture of polycystic ovaries varies considerably. The numerous subcapsular follicular cysts with diameters between a few millimeters and over one centimeter and the reduced number of atretic follicles are the only pathognomonic features. Fibrosis of the capsule has been described as characteristic by some authors (SHIPPEL, 1955; GOLDZIEHER, 1962; TAYMOR, 1963), but this has not been confirmed by other investigators (PLATE, 1958; JONES, 1962). Similarly, other authors claim that there is only an apparent increase in the cells of the theca interna, due to the increased number of atretic follicles (GOLDZIEHER, 1962; GREEN, 1965; ROBERTS, 1960; CHAMBERLAIN, 1964).

Corpora lutea or albicantia have been found in a mean of 22% of polycystic ovaries. This observation proves that ovulation occurs in a considerable number of cases of Stein-Leventhal syndrome (GOLDZIEHER, 1963).

There is a normal number of primordial follicles. The ovarian stroma is pale grey and edematous.

Hyperthecosis (thecomatosis) ovarii rarely occurs in association with the clinical picture of anovulation and hirsutism. In such a case there are large nests of thecal cells laden with lipids in the ovarian stroma (SHIPPEL, 1955; SCULLY, 1963). There are usually only a small number of cystic cortical follicles. The hyperplastic medullary stroma forms a tumor-like mass in the center. These ovaries are often associated with virilization, obesity, hypertension and symptoms of impaired glucose tolerance, all of which indicates adrenocortical hyperfunction. Analogous ovarian changes are observed during pregnancy.

Different forms of androgenic hyperplasia and tumors of the adrenal cortex can give rise to ovarian changes similar to those found in polycystic disease of the ovaries, corresponding to long-lasting anovulation in the presence of increased androgenic activity. There is, however, no enlargement of the ovaries; there are only a few cysts and the number of primordial follicles is reduced.

Increased formation of androgenic active steroids dominates the clinical picture in the syndrome of polycystic ovaries. In addition to the quantitative nature, the origin and biosynthesis of these androgens are of special interest.

A series of different investigations indicate that at least some of the increased amounts of androstenedione and testosterone are produced in the ovaries themselves. Incubation of tissue sections of polycystic ovaries gives rise to a significantly higher formation of androstenedione than in normal ovaries (LANTHIER, 1960; GOLDZIEHER, 1960; WARREN, 1962; ZANDER, 1962). It has also been demonstrated that the androsterone concentration in venous blood of polycystic ovaries is much higher than in normal circumstances in normal ovaries (MIGEON, 1960). Increased amounts of androstenedione and dehydroepiandrosterone were found in the follicular fluid of polycystic ovaries in the absence of 17-β estradiol (SHORT, 1961).

Observations of increased excretion of Δ^5-3 compounds such as Δ^5-pregnanediol and Δ^5-pregnanetriol (SHEARMAN, 1961; STERN, 1963) are of interest in connection with disturbed steroid synthesis of the ovaries. They indicate reduced activity of 3β-OH-dehydrogenase in polycystic ovaries.

On the basis of these investigations it is presumed that steroid synthesis deviates from normal in two ways in the polycystic ovary (Fig. 65):

a) decreased activity of 3β-OH-dehydrogenase and

b) reduced activity of the enzyme causing aromatization.

It is assumed on the basis of the ratios of H3 to C14 during the use of pregnenolone-7-H3 and progesterone 4-C14 in incubation experiments with polycystic ovaries (RYAN, 1965) that in the polycystic ovary steroids are

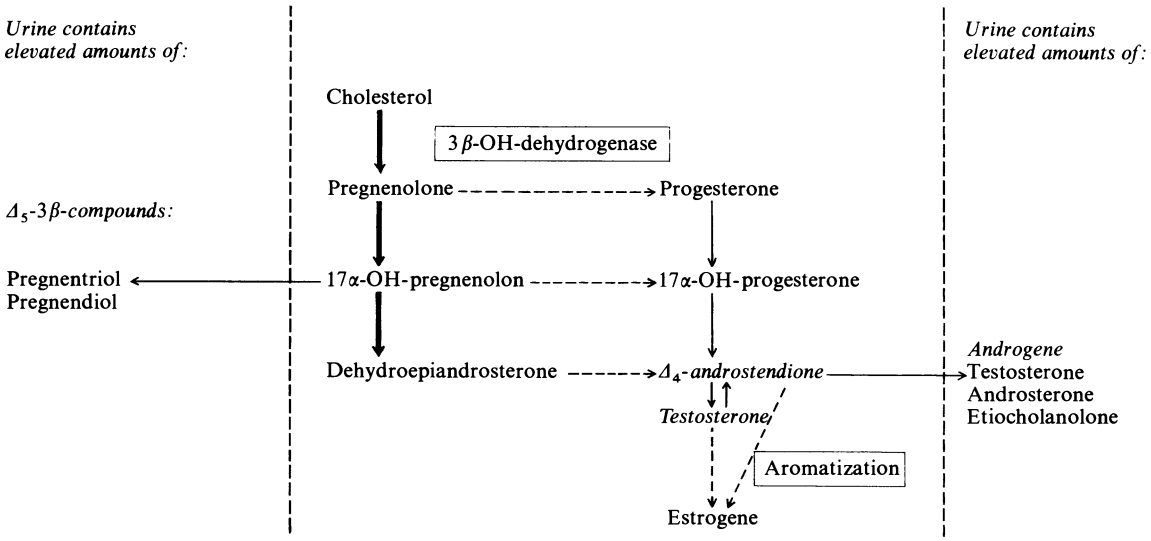

Fig. 65. Excretion of 17-ketosteroids and 17-hydroxycorticoids with the urine in women with polycystic ovaries

mainly synthesized via pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone and androstenedione (Fig. 65) (MAHESH, 1962). Thus, conditions are similar to those in the follicle of the normal ovary, the only difference being that there is an accumulation of androstenedione and testosterone due to the reduced activity of the enzyme causing aromatization of the A ring (SAVARD, 1965) (Fig. 65).

Similar conditions are also found in the ovarian stroma, and it is to be expected that both substances arise from the cells of the theca interna.

The involvement of the adrenal cortex in the syndrome of polycystic ovaries is still controversial, whereas it is generally accepted that the androgen production is increased in polycystic ovaries (JONES, 1964). Stein and Leventhal suggest that only biosynthesis of ovarian steroids is disturbed in the syndrome named after them, and that adrenocortical function is intact. The majority of other investigators, however, suspect that there is concomitant adrenocortical dysfunction in at least some of these women.

Few histological investigations have been performed on the adrenals, and these have never revealed adrenocortical hyperplasia in patients with polycystic ovaries. The absence of hyperplasia does not of course exclude increased production of adrenocortical androgens. Thus results with cortisone (see below) show that there may be adrenocortical hyperactivity in some cases of polycystic ovaries. These patients probably have so-called "borderline adrenal hyperplasia" (GOLD, 1958; ZENER, 1961).

It must not be forgotten, however, that corticoids can increase gonadotropin excretion (SHEARMAN, 1966) and thus act indirectly on the ovaries. 17-Hydroxycorticoids are occasionally found to be elevated and the excretion of 11-oxy-17 ketosteroids is rarely increased. This indicates involvement of the adrenal cortex (JONES, 1953; GREENBLATT, 1953).

It is also known that hypothalamic lesions induced in experimental animals to produce polycystic ovaries also cause hyperplasia of the adrenal cortex at the same time (BARRACLOUGH, 1961).

Particular attention has been devoted to the excretion of metabolites of C-19 and C-21 steroids in the hope of discovering their site of origin (MAUVAIS, 1962), but this has not been revealed. Excretion of 17-ketosteroids and 17-hydroxysteroids may be normal in polycystic disease of the ovaries or elevated in rare cases. In a statistical sample of 338 cases of polycystic ovaries confirmed surgically, 23% showed high values (GOLDZIEHER, 1963). Stein and Leventhal only count patients with normal 17-ketosteroid excretion as cases of the syndrome named after them. A normal 17-ketosteroid excretion does not exclude an elevated production of testosterone. A 100% increase in the formation of testosterone, e.g. from 3 to 6 mg daily, causes in increase of only 1.5 g in the 17-ketosteroid excretion, but 180 g testosterone secreted in a month can produce hirsutism in the female. The raised androsterone and etiocholanolone fraction in the presence of quantitatively normal 17-ketosteroid excretion shows that formation of androgens is raised in these cases of polycystic ovaries.

Pregnanediol excretion corresponds to preovulatory values. Pregnanetriol excretion is normal. In view of the normal pregnanetriol excretion in the Stein-Leventhal syndrome, it is hardly probable that the pregnanetriolone often excreted in increased amounts at the same time is of adrenocortical origin.

Since it has become possible to estimate the *level of testosterone* in the plasma precisely by means of double labeling with isotopes (RIONDEL, 1963), it has been shown that the average value of free testosterone in the plasma is three or four times higher than normal in patients with polycystic ovaries (FORCHIELLI, 1963; LOBOTSKY, 1964; DIGNAM, 1964; KORENMAN, 1965; LLOYD, 1966) (Table 52). This is consistent with the elevated excretion of testosterone glucuronide in the urine (PRUNTY, 1967).

Table 52. Plasma testosterone

Group of patients	Testosterone (μg/100 ml) mean ± SD	17-ketosteroids (mg/24 h) mean ± SD
"Normal" men	0.640 ± 0.20	
"Normal" women	0.036 ± 0.009	11.5 ± 3.5[a]
Women with polycystic ovaries and hirsutism	0.135 ± 0.128	10.4 ± 2.8[a]
Women with polycystic ovaries *without* hirsutism	0.110 ± 0.058	10.0 ± 3.8[a]

[a] LLOYD (1966).

The therapeutic results obtained by STEIN (1963) with the wedge resection in very carefully selected cases, have not been achieved by any other author. A series of laboratory investigations was developed in the hope of differentiating the cases likely to show a favorable response to wedge resection of the ovaries because of the ovarian origin of the androgens. These tests were intended to distinguish between androgens arising from the adrenal cortex and those originating in the ovary. Fractionation of the 17-ketosteroids shows an increase in the androsterone and etiocholanolone fraction in women with polycystic disease of the ovaries. This however yields no information about the site of origin of the androgens. *Dynamic function tests* for differentiation between adrenocortical and ovarian steroids have also proved disappointing. The results obtained vary widely and must be interpreted with the utmost caution. Only about 50% of patients with polycystic ovaries show no significant reduction in 17-ketosteroid excretion in the dexamethasone inhibition test. This may be because 17-ketosteroids arise outside the adrenals, or because there is a state of autonomy for the synthesis of adrenocortical androgens, as has been observed in certain forms of adrenal disorders (GALLAGHER, 1956–57; GOLDZIEHER, 1960). Estimation of the excretion of 17-ketosteroids and fractionations during adrenocortical inhibition with corticoids and simultaneous stimulation of the ovaries with gonadotropins (JAYLE, 1961; MAHESH, 1964) gives no definite results, and only demonstrates the wide variation associated with the Stein-Leventhal syndrome. Interference due to simultaneous inhibition and stimulation of the incretory organs (PERLOFF, 1963; SOHVAL, 1951) and the influence of reciprocal relations in the hypophyseal regulation of adrenal cortex and ovary greatly restrict the value of dynamic function tests. This is also applicable to investigations on the behavior of plasma testosterone under the action of dexamethasone and gonadotropin stimulation (LLOYD, 1966). As the adrenocortical production contributes 20 μg/100 ml to the testosterone in the plasma (PRUNTY, 1967), a pronounced fall in the plasma testosterone level due to dexamethasone indicates raised androgen synthesis in the adrenal cortex. This was found to be the case in three of the nine women with polycystic ovaries investigated by LLOYD (1966).

To summarize the numerous results: it appears possible that there is androgen hyperactivity of the adrenal cortex in some cases of polycystic disease of the ovaries, but there is still no proof of this.

Urinary estrogens and the rate of secretion of estrogens are usually within the normal ranges (BARLOW, 1967). Elevated excretion values have been described exceptionally (BROWN, 1963). It is possible that there are qualitative differences, in the form of reduced estriol excretion, from the normal ovary (BARLOW, 1967).

In keeping with the increased testosterone concentration in the plasma, the androgen/estrogen ratio, which is important for peripheral steroid activity, is also raised (MAHESH, 1962).

Very few results are yet available about the excretion of *gonadotropins* in cases of polycystic ovaries, and they allow no conclusions. Excretion of the total gonadotropins is in no way unusual (PRUNTY, 1967). The few studies in which excretion of FSH and that of LH are measured separately show irregular elevation of LH activity (INGERSOLL, 1959; KEETTEL, 1959; TAYMOR, 1963; KELLER, 1968) while FSH activity is unaltered (BUTT, 1967).

The impairment of estrogen synthesis from androgens in the polycystic ovary has also been disputed. A number of investigators have

observed normal biosynthesis of estrogens *in vitro*, a normal or even elevated estrogen content in the follicular fluid of polycystic ovaries, and a normal secretion rate (BARLOW, 1967). Other investigators suspect that estrogens originate mainly in plasma androgens, and are not secreted as such by the ovaries (MCDONALD, 1966).

The *diagnosis* of polycystic ovaries should be made by elimination, patients with Stein-Leventhal syndrome forming a subdivision (Table 53). The syndrome must be differentiated from the post-puberal form of the congenital adrenogenital syndrome and less frequently from Cushing's syndrome and virilizing tumors of the ovary and adrenal cortex. A raised 11-ketopregnanetriol excretion is pathognomonic of the congenital adrenogenital syndrome. A definite increase in the excretion of 17-ketosteroids indicates an androgen-producing tumor in the ovary or adrenal cortex. A DHEA fraction of over 50% is also indicative of the presence of an adrenal tumor.

Table 53. Syndrome with polycystic ovaries

Stein-Leventhal syndrome	
Sterility/anovulation/oligomenorrhea/amenorrhea/ functional bleeding/ hirsutism (virilization)/obesity	
One or both ovaries enlarged and polycystic (oysterlike)	Normal-sized polycystic ovaries hyperthecosis ovarii
17-ketosteroids and 17-OH-corticoids normal	17-ketosteroids and/or 17-OH corticoids slightly elevated
Increased excretion of Δ_5-3β steroids in the urine	
Ovulation not induced with cortisone	Ovulation induced with cortisone

The many women with so-called *simple or idiopathic hirsutism* must also be differentiated from women with polycystic disease of the ovaries and hirsutism. These women show no detectable disorder of ovarian and adrenocortical function. The cycle is only exceptionally disturbed, and the ovaries show no macroscopic or microscopic changes. The hirsutism is frequently a racial characteristic, and is found particularly in women of Mediterranean races.

The etiology of polycystic ovaries is still open to discussion. A primary disorder of the synthesis of ovarian steroids due to a genetic defect cannot be excluded. A genetic disturbance is suggested by the simultaneous occurrence of a deficit of 3β-hydroxy-steroid dehydrogenase in the adrenal cortex and polycystic ovary (AXELROD, 1965), the simultaneous occurrence of genital anomalies (CHOSSON, 1958), and a chromosomal mosaic (BISHUN, 1964, etc.). [The last factor has, however, not been confirmed by other investigators (BYRD, 1964).] Taking the therapeutic success of wedge resections and of treatment with clomifene or gonadotropins into consideration the current tendency is to evaluate the disturbed ovarian synthesis of steroids as secondary in nature due to impaired hypothalamo-hypophyseal regulation. This view is also supported by animal experiments in which polycystic ovaries or a state of continuous estrus is produced by damaging the "rhythmic" sexual center of the anterior hypothalamus with testosterone (BARRACLOUGH, 1961). Clinical observations in cases with hypothalamic lesions also support this (BARTUSKA, 1967).

The results available at present allow formulation of the following hypothesis on etiology and pathogenesis: some unknown factor causes a disturbance in the rhythmic release of FSH and LH by the anterior pituitary. The rhythmic LH spurt necessary for the release of ovulation in particular is absent. The causal agent can be a constitutional or emotional factor, an endogenous hormonal influence from the adrenal cortex or thyroid gland, or exogenous medicinal or mechanical influence acting on the hypothalamic center responsible for the rhythmic release of gonadotropins. This results in loss of the rhythmic release of gonadotropins, such as occurs in the male. This in turn leads to failure of terminal follicular maturation. Cysts are formed, numerous atresias with functional disturbance in steroid synthesis cause increased androgen production and thickening of the capsule, as SCOTT was able to show experimentally (1956). The capsular thickening, however, is in no way related to the failure of ovulation; removal of one ovary induces ovulation in the other polycystic ovary.

Treatment

Women are primarily forced to consult their physicians because of sterility, severe functional uterine bleeding, and less frequently because of oligomenorrhea or amenorrhea. Even in the absence of any desire for children, treatment of the cycle disorder is indicated because inadequate stimulation of the endometrium frequently leads to atypical hyperplasia (ZANDER, 1962) or even to carcinoma of the body of the uterus (ANDREWS, 1960; GOLDZIEHER, 1962).

Sterility and the possibility of endometrial disorders are not the only reasons for treating these women. Continuous increase in the production of androgens can lead to hirsutism and even to virilization, and the anabolic action of androgens may cause obesity.

The original form of treatment recommended by STEIN and LEVENTHAL (1935) was *wedge resection of the polycystic ovaries*. Very careful selection of patients and resection of an adequate portion of the ovary with hilar tissue are essential for therapeutic success. The final size of the treated ovary should be rather less than that of a normal ovary. The success is very variable and this is certainly partly connected with the choice of cases and the surgical procedure. Unfortunately there are still no criteria for preoperative assessment of the chances of success with the wedge resection (see above). Size of the ovaries and 17-ketosteroid excretion are not important (GOLDZIEHER, 1962; TAYMOR, 1963). STEIN (1963) achieved 95% ovulatory cycles and a conception rate of 80% in a total of 108 cases. These results, however, have not been obtained by any other investigator. It was deduced from a large group of collective statistics that the cycle becomes normalized in a mean of 80% of cases, the limits ranging between 6 and 95% (GOLDZIEHER, 1963) (Table 54). Pregnancy arose in 13 to 89%, average 63%, whereas hirsutism diminished in 16% of the women (range 0–18%). Our experience and that of others (GOLDZIEHER, 1962; TAYMOR, 1963), however, suggests that the curative effect of the wedge resection is only temporary. STEIN disagrees with this on the basis of his own experience (1964, 1967). There is at present no satisfactory explanation for the therapeutic effect of the wedge resection. The reduction in the ovarian tissue producing androgens has some effect. This was deduced from estimations of plasma testosterone before and after surgery (Table 55). It can be assumed, however, that the disturbed ovarian biosynthesis is only quantitatively and not qualitatively changed by the mechanical procedure (ZANDER, 1963).

Table 54. Published results of wedge resection performed in a total of 1079 cases (GOLDZIEHER, 1962)

Result	Prevalence (%)	
	Mean	Range
Regular cycles	80	6–95
Pregnancy	63	13–89
Lessened hirsutism	16	0–18

Table 55. Plasma testosterone (μg/100 ml) before and after ovarian wedge resection (4 patients) (LLOYD, 1966)

Before surgery	After surgery	
0.177	Day 1	0.058
	Day 6	0.098
	1 month	0.082
0.089	4 months	0.030
	18 months	0.037
0.077	16 months	0.081
	21 months	0.037
0.086	Day 1	0.039
	Day 6	0.047

Patent tubes and normal fertility in the husband are necessary requirements for wedge resection. In our opinion, wedge resection should not be performed prophylactically in view of later sterility and hirsutism, and particularly not in teenagers with polycystic ovaries (STEIN, 1964), since relapses are not uncommon and the desired pregnancy usually arises within a few months after surgery.

JONES, HOWARD, and LANGFORD were the first to report on the regulation of cycles with cortisone treatment in women with polycystic ovaries in 1953. Their result have since been confirmed by numerous investigators (GREENBLATT, 1953; SMITH, 1965). The results in cyclic regulation, incidence of pregnancy and hirsutism correspond to those with the wedge resection, even in cases where the 17-ketosteroids are not raised. Cortisone also produces a fall in plasma testosterone levels (LLOYD, 1966). As long as there are no contraindications (TB, gastric ulcer), treatment with cortisone should be tried before wedge resection is considered. We use 10 mg prednisone daily for long-term treatment over 4–6 months. Treatment is continued for 12 months after ovulation arises, and the patient is followed up after discontinuation of the drug to check whether ovulation is still occurring.

In recent times, treatment with clomifene has had a high degree of success in polycystic ovaries (KISTNER, 1961, 1967). About 75% of women with polycystic ovaries begin to ovulate after treatment with clomifene (JOHNSON, 1967). It is best to start with a low dose of 50 mg daily for 4 days because of the sensitivity of polycystic ovaries to gonadotropic stimulation. The therapeutic action is probably due to a direct effect on the synthesis of ovarian steroids as well as to hypothalamic regulation. Ovarian dysfunction recurs in most cases after withdrawal of clomifene. Clomifene is the treatment of choice but should only be used in women who want children, who have patent tubes and whose husbands are normally fertile.

Good results have also been achieved by treatment with gonadotropins (LUNENFELD, 1960; STAEMMLER, 1964; GEMZELL, 1965; JONES, 1965). Because the ovaries are increasingly sensitive to gonadotropin stimulation, the dosage must be adjusted cautiously and patients carefully monitored. It is known that lutein cysts can appear and grow rapidly, leading to rupture and massive intra-abdominal hemorrhage (VAN DE WIELE,

1965). The danger of multiple pregnancies is also recognized. Treatment with gonadotropins is only indicated in individual, carefully chosen cases where other forms of treatment have failed and where there is a wish for children, because of the dangers involved and the high costs (for treatment schedule, Fig. 59).

The cyclic use of oral estrogens and progestins is recommended for young unmarried patients with polycystic ovaries (GOLDZIEHER, 1967). This form of treatment inhibits ovarian and adrenocortical function, thus suppressing the increased androgenic production without causing a peripheral deficit of ovarian hormones. The use of an ovulostatic compound will become established for practical reasons. A marked decrease in the size of bilateral enlarged polycystic ovaries has been described with this form of treatment (GOLDZIEHER, 1967).

4. The Premenstrual Syndrome and Dysmenorrhea

a) The Premenstrual Syndrome

The premenstrual syndrome includes psychological and physical symptoms occurring cyclically in the premenstrual phase (FRANK, 1931).

Psychological symptoms arranged in order of frequency are: nervous tension, irritability, lability of mood, aggressiveness, restlessness or depression, scared moods, insecurity, tiredness (LAMB, 1953; BLEULER, 1954). Psychoses may exceptionally arise (BLEULER, 1954; KROGER, 1962). Psychological symptoms may be associated with disturbances of partiality drives: abnormal hunger or thirst, insomnia, increased libido (BLEULER, 1954). The disturbance in the psychological equilibrium is reflected by the increase in female crimes during the premenstrual period (MORTON, 1953; DALTON, 1964) and by the high frequency of suicide, accidents and illnesses during the second half of the cycle (MCKINNON, 1966).

The social significance of the premenstrual syndrome is greater than the purely medical problem since psychological premenstrual disturbances are more frequent and severe than the physical symptoms.

Physical symptoms in order of frequency (MORTON, 1953) are: mastodynia (70%), abdominal symptoms (approximately 50%) such as distension in the abdomen, congestive states in the small pelvis, edema (approximately 45%) of the hands, feet, and face, headaches (approximately 30%), sometimes in the form of migraine attacks. Premenstrual water retention up to 4 liters with development of edema (THORN, 1938; GREENHILL, 1941; HAUSER, 1959; BRUCE, 1962; ROGERS, 1963) is the only pathognomonic physical symptom. Allergic features such as urticaria, vasomotor rhinitis and asthma occasionally arise cyclically in the premenstruum (DORMAT, 1957).

The data on the *frequency of the syndrome* vary widely depending on the evaluation of symptoms and the group of patients investigated. EICHNER (1959) found the syndrome in 70% of nurses, but less than 7% considered treatment necessary for their symptoms. According to ISRAEL (1967), the syndrome arises in 75% of women. It was present without exception in one group of adolescents studied, but treatment appeared necessary in only 2% (GALLAGHER, 1960).

The pathogenesis is under investigation. Almost all authors agree that *psychological factors* are involved, since the syndrome is frequently encountered in women with neurotic, psycholabile and psychopathic personalities (WILLIAMS, 1952; LAMB, 1953; REES, 1953; BLEULER, 1954; APPLEBY, 1960). In contrast to the situation in dysmenorrhea, there is no basic actual situation of conflict, but rather a latent neurotic attidude due to conflicts in life (KROGER, 1962). The interrelationship of mind and body is summarized by BLEULER (1954): "Premenstrual tension is an emotional shock which arises because of different hormonal, metabolic and physiological disturbances to the state of equilibrium if the psychological development of the woman is predisposed to this".

Metabolic disorders such as hypoproteinemia (MENZER-BENARON, 1963), elevation of blood sugar level (HAUSER, 1959), and hypoglycemia (MORTON, 1953) have been described.

The observation that the syndrome only arises in ovulatory cycles leads to the assumption that hormonal factors have some part in the etiology (GREENE, 1953). Quantitative hormonal investigations in large comparative series have shown, in contrast to earlier theories, that the excretion of estrogens and progesterone lies in the same range for women with the premenstrual syndrome as for other women, and that there is no significant connection with symptoms (LAMB, 1963; MENZER-BENARON, 1963; PRILL, 1963). An increased ergotropic-sympathetic reactive state with hypersensitivity to stimuli (KROGER, 1962; ARTNER, 1965) released by progesterone possibly plays some part. Corticoids may also be elevated (MENZER-BENARON, 1963).

According to some authors, premenstrual water retention has an important effect in the pathogenesis of the premenstrual syndrome (THORN, 1938, 1957; GREENHILL, 1941; FREED, 1945). The edema is thought to be produced

by secondary aldosteronism (STREETEN, 1960), aldosterone secretion being increased by progesterone and psychological states of tension (LAMSON, 1956; VENNING, 1957). This hypothesis is supported by the observation that aldosterone excretion is increased during the premenstrual syndrome, that sodium diuresis is decreased (CIMBERLE, 1961), and that administration of additional progesterone can raise sodium excretion after ovulation (JENKINS, 1961; LANDAU, 1958, 1961). Adiuretin is also considered to be of pathogenic importance in the development of the premenstrual syndrome. Vasopressin given intramuscularly during the luteal phase is alleged to be capable of inducing the premenstrual syndrome (BICKERS, 1952). Elevated adiuretin excretion has been reported during the premenstrual syndrome (ZUSPAN, 1958).

The importance of a "menotoxin" in the development of the premenstrual syndrome (MACHT, 1949; SMITH, 1950) is no longer taken seriously.

Treatment

Treatment with drugs and also psychotherapy alone can be successful. Discouragement from overestimation of the symptoms is important (ROEMER, 1969). The best results are obtained with combined medical and psychological treatment (REES, 1953; KROGER, 1962). Combined preparations containing a diuretic, a progestagen, and a tranquilizer are thought to be effective (BARFIELD, 1962). We have noticed an improvement in some cases treated with a combination of an antihistamine and a bromtheophylline preparation (Donasil). A low-salt, protein-rich diet has a supportive effect (MENZER-BENARON, 1963).

Only a few severe cases require psychoanalysis (KROGER, 1962).

b) Dysmenorrhea

Dysmenorrhea or algomenorrhea signifies either continual or more frequently cramp-like pains in the lower abdomen in association with menstruation. They sometimes begin shortly before menstrual bleeding, but usually with the onset and rarely after the bleeding. The pains may be associated with nausea and vomiting.

The symptoms usually last from a few hours to one day. They seldom persist for more than two days, and only exceptionally throughout menstruation. The pain usually reaches its maximum shortly after the onset of bleeding. Pains due to endometriosis are most severe premenstrually and decline with the onset of bleeding.

Since dysmenorrhea is not an illness but merely a symptom, the underlying illness must be searched for.

Two types of dysmenorrhea are differentiated: *dysmenorrhea without anatomical substrate* (functional, idiopathic, intrinsic, essential) and *dysmenorrhea with anatomical substrate* (organic, acquired, extrinsic, symptomatic). In German terminology, *primary dysmenorrhea* arising with menarche or shortly after menarche is also distinguished from *secondary dysmenorrhea*, which arises in later years. In the English speaking areas, primary and secondary dysmenorrhea are identical to functional and acquired dysmenorrhea.

The data on the *frequency* of dysmenorrhea vary widely since it is a subjective symptom (LOWE, 1951). In addition, it varies with the population group (DAVIS, 1938; DOSTER, 1961) and is dependent on whether mere malaise or inability to work is counted. Severe pains regularly confining the women concerned to bed were found in 3–15% of women in different professional categories (DOSTER, 1961), and 10% of school girls in high school are periodically absent because of dysmenorrhea (HEALD, 1957; GALLAGHER, 1960; GOLUB, 1963). In DOSTER's study 25% were absent once or repeatedly (1961). It has been calculated that 140 million working hours are lost yearly in USA because of dysmenorrhea (KISTNER, 1964). It is therefore an important social problem.

Dysmenorrhea can occur at any age. It is encountered most frequently during the third decade, with a maximum in the 25th year (FLUHMANN, 1963). A large number of organic changes claimed to be the cause of dysmenorrhea can be found in the literature. With a few exceptions there is no evidence of a causal relation.

Endometriosis is the first organic cause to be considered. It can cause the uterus to become fixed and retroflexed. Dysmenorrhea is occasionally produced by acquired stenosis after cauterization or operation of the portio.

A mobile, retroflexed uterus, fibroids, malformations in the absence of cervical or vaginal obstruction, primary stenosis of the internal and external os uteri are no more frequent in women with dysmenorrhea than in women without symptoms (KÖNIG, 1959; JAMES, 1963). Nor is there any causal connection between dysmenorrhea and uterine hypoplasia, which is diagnosed much too often (JEFFCOATE, 1945; KÖNIG, 1959; LUKAS, 1965). The same applies to chronic inflammatory processes in the pelvis.

Organic changes seldom cause dysmenorrheic complaints, whereas psychological factors play an important part in the development of dysmenorrhea (HERSCHBERG, 1960; PRILL, 1964).

According to our experience and that of other authors (HAUSER, 1959; LUKAS, 1963; ROEMER, 1969) dysmenorrhea is due to psychological factors in 90% of cases. The following psychological forces (living relations) play a considerable part (STURGIS, 1962; ROEMER, 1969): loss of domestic security, conflict over own femininity, dependence, hostility, feelings of guilt towards mother or sister (family rivalry), possibly identification with the mother who also suffers from dysmenorrhea (LOMER, 1899) ("familial dysmenorrhea" after A. MAYER, 1925), ambivalence between the subconscious wish to remain a little girl and the conscious drive to become grown up, fear of awakening sexuality, fear of pregnancy, fear of sterility, etc. Dysmenorrhea is thought frequently to be an expression of a demonstrative aggressive protest and resistence (ROEMER, 1969). On the other hand, the association of bleeding and pain is almost archetypically implanted (PRILL, 1961). Dysmenorrhea frequently arises in leptosomatic-asthenic, schizoid types who have difficulty in forming social contacts, and in dysplastic women (infantile, hypoplastic, dystrophic-adipose types). Consideration of the constitution shows that it is not the genital hypoplasia but the psychological immaturity associated with it that is of paramount importance. Psychosexual retardation predisposes to neurotic reactions to age-dependent stress (KRETSCHMER, 1952).

Various mechanisms have been discussed for the pathogenesis of dysmenorrheic pains. The observation that they arise almost exclusively with ovulatory cycles (WILSON, 1940) leads to the assumption that an endocrine factor is the releasing cause. The so-called "endocrine imbalance" has, however, not been proved so far (FLUHMANN, 1938). On the other hand, the rapid premenstrual fall of estrogens, and perhaps also of gestagens, leads to a sympathetic-adrenergic reactive state (Fig. 32). This reduces the stimulus threshold, converting otherwise below-threshold stimuli to stimuli above the threshold (HAMAN, 1944) with pathologic production of pain. The cycle-dependent physical disposition thus favors the development of pains in psychogenic dysmenorrhea, but is merely a predisposing factor. The response of smooth muscle to sympathetic-adrenergic stimuli is increased at the same time (WALTHARD, 1937). The hypothesis that this releases stronger and more frequent dysrhythmic contractions (MOIR, 1936; BICKERS, 1941; WOODBURY, 1947; MILLER, 1953) of the uterine musculature, or a functional sphincter is insufficiently relaxed in the region of the isthmus (YOUSSEL, 1958; MANN, 1961) or vasoconstriction of uterine vessels leads to ischemic pains analogous to conditions in the spiral arteries of the endometrium (MOIR, 1936; WOODBURY, 1947; PRILL, 1962) are plausible, but still purely speculative. More recently a so-called "menstrual-stimulant factor" has been discussed (CLITHERTOE, 1961). This factor has been isolated from menstrual fluid, and it was possible to induce uterine contractions with it (EGLINTON, 1963). It is claimed to be absorbed in increased amounts in dysmenorrhea.

Continuous *premenstrual* pains arising in endometriosis are probably due to tension of the capsule produced by premenstrual vascular congestion.

The colic-like pains in so-called *dysmenorrhea membranacea* are thought to be caused by rejection of incompletely decomposed endometrium resulting from an enzymatic disorder in the endometrium (GREENBLATT, 1954). This however is contradicted by the observation that decidual saccules are rejected painlessly in an ectopic pregnancy.

Diagnosis and Treatment

Since dysmenorrhea is a symptom and not an illness, the cause must first be detected. We adopt the following system: the uncommon organic causes are first detected or excluded by case history and gynecological examination. This, however, is not always absolutely certain. If there is no apparent organic cause, a thorough psychiatric case history must be taken. The psychological noxa can usually be found in this way. In a few cases, and according to other authors in 50% of cases (LUKAS, 1963), a cure is achieved with a brief course of psychotherapy, but it must also be remembered that 23% of cases of dysmenorrhea in young women are cured spontaneously (GOLUB, 1963). In our experience, treatment with analgetics or spasmolytics is required in the majority of women with dysmenorrhea of average severity. This must be supported by psychohygienic measures: sufficient sleep, physical exercise, regulation of bowel action, sensible balance between work and leisure. It is of interest that the most varied types of treatment produce a "cure" in an average of 80% of cases. This is also indicative of the pathogenesis. It can be deduced from this that treatment has a placebo effect, i.e. psychological factors play a dominant role.

In cases of severe dysmenorrhea, inhibition of ovulation by one of the hormonal contraceptives in use practically always results in painless withdrawal bleeding, or at the most with very little pain. The symptoms do however, recur within 2–3 months after discontinuation of ovulostatic. If these women want children the

whole situation must be reexamined with a view to simple (COTTE, 1937), or extensive (HELD, 1943) sympathectomy. After an operation of this type, birth occurs with less pain and more quickly. A birth sometimes leads to the disappearance of dysmenorrhea, but this rule is not very reliable.

The cause of the therapeutic success of a birth is not clear. It was previously presumed that this was due to pressure atrophy of Frankenhäuser's ganglia caused by the advancing head. This, however, now appears unlikely, since symptoms cease almost as frequently even after Cesarean section.

H. The Sterile Marriage

Investigations by various authors (TIETZE, 1950; BARNS, 1953; WHITELAW, 1960) have shown that over 50% of women become pregnant in the first month of regular intercourse without the use of any contraceptive, two-thirds within the first three months, rather more than three-quarters during the first six months and 80–90% within the first year (Fig. 66). Inquiries among soldiers' wives yielded similar results (NOTTEBOHM, 1948). Only one in 20 of the remaining women conceived during the 2nd year. SOUTHAM (1960) found somewhat lower figures, but also showed that only 8% of first pregnancies occurred during the second year of marriage.

Thus, a *marriage* can be described as *sterile* when pregnancy fails to occur after a year of regular intercourse without contraceptive precautions. Other authors (STÖCKEL, 1947; MARTIUS, 1964) do not apply the term sterility until a woman has failed to become pregnant after two years of regular married life where there is a desire for children. This definition is incorrect in both theory and practice. Precious time is unnecessarily lost in waiting, especially in women over 30, who are frequently found in groups of sterile women.

Primary sterility is present when there is no proof of a pregnancy ever occurring, and *secondary sterility* when after having given birth to one or more viable fetuses a woman does not become pregnant again within one year of regular unprotected intercourse.

In contrast to the English terminology, a distinction is made between infertility and sterility in German.

Infertility implies the inability to carry the pregnancy until the fetus is viable. It too can be *primary* or *secondary*. *Habitual abortion* is spoken of when three or more consecutive pregnancies have all failed to reach the stage of fetal viability.

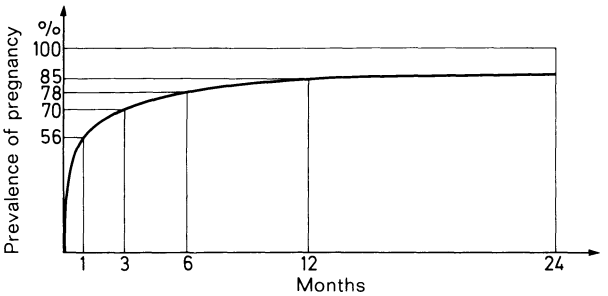

Fig. 66. Prevalence of pregnancy as a function of the period of regular intercourse without contraception. (After WHITELAW, 1960)

1. Frequency

In Europe and U.S.A. 10–15% of marriages are childless. For obvious reasons, the relevant statistics do not distinguish between wanted and unwanted sterility. Figures based on the Swiss population in 1960 allow the conclusion that deliberate childlessness in the early years of marriage plays an important part in this country (Table 56).

Table 56. Number of childless marriages in Switzerland (1960)

Total number of marriages		Number of childless marriages
Of up to 1 year's duration	42942	20317 ≙ 50% (48.0%)
Of 1–2 years' duration	42916	14715 ≙ 34% (34.3%)
Of 2–5 years' duration	40088	8979 ≙ 25% (24.9%)
Of 5–10 years' duration	35522	7057 ≙ 20% (19.8%)
Of 10–20 years' duration	26115	4549 ≙ 17% (17.4%)
Of 20 or more years' duration	475735	70383 ≙ 15% (14.8%)

There is a considerable decline in the number of childless marriages between the 2nd and 5th years of marriage. However, about 22% of marriages are still childless even after at least 5 years. Few women conceive after the 5th year of marriage, and 14.8% of marriages are still sterile after 20 years. In 1941 11.5% of marriages of at least 20 years' duration were childless in Switzerland. So an increased number of childless marriages has been recorded in Switzerland within the last two decades.

The matrimonial difficulties arising from childlessness are multiple. Examination, treatment and counselling of childless married couples are an important part of a doctor's work.

2. Causes

Sterility is a symptom which can be caused by numerous etiological factors. Two or more

etiological factors were present in sterile marriages in 10.2% of our patients (GRUBER, 1973), and in as many as 60% of BALIN's cases (1967). MEAKER (1940) and HAMBLEN (1942), report 2.23 or 4.75 factors per married couple respectively. Prognosis and treatment are only possible after systematic investigation and careful interpretation of the results. However, in no other medical field are indifference, therapeutic nihilism and polypragmasy of the doctor and lack of cooperation, especially from the husband, so pronounced.

Marriage represents a biological unit, and it is therefore logical that investigation of sterility should involve both partners. Systematic investigation according to a set plan is essential for prognosis and therapy. The fertility of a marriage is the sum of the fertility of both partners. Reduced fertility in one partner may result in a sterile marriage as defined above, despite the fact that the other partner is normally fertile. Women who are more responsive to therapy and those who become pregnant after the course of a year without any treatment are placed in the group of subfertile or sterile marriages. Subfertility in one partner can be compensated for by high fertility in the other. The prognosis is much more unfavorable when both partners are subfertile.

Not only female sterility factors but also the male factor is of great practical importance. The data on the percentage involvement of single factors in a group of sterile marriages vary from author to author for different reasons: the "normal values" used in the individual methods of investigation differ since they are empiric, arbitrarily fixed standards and not absolute values. The danger of overestimating a single result, especially if based on only one case, is particularly great in the field of sterility (cf. Section on tubal factor or quality of sperm). Apart from this, the groups investigated differ in their socio-economic structure, age and geographical environment. Thus, the frequency of genital tuberculosis ranges between 0.9%–17.4% (HELD, 1947; CABALLERO, 1966) according to the region. It is for example, of greater importance as a cause of sterility in Israel and Scotland, and especially in Sweden, Spain and India, than in for example Australia and U.S.A. Endometriosis and hormonal factors are more frequently encountered in higher social classes than in lower income groups. This is due partly to the older age at marriage in the former classes. Endometriosis is found more frequently in U.S.A. than in Europe. Inflammatory genital changes are more common in the lower social groups. In addition, the fertility of a woman is greatly dependent on her age (DIDDLE, 1947; WYLE, 1957). Fertility is at its maximum between 15 and 25 years, decreases rapidly by half by the age of 30, and is only $\frac{1}{3}$ to $\frac{1}{6}$ of its original level at 35 (MÜNZNER, 1934). Only 3 of 100 childless women have a child after the age of 40 (Table 57, Fig. 67). The decline in female fertility corresponds roughly to the reduction in the number of primordial follicles in the ovaries (PEARL, 1939; Table 1). Even 100 years ago, DUNCAN (1866) recorded that 90% of Scottish women married between the ages of 20 and 24 became pregnant within 2 years, whereas this was only true of 63% of women married between 30 and 34 and of 15% of those married between 40 and 45.

Table 57. Declining fertility with advancing age in woman (KOPPEN, 1951)

Marriage at	No. of children within			
	1 year	2 years	3 years	4 years
18 years	0.49	0.76	0.96	1.16
35 years	0.14	0.27	0.48	0.62

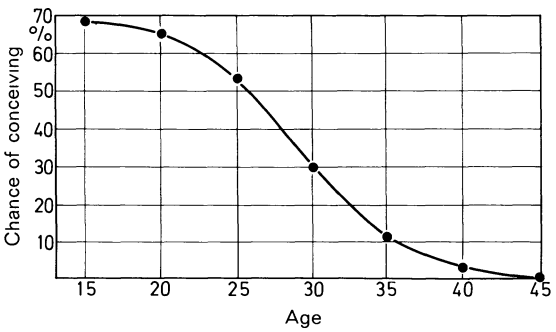

Fig. 67. Female fertility related to age. (After MÜNZNER, 1934)

A comparison of different statistics is further handicapped by different classification principles (ISRAEL, 1967; KISTNER, 1964; BICKENBACH, 1967). In general, involvement of male factors in sterility is 30–40% (GUERRERO, 1964), that of female factors 35–45%, and that of combined factors 10–20% (SLOAN, 1964; GRUBER, 1973). According to most statistics, about 30% of the causes of female sterility are due to changes in the tubes (BALIN, 1967; BICKENBACH, 1967; GRUBER, 1973). GRUBER (1973) investigated 106 cases of primary sterility and the percentage distribution of the main female sterility factors is presented in Fig. 68. In 11.7% of cases both partners prove to have at least one sterility factor. Other investigators have arrived at similar figures for the frequency of individual female sterility factors.

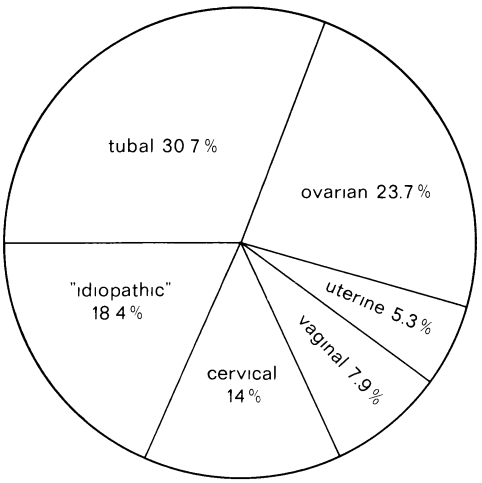

Fig. 68. Percentage proportions of female sterility factors concerned in 106 cases of primary sterility. (After GRUBER, 1971)

The cause of sterility cannot be determined in 10–20% of all sterile couples (GRUBER, 1972). In such cases so-called *idiopathic sterility* is present. This is not surprising since we are still only poorly informed about most of the processes occurring between insemination and impregnation and in the 6–7 days between impregnation and implantation. The diagnosis "idiopathic sterility" should only be made after prolonged and thorough investigation and observation by experienced investigators, and after culdoscopy or laparascopy has also yielded normal findings. In some cases, both partners are subfertile. In others, there may be an immunological incompatibility between sperm and female organism as is suggested by the observation that remarriage with other partners has often resulted in fertility of both partners of the original marriage. According to BEHRMAN (1965), immunological incompetence of this kind is present in 20% of cases of so-called idiopathic sterility. As has been shown by investigations by HERTIG, ROCK and ADAMS (1956), unviable fertilized ova compose a large proportion of so-called reproductive wastage. In this study, 13 (or 38%) of 34 fertilized human ova were found to be abnormal in the first 17 days. Since the rate of spontaneous abortion is 8.2% (JAVERT, 1957), about 30% of impregnated ova are lost without the woman involved becoming aware of this. An indefinite number of these women are classified in the group of idiopathic sterility. If the cases of extra-uterine pregnancy and intra-uterine deaths are also taken into account, so-called reproductive wastage involves over 40% of all ova, not including legal and illegal abortions.

Normal female fertility is dependent on numerous factors. Only a limited number of these can be investigated by methods of investigation currently available. If they all give normal results fertility is probably normal, but the only proof of this is conception and the birth of a living child.

Present-day knowledge of the physiopathology of reproduction and the techniques available for investigation suggest that in practice 6 factors are essential for normal female fertility. These are the so-called vaginal, cervical, uterine, tubal, endocrine, and psychogenic factors.

The most frequent causes are briefly mentioned below. The reader is referred to the appropriate specialized literature for more detailed information (HOTCHKINS, 1944; PALMER, 1950; BERNHARD, 1947; SIMMONS, 1954; BUXTON, 1958; TYLER, 1961; WILLIAMS, 1967; STALLWORTHY, 1966; WESTIN, 1966; THOMAS, 1966; BICKENBACH, 1967; ISRAEL, 1967).

a) The Vaginal Factor

Severe anatomical changes in the vagina alone, such as aplasia, do not cause sterility, since they are associated with severe obstructive malformation of the uterus (so-called Mayer-Rokitansky-Küster syndrome) (HAUSER, 1961). Severe congenital stenosis of the upper third of the vagina very occasionally leads to sterility, but this can be corrected by a vaginal plastic operation.

Severe vaginitis can impair conception due to the presence of numerous leukocytes which damage the sperms enzymatically, or phagocytize them. This is especially applicable to vaginitis and cervicitis caused by trichomonads.

b) The Cervix Factor
(SÉGUY, 1933; HUSSLEIN, 1953; ANTOINE, 1957)

The quality and quantity of cervical mucus are essential to sperm penetration and capacitation (CHANG, 1955). Both are affected by hormonal, anatomic and bacterial factors (p. 538).

Acute or chronic cervicitis can cause sterility (SOBRERO, 1962). Chronic cervicitis may be due to erosions, ectopia or cancerous changes in the portio of the cervix. There may be antibodies in cervical mucus which act cytotoxically against the sperm of the husband. These antibodies can sometimes be demonstrated in the serum, and may lead to the so-called *allergic sterility* in women in whom the other fertility factors are not found to be pathologic (PARISH, 1968).

It is to be expected that in the next few years a series of further factors connected with reproduction will be obtained in the immunological field (KATSH, 1967). This would make the group of patients with idiopathic sterility even smaller.

The Sims-Huhner test, the fern test and the spinnbarkeit of cervical mucus are used for the assessment of the so-called cervix factor (p. 538). The crossed invasion test *in vitro* (MILLER-KURZROCK, 1932) for the investigation of a possible intolerance between sperm and cervical mucus is practically difficult and is therefore of little significance.

c) The Uterine Factor

Traumatic amenorrhea (p. 593) with or without uterine adhesions or synechia (Asherman's syndrome, métrose de réceptivité) can cause sterility. It is seldom seen in this country, but appears to be more common in Italy (MAGGIONI, 1963; STALLWORTHY, 1966).

Inadequate secretory transformation of the endometrium, bringing about a developmental retardation of at least 3 days, is seen in 3–10% of sterile women (GILLAM, 1955). Insufficient luteal conversion of the endometrium may be suspected when the hyperthermal phase lasts for less than 10 days, or when the temperature rise following ovulation occurs slowly in stages (DÖRING, 1952; OBER, 1952). The incidence of tuberculous endometritis is dependent on the geographical region and varies between 0.69–17.4% (CABALLERO, 1966). HELD (1945) found it in 1.6% of sterile women with patent tubes. It is not an absolute obstacle to pregnancy, since there are known cases of pregnancy in women with tuberculous endometritis (FISHER, 1962; STALLWORTHY, 1963). The prognosis depends on the state of the tubes at the onset of therapy.

The incidence of pregnancy varies from approximately 1% (SCHAEFER, 1964) to 15% (SUTHERLAND, 1966), 20% (SNAITH, 1962; RYDEN, 1966) to 40% respectively (SCHAEFER, 1964) if the tubes are patent at the onset of treatment, but the number of tubal pregnancies and abortions is greatly elevated in these women. STALLWORTHY (1963) observed 5 tubal pregnancies and 3 abortions in 17 pregnancies after tuberculous endometritis. SUTHERLAND (1966) described 25 pregnancies in 165 sterile women. Only 6 live children were born, and the remaining pregnancies aborted (8) or were ectopic (11).

The diagnosis of uterine hypoplasia is made much too frequently. The size of the uterus is no measurement of functional capacity.

Hypoplasia responsible for sterility is associated with delayed menarche and retarded, inadequate development of the secondary sexual characteristics. The small, infantile uterus is usually anteverted and anteflexed at an acute angle and is displaced towards the left; the cervix is as long as or longer than the body, and the length of the uterine sound is 6 cm or less. A uterine malformation can result in infertility but not in sterility. Sterility is caused only by uterine aplasia or the uterus solidus in the Mayer-Rokitansky-Küster syndrome (p. 588). The mobile retroflexed uterus itself does not lead to sterility. The fixed retroflexed uterus indicates tubular sterility with endometriosis or a state following pelvic peritonitis.

Fibroids are usually only a concomitant factor and are not involved in the etiology. In exceptional cases they may lead to interstitial closure of the tubes when they are in the relevant position (intramural, and less commonly submucosal fibroids), or they may cause tubal distortion, impairing the mechanism for collection of the ovum (subserous fibroid). On the other hand they are responsible for 20–25% of cases of infertility (ISRAEL, 1967; BUXTON, 1958).

The uterine factor is investigated by means of the endometrium biopsy and hysterosalpingography.

d) The Tubal Factor

Complete bilateral occlusion of the tubes following salpingitis, pelvic peritonitis or endometriosis is one of the most common causes of female sterility. In contrast, so-called partial tubal occlusion is seldom a cause of sterility. This type of occlusion is usually due to functional disturbances. This was deduced from RUBIN'S investigations (1932). He observed practically the same number of pregnancies in women with spastic and stenosed tubes and those with normal tubal patency.

Salpingitis now arises most often after abortion, particularly after criminal abortions, and less commonly with perityphlitis and during the puerperium. The pathogens are mainly E. coli, streptococci and staphylococci. Inflammation of the tubes due to gonorrhea and tuberculosis is quite rare in this country. It is questionable, however, whether gonorrhea has not in fact become more common, but can no longer be demonstrated due to the extensive use of antibiotics. The frequency of tuberculous salpingitis is closely related to the type of patients examined and to geographical factors (RIPPMANN, 1966). SHARMAN (1952) calculated that in Scotland over 25% of tubal occlusions

with primary sterility were due to tuberculosis. About 10% of patients suffering from pulmonary tuberculosis later develop genital tuberculosis (HELD, 1945). In women over 35 endometriosis plays some part in causing tubal sterility (PHILIPP, 1937; RIVA, 1961).

The methods – pertubation, hysterosalpingography, and laparoscopy/culdoscopy – available for investigation of the tubal factor can at the most show whether the tubes are patent or not (p. 627). They provide no information about the physiology of the tubes, which is of the utmost importance for maturation of sperms (so-called capacitation) (CHANG, 1955; NOYES, 1960). Sperms are not capable of fertilizing an ovum until they have been in the female genital tract, particularly in the tube, for 4–6 hours. We do not know how this "sperm maturation" comes about; it may be due to some enzyme activation.

The culdoscopy/laparoscopy alone allows an assessment of the mechanism of collection of the ovum, i.e. the spatial and functional relation between ovary and fimbrial funnel, which is quite frequently impaired by inflammatory and endometriotic changes (KISTNER, 1962). Only in 20–25% of sterile women in whom all other fertility factors are normal are the culdoscopic findings physiological (KELLY, 1956).

e) The Endocrine Factor

There are numerous conditions resulting in endocrine factors which can lead to disorders in the cyclic course of maturation of the ova and ovulation and the formation of estrogens and progesterone. These include: dysfunction and tumors of the hypothalamic-hypophyseal system, such as Simmonds' syndrome and Sheehan's syndrome, ovarian dysfunction, such as polycystic ovaries (p. 609), hyper- and hypothyroidism (Chap. VI), dysfunction or tumors of the adrenal cortex, such as socalled "borderline adrenal hyperplasia" (p. 612), the adrenogenital syndrome, Addison's disease and Cushing's syndrome. Diabetes mellitus and relative insufficiency of the corpus luteum also belong to this group. The last condition is indicated by a stepwise increase in temperature due to the delayed action of progesterone, and by a shortened hyperthermal phase, which lasts less than 10 days, in contrast to the usual 12–13 days (DÖRING, 1952; OBER, 1952). Such cycles are infertile. These cycles are usually shorter than normal and their incidence varies with age (Table 58). They are more common in women with sterile marriages, and depending on the author have been observed in 15–33% of sterile patients (PALMER, 1949, 1953; RAUSCHER, 1959; GRANT, 1959; DÖRING, 1960).

Table 58. Prevalence of anovulatory cycles as a function of age (COLLETT, 1954)

Age	No. of women	Cycles	Anovulatory cyles	
			No.	%
17–18	59	81	25	30.8
20–24	33	112	11	9.8
25–29	21	45	2	4.4
30–34	11	23	0	0.0
35–39	13	33	4	12.1
40–50	11	33	5	15.1
Total	148	327	47	14.3

Endocrine disorders cause amenorrhea (p. 585), oligomenorrhea or anovulation (p. 603) with dysfunctional hemorrhage. Inadequate secretory transformation of the endometrium is also produced. The diagnostic procedure is discussed in the appropriate chapters. Extensive differentiation is obtained from the basal body temperature.

f) The Psychogenic Factor

Psychogenic factors can interfere decisively with reproductive processes centrally by acting via the limbic system in hypothalamic centers (p. 555). Hypothalamic amenorrhea is an example of this [influence of psychological factors on the quality of sperms (Chap. IX, p. 483)]. However it is very seldom possible to differentiate psychological influences from those of organic nature. The diagnosis is made by elimination: comparative series are not available. A few striking cases support the importance of psychological factors, but this is also contradicted by just as many observations. The mode of action is frequently obscure or controversial. Thus it is uncertain to what extent tubal spasm or disturbed uterine motility can influence sperm transport.

Experience has shown that referral of the patient to the psychiatrist is essential in very few cases. Sympathetic listening and discussion of the problems of the married couple are therapeutically effective in many cases.

3. Methods of Investigation (Table 59)

Investigation of a sterile married couple must be carried out systematically according to a fixed plan. The diagnostic procedure is presented in Table 59. We are of the opinion that the investigation must be done separately for each partner. Only in this manner is it possible to obtain a complete history and a reliable impression of the attitude of both partners towards the possibility of having a child.

After completion of the investigations the results should be discussed conclusively with both partners together, and a possible plan of treatment should be decided on. If treatment is hopeless, the reasons must be explained to the couple. This will prevent further useless investigations and enable the couple to become adjusted to the idea of a possible adoption.

Table 59. Examination of the woman

A. Case history (in husband's absence):	
1. General:	Venereal diseases, tuberculosis, hypo- or hyperthyroidism, diabetes mellitus, alcohol, nicotine
2. Gynecological:	Menarche, menstrual cycle (interval, midcycle bleeding, duration of bleeding, mittelschmerz, intermenstrual discharge), induced abortions, adnexitis, gynecological operations, intercourse (frequency, time, technique, orgasm)
3. Psychological:	Reason for wanting children, attitude to husband, marriage, children, husband's parents, interests
B. Status praesens	
1. General:	General condition, hirsutism, virilization, blood pressure, ESR, blood picture, serologic lues reaction, urinalysis (albumin, sugar). If indicated BMR, PBI
2. Gynecological:	Hypoplasia, rigid hymen, vaginitis, cervical erosion, cervicitis, lacerations, macroscopic anatomy of genital organs: position, size, form, and motility of uterus, tubes and ovaries (tumors, adnexitis, parametritis) Shorr and Papanicolaou smears, detailed colposcopy, bacteriological examination of vaginal smear (trichomonas and monilia)
C. Special tests	
1. Basal temperature curve	
2. Endometrial biopsy ± excretion of pregnandiol in urine	
3. Sims-Huhner test, spinnbarkeit, fern-leaf test	
4. Pertubation ± hysterosalpingography	
5. Culdoscopy/Laparoscopy	
6. Hormonal examinations: 17-ketosteroids, 11-OH steroids, pregnandiol, HPG, PBI	

Fertility in a woman is dependent on the anatomy, function and biology of her reproductive system. Various methods are available for examination.

Measurement of the *basal body temperature* or the *temperature on waking* (GILES, 1901; VAN DE VELDE, 1905; RUBENSTEIN, 1938; VOLLMANN, 1940) permits the diagnosis of follicular rupture and formation of the corpus luteum on the basis of the thermogenic action of progesterone (Fig. 69). It is of practical significance in the treatment of the sterile couple for a rough determination of the time of ovulation (DÖRING, 1957). The fact that a corpus luteum can also occasionally be formed in the absence of ovulation slightly limits its value as a method of diagnosing ovulation.

The temperature can be measured orally or rectally. The oral temperature is 0.1–0.2 deg C lower than, but parallel to the rectal temperature (HARTMAN, 1962). The temperature must be taken in the morning for 5 minutes after at least 6 hours' night rest, and if possible always at the same time immediately after waking (temperature on waking). Since the temperature differences are very small, it is important to prepare the thermometer the previous evening and always to use the same instrument. An ordinary thermometer can be used for this purpose, but special thermometers are also available commercially, on which the scale between 35° and 38° is extended, making the reading easier (e.g. Cyclotest thermometer). There is an average rise in temperature of 0.4–0.6 degC 14 ± 2 days before the onset of menstruation (ROCK, 1949), most frequently 1–2 days after rupture of the follicle. This rise may take the form of an increase within 1–2 days or of increments over 3–7 days. In one third of women (PLOTZ, 1950) there is a fall in temperature before the rise. The temperature falls again within one day before the onset

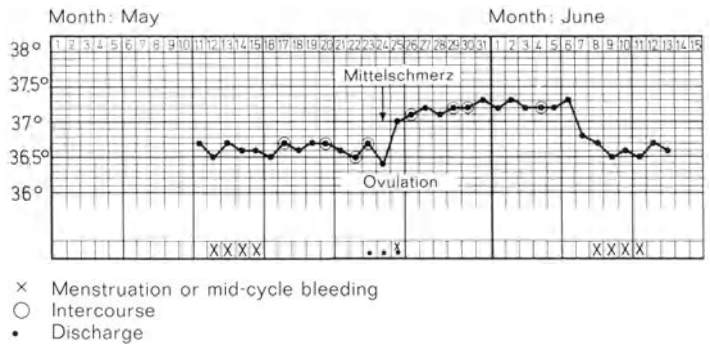

Fig. 69. A typical biphasic basal temperature curve

of menstruation. In 70–80% of women, the basal body temperature lies between 36.3 and 36.8° C postmenstrually, and premenstrually between 36.9 and 37.4° C (PLOTZ, 1950).

On the basis of information obtained from culdoscopic investigations (DOYLE, 1955) and laparotomies (RILEY *et al.*, 1955) permitting direct observation of ovulation, and from successful artifical insemination (WILLIAMS, 1964) it must be concluded that ovulation usually occurs 1–2 days before or after the temperature rise, but that it is also possible that ovulation may also take place earlier or even more than 2 days after the temperature rise (ABARBANEL, 1958; TOMPKINS, 1944, 1945). It is thought that follicular rupture often occurs at the same time as a fall in temperature, shortly before the temperature rises.

It is often difficult to fix the time of the temperature rise. In such cases, VOLLMANN (1940) suggests calculating the average temperature in the cycle and drawing a line through this temperature. The point at which this line intersects the rising arm of the curve is taken as the time of the temperature rise.

The temperature normally remains increased for 12–13 days (hyperthermal phase) and falls again shortly before menstruation to postmenstrual values.

The luteal phase is inadequate if the hyperthermal phase lasts less than 10 days. This leads to sterility. ISRAEL (1967) found a shortened luteal phase in 3.5% of a group of 942 women all of whom had sterile marriages. Probability of pregnancy is almost 97% when the hyperthermal phase lasts for 16 days or longer (BARTON, 1945). The basal temperature curve is monophasic when ovulation fails to occur. The frequency of anovulation is dependent on age and is highest during the first years after menarche (COLLETT, 1954; HARTMAN, 1962; DÖRING, 1963), during the climacteric period, and after gestation. It very rarely occurs in women between the ages of 30 and 35 (DÖRING, 1963). The basal temperature curve must be plotted for at least 3–4 months to determine when and if ovulation has occurred and if luteal insufficiency is possible. The patient uses the same table to record menstruation, intercourse, mittelschmerz, mid-cycle bleeding, increased intermenstrual discharge, dysmenorrhea and tension in the breasts. Possible causes of a rise in temperature, such as headache, indisposition, colds, etc. should also be recorded (Fig. 69).

a) Endometrium Biopsy

This is used to determine the secretory transformation and proliferation of the endometrium. The procedure can be performed in outpatient departments and without an anesthetic. Secretory transformation normally reaches a maximum on the 9th day after ovulation [i.e. 5 days before menstruation (HELD, 1945)], so that the biopsy should be taken around this time whenever possible. The danger of interrupting a pregnancy during this procedure is estimated to be very slight, but to avoid this risk, the 6th postovulatory day has been recommended for the biopsy (KISTNER, 1964). However, at this stage there are no typical luteal stromal changes (spiral arteries with periarterial, pseudodecidual stromal cells). The position of the uterus must be determined before the biopsy. Dilatation of the cervical canal is not necessary. The length of the cavity is also measured with the hysterometer before the biopsy. This measurement does not only reduce the danger of overlooking a perforation, but also gives an objective measurement of the size of the uterus. Uterine hypoplasia, which is much too often diagnosed especially in sterile patients, can be excluded when the cervical/cavity length is 7 cm or more. A flat narrow curette is used for the biopsy. NOVAK recommends the suction curette.

The biopsy is taken in the form of a smear from the posterior and anterior walls, the most suitable material being found in the fundal region. The mucosa obtained is fixed in absolute alcohol. In assessment of the endometrium, one must be aware that secretory transformation is no proof of ovulation having occurred, since a luteinized follicle can produce the same effect. The criteria for secretory transformation have already been discussed on p. 540.

Inadequate secretory transformation of the endometrium is found in 3–10% of sterile women (MARCUS, 1967). In a group of 102 sterile women, 6 (4.8%) showed no signs of a secretory transformation even five days before menstruation (HELD, 1948).

b) The Sims-Huhner Test (Post-Coital Test) (SIMS, 1869; HUHNER, 1913)

This is one of the most valuable means of investigating sterility. It is unfortunately not possible to compare the results of different authors, since the manner in which the test is interpreted varies greatly. A positive post-coital test makes collection of semen by masturbation unnecessary in the cases concerned, as this method of collection may distort the spermogramm due to psychological influences (DANEZIS, 1964). A positive test reveals that quantity and quality of sperms and cervical mucus are adequate, that the male partner is potent and the genital anatomical states of both partners allow for

deposition of sperms in the cervical region. In addition, it can have a therapeutic effect if performed at the right time. The optimal time is shortly before ovulation when the cervical secretion is at its optimum (SEGUY, 1933). The test can also be positive at other times, but no conclusions can be derived if it is negative at other points in the cycle (Fig. 70, ELERT, 1963). A definite prognosis cannot be made from a single negative result. The test must be repeated. Apart from the time at which the test should be performed, there is a series of other points to observe: intravaginal douching must not be performed for at least 48 hours before the test; 3 days' abstinence from intercourse is essential; the examination is performed a minimum of 6 hours and a maximum of 16 hours, ideally 8–12 hours, after intercourse. A good result before 6 hours have elapsed can give rise to false conclusions (DAVIDSON, 1961; STALLWORTHY, 1966). Sperms should not be fertile for more than 24 hours after intercourse. They retain their motility in cervical mucus for twice as long (HARTMAN, 1962). Nevertheless, weakly motile sperms have been observed in the cervical mucus even 134 hours after deposition (TYLER, 1961).

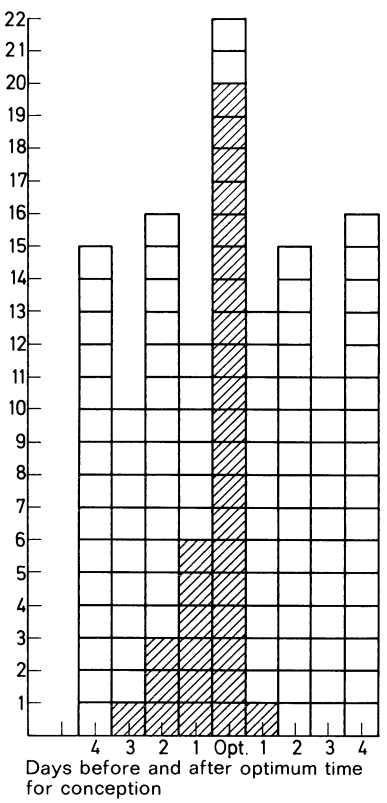

Fig. 70. Distribution of 106 Sims-Huhner tests around the optimum point for conception, determined with the aid of functional cervical diagnosis. Each square represents one Sims-Huhner test and each cross-hatched square represents a positive test. The restriction of positive tests to a few days is clearly apparent. (After ELERT, 1963)

The test is carried out by taking some mucus from the mucous collection in the region of the external os uteri and some from the lower cervical canal. This sample is put on a microscopic slide. The mucus is removed by means of aspiration with a suction pipette, or with the cervical mucus forceps after PALMER, or with a pincette (ROCK). The penetration test is considered positive if average magnification (400 ×) reveals at least 5 sperms moving progressively in one field. Not more than 4 leukocytes per field should be present if the cervical mucus is at its optimum, as it is at the time of ovulation (GRANT, 1958). A larger number of leukocytes at the time of ovulation indicates cervicitis. At any other time of the cycle, it is normal for leukocytes to be present in cervical mucus.

The appearance of the cervical mucus, however, provides no information about its biological value (glucose content, amino acids etc.), i.e. a clear cervical mucus can also be biologically inferior and lead to immobilization of the sperms.

A negative test must be repeated until the reason for it has been found. The result may be negative because the wrong time was chosen, because the cervical mucus was infected or biologically inferior, because there is a disturbance in potency or an anatomical defect impairing insemination, or because quality and/or quantity of the semen is inadequate. If pathogenic organisms are present, bacteriological examination of the cervical mucus and resistence tests are indicated. It is still open to discussion whether an antigen-antibody reaction due to AB0 incompatibility can occur between sperm and cervical mucus (BEHRMAN, 1960, 1967; WHITELAW, 1962). Antibodies which react cytotoxically to sperms of the husband have been demonstrated by immunofluoroscopy in the cervical mucus and blood of sterile women (PARISH, 1968). So-called lethal factors of unknown nature have been reported in the vagina and cervix (MASTERS, 1961).

The fern test (PAPANICOLAOU, 1946; RYDBERG, 1948; CAMPOS DA PAZ, 1953) should be performed on cervical mucus at the same time as the Sims-Huhner test (p. 627, Fig. 71).

At the time of ovulation, a large quantity of thin mucus of high elasticity and reduced viscosity is produced under the maximal action of estrogens. The viscosity is examined by the so-called spinnbarkeit, which is greatest at the time of ovulation (p. 627, Fig. 72).

Fig. 71. Dried cervical mucus taken from a sexually mature woman at the time of ovulation (fern-leaf phenomenon)

c) Pertubation, Hysterosalpingography and Laparoscopy/Culdoscopy

These different examination techniques are complementary rather than competitive. The Rubin test, which reveals whether the tubes are patents, is applied first (RUBIN, 1920, 1932, 1947; SEMM, 1969). It is one of the most important and practical methods in the investigation of sterility. When carried out properly it can reveal whether both tubes are patent or just one, whether a stenosis is present and whether tubal peristalsis is adequate (HELD, 1940). The test tells us nothing, however, about the minute physiology and anatomy of the tubes, e.g. transport of the ovum, the relative positions of fimbrial funnel and ovary, which are important to fertility, localization of a possible obstruction. The apparatus we prefer is the model of SEMM (1969). It permits the necessary simultaneous volumetric and manometric control. The pertubation apparatus developed by Fi-

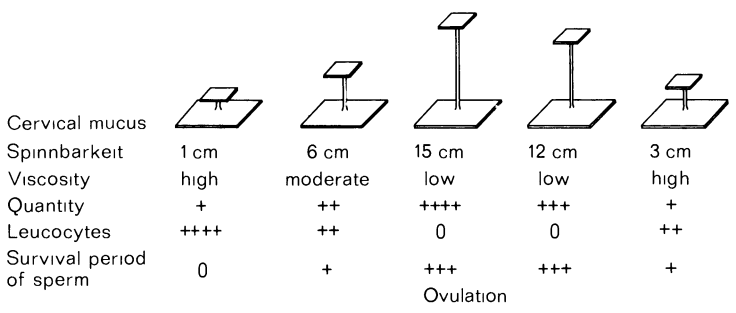

Fig. 72. Changes in the cervical mucus during the cycle. (After COHEN, 1952)

KENTSCHER and SEMM (SEMM, 1969) and by SHARMAN are suitable for scientific and clinical use. A vacuum adapter is used for obturation.

If full use is to be made of the diagnostic possibilities offered by these methods, and false results avoided, the following points must be observed. The best time is between the 4th and 7th days after menstruation. Every pertubation must be preceded by a gynecological examination to obtain information about the state of the portio, position of uterus and state of the ovaries (see contraindications). To exclude any spastic processes in the region of the uterus and tubes, a general anesthetic is given or the patient receives 1 ampoule Spasmalgin 30 min before the examination and 0.5 mg nitroglycerine on a lump of sugar just before the actual pertubation. The portio should be pulled down as little as possible to avoid altering the relative positions of uterus and tubes. If a pressure of 100 mg Hg or 150 mm Hg is reached with a flow velocity of 30 ml/min, the flow of CO_2 must be stopped for 1 min to avoid tubal spasm due to too rapid an increase in pressure. The pressure should not exceed 200 mm Hg. With a flow velocity of 30 ml/min, normal tubes are patent at a pressure between 40 and 90 mm Hg. Stenotic processes are present if persufflation first occurs at a pressure of 140–200 mm. Tubes of normal diameter allow CO_2 flow at a rate of 180 ml/min without causing pressure to rise over 120 mm Hg. This rate of flow thus allows the diameter of the tubes to be examined at the end of the investigation. Since 250 ml CO_2/min are expired through the lungs, 250 ml CO_2/min can be insufflated with no danger to the patient. Not more than 200 ml CO_2 are required for examination of tubal patency. If at least 90–120 ml CO_2 reaches the free abdominal cavity, the subdiaphragmatic collection of gas characteristically gives rise to shoulder pains, usually on the right side. Monitoring by X-ray screening is essential and allows the phenomenon to be objectified. The lower abdomen is auscultated as persufflation is performed. This will not only detect the localization of an obstruction, but the character of the sound of the flow will also make it possible to localize any stenosis. If there is no patency at a pressure of 200 mm Hg this indicates bilateral tubal occlusion. A bimanual gynecological examination should follow every pertubation so that any pneumosalpinx present can be diagnosed. The liver dullness should be percussed before and after the procedure, and X-ray screening performed within 1–2 hours.

Pertubation is contraindicated in the presence of pelvic inflammation and during genital bleeding (air embolism, spread of endometrium).

Though the reason is not understood, the Rubin test has a therapeutic effect in addition to its diagnostic significance. ISRAEL (1967) observed that 4% of his patients with an average sterility duration of 3.5 years became pregnant after pertubation. Other authors report a success rate of 20–30%, which is improbably high (RUBIN, 1920; SHARMAN, 1954; SCHILDBACH, 1950).

A single negative test does not prove a definite occlusion. Although RUBIN (1947) is not of the same opinion, three negative results can still be incorrect. JEFFCOATE (1953) reported 25 pregnancies after obtaining 3 negative pertubations in each case. This is also applicable to the hysterosalpingography (PEEL, 1964; STALLWORTHY, 1966). Examination of the patency at the junction of uterus and tube is very difficult, since the lumen at this point has a diameter of only 100 µm (ROCKER, 1964), and in 75% of cases the course of the interstitial part of the tube is angular (SWEENEY, 1962). In addition, further narrowing occurs under the influence of estrogens, particularly at the time of the examination (HARTMAN, 1962). When the results of pertubation are interpreted, it must be borne in mind that a negative result can be due to a functional closure as well as to an anatomic anomaly. Functional closure is, however, often a result of organic changes. A positive result does not necessarily indicate normal conditions, since peritubal adhesions or endometriosis may still be present.

A *hysterosalpingography* (SEMM, 1969) must be performed to localize the site of obstruction when the tubes are occluded. We do not think that should be carried out routinely in every case of sterility. Unfortunately, the ideal contrast medium has not yet been discovered. Water-soluble media are too rapidly absorbed, so that it its impossible to obtain an X-ray picture after 24 hours, which is essential for the detection of peritubal adhesions. On the other hand, granulomatous formations are more frequent with oil-soluble contrast media.

A *culdoscopy* or *laparoscopy* (DOYLE, 1951; FRANGENHEIM, 1959) is indicated when the patient fails to become pregnant within one year even when the tubes have been shown to be patent and no other sterility factors can be found. It is also indicated when pertubation and hysterosalpingography give obscure results or show that the tubes are not patent.

It allows detection of endometrial or inflammatory changes in the pelvic cavity which cannot be determined by pertubation and hysterosalpingography. This is especially true of peritubal adhesions, which impair tubal motility and the mechanism of collecting the

ovum. Thus, in a group of 82 sterile women with normal clinical and hysterosalpingographic findings, culdoscopy revealed pelvic and/or peritoneal changes in 35% and endometriotic changes in 29% (RIVA, 1959). Only 20–25% of sterile women patients have normal culdoscopic findings. Postinflammatory changes are found in 48% and 26–40% prove to be affected by endometriosis in the small pelvis (KISTNER, 1962). "Idiopathic sterility" should therefore only be diagnosed after culdoscopic/laparoscopic examination. If pertubation and hysterosalpingography show that the tubes are occluded the patency should be tested during laparoscopy by the injection of a colored solution (hydropertubation) of, for example, methylene blue or indigo carmine, into the uterus (so-called three-fold examination of tubal patency). Culdoscopy revealed patent tubes in 30% of patients in a group of women with tubes shown to be occluded by means of pertubation and hysterosalpingography (PERETZ, 1961). The diagnosis of occluded tubes should therefore only strictly be made when the tubes are shown to be obstructed by hydropertubation during culdoscopy or laparoscopy.

4. Treatment of Female Sterility

Improvement of the quality and quantity of cervical mucus is achieved by administering an estriol preparation such as Ovestin in a dose of two tablets of 1 mg daily from days 4–14 of the cycle. Estriol has the advantage that it acts practically exclusively on the cervical mucosa (PUCK, 1958). Due to the strong central inhibitory action on the hypothalamo-hypophyseal system, ethinyl-estradiol preparations (Lynoral, Progynon C) and diethyl stilbestrol should only be given in very small doses: e.g. 0.02 mg ethinyl estradiol, or 0.25 mg stilbestrol daily on days 6–12 of the cycle. Higher doses, such as 0.04 ethinyl estradiol taken daily from day 2 to day 8 of the cycle cause ovulation to be postponed by a week. This form of treatment is thus suitable for displacing ovulation where ovulation occurs during the menstruation phase in the presence of biphasic polymenorrhea.

Uterine Hypoplasia, which is an uncommon cause of sterility, can be influenced pharmacologically by producing a pseudocyesis. Treatment with estrogen-progesterone for 12 weeks can cause the sound length to increase by about 2 cm. For example, Anovlar is given from the 22nd day of the cycle; 1 tablet is taken daily, and the dose is increased by one tablet every 10–14 days until it reaches 3 tablets daily (for at least 3 month).

Surgical correction of *malformations* of the uterus by the Strassmann plastic operation is justified only in cases of habitual abortion.

Enucleation of a fibroid is only indicated in the absence of other sterility factors in the subject and the husband. The success obtained in carefully selected cases is claimed to be surprisingly good (BROWN, 1956; DAVIDS, 1959). STEVENSON (1964) observed full-term pregnancies in 50% of cases.

TANNER (1953) recommends conservative treatment of genital tuberculosis with the tuberculostatic medicaments of choice: streptomycin, PAS, ethambutol, rifampicin, isoniazid.

Hypoplasia of the Endometrium is most probably connected with tubal dysfunction. In such cases where no other sterility factors are present a three-month cyclic ovulostatic therapy is often successful, acting perhaps via a hypophyseal rebound mechanism (KISTNER, 1964).

Inadequate Secretory Transformation of the endometrium can be corrected by either substitution or stimulation treatment (Table 60). We prefer to use an acetoxy-progesterone derivative in oral substitution therapy, because of the slight androgenic action of nortestoids on the fetus. Stimulation with a total of 5000–15000 IU HCG will cause a corpus luteum of menstruation to be converted into one typical of pregnancy (BROWN, 1947; JAYLE, 1965).

Table 60. Treatment of inadequate secretory transformation of the endometrium

A. Substitution treatment
a) 200–250 mg progesterone + 10 mg estradiol 2–3 days after rise in temperature
e.g. Sistocyclin (200 mg progesterone crist. + 10 mg estradiol monobenzoate)
Primosiston (250 mg hydroxy-progesterone capronate + 10 mg estradiol benzoate)
Withdrawal bleeding 12 days later if pregnancy has not occurred
b) Planovin or another inhibitor of ovulation (4 mg megestrol acetate + 50 µg ethinyl estradiol), 1 tablet daily on days 18–25 of cycle
B. Stimulant treatment
Chorionic gonadotropin (HCG)
e.g. 4 doses of 1500 IU HCG, administered on days 4, 6, 8, and 10 of the hyperthermic phase, or
3 doses of 5000 IU HCG, administered on days 3, 5, and 7 after rise in temperature
Clomifene citrate
50 mg/day on days 5–25 of cycle

Until a few years ago, *anovulation* was a therapeutically unconquerable obstacle in practically all cases of sterility. This state of affairs

has changed fundamentally since human pituitary gonadotropins (p. 600) and clomifene citrate have become available (p. 599).

Treatment of Anovulatory Sterility with Gonadotropins is delicate and expensive also (p. 599ff.). Patients for this treatment must be carefully selected, the choice based on general examination and gynecological and endocrine investigations. Absence of other sterility factors is essential. Estimation of the hypophyseal gonadotropins (HPG) is essential. Only women with inadequate or normal amounts of gonadotropins can be considered. Treatment of hypergonadotropic anovulation with gonadotropins is pointless. On the other hand it is of no importance whether a primary estrogen deficit is present or not. Pretherapeutic estimation of urinary estrogens is therefore not necessary. The action of estrogens is monitored before and during treatment by means of Shorr smears, fern test, spinnbarkeit of cervical mucus and diameter of the external os uteri. An endometrium biopsy and a progesterone test are part of the investigation.

The response of the ovaries to gonadotropic stimulation varies widely from one patient to another. The dosage must therefore be adjusted to the individual. Special caution is required in patients with polycystic ovaries, since such ovaries are particularly sensitive to gonadotropic stimulation (p. 615). We do not use the gonadotropin sensitivity test (CROOKE, 1965). We begin with a low dose because of the danger of overstimulation, following the schedule given in Fig. 59.

The patient receives 75 IU HMG/day, e.g. 1 ampoule Pergonal. As soon as the daily Shorr smears, the cervical mucus, and the diameter of the os uteri show a good reaction to estrogens, the patient is given 5000 IU HCG daily for 3 days (e.g. Pregnyl i.m.). This level is usually reached after 7–10 days. Before the dose of HCG is increased, it is essential to perform a careful gynecological examination to make sure that the ovaries are not painful or enlarged. If this should occur, i.e. if overstimulation has occurred, only 1000 IU are given daily for 2–3 days. This reduces the danger of rupture of an induced ovarian cyst. Intercourse should take place a few hours before and 12 hours after administration of HCG.

The HMG doses are doubled in cases in which the doses mentioned have caused inadequate stimulation of the ovaries. Thus the patient receives 150 IU i.m. daily for 10–15 days. Exceptionally this dose is increased to 225 IU HMG (2–3 ampoules Pergonal). As soon as there is evidence that vagina and cervix are reacting well to estrogens and there is a definite rise in urinary estrogens, 5000 IU HCG are given daily for 3–5 days.

From the results available, it can be assumed that human follicular stimulating hormone acts according to the all-or-nothing law. However, there is only a very small difference between the effective dose and that which leads to overstimulation.

The success, measured by release of ovulation, is very good in correctly chosen patients. Ovulation can be produced in all cases. VAN DE WIELE (1965) observed that 60% of these sterile patients became pregnant. More than half of them, however, aborted, and of the viable children there were as many multiple pregnancies as single pregnancies. HMG/HCG treatment has resulted in pregnancy even in patients with Sheehan syndrome who had been amenorrheic for years.

The danger of overstimulation with the formation of cysts and rupture must not be underestimated even when patients are correctly chosen and doses are cautiously regulated. Multiple ovulations are frequently induced, which is a further disadvantage as they can lead to multiple pregnancies, which in turn result in increased abortion and prematurity rates, an increased incidence of toxemia, and more cases of pathologic presentation and abnormal births with corresponding danger to mother and child. It is therefore absolutely essential to make the couple aware of the increased risks before treatment is started. A sustained action is not achieved with this form of therapy. Another ovulation can only be produced by renewed stimulation.

Clomifene citrate given to release ovulation has a number of advantages over *menopausal gonadotropins*: it can be given orally, the number of multiple pregnancies is smaller, there is a lower risk of overstimulating the ovaries, and a better chance of ovulation occurring spontaneously after withdrawal of the treatment. However, there are fewer indications (GREENBLATT, 1961; KISTNER, 1965). On the basis of experience obtained with a few thousand women, the indications can be confined within certain limits.

Clomid (clomifene citrate, chloramiphene, MRL-41) is closely related chemically to the synthetic estrogens, stilbestrol and chlortrianisen (Tace). It is also chemically similar to MER-25, which is an effective antiestrogen but is toxic. Clomid is given orally in the form of a citrate salt. Its spectrum of activity varies in the individual species (SCHREINER, 1967).

In the ovariectomized rodent it has a weak estrogenic action, but inhibits the action of

estrogens when the two drugs are given together. In higher doses, it also markedly reduces the excretion of gonadotropins in the urine. Thus, clomid has both estrogenic and anti-estrogenic effects at the same time in the rodent, and has an inhibitory action on ovulation. It has an entirely estrogenic action in Rhesus monkeys.

In contrast to its effects in rodents, clomid's main effect is to promote ovulation in the human. In the woman, its action is primarily anti-estrogenic, so that it eliminates the effect of an ovulation inhibitor, for example. Gonadotropin excretion is increased and the corpus luteal phase is prolonged in eucyclic women when clomid is taken from days 5–25 of the cycle.

In contrast to MER-25, no toxic effects have yet been observed in women when therapeutic doses are used.

Clomid has proved to be a very effective drug in promoting ovulation in carefully chosen anovulatory patients. In these women, the endogenous production of estrogens is usually adequate and gonadotropin excretion is normal or at the most slightly reduced but not cyclic. Pituitary and ovaries must be intact anatomically, and adrenocortical and thyroid function normal. Due to the absence of a cyclic production of gonadotropins, these women show a cessation in follicular maturation, the endometrium is well developed, and they may show the picture of glandular cystic hyperplasia. The progesterone test is positive.

These patients present clinically with oligomenorrhea or amenorrhea, often associated with sterility due to oligo- or anovulation. This large group of forms of oligo-amenorrhea due predominantly to hypothalamic factors includes: secondary amenorrhea with psychological causes, especially of the normogonadotropic type, undefinable normogonadotropic secondary amenorrhea such as the so-called Stein-Leventhal syndrome, oligomenorrhea with the clinical picture of metropathia haemorrhagica often associated with mastodynia. Furthermore, this group also includes sterility due to hypothalamic oligo- or anovulation found in couples with otherwise normal fertility factors.

Treatment of hypogonadotropic amenorrhea with clomid is not very promising, but the attempt is justified in cases with an otherwise normal endocrinological state. This is applicable, for example, in the cases of secondary galactorrhea such as is found in the Chiari-Frommel syndrome. Panhypopituitarism, which may occur in an advanced Sheehan syndrome or with intrasellar tumors, does not respond to treatment with clomid.

Examination of the retina and sella turcica must therefore also be included in the pretherapy examination. Treatment with clomid is also unsuccessful in hypergonadotropic amenorrhea, for example in premature menopause or gonadal dysgenesia.

The dose is dependent on the patient and on the sensitivity of the ovaries to gonadotropins. An initial treatment with 50 mg clomid is advisable for 4 to 5 days starting between the 5th and 9th days after onset of spontaneous menstruation or bleeding induced by a gestagen (Fig. 73). Ovulation occurs between the 2nd and 41st days after onset of treatment in about 70% of women treated with clomid (JOHNSON, 1966) but usually after 8 to 12 days. Cyclic treatment can be repeated after an interval of at least 4 weeks, and before a new treatment is started, a pregnancy or corpus luteal cyst must be excluded. The highest success rate is obtained in women with the Stein-Leventhal syndrome (approximately 78–82%). A low dose of 50 mg daily is chosen, due to the sensitivity of the ovaries in these women. Pregnancy occurs in over 50% of the patients in whom sterility is due to hypothalamic oligo- or anovulation and in whom other fertility factors are normal. However, about 7.5% of the pregnancies arising as a result of clomid therapy are multiple pregnancies (JOHNSON, 1967). The abortion rate in these women is about 22%, i.e. much higher than in the average population, but similar to that secondarily sterile women

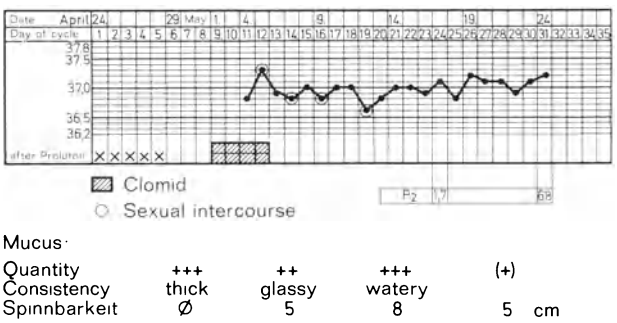

Fig. 73. Temperature curve of a patient treated with clomid (after WYSS, 1967). Next check-up on 27th June = day 65 of cycle, Gravindex positive, clinical examination revealed a 2-month pregnancy, subjective indications of pregnancy

(BUXTON, 1958). Among 672 pregnancies, including those ending in abortion, there were 1.8% newborns with malformations. This figure is not higher than that in a group of untreated fertile women. A low dose is important in the treatment of sterility. A higher dose of clomid can suppress ovulation in the human as it does in rodents, whereas even larger amounts of clomid can cause the cervical mucus to become thicker, viscous and scanty.

Treatment with 100 mg daily for 4–5 days can result in ovulation in individual cases in whom no success has been achieved with low doses.

The production of ovarian cysts, chiefly luteal cysts, is the greatest potential danger of treatment with clomid. Formation of ascites or rupture with intraperitoneal hemorrhage may then occur; such cases have been described. Although there is only a slight danger of this (about 5%) when treatment is of short duration, the risk increases when the duration is more than 10 days and treatment is repeated. The duration of therapy must therefore not exceed 5 days per cycle, and daily doses of over 100 mg must not be given for longer than 5 days. Palpation of the pelvis before, during and after the administration of clomid is therefore absolutely essential. Ovarian cysts that are induced usually disappear spontaneously 3 to 4 weeks after the withdrawal of clomid.

About 15% of the women suffer from hot flushes as a side effect of treatment with clomid. Other side effects which arise considerably less commonly (5%) are: nervousness, headache, giddiness, visual disturbances, loss of hair, nausea, sleeplessness, weight increase, abdominal complaints and pollakisuria.

It is definitely essential to select patients critically by means of pretherapeutic investigations and to monitor the patients during treatment. Apart from the low success rate when patients are not chosen carefully, noncritical use of clomid can also result in serious complications.

The mechanism of action of clomid is still open to discussion. It is certain that in suitable conditions, clomid causes a significant increase in LH activity, whereas FSH excretion is only slightly changed (KELLER, 1966; Fig. 74). Stimulation of LH appears to be the predominant mode of action of clomid. The fall in the FSH/LH quotient (Fig. 75) leads to ovulation. An increased estrogen excretion has been described before the peak of LH excretion, so that conditions analogous to spontaneous ovulation seem to be present. Individual results indicate that clomid acts as a competitive inhibitor to estrogens by occupying specific cell receptors for estrogens. This effect would explain the observation that clomid therapy fails to produce estrogenic effects on the uterus, vagina and breasts, despite normal estrogen levels (antiestrogenic effect). Different receptor organs have been considered for clomid (ROY, 1963, 1964). Certain experiments *in vitro* show a direct influence of clomifene on ovarian enzymes taking part in the biosynthesis of estrogens; it accelerates aromatization of androstenedione and testosterone and the formation of estrone and estradiol by inhibiting cytochrome reduction with an accumulation of NADPH (HAGERMAN, 1966). There does, however, appear to be a direct hypothalamic action. This was demonstrated in investigations in a 30-year-old woman with primary ovarian amenorrhea, showing that the LH-stimulating action of clomid is connected with a definite estrogen level but not with the ovary itself (Fig. 75) (KELLER, 1966).

A trial with thyroid drugs is justified in sterile patients with clinical hypothyroidism or with laboratory findings at the lower normal limits.

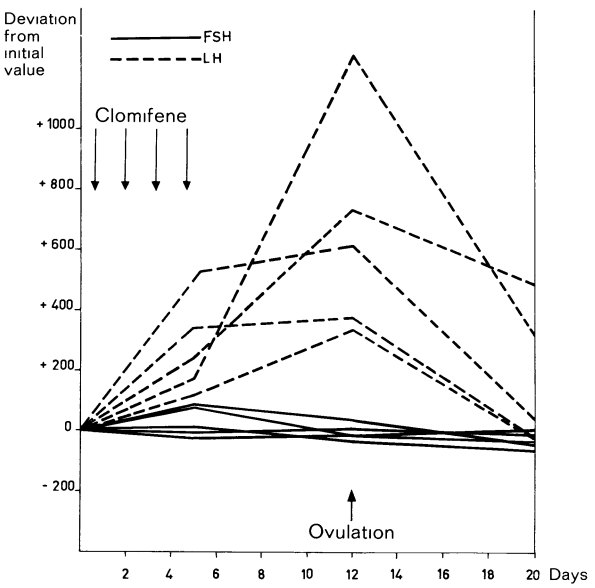

Fig. 74. Percentage increase and decrease in the excretion of FSH and LH with the urine in secondary amenorrhea following clomifene medication (KELLER, 1966)

Treatment with prednisone in a dose of 10–15 mg daily may result in ovulation in borderline adrenal hyperplasia (p. 612). This hyperplasia can present clinically as anovulation, less commonly as a reduced luteal phase, as secondary amenorrhea, hirsutism, acne vulgaris and even as mild hypertrophy of the clitoris.

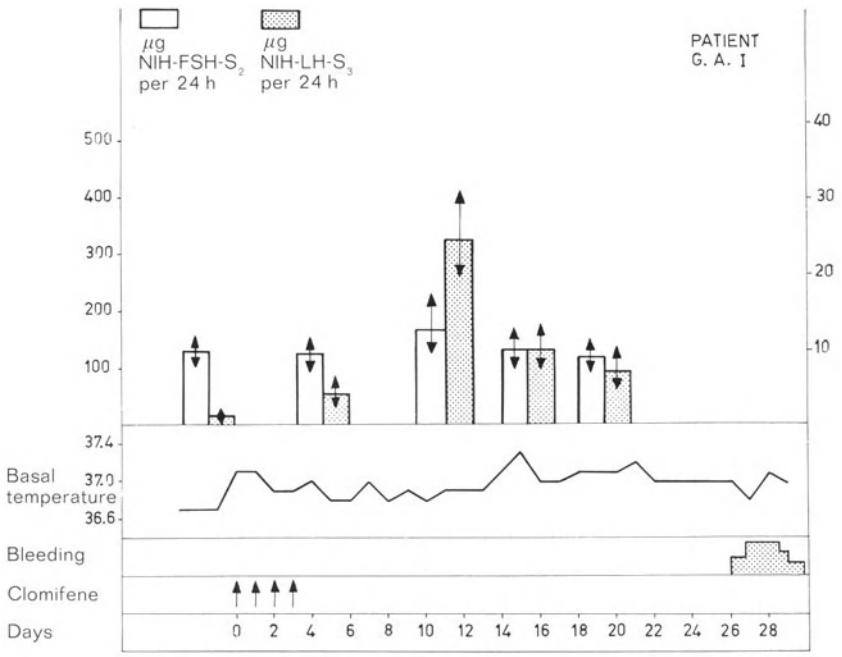

Fig. 75. Excretion of FSH and LH in secondary amenorrhea and anovulation before and after clomifene medication (KELLER, 1966)

Prompt treatment of salpingitis with antibiotics is of decisive importance for future reproductivity. We were not convinced by the material obtained from the Gynecological Clinic in Zurich of the advantages of additional cortisone treatment, which is theoretically justifiable (FUMASOLI, 1969). Residual states, frequency of recurrences, and fertility were no less than were obtained with antibiotic treatment and subsequent resolutive physiotherapy.

The prognosis of fertility after salpingitis is dependent on the state of the tubes at the onset of treatment. This is especially applicable to tuberculous salpingitis (p. 622). Palpable ovarian tumors exclude a later pregnancy. Treatment of genital tuberculosis is carried out with tuberculostatics of first choice.

If all surgical experience is considered, the results of *plastic operations on the tubes* seem to be consistent. These operations are: salpingolysis, fimbriolysis, salpingostomy, end-to-end anastomosis and tubal implantation. Pregnancy later arose in 11 to 17% of patients subjected to these operations (PALMER, 1952; GREENHILL, 1956; SIEGLER, 1956; KISTNER, 1964; BICKENBACH, 1967). Better results reported by individual authors are probably based on a special selection of patients, different tubal pathology and different surgical techniques (MARCUS, 1967; MROUEH, 1967). Tubal occlusion after generalized salpingitis has a considerably worse prognosis than after surgical sterilization.

A pelvic *endometriosis* must always be suspected when the cause of sterility cannot be found. The tubes are usually patent. If the laparoscopy is positive and no other incurable sterility factors can be detected, the diagnosis must be made histologically before treatment is started.

Two kinds of treatment are available, medical and surgical.

Medical Treatment of Endometriosis

The therapeutic procedure introduced by Kistner in 1956 is based theoretically on the observation that pregnancy can retard the development of endometriosis, probably through causing necrosis of the endometrium converted into decidua. The curative effect of pregnancy on endometriosis has, however, become controversial in the light of recent investigations (MCARTHUR, 1965). Treatment consists of induction of a pseudocyesis lasting at least 6–9 months (possibly 12–24 months) by giving progestagens continuously in increasing doses (Table 61).

The side effects are due mainly to the estrogenic components. They are similar to the effects observed in cyclic ovulostatic treatment, but are more frequent and severe. Nausea can be alleviated by taking the tablets with milk, or by using an antacid or antiemetic. Water retention is treated by a saltfree diet, possibly combined with a diuretic. Treatment with

progestagens alone must be substituted if side effects are severe, such as very painful breasts, bad headaches, growth of uterine fibroids, severe unrest, irritability and insomnia. Treatment with progestagens often leads to breakthrough hemorrhage and results in aggravation of skin changes in women with a tendency to acne and with a seborrheic skin. There is an increased risk of thromboembolism.

Table 61. Medicamentous treatment of endometriosis

Oral inhibitors of ovulation or progestagen e.g. Primolut-N Beginning on day 22 of cycle 1 tablet daily for 2 weeks 2 tablets daily for 2 weeks 3 tablets daily for 2 weeks 4–5 tablets as long-term therapy
Primosiston 1.0 ml (250 mg hydroxy-progesterone capronate and 10 mg estradiol benzoate) i.m. once weekly. Increase dose by 0.5 ml every six weeks or if breakthrough bleeding occurs
Depo-Provera 2.0 ml (100 mg medroxy-progesterone acetate) 4 ml i.m. every two weeks; then 4.0 ml every 4 weeks. Oral estrogens should be added if breakthrough bleeding occurs

It is essential to start hormonal treatment without delay in a case where endometriosis has been diagnosed and pregnancy has not occurred within a short time. About 85% of women treated by this regime show a temporary improvement – symptoms disappear and tumors regress (GRANT, 1964). The average duration of remission, however, is only 8–9 months (RIVA, 1962), although remissions lasting for 52 months have been observed (KISTNER, 1964). Some 15–20% show a relapse even 6 months after discontinuation of treatment (RIVA, 1961, 1962; GRANT, 1963, 1964). Information on the frequency of conception after discontinuation of treatment varies between 10–47% (RIVA, 1962; KISTNER, 1966). Conception most often occurs with the second or third spontaneous ovulation.

Results obtained with conservative surgical treatment are somewhat better. On average 52% of 844 women in a pooled group became pregnant postoperatively. This value varied between 39–70% (MARCUS, 1967).

In our opinion, the conservative surgical approach is preferable to medical treatment when these results are compared and the long duration, high costs, frequent side effects and rapid and frequent remissions associated with medical treatment are considered. Conservative surgical treatment means careful excision of all endometrial foci if this is anatomically possible. Foci which cannot be excised because of their anatomical position, e.g. on the rectum or bladder, must be sloughed off electrically. Peritubal and periovarian adhesions must be detached, a fixed uterus must be anteflexed, and finally the presacral nerve must be resected. Postoperatively, the patient receives uninterrupted ovulostatic treatment for 3–4 months, according to the schedule for conservative medical treatment, to prevent growth of any endometrial foci which may have been left behind (MCCOY, 1963; GREEN, 1966).

I. Endocrine-Active Ovarian Tumors

Blastomatous proliferation of different ovarian tissues can lead to the formation of endocrine-active tumors, which can produce steroids, chorionic gonadotropin or thyroxine in quantities giving rise to characteristic clinical pictures (Table 62). Various changes arise according to the predominant hormone secreted: early isosexual differentiation or disturbances, heterosexual changes in the form of defeminization and virilism, Cushing's syndrome, gestotic changes, or hyperthyroidism. Removal of the tumor causes partial or complete regression of these changes.

It is often very difficult to classify these cases histologically or histogenetically if the tumor tissue is very poorly differentiated. In some conditions classification is possible with some degree of probability only when the clinical picture is also taken into consideration. Apart from this, the histological picture of the same tumor may vary widely in different sections.

On the other hand, the endocrine activity of a tumor is no absolute criterion for classification, since different types of tumor cells can demonstrate a similar hormone secretion, i.e. morphological changes need not be associated with changes in the enzyme pattern.

For practical reasons, endocrine-active ovarian tumors are classified by clinical effect in the following discussion (Table 63).

1. Predominantly Estrogen-Producing Tumors ("Feminizing" Tumors)

The estrogen-producing *granulosa-theca cell tumors* are the most common hormone-active ovarian tumors. This term was derived by VON WERDT (1914). They were first recognized as true tumors by LOEFFLER and PRIESEL, however, in 1932, and they described them as

Table 62. Endocrine syndrome and ovarian pathology. (Modified from MORRIS and SCULLY, 1958)

Hormonal status	Syndrome	Pathologic clinical findings	Ovarian pathology
Estrogen excess (or only estrogen)	Feminization estrinism	Anovulation, oligo-amenorrhea, meno-metrorrhagia	
	1. Pseudopubertas praecox	1. Menarche and development of secondary sexual characteristics before 8th year of life, anovulatory cycles accelerated skeletal growth	Follicular cysts (follicular persistence)
	2. Dysfunctional bleeding	2. Breakthrough bleeding in anovulatory cycles; hyperplasia or glandular/cystic hyperplasia of the endometrium; hypertrophy of the myometrium	Polycystic ovaries Granulosa tumors [in exceptional cases lipoid-cell tumors (folliculome lipidique Lecène)]
	3. Postmenopausal bleeding	3. Hyperplasia or glandular/cystic hyperplasia of the endometrium, cornification of vaginal epithelium	Brenner tumors (in exceptional cases cystadenomas, ovarian carcinoma
Androgen excess	a) Defeminization	a) Anovulation, oligo-amenorrhea, meno-metrorrhagia; atrophy of breasts and regression of secondary sexual characteristics, atrophy of endometrium, myometrium and vaginal epithelium, acne vulgaris	Polycystic ovaries with hyperthecosis Arrhenoblastomas Gynandroblastomas Hilus-cell tumors Masculinovoblastomas (virilizing lipoid-cell tumors)
	b) Virilization	b) Amenorrhea, hirsutism, hypertrophy of clitoris, receding hairline, prominentia laryngea and deepening of voice, masculine habitus	Gonadoblastomas (in exceptional cases pseudomucincystomas, Brenner tumors, primary and secondary ovarian carcinomas
Corticosteroid excess	Cushing's syndrome with or without virilization	Obesity of trunk, striae, polycythemiae, diabetic metabolism, osteoporosis	Lipoid-cell tumors
Thyroxine excess	Hyperthyreosis	Anovulation, oligo-amenorrhea, nervousness, tachycardia, exophthalmos, hyperhidrosis, muscular weakness, increased basal metabolism	Struma ovarii (teratomas)

Table 63. Endocrine-active ovarian tumors

1. Tumors producing mainly estrogens (feminizing tumors)
   Granulosa tumors (feminizing mesenchyma after NOVAK), theca-cell tumors = fibroma thecacellulare xanthomatoides ovarii Löffler-Priesel
   Folliculoma lipidique (Lecène = luteinized granulosa tumor)
2. Tumors producing mainly androgens (virilizing tumors)
   a) Androblastomas
      Arrhenoblastomas (Sertoli-Leydig cell tumors)
      Hilus-cell tumors (Leydig-cell tumors)
      Virilizing lipoid-cell tumors (masculinovoblastomas, adrenal-remnant tumors, hypernephroid tumors)
      Gonadoblastomas
   b) Mixed tumors
      Gynandroblastomas
3. Tumors producing corticosteroids
4. Tumors producing chorionic gonadotropins
   Chorioepitheliomas
5. Tumors producing thyroxine
   Struma ovarii (teratomas)

fibroma thecacellulare xanthomatoides ovarii. They are also known as *feminizing mesenchymomas* (NOVAK, 1952) on the basis of their clinical effect and presumptive origin of ovarian mesenchyme. Luteinizing granulosa-theca cell tumors are termed *luteomas*. The frequency of granulosa-theca cell tumors varies between 3 and 7.5% of all ovarian tumors according to the statistics considered (MORRIS and SCULLY, 1958; HERTIG and GORE, 1961; SANTESSON, 1947). Information about the percentages of granulosa cell tumors, theca cell tumors (thecomas) and mixed tumors must be evaluated with reservation (HERTIG and GORE, 1961) since there are no serial section examinations for the majority of these tumors. Granulosa-theca cell tumors are probably the most common (MORRIS and SCULLY, 1958). They are seldom observed before puberty (5%), and are encountered with roughly the same frequency during sexual maturity (55%) and in the postmenopause

(40%) (MORRIS and SCULLY, 1958). They vary in size between a few millimeters and the size of a man's head and are unilateral in 95% of cases (Fig. 76a).

The cut surface of granulosa-cell tumors (Fig. 76b) is homogeneous and soft. There may be necrotic hemorrhagic or cystic areas. Call-Exner bodies are typical histological findings.

Theca-cell tumors (Fig. 77) are solid and firm. The cut surface is yellowish. Characteristic microscopic findings are hyaline, fibrous patches arranged between twirled spindle cells rich in cytoplasm.

In addition, there are undifferentiated sarcoma-like forms which can only be classified on the basis of differentiated sections. It has been shown that granulosa-theca cell tumors have a high ability to convert various precursors of estrogen synthesis into estrogens (MARSH, 1962). Results of the chemical measurements of estrogens in tumor tissue performed by various authors vary vastly. KECSÉS (1963), using paper chromatography, found unusually high values, presented in Table 64. Other authors found considerably lower estrogen concentrations (SAAMELI and JKLÉ, 1959; BRUK, 1960).

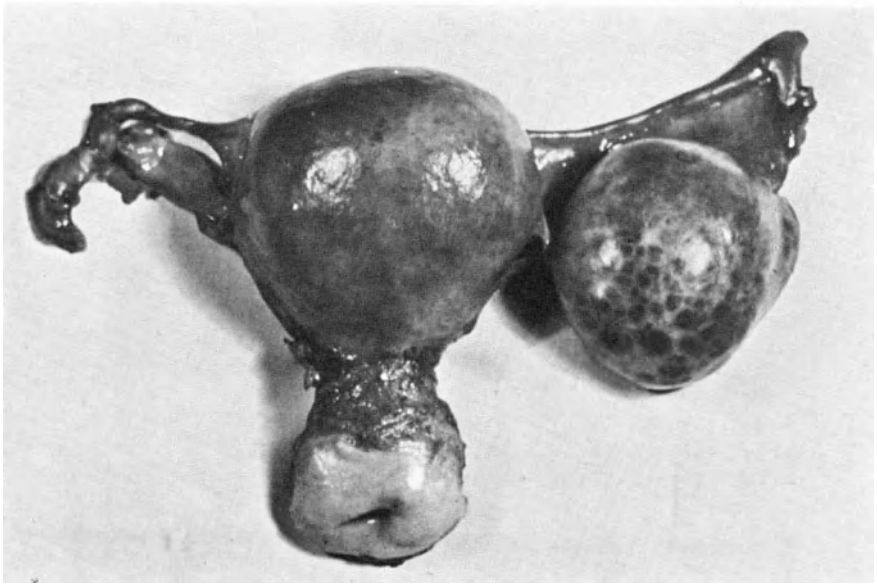

Fig. 76a

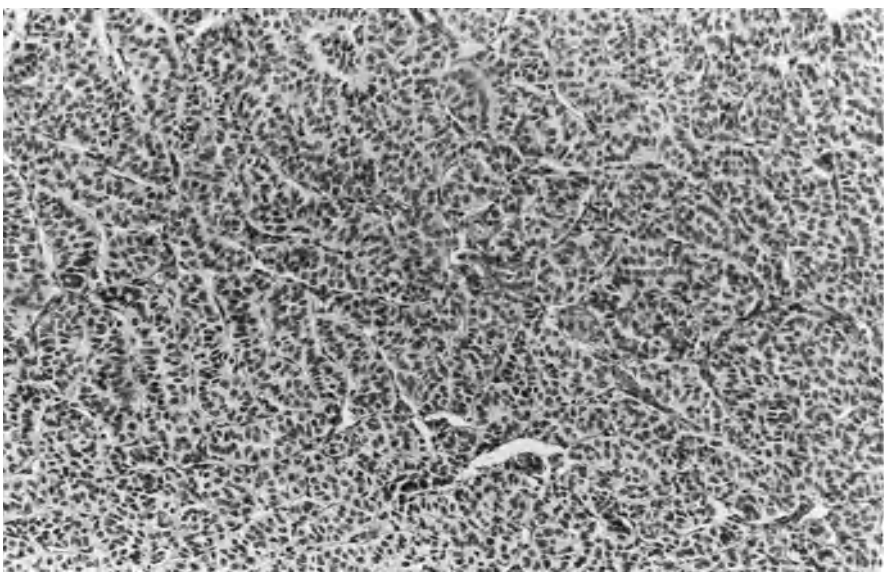

Fig. 76b

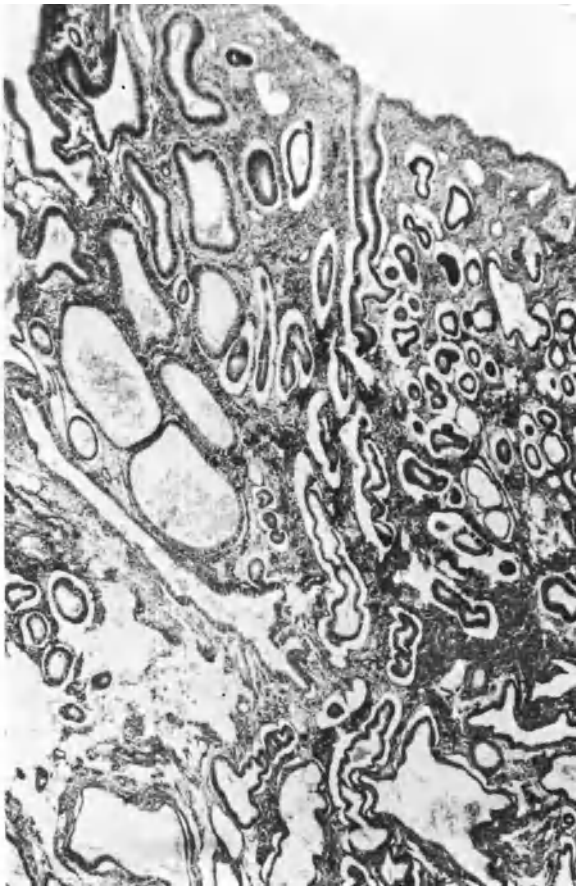

Fig. 76a–c. Left sided granulosa-cell tumor (a) with pseudotubular structure (b). Recurrent uterine bleeding 18 years after the menopause. Endometrium: glandular-cystic hyperplasia (c)

The figures quoted for frequency of local recurrences and metastases vary between 10–33%. Recurrences characteristically arise late (VARANGOT, 1937; DIDDLE, 1952), 15–25 years after removal of the primary tumor (MORRIS and SCULLY, 1958). This is also supported by KOTTMEIER's statistics (1952), which show that 17% of recurrences arise within the first 5 years, and 41% after 5 years. The follicular form is thought to have a considerably better prognosis than sarcomatoid types (KOTTMEIER, 1952), with 22% recurrences as against 71%. These tumors are extremely radiosensitive. There are different ways of looking at the question of whether there is any connection between the granulosa-theca cell tumor and carcinoma of the body of the uterus. Different investigators (INGRAM and NOVAK, 1951; DOCKERTY and MUSSEY, 1951; MANSELL and HERTIG, 1955) have found carcinoma of the endometrium in 14–15% of women with granulosa-theca cell tumors, and in as many as 24 or 27% of cases where the women were over 50. On the other hand, SJÖSTEDT and WAHLEN (1961) did not deduce an increased incidence of carcinoma in 157 cases. This observation was confirmed by EMGE (1953), LARSON (1954) and GREEN (1958–1959). Half of all thecomas are thought to be associated with fibroids (HODGSON, 1945). Meig's syndrome in particular has been described in association with theca-cell tumors.

Estrogen production in the granulosa-theca cell tumor leads to a continuous estrogenic effect on the end organs. This is termed as

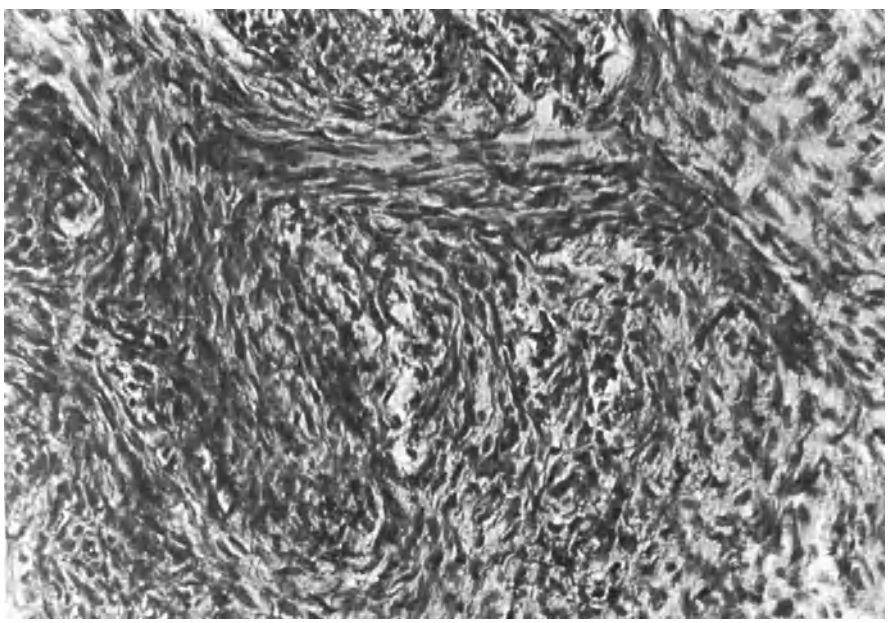

Fig. 77. Theca-cell tumor (LÖFFLER-PRIESEL) of the right ovary in a 68-year-old patient with recurrent uterine bleeding after the menopause

Table 64. Concentrations of estrogens (μg/24 h) in granulosa tumors (KECSÉS, 1963)

	Estrone	Estradiol	Estriol	Total	μg/mg tissue	Urine
Granulosa theca-cell tumor	165.0	0.0	183.0	348.0	24.8	183
Thecoma	0.0	9.2	2.6	11.8	7.3	52
Thecoma	2.0	2.6	0.0	4.6	4.6	50
Granulosa tumor	–	–	–	–	–	64
Anaplastic carcinoma	–	3.0	18.0	21.0	0.3	28
Anaplastic carcinoma	–	10.6	20.0	30.6	0.1	33

estrinism. It is questionable whether partial "hyperestrinism" exists. Hormonal vaginal cytology shows a mere mild to average estrogen effect in the presence of glandular cystic hyperplasia (Fig. 76c) of the endometrium (KÖNIG, 1953).

So-called estrinism results in *precocious pseudopuberty* in the child. This state is characterized by the early development of the genitalia and breasts, the appearance of pubic and axillary hair, anovulatory bleeding before the 9th year, and accelerated increase in height.

During sexual maturity, continuous estrogenic stimulation of the endometrium in the absence of the cyclic influence of progesterone leads to glandular cystic hyperplasia with breakthrough bleeding. This presents clinically as oligomenorrhea or amenorrhea with meno- and metrorrhagia. At the same time, there is swelling of the breasts and hypertrophy of the endometrium.

Analogous changes with bleeding occur during the postmenopause. Climacteric features disappear.

Granulosa-theca cell tumors without the clinical effects described are so rare that the accuracy of the histological diagnosis must be doubted in the absence of the clinical picture (VARANGOT, 1937). Granulosa-theca cell tumors can exceptionally exert an androgenic affect (MORRIS and SCULLY, 1958).

If women with these tumors are young and want children, and the tumor is well-defined and unilateral, treatment is limited to the removal of the diseased ovary. In all other cases, bilateral ovariectomy with hysterectomy is indicated. Infiltration of the surrounding tissues is treated with postoperative radiation. Recurrences also respond very well to radiation.

Some ovarian tumors (cystadenomas, Brenner tumor, ovarian carcinomas) can lead to clinical signs of estrinism. It is assumed that increased amounts of estrogens are produced in the stroma of these tumors (Table 64). Dysfunctional bleeding has been reported in 25% of patients with Brenner tumor, and glandular cystic hypertrophy has been observed in 10% (MORRIS and SCULLY, 1958).

2. Predominantly Androgen-Producing Tumors

Androgenic hormones can be formed in the arrhenoblastoma, gynandroblastoma, hilus-cell tumor, masculinovoblastoma and gonadoblastoma. These are extremely rare tumors, the arrhenoblastoma being the most common of them.

As early as 1900, DAVIS reported the clinical picture of the androgen-active *arrhenoblastoma*. This case involved a 26-year-old woman with defeminization and masculinization, from whom a multilocular cystic ovarian tumor was surgically removed in 1895. In 1905 PICK, and two years later SCHICKELE described the pathoanatomical picture of the so-called *tubular testicular ovarian adenoma*. Endocrine-inactive tumors were present in both cases. R. MEYER (1930) then gave this tumor the name of *arrhenoblastoma*, since he thought the tumor was derived from arrhenocytes, "male-directed" residues of germinal tissue in the medulla and hilus. In Anglo-Saxon literature, the purely descriptive term "Sertoli-Leydig cell tumor" is often preferred since the tumor cells are often similar to immature Sertoli-Leydig cells.

In spite of the aggregation of single observations, the arrhenoblastoma is an uncommon tumor. Thus, up to 1959, HELD and SCHREINER (1959) could only find 187 cases in the literature available to them, and OVERZIER was able to add only 8 more cases up to 1961. JAVERT and FINN (1951) discovered only 3 arrhenoblastomas among 22539 gynecological patients, and not a single one among 74087 obstetric cases. DOCKERTY and MCCARTY (1939), in a resumé of material from the Mayo Clinic between 1900–1936, observed only 4 arrhenoblastomas among 400 solid ovarian tumors. KENT and MCKAY (1960) found only 2 such tumors in y series of 2530 ovarian tumors. We too only found one single case among the histological material from 98663 investigations between 1914–1959 at the Gynecology Clinic of Zurich University.

Only 5% of arrhenoblastomas are bilateral (JAVERT and FINN, 1951). The arrhenoblastoma occurs almost twice as frequently on the right

side (HELD and SCHREINER, 1959). It is most common between the 15th and 30th years. The youngest patient was a girl of $2\frac{1}{2}$ (NOVAK and LONG, 1965).

Observations were originally so rare that the malignancy was not known for a long time and was underestimated. JAVERT and FINN (1951) documented a large sample of patients subjected to prolonged follow-up and found a malignancy index of 22%. This figure was suspected by E. NOVAK even in 1938 and he estimated it even higher on the basis of his wide experience with these tumors (1951). The malignancy index corresponds to that for the granulosa-cell tumor, and many of the recurrences also arise late.

In 80% of the tumors the diameter is between 7–10 cm when they are detected. A few are larger than a man's head. The macroscopic appearance is not characteristic. Arrhenoblastomas can be solid or partly cystic. Yellowish orange areas are frequently encountered. The microscopic picture also varies widely, three main types being distinguishable (R. MEYER, 1930): a highly differentiated tubular form, an intermediary form and an undifferentiated sarcoma-like form. The large eosinophilic interstitial cells containing lipoids are the most interesting functional structure. They probably correspond morphologically and functionally to the Leydig interstitial cells of the testis, and they must be assumed to be the site of formation of the androgenic hormones (Fig. 78a). According to TEILUM (1952), neoplastic proliferation alone of these interstitial cells leads to the formation of the hypernephroid ovarian tumor he considers as an extreme variety of the so-called androblastoma, and he also classifies the arrhenoblastoma in this group.

The clinical picture is characterized by defeminization with subsequent virilism. Oligo- or amenorrhea arises. Meno-metrorrhagia occasionally occurs temporarily. Breasts, endometrium, myometrium and vaginal epithelium

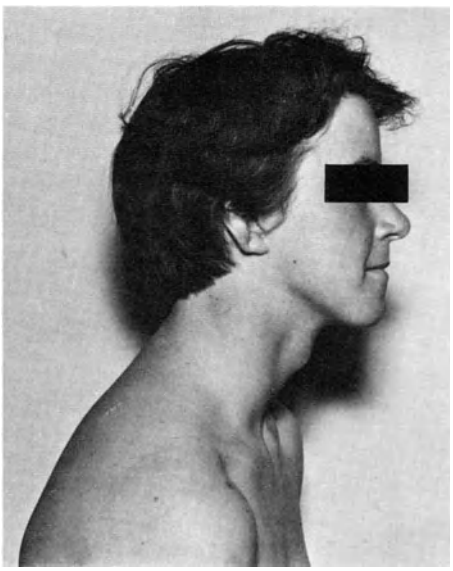

Fig. 78b

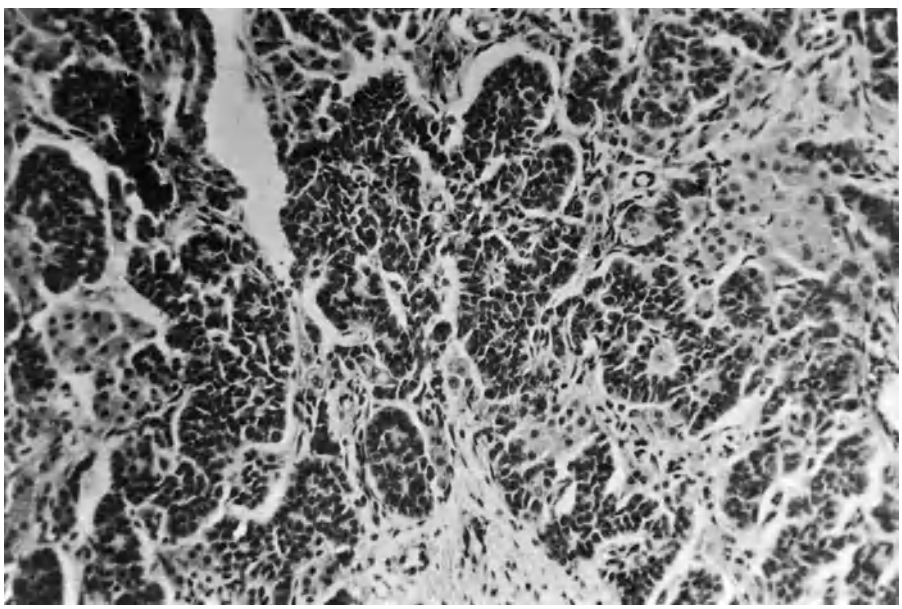

a

Fig. 78a and b. Mixed-type arrhenoblastoma (a) of the right ovary in a 16-year-old girl with virilization. Prominentia laryngea (b)

become atrophic (Fig. 78a). Secondary sexual characteristics regress. Hirsutism and acne arise, the clitoris becomes hypertrophic and frontal baldness appears. The voice becomes deeper and an Adam's apple (Fig. 78b) may be formed. The body stature assumes the masculine form.

Removal of the tumor causes refeminization, but hypertrophy of the clitoris and the deep voice may persist. Recurrences produce defeminization and virilism again (WAGNER, 1930; MEIXNER, 1958).

Chemical investigations of the tumor tissue have allowed the deduction that considerable amounts of androgens are produced by endocrine-active arrhenoblastomas (Table 65a–c). Judging from the clinical picture, these amounts probably correspond to those produced in the male. The heterosexual action of the arrhenoblastoma is often in marked contrast to the excretion of the 17-ketosteroids, which is at the upper normal limit or only slightly elevated in the majority of cases (Table 66). There are, however, numerous reports (HELD and SCHREINER, 1959) of cases where urinary 17-ketosteroids are definitely increased, but these values have never been as high as those found in the presence of tumors of hyperplasia of the adrenal cortex.

Table 65a. Steroids[a] in an arrhenoblastoma in a 24-year-old woman with defeminization and virilization; excretion of 17-ketosteroids within normal range (OBER, 1959)

Metastases of an adrenocortical tumor	45–55

Table 65d. Steroids[a] in an intermediate arrhenoblastoma weighing approximately 80 g on the right ovary of a 16-year-old girl; it had led to defeminization and virilization. Excretion of 17-ketosteroids 32.6 mg/day (HELD, 1959)

	µg/kg tissue
Testosterone	37–75
Δ_4-Androstendione	262–300
Androsterone	375
Progesterone	150
Corticosteroids	0
Estrogens	0

[a] After ANLIKER (1956).

The defeminization and virilism occurring with the arrhenoblastoma must therefore be considered as being mainly a long-term action of relatively slightly increased testosterone production over a long period of time. This assumption is confirmed by the observation that pituitary gonadotropins are reduced but not fully suppressed. With the exception of LOBOTSKY's case (1954), the pregnanediol-pregnanetriol complex is negative, despite the considerable amounts of progesterone which can be demonstrated chemically in the tumor (Table 65).

Not all arrhenoblastomas are endocrine-active. Thirteen of 111 cases in "The American Ovarian Tumor Registry" showed no androgenic action (NOVAK and LONG, 1965). Only about half the differentiated tumors lead to the symptomatology described. About 75% of intermediary tumors are endocrine-active, whereas nearly all undifferentiated types are androgen-active (KRAUS, 1967).

Gynandroblastomas (R. MEYER, 1930) are very uncommon and are mixed tumors consisting of granulosa-cell tumors and arrhenoblastomas. Accordingly, they have an androgenic and an estrogenic effect, but the heterosexual differentiation caused by the androgens dominates the clinical picture (EMIG, 1959). Only 14 certain cases have so far been described (HUGHESDON and FRAZER, 1953; KISTNER, 1964). The diameter of the tumor was found to vary between 1–20 cm. *Hilus(Leydig)-cell tumors* (sympathicotropic-cell tumors) are just as rare (NOVAK and MATTINGLEY, 1960). Characteristic histological findings are Reinke's crystalloids and the arrangement of tumor cells in the region of amyelinic nerve fibers. These tumors are solid, yellowish, with well-demarcated growths in the hilus of the ovary. They seldom have a diameter of more than 5 cm and they are benign. In contrast to arrhenoblastomas they arise mainly during the climacteric or postmenopause. As with arrhenoblastomas, the 17-ketosteroid excretion is at the normal upper limit or slightly elevated (SCULLY, 1963).

Table 66. Excretion of 17-ketosteroids and pregnandiol in the presence of arrhenoblastoma (HELD, 1959)

So-called *virilizing lipoid-cell tumors* (BARZILAI, 1943) are somewhat more common (masculinovoblastoma, adrenal remnant tumor, hypernephroid tumor, diffuse androblastoma). As can be deduced from the large number of names, this is a heterogeneous group; hilus-cell tumors, thecomas or adrenal remnant tumors may be present. Like granulosa cell tumors and arrhenoblastomas, 95% are unilateral. They can also cause defeminization and virilism. Adrenal remnant tumors can also give rise to signs of Cushing's syndrome (MORRIS and SCULLY, 1958). Excretion of 17-ketosteroids is rather more frequently increased than with arrhenoblastomas (MORRIS and SCULLY, 1958). The β-fraction of this excretion may be greatly increased with adrenal rest tumors and values as high as those with adrenal tumors may be reached (BAUER and KARL, 1952; DEVIS, 1956). Lipoid-cell tumors are yellowish brown, solid, partly cystic, well-defined, and arise almost twice as frequently before the menopause as during the postmenopause. They consist mainly of large, round or polygonal cells with rich eosinophilic or clear, vacuolized cytoplasm. Incubation studies have shown that there is a metabolic block where testosterone and androstendione cannot be aromatized by the tumor cells (BRYSON, 1962). Formation of metastases with a fatal outcome has frequently been observed (MORRIS and SCULLY, 1958). The malignancy index is similar to that of the granulosa-cell tumor and arrhenoblastoma and is given as 21% (PEDOWITZ and POMERANCE, 1962).

The *gonadoblastoma* (MORRIS and SCULLY, 1958; SCULLY, 1963) is very rare, and also leads to defeminization and virilism. It consists of immature germinal cells, Sertoli (granulosa) and Leydig (theca) cells. The histological picture is similar to that of the embryonic gonad, hence the name. The tumor has been described most frequently in chromatin-negative patients with female appearance, all of whom had a uterus and tubes. Testes or ovaries have never been found. The tumors are solid. Multiple calcifications are characteristic histological findings and are also conspicuous on X-rays. The few estimations of 17-ketosteroids in the urine have shown normal or slightly elevated values.

The *therapeutic procedure* in all cases of endocrine-active tumors is determined by the age of the patient, and by the local findings and histology. In patients over 40, hysterectomy with bilateral removal of the ovaries is indicated; this is the procedure we adopt for all ovarian tumors. In patients under 40, if the tumor is strictly restricted to one ovary, the capsule is intact and histology can exclude a sarcomatous growth, surgery can be limited to unilateral ovariectomy. If there is the slightest suspicion of malignancy, hysterectomy with bilateral ovariectomy should be performed and followed by radiation.

Apart from the ovarian tumors mentioned, pseudomycincystomas, adenocarcinomas, Brenner tumors, Krukenberg tumors and other ovarian metastases may also be associated with virilism (PLOTZ, 1966). All these tumors show luteinization. The few measurements of 17-ketosteroids excretion so far performed show normal levels (SCULLY, 1963).

Differentiation between the androgen-producing ovarian tumor and tumors and hyperplasia of the adrenal usually presents no difficulties. In the former type, excretion of 17-ketosteroids is often grossly elevated. With the adrenal tumor, the excretion is occasionally over 100 mg/day, the β-fraction being over 50%. In contrast, excretion of androsterone and etiocholanolone is fairly high in the presence of ovarian tumors. Pregnanetriol excretion is increased in adrenocortical hyperplasia, whereas this is not so with adrenogenic ovarian tumors. Prepubertal development of clinical symptoms is indicative of an adrenal tumor or hyperplasia. Since the endocrine-active ovarian tumor can only be palpated in 60% of cases, it can often only be confirmed by means of culdoscopy or laparoscopy. Retropneumoperitoneum and intravenous urogram may be helpful in differentiation. There may be difficulty in differentiating between the ovarian adrenal remnant tumor and the adrenocortical tumor, since the clinical picture and hormonal analytical findings may be identical. Urogram, culdoscopy, laparoscopy and retropneumoperitoneum are further methods of diagnostic investigation. If symptoms such as hypertension, polycythemia, reduced glucose tolerance and striae arise, the possibility of Cushing's syndrome due to hypothalamo-hypophyseal factors must be considered. If this is present there is no virilism and 17-ketosteroid excretion is not greatly elevated.

In the absence of a palpable ovarian tumor, it is difficult to differentiate between borderline adrenal hyperplasia (postpubertal increased formation of adrenal androgens), "idiopathic hirsutism" and the syndrome of polycystic ovaries, which can all give rise to virilism in exceptional cases. Routine measurement of steroid excretion does not help. French authors (NETTER, 1961; MAUVAIS-JARVIS and BAULIEU, 1961; BAULIEU, 1963; JAYLE, 1967) have recommended the combined dexamethasone/HCG test for differentiation of ovarian androgen formation from adrenal androgen formation. This test is performed and interpreted as follows: the patient receives 3 mg dexamethasone daily for 12 days, and in addition 5000 IU HCG on the 6th, 7th and 8th days. Steroid excretion (17-ketosteroids, androsterone, etiocholanolone and dehydroepiandrosterone) are measured before the test and on the 5th and 7th days. In the healthy patient, the 17-ketosteroids fall to less than 2 mg/day. In the presence of increased formation of ovarian androgens, 17-ketosteroid excretion is more than 3 mg/day, and HCG stimulation should produce another rise. Clinical experience with this functional test is still too limited to permit definite assessment of its significance. Results of other investigators (PERLOFF and JACOBSON, 1963; SOHVAL and SOFFER, 1951) appear to restrict the value of this test considerably (cf. Stein-Leventhal syndrome, p. 609).

Rapid progression of the defeminization and virilism is indicative of the presence of an androgen-producing tumor and makes idiopathic hirsutism, postpubertal increased formation of androgens and Stein-Leventhal syndrome unlikely. Culdoscopy and laparoscopy will help in further differentiation in these cases also.

3. Chorioepithelioma

A primary ovarian chorioepithelioma arises from a teratoblastoma (Fig. 79) or from the trophoblastic tissue of an ovarian pregnancy. A secondary chorioepithelioma usually originates in a uterine chorioepithelioma. The primary ovarian tumor is rare, and extremely malignant. Gestational tumors arising in an ovarian pregnancy will respond to cytostatic therapy (Methotrexat, Actinomycin-D, Chlorambucil), whereas those arising in a teratoblastoma are without exception fatal. It may cause precocious pseudopuberty when it occurs before menarche (WILKINS, 1965), probably because of the increased production of estrogens by the ovaries, which is caused in turn by the stimulation of chorionic gonadotropin. Correspondingly, there may be multiple granulosa and theca lutein cysts in the intact ovary. After menarche, acyclic bleeding and signs of a pregnancy are the dominant clinical features. Biological and immunological pregnancy tests are positive.

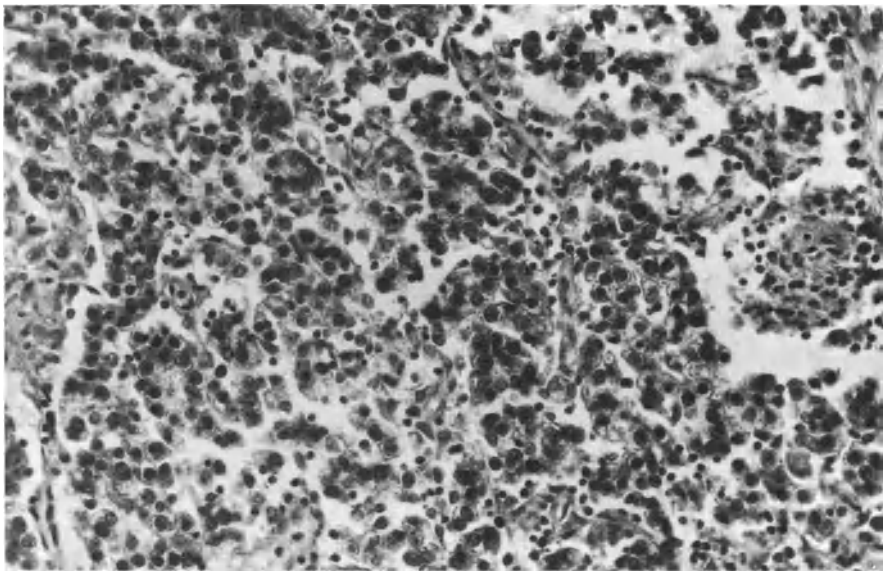

Fig. 79. Teratoma embryonale of the left ovary progressing to chorial carcinoma in a 15-year-old girl. Implantation metastases in the rectouterine pouch. 30000 IU HCG/liter urine; 39.2 mg estriol/24 h

4. Struma Ovarii

Thyroid tissue occurring as a component of a dermoid cyst (teratoma adultum ovarii) is by no means an uncommon finding. Exceptionally, the thyroid tissue predominates to such an extent that a so-called struma ovarii develops. In about 20% of these cases, no other teratomatous tissue can be detected microscopically (SAILER, 1943). Thyroid tissue tumors are bilateral in less than 5% of cases. Macroscopic and microscopic findings correspond largely to those in a nodular colloid goiter. The histological picture usually shows little glandular tissue, and characteristic lobular structures. Adenomatous areas occasionally arise within the colloid goiter (MÜLLER, 1961). About 12% of struma ovarii exhibit carcinomatous regions, and metastases are found in about half these cases (MÜLLER, 1946). Clinical signs of thyreotoxicosis are seen in 10% of cases (SMITH, 1946), but may disappear after removal of the tumor (MÜLLER, 1961). The iodine content only exceptionally corresponds to that of a normal adult thyroid gland, usually being much reduced or completely absent. Dystopic ovarian thyroid tissue can be demonstrated by the radioiodine test in these cases (MÜLLER, 1954).

XI. Pregnancy

PAUL J. KELLER

A. Historical Dates

1904 HALBAN indicated the endocrine function of the placenta.
1928 ASCHHEIM and ZONDEK developed the first usable pregnancy reaction.
1930 PHILIPP proved the placental origin of chorionic gonadotropin.
1929–1934 representation and characterization of estrogens and progesterone from urine in pregnancy by BUTENANDT, DOISY, MARRIAN etc.
1958–1970 Exhaustive investigations of steroid biosynthesis in the feto-placental unit by RYAN, DICZFALUSY, ZANDER and many other researchers.
1960 Development of an immunological pregnancy test by WIDE.
1962 JOSIMOVICH isolated and characterized placental lactogen.

B. Anatomy

1. Development and Structure of the Placenta

The ovum migrates into the uterine cavity within 3 to 4 days after fertilization in the tube. During this time, it undergoes continual cell division, becoming converted into a blastocyst, a hollow sphere consisting of the trophoblast and the embryoblast. The placenta develops from the trophoblast, and the embryo from the embryoblast.

After about 6 days, the blastocyst becomes implanted in the converted secretory maternal endometrium by means of proteolytic ferments of the trophoblast. As early as 10 days after conception, the blastocyst is completely surrounded by endometrial tissue, which becomes increasingly loose and vascular under the influence of progesterone, thus developing into decidua.

The trophoblast is then differentiated into two cell layers. The inner layer is termed as the cytotrophoblast or Langhans's layer and consists of cuboid, well-defined cells. The outer layer is called the syncytiotrophoblast, and the borders of its cells cannot be distinguished. Both layers grow rapidly, and 11 to 13 days after conception, primordial villi develop, bounded internally by the cytotrophoblast and externally by the syncytiotrophoblast. The primordial villi open the maternal lacunae in the endometrium, which has by this time been converted into the decidua. The lacunae thus develop into intervillous spaces filled with blood. The extra-embryonic mesoderm supplies the villi with stroma and capillaries which are later connected to the embryonic circulatory system.

The most important organs are formed in the embryoblast between days 15 and 42 after conception. This phase is termed organogenesis. The definitive placenta also develops during this period. The villi adjacent to the uterine cavity degenerate. This area is called the chorion laeve. In contrast, the villi emanating from the decidua basalis of the uterine wall continue to grow rapidly to form the chorion frondosum and hence the placenta.

The mature placenta is oval or circular in shape. It has an average diameter of 15–20 cm. It is 1.5–3 cm thick and weighs between 500 and 600 g with the umbilical cord. It is bounded on its fetal side, where the umbilical cord is attached, by the chorionic plate consisting of trophoblast and the fibrinoid tissue. The uterine surface is bounded by the basal plate, whose structure is similar. The villous tissue is found between these layers and is compressed into the cotyledons and the intervillous spaces perfused by maternal blood (Fig. 1). The villi themselves consist of a fibrous stroma in which the fetal villous capillary network runs. The villi are bounded by syncytiotrophoblast and cytotrophoblast, the latter disappearing almost completely between the 3rd and 5th months (Figs. 2, 3). The total villous surface is estimated to be about 15 m^2 in the mature placenta (WILKIN, 1965).

Oxygenated maternal blood flows through the spiral arteries of the decidua basalis into the intervillous spaces. There, it perfuses the villi and then returns to the circulation by

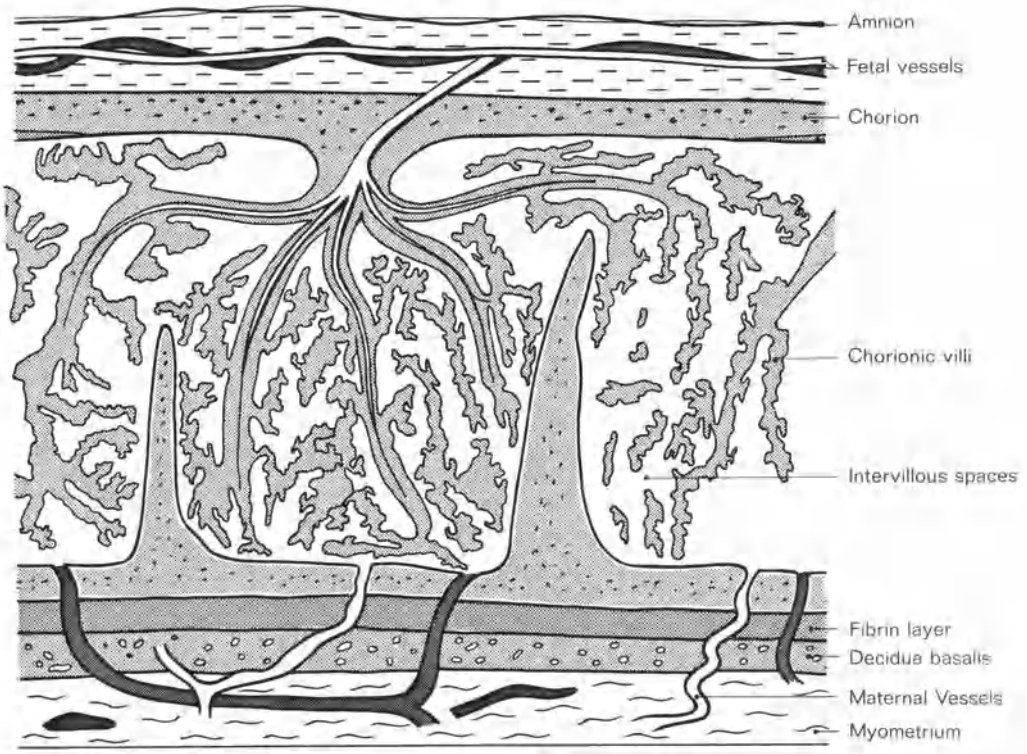

Fig. 1. Schematic representation of the structure of the mature placenta

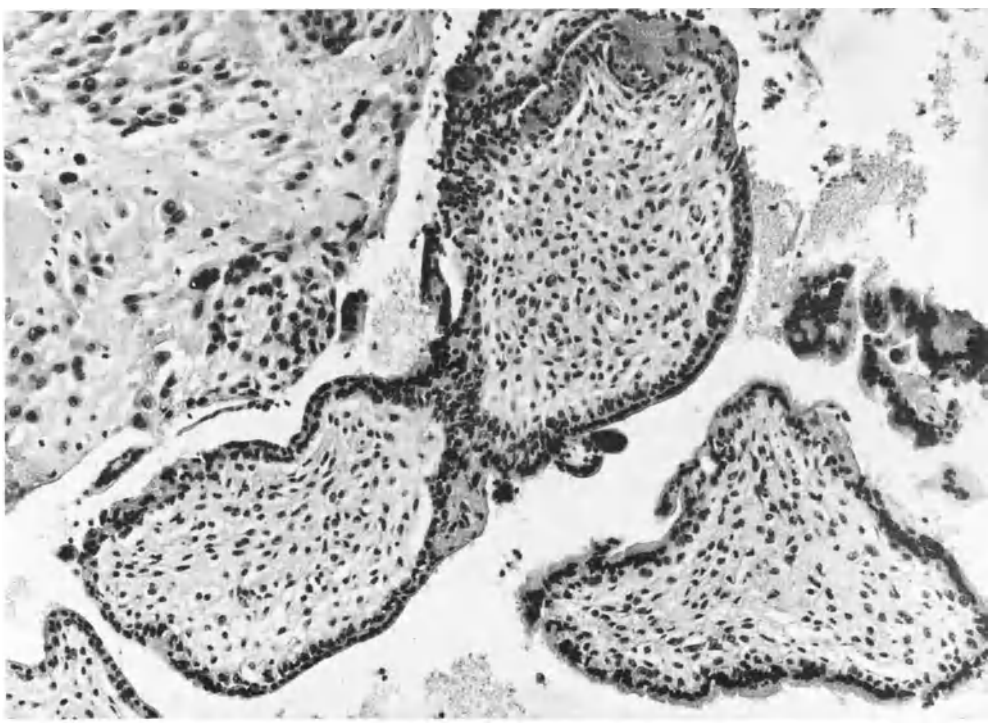

Fig. 2. Histological picture of the chorionic villi during early pregnancy (11th week of pregnancy)

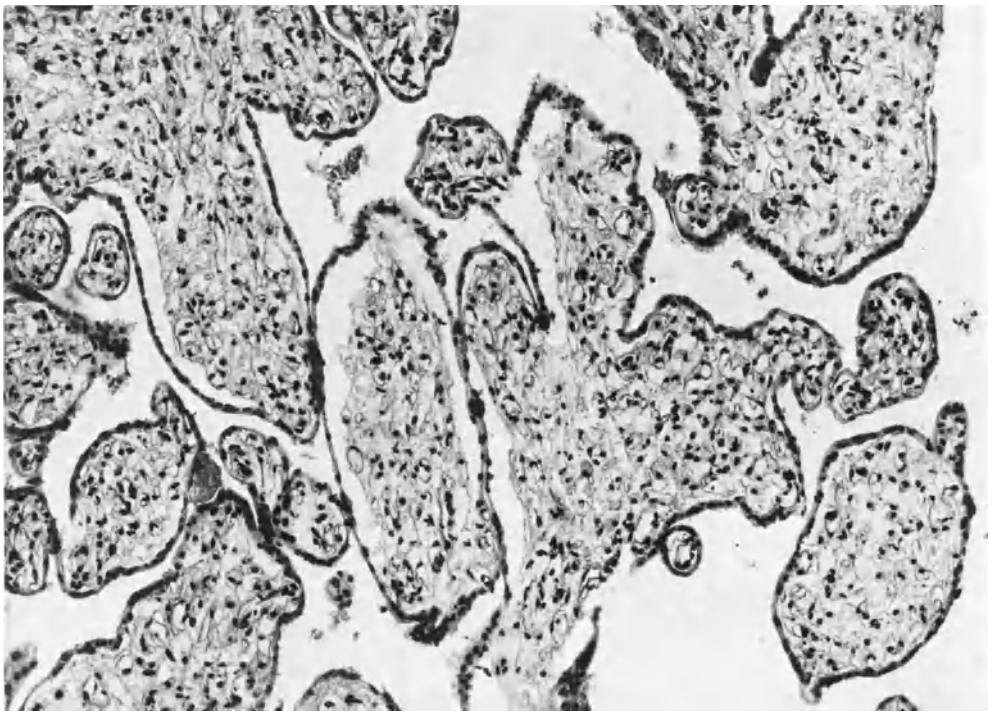

Fig. 3. Histology of the chorionic villi during the last 3rd of pregnancy (39th week of pregnancy)

way of the border sinus and through the veins of the basal plate. Fetal blood flows from two umbilical arteries into the main vessels of the cotyledons and is distributed in the villous capillary system. After being oxygenated, it flows via the umbilical vein back into the fetus. The minute volume of maternal perfusion of the intervillous spaces lies between 375 and 500 ml (BARTELS, 1962; BROWNE, 1954), the minute volume of fetal circulation in the umbilical cord between 150 and 500 ml (GREENFIELD, 1951; ROMNEY, 1955).

Feto-maternal exchange of substances takes place through the syncytiocapillary membrane of the villi. Since the chorion is directly perfused by maternal blood, a hemochorial system is involved. The details of the transplacental transport mechanism have not been explained, but in addition to diffusion processes of varying speeds, active transport and even passage through leaks in the placental membrane may be considered. Apart from this, the trophoblast is also capable of performing a large number of anabolic and catabolic functions, such as the synthesis of fatty acids, proteins, and nucleic acids. Histochemical investigations have facilitated great strides in the relation of individual substances to definite tissue structures.

The fetus is connected to the placenta by the umbilical cord, and is completely mobile in the amniotic fluid surrounded by the fetal membranes. Like the placenta, these membranes consist of fetal and maternal portions, i.e. the amnion, chorion, and decidua.

Details should be obtained from textbooks on obstetrics.

2. Specific Changes of Other Endocrine Glands

a) Hypophysis

The adenohypophysis (anterior pituitary) increases in weight by an average of about 100 mg during pregnancy. The primary histological feature is the large number of pregnancy cells. These cells have large nuclei, stain poorly, and are probably derived from the chromophobe γ cells. The function of these cells has not yet been satisfactorily explained. They are probably an expression of the effect of placental hormones, since similar changes are also found in men suffering from a chorion-epithelioma. These cells regress considerably after the pregnancy.

b) Ovary

The most conspicuous change in the ovary is seen in the corpus luteum, which does not regress after implantation of the fertilized ovum as in the menstrual cycle (see p. 520), but in-

creases in size and is converted into the cystic corpus luteum graviditatis. Histologically, all the signs of an increase in function are present. The layer of theca lutein cells extends and the layer of granulosa cells becomes more vascular. Peripheral vacuolization of the cells increases and more fat globules are deposited in the cells. Degenerative processes begin in the third month of pregnancy; subsequently, the layer of theca cells steadily disappears, the vessels in the layer of granulosa cells recede, and finally, fibrous organization occurs.

Follicular maturation fails to occur throughout the pregnancy due to the absence of rhythmic regulation by pituitary gonadotropins. Nevertheless, a certain degree of follicular growth can sometimes be observed, but the stage of follicular rupture is never reached. Mild cyclic bleeding occasionally arising in the first few months of pregnancy may possibly be due to this state.

c) Adrenal Cortex

The adrenal cortex hypertrophies during pregnancy and there is a measurable increase in weight. Primarily the width of the inner regions of the zona fasciculata (see p. 287) increases. Increased vascularization and the deposition of lipoids can be observed.

C. Biochemistry of Pregnancy- and Lactation-Regulating Hormones

1. Placental Protein Hormones

a) Chemistry

The placenta produces at least two and possibly even several highly molecular protein hormones. Chorionic gonadotropin (HCG, human chorionic gonadotropin) has been investigated most intensively. It is found in large amounts in the placenta, blood and urine even in early pregnancy. The hormone is generally obtained by complicated extraction procedures since it has so far been impossible to synthesize it. The most reliable methods are similar to those used for the extraction of hypophyseal gonadotropins such as alcohol and acetone precipitation, adsorption onto kaolin, permutit or benzoic acid. Additional purification by means of chromatography on ion exchangers such as Decalso, Dowex 2 or Sephadex, and electrophoretic procedures makes a specific activity of 10000–20000 IU/mg possible (Got, 1960; Reisfeld, 1960; Wilde, 1965; Van Hell, 1966). In spite of these astonishing results, there is still no absolute certainty that pure HCG can be obtained. Several compounds fulfil the criteria for homogeneity in electrophoresis, ultracentrifugation and immunochemistry, but even one of the purest fractions seems to consist of different biologically active parts (Van Hell, 1966). In the circumstances, it is not surprising that the chemical constitution has not been fully explained and that there is some controversy about the matter. It has been confirmed that HCG is a glycoprotein and that the fairly high proportion of sugar consists mainly of mannose and galactose (Got, 1960). According to Blobel (1962), there are also 10% hexoses, 12% hexosamine, and 6% neuraminic acid. The last component is of special interest since splitting with neuraminidase or 0.01 N HCl leads to a loss of biological activity. The protein component consists of numerous chains of amino acids, asparaginic and glutaminic acids being the two most predominant. The molecular weight is probably about 30000 (Got, 1959; Nydick, 1964), but figures vary. The isoelectric point lies between 3 and 4 (Got, 1959; Reisfeld, 1960). HCG is very stable in the desiccated form. Heating causes a loss of biological activity. It can also be destroyed by a series of chemicals, particularly by urea.

Placental lactogen (HPL), isolated by Josimovich in 1962, is also of importance. On the basis of its properties, a number of other names have been suggested, such as HCS (human chorionic somatomammotropin) or CGP (chorionic growth hormone prolactin). This hormone can be obtained from homogenized or lyophilized placenta by means of alkaline, aqueous extraction followed by precipitation of the active fraction with ammonium sulfate. Gel filtration on Sephadex (Florini, 1966) is particularly suitable for further purification. HPL is chemically and immunologically closely related to human growth hormone. It is a highly molecular polypeptide. The most important amino acids are again asparaginic and glutaminic acids and leucine. The molecular weight is about 38000 (Florini, 1966; Catt, 1967). Measurements in 5 N guanidine gave rise to values half as high. This could mean that the hormone is present in the dimerous state in aqueous solution. Absolute homogeneity has apparently not yet been achieved.

In addition to these well characterized substances, the placenta also appears to synthesize a thyrotropic protein (HCT, human chorionic thyrotropin) which is chemically quite similar to the corresponding pituitary hormone. Extraction and purification are achieved by methods similar to those used for other placental protein hormones (Hennen, 1969). An exact characterization has yet to be performed.

b) Formation

It is firmly established that HCG arises from the placenta. The most important evidence in support of this fact appears to be provided by the absence of any considerable gonadotropic activity in the hypophysis of a pregnant woman (PHILIPP, 1930), the rapid fall of the HCG titer after removal of the placenta, and the production of this hormone in placental tissue *in vitro* (STEWART, 1948). The question of cellular origin presents more difficulties. Specific histochemical investigations with fluorescent antibodies have led to the conclusion that HCG is formed predominantly in the syncytiotrophoblast although other placental structures also show some degree of activity (MIDGLEY, 1962; LEZNOFF, 1963).

Nor is there any further doubt that HPL is also produced in the placenta. It disappears rapidly after removal of the placenta, and no significant amounts are demonstrable in the hypophysis or fetus. It is produced principally in the syncytiotrophoblast and not in the cytotrophoblast, as has been shown by histochemical studies (SCIARRA, 1963).

Assertions about other proteins hormonal nature which may be present in the placenta seem premature.

c) Metabolism

HCG is primarily released into maternal blood. Minute amounts however, also reach the fetal circulation by routes which are still obscure. It can also be domonstrated in the amniotic fluid and in all maternal tissues. It is excreted mainly in the urine, the average renal clearance lying between 0.38 and 0.95 ml/min (JOHNSON, 1950; LORAINE, 1950). A small amount also appears in the milk. HCG values decrease rapidly after birth (see p. 693) and less than 10% of the antenatal circulating activity can be detected in the urine (WILSON, 1949). The manner of inactivation is unexplained. The liver appears to have no part in this (LEEB, 1956). It seems rather doubtful that postulated inhibitors (SOFFER, 1961) exert any influence.

HPL and HCG are metabolically similar. Most of the activity of HPL is found in maternal serum and in retro-placental blood. Mere traces are the most that can be demonstrated in the fetal circulation (KAPLAN, 1965). The concentration in the amniotic fluid is about 10 to 20 times higher than that in the maternal circulation (KELLER, 1970). The hormone disappears exceptionally quickly after removal of the placenta. The biological half-life is about 20 min (BECK, 1967). Only small amounts of HPL are found in maternal urine, and the renal clearance lies between 0.003–0.007 ml/min (KELLER, 1970). The method of inactivation of this hormone is also unexplained.

2. Steroid Hormones

a) Chemistry

A large number of C_{18}, C_{19} and C_{21} steroids have been demonstrated in the placenta. Among the C_{18} steroids, estrone, estradiol, and particularly, estriol are the most important hormones found. This is a similar state to that in non-pregnant women. Androstenedione and dehydroepiandrosterone are the most important C_{19} steroids, and progesterone and pregnenolone, the most significant C_{21} steroids. The most important structural formulae are presented in Fig. 4. Further details of steroid chemistry and the question of nomenclature, are gone into on p. 288.

b) Formation

Placental steroid hormones are probably produced principally in the syncytial part of the villous system. The complicated process can be investigated by means of incubation experiments *in vitro* which involve incubation of tissue sections or placental homogenates with the suspected precursors in predetermined conditions. The metabolites produced are then analyzed. Perfusion studies are even more conclusive. The placental vascular system is perfused *in vitro* or *in vivo* with the initial material in a suitable medium.

Numerous studies have shown that the placenta produces estrone and estradiol mainly through transformation of C_{19} steroids, particularly dehydroepiandrosterone (DHA), probably formed in the adrenal cortex of mother and fetus. These precursors reach the placenta predominantly in sulfate-conjugated form. There they are hydrolyzed by enzymes, converted into androstenedione and 19-hydroxyandrostenedione by 3β-hydroxysteroid dehydrogenase and 4,5-isomerase, and then aromatized (Scheme 1). The fetus can probably also aromatize very small amounts of androstenedione into estrone and estradiol.

Since the placenta contains only small amounts of 16α-hydroxylase or none at all, the formation of estriol is more complex. This process probably involves 16-hydroxylation of DHA-sulfate in the fetal liver. This substance is then hydrolized again in the placenta and converted into estriol by means of 3β-steroid dehydrogenase, 4,5-isomerase, aromatizing enzymes and 17β-steroid dehydro-

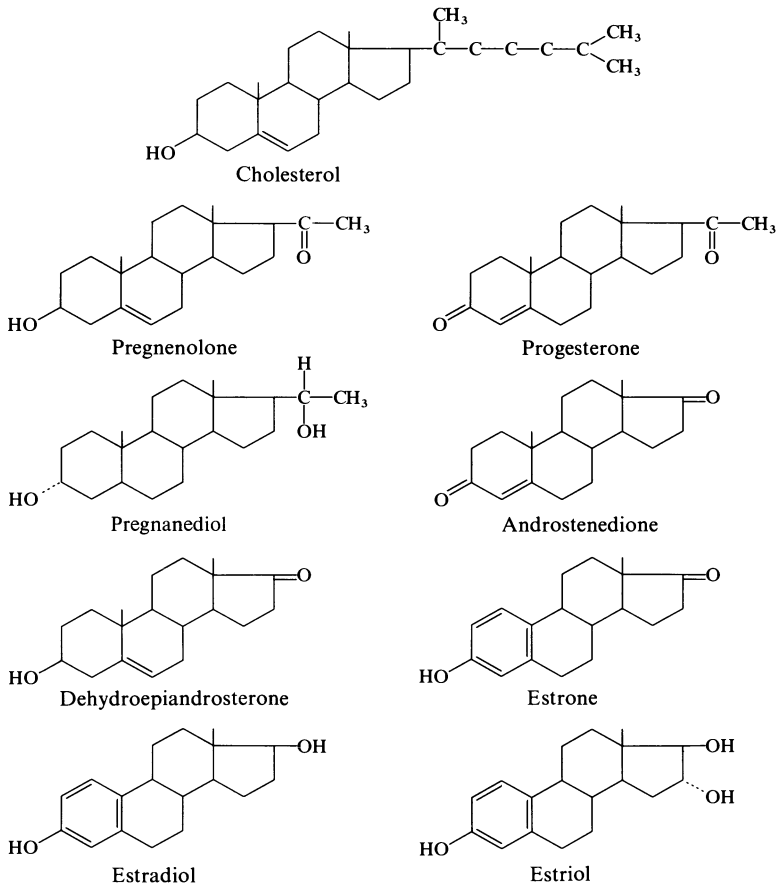

Fig. 4. Structural formulae of some important steroids of the feto-placental unit

genase. Transformation can occur via 16α-OH-androstenedione and 16-OH-estrone or more slowly via androstenetriol and 16α-OH-testosterone (DELL'AQUA, 1967). A second route, also via the fetus, consists in conversion of sulfated estrone present in the placenta by means of 16-hydroxylase into 16-OH-estrone sulfate. This then reaches the placenta again, is hydrolyzed there, and transformed into estriol by 17β-steroid dehydrogenase in the way already described.

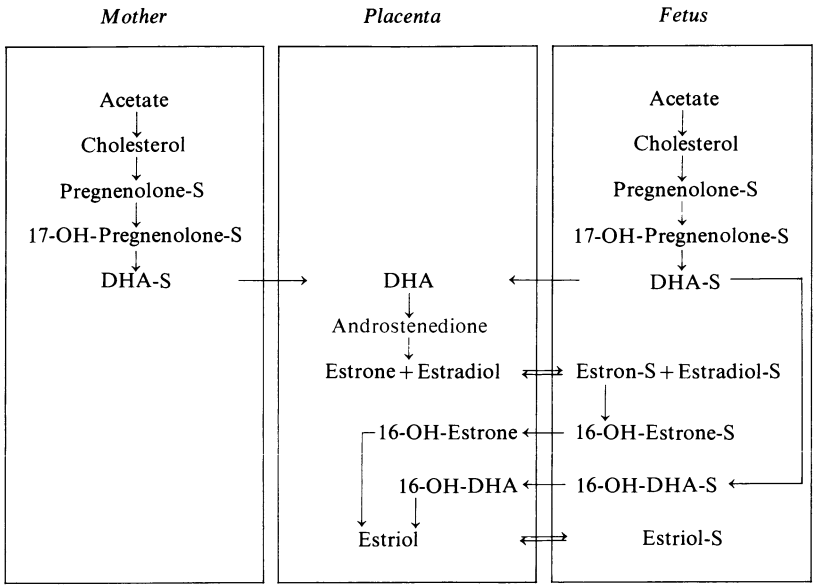
In addition to the placenta, the fetus is probably also capable of producing estrone and estradiol from DHA formed from pregnenolone. Limited amounts of estriol can be synthesized directly.

Progesterone (Scheme 2) is synthesized in the placenta mainly from pregnenolone or pregnenolone sulfate by means of 3β-hydroxysteroid dehydrogenase. Pregnenolone and pregnenolone sulfate are obtained either from the maternal or fetal circulation or are formed from cholesterol in the fetus and mother. Formation of cholesterol from acetate (ZANDER, 1966) is not necessarily of great importance in the placenta. Appropriate hydroxylation processes allow the derivation of small amounts of 20α-hydroxyprogesterone, and probably 6β-16α-, 17α- and 20β-hydroxyprogesterone from progesterone.

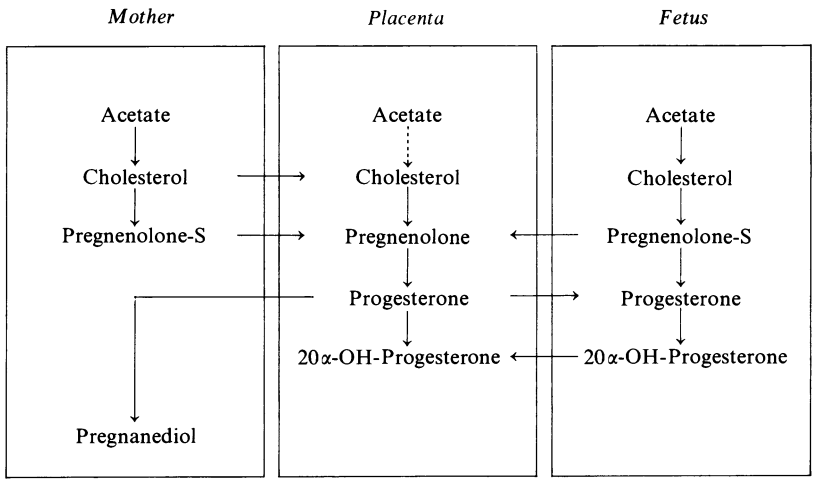
The fetus can produce cholesterol from acetate and is able to convert small amounts in the adrenal cortex into pregnenolone and progesterone. This route is presumably of only slight importance. The maternal production of progesterone is practically insignificant. Neither castration nor adrenalectomy results in a marked fall of progesterone metabolites during pregnancy. (DICZFALUSY, 1961; HAMMERSTEIN, 1965; HARKNESS, 1966).

Androgens found in the placenta, especially androstenedione and dehydroepiandrosterone, are of particular metabolic importance as precursors of estrogens. They are probably produced mainly in the fetal and maternal adrenal cortex.

Scheme 1. Fundamentals of the biosynthesis of estrogens in the placenta



Scheme 2. Fundamentals of the biosynthesis of progesterone in the placenta



c) Metabolism

The metabolism of steroid hormones during pregnancy is also extremely complex since numerous systems are involved at the same time, such as the placenta, adrenal cortex, gonads, fetal liver and maternal endocrinium. Transformation is effected by an extensive enzymatic system including a large number of different hydroxylases, hydroxysteroid dehydrogenases, isomerases, desmolases, sulfatases, sulfurylases, glucuronidases and glucuronylases.

The placenta produces increasing amounts of all the estrogens during the course of pregnancy. Estrone and estradiol can be converted into each other. Both steroids are released into the fetus and sulfated there. They are still partly in the sulfated form when they return to the placenta, where the conjugate is enzymatically hydrolyzed. As has been described already, 16-hydroxylation can also occur in the fetus, permitting subsequent transformation into estriol by the placenta (see p. 671). Only limited amounts of estrone and estradiol are found in the amniotic fluid and meconium. Large amounts of estriol are exchanged between the placenta and the fetal circulation. It also reaches the maternal circulation together with the other two estrogens, but its concentration in the maternal plasma is considerably lower

than that in the umbilical blood. Estriol is present mainly in the form of sulfate in the fetal circulation, whereas it is found mainly as a glucuronide or double conjugate in maternal blood, amniotic fluid, and meconium (TOUCHSTONE, 1963).

Excretion of the estrogens in urine varies. The renal clearance for estrone is 11.9, for estradiol 8.8, and 205 ml/min for estriol (BROWN, 1960, 1964). It is possible that sulfate and free estrogens are not excreted through the renal tubules, or only to a slight extent. This would explain the great differences, since in the plasma, estrone is present predominantly in the free form, estradiol as a sulfo-conjugate, and estriol as a glucuronoside or double conjugate. In addition to the classic estrogens mentioned, at least 20 other estrogenic metabolites can be found in the urine during pregnancy, such as 6α-hydroxyestrone, 15α-hydroxyestrone, -estradiol and -estriol, 15β-hydroxyestrone and -estradiol, 16α-, 16β- and 18-hydroxyestrone, 16-keto estrone and -estradiol, 16-, 17- and 16,17epi-estriol, 2-methyoxyestrone, -estradiol and estriol and others. Fetal urine contains mainly estriol and small amounts of estrone and estradiol (DICZFALUSY, 1957).

Increasing amounts of progesterone are also produced. About a third of it is liberated into the fetal circulation and two thirds into the maternal circulation (ZANDER, 1959). Investigations of the concentrations of progesterone and its metabolites in the umbilical cord have shown that mainly progesterone is present in the vein, whereas 20α-, 20β- and 17α-hydroxyprogesterone are found in the artery. From these findings it can be concluded that the progesterone released from the placenta into the fetus is probably hydroxylized by the fetal adrenal cortex and is returned to the placenta chiefly in the form of 20α-hydroxyprogesterone (ZANDER, 1961; LURIE, 1966). Further, incubation studies have shown that the fetal adrenal cortex can form small amounts of androgens from progesterone over 17α-hydroxyprogesterone and that corticoid synthesis is also possible through hydroxylation processes at C_6, C_{11}, C_{16}, C_{17}, C_{20}, and C_{21}. The placenta, in contrast, is unable to convert progesterone into estrogens or androgens.

Large amounts of the progesterone released into the maternal circulation are deposited in the adipose tissue (HASKINS, 1950; ZANDER, 1959). On the other hand, progesterone is probably converted mainly into pregnanediol in the liver and glucuronized there as well as in the kidneys and peripheral tissues. Excretion occurs in the urine, feces and bile. In addition to pregnanediol, progesterone, 15α-hydroxyprogesterone, pregnenolone, pregnanetriol and other derivatives can be demonstrated in the urine. The conversion rate of progesterone into pregnanediol has been estimated to be 6 to 30% (KLOPPER, 1956; PEARLMAN, 1957).

In the fetus, progesterone is catabolized in the liver mainly into pregnanediol and small amounts of pregnenolone. Pregnanediol, which is probably also sulfated principally in the liver, either returns to the maternal circulation via the placenta or is excreted in the bile and fetal urine und can thus be demonstrated in amniotic fluid (KLOPPER, 1959). In contrast to the situation with estriol, the fetus does not influence progesterone production in the placenta. This has been shown by ligation of the umbilical cord (CASSMER, 1959).

3. Prolactin

Prolactin is thought to be identical to the luteotropic hormone (LTH). Its relation to milk secretion is particularly interesting. The existence of this substance as a separate principle has also been confirmed in the human and in many other mammals. It is possible to extract lactogenic activities from the human adenohypophysis, and to separate prolactin from HGH, which also has lactotropic and luteotropic properties.

a) Chemistry

The most exact information available is that on ovine prolactin, which is extracted from the anterior pituitary lobe by precipitation with alcohol, fractionated salting out, and purification by chromatography on DEAE-cellulose. Chemically it is a polypeptide with an estimated molecular weight of 23300 (DIXON, 1964). Asparaginic and glutaminic acids, and leucine, are the amino acids predominantly present. The isoelectric point is about 5.7. Prolactin isolated from the cow and pig shows similar properties.

b) Formation

Prolactin is formed in the adenohypophysis, possibly in the acidophil cells which can be stained with erythrosine. During pregnancy in mammals, these cells show increasing secretory activity which becomes even more intensified with the onset of lactation. The prolactin content of the anterior lobe of the hypophysis also rises during pregnancy and remains elevated during lactation. The average concentration in sheep is between 30 and 40 IU/mg.

c) Metabolism

Secretion of prolactin, like that of other anterior pituitary hormones, is regulated by the hypothalamus, principally through a prolactin inhibiting factor (PIF, see p. 30). The existence of a corresponding releasing factor (PRF) is still speculative. Low doses of estrogens can stimulate prolactin secretion directly or indirectly via the hypothalamus. Thyroxine also has a similar effect (MEITES, 1966). Progesterone, testosterone, and cortisol are also thought to be able to suppress the prolactin inhibiting factor thus leading to increased prolactin secretion (SAR, 1968).

Demonstration of this hormone (see p. 701) in the blood, and particularly its specificity, presents considerable technical problems. Results so far published must therefore be accepted with reservations, especially results in man. Measurements in sheep, however, have shown that prolactin activity in the serum is slight and is not changed during pregnancy but is greatly raised during lactation in both serum and adenohypophysis. These findings, however, are contradictory (FORSYTH, 1967).

No confirmed evidence is currently available on the manner of excretion and metabolism.

4. Oxytocin

Oxytocin plays a decisive role in the hormonal regulation of birth (see p. 692) and lactation (p. 696). It is an octapeptide with a molecular weight of about 1000. It is probably formed in the ganglia of the supraoptic and paraventricular nuclei from where it passes to the neurohypophysis. The primary effect of oxytocin is to reinforce the contractions of the uterus and of the myoepithelial cells of the mammary glands. Its very rapid breakdown is partly due to an oxytocinase, which is probably produced in the placenta during pregnancy. More details are given on p. 692.

D. Normal Pregnancy

1. Hormone Production in the Placenta

The placenta has numerous functions, gas and energy exchange between maternal and fetal organisms being of primary importance. In addition, the placenta is an extremely versatile endocrine system, which forms numerous steroids and protein hormones from the beginning of pregnancy. Thus, it not only controls pregnancy itself, but is also involved to a considerable extent in the specific changes of the maternal organism. Its efficiency is amazing. Protein hormones now known to be produced autonomously in the placenta exert luteotropic, mammotropic, somatotropic, anti-insulin, and probably thyrotropic effects. Biosynthesis of steroids is also of utmost importance, but in the case of these hormones the fetal-placental interplay is of greater significance.

The most important confirmed or postulated components of the placenta are summarized in Table 1.

Table 1. Survey of placental hormones

Hormones	Formation in placenta	Main actions
Chorionic gonadotropin (HCG)	Confirmed	Luteotropic, influences steroid biosynthesis
Placental lactogen (HPL)	Confirmed	Somatropic, lactotropic, anti-insulin, influences steroid biosynthesis
Chorionic thyrotropin	?	Thyrotropic
Estrogens	Confirmed	Prepares maternal organism for birth and lactation, uterotropic
Gestagens	Confirmed	Prepares maternal organism for birth and lactation, relaxes uterus
Androgens	Confirmed	Intermediate metabolic importance in steroid biosynthesis
Corticosteroids	?	Mineralo- and glucocorticoid
Relaxin (hormone?)	?	Loosening of the symphysis, uterine relaxation

a) HCG

Production, secretion, and excretion of HCG during normal pregnancy have been studied by numerous investigators by means of biological, immunological and radio-immunological methods. The results of these investigations are on the whole consistent. Absolute values, however, are often more difficult to compare. The trophoblast begins to form HCG as soon as 10–14 days after conception, first in small amounts and then in rapidly increasing amounts. After approximately 10 weeks, an average peak value of 450 IU per g placenta is reached (DICZFALUSY, 1953). The titer rapidly falls to less than 50 IU per g in the fourth month and does not alter significantly during the further course of pregnancy (Fig. 5).

HCG levels in the serum behave in a similar manner. The maximum values are again attained between the 8th and 12th weeks and the level then declines rapidly. Relation of the

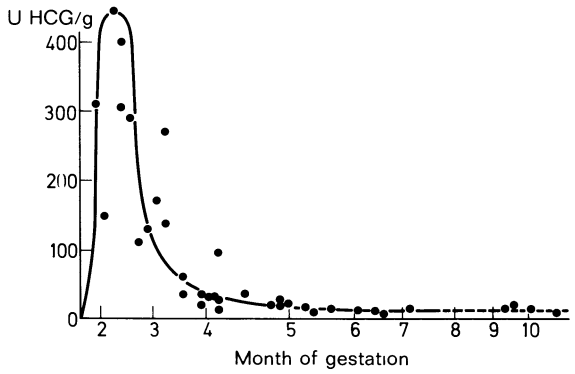


Fig. 5. HCG concentration in the placenta in a normal pregnancy (biologically measured). (After DICZFALUSY, 1953)

level of the titer to the sex of the fetus as postulated by BRODY (1965), appears extremely questionable.

22 to 24 days after conception, or 36 to 38 days after the last menstrual period, the level in the urine is in excess of 1000 IU/l. At this stage, the more sensitive of the conventional pregnancy tests are positive. The amount of HCG excreted in the urine also rises steeply, reaching immunochemical values of 80000 to 240000 IU/l between the 8th and 12th weeks (KELLER, 1966). Between the 13th and 17th weeks, the titer falls just as rapidly and remains between 5000 and 30000 IU/l (Fig. 6) for the rest of the pregnancy. Values can fall below 1000 IU/l in individual cases without any detectable disturbance of fetoplacental function. The striking agreement between placental urinary relations can be deduced from Fig. 5 and 6.

The importance of HCG production with its typical maximum in the first trimester has not been altogether explained. It is assumed that stimulation of the corpus luteum of pregnancy is one of the possible functions of this hormone. Indeed, numerous investigations have shown that HCG has strong luteinizing and luteotropic effects and can prolong the luteal phase in the human. *In-vitro* experiments on the human corpus luteum have also shown that incorporation of C_{14} into progesterone, 17α-hydroxyprogesterone, estradiol and estrone is increased under the influence of HCG (RICE, 1964). A stimulating action on the biosynthesis of progesterone (MASON, 1962) and on the activity of the endopeptidases (JUNG, 1962) has also been demonstrated in animal experiments.

The action on the placenta itself has only been explained to a small extent. Nevertheless, perfusion studies have shown that HCG stimulates the transformation of 16-hydroxylized C_{19} steroids into estriol (TROEN, 1961; 1962; VARANGOT, 1962). The influence of HCG on steroid biosynthesis can be considered as proven. It is still not possible to say with certainty whether the fetal endocrine system is also subjected to a stimulating influence, and if so, to what extent. It appears, however, that the adrenal cortex, testes, and ovaries can be influenced. HCG production is largely independent of fetal function. Ligature of the umbilical cord in utero does not diminish the titer (CASSMER, 1959).

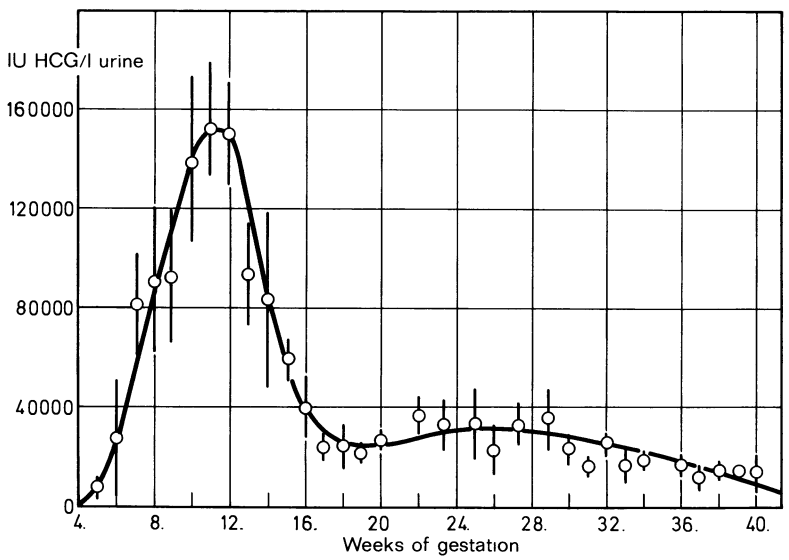

Fig. 6. Urinary HCG excretion during normal pregnancy, average values and standard deviations. (Immuno-chemical assay, after KELLER, 1966)

The question of regulation of HCG production is just as difficult as the question about the meaning of the production. The existence of a feedback mechanism similar to that between sex hormones and the release of hypophyseal gonadotropins is somewhat questionable although various authors have thought that they observed a discrete fall in the HCG titer under the influence of synthetic estrogens and gestagens. Positive and negative effects of estriol and dehydroepiandrosterone have been postulated (LAURITZEN, 1966). Whether large amounts of HCG inhibit continued production also appears questionable. Nevertheless, a slight fall has been reported after injection of HCG (DICZFALUSY, 1956). Precise methods of estimation may solve some of these problems in the next few years.

b) HPL

Human placental lactogen is demonstrable in the trophoblast as little as $3\frac{1}{2}$ weeks after fertilization and its concentration remains more or less constant (1–10 g per 100 g placenta) throughout pregnancy (JOSIMOVICH, 1964). In contrast, plasma levels continue to rise during the course of pregnancy (Fig. 7). Plasma HPL can generally first be detected between the 7th and the 8th weeks. Average values reach a level of 0.5 µg/ml in the 12th week, 2.5 µg/ml in the 24th week, and 6 µg/ml after the 35th week (KELLER, 1970). Only very little HPL is excreted in the urine. The daily production at the end of pregnancy is estimated to be 0.3–1 g.

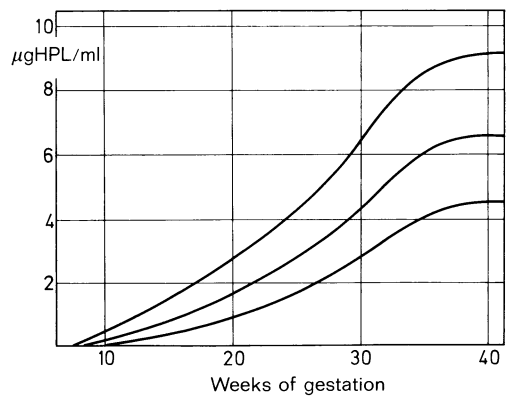

Fig. 7. HPL concentration in serum during normal pregnancy, average values and normal 95% range. (Radioimmunoassay after KELLER, 1970)

The function of placental lactogen is also difficult to define. The fact that only traces of this hormone can be demonstrated in the fetal circulation leads to the conclusion that the main effect must be exerted in the placenta and maternal organism.

There is no doubt that HPL has a weak somatotropic action. This can be shown by animal experimentation, both in the tibia test and in the uptake of labeled sulfate in the costal cartilages of hypophysectomized rats (KAPLAN, 1964). It also induces a general increase in the weight of mice and rats (FRIESEN, 1965). In experimental conditions, nitrogen retention in the human appears to be less pronounced under the influence of HPL than under that of growth hormone. In contrast, high doses of HPL cause a rise in free fatty acids (GRUMBACH, 1966). In addition to its action on fat metabolism, HPL also has a definite diabetogenic, anti-insulin effect on sugar metabolism. This may explain the deterioration of latent diabetes during pregnancy (see p. 801). The physiological significance of this function may be associated with an increase of glucose supply in the pregnant organism through mobilization of free fatty acids (GRUMBACH, 1966).

Like human growth hormone, HPL also exerts a prolactin-like, mammotropic effect, as can be demonstrated on the crop sac of the pigeon and in the secretion of milk in pregnant and pseudo pregnant rabbits. The lactogenic action can also be seen in tissue cultures of the milk glands of mouse, where synthesis of casein is promoted in the presence of insulin and cortisol and the number of cells increases at the same time (TURKINGTON, 1966). The action of HPL is very similar to that of prolactin in animal experiments.

The luteotropic action is another property of this hormone. In animal experiments it can be potentiated by HCG (JOSIMOVICK, 1966). Nothing can be said about this action in the human at present.

The influence on the placenta and its production of steroids is still controversial, but can be considered likely. Stimulation of the conversion of 16-OH-dehydroepiandrosterone into estriol has been demonstrated (TOMINAGA, 1967).

c) Other Protein Hormones

Most recent investigations have shown that, in addition to the two well-characterized placental protein hormones already mentioned, there may be a chorionic thyrotropin (HCT, human chorionic thyrotropin) which may be responsible for the relatively high thyrotropic activity of the serum in pregnancy (HENNEN, 1969).

Placental extracts also contain adrenocorticotropic activity (JAILER, 1950; NEHER, 1961), but

this probably arises from the maternal adenohypophysis rather than from the placenta itself.

Relaxin is another substance which can be extracted not only from the placenta, but also from the uterus and ovaries (HISAW, 1950; ZARROW, 1958). It is a polypeptide which is claimed to cause a loosening of the pelvic ring as well as relaxation of the uterine musculature and dilatation of the cervix. The hormonal nature of this substance is doubtful.

d) Estrogens

During pregnancy the concentration of estrogens rapidly increases in the placenta, maternal blood, and urine. The three classic estrogens are present predominantly in the free form in the placenta. Data about the amounts vary. According to DICZFALUSY (1961), at the end of pregnancy there are 37–64 µg estrone, 3–142 µg estradiol and 125–287 µg estriol per kg of fresh weight. A considerably smaller amount is present in the conjugated form. In addition to the estrogens mentioned, 16-epiestriol, 17-keto estradiol and 6-methoxyestrone have been isolated from the placenta. The rate of secretion of total estrogens has been estimated to be 1 mg in the 10th week, 20 mg in the 20th week and between 40–100 mg at term (BROWN, 1957).

More is known about the behavior of estrogens in the blood. After conception there is no initial premenstrual fall. Levels then rise continuously, until at term the concentration of estrone, estradiol and estriol is found to lie between 2 and 26, 1 and 5, or 3 and 30 µg/100 ml plasma, depending on what technique is used. The quotient

$$\frac{\text{estriol}}{\text{estrone} + \text{estradiol}}$$

rises during the course of pregnancy and is about 4 at term. Similar values of estrone and estradiol are found in fetal blood, but there is a preponderance of sulfo-conjugated estriol so that the above quotient is about 30.

The excretory relations are of special importance for diagnostic reasons to be discussed later. Again, there is no premenstrual fall after conception, and a mid-cyclic titer is attained 14 days after fertilization (Fig. 8). The ratio

$$\frac{\text{estriol}}{\text{estrone} + \text{estradiol}}$$

rises from approximately 1 to 10 from the beginning of pregnancy to term, with a 1000-fold increase in the excretion of estriol during this period and a mere 100-fold increase in the excretion of estrone and estradiol (Fig. 9).

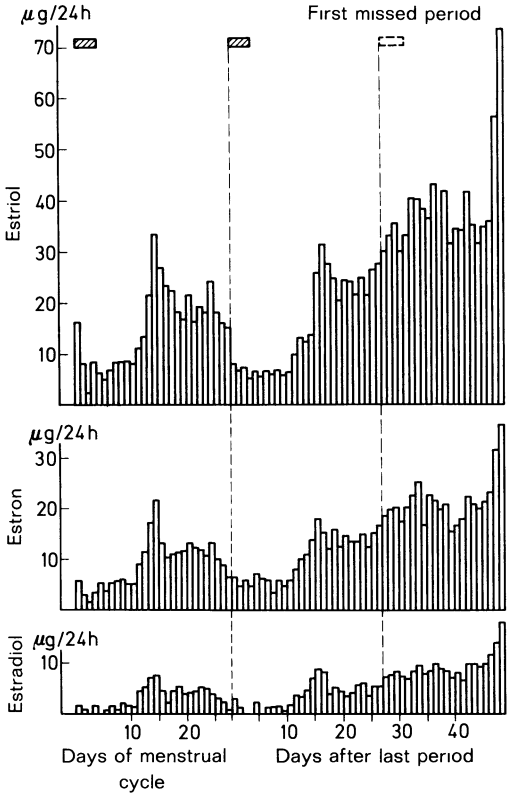

Fig. 8. Urinary excretion of estrone, estradiol and estriol before and after conception. (After BROWN, 1956)

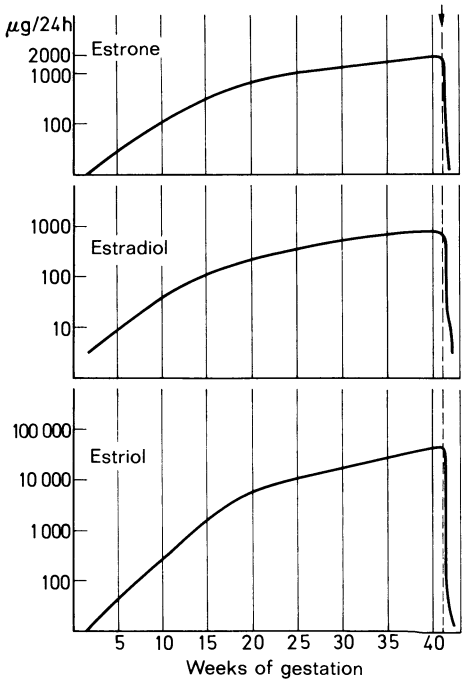

Fig. 9. Excretion of estrone, estradiol and estriol during a normal pregnancy. (After original values from BROWN, 1956)

This is probably due to renal factors as mentioned above.

The physiologic importance of the enormous amounts of estrogens during pregnancy has not been fully explained. A primary factor may be the growth-promoting action on the uterus by increasing protein synthesis. Furthermore, it is known that electrolyte shifts at the cell membrane of the myometrial cell occur together with changes in membrane potential. These are important for contractility. Estrogens also have a considerable effect in the preparation of the organism for lactation (see p. 694).

e) Progesterone

The concentration of progesterone in the placenta also increases during pregnancy, reaching an average value of 1.9 mg/kg at term. This value is lower than concentrations found in earlier stages of pregnancy, but the total progesterone increases (Fig. 10). In contrast, the myometrial concentration rises throughout pregnancy. The secretion rate is estimated to be between 30–250 mg/24 h in the first two trimesters and between 190–840 mg/24 h in the last trimester (SALOMON, 1962; TAUBERT, 1963; RYAN, 1966; ZANDER, 1967). A large amount of the progesterone reaching the circulation is stored in the adipose tissue.

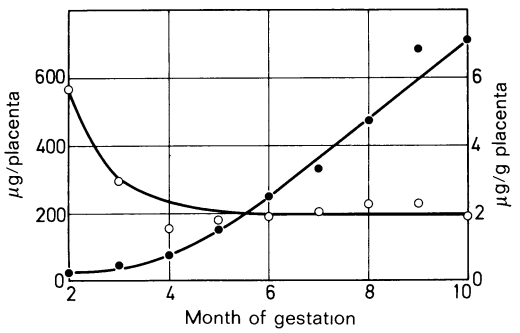

Fig. 10. Total amount of progesterone and progesterone concentration per g placenta during normal pregnancy; average of 80 estimations. (After ZANDER, 1956)

The level of progesterone in maternal blood also rises considerably. Values lie between 5 and 7 µg/100 ml plasma in the first trimester, between 2 and 10 µg/100 ml in the 2nd trimester, and between 4 and 36 µg/100 ml plasma in the last trimester (SHORT, 1959; 1962; VAN DER MOLEN, 1963; AITKEN, 1958). The highest concentrations are found in retro-placental blood and in the umbilical vein. In the umbilical artery, there is a predominance of progesterone metabolites, hydroxylized at positions 20 and 17. These metabolites have a less pronounced progestational action (see p. 674).

As in the non-pregnant state, pregnanediol, principally in the glucuronidized form, is the most important excretory product of progesterone (see p. 674). Excretory values rise from 4–8 mg/24 h at the beginning of pregnancy to 20–80 mg/24 h at term (Fig. 11).

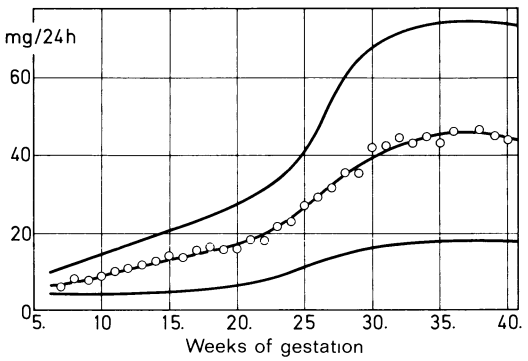

Fig. 11. Pregnanediol excretion in urine during normal pregnancy, average and normal 95% range. (After SHEARMAN, 1959)

The physiological significance of progesterone and its metabolites in the human also remains obscure. On the basis of animal experiments, it is assumed that their primary function is to preserve pregnancy by maintaining uterine relaxation despite neurohypophyseal influences (see p. 692). Furthermore, together with estrogens, they play an important part in preparing the maternal organism for birth and lactation (see p. 694).

f) Androgens and Corticosteroids

As was seen in the description of the formation and metabolism of placental steroids, androgens are important as intermediate products in the biosynthesis of estrogens. This is especially applicable to dehydroepinandrosterone and androstenedione. Adrenosterone and 11β-hydroxyandrostenedione have also been demonstrated in umbilical blood (ZANDER, 1962). Cortisol can be found in the placenta and in umbilical blood (NEHER, 1961). There is no doubt that the fetal adrenal cortex is capable of forming cortisol from progesterone, and possibly from acetate, even in the first half of pregnancy. The cortisol so formed reaches the placenta and the maternal circulation. On the other hand no definite evidence of direct biosynthesis in the placenta has yet been produced (DICZFALUSY, 1964). This is also true of other corticosteroids, although it is possible to isolate small amounts of aldosterone from the placenta (BERLINER, 1956).

2. Feto-Placento-Maternal Hormone Exchange

The maternal and fetal compartments and the placenta form an endocrine unit which can only be understood as a whole, especially in relation to the steroid hormones (Scheme 3).

Maternal protein hormones as a rule do not pass through the placental membrane into the fetus, or only in minute amounts. Potent amounts of TSH and ACTH are hardly likely to reach the fetal circulation (TOROK, 1951; KNOBIL, 1959). The same applies to HGH (GITLIN, 1965; LARON, 1966). HCG can be demonstrated but its concentration in the fetus is significantly lower than that found in maternal blood and tissues. HPL is found virtually only in the placenta and the maternal organism. Insulin does seem to pass the placental barrier to some extent, but concentrations in umbilical blood are substantially lower than those in the mother (JOSIMOVICH, 1961).

Hormones from the thyroid gland and corticosteroids (MIGEON, 1956) reach the fetus only very slowly (GRUMBACH, 1956). The clinical improvement observed during pregnancy in patients with Addison's disease has led to the conclusion that these steroids may also be liberated from the fetus and pass to the mother. There is no doubt that large amounts of androgens can be transferred to the fetal circulation, where they can result in virilization of the female fetus.

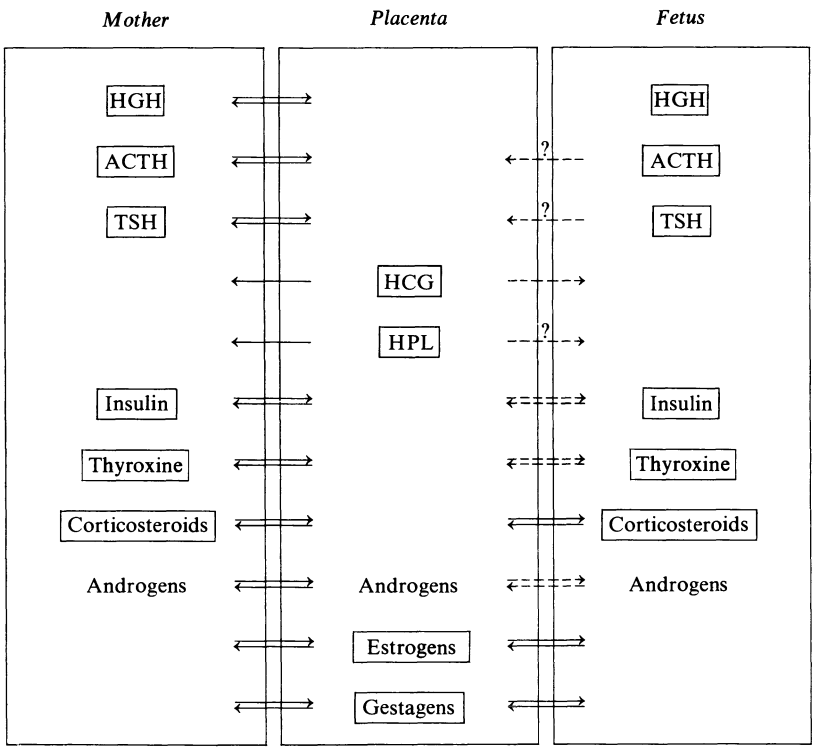
Relationships between the remaining sexual steroids are considerably more complicated. These hormones have been described in section C. Estrogens and progesterone circulate freely between the fetal, placental, and maternal compartments. Since the placenta is capable of producing progesterone independently but cannot form any significant amounts of estrogens, particularly estriol itself, this exchange has a very important effect on the biosynthesis of steroids. The fetal compartment contains precursors of estrogens, such as dehydroepiandrosterone and is also capable of 16-hydroxylation. Steroids are generally present in the conjugated form in the maternal and fetal systems and in the free form in the placenta.

3. Function of Other Endocrine Glands during Pregnancy

a) Hypophysis

Placental steroids inhibit gonadotropin production of the adenohypophysis during pregnancy (PHILIPP, 1930; BETTENDORF, 1966). Recently, however, there has been radio-immunological evidence of FSH-activity in the serum so that some reservation is still indicated before

Scheme 3. Simplified representation of the feto-placento-maternal hormone exchange



a definite conclusion is possible. Formation of TSH, ACTH, HGH, and MSH as a whole may be increased, as suggested by the intensive activity of the thyroid gland, enlargement of the adrenal cortex, and the acromegalic features occasionally observed. The exact extent of the increase in prolactin formation (see p. 674) during pregnancy is not known. Similarly, no definite facts can be given about the function of the neurohypophysis and the secretion of vasopressin and oxytocin during pregnancy.

b) Ovary

The corpus luteum of pregnancy is capable of producing both estrogens and progesterone from cholesterol. The average progesterone concentration is about 12 μg/g. Lutein cells may also produce active androgenic hormones and, in rare cases, hyperplasia of these cells gives rise to transitory virilization.

The hormonal function of the corpus luteum may be involved in the preservation of pregnancy in the early months. In the human, the trophoblast is capable of synthesizing adequate amounts of progesterone at a very early stage. In certain types of animals, such as the cow, rabbit, and rat, in contrast, the corpus luteum is essential for the preservation of pregnancy.

c) Adrenal Cortex

The levels of 17-hydroxycorticosteroids in the plasma rise during pregnancy (GEMZELL, 1953). It is not certain how far this rise can be attributed to increased function of the maternal adrenal cortex. As has been mentioned above, the clinical improvement in patients with Addison's disease during pregnancy suggests that the fetus, or less probably the placenta, is actually involved in the production of corticosteroids.

The level of cortisol also rises, but this is probably mainly because estrogen induces increased binding to a plasma globulin called transcortin (SANDBERG, 1959). This results in extension of the biological half-life, with a resultant rise in the total amount of cortisol. Since cortisol bound to transcortin appears to be biologically inactive, no clinical signs of hypercorticism normally appear during pregnancy. No cortisol can be demonstrated in women with adrenocortical insufficiency, and extra-adrenal sources therefore appear to have no measurable effect (BAULIEU, 1957).

Production and secretion of aldosterone are also increased by as much as ten times during pregnancy (VAN DE WIELE, 1960; STARK, 1963). This rise fails to occur in women who have undergone adrenalectomy (LAIDLAW, 1958), so that it can be assumed that the maternal adrenal cortex is the chief producer of aldosterone in these cases as well.

An adrenal cortex with absolutely intact function is not essential for conception and the preservation of pregnancy. Pregnancy can continue to term without complications even in women with clinically manifest hypofunction.

d) Thyroid Gland

The thyroid gland increases considerably in size during the course of pregnancy and more thyroxine is formed (FREEDBERG, 1957). The concentration of thyroxine in the plasma also rises, but as in the case of cortisol, this rise is primarily due to an estrogen-induced increase in the binding of thyroxine to plasma proteins.

Severe hypo- and hyperfunction of the thyroid gland can have only negligible effects on pregnancy since sterility is present in most of these cases.

4. Hormonal Effects on the Maternal Organism

The enormous production of sexual steroids and protein hormones by the placenta leads to a series of changes in the genital and extragenital regions, which are directed partly at metabolic adjustment to pregnancy and partly at preparation of the organism for birth.

a) Uterus

The weight of the uterus increases 12 to 20 times and its internal volume increases 600 to 800 times (CRETIUS, 1967). The increase in size is due mainly to hypertrophy of muscle cells already present, and less to hyperplasia, which is only of importance during the early stages of pregnancy. Muscle cells may undergo a tenfold increase in length. Animal experiments have shown that the effects of estradiol are virtually limited to hypertrophy, estradiol and progesterone together have a hyperplastic action, and progesterone alone has practically no effect (BRODY, 1961). Thus, hormonal regulation of uterine growth appears to be complex. There is an accumulation of contractile proteins in the myometrium and the energy donors, such as ATP, creatine phosphate and glycogen, increase under the influence of estrogens. The ionic content is subject to displacement, which is partly responsible for the motility of the uterus and is most probably also due to the action of steroids (see p. 692). The myometrial

water content increases, resulting in a rise in tissue fluid.

The vascular system of the uterus also shows characteristic changes. The spiral arteries become stretched and widened and there is a true increase. The vessel walls become hypertrophic. Vascularization rises from 50 ml/min to 500–750 ml/min (CRETIUS, 1967).

The mucosa of the body of the uterus is converted from the secretory stage into the true decidua, mainly under the influence of progesterone and the synergistic action of estrogens. The decidua thickens very quickly and is differentiated into the superficial stratum compactum and the stratum spongiosum lying beneath. Thus, there is extensive enlargement of the glands, which also show signs of increased secretion, and the interstitial tissue is considerably displaced.

The same hormonal influences produce changes in the cervix. The connective tissue becomes loosened, and vessels increase in number and size. Hyperemia of the venous network presents clinically as lividity. Cervical glands proliferate internally, branch, and penetrate into the connective tissue. They secrete thin clear mucus which does not usually show the arborization phenomenon on drying.

b) Vagina

As in the cervix, the tissues in the vagina become looser, which helps to ease the process of birth later on. Width, length, and distensibility increase, vascularization becomes more marked and the veins become dilated. The thickness of the vaginal epithelium increases, principally under the influence of estrogens. The intermediate layer in particular becomes thicker. Desquamation of cells is accelerated and vaginal secretion is increased. Cells in the vaginal smear are predominantly from the intermediate layer.

Vulva, perineum, and pelvic floor show similar signs of loosening.

c) Mammary Glands

Hormonal preparation of the mammary glands for lactation is dealt with in Section G.

d) Skeleton

All joints in the pelvic region become softened during the course of pregnancy under the influence of the sexual steroids. Changes are most marked in the symphysis, which becomes several millimeters wider. These processes can also be considered to be directed mainly at easing the birth. It is not clear at present to what extent other factors, for example relaxin (see p. 678) are involved in this process.

e) Skin

The skin also shows a series of changes in pregnancy, some of which are due to the action of hormones. Accentuated pigmentation is seen in 75% of women towards the end of pregnancy, especially in the regions of the breasts, linea alba, vulva and perineum. This may be quite pronounced in brunettes. Yellow or brown patches often form on the face. This is termed chloasma. These changes are due to the action of estrogens and possibly also to the increased release of melanophoric-stimulating hormone (MSH) from the adenohypophysis. According to ROTHMAN (1954), progesterone is able to activate this hormone and possibly also the melanocytes directly.

Striae gravidarum are observed in many pregnant women, particularly on the abdomen, but also on the breasts and buttocks, and can be attributed to mechanical over-distension as well as to constitutional predisposition and the action of corticosteroids.

Vascular changes are quite common and can take the form of teleangiectatic, spidery vascular patterns on the legs, upper arms and occasionally the face. These may be due to the action of estrogens.

f) Gastrointestinal Tract

Peristalsis is often reduced in the early months of pregnancy. There is a tendency to constipation. Progesterone may be of importance as well as parasympathetic adaptation, since it generally reduces the tone of smooth muscle. Similar features have also been observed in the gallbladder, the ureters, and the renal pelvis.

g) Water Balance

Estrogens cause retention of sodium and water and increase vascular permeability. As in the premenstrual phase, they act with progesterone to produce loosening of the tissues, and the extracellular fluid increases by 2–4 liters. About two thirds of this amount are found in the interstitial tissue space where the water-binding capacity increases. Thus, even in normal pregnancy, there is an increased tendency to edema.

h) Basal Temperature

The basal temperature (see p. 567) remains in the hyperthermal region for 3–4 months after the onset of pregnancy. This is due to the action

of progesterone. The temperature later falls despite the steady increase in the production of progesterone. The reasons for this are unknown, but the temperature remains low until birth occurs. Absence of menstruation in the presence of a raised temperature on waking generally suggests early pregnancy.

E. Pathology of Pregnancy

1. Abortion

a) Terminology

Abortion or miscarriage signifies the premature termination of pregnancy during the first 22 weeks. The fetus is usually not viable. A distinction is made etiologically between spontaneous, legal therapeutic, and criminal abortion. Mild bleeding with an undilated cervical canal is termed threatened abortion. When the cervical canal begins to dilate, the abortion is incipient and can usually no longer be prevented. The products of conception are subsequently either partially or completely expelled, i.e. the abortion is incomplete or complete. During the early weeks of pregnancy, this process occurs in one stage. Later, it occurs in two stages, as at birth, with expulsion of the fetus first, followed by the placenta. Occasionally, the rejected fetus is retained and the abortion is then termed a missed abortion. If three or more abortions occur in succession, the term habitual abortion is used. An abortion can be complicated by fever and bacterial invasion of the tissues, especially after illegal intervention, resulting in a febrile or septic abortion.

b) Frequency

Abortion, which is most frequent during the 2nd and 3rd months of pregnancy, is one of the most important complications of pregnancy. Exact statistical data are difficult to obtain since the number of clinically undetected cases remains unknown. It is generally estimated that about 10% of the total number of pregnancies end in spontaneous abortion. Illegal abortions are, however, much more significant since they are estimated to be up to four times more frequent than spontaneous abortions on average, depending on the country. The frequency of habitual abortions is very low and its incidence is estimated as one in every 300 to 400 births (KÄSER, 1961).

c) Pathogenesis

Pathogenic factors causing abortion can be divided into maternal and fetal factors. In the former group, intrauterine changes are of primary importance. Thus, malformations such as bicornuate uterus, abnormal positions, fixed retroflexion, fibroids, cervical incompetence or genital hypoplasia can be responsible for an abortion. Infections in the mother, severe generalized ilnesses, accidents, toxic states, and even psychological factors are also of significance.

Among the fetal causes, abortive ova are particularly important. Malformations of the embryoblast and trophoblast are often combined. According to HERTIG (1949, 1956), malformations can be demonstrated in 50% of young ova not implanted. Even after implantation, malformations are found in 35%. Chromosomal aberrations are of considerable importance as an etiological factor and can be found in 20–25% of early abortions (KERR, 1966). Trisomics, X-monosomics and triploids are particularly common. Sperm anomalies are probably also important. According to JOEL (1962), highly pathologic spermiograms are found in 5.8% of cases of habitual abortion.

The part played by endocrine factors is still difficult to assess. Most of the changes demonstrated in the hormonal pattern could be of secondary nature and could be an expression of damage to the trophoblast or embryoblast or both. Falls in the levels of HCG, HPL, estrogens and progesterone also permit of this interpretation. Nevertheless, it is still assumed that a hypofunctional corpus luteum graviditatis during early pregnancy, insufficient preparation of the uterus through sexual steroids, and thyroid activity may be of significance.

d) Methods of Diagnosis

Abortion is diagnosed primarily by clinical means. However, hormonal diagnostic methods can be of additional use since in doubtful cases information on the state of the trophoblast may be obtained.

Estimation of chorionic gonadotropin in the plasma and urine is most important. Almost normal titers are characteristic of an imminent abortion as long as pregnancy is still intact. The prognosis is favorable if the HCG value is normal. If considerable damage has already occurred in the trophoblast, the HCG titer is extremely low (Fig. 12). Values below 1000–2000 IU HCG/l urine at the time of the physiological maximal excretion, between the 7th and 12th weeks of pregnancy, suggest that conservative treatment is useless. The titer is also quite low in comparison to the duration of amenorrhea in missed abortion. Surviving placental tissue can, however, still result in positive pregnancy tests for some time.

The excretion of estrogens and pregnanediol is also reduced in cases of abortion. The practical significance of such measurements is limited in contrast to results obtained in the 2nd and 3rd trimesters.

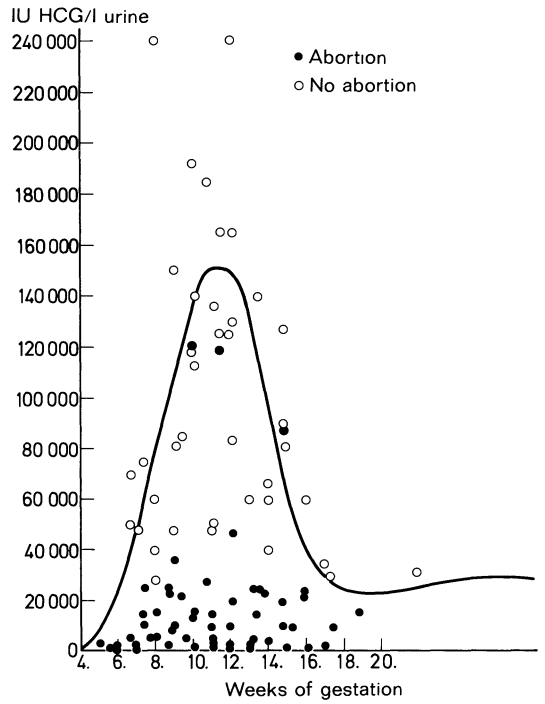


Fig. 12. HCG excretion in urine in cases of imminent abortion with favorable and poor prognosis (immunochemical assay). The curve corresponds to average normal excretion. (After KELLER, 1966)

e) Treatment

Treatment of an abortion with hormones is, of course, only indicated if the pregnancy is still intact, i.e. in a case of threatened abortion. Hormones can also be used prophylactically in habitual abortions and occasionally where pregnancy is exposed to extreme risks or during surgery. Gestagens in high doses are used in these cases, sometimes in combination with estrogens, in the hope that they will have a favorable effect on the endometrium and cause the myometrium to relax (see p. 691). The effect of such measures is, however, still doubtful. Numerous drugs can be used, but care must be taken to ensure that steroids with intrauterine virilizing effects are avoided. Allylestrenol (Gestanon) can be particularly recommended for oral use. It is a very potent gestagen which is thought to have a placentotropic action. A dose of 15–30 mg daily, divided into three doses should be taken for about a week in a case of threatened abortion. In habitual abortion, 5–10 mg must be given daily as a long-term treatment as soon as possible after menstruation is missed. This treatment should be continued for several weeks over the critical point, i.e. to the time at which previous pregnancies were lost. Progesterone can also be given intramuscularly, for example as Lutocyclin in oily solution or crystalline suspension. The daily dose should be between 25 and 100 mg in a case of threatened abortion. If the crystalline suspension is used, weekly injections can be given. Intramuscular injections of 250 mg 17α-hydroxyprogesterone capronate (Proluton-depot) every 2nd or 3rd day have proven very satisfactory. This compound can also be used in combination with an estrogen, for example estradiol valerianate in the form of Gravibinon. 1 ml of this drug (250 mg 17α-hydroxyprogesterone capronate, 5 mg estradiol valerianate) should be given daily over a week in threatened abortion. 2 ml weekly are sufficient in later stages and in cases of habitual abortion, where treatment must start as soon as possible and be continued long after the period which is critical in each case individually.

General management and strict bed rest are even more important than all therapeutic hormonal measures. Spasmolytics such as benzodiazipines (e.g. Valium) can be used as a supportive measure. Surgical procedures such as cerclage can be considered for cervical incompetence. Success of this treatment is often difficult to assess and depends on the pathologic factors already described.

2. Extra-Uterine Pregnancy

In an extra-uterine pregnancy the fertilized ovum becomes implanted outside the uterine cavity. The most common sites are the ampullary and isthmus of the tube. Formation of folds after specific or nonspecific inflammatory processes, a diverticulum, endometriosis and possibly also impaired motility of the tubes are pathogenic factors coming into consideration. The incidence of extra-uterine pregnancy is calculated as one in every 100 pregnancies.

Due to lack of space, developmental disorders usually arise very early with rupture of the fetal membranes. If the membranes rupture inwards tubular abortion occurs, while outward rupture of the membrane results in tubular rupture, which is much more dangerous and potentially fatal.

The diagnosis is made clinically, but hormonal investigations can occasionally be of use. Since the placenta is relatively small and there is also placental damage at the time clinical symptoms arise, the HCG level in the

serum and urine is usually considerably reduced (Fig. 13). Conventional pregnancy tests are therefore often negative.

Surgery is usually necessary.

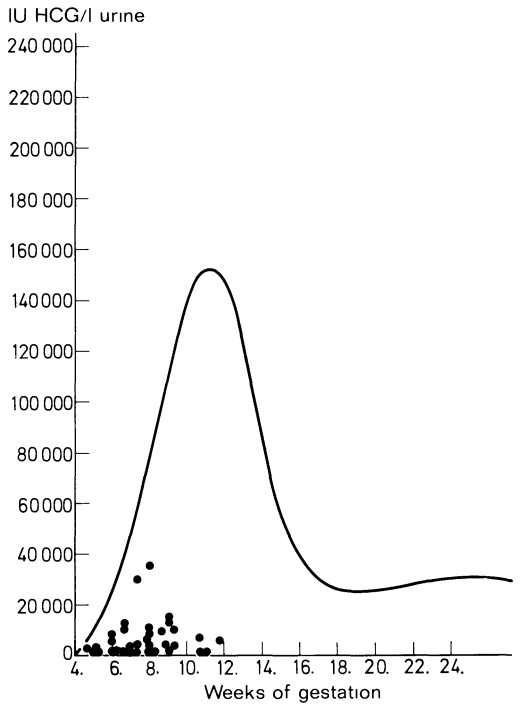

Fig. 13. Urinary HCG excretion in extra-uterine pregnancy (immuno-chemical assay). The curve corresponds to average normal excretion. (After KELLER, 1966)

3. Toxemias of Pregnancy

a) Hyperemesis Gravidarum

This condition is observed from the 2nd to 4th months of pregnancy and is therefore also termed early toxemia. Vomiting, often independent of the time of day and intake of food, is the dominant feature. This can cause electrolytic and metabolic disorders with adynamia, dehydration, weight loss, and tendency to syncope. The etiology is not clear, although psychological factors certainly play a part.

There is some controversy about the extent of endocrine involvement. HCG values are generally slightly increased. Since hyperemesis also commonly occurs in cases of hydatidiform mole with excessive HCG production, a certain connection is conceivable. Corticosteroid production and excretion are reduced, but the adrenal cortex responds fully to ACTH (STAEMMLER, 1956). Because of this, relative central adrenocortical insufficiency used to be considered a pathogenic factor, but even today, no definite pronouncement can be made about which of these changes are merely of secondary nature.

Environmental changes and psychological support are often the primary measures of treatment and can be obtained by admission to hospital. Sedatives can be of additional help. Antiemetics can be useful, but a certain amount of caution is necessary as a rule during the period of organogenesis. It is important, therefore, to treat the metabolic disturbance with infusions of adequate amounts of fluid, saline, and glucose. Later, a nourishing, easily digested diet can be considered. There is still no proof of any benefit obtained from treatment with hormones such as ACTH and corticosteroids. With correct treatment, the prognosis for the further course of pregnancy can be considered favorable.

b) Toxemia in Late Pregnancy

Toxemia in late pregnancy, also termed as EPH-gestosis, represents an exceptionally complex condition. Details can be obtained from textbooks of obstetrics. Clinical symptoms primarily include hypertension, proteinuria and formation of edema. The frequency of toxemia varies between 3.6% and 24.3% according to classification and region (FRIEDBERG, 1967). The rate is higher in primigravidas, especially those who are much younger or older than average, in multiple pregnancies, and in cases of hydatidiform mole. In severe cases, the features are characterized by tonic-clonic convulsions that progress into eclampsia, which is potentially fatal to mother and child.

There is still some controversy about the pathogenesis. Toxic, anaphylactic, endocrine, and metabolic factors have been considered. It is now generally assumed that uteroplacental ischemia may be involved. Animal experiments (OGDEN, 1940; BERGER, 1963) allow the conclusion that hypertensive substances may be liberated from the placenta in a manner reminiscent of the Goldblatt mechanism in the kidneys. It is also conceivable that this may cause constriction of the renal vessels with the result that angiotensin is released, causing a further rise in blood pressure. Adoption of any definitive attitude to these questions would be premature.

The primary pathophysiological finding is the generalized spasm of the arterioles, which leads to restriction of the circulation. Vascularization of the uterus and placenta may be considerably reduced, and the placenta may often show numerous infarcts of varying severity. In the kidneys, there are vascular constrictions and blocks in the region of the glomeruli. The glomerular filtrate may be greatly reduced, and

increased capillary permeability for plasma proteins may lead to proteinuria at the same time. Formation of edema is due to increased water and sodium retention in the interstitial space. The intravascular volume is diminished.

Endocrinological findings show that HCG values are discretely or quite markedly raised in the placenta (LORAINE, 1953), serum, and urine (LORAINE, 1950; VENNING, 1958). The renal clearance of this hormone can, however, be reduced in severe cases. The HPL level is normal in mild cases and often greatly reduced in severe cases (KELLER, 1970).

Estrogen values are reduced to varying degrees in the placenta, serum (RAY, 1963; RATANASAPA, 1967), and urine. In mild cases of pre-eclampsia, estriol excretion varies little from normal values, but in grave cases it falls considerably with no definite correlation between excretion and severity of the toxemia.

Placental progesterone is not greatly lowered (KUMAR, 1966), but its rate of production is not known. Normal or slightly reduced values are found in the plasma (SIMMER, 1959; COYLE, 1962). Pregnanediol excretion is only slightly pathologic in mild cases, but in contrast, may be grossly reduced in severe toxemia. The effect of restriction of the renal clearance has not been conclusively explained.

Aldosterone excretion is thought to be significantly lowered, possibly as a result of sodium retention. STARK (1963) gives an average value of 25 μg per day in comparison to 80 μg per day in healthy women at the end of pregnancy. The excretion of 17-hydroxycorticosteroids varies and allows no definite conclusions.

Dietary measures are the primary form of treatment of toxemia. Hypotensive drugs (Serpasil, Nepresol), sedatives (magnesium sulfate, barbiturates, phenothiazines), and diuretics (Hygroton, Lasix) can be used in severe cases. Details can be obtained from obstetrics textbooks.

The prognosis for severe toxemia is very poor when related to perinatal mortality. According to available statistics, fetal mortality is estimated at between 14 and 39% (FRIEDBERG, 1967) in eclampsia, and the mean maternal mortality between 4 and 6% (KYANK, 1963).

4. Rhesus Incompatibility

Rhesus immunization leads primarily to fetal damage. Placental changes can be considered secondary in nature. HCG values in the plasma and urine are occasionally found to be above normal limits. HPL titers have not so far been very characteristic. Estriol excretion is significantly lowered only in severe cases. Pregnanediol excretion is little changed, as is consistent with the findings above. Assessment of the fetal state is best done by means of spectral analysis of the amniotic fluid for the presence of biliary pigments.

Intra-uterine transfusions are now possible for the treatment of severe cases. Clinical improvement can be confirmed by a rise in estriol values in the urine (WYSS, 1970).

5. Multiple Pregnancies

The main result of a multiple pregnancy is an increase in the placental mass and total fetal weight. Production and excretion of HCG and HPL are correspondingly moderately raised. Elevated estriol (SCHWERS, 1968) and progesterone (SHORT, 1959) values are also found in the maternal plasma. Excretions of estriol and pregnanediol are generally within normal limits.

6. Prolongation of Pregnancy

The death rate in babies rises when pregnancy is prolonged by more than 10 days (MARTIUS, 1964). A higher incidence of placental infarction and impaired oxygen supply to the fetus can be observed. The causes of prolongation of pregnancy are obscure. In addition to individual variations, endocrine factors may also play some part, but the whole problem is still in a speculative phase (see p. 693).

According to ROSENKRANZ (1939), the estrogen and progesterone contents of the placenta are lowered in prolonged pregnancies. Plasma values are contradictory. Estriol and pregnanediol levels in the urine are normal or slightly reduced except in cases where there are manifest signs that pregnancy is impaired. Differentiation between true prolongation of pregnancy and biological postmaturity of the child is not possible in this way.

Supervision of a prolonged pregnancy is best done by physical means such as amnioscopy and cardiotocography rather than by diagnostic hormonal measures.

7. Fetal Malformations

Malformations, particulary anencephaly, are of special endocrinological interest. The fetal adrenal cortex shows pronounced hypoplasia in such cases. Growth is usually normal until the 20th week of pregnancy. Thereafter, the fetal zone undergoes atrophy or development comes to a stop. It is possible that HCG regulates the first phase of development, and that after

this, the hypothalamo-hypophyseal system is essential for normal development but is absent in the anencephalic fetus. It is not certain whether fetal LH (BENISCHKE, 1956) or ACTH (LANMAN, 1961) plays the crucial role.

The hypotrophic or atrophic adrenal cortex of these babies is unable to form the precursors necessary for the formation of estriol in the placenta (see p. 671), all of which must therefore be obtained from the maternal organism. It is thus not surprising that estriol excretion is usually extremely low. In contrast, placental function itself is more or less intact and progesterone production and pregnanediol excretion lie within normal limits (Fig. 14). The diagnosis can sometimes be suspected from this finding alone.

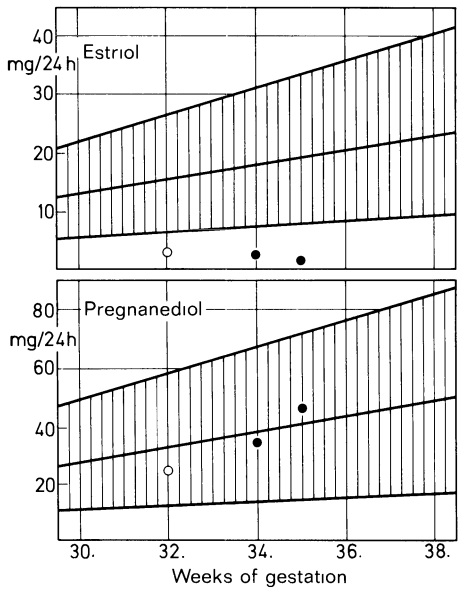

Fig. 14. Estriol and pregnanediol excretions in urine in anencephaly. The shaded zones correspond to normal 95% excretion limits. (After WYSS, 1970)

Other malformations usually produce no definite hormonal displacements. Estriol excretion can, however, occasionally be reduced in mongolism (MICHIE, 1967; WYSS, 1970), but it is not known whether hypoplasia of the adrenal cortex is involved.

8. Hydramnios

Placental function is usually not disturbed in hydramnios. Significant hormonal changes are found only in association with pathogenic anencephaly, diabetes, or multiple pregnancy.

9. Intra-Uterine Fetal Death

The placenta can sometimes maintain its endocrine function for a certain length of time after intra-uterine death of the fetus. Because of this, hormone values generally fall significantly more slowly than during the puerperium. Estriol excretion first falls within roughly 3 days to values below 200 μg/24 h. It then remains constant for some time since the placenta continues to receive estrogen precursors from the maternal organism, although in inadequate amounts. The mother probably also takes over the 16-hydroxylation required for placental formation of estriol.

Progesterone production can remain normal for days or even weeks, provided, of course, that there is no primary damage to the placenta. As a result, pregnanediol excretion in the urine also falls slowly. The same is applicable to the production and excretion of HCG and probably also HPL.

10. Hydatidiform Mole and Chorionepithelioma

a) Hydatidiform Mole

The hydatidiform mole is a benign malformation of the placental villi, which become distended in a characteristic manner (Fig. 15). A fetus is usually completely absent. It is a rare complication and an average frequency of 0.005–3.7% of all pregnancies has been calculated (HÖRMANN, 1965). Geographical distribution is important. For example, the hydatidiform mole is considerably more common in the Far East than in Central Europe.

Proliferation of the syncytioblast and cytotrophoblast in particular is a striking histological finding (Fig. 16). The stroma is swollen and edematous and contains few cells and vessels. Usually the whole placenta is involved in this change, but occasionally only individual sections are affected.

There is controversy about the pathogenesis of the hydatidiform mole. Developmental disturbances of the villous vessels (HÖRMANN, 1958), premature loss of the embryonal circulation, infections, etc. have been considered.

The hydatidiform mole usually becomes clinically manifest in the 3rd or 4th month. Often, a watery-sanguinous discharge is the first symptom and clear vesicles can occasionally be found in the discharge, confirming the diagnosis. The uterus is exceptionally large for the duration of amenorrhea. It is often of a doughy consistency. Heart sounds are absent and no fetal parts can be palpated.

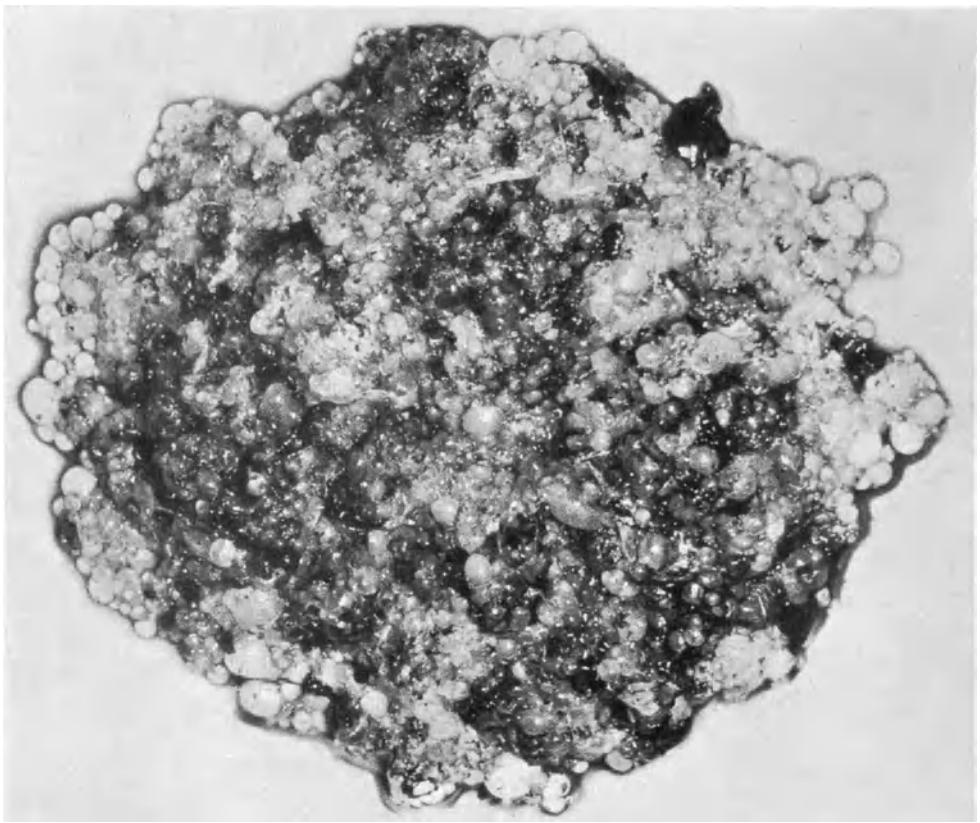

Fig. 15. Hydatidiform mole after expulsion

The hydatidiform mole is hormonally active and forms predominantly chorionic gonadotropin. The HCG titer is therefore greatly elevated in the mole itself as well as in the serum and urine (Fig. 17). The differences between the physiological excretion maxima are not sufficient to make a diagnosis, but values of 200000 to 2000000 IU HCG/l urine are evidence of a mole when pregnancy has reached the fourth month or beyond. Lower values, however, do not exclude a mole.

Production and secretion of HPL are usually greatly reduced in comparison to values found in a normal pregnancy of the same duration. The counteracting behavior of these two protein hormones can support the diagnosis.

The hydatidiform mole is probably capable of producing the same amounts of estrogens and progesterone as the normal placenta. However, estriol values in the urine are markedly reduced due to the absence of a fetus and thus an adequate supply of estrogen precursors to the placenta (FRANDSEN, 1964). Pregnanediol excretion lies within normal limits or is slightly lowered (STITCH, 1966; KAISER, 1953).

Probably due to the enormous production of HCG, bilateral lutein cysts, sometimes very large, are found in about 10% of cases. These cysts can also produce estrogens and progesterone and regress spontaneously after removal of the mole.

Treatment consists in surgical removal of the hydatidiform mole. This must be done very carefully and thoroughly. Frequent follow-ups with pregnancy tests are absolutely essential to avoid overlooking malignant degeneration into a chorionepithelioma. When the hydatidiform mole is completely removed, a negative result can be expected after two weeks at the latest. Otherwise at least semi-quantitative HCG estimations are necessary (see p. 699). The titer should continue to fall and any rise necessitates immediate thorough investigation.

b) Chorionepithelioma

The chorionepithelioma arises from malignant degeneration of the chorionic epithelium. It is very malignant, infiltrating locally and extending destructively. It metastasizes by way of the blood stream into the lungs and vagina. Microscopic examination shows proliferations of partly atypical chorionic epithelial cells of the

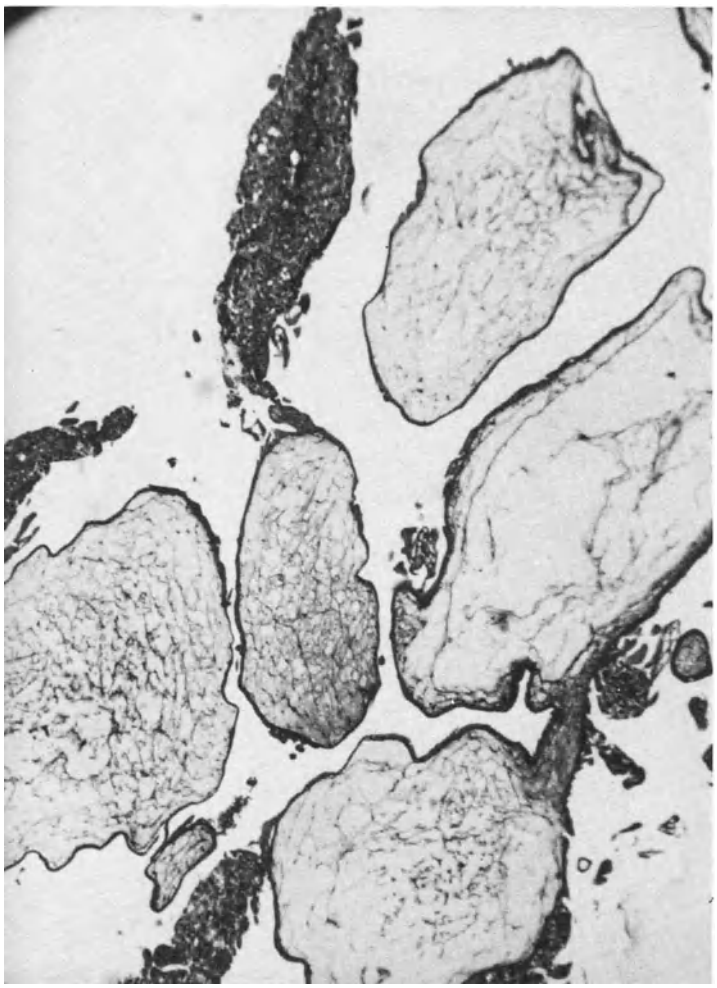

Fig. 16. Histological aspect of a hydatidiform mole

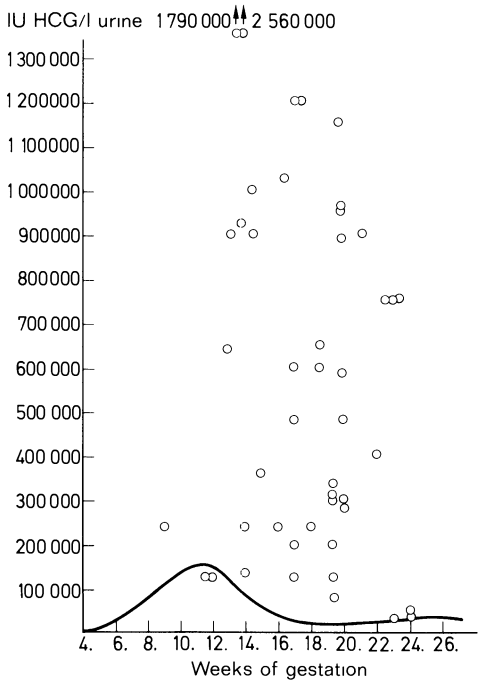

Fig. 17. Urinary excretion of HCG in hydatidiform mole (immuno-chemical assay). The curve corresponds to average normal excretion. (After KELLER, 1966)

syncytioblast and cytotrophoblast (Fig. 18). A more benign form, the chorionepitheliosis is thought to be distinguishable from malignant chorionepithelioma or choriocarcinoma (SCHOPPER, 1949) as the metastases present are not autonomous. Diagnosis by histological examination requires great experience.

The chorionepithelioma develops subsequent to a hydatidiform mole or abortion in about 40% of cases. In 20% it develops following a normal pregnancy (NOVAL, 1954). The latent period can be as long as 10 years. The frequency is one case in 8000–40000 pregnancies. There are strong regional variations, and like the hydatidiform mole, the chorionepithelioma is especially common in the Far East.

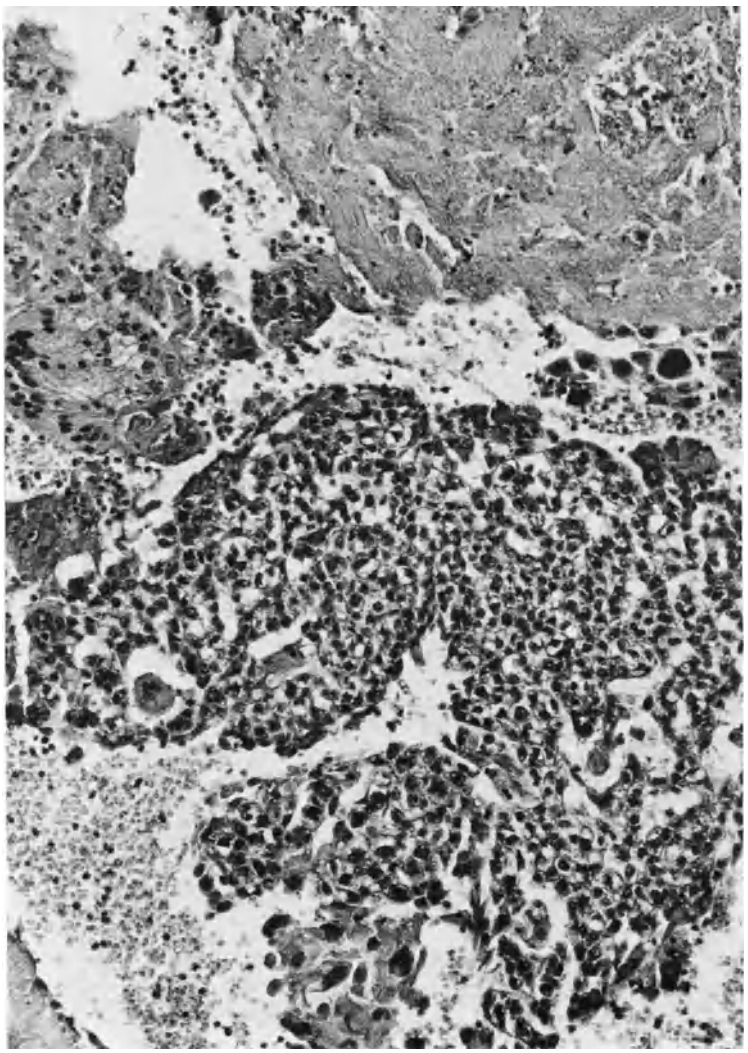

Fig. 18. Histological aspect of the chorionepithelioma

The hormone production is similar to that found with the hydatidiform mole. The formation of HCG, however, varies according to the differentiation of the tumor. Urinary excretory values are occasionally at the lower limits of sensitivity of the usual pregnancy tests commercially available. These values may, however, reach titers of 1 000 000 IU/liter. As in the case of hydatidiform mole, lutein cysts may also be observed.

Depending on the type, the chorionepithelioma is probably also capable of producing estrogens and progesterone. The irregular rise in the excretion of sexual steroids could, however, also be due to strong or mild stimulation of the ovaries by HCG.

Treatment lies mainly in the hands of specialists in oncology. In addition to surgical treatment, drugs, in particular aminopterin (Methotrexate), possibly in combination with other cystostatics (Leukeran, D-actinomycin), have recently been introduced into the treatment. HCG must be measured continually at each follow-up. Measurement of the excretion of estrogens and pregnanediol is of little practical value.

11. Hormonal Control of the Endangered Pregnancy

A short summary of the possibilities and indications of the usual present-day hormonal analyses used in monitoring an endangered pregnancy is presented below (Table 2).

Estimation of HCG is particularly suitable for controlling trophoblastic function in the

Table 2. Diagnostic significance of hormonal analysis in pathological pregnancies

	HCG	HPL	Estriol	Pregnanediol
Abortion	+++	+	−	−
Extra-uterine pregnancy	+++	−	−	−
Hyperemesis gravidarum	−	−	−	−

Plural pregnancy	−	−	−	−
Prolonged pregnancy	−	+	+	−
Fetal malformations	−	++	+++	++
Hydramnios	−	−	++	+
Intra-uterine fetal death	−	++	+++	++
Diabetes	−	+	+++	++
Hydatidiform mole	+++	+++	−	−

first trimester of pregnancy. HCG values are normal or only slightly reduced in cases of threatened abortion with a good prognosis. Greatly reduced values are generally found in cases with a poor prognosis. Low HCG titers are also characteristic of extra-uterine pregnancies. Values found in cases of hydatidiform mole and chorionepithelioma are usually slightly or excessively increased in comparison to those observed during a normal pregnancy.

HPL levels are low in cases of abortion where trophoblastic function is already impaired, in severe toxemia of pregnancy, and particularly with the hydatidiform mole. HPL is probably a measurement of almost pure placental function.

Excretion of estriol reflects placental as well as fetal function and is therefore especially suitable for early detection of fetal danger during the second half of pregnancy. Lowered values can be found as an expression of limited fetal production of precursors of estrogens in toxemia, diabetes, rhesus incompatibility, fetal malformations, and hydatidiform mole. Since individual values vary widely, estriol excretion must be measured regularly in endangered cases in order to recognize a fall as soon as possible.

Pregnanediol values again represent almost only placental function. The conclusive value is generally less than that obtained by measuring estriol; indications are roughly the same for both. In rare cases, however, placental insufficiency can first present as a reduction of pregnanediol excretion. On the other hand, the discrepancy between normal pregnanediol levels and low estriol levels in the presence of a living fetus can occasionally lead to the diagnosis of anencephaly.

In order to compensate for the disadvantage of true statistical methods of estimation, functional tolerance tests of the feto-placental unit using estrogen precursors, in particular dehydroepiandrosterone sulfate (DHA-S), have been suggested (Lauritzen, 1969; Van der Crabben, 1970). In the presence of intact function, intravenous administration to the mother results in 16-hydroxylation in the fetus with transformation into estriol in the placenta. As early as two hours afterwards, increased amounts of estriol are found in the plasma and urine. Important prognostic conclusions should be possible from the latent period and the degree of the rise. According to our experience, no binding conclusions can yet be made on this basis (Keller, 1970). In addition to hormonal diagnosis, amnioscopy, microanalysis of fetal blood, apparative registration of cardiac frequency, and analysis of the amniotic fluid now occupy a commanding position in supervision of the endangered pregnancy.

F. Hormonal Control of Birth

The causes of onset of labor have always been subject to numerous speculations. Spontaneous activity of the myometrium is directly influenced by four factors according to present-day knowledge – volume of the uterus, oxytocin, progesterone and estrogens. It must therefore be assumed that endocrine factors play a decisive role in the mechanism inducing birth. Details continue to remain uncertain for the time being, particularly in the human, and the whole concept is merely hypothetical (Fig. 19).

1. Steroid Hormones

There is particular controversy about the influence of estrogens on myometrial activity. In rats, ovariectomy results in considerable impairment of the process of birth or even complete arrest, while substitution with estrogens restores the normal process (Csapo, 1969). This suggests that estrogen deficiency would reduce uterine excitability and response. On the other hand, high doses of estrogens lead to premature birth in the same experimental animal (Csapo, 1969). The nervous response is also decreased in rabbits (Marshall, 1969). At the same time

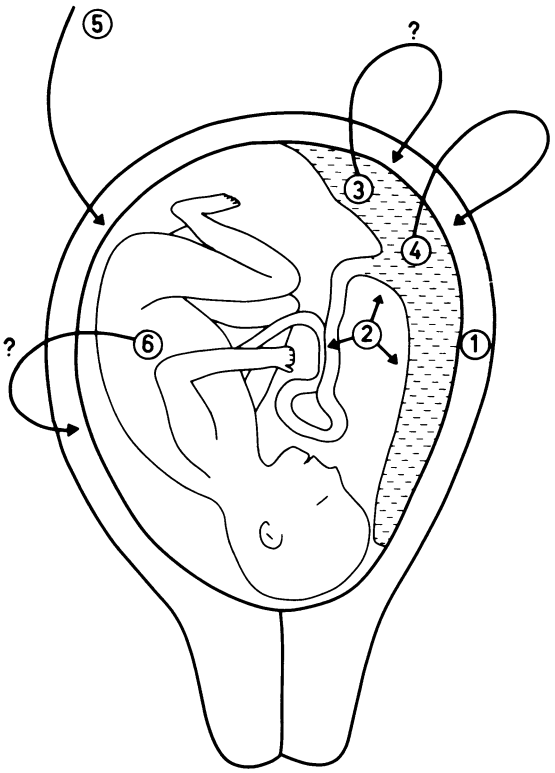

Fig. 19. Schematic representation of a few factors controlling induction of labor. *1* increase of myometrial activity, *2* internal uterine volume, *3* estrogens, *4* progesterone, *5* oxytocin, *6* fetal adrenal cortex

the membrane potential of the stimulation apparatus rises due to the increase in intracellular potassium ions.

The situation is more complex in the human. After intra-uterine death of the fetus associated with a massive fall in estrogen levels, labor does occur spontaneously after a varying interval, and contractions can also be induced without estrogen substitution. TURNBULL's findings (1967) are of interest. High estriol values and low estrone levels in the urine during the 34th week of pregnancy are claimed to be associated with early onset of labor, and low estriol levels and high estrone levels in the urine with prolonged pregnancies. According to these findings, estrogens may very well have a certain, but not necessarily essential influence on induction of labor.

More is known about the action of gestagenic hormones. In numerous animal experiments, progesterone suppressed neural excitability and uterine response to oxytocin, but this does not appear to be the case in guinea pigs (PORTER, 1969). In the woman, this blocking effect not only exists during pregnancy but even during the second half of the menstrual cycle. This is probably due to a displacement of the ionic distribution in the myometrial cells, with a shift of Ca ions in favor of Mg ions (COUTINHO, 1962).

These observations suggest that withdrawal of progesterone induces labor. In fact, PULKKINEN (1969) was able to show that the progesterone level fell in the blood before the onset of uterine contractions in legal abortion induced by intra-amniotic injection of hypertonic saline. Low values are also often found in spontaneous abortion. However, there is still no proof of a fall in progesterone levels prior to the onset of normal labor. CSAPO (1969) assumes that there is probably a state of equilibrium throughout pregnancy between the labor-promoting increase in uterine volume and the suppressive influence of the rising progesterone level, and that labor starts at term or prematurely when the ratio rises above a critical value.

2. Oxytocin

There is no doubt whatever that oxytocin can induce uterine contractions in women and animals. This hormone alone is not, however, the only factor responsible for induction of labor. This statement is supported by the facts that physiological doses of oxytocin do not induce labor during normal pregnancy, and that hypophysectomized women can have a normal labor.

During labor, the oxytocin titer in the plasma rises. This titer lies between 20–40 μ U/ml at the beginning of dilatation, which is no higher than in the non-pregnant state. When the cervix is dilated to about 5 cm, peak values of 2–4000 μU/ml are rapidly attained, and just as rapid a fall occurs within one hour after delivery (COUTINHO, 1962). Oxytocin must primarily be considered as a regulator of spontaneous uterine activity and not as a true inducer. Its action is dependent on adequate hormonal preparation. This can be demonstrated particularly well on the uterus of the menopausal woman, which responds to oxytocin only after appropriate preparation with sexual steroids. As mentioned above, progesterone and its influence on intracellular ionic relations are of primary importance.

The therapeutic value of oxytocin in the induction of labor and for weak contractions is of course not limited by these considerations.

3. Fetal Influences

From experiments with animals it has been recognized that corticosteroids can induce labor towards the end of pregnancy, particularly in cows and sheep (JÖCHLE, 1969). It is therefore

conceivable that the fetal adrenal cortex may have some effect in the induction of labor. In fact, extreme hypoplasia of the adrenal cortex results in prolongation of pregnancy in the cow. The same effect can be achieved in sheep by destruction of the hypophysis. As long as adrenalectomy is not performed at the same time, labor can be induced by intrafetal injections of ACTH (LIGGINS, 1967). In contrast, adrenocortical hyperplasia in goats produces a tendency to habitual abortion.

It is not known to what extent these findings can be applied to the human. Nevertheless, there is a tendency to prolonged pregnancy in anencephaly with extreme adrenal hypoplasia in the absence of hydramnios, whereas it has been found that the fetal adrenal cortex is markedly enlarged in unexplained premature births (TURNBULL, 1969).

G. The Postpartum Period

1. The Puerperium

With expulsion of the placenta the maternal organism loses the endocrine gland regulating pregnancy. Steroids as well as placental protein hormones disappear from the blood and urine very rapidly, as long as no placental tissue has been retained in the uterus.

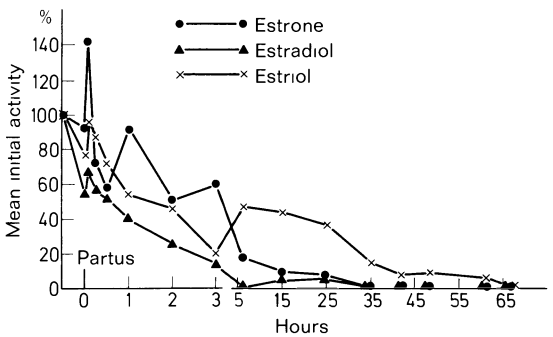

Fig. 20. Concentrations of estrone, estradiol and estriol in peripheral blood after expulsion of the placenta. (After ROY, 1963)

Estrogen levels in the plasma fall by 90% within one or two days (Fig. 20). Estradiol seems to disappear most quickly and is no longer measurable as early as 6 hours after the birth on average. Estrone takes 18–24 hours to disappear, and estriol about 42–60 hours (ROY, 1963). Urinary values of estradiol and estrone fall to normal non-pregnant limits within 2–3 days, and estriol excretion returns to normal within 7–8 days.

Progesterone also disappears from the maternal circulation within a few hours (Fig. 21), which is not astonishing in view of the extremely short half-life of about 5 min (SHORT, 1959). The level of the chief metabolite, pregnanediol, in the urine undergoes a steep fall during the first four postpartum days, followed by a more gradual decline. Non-pregnant normal values are reached within 6 days.

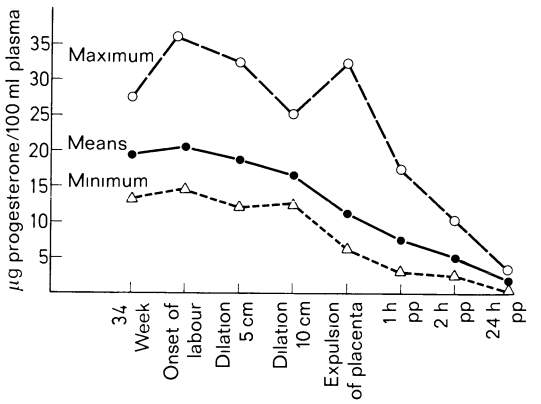

Fig. 21. Progesterone concentration in peripheral blood after expulsion of the placenta (gas chromatography). Average values and maximal deviation in 13 women. (After ZANDER, 1967)

The two most important placental protein hormones behave differently after birth. Plasma HCG falls by 50% within about 4 hours but small amounts are often still demonstrable after 10 days. Similar relations are found for urinary excretion, and the usual pregnancy tests are generally negative 1–2 days after, although they can occasionally remain positive for weeks.

In contrast, HPL disappears significantly more quickly, although hardly any is excreted in the urine and very high titers are present towards the end of pregnancy. This hormone is hardly demonstrable 3–4 hours after complete expulsion of the placenta (Fig. 22).

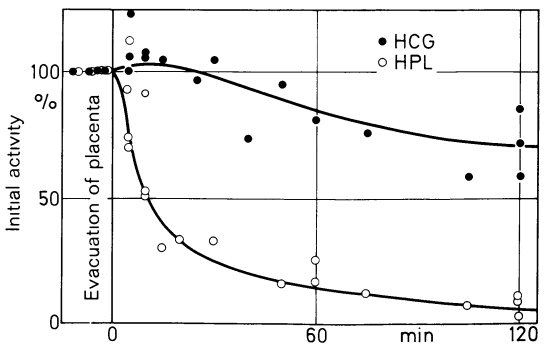

Fig. 22. HCG and HPL concentrations in the serum of 4 women after manual removal of the placenta (radioimmunoassay). (After KELLER, 1971)

Features of involution occur rapidly in parallel to these quick endocrine changes. The uterus regains its original form and size within 6 weeks, and after rejection of the decidua the normal endometrium regenerates within the same period of time. Changes in extragenital organs due to pregnancy also regress quickly.

2. Lactation

a) Anatomy and Physiology

The female mammary glands consist of 15–20 lobes separated from each other by connective tissue. Each lobe sends a lactiferous duct to the mamilla, where it dilates into the lactiferous sinus. The individual lobes are further subdivided into lobules which in turn consist of alveoli lined with *cylindrical* epithelium. In addition to the true glands, large amounts of adipose tissue are also present in the breasts. Smooth muscle is also found in the subareolar area and is responsible for erection of the nipples.

The breasts start to increase in size during the first trimester. The glandular tissue becomes more consistent, and the subcutaneous venous network and pigmentation become more marked. Microscopic findings are an increase and enlargement of the tubules and alveoli. There is no substantial secretion of milk but colostrum is formed.

After delivery, the so-called "rushing-in" of milk occurs during the first few days. The breasts become distended and are often tense due to intense hyperemia. All alveoli and discharging ducts are distended with milk. The normal mean daily production in both breasts together lies between 250 and 350 g one week after birth but can rise later to 1000 g.

During weaning, painful congestion is occasionally observed at first, but signs of involution soon appear. Numerous alveoli atrophy, so that a state almost identical to that prior to pregnancy is eventually achieved.

b) Hormonal Regulation

Lactation can be divided into four quite differently regulated phases; namely, mammogenesis (preparatory development of the breasts), lactogenesis (induction of milk secretion after delivery), galactopoiesis (maintenance of lactation), and finally, true ejection of milk during the act of suckling.

Hormonal preparation of the female breasts, *mammogenesis*, begins as early as puberty. The predisposed alveolar tissue develops under the influence of estrogens, and the lactiferous ducts begin to branch. HCG may also play a certain role at this stage of development. During pregnancy, the increasing amounts of estrogens produced lead to proliferation of the glandular ducts in particular. Progesterone results in further growth of the alveoli which continue to increase in number. HPL (see p. 670), corticosteroids, and thyroid hormones are probably also involved in the development (Fig. 23a).

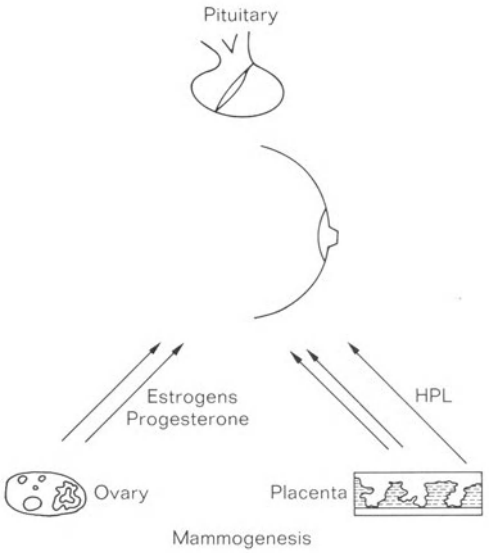

Fig. 23a. Hormonal regulation of mammogenesis

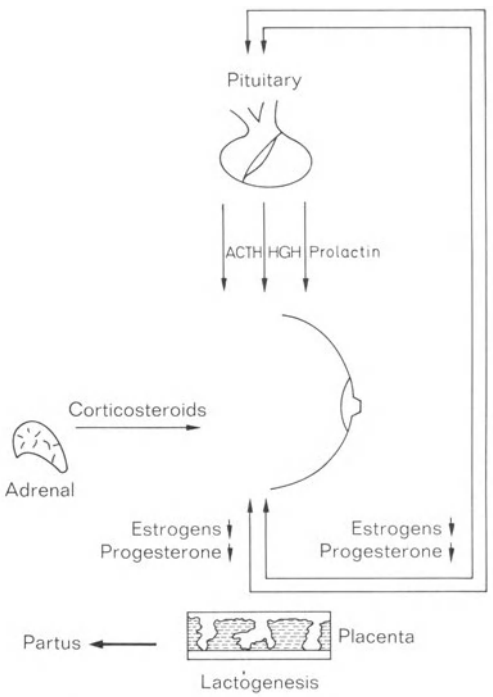

Fig. 23b. Hormonal regulation of lactogenesis

Induction of lactation, *lactogenesis*, is a very complex process (Fig. 23b). Loss of the high estrogenic and progesterone activity after expulsion of the placenta is a causal factor of primary importance. It is probable that during pregnancy these two hormones reduce the peripheral response of the alveoli to lactogenic factors and also inhibit the release of prolactin or other prolactin-like substances. Numerous experiments have indicated that prolactin certainly has a varying influence on lactogenesis, but its exact meaning in the human is still under investigation. Lactogenic, luteotropic and crop sac-stimulating properties, as well as the ability to act synergistically with estrogens to stimulate alveolar and tubular growth of the mammary glands, can also be attributed to purified HGH to an extent. Preparations with somewhat varying properties have been produced (see p. 674), and artefacts may be involved. However, there are other reasons to believe that prolactin and HGH exist in related but different forms in the human and that HGH at least is not essential for lactation. CANFIELD (1965) has shown that prolactin activity and HGH are increased during the phase of lactation and in galactorrhea in the absence of acromegaly. ROTH (1967) reported a marked rise in HGH activity and not in LTH activity after insulin-induced hypoglycemia. RIMOIN (1968) found that pregnancy and lactation were normal in cases of dwarfism with isolated HGH deficiency. PEAKE (1969) described a hypophyseal tumor in man, with LTH activity but no HGH activity. Lactogenesis is also dependent in some unexplained manner on corticosteroids and ACTH. Placental lactogen (see p. 670) is of little importance in this phase despite its prolactin-like action, because of its very rapid degeneration after expulsion of the placenta.

Galactopoiesis, the maintenance of milk secretion, is also dependent on various hormonal influences, particularly on prolactin, HGH, and TSH (Fig. 23c). Animal experiments have revealed that ACTH and corticosteroids are also essential (TALWALKER, 1961) and that corticosteroids probably also stimulate the formation of certain enzymes of the mammary glands. Estrogens and progesterone, on the other hand, have almost no effect in this phase. Ovarectomized women can breast-feed normally. Parathormone and insulin possibly also influence galactopoiesis but are not essential. Psychological factors, such as the stimulus from continual suckling, which probably influences prolactin secretion via neural paths, are of greater importance. Loss of these factors results very quickly in drying up of milk formation.

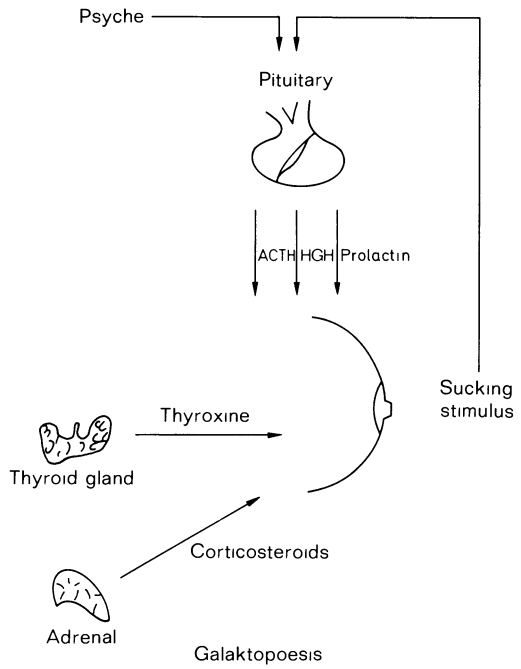

Fig. 23c. Hormonal regulation of galactopoiesis

True milk ejection during breast-feeding (Fig. 23d) is governed primarily by oxytocin which is released from the neurohypophysis through the suckling stimulus by means of a neurohumoral reflex arc. Oxytocin then causes contraction of the myoepithelial elements of the mammary glands (milk let-down effect). The necessary rise in intracanalicular pressure is mainly promoted by the chewing and sucking movements of the child. It is still not exactly

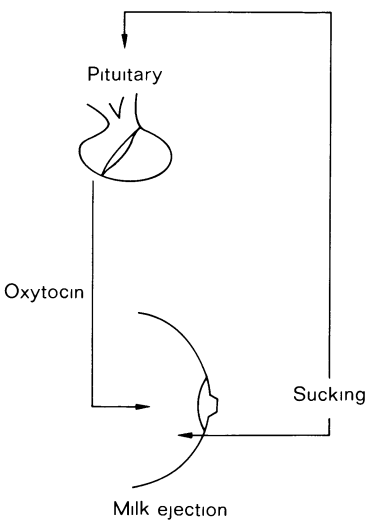

Fig. 23d. Hormonal regulation of milk ejection (Milk let down)

known whether oxytocin also exerts a central influence on prolactin release. Vasopressin may have effects vaguely similar to those of oxytocin.

c) Suppression of Lactation

When necessary, lactation can be suppressed by the administration of sexual steroids. Estrogens may be used alone or in combination with androgens or gestagens. Milk secretion already in existence can be inhibited in this manner, and induction of lactation can also be prevented if the hormones are used at the right time. Inhibition of prolactin secretion might have a considerable effect in suppressing lactation. The most potent lactation suppressing agent today with practically no side effects is 2-Br.-α-ergocryptine (FLÜCKIGER, 1968; BRUN DEL RE (in print)). It inhibits the release of prolactin from the anterior pituitary. 5 mg daily p.o. suffice to stop laction. (See also Chap. V, p. 83).

The following drugs also have proven satisfactory for the suppression of lactation before the onset of breast-feeding: ethinyl estradiol (Lynoral, Progynon M) in a dose of 0.2 mg for about 6 days, or diethyl stilbestrol (Oestremon) in a dose of 1 mg for 6 days. Estradiol dipropionate (Ovocyclin) in a dose of 10 mg can also be given intramuscularly for 2–3 days or 1 ampoule Ablacton (combination of 5 mg estradiol benzoate, 8 mg estradiol valerianate, 20 mg norethisterone acetate and 180 mg testosteronoenanthate) immediately after delivery.

Success is generally better, the earlier administration of drugs is started. Sometimes larger doses are needed in women who have already started to breast-feed, and individual response varies. An intramuscular injection of 10 mg Ovocyclin/day for 2–3 days or 1 ampoule of Ablacton can be recommended in these cases too. Supportive measures are restriction of fluid intake, supportive bandages for the breasts, cold compresses, laxatives and diuretics.

d) Pathologic Lactation

Deficient milk production (hypogalactia) or failure to produce milk (agalactia) may be due to anatomical and functional factors, such as hypoplasia of the glands, anomalies of the nipples, previous mastitis and weak suckling by the infant. Postpartum hypopituitarism (see p. 92) is the most common of the rare endocrine causes.

Hormonal treatment in deficient milk production is not very successful except in true disorders of milk output. In cases where the breasts are not very productive, oxytocin, for example in the form of an intranasal Syntocinon spray (4–5 IU) shortly before breast feeding, can be useful. Sublingual tablets are also available for the same purpose. The milk is expelled from the alveoli into the larger draining ducts under the influence of oxytocin, i.e. emptying is promoted. The amount of milk is thought to be increased at the same time.

Persistent lactation after weaning, as is seen in combination with amenorrhea and genital hypoplasia in the Chiari-Frommel syndrome (see p. 602), is another endocrine disorder of milk production.

Puerperal mastitis, the most common complication during breast feeding, is of no endocrinological significance.

3. The Menstrual Cycle

a) Physiology

With the loss of excessive steroids produced by the placenta, the adenohypophysis resumes the secretion of normal amounts of gonadotropins from about the 10th day after birth (KELLER, 1968). The time at which the first menstruation occurs, however, is extremely variable and depends, among other factors, on lactation. According to SHARMAN (1956), 91%

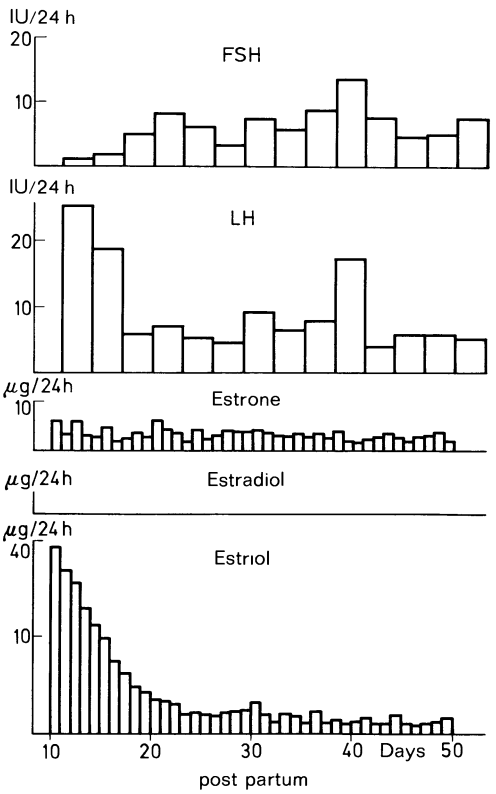

Fig. 24. Urinary excretion of FSH, LH and estrogens during lactation. (After original figures from individual cases of KELLER, 1968, and BROWN, 1956)

of women who do not breast-feed menstruate during the first three months after delivery, and only 33% of women who do breast-feed; the cycles are often anovulatory, especially when arising early. In the above investigations, it was found that the 42nd postpartum day was the earliest time at which ovulation occurred in the group of women not breast-feeding, and the 31st week in women who were breast-feeding.

The reasons for amenorrhea during lactation are not explained. The secretion of FSH and LH does not appear to differ much from that during the normal menstrual cycle, and a few LH peaks have even been observed (Fig. 24). In contrast, estrogen excretion remains very low after the puerperium and is still reduced even in the first ovulatory cycle (BROWN, 1956). From this it can be assumed that ovarian response to gonadotropic hormones is temporarily reduced.

There is no doubt that fertility is considerably reduced during the phase of lactation, but there is no absolute protection against conception since ovulation may occur occasionally during this time.

b) Pathology

Gonadotropic function of the anterior lobe of the hypophysis can occasionally be diminished for a long time following birth, so that a picture of secondary, usually hypogonadotropic amenorrhea arises. The prognosis is favorable on the whole.

Sheehan's syndrome due to postpartum hypopituitarism is a much more severe complication (see p. 91). It arises subsequent to delivery complicated by severe hemorrhage or collapse resulting in ischemic necroses of the adenohypophysis. Symptoms can vary widely, depending on the degree of destruction. In typical cases, gonadotropic as well as thyrotropic and adrenocorticotropic regulation are affected. Gonadotropic function seems to be the most sensitive. Agalactia, genital hypoplasia, amenorrhea, adynamia, pigmentation disturbances and loss of secondary sexual hair are early symptoms. Details of the later symptoms, diagnostic methods and therapy can be found on p. 93.

H. Endocrinological Methods of Investigations during Pregnancy

1. Pregnancy Reactions

Pregnancy reactions for the early diagnosis of pregnancy are now based almost exclusively on the qualitative detection of HCG. Special discussion is necessary since these tests, which can now be performed by any doctor in his own laboratory, offer considerable practical advantages over the quantitative methods of determination in technical simplicity and stability, reliability, and most of all the amount of time involved.

a) Biological Methods

Until recent years, only animal tests were available, and numerous different reactions were recommended during the course of time. The Ascheim-Zondek test proved particularly suitable. In this test the urine under investigation is filtered and injected into infantile mice at regular intervals. The result is positive if follicles develop after four days; these follicles show hemorrhages, which look like spots of blood, and corpora lutea. The hyperemic reaction in rats occurs more quickly (KUPPERMAN *et al.*, 1943). The urine is best administered intraperitoneally in infantile animals, and an obvious hyperemia can be seen in the ovaries as early as a few hours after injection in a positive case. The Friedman reaction in adult female rabbits is based on a similar principle. The urine is injected in the vein of the ear, and if adequate amounts of HCG are present, hemorrhagic follicles and corpora lutea develop 48 hours later. The animals can be used for further pregnancy reactions after the laparatomy.

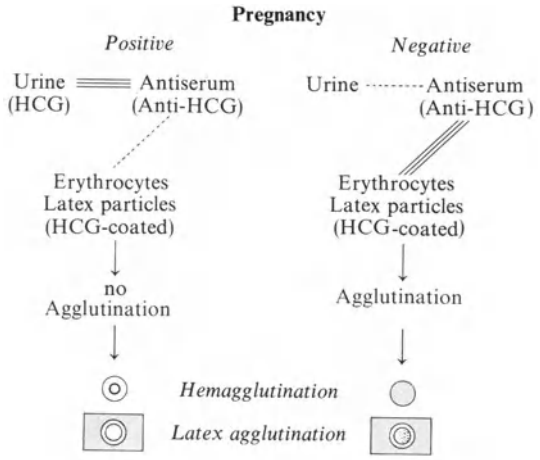
Finally, the release of spermatozoa by male amphibia can also be used as a pregnancy test, as in the Galli-Mainini reaction in sexually mature toads or frogs. The urine is injected into the dorsal lymph sacs of the animals. Then, urinary specimens are taken at short intervals from the cloaca and microscopically examined. Spermatozoa are found in positive cases.

All the reactions mentioned are highly reliable but most have been completely abandoned today in favor of the immunochemical pregnancy tests because of the costly expenditure of time and the problem of keeping the animals.

b) Immunological Methods

The agglutination-inhibition tests, based principally on WIDE's work (1960), are most frequently considered for practical purposes. The reaction involved is an immunochemical reaction between tanned sheep erythrocytes coated with HCG and a specific antiserum against HCG. Agglutination normally arises but is inhibited if HCG, for example in the form of pregnant urine, is added to the system. This results in binding of the antiserum available (Scheme 4).

Scheme 4. Principle of immunological pregnancy reactions



Latex particles coated with HCG can also be used instead of erythrocytes.

The Pregnosticon Test (N. V. Organon) is the most extensively used hemagglutination test and is commercially available. The ampoules contain HCG-coated erythrocytes, antiserum and the buffer substance in lyophylized form for this procedure. The test is performed as follows: an ampoule is opened, 0.1 ml filtrated urine from a morning specimen and 0.4 ml distilled water are added. The ampoule is shaken for a short while and put into a stand with a mirror (Fig. 25). The result is read after the system has been allowed to stand undisturbed for two hours. Inhibition of agglutination, i.e., a positive reaction, is expressed by the development of a marked red-brown sedimentation ring at the bottom of the ampoule. Agglutination is depicted by a diffuse carpet of erythrocytes (negative reaction) (Fig. 26). The sensitivity is about 1000 IU HCG/l, and positive results can be expected on average after the 22nd to 24th day following conception. The degree of accuracy is extremely high, but false-positive patterns can be observed occasionally if urine or glassware are contaminated with detergents or soap, or in cases where the luteinizing hormone is excreted in abnormally high amounts and cross-reacts with the HCG, as, for example, in certain endocrinopathies, early in the climacteric or at mid-cycle. False-negative results only occur with very low HCG values as in extra-uterine pregnancies and during the very early stages of pregnancy.

The latex-agglutination inhibition tests, such as Gravindex (Ortho) or Pregnosticon-Planotest

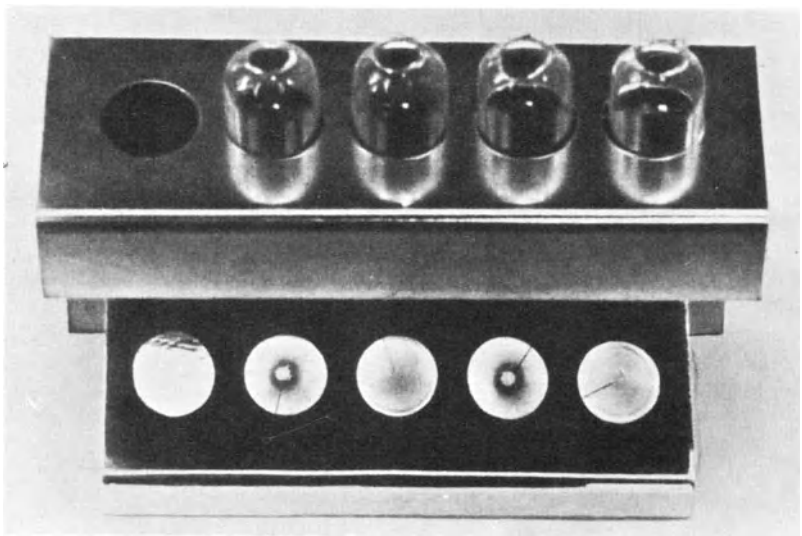


Fig. 25. Pregnosticon test. Stand with mirror and inserted ampoules

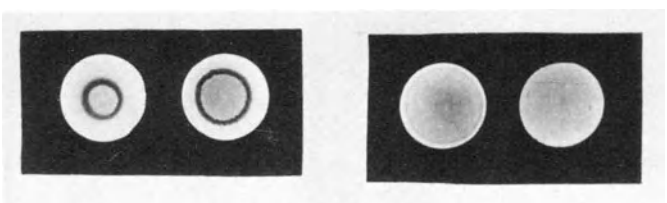

Fig. 26. Positive (left) and negative (right) hemagglutination test (Pregnosticon)

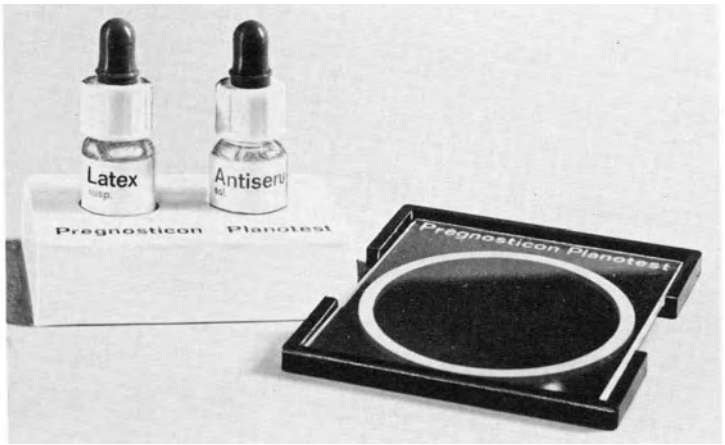

Fig. 27. Pregnosticon-Planotest. Microscope slide, small bottles with latex suspension and anti-serum

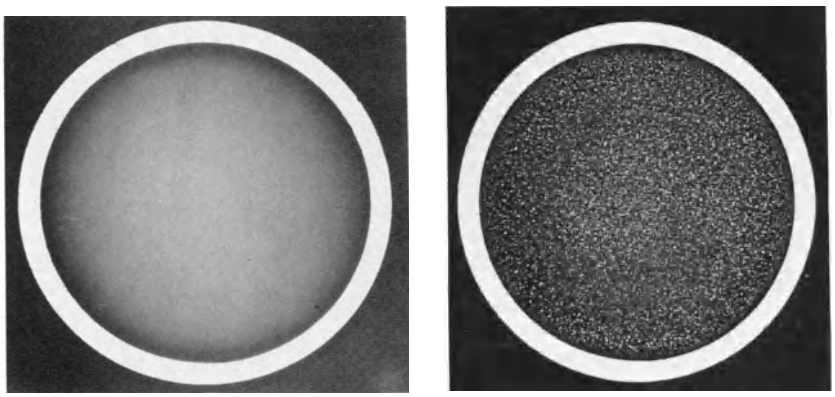

Fig. 28. Positive (left) and negative (right) latex agglutination test (Pregnosticon-Planotest)

(N. V. Organon), take even less time. In this procedure (Fig. 27) a drop of morning urine and a drop of antiserum are mixed together for 30 sec on a microscope slide with a ring drawn on it. A drop of latex suspension is then added, and the mixture is spread out to fill the size of the ring by means of a small plastic rod. The slide is tilted back and forth for 2 min to mix the substances. In a positive case agglutination is inhibited and the suspension remains milky and cloudy. In a negative case, agglutination of the latex particles occurs (Fig. 28). The sensitivity is about 3000 IU HCG/l, and positive results can be expected 24–26 days after conception. The degree of accuracy is also very good except in cases with very low HCG values, as in extra-uterine pregnancies.

2. Quantitative HCG Estimation

a) Biological Method

HCG is measured quantitatively on the basis of reactions not dependent on steroid influences. Increase in weight of the whole prostate or the ventral lobe (LORAINE, 1950; APOSTOLAKIS, 1958), of the seminal vesicles or of all the accessory sexual glands (DICZFALUSY, 1954) in infantile male rats has proved most satisfactory. The ascorbic acid-depletion test has also given good results (PARLOW, 1959), whereas the large number of other biological methods recommended are inferior in precision, specificity, and sensitivity. This is also applicable to the semi-quantitative method of the classic pregnancy reactions by means of dilution series. The results should always be given in IU for which the first and second international standard preparations were established in 1939 and 1954 respectively.

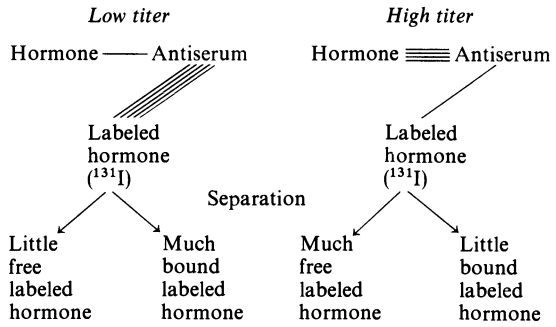
b) Immunological Methods

HCG in the urine can be measured semi-quantitatively with the hemagglutination and latex-agglutination tests described (see p. 697) by applying a corresponding dilution series to the urine under investigation. The titer searched for is calculated on the basis of the neutral point

of the last still positive dilution. This method is still of considerable importance in clinical work, for example, in diagnosing the hydatidiform mole.

A complement-fixation reaction for serum has been worked out by BRODY (1960), but it has aroused little practical interest. Chorionic gonadotropin is best and most reliably measured by radioimmunological methods. These procedures are based on competitive binding between HCG labeled with ^{131}I or ^{125}I and the HCG to be measured in the serum to a specific antiserum obtained from rabbits or guinea pigs. After an incubation period the bound fraction is separated from the free fraction by means of chromatoelectrophoresis, chemical, or immunological precipitation procedures, and the ratio can be determined by measurement of the radioactive impulses. If the HCG titer is low, then at a certain adjustment of the system, a large proportion of labeled HCG can be bound. If the titer is high, only a small amount of antiserum is still available for binding with the labeled hormone (Scheme 5).

Scheme 5. Principle of radioimmunological estimation of protein hormones



After an appropriate standard curve has been established, a very precise quantitative system can be constructed. This system is also extremely sensitive and is most suited for serum, whereas urine must be previously dialyzed and results obtained are less reliable.

3. Methods for Estimating HPL

a) Biological Methods

HPL cannot be uniformly tested biologically because of its various types of actions. The tibia test is the first test of importance and is also used for determining HGH, a closely related compound (see p. 123). Theoretically, the classical pigeon crop sac test (see p. 701) and the deciduoma test (see p. 701) can also be considered on the basis of the prolactin-like and luteotropic properties, but these methods are really of little use for the estimation of HPL.

b) Immunological Methods

In theory, HPL can be determined in the same manner as HCG; the method of choice is the radioimmunological technique (SAXENA, 1968). Separation of the bound and free fractions can easily be done by means of a charcoal-dextran system. Unfortunately, no international reference preparation is yet available, so that results must be given in equivalents of purified material.

4. Estimation of Estrogens

In theory, estrogens can be estimated by biological (see p. 547), chemical, and now also by immunological methods. For research purposes, numerous precise but costly and tedious methods are now available. The discussion below is limited to practical important methods for use with urine during pregnancy.

Estrogens can be measured as a whole; the methods after JAYLE (1959) and ITTRICH (1958) are particularly suitable for this purpose. JAYLE'S method entails enzymatic hydrolysis, conversion of the estrogens into their methyl ether, and colorimetric estimation by means of the Kober reaction. ITTRICH'S method involves extracting the Kober chromogens with p-nitrophenol and then measuring them by fluorimetric means.

For practical purposes the shorter modification after BROWN (1963) has also proved suitable. The urine is hydrolyzed with acid, extracted with ether and sodium hydroxide and incubated with dimethyl sulfate. Further purification is achieved by oxidation with $KMnO_4$ and extraction with benzol. The Kober reaction is then carried out directly with sulfuric acid and hydroquinone and colorimetrized at 465, 515 and 565 nm. The procedure does not necessitate any special apparatus and is very reliable for measuring high concentrations of estriol. With some modifications and the use of an extractor, the method can be done semiautomatically (BROWN, 1968). If the necessary apparatus is available, estriol can also be measured quickly and reliably by means of gas chromatography.

5. Estimation of Pregnanediol

In addition to estrogens, progesterone is also of practical interest during pregnancy. Determination of serum progesterone is for the time being restricted to experienced centers, so that

routine investigation is usually limited to the measurement of pregnanediol, the main metabolite excreted. In addition to gas chromatographic methods, the method of KLOPPER (1958) has proved particularly suitable for routine purposes. It involves hydrolysis with hydrochloric acid, extraction with toluene, purification of the total extract with NaOH and $KMnO_4$, primary chromatography on aluminium oxide with ethyl alcohol and benzol, acetylization and further purification with sodium bicarbonate, followed by a second chromatography of pregnanediol acetate on aluminium oxide with benzol. Colorimetry occurs at 425 nm. The method is highly reliable and specific although somewhat time-consuming.

6. DHAS Test

In this procedure, dehydroepiandrosterone sulfate (DHAS) is given to the mother intravenously to test the state of the fetoplacental unit. Estriol is measured in the urine or plasma before and after administration of this compound. Details of the procedure are still insufficiently worked out and DHAS is not available for general use in a suitable form. The results are also contradictory so that a detailed presentation is not appropriate at this point.

7. Estimation of Prolactin

The proliferation test on the pigeon's crop sac is the method most extensively used for the demonstration of prolactin activity. Originally, the material was administered to the animal intramuscularly and the increase in weight of both crop sacs served as the end point. Intradermal application is now generally prefered because of the higher sensitivity. Nonspecific inflammatory effects are prevented by giving prednisone at the same time. The proliferative zones can either be measured, histologically assessed, or excised and weighed.

Another possibility is to test the lactogenic effect on the mammary glands of rabbits. The material is introduced into the duct of the teat. A similar principle is involved in the measurement of the *in-vitro* lactogenic effect on tissue cultures or sections of mammary glands of mice. This method is highly sensitive.

The luteotropic activity of prolactin can either be determined by means of the formation of a deciduoma in intact and hypophysectomized mice or by means of the hyperemic effect in the corpus luteum (KOVACIC, 1963). Pregnanediol excretion in hypophysectomized, adrenalectomized rats has also been used to assess luteotropic activity (BLOBEL, 1966).

A very recent development is the successful application of immunological methods to the measurement of prolactin. Radioimmunological methods are again of primary interest (JACOBS, 1972).

Results in the human, however, are still controversial.

XII. Disorders of Sexual Differentiation (Intersexuality)

A. PRADER

A. Definition and Terminology

Strictly speaking, *intersexuality* signifies the presence of intersexual external genitalia, i.e. genitalia which are neither definitely male nor definitely female. In the broader sense, however, all disorders of prenatal sexual differentiation belong to intersexuality. The almost incalculable multiplicity of abnormal sexual differentiation can be divided into three major groups:

1. *Abnormal gonadal development.* This is commonly the result of an abnormal set of chromosomes which in turn frequently leads to abnormal genital development.

2. *Abnormal genital development in the presence of normal testes* and usually normal male set of chromosomes (male pseudohermaphroditism).

3. *Abnormal genital development in the presence of normal ovaries* and normal female set of chromosomes (female pseudohermaphroditism).

The traditional classification of abnormal sexual differentiation into true hermaphroditism, male pseudohermaphroditism and female pseudohermaphroditism does not include the entire spectrum of this classification. *True hermaphroditism* with ovarian and testicular tissue is only one of the many forms of abnormal gonadal development. In contrast, the term *male pseudohermaphroditism* correctly includes abnormal genital development in the presence of normal testes (male intersexuality, androgynia), and the term *female pseudohermaphroditism* includes abnormal genital development in the presence of normal ovaries (female intersexuality, gynandria).

Finally, the acquired forms of intersexuality, in which heterosexual symptoms arise for the first time postnatally, can also be classified under intersexuality, in the broader sense of the word. Hirsutism and virilization are present in the female sex, and gynaecomastia and feminization in the male sex. These acquired syndromes are not dealt with here but in the Chapters on the adrenals, testes and ovaries.

B. Embryology

The manner and stages of normal sexual differentiation known today can be summarized in a simple scheme (Fig. 1). The sex chromosomes (XX in the woman, and XY in the man) decide whether male or female gonadal differentiation occurs. The gonads in turn regulate prenatal genital differentiation, postnatal development of the secondary sexual characteristics and also psychosexual development to a certain degree. Animal experiments in recent years have shown that testosterone from fetal or neonatal testes exerts an irreversible branding effect on the brain (HARRIS, 1965).

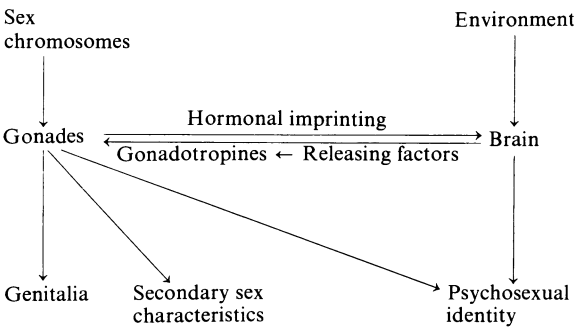

Fig. 1. Sex differentiation

In animal experiments, this branding or lack of it determines the future sexual behavior, settles the question of cyclic or non-cyclic female gonadotropin production in the future and thus influences fertility. It is not yet known whether this basically important process of branding is also applicable to man. The psychosexual development in man is a very complex process which is not only determined by anatomical and hormonal factors but by effective psychological environmental influences as well.

Gonadal differentiation (Fig. 2) occurs during the first few embryonal months. Undifferentiated gonads consist of cortex and medulla. In the boy, the medulla differentiates into the testis between the 6th and 8th weeks. This differentiation

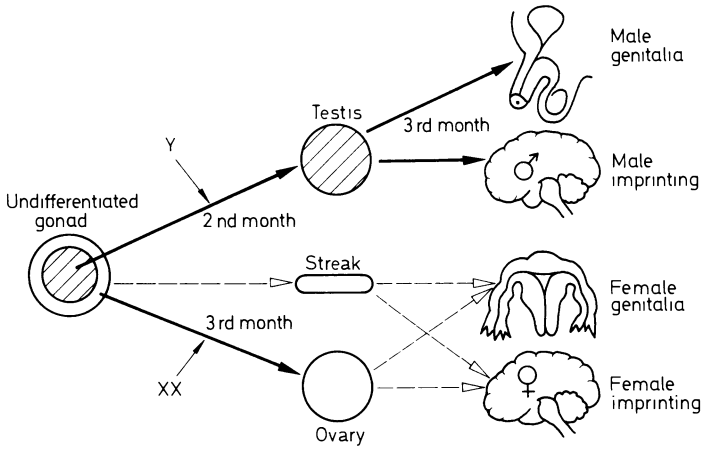

Fig. 2. Gonadal and genital differentiation

necessitates the presence of a Y chromosome. Differentiation of the medulla into the ovary occurs a few weeks later provided two X chromosomes are present and Y chromosomes absent. Normal gonadal differentiation is presumably also dependent on the presence of primordial germ cells. It is not known whether antagonistic inductors in the cortex and medulla play a part during normal gonadal differentiation, or whether the presence of a single inductor alone is sufficient to cause testicular differentiation, and absence of this inductor results in ovarian differentiation. In man, there are no known hormonal disorders of gonadal differentiation whereas in certain bovine races an intersexual form termed a "freemartin" is known, which may possibly be due to hormonal factors. The chromosomal male twin of heterosexual twin calves develops normally, whereas the chromosomal female twin is subjected to intersexual gonadal and genital development and is later similar to an animal subjected to early castration in stature, sexual instinct and fertility. Prenatal circulatory anastomoses presumably have some part in the development of this intersexual form. Despite intensive research the exact cause has still not been explained.

Genital differentiation in the male sex is regulated by biochemical factors of the fetal testes, whereas similar influences are not present in the fetal ovary in the female (Fig. 2). The famous animal experiments by JOST and clinical experience have shown that genital differentiation is also of the female type when fetal testes are completely absent or are present as undifferentiated streaks (p. 714). In summary, male genital development is an active, induced process and female genital development an autonomous passive process.

Genital differentiation is schematically presented in Fig. 3, and the homologous genital structures in man and woman are given in Table 1. Genital differentiation reaches a neutral stage at the end of the second fetal month. The internal genital system consists of Wolffian ducts and Müller's ducts, and the external genitalia of the urogenital sinus and genital eminences. In the boy, the ductus deferens, epididymis and seminal vesicle develop from the Wolffian duct during the 3rd month, while Müller's duct degenerates. In the girl, the Wolffian duct

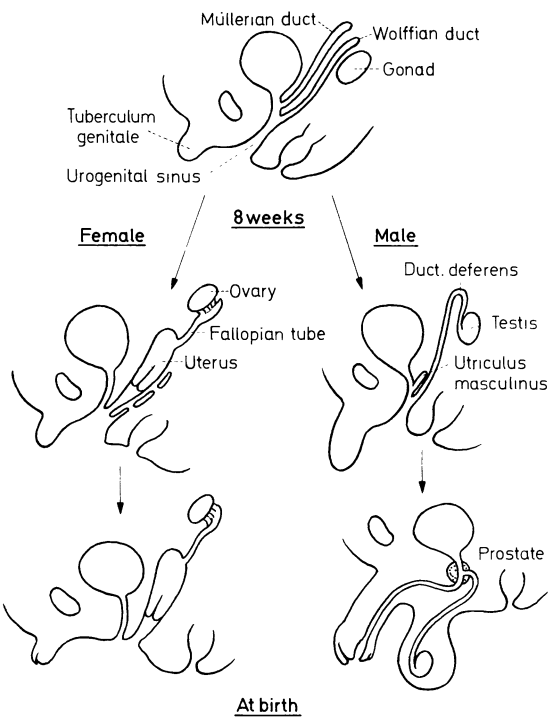

Fig. 3. Genital differentiation

Table 1. Homologous genital structures in man and woman

Male	Undifferentiated stage	Female
Testis Seminiferous tubules Rete testis	Gonads Cortex Medulla	Ovary Cortex Rete ovarii
Epididymis Efferent ductules Appendix epididymis	Epigenitalis (upper group of Mesonephric ducts)	Epoopheron Appendix vesiculosa
Paradidymis Aberrant ductule	Paragenitalis (lower group of mesonephric ducts)	Paroopheron
Ductus epididymidis Ductus deferens Glandula vesiculosa Ductus ejaculatorius	Wolffian duct	Gartner's duct
Appendix testis Utriculus masculinus	Müller's duct	Tuba uterina Uterus Vagina
Colliculus seminalis	Müller's cumulus	Hymen
Urethra (distal of coll. seminalis) Prostate Bulbo-urethral glands	Urogenital sinus	Vestibulum Para-urethral glands Vestibular glands (BARTHOLINI)
Penis	Genital protuberances	Clitoris
Scrotum Scrotal raphe	Genital tori	Labia majora Posterior commissure
Corpus cavernosum urethrae	Genital folds	Labia minora

disappears, whereas the uterus, tube and upper vagina arise from Müller's duct. Development of the external genitalia in the boy is characterized by growth of the genital eminence into the penis, fusion of the genital folds to form the penile urethra and fusion of the genital tori to form the scrotum. In the girl, the labia minora arise from the genital folds and the labia majora from the genital tori.

Active induction of male genital differentiation is presented in Fig. 4. Our knowledge is based largely on experimental work done by JOST in animals, but clinical experience shows that it is applicable to the human as well. The fetal testis acts in three ways on genital development, it stimulates the differentiation of the Wolffian duct to a vas deferens and suppresses the differentiation of Müller's duct into the tube and the uterus.

Induction of external male genital development is due to the action of androgenic hormones. This effect can be imitated by testosterone and is probably exerted by testosterone produced by Leydig cells in the fetus. The vasa deferentia develop from the Wolffian ducts, and in the presence of only one testis, only one vas deferens develops, on the same side as the testis and never on the contralateral side. This effect can be simulated by direct contact with a testosterone crystal but not by an injection of testosterone. Obviously, a local active factor is involved, which presumably is the high

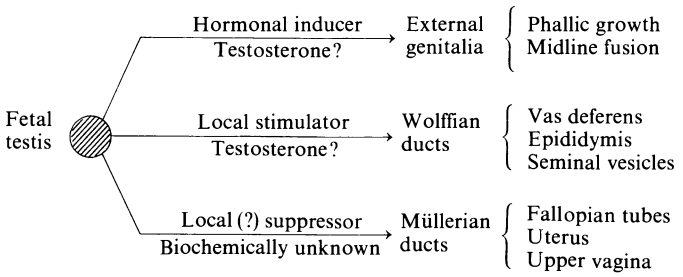

Fig. 4. Differentiation of male genitalia (9th to 13th week)

concentration of testosterone in the Leydig cells of the fetal testis. Suppression of tubal and uterine development from Müller's ducts cannot be imitated by means of testosterone. Here, a still unknown biochemical factor of the fetal testis is involved, this factor being independent of testosterone production.

Thus the fetal testis exerts an androgenic effect; in low concentrations the androgenic hormones stimulate external genital development, and in high concentrations they stimulate development of the vas deferens. On the other hand, the fetal testis has another effect, independent of its other actions, which suppresses the development of the tube and uterus. Absence of androgenic hormones (p. 726) and failure to suppress Müller's ducts (p. 725) are known in human pathology. Such disorders result in the development of male pseudohermaphroditism. There are also abnormal androgenic influences (p. 730) known to affect female genital development and resulting in female pseudohermaphroditism.

C. Methods of Investigation

Investigation should clarify the genital state, chromosomes, gonadal relations and the pathogenesis of the disorder. Investigation of the internal genital organs is difficult, chromosome investigations time-consuming and direct examination of the gonads only possible by means of a laparotomy or laparoscopy. For these reasons, an attempt is first made to solve the problem by indirect methods by relating genetic and anamnestic data, and by a general physical examination and estimation of the sex chromatin. Costly chromosome investigations and exploratory laparotomies are necessary only in selected cases.

The *history* often offers valuable help. Inquiries must be made about similar cases in the family history, about primary amenorrhoea in the case of women, and a special attempt must be made to determine whether there has been any history of an adrenogenital syndrome in siblings (vomiting during babyhood, acceleration of somatic development, virilization). In the personal history, it is important to find out whether genital peculiarities were obvious at the time of birth, how somatic development proceeded during the first years of life, at what time and to what degree secondary sexual characteristics arose, how long the female patient has been menstruating and whether the patient has already undergone genital and intra-abdominal operations and herniotomy. If possible, one should try to obtain a picture of the intellectual, psychic and psychosexual development.

General physical examination must in particular determine exact body measurements, special characteristics of stature, dysmorphic signs, malformations and the degree of development of secondary sexual characteristics.

An exact *psychopathological examination*, with special reference to psychosexuality, is essential after the second year of life.

External genital findings are of extreme importance. There are merging transitional stages between pure female and pure male external genital development, and we have arbitrarily divided them into five stages (Fig. 5). Type I (Fig. 5) shows enlargement of the clitoris without other genital changes. In Type

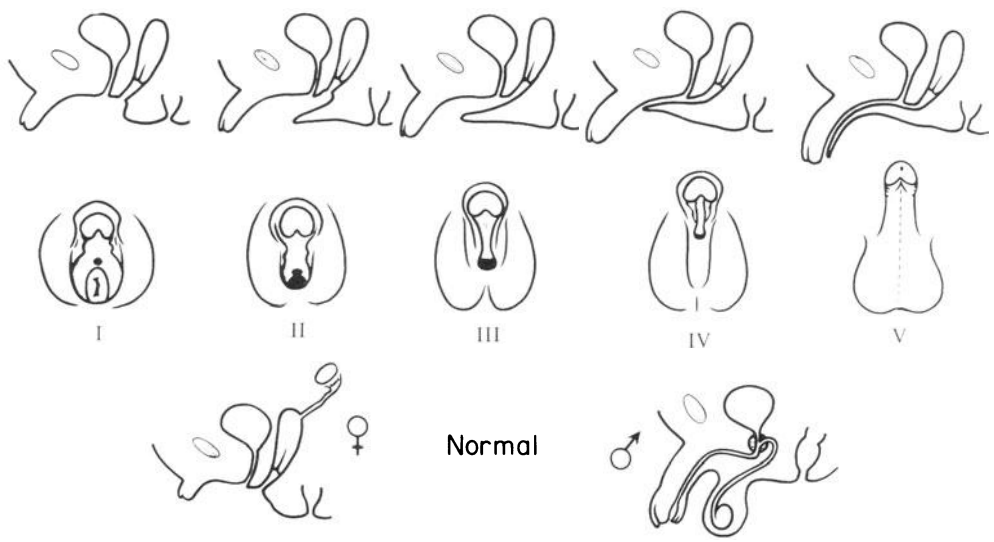

Fig. 5. Intersexual external genitalia, Types I–V

II (Fig. 5), in addition to clitoric enlargement, there is a wide funnel-shaped urogenital sinus which contains the openings of the vagina and urethra. In Type III (Fig. 5), the urogenital sinus is narrower but still funnel-shaped. In Type IV (Fig. 5), only a small urogenital opening can be seen at the base of the phallus. In Type V (Fig. 5), the urogenital opening is found at the tip of the phallus as in the normal male. Perineal hypospadias corresponds to Type IV, whereas hypospadias of the glans and penis lies somewhere between Type IV and V. The various types can be explained by androgenic stimulation varying qualitatively and quantitatively. Outward appearances do not indicate whether the sex hormones and gonads are male, female or abnormal, and no diagnosis can be made about the original disorder. The view that the aspect of external genitalia does not permit diagnosis of the cause is of fundamental importance. In boys, Types I–IV represent inadequate androgenic stimulation. In girls, Types III–V are only possible if abnormal androgenic stimulation is present as early as the 3rd month. Quite mild androgenic stimulation, or perhaps androgenic stimulation arising for the first time after birth, can result in Type 1.

Investigation of the internal genital state is more difficult. If there is only one urogenital opening, then the question arises of whether a vagina opens in the urogenital sinus lying posteriorly, or whether a male urethra with a typical colliculus seminalis is present. As a rule, this question can be answered by means of a sound, ureteroscopy and X-rays using contrast media (urethro-vaginogram). If there are separate urethral and vaginal openings, the depth of the vagina can be determined by introducing a sound. Direct vaginal examination, with a urethroscope in the child and with a speculum in the adult, and rectal palpation will show if a uterus is present or not.

Estimations of the excretion of 17-ketosteroids and when possible of testosterone in the urine and plasma are the most important *hormonal* investigations for recognizing androgenic influence. When an adrenogenital syndrome is suspected, estimation of pregnanetriol excretion usually gives some diagnostic indication (p. 369). The question of estrogenic influences arises only during puberty and can be assessed just as well by means of the secondary sexual characteristics and the vaginal smear (p. 535) as with the aid of measurements of urinary estrogens. Estimation of gonadotropins is of great value. After the appearance of the first secondary sexual characteristics, biological assay of urinary gonadotropins permits differentiation between high levels in primary gonadal insufficiency (hypergonadotropic hypogonadism, p. 460) and lowered values in hypophyseal insufficiency (hypogonadotropic hypogonadism, p. 469). This investigation is pointless at an earlier stage since the method is not sensitive enough. With new radioimmunological methods for measuring FSH and LH in urine and blood, it is often possible to recognize abnormally high or abnormally low values even before puberty.

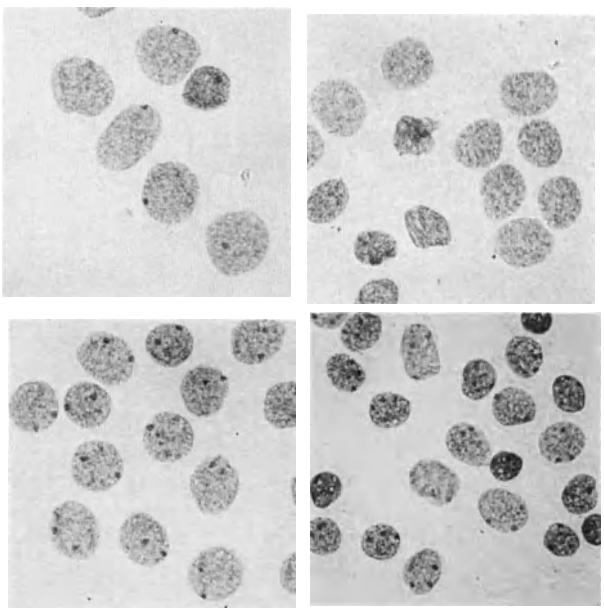

Fig. 6. Sex chromatin in the hair root: Upper left; chromatin-positive in normal XX woman; upper right; chromatin-negative in normal XY man; lower left; double sex chromatin in XXX girl; lower right; triple sex chromatin in XXXY boy. (From SCHMID, 1967)

Investigation of the sex chromatin in the buccal smear or hair root (Fig. 6) yields information about the number of X chromosomes present. This investigation is based on the fact that only one X chromosome is genetically active whereas additional X chromosomes are genetically inactive and only genetically inactive X chromosomes are visible as sex chromatin bodies. The number of X chromosomes thus exceeds the maximal number of sex chromatin bodies per cell nucleus by one. Sex chromatin findings reveal nothing about the number of Y chromosomes. Thus, a limited number of karyotypic possibilities are still open which can be determined through direct chromosomal examination. Recently however, *fluorescent staining of the Y chromosome* with quinacrinedihydrochloride (Atebrin) has been recommended (PEARSON, 1970). This investigation is just as

simple as examining sex chromatin, and the number of Y chromosomes present can be recognized directly. The two investigations are complementary and it should be possible in the future to assess the set of sex chromosomes without the costly direct chromosome examination.

In the presence of an abnormal constellation of sex chromosomes, it is possible to determine in certain cases, such as color blindness and Xg blood groups of patients and members of the family, from the X chromosomal properties how this chromosomal disorder arose and whether it was due to a chromosomal disturbance during oogenesis in the mother or during spermatogenesis in the father (RACE and SANGER, 1969).

Investigation of *dermatoglyphics* can also be of interest where a disorder of the sex chromosomes is suspected. The number of skin grooves of the finger pulp is inversely proportional to the number of sex chromosomes, i.e. increased in the presence of XO, lowered with XXY and greatly reduced with XXXXY etc. (PENROSE, 1968).

Direct determination of the gonadal sex is only possible by gonadal biopsy or the detection of spermatozoa in the ejaculate. Usually however, the diagnosis can be closely limited by consideration of the other findings so that there is no longer any doubt about the gonadal sex and the gonadal biopsy becomes superfluous. This is true for most of the classic syndromes such as Klinefelter's syndrome, Turner's syndrome, testicular feminization, adrenogenital syndrome etc. Biopsy of the gonads is thus only seldom necessary.

D. Review and Classification

There is presently no truly satisfactory classification for the numerous disorders of prenatal sexual differentiation, since etiology and pathology of the various forms are only partly clarified. The classification used below is based partly on anatomical and partly on pathological aspects. Abnormal gonadal development is discussed on p. 712, male pseudohermaphroditism on p. 724 and female pseudohermaphroditism on p. 730. The individual syndromes are also indicated in the same sections.

E. Abnormal Gonadal Development

The synopsis in Table 2 gives a survey of the numerous forms of abnormal gonadal differentiation. Hypergonadotropic primary hypogonadism is present in all forms (p. 460) and with few exceptions is associated with sterility resistent to therapeutic measures.

As has been mentioned, these disorders are frequently but not always the result of a sex chromosome anomaly. Like chromosome disturbances, most of these syndromes are therefore not hereditary. However, the reverse conclusion must not be drawn that every disorder of the sex chromosomes is associated with abnormal gonadal development and sterility. Normal gonadal development and normal fertility are usually found in two common syndromes, the XXX and XYY syndromes.

The chromatin-positive, true Klinefelter's syndrome (p. 464) is the most common syndrome among *patients with male external genitalia.* In the majority of cases, an XXY karyotype is the cause. A similar clinical picture with a normal XY karyotype is termed *chromatin-negative, pseudo-Klinefelter's syndrome* (p. 468). The pathogenesis of the syndrome XX men is the least understood of the various syndromes

Table 2. Disorders of prenatal sexual differentiation

A. Abnormal gonadal development

Disorders of sex chromosomes common.
Majority of syndromes not hereditary.

1. Male external genitalia

- Chromatin-positive Klinefelter's syndrome: usually XXY.
- Chromatin-negative Klinefelter's syndrome: XY. Very heterogeneous group.
- XX men.
- Male Turner's syndrome: usually XY. Heterogeneous group.
- Congenital anorchia: XY.

2. Female external genitalia

- Turner's syndrome (gonadal dysgenesis) with bilateral streaks and dwarfism: usually XO, rarely XXqi, XO/XX and many others, occasionally transition to rudimentary ovaries or rudimentary testes and to asymmetrical gonadal dysgenesis.
- Pure gonadal dysgenesis with bilateral streaks without dwarfism: XX form with autosomal recessive mode of inheritance and XY form inherited though healthy women, occasionally transition to rudimentary ovaries or rudimentary testes.

3. Intersexual external genitalia

- Asymmetric mixed gondal dysgenesis with one streak and one rudimentary testis: usually XO/XY, less frequently XY or XX/XY, occasionally transition to Turner's syndrome, pure XY-gonadal dysgenesis and to rudimentary testes (dysgenetic form of male pseudohermaphroditism).
- True hermaphroditism. Fully differentiated ovarian and testicular tissue, usually XX, less commonly XX/XY etc.
- Agonadism. No gonads and no internal genital structures:
  XY. Hereditary?

Table 2 (continued)

B. Abnormal genital development in presence of normal testes = Male pseudohermaphroditism

Usually normal male XY karyotype.

Most syndromes hereditary.

1. Male external genitalia

- Oviduct persistence (hernia uteri inguinalis): autosomal recessive heredity.

2. Female external genitalia

- Testicular feminization ("hairless women"): Heredity through healthy women.
- Disorders of testosterone synthesis (see below).

3. Intersexual external genitalia

Very large group, little explained. Numerous cases before puberty unclassifiable.

- Disorders of testosterone synthesis: autosomal recessive heredity of enzyme defect.
  - In testes and adrenals: 20-hydroxylase, 3β-dehydrogenase, 17-hydroxylase.
  - In testes alone: 17-reductase, 17-desmolase.
- Incomplete testicular feminization with female pubertal development: heredity via healthy women.
- Hereditary vulviform perineal hypospadias: autosomal recessive heredity.
- Chromosome disorders XO/XY.
- Dysmorphic syndrome: Smith-Lemli-Opitz syndrome, Russel's dwarfism, Ullrich-Feichtinger syndrome, trisomia 13 etc.

C. Abnormal genital development in the presence of normal ovaries = female pseudohermaphroditism

Normal female XX karyotype.

Male or intersexual external genitalia

- Congenital adrenogenital syndrome: various autosomal recessive heredities of enzyme defects: 3β-dehydrogenase, 11β-hydroxylase, 21-hydroxylase.
- Transplacental virilization through exogenous steroids: administration of androgens or synthetic gestagens during pregnancy.
- Transplacental virilization due to androgenic tumors in the mother: ovarian and adrenocortical tumors.
- Complex urogenital malformations, renal agenesis.
- Idiopathic hypertrophy of the clitoris.

of this group. Anorchia (p. 461) and the syndrome of prepubertal castration (p. 461), i.e. the absence of testes in otherwise normal boys, must be due to secondary destruction of the testes after the 3rd fetal month, since otherwise induction of the external genitalia would not have been male (p. 708).

Turner's syndrome is most common in *patients with female external genitalia* (p. 713). It is characterized by the combination of rudimentary dysgenetic gonads or "streaks" with dwarfism and various dysmorphic features. The classical karyotype is XO, although many other karyotypes can occur. In *pure gonadal dysgenesis* (p. 721), which is a rare condition, there is an XY or XX karyotype present, but anatomical and functional gonadal findings are exactly the same, whereas dwarfism and dysmorphic characteristics found in TURNER's syndrome are missing.

Abnormal gonadal development in *patients with intersexual external genitalia* is seen particularly with *mixed or asymmetric gonadal dysgenesis* (p. 721) and in *true hermaphroditism* (p. 722).

1. Turner's Syndrome (Gonadal Dysgenesis)

This syndrome was first described by MORGAGNI as far back as in 1760, and involves individuals with internal and external normal female genitalia and functionless rudimentary gonads (streaks). In addition to the two obligatory findings, *dwarfism* and *hypogonadism*, a dysmorphic syndrome is often associated with a sphinx face, pterygium formation at the neck, shield-shaped thorax and other characteristics. Dwarfism, the dysmorphic syndrome and hypogonadism together produce a characteristic clinical picture. The dysmorphic syndrome by itself was previously also known as the Bonnevie-Ullrich condition, but this term was stretched so far clinically that it led to more confusion than clarity. Together with hypogonadism, this syndrome was later termed as ovarian agenesis or Turner's syndrome (TURNER, 1938) or Ullrich-Turner syndrome. Since rudimentary gonads are present and show neither specific ovarian nor specific testicular elements, the term ovarian agenesis is not suitable. Today, the terms Turner's syndrome and gonadal dysgenesis are usually used, although the term gonadal dysgenesis is also used for the syndrome of asymmetric mixed gonadal dysgenesis, and by some authors even for other syndromes, such as for example Klinefelter's syndrome.

a) Genetics, Chromosomal Findings and Pathogenesis

An X chromosome is missing in the majority of cases. The *karyotype* is therefore 45,XO. The *sex chromatin* is correspondingly *negative*. Investigations of the Xg blood group in female patients and parents have shown that the X chromosome present is usually derived from the father (RACE and SANGER, 1961), i.e. an ovum with a normal X content is fertilized by a sperm without a sex chromosome or one X chromosome is lost again after fertilization. In agreement with this, it is found that the mean maternal age is not raised, contrary to the situation in certain other chromosome

disorders (Down's syndrome, Klinefelter's syndrome).

In addition to the classic XO karyotype, there are other karyotypes with structural disturbances or mosaics. About a third of all cases of TURNER's syndrome belong to this group. Patients in this group are chromatin-positive almost without exception. The most common structural disorders are the iso-chromosome (XXqi), the absence of the short arm (XXp-) and the ring chromosome (XXr). The XO/XX karyotype is the most frequent form of mosaic. There are other more complicated forms of mosaics but usually XO is a part of them. An intact Y chromosome is never found in a classic Turner's syndrome but a structurally abnormal Y (XYpi or XYqi) is found in rare cases. Further, a clinical syndrome similar to Turner's syndrome is occasionally seen in association with an XO/XY mosaic (p. 721).

The *development of individual symptoms* has only been partly explained. The absence of two whole X chromosomes is the cause of the gonadal dysgenesis and explains the female genital development which occurs without exception (p. 708) and the hypogonadism. The dysmorphic features and dwarfism are not results of the hypogonadism, or they could not be present even before puberty. Everything indicates that they are a direct result of the absence of the short arm of an X chromosome (or long arm of the Y chromosome) (FERGUSON-SMITH, 1961). This presumably also applies to the osteoporotic-like bone dystrophia which can be determined before puberty as well.

As is to be expected with chromosome disorders, *affection of siblings is extremely rare.* In two cases, an XO female patient had a normal XY twin brother (TURPIN, 1961). In another case, an XO/XX mosaic was observed in mother and daughter (DE MEYER, 1970).

b) Incidence

The incidence of the chromatin-negative Turner's syndrome among newly born girls is 1 : 2700 (TAYLOR, 1967). Since a third of all the cases of Turner's syndrome found later on are chromatin-positive, the total incidence is about 1 : 1800. The incidence is much higher in spontaneous abortions, there being one chromatin-negative case in 18 abortions (PAWLOWITZKI, 1966). This signifies that the XO Turner's syndrome is very common in embryos and usually acts as a prenatal lethal factor.

c) Pathology

The gonads are inconspicuous cord-like or strip-like structures of a whitish colour, lying in the normal ovarian position (Fig. 7). In abortuses with the XO karyotype, normal ovarian differentiation is seen as with the XX karyotype, in the third month with primordial ova and pregranulosa cells. Later, these elements disappear, leaving behind connective tissue similar to the ovarian stroma, containing a few rudimentary mesonephric tubules and quite frequently also nests of epitheloid cells (paraganglionic cells, hilar cells, interstitial cells). These cell nests occur in both chromatin-negative and chromatin-positive patients. Graafian follicles and seminiferous tubules are completely absent in classic cases. The incidence of ovarian tumours is not increased. Internal genital organs are normally formed but the uterus and tubes remain hypoplastic even in adulthood. The adrenals are as a rule normal.

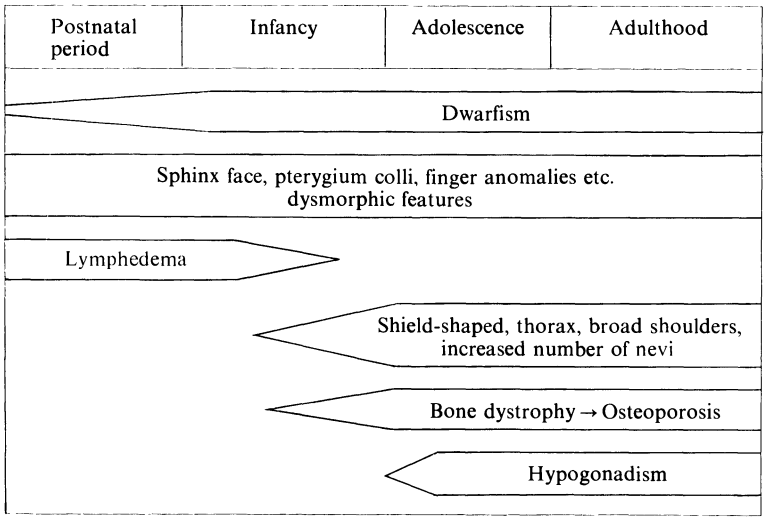
Table 3. Symptoms of TURNER's syndrome dependent on age



d) Clinical Features

Symptoms depend on the age of the patients and on the intensity of dysmorphic characteristics (Table 3). Since these features are often more conspicuous and are noticed much earlier than hypogonadism, they are described first in the fully developed stage, although they are only facultative features in contrast to hypogonadism which is obligatory.

Dwarfism is occasionally already present at the time of birth. More frequently however, these children are of normal size at birth but then simply grow more slowly so that the retardation in growth becomes increasingly obvious. In addition, there is no pubertal spurt in growth due to the hypogonadism. The adult patient is usually 130–150 cm tall. During childhood, the bone age is only insignificantly behind the child's age. In young adults, however, epiphyseal fusion and thus cessation of growth are frequently delayed by 3–4 years, but the growth deficit is not compensated for during this delay.

Face and neck show a series of typical features giving rise to a sphinx-like picture (Figs. 8 and 9): anti-mongoloid slant of the eyes, epicanthus, short nose, large, low-set, poorly shaped ears, carp-like mouth, narrow high palate, short jaw (micrognathia), broad short neck, pulling pterygium colli from insertion of ear to shoulder, and low broad hair line on the neck. Ptosis, pareses of ocular muscles, minor malformations of the eyes and glaucoma are quite common findings. Chronic otitis is also common.

The shoulders are often conspicuously broad. The thorax in the older child and adult, and frequently also even at an earlier age, is obviously short and wide and has a flat depression on the anterior aspect, so that one speaks of a shield-shaped thorax (Figs. 10 and 11). The circumference of the thorax is too large compared to the height of the patient. The nipples are often hypoplastic, i.e. even smaller than a baby's, and are strikingly wide apart (Fig. 10).

The *extremities* also show typical features. The elbows are in a slight or accentuated valgus position. Exostotic-like thickening of the medial tibial condyl is often found in the region of the knee. Lymphedema of the dorsum of the hands and feet is not uncommonly found in the baby and infant (Fig. 8). This edema disappears over a few years and is only found exceptionally in the older child. Shortening of the metacarpals and metatarsals is occasionally seen (brady-metacarpia) as in pseudo-hypoparathyroidism. The dorsal flexion folds of the fingers and toes are often strikingly deeply furrowed, and the nails are often small and deeply embedded. Minor finger anomalies, such as partial syndactylia, klinodactylia etc., are also common.

Apart from pterygium colli, the *skin* also shows several peculiarities. In the baby, the skin of the neck is conspicuously flaccid and loose (cutis laxa) (Fig. 8) similar to that seen in mongoloid idiots (Down's syndrome). This feature disappears after babyhood. A large number of small and large *nevi* are seen on the whole body during infancy and adulthood (Fig. 12).

X-rays show thick cord-like bone dystrophy and a single X-ray of the hand alone often suggests the diagnosis. The vertebral column often shows signs of kyphosis with Scheuer-

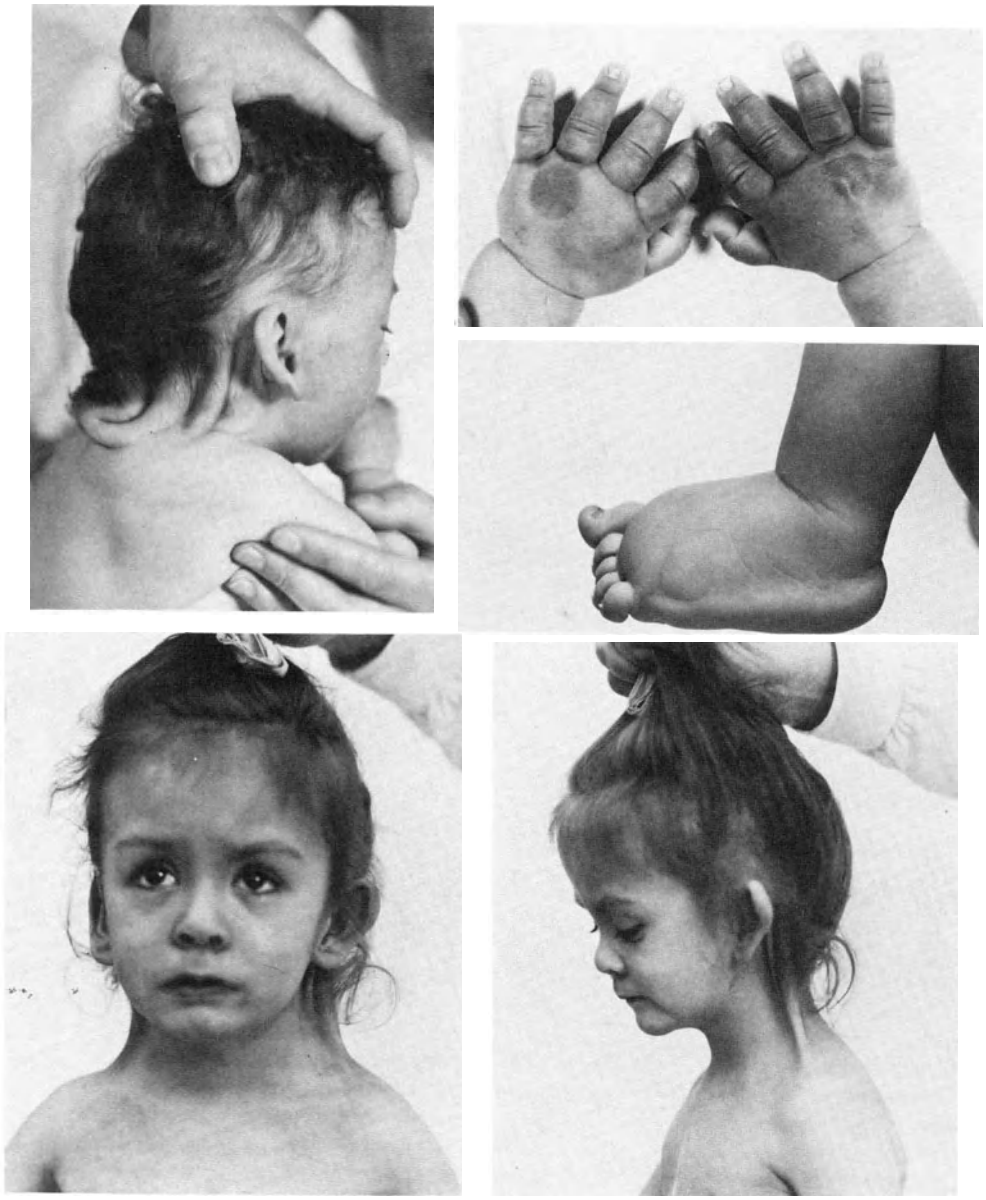


Fig. 8. Girl with XO-Turner's syndrome at ages of 5 months and 2 years. In the baby, loose neck creases, low-set ears, lymphedema of hands and feet and small, deeply embedded nails are typical. At 2 years of age, typical sphinx face with ears inserted low and define pterygium colli. (From PRADER, 1962)

mann-like changes at a very early age, which later become even worse due to true osteoporosis.

Malformations of the kidneys and heart are quite common. Unexplained hypertension in the absence of a cardiac defect or renal malformation is also seen not uncommonly. Anomalies which normally occur less frequently in females than in males are of special interest. *Stenosis of the aortal isthmus* and *red-green color blindness* (an X chromosomal recessive heredity) belong to this group of anomalies, and are both found remarkably frequently in Turner's syndrome.

In contrast to the dysmorphic features described so far, which can occur in various combinations and intensities, *hypogonadism* is obligatory for the diagnosis. It of course only becomes obvious after the 13th or 14th year of life when the expected development of the breasts fails to occur and menarche never takes place. The genitalia remain infantile (Fig. 13), and no estrogenic effects can be found in the vaginal smear. In contrast to the

Fig. 9. Typical facial features in Turner's syndrome: antimongoloid slant of the eyes, short nose, large, badly formed ears, short lower jaw, thick, short neck and pterygium colli

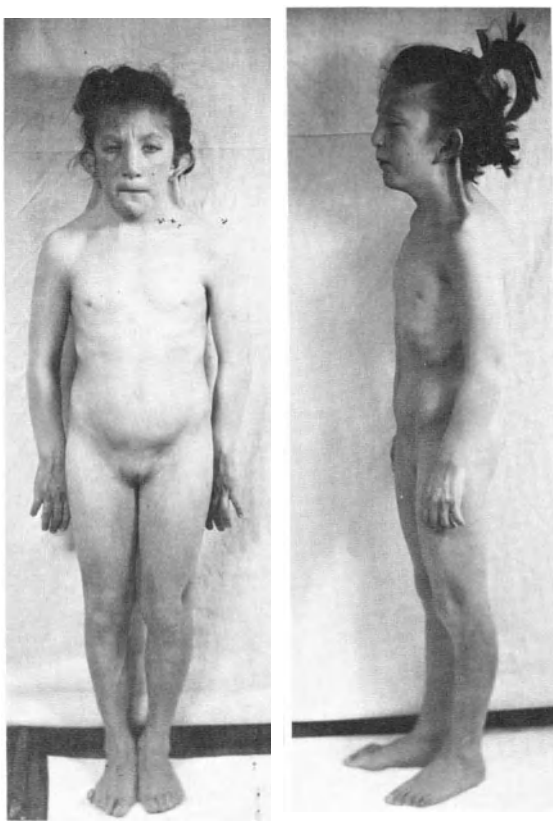

Fig. 10. 12-year-old girl with extreme dwarfism (116 cm) and dysmorphic characteristics (elderly sphinx face, pterygium) of Turner's syndrome

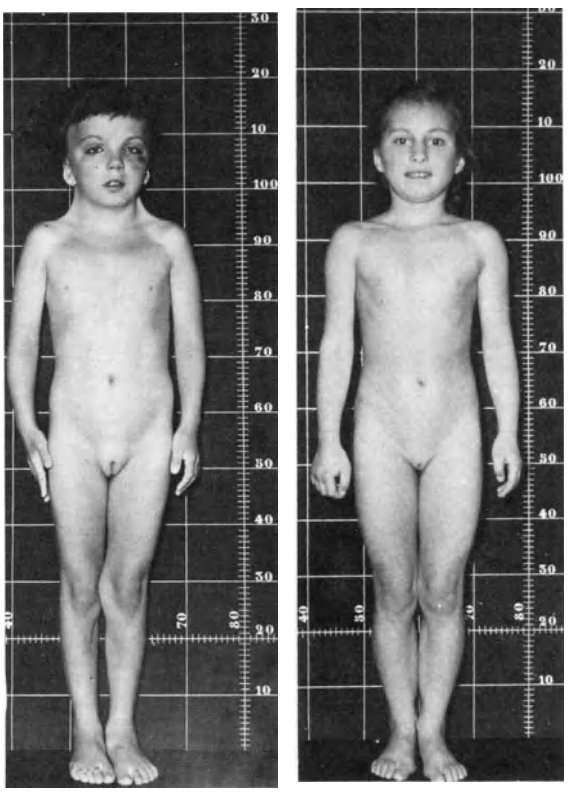

Fig. 11. Two girls of small stature with XO-Turner's syndrome at the ages of 9 and 11 years. Marked dwarfism in both. Dysmorphic characteristics very definite in one (left) and absent in the other (right)

complete absence of estrogenic features, pubic and axillary hair are not entirely absent, but appear later than normal and are poorly developed. It is assumed that this is induced by adrenocortical androgens (Chap. XIX).

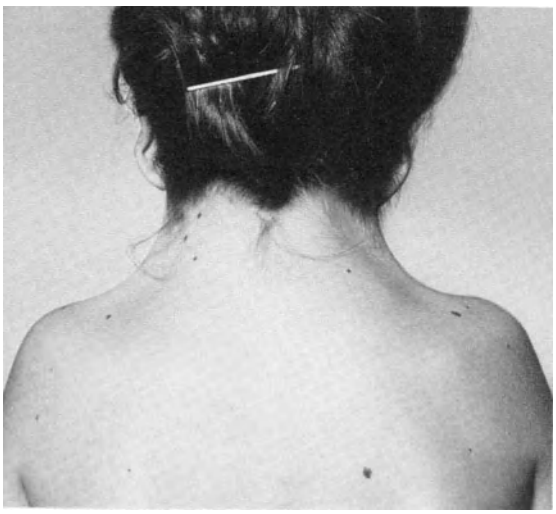

Fig. 12. Neck of a 9-year-old girl with XO-Turner's syndrome. The wide neck, low hair line, pterygium colli and numerous naevi are typical

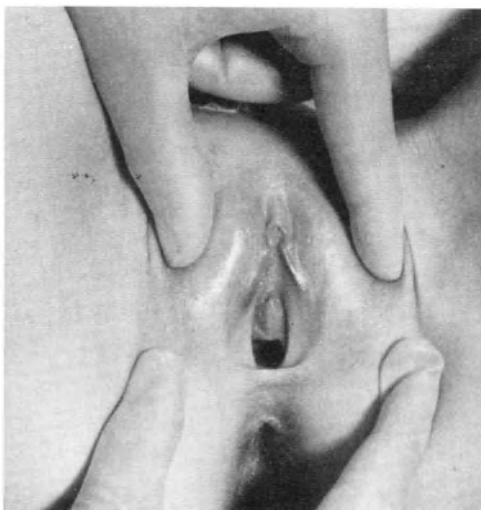

Fig. 13. Infantile genitalia in a 19-year-old female patient with XO Turner's syndrome. (From HAUSER, 1961)

Due to the hypogonadism, fusion of the epiphyses is somewhat delayed in the adolescent and young adult, so that duration of growth is also prolonged. This often results in mild eunuchoid proportions in the adult with body height exceeding arm span, in spite of dwarfism. A further result of estrogen deficiency is osteoporosis which is often found in adults, and which has adverse effects on any changes in the vertebral column, giving rise to back pains.

An increased incidence of diabetes and lymphocytic thyroiditis has been observed repeatedly in adult patients. There is also an increased incidence of thyroid antibodies, which gave rise to some discussion on whether Turner's syndrome or the XO constellation is associated with a predisposition for forming auto-antibodies.

Intelligence is usually somewhat reduced, especially compared with that of other members of the family. The mean intelligence quotient is 85 (ZUEBLIN, 1969). Usually, however, the patients appear more intelligent since they are capable of adjusting well to social conditions. The *psyche* is usually of female nature but shows definite infantile tendencies. The personality is not very striking and there is a lack of initiative and drive. It is interesting to note that stereoscopic perception and orientation are considerably impaired.

The *expectancy of life* is not impaired. Even MORGAGNI's patient reached an age of 66.

As has been mentioned many times already, the clinical picture varies very widely in Turner's syndrome. There is only a very slight interrelation with chromosomal findings which is hardly of any diagnostic value. Nevertheless, the following rough relations between karyotype and the clinical picture can be adhered to: The classic picture is found particularly with karyotype XO. Dwarfism is obligatory. Dysmorphic features are found in most of the XO patients, are usually well developed and seldom completely absent. Hypogonadism is also obligatory, but a few cases can be seen where there is mild development of the breasts and irregular menstruation. In such cases, the gonads are not true streaks but rather hypoplastic ovaries. Fully developed secondary sexual characteristics and fertility have so far only been found in one pure XO case (BAHNER, 1960). Slight hypertrophy of the clitoris is seen in a few cases, as well as marked pubic hair which is probably a result of increased androgen production due to the larger number of hilus cells in the ovaries.

The clinical picture resulting from structural changes in the X chromosome is similar to that seen with the XO karyotype. The situation is different in mosaic cases with normal XX line. Here, dwarfism and hypogonadism can be absent, so that *all transitions between the classic Turner's syndrome and normal female development can occur.*

If one also includes the cases of XO/XY mosaic with rudimentary testes (p. 721) and a few clinical symptoms of Turner's syndrome,

then here as well *all transitions between Turner's syndrome and normal male development can arise.*

e) Hormone Findings

As can be expected from the clinical picture, *estrogens* are greatly reduced in older girls and adult patients. *Gonadotropins* are usually greatly elevated. This finding can be demonstrated even during childhood in the majority of cases, if modern radioimmunological methods of estimation are used and results are compared with normal values for the corresponding ages. Excretion of *17-ketosteroids* and *androgens* is reduced or lies in the lower normal limits. Excretion of dehydroepiandrosterone appears to be somewhat elevated and androsterone excretion somewhat diminished.

f) Diagnosis and Differential Diagnosis

The diagnosis is easy in female patients over 15 years presenting with the fully developed syndrome. The dwarfism, typical external appearance, the primary amenorrhea and manifest hypogonadism immediately suggest this syndrome. If the buccal smear is chromatin-negative, then the diagnosis of an XO Turner's syndrome is confirmed. If the buccal smear is chromatin-positive, examination of the chromosomes is required in order to confirm the diagnosis. Exploratory laparotomies and gonadal biopsies were performed earlier but are no longer justified in classical cases.

The diagnosis is more difficult in *younger patients* since the hypogonadism is not yet recognizable. Diagnostic difficulties can also arise when dysmorphic features are only discretely developed or completely absent. Differential diagnosis of dwarfism, dysmorphic characteristics and hypogonadism are dealt with separately in the next section.

Dwarfism in a girl should always bring the possibility of Turner's syndrome to mind. Discrete characteristics of dysmorphia should then be looked for and the sex chromatin examined in every case to detect at least the more common chromatin-negative cases. Dwarfism combined with hypogonadism also suggests pituitary *dwarfism*. In hypophyseal hypogonadism, dysmorphic features are absent, bone age is usually more retarded and there are usually other signs of hypophyseal insufficiency. In Turner's syndrome, gonadotropin levels are elevated and growth hormone in the plasma can be stimulated by normal measures. In pituitary dwarfism, gonadotropins are normal or diminished and growth hormone levels cannot be stimulated.

In addition to *hypogonadism* in Turner's syndrome, *pure gonadal dysgenesis* and *isolated gonadotropin deficiency* (idiopathic eunuchoidism in the woman) must also be considered. In both cases, there are no signs of dwarfism and dysmorphic features found in Turner's syndrome.

Dysmorphic features when classically developed are extremely characteristic of Turner's syndrome, so that an experienced physician suspects the diagnosis even in the baby and small infant. Often however, these features are so discrete that they must be searched for. Even when the features are well developed, an inexperienced individual can mistake the syndrome for other dysmorphic syndromes and pseudo-Turner's syndrome in particular (see below). In the presence of a Turner-like dysmorphic syndrome with additional dysmorphic features, Turner's syndrome is less probable.

The *pseudo-Turner's syndrome or Noonan's syndrome* is not a very well defined syndrome. Turner-like dysmorphic features are present, but chromosomal disturbances and also hypogonadism as a rule are missing. It occurs in both sexes. The *male Turner's syndrome* can basically also be counted to this group (see p. 720). The syndrome is occasionally familial. The patients are usually but not always of small stature. They show signs of a Turner-like dysmorphic syndrome, but these features usually deviate from Turner's syndrome in single characteristics. In the majority of cases, there is some cardiac malformation. This fact contrasts with findings in Turner's syndrome, but stenosis of the aortal isthmus is never found. In other cases, in addition to the classical lateral pterygium colli, pterygium may also develop in the anterior region of the neck, in the axilla, at the elbow and back of the knee joint. Such cases of the *pterygium syndrome* do not belong to Turner's syndrome. In *arthrogryposis*, dwarfism and dysmorphic features similar to those in Turner's syndrome are found in addition to the stiffening of joints. The sex chromosomes and gonadal function are normal in all these dysmorphic syndromes.

g) Treatment

Whereas sterility cannot be corrected, suitable substitution therapy with female sexual hormones can cause the appearance of secondary sexual characteristics and menstruation at any time. In a few cases, it is questionable whether such treatment really has any sense or whether the patient would not be happier and come through life with less trouble if left untreated.

The internal and external situation must be examined individually for each case before any decision is made.

Substitution therapy should not be commenced before the normal age for the onset of puberty, i.e. not before the 13th–14th year. Since prolonged treatment over decades is involved, oral hormone preparations are preferable. Cyclic treatment with estrogens is the simplest method: 0.5–1.5 mg diethylstilbestrol or 0.05–0.1 mg ethinylestradiol daily for three weeks, followed by a week's break before beginning again. Combined substitution with estrogens and gestagens (p. 601) is better. One of the sequence preparations (p. 568f.) usually used as ovulation inhibitors is today very often used instead.

With this treatment mammary glands, labia minora, vagina and uterus develop as in normal female puberty. However, not uncommonly development of the breast is not quite ideal; the nipples can often become strongly pigmented, and an almost black and crust-like thickening can arise in the mamillary epidermis due to treatment with stilbestrol. Menstruation occurs regularly every 4 weeks. Sexual hair, previously poorly developed, becomes more marked. The cause of this is presumed to be the effect of estrogens leading to increased androgen production by the adrenal cortex, via the pituitary. However, body hair as a whole also increases, although not excessively. Urinary 17-ketosteroids rise to normal values for an adult woman and elevated levels of gonadotropins fall.

If epiphyseal fusion is not yet complete, this form of treatment leads to a definite, but usually modest *acceleration of growth*, but it is not certain if the final height is materially improved. The treatment can at the same time inhibit and favourably influence an osteoporosis already present. Certain authors think that as long as epiphyseal fusion has not yet occurred, growth can be more favourably influenced by administering additional doses of anabolic steroids, or by giving these steroids alone. Unfortunately there is no form of treatment from which definite improvement in growth and the ultimate adult height can be expected.

The infantile psychological characteristics and poor sexuality improve considerably with treatment. The patients become more mature mentally, and steadily realize more or less normal sexuality so that marriage can be successful even in the sexual respect. There is therefore no reason to object to the marriage of a treated patient providing both partners are fully informed about the sterility of the woman.

2. Male Turner's Syndrome

Occasionally, male individuals are seen who have normal male genitalia, but become conspicuous by poor growth and dysmorphic features similar to those found in Turner's syndrome (Fig. 14). This condition is called male Turner's syndrome if hypogonadism is present, and Noonan's syndrome in the absence of hypogonadism. These two states probably belong to a heterogeneous group. The presenting features are the dysmorphic characteristics with pterygium colli, sphinx face and cubitus valgus. A cardiac defect may also occasionally be present. Intelligence is frequently slightly impaired. Puberty is not very marked and the testes remain small because of deficient tubular development. However, absolutely normal testicular development and normal puberty are also often found in the same phenotype.

Examination of the chromosomes usually reveals an XY karyotype. There can be a familial occurrence. An XO/XY mosaic is also found

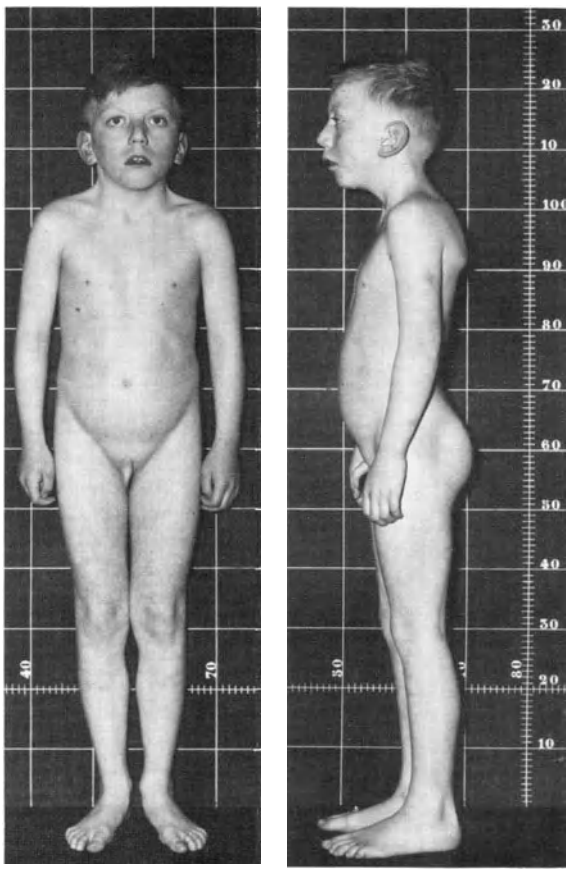

Fig. 14. 11-year-old boy with the male Turner's syndrome: small stature, sphinx face, short and broad neck, small nipples, bilateral cryptorchidism and mild mental deficiency

occasionally. Mixed gonadal dysgenesis with intersexual external genitalia is classically associated with this mosaic. In extreme cases with normal male genital formation and obvious dysmorphic features of Turner's syndrome, it is a matter of opinion whether one uses the term "male Turner's syndrome" or "mixed gonadal dysgenesis".

3. Pure Gonadal Dysgenesis

Pure gonadal dysgenesis, occasionally also termed as Swyer's syndrome, involves individuals with internal and external normal female genitalia and functionless rudimentary gonads (streaks), as does Turner's syndrome. In contrast to Turner's syndrome, neither dwarfism nor dysmorphia is present.

The *karyotype* is XX or XY. There is a familial incidence for both types. The chromatin-positive XX form is probably inherited through an autosomal recessive gene. The chromatin-negative XY form appears to be transmitted only through healthy women so that recessive inheritance of one X chromosome appears probable. In any case, two different genotypes are involved. It is unknown whether sporadic cases belong exclusively to these two genotypes or whether other causal factors are present. In a few cases, the alleged Y may really be an Xq, i.e. an X with deletion of the long arm (KARL, 1967). Absence of male genital differentiation in the XY form can be explained by the absence of fetal testes which are essential for the induction of male genital development (p. 708).

The *gonads* are streaks, similar in appearance to those in Turner's syndrome (p. 714). Histologically, they consist largely of only fibrous stroma. A few follicular elements or accumulations of hilus cells are occasionally found. In the XY form, rudimentary tubules can also be seen occasionally.

Malignant gonadal tumours, gonadoblastomas or dysgerminomas, were found in 7 of 26 XY cases (BARR, 1967).

The striking *clinical feature* is the absence of secondary sexual characteristics or the very poor development of these. Body proportions are often eunuchoid. Enlargement of the clitoris is occasionally found in the XY form. Estrogen excretion is reduced, whereas gonadotropins in the blood and urine are raised.

Asymmetric mixed gonadal dysgenesis must be considered in the *differential diagnosis*. Pure gonadal dysgenesis with an XY karyotype as well as an asymmetric mixed gonadal dysgenesis with an XY or XO/XY karyotype can be present in a chromatin-negative patient of normal height, with hypertrophy of the clitoris and rudimentary testes. In the latter type of dysgenesis, a testis can be found on one side, giving rise to male pubertal development. The danger of tumors is similar in both syndromes.

4. Asymmetric Mixed Gonadal Dysgenesis

This syndrome is applied to individuals with intersexual genitalia, with one testis on one side and a rudimentary gonad (streak) on the other side. Dwarfism and dysmorphic features similar to those in Turner's syndrome may also be observed. There are about 50 known cases so far.

The sex chromosome mosaic XO/XY is the cause of this syndrome in the majority of cases. The XO line explains the rudimentary gonads and the clinical Turner's elements, whereas the XY line explains testicular development and the at least partial male genital development. The XO/XY mosaic probably arises from a Y loss during one of the first mitoses after fertilization. Most cases with the XO/XY mosaic show asymmetric mixed gonadal dysgenesis. In a few cases however, streak gonads are also found bilaterally, associated with a more or less definite Turner's syndrome, or bilateral testes with intersexual genital development, i.e. with the clinical picture of male pseudohermaphroditism are found (p. 724).

In addition to the XO/XY mosaic, there are also cases of asymmetric mixed gonadal dysgenesis with the XY karyotype, XX/XY mosaic and other complicated mosaic forms.

The intersexual external genitalia are the striking *clinical* feature. All stages between mild clitoral hypertrophy and mild hypospadias occur (Fig. 15). Pure female or pure male

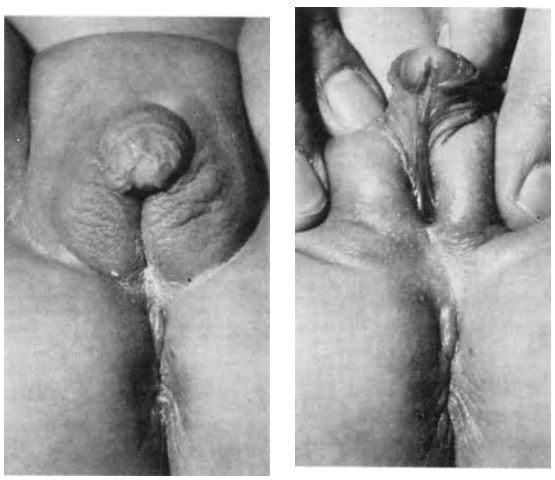

Fig. 15. Intersexual genitalia (Type III) in asymmetric mixed gonadal dysgenesis with XO/XY karyotype

external genitalia are extremely rare. The remaining physical development is not obtrusive or as in Turner's syndrome, dwarfism and Turner-like dysmorphic features such as sphinx face, pterygium colli and shield thorax can be found, though to a lesser degree. Secondary sexual characteristics are usually of the male type but often not very marked. There may be slight development of the breasts but menstruation fails to occur.

The unilateral *testis* usually lies intra-abdominally, but can also occasionally be situated in the inguinal region or scrotum. The degree of differentiation varies, and the testis can be rudimentary or even almost normal. On the other side of the body, a rudimentary streak-type gonad lies in the position of an ovary, as in Turner's syndrome. Occasionally no gonad at all can be found on this side. A rudimentary uterus is usually present. A tube is usually found on the same side as the rudimentary gonad, and a tube or a ductus deferens or both can be found on the side with the testis. The deficient male development of the external genitalia and inadequate suppression of the Müller's derivatives indicate the insufficiency of the fetal testis. Development of *malignant tumors* is common on the side with the streak and the side with the testis. In one study a gonadoblastoma or seminoma was found in 11 of 40 cases (AARSKOG, 1970).

The *diagnosis* of an asymmetric mixed gonadal dysgenesis must therefore always be considered when external genitalia are intersexual, the sex chromatin is negative and when only one gonad or none at all can be palpated in the scrotum or inguinal region. In this situation, surgical exploration with gonadal biopsy is indicated. If asymmetric mixed gonadal dysgenesis is found, the intra-abdominal testis as well as the streak-like gonad should be removed because of the danger of tumors. If the external genitalia are more masculine the child is brought up as a boy and the state of the genitalia corrected surgically. If the genitalia are more of a feminine nature, the child is declared a girl, external genitalia are corrected by appropriate surgical measures, any testicular tissue present is removed, and substitution therapy with female sex hormones is introduced at the age of puberty.

5. XX Men

About 40 individuals have been described with confirmed testes and a pure XX sex chromosomal configuration (DE LA CHAPELLE, 1964, 1970). They show normal male sexual differentiation, normal male stature, normal growth, normal adult height, normal body proportions and normal intelligence. The latter findings contrast to the classic Klinefelter's syndrome. The testes are too small but not always as small as in Klinefelter's syndrome. The condition resembles that in Klinefelter's syndrome in that the secondary sexual characteristics are often not very well developed and gynecomastia is commonly present. Androgen production is correspondingly somewhat reduced and gonadotropin excretion is raised. The histological picture of the testis is sometimes similar to that found in Klinefelter's syndrome and sometimes similar to the picture in aplasia of the germinal cells.

Since according to present day knowledge a testis can only develop in the presence of a Y chromosome, it is difficult to explain how this syndrome develops. An XX/XY mosaic and an XX/XXY mosaic have been discussed, where the line contained in Y has disappeared or is not found on examination. Another theory is that partial exchange occuring between X and Y chromosomes during meiosis could cause the X chromosome to acquire similar testicular-determined properties (X^y) to the Y chromosome (FERGUSON-SMITH, 1966). Since according to LYON'S hypothesis, it is a matter of coincidence whether the X or X^y is active more frequently, either ovaries (normal woman) or testes (XX man) or ovaries and testes (true hermaphroditism) could develop.

6. True Hermaphroditism

The term true hermaphroditism is used when the gonads definitely contain both testicular and ovarian tissue. Over 200 cases have so far been described.

Very little is known about the *etiology and pathogenesis*. Most cases are chromatin-positive. More than half the cases show a normal set of female XX chromosomes. In such cases, the same speculations (partial exchange between X and Y with development of an X^y) can also be adapted for the syndrome with XX men. Bilateral ovotestes have been observed in siblings of two families. The karyotype was measured only in one family and was XX (ROSENBERG, 1963). The XY karyotype and other mosaic forms arise as well as the XX karyotype. The XX/XY mosaic is the commonest mosaic form. In a few cases, two different populations of erythrocytes and plasma proteins have been demonstrated, so that it can be assumed that an ovum with two nuclei is fertilized by two different sperms (dispermia). Of special interest is the observation of a true XX/XY hermaphrodite and an XX man in the same generation

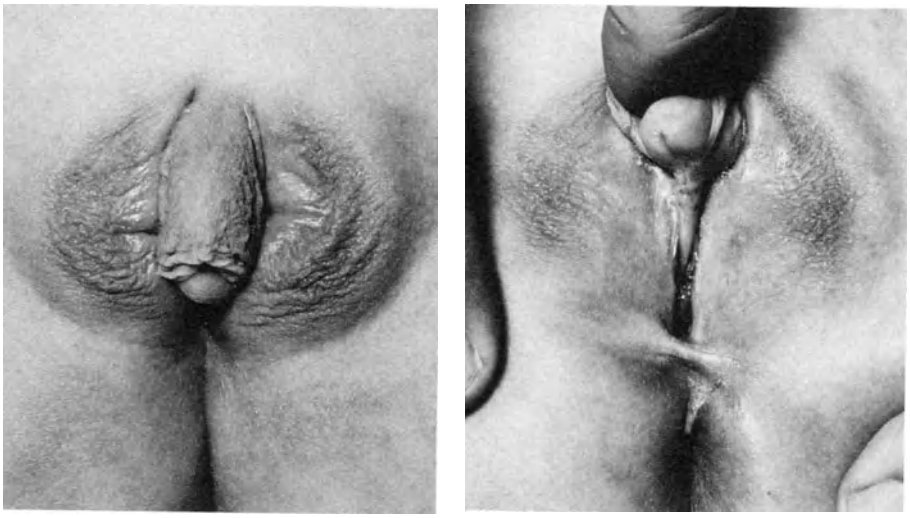

Fig. 16. Intersexual genitalia (Type II) in true hermaphroditism with a testis on the right side and an ovary on the left. (From PRADER, SIEBENMANN, and BETTEX)

of siblings (BERGER, 1970). True hermaphroditism is not always found with an XX/XY karyotype; asymmetric mixed gonadal dysgenesis (see p. 721) or more or less normal testicular development with or without hypospadias (male pseudohermaphroditism, p. 724) can also be associated with this mosaic (AARSKOG, 1970).

The *external genitalia* almost always have an intersexual appearance, Types III and IV (Figs. 5 and 16, p. 710, 723) occur most frequently, so that the majority of patients are brought up as boys. Purely male or purely female external genitalia are extremely rare.

The *gonads* are situated intra-abdominally, in the inguinal region, or in the labia or scrotum. Bilateral ovotestes are found in a quarter of cases (bilateral form), and an ovary on one side with a testis on the other side in another quarter of cases (lateral or alternating form). In the remaining cases, an ovotestis is present on one side and either an ovary or a testis is found on the other side (unilateral form). Testicular tissue is found significantly more commonly on the right side and is usually less differentiated than the ovarian component. Mature ova develop quite frequently whereas mature spermatozoa are rarely formed. Mature follicles as well as mature spermatozoa are occasionally observed in the same patient, so that fertility or even self-fertilization is theoretically possible. Until now however, there is no known case of definite fertility.

The *internal genitalia* usually show male as well as female characteristics, and all imaginable combinations can arise. In the presence of a pure male or female gonad, the genital passages on the same side are usually of the same sexual character as the gonad. However, a Fallopian

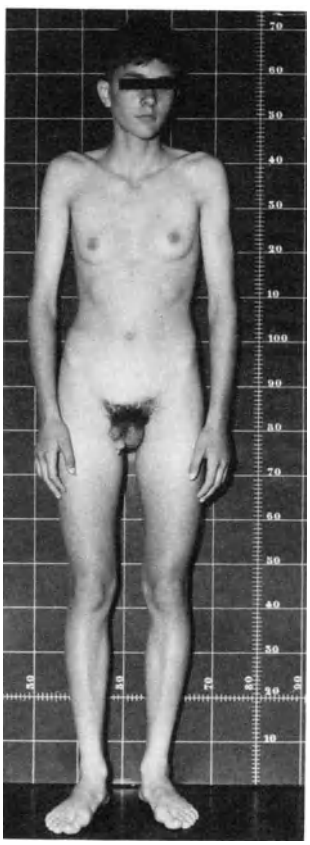

Fig. 17. 14-year-old youth with true hermaphroditism: hypospadias scrotalis (wears a post-operative urethral catheter), male stature, feminine breast development, bilateral ovotestis (left scrotal, right inguinal)

tube is usually present on the side of an ovotestis. A rudimentary or fully developed uterus is present in the majority of cases. Inguinal hernias are common.

Secondary sexual characteristics (Fig. 17) arise at the normal age and soon become more pronouncedly female or male. The course of this development cannot be predicted from the gonadal and genital findings. Female breast development arises in most cases. Menstruation occurs in about half the cases. Mentality and sexuality vary from case to case.

The *diagnosis* is not easy and is probably frequently missed. The condition must be considered in every case where external genitalia are intersexual. This is particularly applicable to chromatin-positive cases which would not be classified as nonadrenal feminine pseudohermaphroditism (p. 730) after exclusion of the adrenogenital syndrome. The true diagnosis is based on bilateral gonadal biopsies, but since biopsy from an ovotestis can reveal ovarian or testicular tissue alone under special circumstances, even bilateral biopsy is no certain method for confirming true hermaphroditism.

7. Agonadism

A special form of intersexuality termed agonadism has been described in 7 individuals brought up as girls (OVERZIER, 1956). Gonads were completely absent in these patients. No derivatives or merely rudimentary derivatives of the Wolffian and Müller's ducts were found. The external genitalia consist of a lump, similar to a somewhat enlarged clitoris. A normal urethra opens below. Other external and internal genital structures are absent. The karyotype was found to be XY in all three cases examined by one author (RATH, 1968). Involvement of siblings has been observed once (OVERZIER, 1956). Etiology and pathogenesis are not clear. According to present-day embryological knowledge (p. 708), absence of gonads should lead to female development, as is the case in Turner's syndrome. It is possible that the disturbance occurs at a much earlier stage, i.e. even before development of the Wolffian and Müller's ducts. According to OVERZIER'S theory, the "initial induction" of the gonadal "initial induction" of the gonadal "*anlage*" on the development of the genital ductile system is missing.

In order to avoid misunderstandings, it is stressed here that the terms agonadism and anorchia are used in quite different circumstances. Normal male genital development is associated with anorchia (p. 461).

F. Abnormal Genital Development in the Presence of Normal Testes (Masculine Pseudohermaphroditism)

Male pseudohermaphroditism indicates female or intersexual genital development in individuals with normal testes and usually also with a normal male XY karyotype. This is a very large group of various disorders which are compiled together in a survey presented in Table .

The pathogenesis of these disturbances is only partly explained. Fig. 18 shows once more the androgenic stimulation on genital development through the fetal testes and the nonandrogenic action of the fetal testes causing suppression of the oviduct (p. 709). If the unknown chemical factor of the fetal testes causing oviduct suppression is absent, male genital development occurs but uterus and tubes also develop at the same time. This is the syndrome of *hereditary persistence of the oviducts* (p. 725). If the periphery fails to respond to the normal androgenic stimulus of fetal testes, then female genital development occurs. Tubes and uterus are, however, not present due to the nonandrogenic action of the testes suppressing the oviducts. This gives rise to the syndrome of *testicular feminization* (p. 726). If *biosynthesis of testosterone* is disturbed in the fetal testes, then the external genitalia will be intersexual or feminine depending on the extent of the synthesis disorder, and the internal genital organs will develop normally (p. 725). Apart from these disturbances where the pathogenesis is understandable, there are numerous others whose pathogenesis is not yet known.

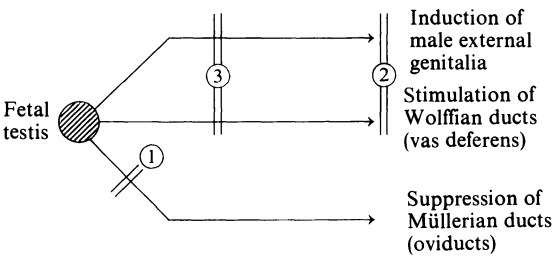

Fig. 18. Abnormal sex differentiation in male pseudohermaphroditism (XY-karyotype with normal testes). *1* Deficient suppression of oviducts: persistent oviducts. *2* Unresponsiveness to testosterone: testicular feminization. *3* Defective biosynthesis of testosterone: various enzyme defects

The situation is particularly confusing in male pseudohermaphroditism with intersexual external genitalia. Here, numerous individual cases cannot be classified satisfactorily before puberty. This is especially tragic in newborns and children, since a prognosis about the later development of puberty is impossible without a clear

classification, and this renders the decision about which sex the child should adopt more difficult. Classification in this group is based particularly on the nature of the secondary sexual characteristics and on the inheritance. *Incomplete testicular feminization* with mild masculinization of the external genitalia and female secondary sexual characteristics and the *similar syndrome with hypospadias and gynecomastia* in the presence of male secondary sexual characteristics (p. 729) are inherited through healthy women as testicular feminization (recessive X chromosome). In contrast, *hereditary vulviform perineal hypospadias* with male secondary sexual characteristics is inherited through a recessive autosomal gene. In a few cases, there is *a disturbance of the sex chromosomes* (p. 721) which can occasionally lead to quite well established testicular development and normal secondary sexual characteristics. Only the incomplete masculinization of the external genitalia and incomplete suppression of development of the uterus and tubes show that testicular development is probably not quite normal.

Finally, masculine pseudohermaphroditism with intersexual external genitalia is often found together with other malformations or as part of a dysmorphic syndrome (Table 2). Reference must be made here to pediatric textbooks on this subject.

1. Oviduct Persistence

The syndrome is also termed as internal masculine pseudohermaphroditism or as the uterine hernia syndrome. This syndrome involves mainly the absence of embryonal suppression of Müller's ducts in otherwise normal men. Either the biochemical factor concerned is absent in the fetal testes (p. 710) or Müller's ducts fail to react to it.

In known cases either unilateral or bilateral cryptorchidism is usually present and there is also a unilateral inguinal hernia. During the course of the operation, the surgeon finds a small uterus with Fallopian tubes in the abdomen or in the hernia in the presence of more or less normal testes and a normal or hypoplastic ductus deferens. The patients are otherwise unremarkable and show normal male development of the primary and secondary sexual characteristics. The degree of development of the testes depends on the position. Atrophy is often claimed to be present but normal fertility has also been confirmed in a few cases. A tumor arises in the majority of cases with intra-abdominal testes (termed teratoma, carcinoma or seminoma).

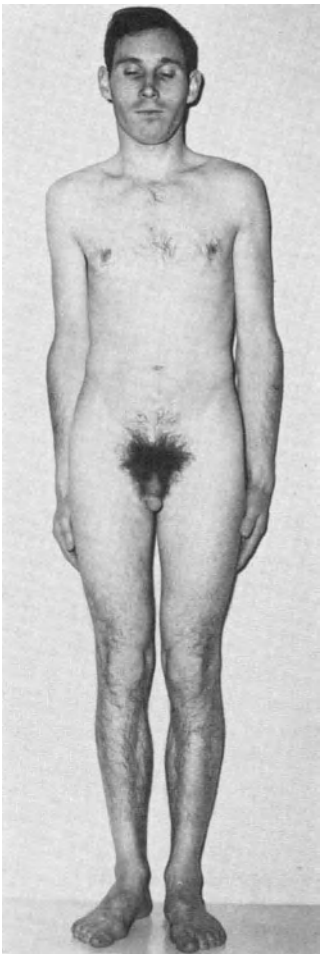

Fig. 19. 30-year-old, unobtrusive man with familiary oviduct persistence: bilateral cryptorchidism, right-sided inguinal hernia operated on at age of 18, contained uterus with tubes and testes; intra-abdominal testicular tumour (seminoma) was operated on at age 20

The diagnosis can only be made during surgical repair of cryptorchidism or during herniotomy. There are 70 recorded cases. We know of three families in which siblings were affected, which makes a sex-limited autosomal recessive inheritance appear probable.

2. Disturbances of Testosterone Synthesis

There is a series of autosomal recessive disturbances of the synthesis of steroids, of adrenocortical steroids and of testosterone formed in the Leydig cells. They can probably all be inherited. Testosterone synthesis alone may be affected, and whereas in this case genital development is uninfluenced in the girl, the deficiency of testosterone in the fetal period causes masculine pseudohermaphroditism with abnormal external and normal internal genitalia in the

boy. It also leads to reduced testosterone concentrations in the blood and urine, which cannot be stimulated by chorionic gonadotropin (HCG).

The enzyme defects so far known about are listed in Table 2 and their biochemical localization presented in Fig. 27, p. 358. Since most of the disorders are discussed fully in the chapter on the adrenal cortex, a short account is sufficient here.

In lipoid hyperplasia of the adrenals (p. 323) there is a *20-hydroxylase or other defect* which makes conversion of cholesterol into Δ5-pregnenolone impossible. The male newborn therefore suffers from an adrenal insufficiency and external genitalia are feminine or intersexual.

In the *congenital adrenogenital syndrome* with a *3β-dehydrogenase* defect (p. 371), conversion of 3-hydroxy-Δ5 steroids into 3-keto-Δ4 steroids is blocked. No glucocorticoids and no testosterone can be formed, but large amounts of dehydroepiandrosterone. This latter compound has a limited androgenic action. Adrenal insufficiency and female or intersexual external genitalia arise in the newborn boy.

Deficiency of *17-hydroxylase* (p. 359) has been little investigated in male individuals (p. 339). It blocks the synthesis of cortisol, testosterone and all other androgenic steroids. It also results in female or intersexual external genitalia in the newborn boy.

Deficiency of *17-desmolase* is the most recently described impairment of testosterone biosynthesis (ZACHMANN, 1971).

Deficiency of 17-reductase prevents conversion of androstenedione to testosterone. This defect has been seen in a male individual brought up as a girl, who had intersexual external genitalia and normal pubic hair. *In vivo*, the concentration of androstenedione in the blood was many times higher than normal and it was not possible to obtain the conversion of androstenedione to testosterone by means of excised testicular tissue.

3. Testicular Feminization

Testicular feminization has been known about for a long time and it is a sharply defined form of masculine pseudohermaphroditism. The term "testicular feminization" (MORRIS, 1953) is not really correct with regard to the pathogenesis, but it is precise and short. The following description would be more correct and cautious: "hereditary intersex form in the presence of an

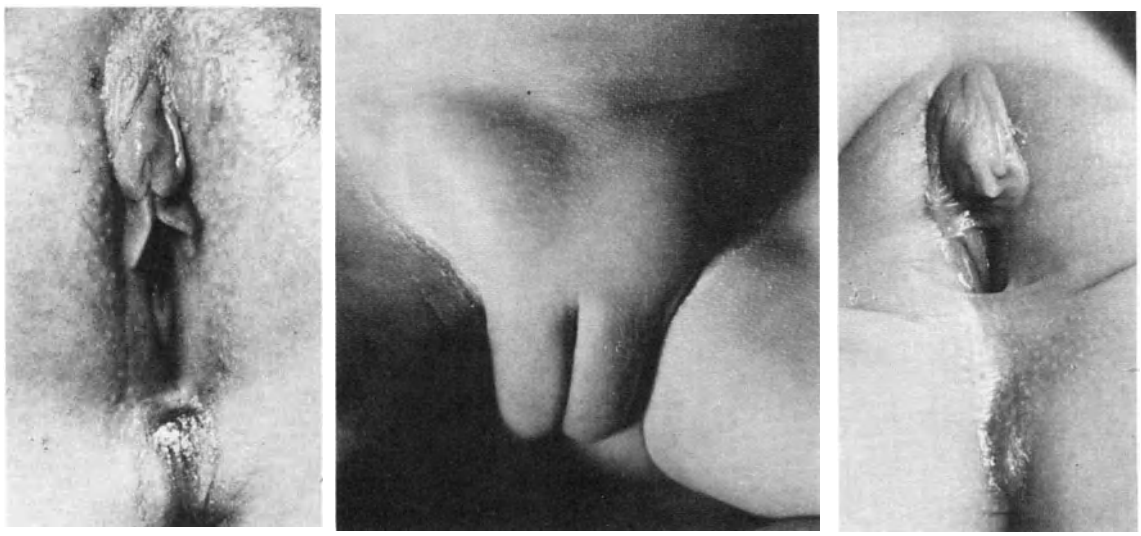

Fig. 21. External genitalia (left) and inguinal testes (middle) in testicular feminization. Right: external genitalia in incomplete testicular feminization

Fig. 22. 21-year-old woman with testicular feminization. Normal female breast development, axillary hair absent

individual of female appearance, but with male chromosomes and gonads in the absence of a uterus and sexual hair". Stressing the presence of only one symptom, WILKINS described these patients as "hairless women with testes". The frequency is estimated as 1 : 20000 to 1 : 60000.

Although the patients possess a normal male XY karyotype and testes, external genital features, breast development, voice and stature and psyche are absolutely feminine (Fig. 22), so neither the patients nor relatives doubt the sex. The feminine beauty and the well developed breasts are in fact often commented on in these patients. Usually they are tall and long-legged. Primary amenorrhea, which is always present, and sterility are *suggestive symptoms*, as well as the complete absence of pubic and axillary hair and the presence of inguinal swellings or definite inguinal hernias.

Primary amenorrhea and sterility quickly lead to recognition of the disorder after thorough gynecological examination. The external genitalia are normal or hypoplastic (Fig. 21). Breast development is normal. The sparse pubic hair, the too-short vagina ending blindly, the absence of an uterus and very often also of ovaries are striking findings. In the adult patient, small tumors which can also reach the size of a fist are found in the small pelvis or in inguinal hernias. These tumors are usually benign tubular adenomas. The vaginal smear shows normal or rather limited estrogenic effects.

Axillary hair is completely absent in the classic case. *Pubic hair* is usually present but sparsely developed.

Inguinal hernias are frequently present. They frequently arise in babies (Fig. 21) but can arise later on just as commonly. Usually they form a protrusion the size of a nut or plum above the labia majora. They occasionally give rise to pain, but mainly to vague complaints. The gonads can usually be definitely palpated. These testes are an important finding, and in infancy they are often the only indication of testicular feminization.

Hormonal findings show that testosterone levels in the blood and urine lie within normal male ranges, and that estrogen values are in the lower normal female range. Excretion of 17-ketosteroids is negligible. Levels of gonadotropins are usually slightly raised.

Examination of the internal genital organs during an exploratory operation or a herniotomy reveals the following features: uterus and tubes are absent or mere rudiments are found. The tubes may be connected with the blind-ending vagina. A rudimentary spermatic cord is occasionally found instead of a tube. The gonads are situated intra-abdominally, in the inguinal canal or very often also in the inguinal hernial sac.

Histology of the testes is exactly similar to that of undescended testes. The seminiferous tubules are usually lumenless and contain only Sertoli cells. Immature elements of spermatogenesis are rarely present, and mature spermatozoa even more rarely (KOLLER). A normal number or even an increased number of Leydig cells are present in the adult. Very often tubular adenomas which may be small or the size of a fist are also found (PICK's tubular adenoma of the testis, p. 491). The incidence of malignant tumors also tends to be high, but they are not nearly as common as in true gonadal dysgenesis and asymmetric mixed gonadal dysgenesis. The adrenals usually show no peculiarities.

The disorder is *hereditary*, is always transmitted only through healthy women and affects statistically half the male offspring. Carriers themselves also have extraordinarily poorly developed sexual hair and puberty is often claimed to have started very late. In the classic family tree (Fig. 23), siblings and aunts on the maternal side are affected, whereas the carriers (female) and a few other healthy female members of the family have poorly developed sexual hair. Since patients cannot propagate, consideration of such family trees does not exclude the possibility of an X chromosomal sex-bound recessive inheritance or an autosomal dominant mode of inheritance with sex-limited action.

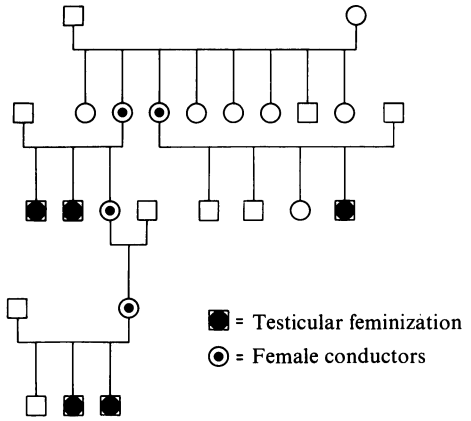

Fig. 23. Genealogical tree in testicular feminization: transmission only through healthy women. (From PRADER, 1957)

Current knowledge of the *pathogenesis* is incomplete, but there can be no doubt that the testes determine puberty of a feminine nature. In this respect, the term "testicular feminization" is justified, and is substantiated by the *effects of castration.* After surgical removal of the gonads, pronounced features of failure arise in the adult patient. Breast development regresses, the vaginal mucosa becomes atrophic, patients suffer from hot flushes, the excretion of estrogens and androgens falls and gonadotropin excretion rises.

All investigations so far indicate a *peripheral resistance to testosterone or androgens.* Testosterone production in the testes corresponds to normal male levels although the testicular tissue in vitro demonstrates a relative 3β-dehydrogenase deficiency. The effects of testosterone, however, are absent. This can be easily detected clinically and by metabolic methods. High doses of testosterone produce no signs of virilization, no hypertrophy of the clitoris, no change in voice, no increase in sexual hair or hair follicles. An anabolic effect is also absent, i.e. the usual fall in urinary excretion of phosphorous, nitrogen and citric acid fails to occur. It can therefore be presumed that resistence to androgens is already present in the fetus, resulting in suppression of male genital differentiation dependent on testosterone whereas suppression of Müller's ducts, which is independent of testosterone, occurs normally with failure of uterus and tubes to develop (p. 709, 724).

The biochemical nature of the resistence to androgens has still not been explained. It appears that testosterone can only be effective if it is first reduced to dihydrotestosterone in the tissues and that this process is inadequate in testicular feminization. This might be due to a 5α-reductase deficiency or to the increased binding capacity for testosterone in the plasma (MAUVAIS-JARVIS, 1970). The deficiency of dihydrotestosterone does not, however, offer a satisfactory explanation for the resistence to androgens, since in testicular feminization dihydrotestosterone exerts just as weak an anabolic effect as testosterone, in contrast to the effect seen in healthy subjects (STRICKLAND, 1969). Trials with rats suffering from a biologically similar hereditary disorder have given reason to believe that dihydrotestosterone is not taken up and bound by the cell nuclei (BARDIN, 1970).

The fully developed syndrome is so characteristic that the *diagnosis* can be made without the help of gonadal biopsies. In the adult, the diagnosis is made on the basis of the following main features: primary amenorrhea, abnormally sparse sexual hair, short, blind-ending vagina, negative sex chromatin associated with a woman of normal height and with normal female development of the breasts. The diagnosis is even simpler if hernias are present and if the same disorder is found in relatives on the maternal side. In children, many important symptoms are not yet present so that investigation is more difficult, but gonadal biopsy is still not essential. This diagnosis must be considered in every girl with an inguinal hernia, and the sex chromatin and the length of the vagina must be determined preoperatively.

The *differential diagnosis* includes pure gonadal dysgenesis with XY karyotype (p. 721), although in this condition secondary sexual characteristics are poorly developed and a uterus is present. Hypertrophy of the clitoris is not a sign of pure testicular feminization, but of one of the many syndromes discussed under masculine pseudohermaphroditism with intersexual genitalia (Table 2, p. 712). Differentiation is particularly important during infancy since puberty of the female type can be definitely predicted in cases of testicular feminization, whereas a masculine puberty is more likely and often almost certain in the other conditions.

There is no *treatment* for this condition. No hormone treatment can correct the amenorrhea and sterility since uterus and ovaries are missing. All that can be done is to orientate the patient or her relatives about the genital findings, prognosis (sterility) and about the heredity. In children, it is important to stress that normal female puberty will arise in spite of the absence of the uterus. The patients will naturally be looked upon as female individuals and care should be taken to avoid disclosing the gonadal and chromosomal sex. The mistake, which so commonly arises from the lack of knowledge, of declaring these children boys and masculinizing the genitalia as well as possible by surgical means has a disastrous effect with the develop-

ment of female puberty and female secondary sexual characteristics.

Bearing in mind the possibly increased risk of malignant testicular tumors, the only therapeutic problem is the question of whether the testes should be removed at the time of herniotomy and the hormone loss later replaced by long-term estrogen treatment. It is important not to remove the testes in children where this danger does not exist, but to place the testes in the abdominal cavity thus making spontaneous development of female pubertal characteristics possible. Later, one would not hesitate to remove hernias and gonadal tumors by castration and to introduce subsequent substitution therapy with female sexual hormones.

4. Incomplete Testicular Feminization and Similar Syndromes

Apart from classic testicular feminization, there is another syndrome which resembles testicular feminization in the testes and internal genital development. In this syndrome however, there is hypertrophy of the clitoris with genital Types I–III (Fig. 5), sexual hair of the female type and poor development of the breasts. Inheritance occurs through healthy women as in testicular feminization (DIEFENBACH, 1912; SCHERBAK, 1934; LUBS, 1959). The picture is always the same within a family. The term *incomplete or partial testicular feminization* seems appropriate, although no evidence of partial resistence to testosterone has so far been produced.

There are two syndromes in which male genital differentiation is somewhat more obvious and which have the same mode of inheritance. One of these is the *Gilbert-Dreyfus syndrome*, in which there is scrotal hypospadias (genital Type IV), scrotal testes, a male stature, male puberty and gynaecomastia. The other is the *Reifenstein syndrome*, characterized by hypospadias and gynaecomastia associated with an entirely male appearance, although the testes are rather small and secondary sexual characteristics are not very marked.

Testicular feminization and the two syndromes just mentioned can be considered as different stages of inadequate differentiation of the external male genitalia (FEDERMAN, 1967). The range extends from testicular feminization with complete deficiency of androgenic genital induction to the normal man with completely normal genital differentiation (Table 4). The factors common to these syndromes are inheritance through healthy mothers, absence of a true androgen deficiency despite a deficiency of androgenic effect, and almost normal suppression of Müller's ducts which is independent of androgens. It can still not be definitely said whether these are clearly definable disorders, each due to a different cause, or whether they are all *one* syndrome with varying interfamilial pronouncement and whether a gradually variable resistence to androgens is present. Resistence to androgens has so far only been demonstrated in testicular feminization.

Classification is, however, difficult in individual cases with intersexual external genitalia and where no information can be obtained about the inheritance from the family history. A pseudovaginal perineal hypospadias may also be present and in practice classification is often impossible.

5. Hereditary, Vulviform, Perineal Hypospadias

This term (also "pseudo-vaginal, perineoscrotal hypospadias") is applied to a group of individuals with intersexual external genitalia, with no uterus or tubes, and in whom normal male puberty occurs.

The genital findings can vary considerably, from a more female appearance with enlarged clitoris and genital Types II–III (Fig. 5) with abdominal testes to a more male appearance with perineal hypospadias, i.e. with intersexual

Table 4. Forms of masculine pseudohermaphroditism with varying degrees of androgenic genital differentiation, inherited through healthy mothers

	Uterus, tubes	Ductus deferens	External genitalia (Fig. 5)	Sexual hair	Breast development	Stature
Female phenotype						
– Testicular feminization	–	–	Female	–	++	Female
– Incomplete testicular feminization	–	+	I–III	+	++	Female
Male phenotype						
– Gilbert-Dreyfus syndrome	–	+	III–IV	+	+	Male
– Reifenstein syndrome	–	+	IV–V	+	+	Male
Normal male	–	+	Male	+	–	Male

genitalia of Types III–IV and scrotal or abdominal testes. In the former case, the individual is brought up to begin with as a girl, and in the latter case as a boy.

The common factor is the mode of inheritance, which in contrast to incomplete testicular feminization is not via the mother, but autosomal recessive. This is supported at least by the frequency of the condition in siblings and consanguinity of the parents when maternal aunts are not affected. The pathogenesis is unknown.

During infancy it is often impossible to differentiate between incomplete testicular feminization, which would lead to later development of female puberty, and the form discussed here, with development of male puberty, particularly if the family history gives no indication of the mode of inheritance and if the course of puberty is not helpful. It is not known either if sporadic cases with a rudimentary uterus belong here to this group. Our very inadequate knowledge of this form of masculine pseudohermaphrotitism makes it almost impossible to classify any individual case and arrive at a prognosis.

The mode of inheritance is also autosomal recessive in milder cases of hypospadias with scrotal or imperfectly descended testes. Puberty arising later is nearly always of the male type, so that surgical and psychological measures present no problems.

G. Abnormal Genital Development in the Presence of Normal Ovaries (Feminine Pseudohermaphroditism)

Feminine pseudohermaphroditism signifies male or intersexual genital development in individuals with normal ovaries and a normal female XX karyotype. The disorders conforming to this definition are grouped together in a survey presented in Table .

An abnormal effect of androgens on female genital differentiation is the most common reason for this partial to complete masculinization of the external genitalia (Fig. 24). The fetal ovaries exert no active stimulation on genital development. Genital development is always of a feminine nature in the absence of active androgenic stimulation (p. 708). An abnormal effect due to endogenous androgenic hormones of the fetal adrenal cortex is found in the *congenital adrenogenital syndrome* (p. 360). The abnormal action of exogenous hormones can be termed *transplacental virilization* (p. 731). These hormones are either androgenic or gestagenic steroids given to the mother during pregnancy or androgenic steroids secreted by ovarian or adrenocortical tumors in the mother.

The degree of masculinization of the external genitalia depends on the timing and severity of the androgenic influences. It is interesting to note that the androgenic influences are never strong enough (or never early enough) to cause development of a *ductus deferens*. Since the suppressive action exerted by the testes on the oviducts is not of an androgenic nature (p. 710), tubes and uterus develop in the normal way. Thus, only external genital development, and not internal genital development, is masculinized.

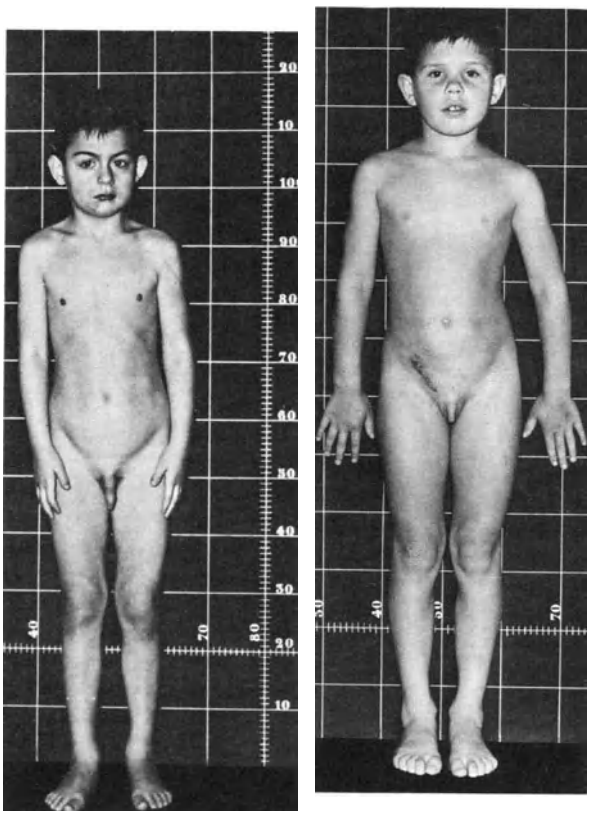

Fig. 24. Two girls with completely masculine external genitalia (genital Type V) and apparent bilateral cryptorchidism. Patient on the left; almost 5 years old, pubic hair beginning to appear in congenital adrenogenital syndrome with extreme virilization. (From PRADER, 1958.) Patient on the right: 7 years old, normal physical development and extreme transplacental virilization resulting from an androgenic adrenocortical tumour in the mother. (From MÜRSET, 1970)

The pathogenesis of these forms of feminine pseudohermaphroditism is understandable but there are cases with *complex urogenital malformations* where the pathogenesis is unknown. Some *newborns with renal agenesis* belong to

this group. Further, a special form is described where the urethra is double, consisting of vaginal and clitoric portions, is very narrow and can give rise to urinary retention.

The great majority of cases of feminine pseudohermaphroditism can be easily classified under one of the known forms. Occasionally however, cases of idiopathic hypertrophy of the clitoris or idiopathic feminine pseudohermaphroditism with normal feminine puberty can occur, but the etiology has not yet been fully explained. It is conceivable that androgenic influences from the placenta might be involved, but nothing is known about this at present.

Transplacental Virilization

If *testosterone* or *methyltestosterone* or one of the other *androgens or anabolic steroids* is given to a woman during pregnancy, the external genitalia of the newborn girl will show definite features of masculinization even when no signs of virilization are to be found in the mother. The same is true of *synthetic gestagens*, particularly ethinyl nortestosterone (nor-ethindrone) and ethinyl testosterone (etisterone) which are used in threatened abortion. *Progesterone* and *diethylstilbestrol*, which are effective in the adult, probably also have virilizing actions. Administration of large doses during the first three months of pregnancy can result in very severe Types IV–V masculinization of the external genitalia, so that the newborn may be mistaken for a boy with cryptorchidism. Milder doses or later treatment results only in hypertrophy of the clitoris. The fetus is apparently especially sensitive before and during the period of genital differentiation, and shows an androgenic reaction to steroids which produce no or hardly any androgenic response in the adult woman. The internal reproductive organs are always female. Occasionally, bone maturation is found to be advanced in newborns. Later growth and development run a normal female course appropriate to the age.

In the same manner, partial to complete masculinization of the external genitalia due to *an androgenic tumor in the mother* has been observed in a few cases. Usually an *arrhenoblastoma* is responsible, but an *androgenic adrenocortical tumor* (Fig. 24) was found in one case. The findings are exactly the same as those following administration of androgens or gestagenic steroids during pregnancy. It is extremely rare for a maternal tumor to have hormonal effects on the fetus as a virilizing tumor usually results in amenorrhea and sterility.

H. Diagnosis and Differential Diagnosis

1. Intersexual Genital Appearance

The problem of classifying the sex arises usually in the newborn, but also occasionally only later, in the presence of external intersexual genitalia. Precise investigations should follow as soon as possible after birth to put an end to the tragic uncertainty and to come to the decision which will prove most suitable in the long run. To gain time it is advisable to choose a neutral name adaptable to girl or boy (Lesley/Leslie, Christine/Christopher).

It is essential to realize that while the *genital examination* is extremely important, it is never sufficient on its own to permit a diagnosis (p. 710).

The situation is somewhat simpler in the *older child and adult* since a change of sex is no longer likely insofar as the psychosexual orientation does not definitely oppose the sex so far adopted. The different possibilities presented in Table must be kept in mind during investigation. Differential diagnosis must be based on a precise case history and thorough physical examination, with careful consideration of the following points: age at puberty (premature and of the male type in the adrenogenital syndrome), position of the gonads, absence of pubertal development (agonadism), development of male puberty (asymmetric mixed gonadal dysgenesis, hypospadias-gynecomastia syndrome, hereditary vulviform perineal hypospadias and mild forms of hypospadias, adrenogenital syndrome), development of female puberty (incomplete testicular feminization, transplacental virilization) and mixed puberty (true hermaphroditism, hypospadias-gynecomastia syndrome): amenorrhea in the presence of female puberty (incomplete testicular feminization). Important laboratory tests are: excretion of 17-ketosteroids (raised in the adrenogenital syndrome), the sex chromatin in the buccal smear and hair root and Y-fluorescent staining. The last two tests (p. 711) provide information about the number of X and Y chromosomes. When all these aspects of investigation fail to permit a definite diagnosis, exact investigation of the chromosomes and a gonadal biopsy are indicated.

Investigation is considerably more difficult in *newborns*. Here too the different possibilities given in Table 2 must be kept in mind. The family history may indicate an hereditary syndrome (various syndromes of masculine pseudohermaphroditism and the adrenogenital syndrome). An exact history of the pregnancy may suggest a transplacental virilization. The clinical state (pigmentation, salt-depletion syn-

drome) and excretion of 17-ketosteroids and pregnanetriol will lead to recognition of the adrenogenital syndrome. Sex chromatin and fluorescent staining of the Y chromosome facilitate assessment of the sex chromosomes. If an XX karyotype can be assumed then the findings of the investigations so far will permit a definite diagnosis at least as regards the possibility of a true hermaphroditism. When an XY karyotype can be assumed, abnormal gonadal development or masculine pseudohermaphroditism is probable. In these cases, examination of the chromosomes and gonadal biopsy are indicated.

2. Female Genital Appearance

In addition to the full clinical picture, there are a number of trivial and more incidental clinical findings in individuals of female appearance, which may indicate the possibility of a gonadal disorder or of masculine pseudohermaphroditism and make at least the determination of the sex chromatin desirable. A negative sex chromatin does not chance the fact that these individuals must be considered female in practical life, but it is of importance in the prognosis of growth, secondary sexual characteristics and fertility and in counseling the patient and relatives about heredity.

Turner's syndrome must be considered:

a) in all girls with unexplained dwarfism,

b) in all girls and women with pterygium colli, or any of the dysmorphic characteristics associated with TURNER's syndrome,

c) in all girls and women in whom pubic hair has developed but not the breasts,

d) in all women with primary amenorrhea.

Pure gonadal dysgenesis must also be considered when c) and d) apply.

Testicular feminization must be considered:

a) in all girls and women with inguinal hernias in which the gonads can be palpated.

b) in all women with primary amenorrhea,

c) in all women with no pubic hair.

Impaired *testosterone synthesis* must be considered in every baby of female appearance who shows signs and symptoms of the Addisonian type in the early months of life (pigmentation, anorexia, vomiting, dehydration etc.).

3. Male Genital Appearance

In these cases too there are certain features which while not striking in themselves must suggest a gonadal disorder or masculine or feminine pseudohermaphroditism. The sex chromatin at least must be determined in investigating these findings. The practical consequences of the exact diagnosis depend largely on the age of the patient (p. 733). In adult individuals they are limited to the prognosis (sterility) and a possible substitution therapy with testosterone.

Klinefelter's syndrome must be considered:

a) in every case of gynecomastia,

b) in the presence of too small testes despite visible secondary sexual characteristics,

c) in every case of male sterility.

Anorchia must be considered:

a) in every case of bilateral cryptorchidism,

b) in the absence of puberty despite a bone age of more than 13 years.

Persistence of the oviducts must be considered in men of normal male appearance with inguinal hernias and cryptorchidism.

Transplacental virilization must be considered:

a) in bilateral cryptorchidism,

b) if female puberty develops in spite of male external genitalia.

Bilateral cryptorchidism is always suggestive of a disorder of the gonads and/or of gonadal differentiation and therefore always necessitates determination of the sex chromatin. Sex chromatin is usually found in anorchia, in all forms of feminine pseudohermaphroditism, and quite frequently in Klinefelter's syndrome, in XX men, in the male Turner's syndrome, in persistence of the oviducts and in all forms of intersexual external genitalia.

I. Psychosexuality

The question of whether psyche and sexual drive in intersexuality correspond more to the genetic sex and gonadal sex or more to the nature of the genitalia and secondary sexual characteristics is one to which all investigators have always devoted a great deal of attention, and is of the utmost importance for the medical measures adopted.

The subject is widely discussed in the literature, but the information is difficult to classify and even more difficult to reduce to a common denominator. Observations about testicular feminization seem to be most consistent. It has been noticed that these genetically male individuals with testes are female not only in all physical characteristics, but also in their psyche. They are often able to have a harmonious marriage, and normal libido has often been reported. This and similar experiences have led to the view that the psychosexuality of intersexual individuals is dependent only on the character of the external genitalia and environmental influences and not on the chromo-

somes or gonads. This interpretation is applicable to some patients but there are certainly exceptions as well. It would be dangerous to make the generalization that the psychosexuality in healthy subjects was also determined only by external factors, i.e. up-bringing and environment. The most significant observations are those which reveal that the psychosexuality of numerous patients with intersexuality cannot be described simply as male or female, but is frequently poorly and inadequately developed, as in gonadal dysgenesis and in the congenital adrenogenital syndrome. It is really fundamentally wrong to ask whether the sexual drive takes a male or female trend. This explains why such patients often accept and believe in the sex allotted by their environment on the basis of their external genitalia, and why they become well adjusted even if this sex opposes the genetic and gonadal sex. The position is quite different when this natural process of adjustment is suddenly destroyed by a forcible change of sex brought about by external factors. Reasonably harmonious psychic development is hardly possible after such an event and psychoreactive disturbances, which are otherwise rare in patients with intersexuality, can then be expected. Intelligence of the intersexual lies within normal ranges.

K. Therapy and Choice of Sex

The responsibility inherent in the decision about suitable measures to be taken in the case of intersexual individuals is unusually great. The decision is based on a thorough somatic investigation and on the knowledge of psychosexuality presented in the previous section. In patients past babyhood, the decision is also based on a precise psychopathological investigation. In summary the following principles can be compiled:

1. *Individuals with purely female external genitalia* (pure gonadal dysgenesis and testicular feminization) are brought up in accordance with the genital sex. This usually occurs anyway before the diagnosis is made. Thus, the time at which the diagnosis is made does not affect the choice of sex. It would be a tragic mistake to attempt to bring up these individuals in a way corresponding to their chromosomal sex. It is best not to reveal the fact of the intersexuality, and just to discuss the prognosis of puberty and sterility. In testicular feminization, secondary sexual characteristics are of a female nature in any case. Substitution with female sexual hormones is necessary in pure gonadal dysgenesis.

2. *Investigations should be performed and the decision about further procedures made in the first year of life in all patients with intersexual external genitalia and in female patients with male external genitalia* (severe form of the adrenogenital syndrome and of transplacental virilization) in order to avoid the necessity of changing the sex later on and the associated unfavourable psychological effects as far as possible.

3. *If investigations are successfully performed in the first year or at least not later than in the second year of life*, the following measures are advisable:

a) *Girls with feminine pseudohermaphroditism and intersexual or male genitalia* are brought up according to their true sex, as girls. Female secondary sexual characteristics will develop in the adrenogenital syndrome if consistent cortisone treatment is given, and in other forms of feminine pseudohermaphroditism, female secondary characteristics will develop spontaneously. The external genitalia should be corrected surgically during the first year of life.

b) *Boys with masculine pseudohermaphroditism and intersexual genitalia and all individuals with abnormal gonads and intersexual genitalia* are brought up as belonging to the sex which corresponds best to the external genitalia. This solution must be urged since genitalia with an almost completely female appearance cannot be successfully masculinized by surgical means and since these patients, and also their parents, will have less doubts about their sex, the better the external genitalia corresponds to the assumed sex. The genitalia are corrected as much as possible by surgery, and gonads are removed if they do not correspond to the chosen sex. This appears drastic at first glance, but has no significant effect on fertility since these individuals are usually sterile, and ensures that a heterosexual puberty cannot arise later on. The parents of these castrated children must be informed that hormone therapy is essential later on for the development of pubertal characteristics.

c) To guarantee as normal a sex education as possible, the parents must be convinced from the very beginning that the correct sex has been chosen. Surgical procedures for normalization of the external genitalia should be performed as early as possible to remove any possible doubt.

4. If the case is *investigated only later*, the question of whether the sex so far accepted can still be changed under certain circumstances arises. Since sexual identification occurs during the first years of life and is settled at school age at the latest, and since any involuntary change

of sex can have unfavorable psychological effects in later life as experience has shown, there should be *no change in sex in general after the third year of life*. Even when the early decision proves wrong, it is better to stick to the sex so far assumed and to salvage the situation as best as possible by means of treatment with hormones, plastic surgery and even removal of the gonads in special circumstances. This means, for example, that a girl with feminine pseudohermaphroditism, brought up as a boy, must continue to be looked upon as a boy, and the ovaries should correspondingly be removed to prevent the development of a female puberty. An exception to this principle is made nevertheless, if a strong psychosexuality arises in definite opposition to the sex so far assumed. Such cases are, however, uncommon.

5. The following question presents a special problem: *should abdominal testes be removed prophylactically because of the increased danger of malignancy*? The danger of a malignant gonadoblastoma or dysgerminoma is so great in pure XY-gonadal dysgenesis and in asymmetric mixed gonadal dysgenesis that removal of streaks and testes must be undertaken even during infancy. The danger of malignant tumors is slight in testicular feminization, so it is better to leave the testes since they render development of puberty possible. If a hernia has to be operated on later on or a benign testicular tumor has to be removed, castration is more justified in such cases since these patients are sterile. The situation in masculine pseudohermaphroditism with intersexual genitalia of more masculine appearance is similar to that in cryptorchidism. When the testes cannot be placed in the scrotum by surgical means, removal of the testes is indicated with subsequent substitution treatment with testosterone. Later development of a tumor in abdominal testes would probably not be recognized early enough, whereas the situation can be easily detected in scrotal testes.

XIII. The Pancreas

G. R. CONSTAM

With Contributions by

E. R. FROESCH, CHR. HEDINGER, G. KISTLER, P. H. ROSSIER, H. STEINER, and G. TÖNDURY

A. Historical Dates

G. R. CONSTAM

Around 1500 B. C., Papyrus Ebers, Egypt; description of abnormal polyuria, possibly diabetes mellitus.

6th century B. C. The Indians differentiated the asthenic from the sthenic form of diabetes mellitus. In the Ayur Veda of Susruta, the illness is termed as "madhumeha" or "honey-urine".

A few centuries B. C., the Chinese recognized the sweet taste of the urine.

30 B. C. to 50 A. D. AULUS CORNELIUS CELSUS described a condition in which much urine was excreted.

30 to 90 A. D. ARETAEUS OF CAPPADOCIA gave the same description as CELSUS and called it "diabetes".

131–201 A. D., GALEN described diabetes as a weakness of the kidneys.

860–932 RHAZES, an Arabian physician, discussed the treatment of diabetes mellitus.

980–1027 AVICENNA believed that the liver was particularly affected in diabetes, and observed the connection between diabetes, furunculosis and impotence.

1621–75 THOMAS WILLIS, in Oxford, distinguished diabetes mellitus from diabetes insipidus, and showed that the urinary sugar was increased in the former condition.

1682 JOHANN CONRAD BRUNNER observed polyuria and polydipsia in a dog after removal of the pancreas.

1774 ROBERT WYATT suspected the presence of a substance similar to sugar in the urine and blood. He obtained this substance by evaporating the urine.

1776 DOBSON demonstrated a fermentable sugar in the urine and the sweet taste of the blood of diabetic patients.

1788 THOMAS CAWLEY suspected a connection between diabetes and changes in the pancreas.

1796 ROLLO recommended a low-calory diet in the treatment of diabetes and described the smell of acetone.

1815 CHEVREUL identified the sugar in diabetes as glucose.

1806–86 BOUCHARDAT utilized fermentation tests, the polarimeter and solutions of copper salts, for estimating sugar. He substituted fat and alcohol for carbohydrates, emphasized the value of green vegetables, of a low calory diet, and of much physical activity. He introduced days of fasting and the use of alkali, and discovered gluten bread.

1848 HERMANN VON FEHLING described the urine test which was later named after him.

1849 CLAUDE BERNARD discovered glycogen in the liver, and the "piqûre". He made quantitative estimations of the sugar in the blood.

1869 PAUL LANGERHANS discovered the islet cells of the pancreas.

1882 CHAUFFARD and HANOT described the combination of pigment-cirrhosis and diabetes as "bronze diabetes".

1889 V. RECKLINGHAUSEN revealed the nature of the two pigments of "bronze diabetes", and introduced the term hemochromatosis.

1889 O. MINKOWSKI and J. VON MERING incidentally discovered that total pancreatectomy in a suitable experimental animal produces diabetes.

1891 GIULIO VASSALE ligated the excretory ducts of the pancreas, which led to the destruction of the acini, but not of the islet cells.

1892 O. MINKOWSKI produced temporary disappearance of diabetes in dogs by subcutaneous implantation of the excised pancreas.

1893 LAGUESSE suspected that the islet cells formed a hormone.

1895 V. NOORDEN developed a technique of dietary therapy, stressed the formation of sugar from protein, and introduced the course of oats as a treatment.

1898–1962 E. P. JOSLIN untiringly improved the treatment of diabetes mellitus.

1906 NAUNYN studied the metabolism in diabetes, particularly in diabetic acidosis. He emphasized the familial occurrence

of the disease, and the value of a just adequate nourishment in the prophylaxis and in the treatment of the metabolic disturbance.

1908 ZUELZER gained an alcoholic extract from the pancreas, which after being injected, produced shock – probably of hypoglycemic nature – causing the trial to be discontinued.

1909 DE MEYER gave the name insulin to the still hypothetical hormone of the islet cells.

1913 F. M. ALLEN became famous for his hunger cures. He also contributed to the knowledge of carbohydrate metabolism.

1918 C. K. WATANABE produced hypoglycemia in the animal with an injection of guanidine.

1921 N. C. PAULESCO in Rumania reported "pancréine", i.e. a blood sugar-lowering extract from pancreas of dogs or cattle, which he had discovered during the First World War (1914–18).

1921 FREDERICK G. BANTING and CHARLES H. BEST discovered insulin.
F. C. MANN and T. B. MAGATH showed that hepatectomy results in hypoglycemia.

1924 B. A. HOUSSAY and MAGENTA noticed that hypophysectomy increases sensitivity to insulin.

1924 SEAL HARRIS suspected hyperinsulinism as a cause of spontaneous hypoglycemia.

1926 E. FRANK, M. NOTHMANN, and A. WAGNER introduced biguanidines into the treatment of diabetes which, however, was abandoned in 1940.
ABEL succeeded in crystallizing insulin.

1927 WILDER, ALLAN, POWER, and ROBERTSON published the first case of organic hyperinsulinism.

1929 HOWLAND, CAMPELL, MALTBY, and ROBINSON removed an islet-cell tumor and cured a case of hyperinsulinism for the first time.

1936 H. C. HAGEDORN produced the first reliable insulin with prolonged action.

1937 F. G. YOUNG discovered meta-pituitary diabetes.
H. R. JACOBS observed alloxan-hyperglycemia.

1942 GUEST pointed out hypokalemia during the treatment of diabetic acidosis.

1942 M. JANBON noticed the hypoglycemic action of one of the sulfonamides recommended for the treatment of typhoid fever.

1943 DUNN, SHEEHAN, and MACLETCHIE discovered alloxan-diabetes.

1944 A. LOUBATIÈRES explained the mode of action of certain hypoglycemic agents.

1955 H. FRANKE and J. FUCHS observed hypoglycemia produced by another sulfonamide, and suggested that it should be used therapeutically in diabetes mellitus.

1955 F. SANGER discovered the structural formula of the insulin molecule.

1957 G. UNGER introduced phenethyl biguanide into the treatment of diabetes.

1957 S. A. BERSON and R. S. YALLOW measured the insulin content of the plasma by radioimmunological methods.

1964 H. ZAHN in Germany, KATSOYANNIS in U.S.A, and NIU CHING-I in China (1965), all independently succeeded in synthesizing insulin.

1967 D. F. STEINER and P. OYER isolated proinsulin.

1969 Mrs. D. G. HODGKIN discovered the three-dimensional structure of pig insulin.

B. Embryology and Histology

G. TÖNDURY and G. KISTLER

In the human embryo 3 to 4 mm in length, two entodermal outpocketings arise on opposite sides of the primitive duodenum. One of the epithelial buds grows out from the dorsal wall of the gut, just above the hepatic diverticulum; it forms the *dorsal* pancreas. The *ventral* pancreas, on the other hand, originates in the caudal angle between hepatic diverticulum and gut. When the embryo is about 12 mm long, the two primordia meet, and when it is about 16 mm, they fuse to produce a joint organ. With the exception of the major parts of the head and the uncinate process, which are derivatives of the ventral bud, most of the mature gland is formed by the dorsal pancreas anlage. Both primordia are crossed by an axial longitudinal duct. The duct of the dorsal anlage originates directly from the wall of the duodenum, whereas the ventral duct opens into the stem of the elongating common bile duct. When duodenal torsion has brought the two primordia into close side-by-side contact, the ventral duct taps its dorsal counterpart. The major pancreatic duct of the mature gland (duct of Wirsung) results, therefore, from the fusion of the ventral duct with the distal segment of the dorsal duct. The proximal stem segment of the dorsal duct, on the other hand, constitutes the accessory duct of Santorini, which usually retains its connection to the duodenum as well.

The islets of Langerhans develop from epithelial cells of the outgrowing pancreatic ducts. They are, therefore, of entodermal origin. Even

in the embryo of 18 mm in length (age about 7 weeks), the terminal and side buds of the primitive ducts contain a few granular cells which can be selectively blackened by silver-salt solutions. These cells multiply and form single solid sprouts which enlarge to become the fetal (and early post-natal) islets. These so-called primary islets consist of a central mass of insulin-producing type-B cells which are surrounded by a compact layer of glucagon-synthesizing type-A cells (FERNER, 1952). Between these two subdivisions, a transitional zone containing agranular cells soon develops. Here, type-A cells appear to be transformed continuously into type-B cells. The core of the islet thus enlarges considerably and the islet itself resembles more and more the one found in the adult pancreas.

The mature islets of Langerhans are rounded or ovoid epithelial complexes usually situated

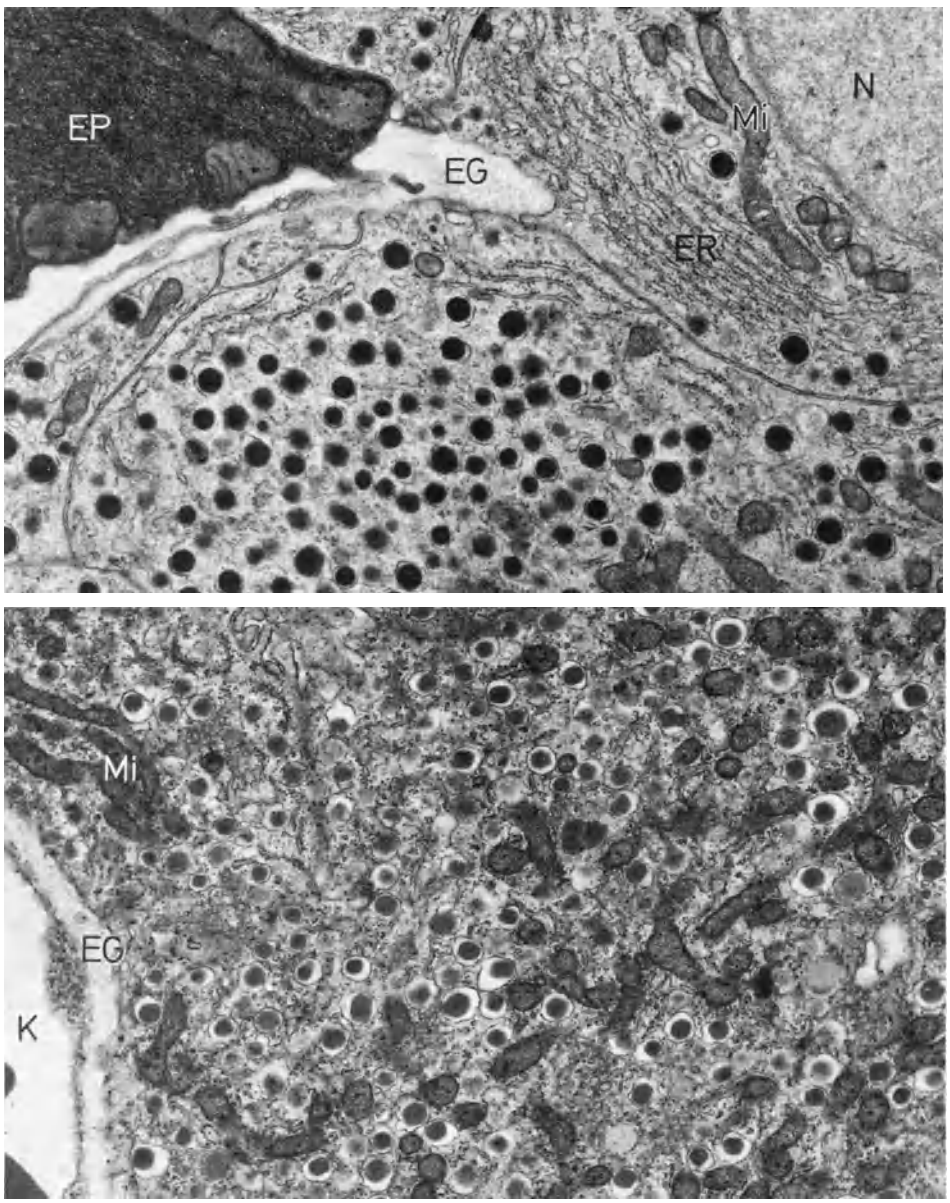

Fig. 1a and b. The granules of the glucagon-producing A-cells are electron-dense and separated from the surrounding membrane by a narrow, clear zone. In contrast, the often eccentrically located content of the granules of the insulin-synthesizing B-cells (lower half of the picture), usually display a much wider halo. Both types of granules are scattered throughout the cytoplasmic ground substance, but tend to be more numerous in the cell portions contacting the capillaries. *EP* exocrine pancreas; *K* capillary; *N* nucleus; *ER* rough-surfaced endoplasmic reticulum; *Mi* mitochondria; *EG* extravascular, interstitial space containing fibroblast processes as well as collagenous fibrils. × 12000

in the central portions of the lobules of the exocrine pancreas. They may also, however, be found in the interlobular connective tissue or associated with the smaller branches of the pancreatic ducts. Although the islets are scattered throughout the exocrine pancreatic parenchyma, they are more numerous in the tail than in the head or body of the gland.

The highly vascularized islets receive their blood supply through branches of the interlobular arteries which arise from both the celiac trunk and the superior mesenteric artery. The thin capsule of reticular fibers separating the islets from the exocrine parenchyma is usually penetrated by one arteriole. Within the islet, this arteriole splits up into a number of anastomosing capillary loops which are in intimate contact with the epithelial cords, like the vas afferens in a kidney glomerulum. The endothelium of these capillaries varies considerably in thickness. In attenuated portions of the endothelial cells, typical fenestrae (endothelial pores) are present. A few vasa efferentia convey the blood into the interlobular venules of the exocrine pancreas.

The functional significance of the unmyelinated nerve fibers found to penetrate into the islets is still a matter of dispute. In various mammalian species, the nerve fiber terminals found in close proximity to the A-type cells contain synaptic vesicles which differ morphologically from those observed in axon endings contacting B-type cells. It is postulated that the innervation of the A-cells is cholinergic, whereas that of the B-cells is adrenergic (WATARI, 1968).

Light microscopy reveals that the islet cells are less stainable than the acinar cells of the exocrine pancreas. In hematoxylin and eosin preparations, the cytoplasm of these cells appears more or less homogeneous, but with the Mallory-azan stain, three types of cells can be easily distinguished, all of them displaying distinct granules in their cytoplasm. The *A-cells*, which are found predominantly at the periphery of the islets, contain granules which stain red and are insoluble in alcohol. The somewhat smaller granules of the more centrally located *B-cells*, on the other hand, stain orange and are dissolved in alcohol. A third cell type, the so-called *D-cell*, is scattered throughout the islet. It displays granules which stain blue. In some mammalian species, a fourth, *agranular* cell type has been described. It is usually referred to as the *C-cell*.

Electron microscopy shows that the A- (or alpha) cells contain large numbers of membrane-bound, electron-dense granules. Characteristically, the granule is separated from its membrane by a very narrow, electron-translucent cleft (Fig. 1a). A few profiles of rough-surfaced endoplasmic reticulum, and rather small, ovoid or elongated mitochondria are scattered throughout the cytoplasmic ground substance. The inconspicuous Golgi apparatus is situated in a juxtanuclear position. The size and electron density of the granules of the B-cells (beta cells) vary considerably in the different mammalian species. The clear zone separating the often eccentrically-located granulum from its membrane is usually much wider than in the A-granules (Fig. 1b). In the human B-cells, some of the granules contain rounded or polygonal cristalloid structures which display an internal periodicity. The mitochondria of this cell type appear to be more numerous than in the A-cells. The Golgi complex is well developed. Between the granules, elongated and vesicular profiles of the rough-surfaced endoplasmic reticulum are intermingled with free ribosomes and small vesicles. The granules of the D-cells (delta cells) are larger and much less electron-dense than those of the A- and B-cells. The functional significance of this cell type is still a matter of dispute. The presence, in some mammalian species, of A- and D-type granules within the same cell, would seem to corroborate the assumption that the D-cell (delta cell) is an altered A-cell. However, D-cells are also present in young individuals and lack degenerative changes in the nucleus and cytoplasm.

C. The Islet Cell Apparatus, Metabolic Regulation, and Pathophysiology of Diabetes Mellitus

E. R. FROESCH

Diabetes mellitus is the most common endocrine disease. Contrary to the majority of the hyper- and hypofunctional endocrine syndromes, diabetes mellitus ist one of GARROD'S "inborn errors of metabolism" (STANBURY, 1966). But even among these diseases, diabetes mellitus is peculiar in that the disturbance of carbohydrate metabolism, glucose intolerance, is usually not congenital, but rather becomes apparent later in life. The lack of insulin is, therefore, not congenital in most cases, but develops sooner or later during life. The current opinion is that insulin deficiency is not due to a single genetic defect and that exogenous factors accelerate the manifestation of underlying condition as diabetes mellitus. In order to understand diabetes mellitus as a disease, and its management and therapy, an elementary knowledge of the important metabolic processes and their control is essential.

1. Energy Exchange and Intermediary Metabolism

Every living cell has a basal energy requirement, i.e. it needs fuel and oxygen. Oxidation of substrates helps to maintain a constant temperature and yields the energy for synthetic processes occurring constantly in the organism. In poikilothermic animals, the basal metabolic rate varies according to the outside temperature. This is a result of the temperature-dependent enzyme reactions. All enzymes have an optimum temperature and, in general, operate more slowly at lower temperatures. At low temperatures, breakdown and turnover of ribonucleic acids and desoxyribonucleic acids are slowed, and so are protein and enzyme synthesis, resulting in a fall of the basal energy requirement. In the warm blooded, the situation is reversed and the body temperature is maintained at a constant level. At lower temperatures the heat loss, and thus heat production and energy requirements, increase.

The energy obtained through the oxidation of substrates is not only converted to heat but is stored in the form of energy-rich phosphate The energy reserves may then be used for biosynthetic processes or for muscle contraction.

Adenosine triphosphoric acid (ATP) is the most important energy-rich co-enzyme and it is formed during the process of oxidative phosphorylation. ATP transfers energy-rich phosphate onto glucose with the help of hexokinase or glucokinase, thus converting glucose to glucose-6-phosphate, a compound richer in energy and more reactive than glucose.

In muscle, creatine phosphate is another important energy-rich coenzyme. During muscular exercise, creatine phosphate gives off its phosphate to adenosine diphosphate to form ATP, providing the energy for muscle contraction. The creatine liberated is either broken down to creatinine and excreted in the urine, or phosphorylated with ATP to form creatine phosphate again during muscle rest.

Different metabolic pathways are open to glucose-6-phosphate. When substrate is abundant, it is converted to glucose-1-phosphate and glycogen by the insulin-sensitive glycogen-synthetase. Glycogen is then stored (LARNER, 1964; LELOIR, 1964). The storage of glycogen in liver and muscle is limited, in contrast to the storage of fat in adipose tissue.

Maximum glycogen reserves of the body amount to 200–400 g (800 to 1600 calories) and cover the energy requirement for one day at the most.

The conversion of glucose to fat is a complicated process. Glucose-6-phosphate goes all the way through glycolysis down to pyruvate, which is decarboxylated to acetyl-coenzyme A. Two molecules of acetyl-Co A condense to form acetoacetyl-Co A (mitochondrial synthesis of fatty acids) or else, acetyl-Co A fixes CO_2 and forms malonyl-Co A (cytoplasmic synthesis of fatty acids) (LYNEN, 1967). The chains become longer through further condensation with acetyl-Co A and are then reduced to fatty acids by triphosphopyridine nucleotide ($NADPH^+$) and diphosphopyridine nucleotide ($NADH^+$). Fatty acids are then esterified with alphaglycerophosphate to phosphatidic acid and finally to triglycerides, in which form they are stored. The $NADPH^+$ needed for the reductive synthesis of fatty acids is formed predominantly in the pentose-phosphate shunt, whereas $NADH^+$ arises mainly in the tricarboxylic-acid cycle. Fatty-acid synthesis corresponds to the activity of the pentose-phosphate shunt, from which the essential reducing potential is derived.

During anaerobic glycolysis 1 molecule of glucose and 2 molecules of ATP produce 2 molecules of lactic acid and 4 molecules of ATP. During glycolysis 2 molecules of ATP are gained from every molecule of glucose. However, only a small part of the available energy of the glucose molecule is liberated in this way. During complete oxidation of glucose to H_2O and CO_2 in the tricarboxylic-acid cycle, a further 30 ADP molecules are phosphorylated to ATP. The oxidation of the substrates is coupled with the formation of energy-rich ATP. For each molecule of oxygen 3 molecules of ATP are formed. The biologic oxidation becomes a highly efficient combustion machine as a result of this coupling of oxidation to the formation of ATP as an energy store. Approximately 40–50% of the energy liberated during the biological combustion of glucose and fatty acids are not released as heat but rather used for synthesis.

a) Regulation of Energy Exchange

The energy requirement of the muscle is not related to the substrate supply. It depends primarily on muscular work. The uptake of substrate and oxygen from the blood is, therefore, dependent on the work performed. It is in part controlled by hormones during the phase of rest and storage. During acute muscular activity, ATP is used and is later replaced by ATP generated during glycolysis. The musculature extracts free fatty acids and glucose from blood as an energy source during prolonged excercise.

We now face the complex question of how the uptake of combustible substances by different tissues is regulated. Two major factors come into play: 1. the need of the tissue for com-

bustible substances to cover its energy requirement, 2. the supply of combustible substances.

The local needs of a certain tissue for substrate cannot be controlled by hormones which act indiscriminately on all tissues. A working muscle, for example, must itself be capable of adjusting to its elevated energy requirement during work by an increased uptake of substrate (SANDER, 1964). Therefore, two fundamentally different regulations for the uptake of glucose by muscle must exist. One is controlled by insulin and affects glucose transport. The other is controlled intracellularly through stimulation of certain enzyme reactions.

b) Mechanism of the Insulin-Independent Uptake of Glucose by the Muscle during Work (compare Fig. 2)

Glycolysis is regulated by three processes:

1. Through the activity of phosphorylase which splits off the terminal glucose molecule of the glycogen chain by phosphorylating them with inorganic phosphorus to form glucose-1-phosphate (ILLINGWORTH, 1964);

2. through the transport of glucose through the cell membrane, and

3. through the activity of two key enzymes, hexokinase and phosphofructokinase, which perform irreversible reactions which are inhibited by their end products (HELMREICH, 1964).

1. Glucose + ATP $\xrightarrow[Mg^{++}]{\text{Hexokinase}}$ Glucose-6-phosphate + ADP.

2. Fructose-6-phosphate + ATP $\xrightarrow[Mg^{++}]{\text{Phosphofructokinase}}$ Fructose-1,6-diphosphate + ADP.

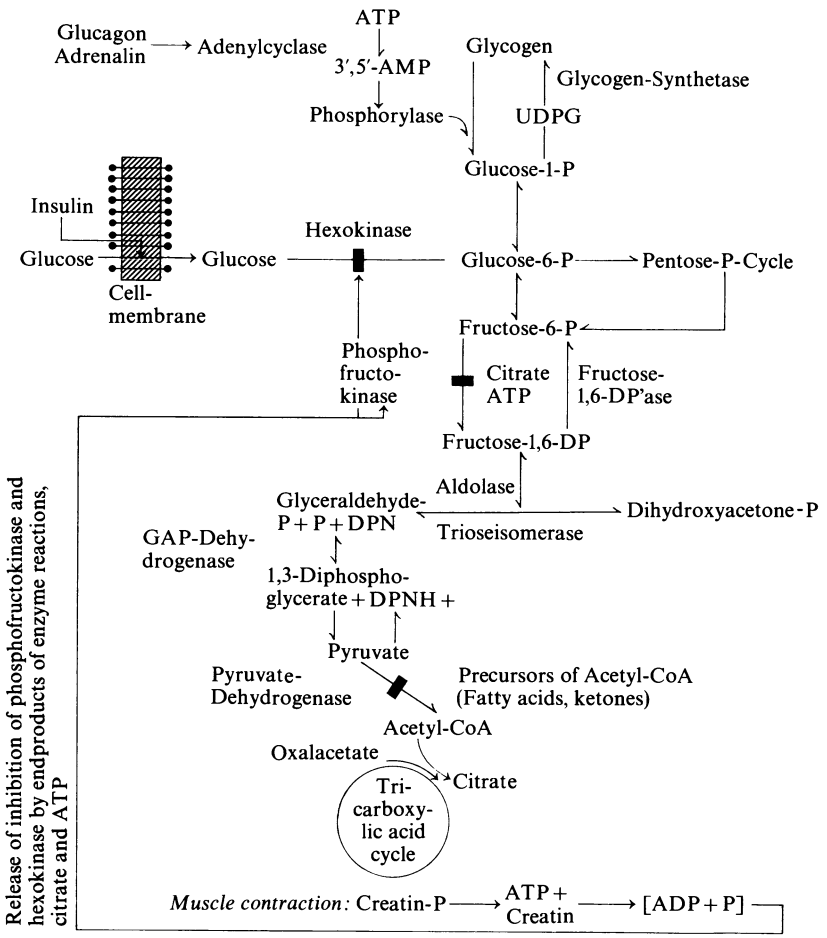

Fig. 2. The phosphorylating enzymes, glucokinase, hexokinase and phosphofructokinase are the key enzymes in glycolysis. Hexokinase and phosphofructokinase are inhibited by their enzymatic end products. Fatty acids and ketone bodies inhibit pyruvate dehydrogenase and the entire glycolysis by their oxidation to acetyl-coenzyme A and competition for coenzyme A. Apart from this, citrate accumulates and causes an inhibition of phosphofructokinase. During muscular contraction, ADP and inorganic phosphate arise from energy-rich ATP. Both products help to prevent substrate inhibition of hexokinase and phosphofructokinase and lead to increased glucosephosphorylation and glucose oxidation

Phosphorylase occurs in an active (a) and an inactive (b) form (KREBS, 1964). Phosphorylase-kinase converts phosphorylase from the b-form into the a-form. K^+ and Ca^{++} ions and cyclic 3′,5′-adenosine monophosphate catalyze this process. However, the exact mechanism by which electrical stimulation and the contraction of muscle fiber activate phosphorylase, thereby making glycogen available for anaerobic glycolysis, remains to be explained (DANFORTH, 1965; HELMREICH, 1965; BUEDING, 1965).

The accumulation of fructose-1,6-diphosphate has a contrary effect, leading to an increase of glucose-6-phosphate concentration and thus to an inhibition of glucose phosphorylation. Inorganic phosphate seems to counteract this inhibition so that glycolysis is resumed. It may be assumed that among other factors, muscular activity stimulates glycolysis through an elevated level of intracellular inorganic phosphate. During muscular contraction, ATP supplies the energy and is converted to ADP and inorganic phosphate. The increase in inorganic phosphate would then prevent substrate inhibition of phosphofructokinase and re-establish glycolysis (UYEDA, 1965).

Insulin promotes the transport of glucose through the cell membrane and determines how much glucose is taken up and stored as glycogen and triglycerides in tissues. Compared to the effect of insulin, the inhibition of glycolysis by fatty acids is probably only of minor physiologic and pathophysiologic significance.

When glucose turnover is increased through muscular activity or during anoxia (Pasteur effect), glucose is also transported into the cells by so-called "facilitated diffusion". The relationship between energy exchange of the cells and activation of this transport process has not been explained.

The uptake of glucose by muscle is inhibited by the simultaneous uptake of other substrates, in particular by fatty acids, ketone bodies and pyruvic acid (OPIE, 1963; RANDLE, 1964; WILLIAMSON, 1965). Two mechanisms are important: The ratio of acetyl-coenzyme A to coenzyme A increases with a rising supply of fatty acids and ketone bodies. Pyruvate dehydrogenase, which converts pyruvate to acetic acid, is inhibited. In addition, the citrate concentration increases and inhibits phosphofructokinase.

The different factors which influence the utilization of glucose by muscle not directly through the membrane-transport system, but rather through a step in the intermediary metabolism, are still being discussed. A detailed discussion of this problem would lead too far. We still do not know whether the excessive supply of substances such as fatty acids which inhibit glucose uptake by muscle, is causally connected with glucose intolerance (see Fig. 2).

c) Free Fatty Acids as a Source of Energy for Muscle

Glucose supplies only a small part of the energy required by resting and exercising muscle. Free fatty acids and ketones are the main source of energy. They are released into the blood from adipose tissue after hydrolysis of stored triglycerides (lipolysis). The oxidation of glucose, fatty acids and ketones increases in muscle during work (INGLE, 1955; HAVEL, 1963). Glucose contributes only 10–15% and free fatty acids and ketones 70–90% to the total energy expenditure of excercising muscle (PAUL, 1967).

d) Regulation of Glucose Transport through the Cell Membrane

The membranes of most cells are impermeable to glucose. Glucose does not diffuse freely into the cells. Erythrocytes and parenchymal liver cells contain free glucose. Glucose is transported into the cells by a carrier mechanism not requiring energy (facilitated diffusion) (WILBRANDT, 1961). This mechanism of facilitated diffusion differs in principle from pumping transport mechanisms by which a concentration gradient may be overcome, as for instance during glucose absorption in the gut or renal tubular reabsorption of glucose. These active transport pumps necessitate energy for functioning. They are coupled in some form to ATP-ases which supply the necessary energy for the transport against a concentration gradient by splitting energy-rich ATP (CRANE, 1960).

The transport of glucose is the limiting step of total glucose utilization by muscle and adipose tissue, the two major tissues which are sensitive to insulin (FROESCH, 1962; CROFFORD, 1965; MORGAN, 1961). Teleologically this makes good sense. The transport process can be increased instantaneously by insulin. Excessive amounts of enzymes in the cells are ready to phosphorylate and oxidize glucose or to store it in the form of glycogen or fat, depending on the tissue and the needs. Insulin exerts other actions on the cells not related to transport. Its effect on transport is certainly the most important. Stimulation of enzyme synthesis would necessitate too much time to ascertain glucose homeostasis.

2. Glucose Metabolism in the Liver

Glycogenolysis, Gluconeogenesis and their Regulation (see Fig. 3)

The daily calorie requirement of man at rest lies around 25–30 calories per kilogram of

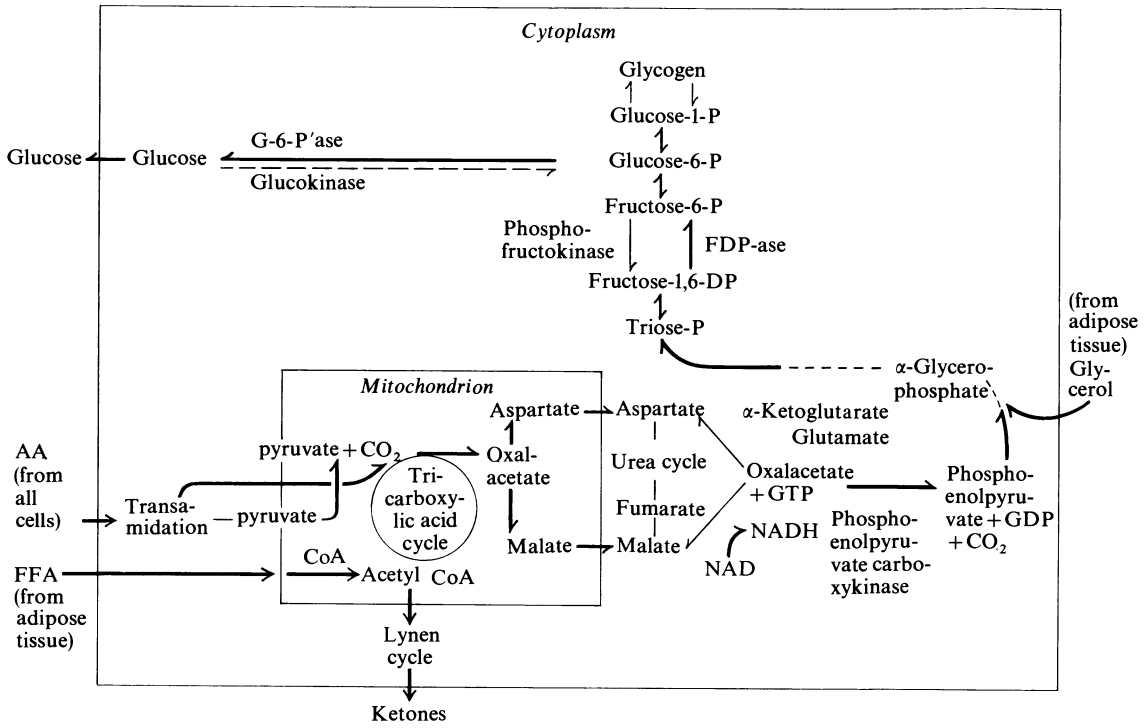

Fig. 3. Gluconeogenesis begins with the transamidation of amino acids to pyruvate and intermediary products of the tricarboxylic acid cycle. The flux of aminoacids from the periphery to the liver increases in anti-anabolic, catabolic situations such as fasting and diabetes and under the influence of glucocorticoids. As has been shown recently, free fatty acids appear to activate gluconeogenesis. Free fatty acids are converted to acetyl coenzyme A in the mitochondria and compete with pyruvate for coenzyme A which serves for its activation to acetyl-Co A by pyruvate oxidase. Acetyl-coenzyme A inhibits this enzyme. In this way, more pyruvate becomes available for conversion to oxalacetate. This latter substance can only be transferred to the cytoplasm after conversion to malate or fumarate and can then be used for gluconeogenesis after reconversion to oxalacetate. The mitochondrial conversion of oxalacetate to malate is accelerated by $NADH^+$ produced by the oxidation of free fatty acids. The activities of the key enzymes in gluconeogenesis (transaminases, phosphoenolcarboxykinase, pyruvate carboxylase, fructose-1,6-diphosphatase and glucose-6-phosphatase) are elevated when gluconeogenesis is stimulated by insulin deficiency, glucocorticoid excess or both. It has not been clarified whether this increase in enzyme activities is due to substrate induction or another type of enzyme induction. This scheme should, above all, stress the significance of the supply of free fatty acids to the liver for the activation of gluconeogenesis

ideal body weight. About 2/5 of the total calories are covered by carbohydrate. This percentage is fundamentally altered during fasting. The organism now uses up its fat reserves. The carbohydrate reserves consist of a maximum of 150 g each in the liver and muscle and are rapidly spent. Glucose consumption now contributes only about 10% to total calorie expenditure, the rest being covered by fat. Since the glycogen reserves are used up after approximately 48 hours, the liver must now supply glucose. The liver, the proximal renal tubules and the mucosa of the small intestine contain glucose-6-phosphatase, an enzyme which splits off glucose from glucose-6-phosphate and releases it into the blood.

The calorie requirement of the brain is about 400 calories per day, so that during fasting major portions of the glucose produced via gluconeogenesis are used up by the brain, whereas most other cells oxidize mainly free fatty acids and ketone bodies.

The acute release of glucose from the liver necessitates an activation of glycogenolysis. Adrenaline and glucagon increase glycogenolysis by activating phosphorylase. This activation occurs, as in muscle, through the so-called "second messenger", cyclic 3′,5′-adenosine monophosphate. Glucagon stimulates adenylcyclase and the 3′,5′-adenosine monophosphate formed in turn stimulates phosphorylase kinase which converts phosphorylase B to phosphorylase A (SUTHERLAND, 1965). This enzyme is now responsible for the splitting off of the marginal glucose residue of glycogen and its conversion to glucose-1-phosphate. According to recent investigations, it seems probable that the activation of phosphorylase is the major physiologic action of glucagon (SOKAL, 1966). Whereas very small physiologic doses of glucagon stimulate

glycogenolysis, larger doses of adrenaline are needed to achieve the same effect.

This acute regulation of blood sugar through glycogenolysis is supported by hepatic gluconeogenesis, which is responsible for the maintenance of normal blood glucose and glycogen stores during fasting. The main precursors of glucose formed via the gluconeogenetic pathway are certain amino acids and glycerol.

Amino acids are deaminated and transaminated to pyruvate or to intermediate products of the tricarboxylic acid cycle and can form glycogen and glucose. Glycerol liberated by lipolysis of triglycerides is the second most important endogenous precursor of glucose. At a caloric requirement of 2500 calories, about 2000 calories are generated by the combustion of fatty acids and ketones (210 g). Since these calories are liberated mainly from triglycerides, about 25 g of glycerol are released from adipose tissue at the same time and can then be converted to glucose. The remaining amount of glucose, approximately 75 g, arises from the amino acids, as has already been mentioned. The nitrogen of these amino acids appears in the urine (10 g of nitrogen correspond to 62 g of protein).

The regulation of gluconeogenesis by hormones and substrates is extremely complex. Glucagon first induces glycogenolysis and subsequently leads to increased gluconeogenesis (EXTON, 1966). A rise in the concentration of free fatty acids also leads to an increase in gluconeogenesis (STRUCK, 1965). The work of LARDY and his team has led to a better understanding of the intermediary metabolism of the liver and the most important controlling points (Fig. 3) (LARDY, 1965).

3. Chemistry, Synthesis, Biosynthesis, Secretion and Effects of Insulin

a) Chemistry and Synthesis

BANTING and BEST in Canada and PAOLESCO in Rumania succeeded in extracting insulin from the pancreas in 1922. This event precipitated tremendous research efforts to elucidate the chemical and biological properties of insulin. It led from its purification by ABEL (1926) to the clarification of the structural formula by SANGER (1955), to its synthesis (MEIERHOFER, 1963; KATSOYANNIS, 1964; ZAHN, 1967; Institute of Biochemistry, Academia Sinica, 1966).

b) Biosynthesis and Secretion of Insulin

STEINER (1967) has demonstrated the presence of a precursor of insulin, proinsulin, in the pancreas, from which insulin is split off by the catalytic action of several enzymes. Proinsulin is synthesized by the ribosomes and transferred to the Golgi apparatus where most of the splitting of proinsulin to insulin takes place. Insulin is then packed into granules which are lined up along microtubules close to the membrane of the B-cell. The biosynthesis of insulin

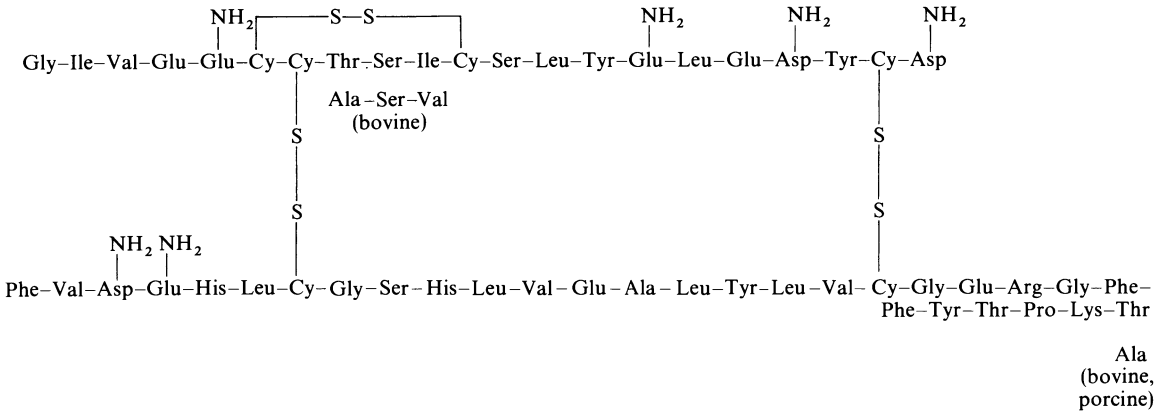

Fig. 4. Human insulin is a protein with a molecular weight of 5734. The isoelectric point lies at pH 5.6. It consists of 2 polypeptide chains, the A and the B chain which are linked by 2 disulfide bridges. The A chain with 21 amino acids contains another disulfide intra-chain linkage. The B chain is composed of a total of 30 amino acids. The biologically active centre of insulin is unknown. Small changes of the structure appear to alter the spatial arrangement of the insulin molecule so that biological activity is lost. Splitting of the disulfide bonds, alterations of the two histidine residues and splitting off of the 8 C terminal amino acids of the B chain result in loss of activity. The removal of the C-terminal threonine alone does not change the activity of insulin, this is changed when the end terminal asparagine of the A-chain is simultaneously removed (SLOBIN, 1963). The amino acids in positions 8–10 of the A chain differ in the human, bovine, procine and sheep insulins. A comparison between guinea-pig and human insulin shows that they differ in 14 amino-acid residues. The chemical synthesis of the A and B-chain by the conventional methods of peptide synthesis and by the solid-state method of MERRIFIELD (1967) no longer appears to present great difficulties. However, the linkage of the disulfide bonds and the combination of the two chains to form insulin has not yet been possible on a large scale

should not be confused with the process of insulin secretion. Different mechanisms are involved in insulin secretion: granules containing insulin are surrounded by the cell membrane and expelled by the process of emeiocytosis or exocytosis. Whether or not another secretory mechanism exists is not known (LACY, 1965). Nothing is known about the regulation of insulin biosynthesis. The islet cells seem to know when to produce new insulin, namely when insulin is being secreted and the insulin content of the cell decreases.

c) Regulation of the Secretion of Insulin

Until a few years ago, insulin secretion was believed to be controlled only by the blood-sugar level. In the meantime, a large number of substances which promote or inhibit insulin secretion has been discovered. Since CONARD's investigations on glucose assimilation (1955) it has been established that insulin secretion is stimulated more markedly by orally administered glucose than by intravenously injected glucose. SAMOLS (1965) and other authors (KETTERER, 1967) have repeatedly shown that glucagon stimulates the secretion of insulin even before the blood sugar rises. Following oral glucose, glucagon seems to be secreted before insulin secretion is increased (SAMOLS, 1965). This sequence of events tells us nothing about the importance of glucagon as an insulin secretagogue. Secretin given intravenously also causes insulin release (DUPRÉ, 1966). Some authors have a concept of a whole chain of gastrointestinal hormones (pancreozymin, gastrin, secretin, glucagon) which have to be secreted in the right sequence to lead to a timely insulin secretion (UNGER, 1967).

In addition to glucose, amino acids are also physiologic stimulators of insulin secretion. It has been known for a long time that leucine stimulates the secretion of insulin and that it can cause hypoglycemia (SCHWARTZ, 1959). A mixture of amino acids and single amino acids can also stimulate insulin secretion. In order of potency these are: arginine, lysine, leucine, phenylalanine, valine and methionine (FAJANS, 1967). Leucine is the only amino acid that causes hypoglycemia. In contrast to leucine, the action of the other amino acids is not potentiated but rather diminished by prior treatment with sulfonylureas. Leucine and all other amino acids seem to stimulate insulin secretion through different mechanisms. The effects of glucose and arginine on the B-cell are mutually potentiated. The insulinotropic action of amino acids is of phylogenetic interest. Certain fish and other animals live on protein and fat alone. In these animals, insulin appears to affect in particular the transport of amino acids into the cells and protein synthesis. It is reasonable to assume that insulin secretion is regulated mainly by the plasma concentration of amino acids in these animals.

Glucose is the main physiologic stimulus of insulin secretion in man. The significance of glucagon and secretin is not yet certain. It is possible that cyclic 3′,5′-AMP, the "second messenger", is also a mediator of insulin secretion (MALAISSE, 1967).

Adrenaline and noradrenaline prevent an adequate insulin release in response to glucose. Whether physiologic or pharmacologic concentrations of catecholamine are needed for inhibition of insulin secretion has not been assessed (PORTE, 1968). Hypokalemia can also lead to paralysis of the secretory process in the B-islet cells and the reduced glucose tolerance in patients with aldosteronism is related to hypokalemia (GRODSKY, 1966). Other ions, in particular Ca^{++} influence insulin secretion as well (MILNER, 1967; MALAISSE, 1971).

d) Pharmacology of Insulin Secretion

The diabetogenic effect of diazoxide (FAJANS, 1966; GRABER, 1966) is due mainly to inhibition of insulin secretion. Mannoheptulose (SIMON, 1966) is a very potent inhibitor of insulin secretion. Its effects are reversible, the side effects on liver metabolism are negligible. The original observation made by LOUBATIÈRES (1957), that sulfonylureas have a hypoglycemic effect by way of B-islet cell stimulation, has stood up to all criticism. Estimations of immunoreactive insulin in the blood before and after acute intravenous administration of sulfonylureas show that insulin secretion is stimulated within a few minutes (SAMOLS, 1965). Insulin secretion after sulfonylurea administration is short-lived under normal circumstances and prolonged in patients with B-islet cell adenoma.

Pentoses and pentitoles promote insulin secretion. It is assumed that these sugars are funneled into the pentose-phosphate shunt and that they supply extra energy for insulin secretion (KUZUYA, 1966; HIRATA, 1968). No other hypoglycemic drug acts via the B-islet cells (biguanides, synthalin, salicylic acid, hypoglycine).

e) Inactivation of Insulin in the Organism

It is occasionally stated that hormones are destroyed while acting on the receptor. This certainly does not apply to insulin. Intact adipose tissue, which is one of the main target

organs of insulin, inactivates hardly any insulin (PIAZZA, 1959).

Insulin has a very short biologic half-life. In the rat it is 3 min (BÜRGI, 1963), in the dog about 20 min (CAMPBELL, 1967), and in the human about 10 min (WELSH, 1956; CERASI, 1964). Insulin is split into A- and B-chains, mainly in the liver, by the enzyme insulin-glutathione-transhydrogenase (TOMIZAWA, 1962). This enzyme is also present in the kidneys, which contribute to the rapid inactivation of insulin. Small amounts of insulin are excreted in the bile (DANIEL, 1967).

Insulin is filtered through the glomerula and is almost completely reabsorbed. Nevertheless, about another 1% of the total amount of insulin secreted is excreted as such in the urine in conditions of tubular dysfunction (CHAMBERLAIN, 1967).

The biologic half-life of insulin is prolonged in people who have been treated with insulin over a long period of time (WELSH, 1956). Insulin antibodies then present in blood bind insulin so that enzymatic degradation by insulin-glutathione-transhydrogenase is prevented. Insulin has a prolonged action since it cannot be broken down because it is bound to the antibodies and is released only gradually (FANKHAUSER, 1963; CROUGHS, 1965).

f) Insulin in Blood

Insulin forms polymers in neutral solution. It is assumed but has not been proved that insulin circulates as a dimer or tetramer in blood. Until now, no specific carrier protein of insulin has been found in blood, although for some time the alpha-2-macroglobulins were considered to have this function (ZAHND, 1963). Endogenous human insulin reacts with insulin-antibodies which were produced in the guinea pig by injecting crystalline pancreatic insulin.

One cannot conclude from this that crystalline insulin extracted from the pancreas and filled into ampoules is the same chemical substance as the endogenous insulin circulating in the blood, although the antibodies cannot differentiate between the two.

Insulin in blood can also be assayed biologically *in vitro* using rat adipose tissue. The immunoreactive insulin in the serum corresponds to the insulin-like activity (ILA) which is inhibited by antibodies (FROESCH, 1967). The normal values of ILA for normal subjects in the fasting state lie between 10 and 30 micro-units per ml of serum, the average value being 20 micro-units per ml. The immunoreactive insulin increases rapidly after a single intravenous injection of glucose, reaches a maximum of 100 micro-units per ml after 2–5 min and falls to the original value 30–60 min after glucose administration (SAMOLS, 1965). The concentration of insulin in blood and its rise after glucose administration appear to be dependent on body weight and age, among other factors. Overweight patients with normal glucose tolerance often show an excessive rise in plasma insulin in response to glucose administration (KARAM, 1963).

g) Biological "Insulin-Like" Substances in the Serum

The serum contains protein which promote the uptake of glucose by muscle and adipose tissue *in vitro*, and which also simulate the antilipolytic effect of insulin. The so-called "nonsuppressible" or "atypical" insulin activity of the serum is the most important of these substances (FROESCH, 1967). Nonsuppressible ILA is not inhibited and is not bound by antibodies to insulin. Serum contains about 200 micro-units of nonsuppressible ILA and 20 micro-units of suppressible ILA. Suppressible ILA corresponds to immunoreactive plasma insulin. The nonsuppressible ILA can probably not be attributed to a single molecule. The main part is a protein with a molecular weight between 70000 and 150000 (BÜRGI, 1966; JAKOB, 1968). This molecule appears to be inactive *in vivo*, at least under standard conditions. The reason for this is not clear. Nonsuppressible ILA is not decreased in diabetics, in diabetic ketosis, or in the pancreatectomized dog. These and other observations make it seem unlikely that nonsuppressible ILA has any physiologic significance in glucose homeostasis or that it originates in the pancreas (FROESCH, 1967). The hypothesis according to which the large molecule with nonsuppressible ILA might pass through the cell membrane only when capillary permeability is increased (muscular activity, inflammation) is still open to discussion. In this way, in contrast to insulin, whose action is systemic, nonsuppressible ILA might act locally where extra glucose is needed.

A small protein with a molecular weight of 8000 with nonsuppressible ILA has been extracted from serum and partially purified (BÜRGI, 1966). It has the same effects as insulin on adipose tissue, and appears to stimulate glucose uptake by muscle more actively than its uptake by adipose tissue (FROESCH, 1966). The purified molecule with nonsuppressible ILA contains neither A- nor B-chain and probably has 3 disulfide bonds. It is an interesting molecule. The elucidation of its structure may help to find the biologically active centre of insulin. Lately, nonsuppressible ILA has been

shown to be a potentgrowth factor for fibroblasts in culture and a potent sulfation factor (somatomedin) (MORELL, 1973; ZINGG, 1973).

h) The Action of Insulin on the Transport of Glucose

Today, there is absolutely no doubt that the theory first formulated by LEVINE and GOLDSTEIN (1955), according to which insulin accelerates glucose transport into the cell, is correct. This effect of insulin on glucose transport has been investigated thoroughly in muscle and in adipose tissue (PARK, 1961; CROFFORD, 1965; MORGAN, 1964). The action of insulin on glucose transport sets in as soon as insulin comes into contact with the cell, and stops immediately when insulin is neutralized by anti-insulin serum (FROESCH, 1963). It is to be assumed that insulin combines in a reversible manner with the membrane and that it changes its configuration. Insulin accelerates the transport of glucose in adipose tissue *in vitro* even in concentrations as low as 1–10 micro-units per ml. These concentrations correspond to those found in the serum of fasting men. When glucose transport in adipose tissue and in muscle is accelerated maximally by insulin *in vitro*, glucose phosphorylation in the cell may become a rate-limiting factor for total turnover, and glucose in the free form may accumulate in the cell (FROESCH, 1963; MORGAN, 1961). It is not likely that this ever occurs under physiologic conditions. Insulin is released in particular after the intake of starch or glucose, which accounts for the fact that glucose reaching the blood during the resting state is stored in the tissues. Glucose is not oxidized, but rather stored. The regulation of glucose uptake by insulin is different from stimulation by muscular exercise. Whereas a glucose load can be stored only under the influence of insulin, increased energy requirement of the cell determines the glucose uptake in conditions of exercise and glucose need.

i) Effects of Insulin which are Independent of Glucose (see also Fig. 5)

The transport theory is correct, but the effect on glucose transport is certainly not the only action of insulin. Insulin promotes the transport of amino acids into muscles and fat cells and their incorporation into protein (MANCHESTER, 1965; SCHARFF, 1965; CARRUTHERS, 1962; KRAHL, 1964). The uptake of potassium by the cell is only increased in the presence of glucose. Insulin raises the resting electric potential of the adipose-tissue cell in the absence of glucose in the medium (BEIGELMAN, 1962). The anti-lipolytic effect of insulin is of special importance to consideration of the metabolic disorders in diabetes mellitus. Insulin inhibits the release of glycerol and free fatty acids by adipose tissue of the rat regardless of whether glucose is present in the medium or not (FROESCH, 1965; JUNGAS, 1963; MAHLER, 1964). Triglyceride-lipase determines the rate of lipolysis and is inhibited by insulin. In addition, insulin appears to influence glycogen metabolism. Insulin inhibits phosphorylase and activates glycogen synthetase in such a way that glycogen is less rapidly broken down and more rapidly synthesized (JUNGAS, 1966; FROESCH, 1967). It

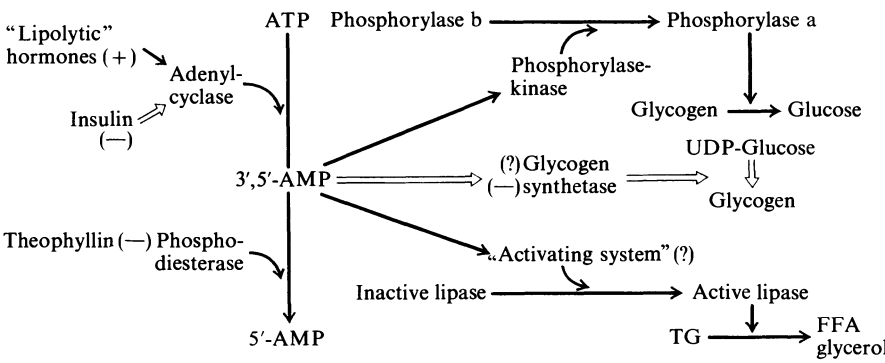

Fig. 5. The action of insulin on lipolysis and glucose metabolism is partly independent of glucose in the medium and occurs as rapidly as its effect on glucose transport. The concentration of cyclic 3',5'-AMP in adipose tissue decreases under the influence of insulin and increases under stimulation of lipolysis by glucagon, the adrenal medullary hormones and ACTH. These hormones seem to influence the formation of 3',5'-AMP by activation of adenylcyclase. This enzyme is localized in the membrane and releases 3',5'-AMP, the so-called "second messenger", into the cell. There it activates lipase and phosphorylase and probably inhibits glycogen synthetase. The causal relations between 3',5'-AMP and the activation of enzymes is, however, not yet fully explained. The effect of 3',5'-AMP is much less pronounced or absent in the homogenate or in the case of purified enzymes, and it will be difficult to prove that activation of these enzymes is really caused by an increase in the concentration of 3',5'-AMP and not simply by a concomittant phenomenon.

is interesting to note that all three enzymes involved are probably bound to their insoluble substrate in the cell. This assumption has led to speculations that insulin which does not penetrate into the cell itself may liberate some substance from the membrane into the cell, which could then influence the activity of these structurally bound enzymes within the cell. BUTCHER (1966) has demonstrated that insulin inhibits adenylcyclase which converts ATP to cyclic 3′,5′-AMP, the so-called second messenger. This cyclic compound promotes all processes in adipose tissue which provide energy for other tissues, i.e. lipase and phosphorylase. Inhibition of the formation of cyclic 3′,5′-AMP would, in contrast, promote the storage of glycogen and fat. Thus, in addition to its stimulation of glycogen and lipid storage through increased glucose uptake, insulin also inhibits the intracellular breakdown of glycogen and fat. These interrelations are presented in Fig. 5.

k) Effects of Insulin on Protein Synthesis (see also Fig. 6)

One characteristic of the diabetic state is a partial loss of activity of certain enzymes in various tissues. Hexokinase and glucokinase activities are decreased (SOLS, 1965). In adipose tissue of diabetic animals the activity of lipoprotein lipase is low, while in muscle it is higher than normal (HOLLENBERG, 1965). Insulin administration for 12 to 24 hours will normalize these enzyme disorders in diabetic tissue. It is not yet certain whether insulin restores protein and enzyme synthesis to normal by acting

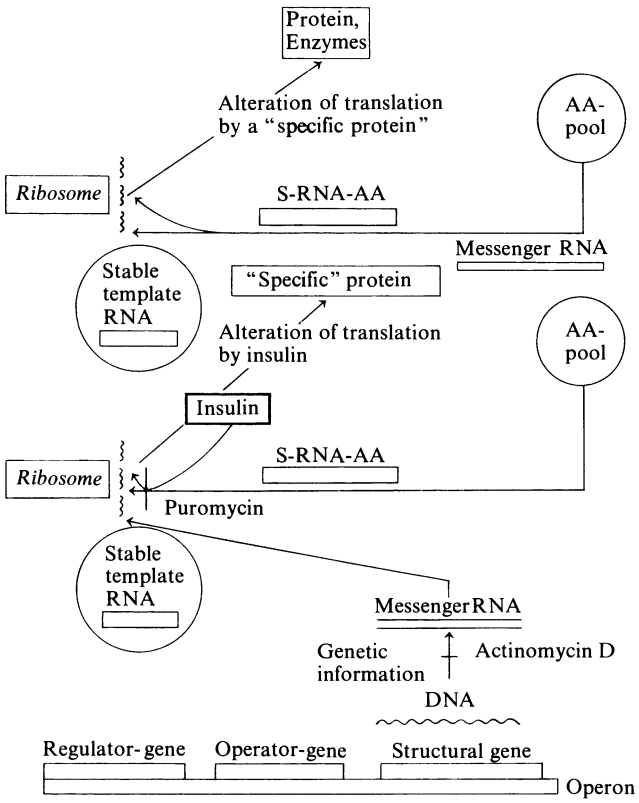

Fig. 6. Effects of insulin on protein synthesis. With few exceptions insulin acts only on intact cells. It stimulates the synthesis of enzymes which are important for the storage of glycogen and fat (among others: glucokinase, glycogen synthetase, glucose-6-phosphate dehydrogenase, pyruvate kinase, citrate cleavage enzyme, acetate thiokinase) and decreases the synthesis of those enzymes in the liver which determine the rate of gluconeogenesis (glucose-6-phosphatase, fructose-1,6-diphosphatase, phosphoenolpyruvate-carboxy kinase, pyruvate carboxylase). It has not been possible to demonstrate that insulin acts directly on enzyme synthesis. Some insulin effects are certainly secondary to its primary action on the cell membrane (glucose transport, adenylcyclase). The work of WOOL is very important since he has demonstrated for the first time a clearcut action of insulin on the ribosomes. According to WOOL (1965, 1967) insulin alters the translation of genetic information at the level of the ribosomes. Since this effect is inhibited by puromycin and cycloheximid but not by actinomycin D, insulin does not appear to affect transcription, i.e. the transmission of genetic information from DNA to RNA but rather protein synthesis at the level of the ribosomes. According to WOOL insulin brings about the synthesis of some "specific" protein which then induces a chain of further reactions resulting in the synthesis of particular proteins and enzymes. This interpretation of the action of insulin on ribosomes still is somewhat speculative. (According to WOOL, 1966)

directly on DNA or RNA synthesis or by way of its effects on the cell membrane and intermediary metabolism. WOOL's work is very interesting and important. He was the first to show that insulin acts on cellular components, the ribosomes. According to WOOL (1965, 1967), insulin changes the translation of the genetic information into protein synthesis at the ribosomes in a short time. Since actinomycin D does not influence this effect of insulin, whereas puromycin and cycloheximide do, insulin does not seem to act on transcription, i.e. the transmittance of the genetic information from DNA to RNA, but rather on protein synthesis at the ribosomes. According to WOOL, insulin stimulates the synthesis of a "specific" protein, which could further influence the synthesis of other protein molecules and enzymes in a chain of reactions. This interpretation of the action of insulin on isolated ribosomes is, however, still a matter of speculation and debate.

l) The Action of Insulin on the Liver

The question of whether insulin influences liver metabolism directly appeared to be solved when no action was detected on liver slices *in vitro* (RENOLD, 1955). Insulin does not act on glucose transport into the liver cell. The concentration of glucose in the cytoplasm of the hepatic cells is roughly the same as that in the blood in the presence and absence of insulin (CAHILL, 1958). However, in recent times, different research groups have demonstrated unequivocally that insulin decreases the release of glucose, the rate of gluconeogenesis and the production of urea both *in vivo* and in the perfused liver *in vitro* (COMES, 1961; DE BODO, 1963; MADISON, 1965). The mechanism of this hepatic action of insulin is not explained. Since some of these insulin effects are inhibited by substances which block protein synthesis, it may be assumed that insulin promotes the synthesis and formation of enzymes and exerts some of its effects on the liver in this way (SOLS, 1965). Insulin also inhibits the biosynthesis of enzymes essential to gluconeogenesis (WEBER, 1965).

4. The Acute Metabolic Disorder in Diabetes and Diabetic Coma

E. R. FROESCH and P. H. ROSSIER

a) Consequences of Absolute Insulin Deficiency (see Fig. 7)

The acute metabolic disturbance in diabetes mellitus is the direct result of the complete or almost complete deficiency of insulin. Diabetic coma in man can be exactly reproduced in experimental animals by destruction of the B-islet cells with alloxan or streptozotocin, by total pancreatectomy, by the inhibition of insulin secretion with mannoheptulose and by blockade

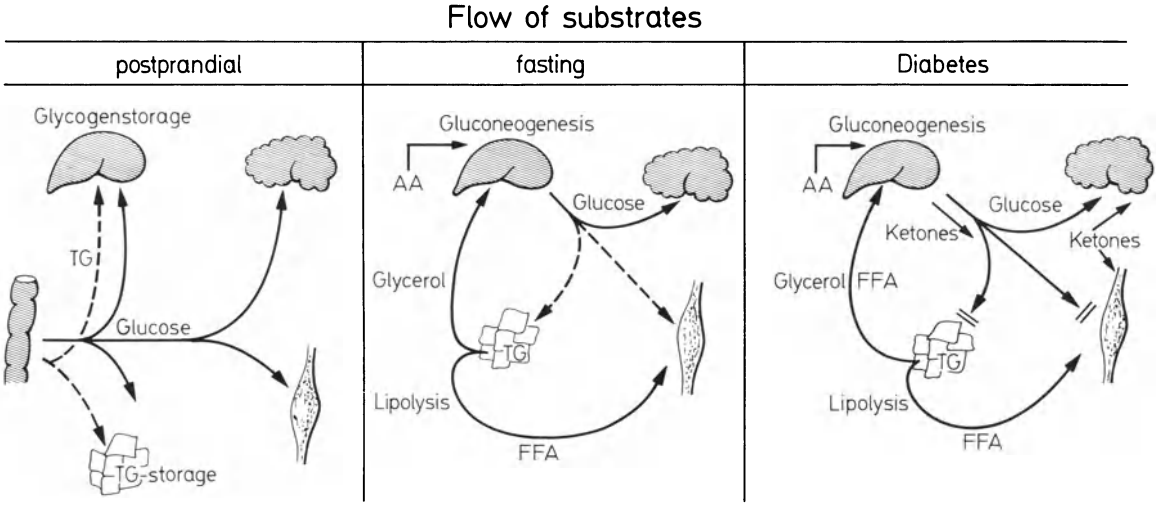

Fig. 7. Scheme of the metabolism of the most important fuels after eating, fasting and in the acute diabetic stage. Insulin is an absolute prerequisite for the storage of glucose as glycogen and fat and for the uptake and storage of fat in adipose tissue. Insulin increases glucose uptake of adipose tissue and increases the activity of lipoprotein lipase which enables the fat cell to hydrolyze chylomicrones and to take up the fatty acids which are esterified with α-glycerophosphate and stored as triglycerides. Free fatty acids released by adipose tissue are the major fuel of the fasting and diabetic organism. The massively increased release of free fatty acids by diabetic adipose tissue is due to decreased reesterification and stimulated lipolysis. Part of the free fatty acids taken up by the liver are oxydized to ketone bodies which also serve as a fuel but eventually flood the diabetic organism. (From FROESCH *et al.*, 1966)

of circulating insulin with anti-insulin serum. The animals die in diabetic ketosis 48 hours after the beginning of an infusion with high doses of neutralizing anti-insulin serum (ANDERSON, 1963). Experimental hyperglycemia and ketosis are reversible when insulin is administered at the right time and in sufficiently high doses.

Hyperglycemia arising within a few minutes after withdrawal of insulin is due to the immediate cessation of glucose transport into muscle and adipose tissue cells. The half-life of glucose increases rapidly in the rat from the normal 20 min to between 40 and 60 min after the injection of anti-insulin serum. The liver contributes to the hyperglycemia only after a while by increasing gluconeogenesis.

Under such conditions, glucose is no longer a major substrate for cellular metabolism. Free fatty acids and ketones serve as the main substrate. They arise entirely from adipose tissue. Lipases liberate free fatty acids from depot triglycerides. They are in part reesterified. The release of free fatty acids from adipose tissue is determined by the intracellular reesterification with alphaglycerophosphate derived from glucose and by the activity of the lipases (VAUGHAN, 1965). When insulin is absent, no more glucose is available for the reesterification of fatty acids, so that they are released into the blood. It is still unknown to what extent direct inhibition of lipolysis of adipose tissue by insulin and the removal of this block determine the release of free fatty acids. Stimulation of lipolysis by lipolytic hormones and inhibition of lipolysis by insulin fulfill all criteria of a neatly regulated metabolic system. Lipolysis is not only active when insulin is absent and lipolytic hormones, such as adrenaline, circulate in increased amounts. Lipolysis is also very active when animals are fed after prolonged periods of fasting, and lipolysis is then especially strongly inhibited by insulin (FROESCH, 1965).

During insulin deficiency the organism switches over from the oxidation of glucose to the consumption of fat, i.e. free fatty acids. Adipose tissue is the only organ which possesses an unlimited capacity for the storage of potential energy in the form of neutral fats. During fasting and in the diabetic state it provides almost all the energy for all other tissues. Only the brain and the erythrocytes continue to use glucose.

The release of free fatty acids from adipose tissue during fasting slightly exceeds the requirements of the organism. During complete insulin deficiency the free fatty acid release is no longer adjusted to the actual needs and ketone bodies are formed from free fatty acids.

b) Formation of Ketone Bodies and Ketosis

Ketone bodies are formed exclusively in the liver from acetyl CoA in a cycle described by LYNEN (1958). Acetyl-CoA accumulates in the liver by excessive beta-oxidation of fatty acids. During glycolysis, every molecule of pyrurate may give rise to a molecule of oxalacetate from which citrate is derived for the Krebs cycle. The same does not apply to the breakdown of fatty acids. Acetyl-CoA increases and ketone bodies are formed. This is in no way a process limited to diabetes mellitus. Whenever the liver is flooded with free fatty acids formation of ketone bodies is increased. Even the non-diabetic liver extracts a large percentage of the fatty acids supply and oxidizes them to ketone bodies. The formation of ketone bodies is for the most part a function of the concentration of free fatty acids in the blood (AYDIN, 1963).

Depending on the pH of the urine, the ketoacids are excreted partly as undissociated free acids and partly as sodium and potassium salts. During ketosis, sodium and potassium is lost. Since the water loss is greater than the cation loss, hypokalemia becomes apparent only during rehydration.

c) Causes of Hyperosmolarity and of Dehydration (see Fig. 8)

Insulin deficiency is the cause of the water and electrolyte inbalance in diabetic coma. These processes are presented schematically in Fig. 8. The first phase of diabetic decompensation begins with a rise in blood sugar. Serum osmolarity rises and for compensation water flows from the cells into the extracellular space. Temporary hypervolemia results and leads at first to a brief fall in aldosterone secretion and renal loss of sodium and chloride. On the other hand, the osmoreceptors in the hypothalamus are stimulated to release ADH so that more water is reabsorbed in the kidneys. This regulation mechanism may function only in the first phase of diabetic decompensation and later be overrun by a much more important mechanism. The renal tubules can reabsorb a maximum of 350 mg of glucose per minute. When more glucose is filtered through the glomerula it is lost in the urine. On the other hand, the concentrating capacity of the kidneys is limited to a maximum of 1000 mOsmol/l. With a blood sugar of 712 mg% and a glomerular filtration rate of 125 ml per minute, 540 mg of glucose or 3 mOsmoles are excreted per minute. The kidney needs at least 3 ml of water per minute or 180 ml per hour for the excretion of this amount of glucose alone. In addition, the concentrating

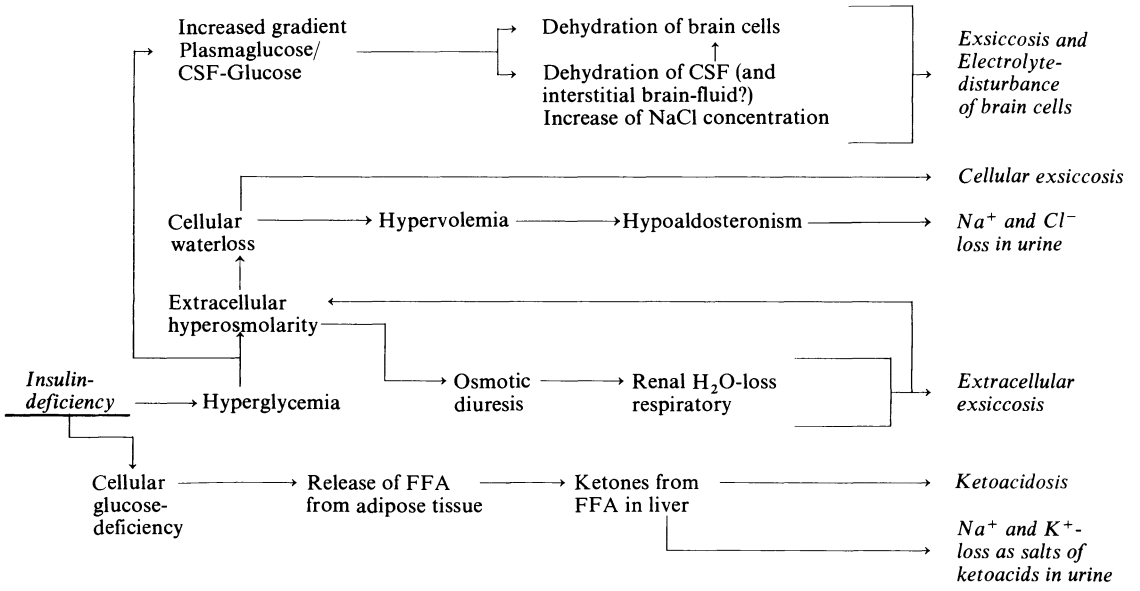

Fig. 8. Causes of hyperosmolality, exsiccosis and ketoacidosis in diabetic decompensation. (From FROESCH *et al.*, 1966)

capacity of the kidneys is limited during osmotic diuresis and seldom exceeds 600–800 mOsmoles/l. As soon as this enormous loss of water is no longer compensated for by drinking, a water deficit develops leading to severe hypertonic dehydration. This renal water deficit is further increased by respiratory loss of water due to the deep Kussmaul-type breathing.

The hyperosmolarity of the serum, primarily due to hyperglycemia and water loss, now increases further since the end-products of cellular metabolism can no longer be excreted because of renal failure due to circulatory factors. End-products of metabolism such as urea accumulate. As mentioned above, the organism attempts to correct hyperosmolarity of the serum by the flow of water from the cells into the interstitial space and into the blood. With the exception of erythrocytes and liver cells, most other cells in the body contain no free glucose. The intracellular osmolality of these cells is not affected directly by the rise in blood sugar, but secondarily by the cellular loss of water into the interstitial fluid and the blood.

d) Effects of Ketoacidosis, Hyperosmolarity and Dehydration on the Metabolism of the Brain

What are the causes of the disturbance of brain metabolism leading to cerebral coma? This question cannot yet be adequately answered even now. There is a pronounced potassium deficit in diabetic ketosis. Intracellular potassium is replaced by sodium and hydrogen ions. We would, therefore, expect an intracellular acidosis also in diabetic coma. A massive increase of CO_2 causes narcosis. CO_2 content and pressure in the plasma are especially low in metabolic acidosis due to hyperventilation. Is the metabolic disturbance of the brain directly responsible for the coma? Is the cellular dehydration responsible? During hyperglycemia, the sugar level in the cerebrospinal fluid is much lower than the blood sugar, so that an osmotic gradient is built up between the blood and the cerebrospinal fluid. It is temporarily compensated by a loss of water from the cerebrospinal fluid and a resultant rise of the sodium chloride concentration (FROESCH, 1967). The ratio of blood glucose to cerebrospinal fluid glucose averages 1.9. The quotient is smaller at low blood sugar concentrations and rises to above 2 at blood sugar values above 1000 mg%. A comparison between the chemical composition of serum and that of cerebrospinal fluid (CSF) shows that CSF sodium is always more or less markedly elevated in diabetic coma, in spite of normal sodium levels in the serum. Can we conclude from this that the brain cells are bathed in a fluid in which the sodium content is elevated and rises as the glucose gradient between blood and CSF rises? Whereas the cerebrospinal fluid is formed by the ependyma of the choroidal plexus and also partly reabsorbed there, we know little about the interstitial fluid of the brain and its formation. The interstitial space which is thought to make up to 30% of the weight of the brain cannot be

localized under the electron microscope (TSCHIRGI, 1960). The capillaries are densely surrounded by the foot-like elongations of the astrocytes. A few authors hold that the so-called blood CSF barrier is formed by these parts of the astrocytes and the astrocytes themselves. The formation of the CSF is certainly not the same as the formation of the interstitial fluid of the brain. Furthermore, the CSF is renewed 2 to 4 times daily, a turnover which could not provide the brain with enough glucose and oxygen. What do we know about the blood/brain barrier in relation to glucose? According to TSCHIRGI (1960) the glucose content of the brain is, on average, 25–40% lower than the blood sugar and it changes in a parallel manner with the blood sugar. When the blood sugar rises to 800 and 1600 mg%, however, the glucose content of the interstitial fluid of the brain does not increase above 300 mg%. As a result of this, the ratios differ from those in the CSF, but they do indicate similar trends, i.e. an ever-increasing osmolality gap resulting in dehydration of the brain cells as the blood sugar increases. As early as 1932, ROSSIER made the observation that hyperventilation lasts longer than the acidosis of the blood and may occasionally lead to respiratory alkalosis. An explanation for this fact was found in recent investigations which show that the pH of the CSF lags behind the pH of the blood during treatment, since the organic acids pass the blood/CSF barrier only sluggishly. The low pH of the CSF continues to stimulate the respiratory center, even when the blood pH is already normal (see Table 1).

5. Diagnosis, Differential Diagnosis and Prognosis of Diabetic Coma

E. R. FROESCH and P. H. ROSSIER

a) Diagnosis and Differential Diagnosis

The diagnosis of a typical case of diabetic coma is very simple. In the majority of patients, diabetes mellitus was known to be previously present. We then have to differentiate between a hyper- and a hypoglycemic coma. The red, dry skin, the slow smoothing out of the elevated skin folds, the soft eye bulbs, the flat, fast pulse rate, the Kussmaul breathing, and finally the smell of acetone are unequivocal signs of the classical diabetic coma. Apart from the positive urine sugar and acetonuria, the determination of a highly elevated blood sugar is essential for the diagnosis. Today, this can be done rapidly with the Dextrostix at the bedside. Occasionally ketone bodies are also elevated when the blood sugar is very low during a prolonged hypoglycemic coma. It may then be mistaken for a diabetic coma since glucose may still be present in the urine from previous hyperglycemia. This stresses the importance of a rapid blood sugar determination for the diagnosis of diabetic coma.

Hyperosmolar, non keto-acidotic diabetic coma may present special difficulties (ROSSIER, 1961; STÖTTER, 1962). Often it is the first manifestation of diabetes mellitus, and the coma is not always preceded by a period of polyuria and polydipsia, especially when the renal function is already impaired in elderly patients. In addition, Kussmaul breathing and the smell of acetone are

Table 1. Blood and cerebrospinal fluid (CSF) in diabetic coma before, 6 and 24 hours after the beginning of treatment

	Predominantly ketoacidotic coma					
	Before therapy		6 hours after start of therapy		24 hours after start of therapy	
	Blood ($n=8$)	CSF ($n=8$)	Blood ($n=7$)	CSF ($n=7$)	Blood ($n=4$)	CSF ($n=4$)
Na^+ (meq/l)	135.8	156.0	138.8	147.0	140.5	151.0
Cl^- (meq/l)	95.8	134.7	101.1	123.5	96.0	116.7

absent. The blood pressure often falls even in the early stages of hyperosmolar coma.

b) Prognosis of the Diabetic Coma

Diabetic coma carries an average mortality of 10–20%. The definition of diabetic coma is of extreme importance in a comparison of the results of different medical centers. This is brought out by the Frankfurt study (PFEIFFER, 1960). In this study 83 cases of diabetic coma were admitted from 1954 to 1959, and 16 of these died from the coma itself and a further 16 from other causes. Not one of the 215 diabetics referred in the same period for admission in the precomatose state died. These figures indicate how very important it is to start treatment as early as possible, since the prognosis gets rapidly worse with the duration of the unconsciousness. Of the 16 patients mentioned above, who died in and of the diabetic coma, the unconsciousness lasted longer than 10 hours before treatment was started in 14 patients, and was even longer in 2 patients in whom diabetes mellitus had not been diagnosed before the comatose episode. The prognosis is unfavorable in elderly patients, mainly because of the higher risk of cardiovascular complications. The longer diabetes has been present, the worse is the prognosis. In addition, all severe precipitating and concomitant illnesses, such as myocardial infarction, arteriosclerosis, gangrene, uremia and infections, influence the prognosis unfavorably. In contrast, the level of the blood sugar does not seem to be of importance for the prognosis. Several unfavorable prognostic factors not infrequently occur together in hyperosmolar diabetic coma. This is often seen in elderly patients with preexisting cardiovascular disease. In many, circulatory failure which may be resistant to therapy is present from the very beginning or may develop during the course of treatment.

6. Treatment of Diabetic Coma

a) Treatment Schedule in Use since 1960 in the Department of Medicine, University of Zürich (ROSSIER, 1960)

1. *Insulin by slow infusion:* Decrease of blood sugar, osmolality, free fatty acids, ketone bodies and amelioration of acidosis.
2. *Hypotonic fluid administration:* Correction of the exsiccosis and of the hypertonic dehydration.
3. *Na^+ administration, half of it being given as bicarbonate:* Compensation of the sodium loss and of the metabolic acidosis.
4. *K^+ administration starting between the 4th and 6th hours:* Compensation of the previous potassium loss and the potassium displacement into the cells during insulin therapy.

Intravenous fluid for diabetic coma:

1/3 as physiologic NaCl solution
1/3 as physiologic Na-bicarbonate solution (1/6 molar, 14 g/l),
1/3 as H_2O.

In uncomplicated coma:

1st hour	1 liter with 100 units of soluble insulin,
2nd hour to 4th	1 liter with 100 units of soluble insulin,
5th to 12th hours	1 to 2 liters with 50 to 200 units of soluble insulin,
13th to 24th hours	1 to 2 liters with insulin according to needs.

Potassium replacement: 20 to 40 meq/h (1.5–3 g of KCl).

Glucose: The hypotonic "coma" solution is replaced by a 5% glucose infusion when the blood sugar approaches 250 mg%.

b) Amount of Fluid (see Table 2)

Table 2. Water- and electrolyte deficit in diabetic coma according to various authors

	JOSLIN (1959)	MACH (1953)	DEROT (1961)	BUTLER (1950)
Water (ml)	6866	4000–5000	5000–8500	7000
Na^+(meq/l)	351	350– 700	350– 700	350
K^+ (meq/l)	493	400– 600	350– 420	420
Cl^-(meq/l)	430	250– 600	350	280

As already discussed in the section on the causes of dehydration, the water deficit exceeds the sodium deficit, resulting in hypertonic dehydration. Correspondingly, a hypotonic solution should be used for rehydration. It has been shown that the results of therapy obtained with hypotonic solutions are almost the same as those obtained with isotonic fluids. On the other hand, hypertonic solutions are strictly contraindicated.

The fluid deficit in diabetic coma varies from about 4 to 9 liters (average 5.5 liter), and this amount of fluid must be replaced. The rate of fluid administration must be adjusted to various factors. In the young diabetic without cardiac disease, 6 to 8 liters may be given intravenously in 24 hours. In the elderly patient fluid must be administered with caution. The danger of overloading the circulation and thus causing pulmonary edema is serious. Such patients should generally not be given more than 4 liters intra-

venously in 24 hours. As soon as these patients regain consciousness and as soon as the danger of aspiration is overcome, further rehydration can occur without any risk by the oral route.

c) The Composition of the Intravenous Solution

An essential requirement for any solution is its readiness for use at any time, so that treatment can be started promptly. For this reason JOSLIN (1959) recommended physiologic saline, although this solution is isotonic and not hypotonic. The major advantage of saline is that it is always ready and available.

The solution of 1/3 physiological saline, 1/3 physiological sodium bicarbonate and 1/3 water has the same advantage in being indefinitely stable (ROSSIER, 1960). This solution is hypotonic with an osmolality of 210 mosmol/l. The ratio of sodium to chloride is 2 : 1 and the bicarbonate content is 55 meq/l. The Hausmann solution for diabetic coma, commercially available in Switzerland, has a similar composition. Sodium lactate, which was formerly often used instead of sodium bicarbonate, has lost its place in the therapy of the diabetic coma, since spontaneous hyperlactatemia is relatively frequent in these patients (HUCKABEE, 1961). The organism should not be flooded with organic anions, the utilization of which is not guaranteed (SCHWARTZ, 1962).

Tris buffer has repeatedly been recommended for the treatment of coma. We have no personal experience of this use of the solution and do not understand the reasoning behind this therapy.

d) Treatment with Intravenous Insulin
(See Therapeutic Schedule)

Treatment with insulin, like fluid administration, must be started at once after the diagnosis of diabetic coma has been made. The extremely high doses of insulin often used are not necessary if insulin is administered in an intravenous drip. The biological half-life of insulin in the human is about 10 min. If 200 units of insulin are injected intravenously, 100 units are destroyed by the liver after 10 min, and only 12 units are circulating in the blood after 1 hour. The major part of the insulin is removed by the liver and inactivated before having exerted any effect on peripheral tissues. The situation is quite different in diabetics with extremely high titers of insulin antibodies in the blood which cause insulin resistance. The inactivated insulin bound to insulin antibodies circulates for much longer in the blood than free insulin. In such patients the circulating antibodies must first be saturated before insulin can act (FRANKHAUSER, 1964). In this case, single injections of high doses of insulin are indicated for the saturation of antibodies.

Subcutaneous or intramuscular administration of insulin achieves an insulin depot. The unknown factor in this type of insulin therapy is the absorption rate, which can be appreciably slowed down in diabetic coma because of the poor circulatory state. Therefore, we never know exactly how much insulin has already been inactivated, how much is still circulating in the blood and how much remains to be absorbed from the depot at any given time during treatment with subcutaneous insulin. The logical and correct treatment with insulin in an intravenous drip was not used previously because nothing was known about the stability of insulin in neutral or slightly alkaline solutions. VÖLLM (1960) tackled the problem of the stability of insulin in our laboratory and demonstrated that insulin lost none of its activity when it was stored at 37 °C for over 24 hours in a solution of physiological sodium bicarbonate. Since then we have not observed any failures to respond to an intravenous insulin drip. The favorable results previously reported have been fully confirmed in other hospitals and the intravenous insulin application is now routine in most Swiss hospitals. The dosage of insulin can be adjusted much more simply in this way than with subcutaneous injections. There is also no danger of hypoglycemia, since no depot of insulin is applied and since the action of the intravenously administered insulin lasts at the most 30 min to one hour after the drip is finished. We are convinced of the simplicity and of the practical advantages of the treatment with insulin in an intravenous drip, yet we do not know whether the prognosis of diabetic coma has been improved by this method. Despite rapid normalization of the metabolic situation, refractory irreversible circulatory collapse of unknown etiology still proves fatal to too many patients. The fatal outcome of the diabetic coma is frequently due to irreversible brain damage. However, not all cases can be explained in this way, since circulatory failure is not always preceded by severely disturbed brain function and deep coma.

e) The Dosage of Insulin

The principle that too much insulin at the beginning of the treatment of the diabetic coma can only help and causes no damage, is certainly correct. In our experience 100 units of insulin during the first hour after the onset of therapy, and a further 100 units in the following 3 hours given intravenously in a drip, exert optimal effects on the metabolism which can hardly be

surpassed by higher doses of insulin. Diabetics who have high antibody titers and are resistant to insulin are probably the exception to this rule and require much more insulin. ROOT recommended (1959) that the insulin dosage be chosen according to the blood sugar level. It is questionable whether the blood sugar is really a good metabolic index of the severity of the condition. We believe that the insulin doses in our treatment schedule are adequate for the majority of cases and actually exceed the amount of insulin necessary for optimal metabolic effects.

Insulin is given intravenously for as long as the intravenous drip is administered. As soon as the patients regain consciousness, fluid can be taken orally, and insulin may be given subcutaneously.

f) Potassium Replacement
(See Therapeutic Schedule and Table 2)

Patients in diabetic coma are in a negative potassium balance which needs not always be reflected by a low potassium concentration in serum. The potassium deficit is primarily intracellular and can reach values of up to 600 meq (see Table 2). The serum potassium level in diabetic coma can be normal, low or even slightly elevated. Therefore, potassium should not be given intravenously at the beginning of therapy. As soon as the cells resume the uptake of increased amounts of glucose under the influence of insulin and store it as glycogen, they also take up potassium. The danger of hypokalemia now becomes real. As soon as the blood sugar begins to fall quickly potassium must be administered. This is usually 4 to 6 hours after beginning of treatment and can occasionally occur after as little as 2 hours. Only a small part of the cellular potassium deficit can and must be compensated for by intravenous potassium administration, since most of the patients can take potassium orally when they regain consciousness.

As a general rule, not more than 40 meq of potassium (3 g KCl) should be given in a drip in one hour.

g) Treatment with Carbohydrates

Hyperglycemic coma is by definition characterized by an excess of glucose in the blood. Insulin deficiency alone is responsible for the fact that the cells cannot use it. Therefore, administration of glucose at the beginning of the treatment of the coma is incorrect. Glucose increases hyperosmolarity, one of the main causes of the dysfunction of the brain, and makes it impossible to judge the success of insulin therapy by measuring blood glucose.

In our therapeutic schedule, the rule that the hypotonic salt solution should be replaced by a 5% glucose solution as soon as the blood sugar approaches the 250 mg% limit has proved satisfactory. Fructose therapy is still open to discussion. There is no doubt that fructose should theoretically improve the metabolic state. Liver and adipose tissue, which are really the organs responsible for ketoacidosis, can utilize fructose independently of insulin. Despite this fact, the metabolic state of the liver can not be fully normalized with fructose alone. Furthermore, fructose, sorbitol and xylitol are also rapidly converted to lactate and may lead to lactic acidosis. At this point, the liver has the tendency to convert a large part of these substances to glucose. Fructose, therefore, leads to a rise in the blood sugar, so that the effectiveness of insulin therapy can no longer be assessed by blood sugar determinations in the first hours of the treatment of the coma (NABARRO, 1955). We have recently shown that the uptake of fructose by diabetic adipose tissue is reduced roughly to the same extent as glucose uptake, so that the administration of fructose alone cannot completely normalize the metabolic disturbance of diabetic adipose tissue (FROESCH, 1965).

Nevertheless, diabetic adipose tissue has more carbohydrate at its disposal in the presence of both glucose and fructose, since both hexoses are taken up and metabolized independently of each other. Diabetic adipose tissue releases less free fatty acids when incubated with glucose and fructose together than with glucose alone. The suppressed activity of enzymes important in fat synthesis in the diabetic liver is normalized by fructose without insulin (KORNACKER, 1965).

h) Consequences of our Knowledge about the Importance of Hyperosmolarity for the Therapy of Diabetic Coma

There is no clear distinction between acidotic and hyperosmolar diabetic coma. Every patient with diabetic ketoacidosis also has a more or less pronounced hyperosmolarity. On the other hand, the pure hyperosmolar diabetic coma does not occur very frequently. The principles of treatment are the same for both forms of coma. Fluid therapy should be carried out energetically in patients in hyperosmolar coma, provided that the circulatory state of the patient permits this. We use the same hypotonic solution as for the treatment of ketoacidotic coma. It is a matter of opinion whether sodium bicarbonate should be replaced by sodium chloride.

As far as the pathophysiology of the hyperosmolar coma is concerned, the complete absence of ketosis in these patients is still unexplained. One must assume that insulin is still secreted in sufficient amounts to keep pace with the flooding of the liver with free fatty acids. Hyperglycemia must then be explained by an enormous increase of gluconeogenesis in the liver. After successful treatment of hyperosmolar coma, diet alone or combined with sulfonylureas is often adequate. This proves that the B-islet cells are still capable of secreting insulin. TEUSCHER (unpublished observation) has even succeeded in treating a patient in hyperosmolar coma with sulfonyl ureas and intravenous fluids without insulin.

However, caution must be exercised in the therapy of diabetic coma. From the electrolyte findings in Table 1, it can be deduced that the osmotic gradient between blood and cerebrospinal fluid can be temporarily reversed during the treatment with insulin when the blood sugar falls rapidly. This would cause a flow of water from the blood back into the CSF, the interstitial fluid of the brain and from there into the brain cells. Cerebral edema or swelling could arise from too vigorous treatment of the dehydrated patient. This assumption is only correct if we can apply our findings in the CSF to the interstitial fluid of the brain, a question which is not yet resolved. The formation of CSF is a very slow process compared to the formation of the interstitial fluid of the brain. It is, therefore, not astonishing that the sugar in the CSF lags considerably behind the blood sugar during the development of hyperglycemia as well as after the return to the normal state during treatment. The rapid turnover of the brain fluid also makes it unlikely that a negative osmotic difference can develop, as in the CSF. Nevertheless, this phenomenon should be further observed, since we still have no pathogenetic explanation for the fatal outcome of many cases of diabetic coma who recover first and then fall into a deep irreversible coma suggestive of cerebral edema.

7. Pathogenesis and Etiology of Diabetes Mellitus

E. R. FROESCH

a) The Inheritance of Diabetes Mellitus

Diabetes mellitus is the most common inherited metabolic disease, but its mode of inheritance is not yet known. This may be due to the fact that glucosuria is only a symptom of a generalized disease, and that other than hereditary factors determine the time at which glucose intolerance develops.

The chances are greater than 70% that the identical twin sibling of a diabetic counterpart will develop diabetes. Nearly 50% of all children of diabetic parents under the age of 40 will develop diabetes sooner or later. However, other cases of diabetics are found only in about 30% of the families of diabetes.

VALLENCE-OWEN (1965) believes that diabetes mellitus is transmitted by an autosomal dominant gene. This opinion is based on his findings that an insulin antagonist (synalbumin antagonist) could be demonstrated in the serum of all diabetics and one of their parents. These findings are fascinating because, for the first time, it appeared as if the trait of diabetes mellitus could be successfully traced from birth on. If this finding can be confirmed, the mode of inheritance of diabetic mellitus will soon be clarified. However, geneticists doubt this theory. The gene frequency in the western population is estimated to be about 22%. 5% are predisposed to diabetes, and 2–3% develop manifest diabetes. It was previously assumed that an autosomal recessive gene with incomplete or variable penetrance could best explain the mode of transmission of diabetes mellitus (STEINBERG, 1965). As long as the homogeneity of the diabetic syndrome has not been confirmed, this mode of inheritance remains doubtful. A simple autosomal recessive inheritance is also unlikely because the frequency of diabetes in children of 2 diabetic parents in whom diabetes became overt after 40 is very low (COOKE, 1966).

In a very thorough Swedish study, GRÖNBERG (1968) concluded that epidemiological knowledge about diabetes mellitus could be accounted for by 4 genetic hypotheses:

1. Autosomal dominant inheritance, in which the manifestation is diminished in the male, or in which cases of "nonessential" diabetes are more frequent in the female.
2. Autosomal recessive inheritance with the same restrictions as in 1.
3. Sex-linked dominant inheritance.
4. Multifactorial inheritance with the same restrictions as in 1.

These authors hold a sex-linked dominant inheritance as the most likely hypothesis.

NEEL (1962) thinks that a multifactorial inheritance of diabetes mellitus with 4 diabetogenic genes is more probable, based on the hypothesis of the "thrifty genotype" (NEEL, 1968).

According to this theory, it is to be expected that the severity of diabetes is dependent on whether a complete or an incomplete set of

diabetogenic genes is present. The comparison with spontaneous diabetes in animals also leads to the same conclusions. In the Chinese hamster, spontaneous diabetes mellitus occurs frequently and "juvenile" forms of diabetes as well as adult type diabetes are seen (GERRITSEN, 1967). Diabetes in the Chinese hamster is comparable to human diabetes mellitus in many ways. It is interesting to note that the mode of inheritance in this animal cannot be explained by a single gene, but rather by a set of 4 diabetogenic genes (BUTLER, 1967).

b) "Exhaustion" of the B-Islet Cells

Although a more or less complete failure of insulin secretion and hyalinosis of the islets of LANGERHANS are characteristic of the end stage of diabetes mellitus, the primary and inherited metabolic disturbance need not be situated there. It is conceivable that humoral factors could lead to a destruction of the islets of LANGERHANS. The possibility of a destructive autoimmune inflammatory process is currently being discussed as a possible cause. This point of view is not only fashionable but is supported by some observations mentioned below. One biological principle, which can also be applied to endocrinology in general, very strongly speaks against an "exhaustion" of the islet cells due to increased insulin requirements (FROESCH, 1965). When an organ, or an endocrine gland, is placed unter strain, it hypertrophies. In autoimmune diseases which lead to a decreased function of certain areas, other areas undergo temporary hypotrophy. Hypertrophy in HASHIMOTO'S goiter, a classic endocrinological autoimmune disease, is very typical. Hypertrophy of the thyroid gland quarantees a normal function for a long period of time, after which hypothyroidism develops. One could reason in favor of the "exhaustion theory" that the case of the islets of Langerhans is different: they lie as clusters of cells within a gland with exocrine function. In different animals with inherited diabetes mellitus, where the primary pathogenetic factor is increased insulin requirement, a hypertrophy of the islets is regularly found. Islet hypertrophy is particularly pronounced in akomys obesus (PICTET, 1967), and in different breeds of the obese-hyperglycemic mouse (New Zealand, Bar Harbour) (HELLMANN, 1965). In contrast, true hyperplasia of the islets has not been described in human diabetes mellitus, except in newborns of diabetic mothers. There is no proof that insulin requirement is increased in prediabetic subjects. Exhaustion of the islet cells must, therefore, be refuted as an important pathogenic mechanism because at no stage of the disease islet hyperplasia is found. The exertion of the islet cell apparatus by increased food intake and other exogenous factors can, of course, play a role in the development of islet cell insufficiency. These cells are unable to react in the normal manner with hyperplasia. A primary disorder of the B-cells of the islets is likely to be at least one of the genetic disturbances of diabetes mellitus.

c) Insulin in the Blood of Diabetic Subjects

WRENSHALL and BEST (1956) extracted little or no insulin at all from the pancreas of juvenile diabetics who had died of various causes. They also found a decrease in the insulin content in the pancreas of adult-type diabetics which paralleled the duration of hyperglycemia and glucosuria. Levels of immunoreactive insulin in the serum of juvenile diabetics are reduced and there is no increase in response to glucose (SAMOLS, 1965). In adult type diabetics the fasting values of the serum insulin may still be normal, but the rise after glucose administration is absent or reduced and delayed (SELTZER, 1967). Homozygous twins of diabetic subjects and children of two diabetic parents of the juvenile type, i.e. prediabetics by definition, already show a diminished pancreatic response to glucose before glucose intolerance becomes manifest (TAYLOR, 1967).

Overweight patients with latent diabetes often show a very special insulin response: the rise of immunoreactive plasma insulin after glucose administration is delayed, but may occasionally be even greater than normal after 2–3 hours when the blood sugar has risen to very high levels. This late insulin response can lead to hypoglycemia 3–4 hours after glucose intake (KARAM, 1963; YALOW and BERSON, 1960; SELTZER, 1967). These findings have been misinterpreted and have given rise to the erroneous expression of "hyperinsulinism in diabetes mellitus", causing some researchers to look even harder for insulin-antagonists in pre- and latent diabetes.

In our opinion such a delayed, and later on excessive, reaction of the islet cells can be explained by a relative and not yet complete decompensation of the genetically inferior islet-cell apparatus. When insulin is not released at the right time, hyperglycemia develops rapidly, stimulating the islet cells to secrete more insulin. In the diabetic, the insulin reserves are diminished and are replenished only slowly. The fact that the delayed excessive reaction may sometimes lead to hypoglycemia is consistent with this view, since extra insulin is needed to restore glucose homeostasis.

According to ANTONIADES (1965) insulin is present in the blood in a "free" and a "bound" form. The liver would convert the inactive "bound" insulin into the "free" active form during hyperglycemia. According to the research of this investigator this process would be disturbed in the diabetic. There is no evidence whatever that bound insulin contains insulin. A relationship between the partially purified nonsuppressible insulin-like activity and so-called bound insulin is more likely.

It should be stressed that the research on immunoreactive insulin in the serum has revealed many new facts about the secretory capacity of normal and diabetic islet cells. On the other hand, all hypotheses of the islet cell disturbance in diabetes based on the measurement of ILA (biological insulin-like activity) have proven erroneous.

d) Insulin Antagonists and Inhibitors

α) Endocrine Factors

Since HOUSSAY's animal experiments (1932, 1936) we know that pituitary and adrenal hormones counteract insulin. Growth hormone, glucocorticoids, catecholamines and glucagon all elevate the blood sugar. Cortisol and glucagon stimulate gluconeogenesis, whereas catecholamines and also glucagon increase glycogenolysis. Apart from this, adrenaline inhibits insulin secretion by the B-cells (PORTE, 1966) and glucose phosphorylation in the muscle cells (GROEN, 1958; MIALHE, 1965). The action of growth hormone is complex (see p. 85ff.). The hyperglycemic action of growth hormone is partly due to a stimulation of lipolysis and a consecutive increase of the plasma free fatty acids which compete with glucose for oxidation by muscle.

Diabetes can be evoked in animals by all these hormones, providing that the islet-cell apparatus has been damaged previously by partial surgical removel or chemical damage. In the pathogenesis of human diabetes mellitus there is no indication of a causal role of any insulin antagonistic hormone. The incidence of overt diabetes mellitus in acromegaly, pheochromocytoma and in Cushing syndrome is about 20–30% which corresponds to the estimated frequency of diabetic genes in the population. The endocrine antagonists are no longer believed to play a role as causal factors in the pathogenesis of essential diabetes mellitus.

β) Other Humoral Factors

VALLENCE-OWEN has been investigating the significance of the synalbumin antagonist for the past 15 years. This substance is thought to occur in increased concentrations in the serum of diabetics (1965). This antagonist inhibits the action of insulin *in vitro* on the rat diaphragm, but not on rat adipose tissue. Since the level of the antagonist is found to be elevated already in the potential diabetic, obesity before the onset of diabetes and the "exhaustion" of the islet cell apparatus occuring later could be explained by this antagonist and transitory hyperinsulinism. VALLENCE-OWEN believes that the antagonist is the B-chain of insulin bound to albumin. Conclusive evidence for this has never been presented, although there are no obvious technical difficulties in the way of testing the hypothesis.

In has been claimed that an insulin antagonist arises in the serum during diabetic ketosis. This insulin antagonist inhibits the action of insulin on the rat diaphragm, but not on rat adipose tissue (FIELD, 1956). This substance has not yet been characterized.

e) Tissue Resistance to Insulin in Decompensated Diabetes and in Obesity

Whereas the importance of the insulin antagonists in the pathogenesis of diabetes mellitus seems to be decreasing, tissue resistance to insulin has been demonstrated after prolonged insulin deficiency. Thus, the liver loses its ability to act as a regulator of glycemia soon after the development of insulin deficiency. Since we do not know how insulin acts on the liver, the failure to respond to insulin after insulin deficiency of short duration is also unexplained. If a diabetic patient's response to insulin is weak or delayed, this signifies that the liver continues to release increased amounts of glucose, or that the peripheral tissues do not take up sufficient amounts of glucose. The glucose turnover is elevated in steroid diabetes: peripheral tissues assimilate more glucose than the tissues of a healthy person, but the liver produces relatively more glucose, so that hyperglycemia can result despite an increase peripheral glucose uptake.

Muscle and adipose tissue lose their ability to take up glucose and to respond to insulin only after a long period of insulin deficiency. This has been proved by conclusive animal experiments and also by findings in man. The arterio-venous glucose difference is greatly reduced in the decompensated diabetes and cannot be acutely normalized by insulin (BUTTERFIELD, 1965; ZIERLER, 1964). When insulin is administered for a prolonged period of time, the diabetic patient's tissues are normalized and behave like those of normal subjects. We can conclude

from this that tissue resistance to insulin in the diabetic is a result and not the cause of the insulin deficiency.

The metabolism of the obese subject with normal glucose tolerance has been examined by measurements of arterio-venous catheterization. It has been shown that the muscle of the obese takes up less glucose than that of the non-obese and that its response to insulin is less pronounced (RABINOWITZ, 1962). The obese is, therefore, in a certain way resistant to insulin. The insulin values in the blood of the obese are usually higher in the fasting state and after glucose loading than in the normal, healthy person (KARAM, 1963). Both metabolic defects – reduced insulin sensitivity and increased insulin values – return towards normal as soon as the obese subject reaches his ideal weight by a reducing diet and increased physical activity. These facts cannot be explained for the time being.

f) Diabetes Mellitus as an Autoimmune Disease

Autoimmune mechanisms have been considered as pathogenic factors in several endocrine disorders, such as primary myxedema, Graves' disease and idiopathic, non-tuberculous adrenocortical insufficiency (see p. 313). Since diabetes mellitus coincides frequently with the latter condition and occasionally also with primary myxedema, it seems reasonable to look for an autoimmune process in diabetes mellitus also.

About 30% of newborns of diabetic mothers show eosinophilic infiltration of the islet tissue. Many juvenile diabetics show lymphocytic infiltration of the islet tissue within the first weeks of the onset of diabetes mellitus (VON MEYENBURG, 1940; LE COMPTE, 1958). Analogous to Hashimoto's thyroiditis, these infiltrations have been termed "insulitis". No humoral or cellular antibody has yet been demonstrated in the untreated diabetic, so that the most important piece of evidence of an autoimmune disease is still missing. It is interesting to note that antibodies can be produced by extracted insulin from one species when injected into the same species (RENOLD, 1966). In animals immunized in this way lymphocytic infiltrations similar to those found in juvenile diabetics are occasionally seen around the islet cells (LE COMPTE, 1966). These may occasionally lead to diabetes mellitus (GRODSKY, 1966).

g) Manifestation Factors: Nutrition, Obesity and Muscular Activity

The frequency of the genes for diabetes mellitus varies from population to population. The estimated frequency of diabetes depends heavily on environmental factors. This is particularly evident in various population groups in South Africa. Diabetes mellitus was quite uncommon among the Indian immigrants as long as they belonged to the proletariate of the home country, food being scarce and physical work hard. With the ascent into the middle class as merchants, food became richer and work in the fields was replaced by sitting behind a desk. People became obese and there was a "diabetes explosion". Today, up to 40% of the Indian population in certain regions of South Africa are diabetics (CAMPBELL, 1963). Similar reports have been made about Jews returning to Israel from Yemen (COHEN, 1963), and about certain North American Indian tribes (WEST, 1965).

In Europe, the decreased frequency of diabetes mellitus in wartime and the rising incidence during peace and prosperous periods are familiar facts.

The sand rat (Psamomys obesus) can be compared to the human. These rats develop diabetes when they are removed from their natural environment in the sand desert, which offers a sparse diet and free movement, into cages with restricted movement and free access to laboratory food (HACKEL, 1967).

NEEL (1962) has formulated the interesting concept of the "thrifty genotype" of the diabetic. Neel assumes that the chances of survival for the potential diabetic were favorable when periods of abundance alternated with periods of starvation, and that the diabetogenic gene has thus persisted into modern times. The 20th century of the western civilisation with its technology, increasing automatization and general abundance changed this totally. Today, the diabetic gene is still inherited because of successful treatment of diabetes.

It is futile to speculate on whether sugar or fat is the noxious agent needed for diabetes mellitus to become overt. It is rather a matter of simple overnourishment, since fat is not eaten without sugar, and conversely, sucrose not without fat. In any case, the increased use of sucrose alone cannot be held responsible for obesity and the increasing occurrence of diabetes mellitus. Patients with a hereditary fructose intolerance, for example, can become grossly overweight without any difficulty, although they do not eat mono- or disaccharides and eat nothing but starch, fat and protein (FROESCH, 1966). The remission of diabetes mellitus by restriction of calories and increased muscular activity is one of the dramatic and pleasing results that a physician can experience. They prove that excessive demands on a primarily inferior islet cell apparatus greatly accelerate the onset of the metabolic disturbance.

8. The Pathogenesis of Diabetic Angiopathy and Neuropathy

a) Diabetic Macroangiopathy

Atheromatous involvement of the large arteries (coronaries, arteries of the extremities etc.) is more frequent in diabetics than in normal subjects. Histology shows unspecific lesions, which are also found in non-diabetics. However, these lesions tend to appear earlier in young patients with diabetes mellitus. It is not yet certain whether these lesions are the sequelae of hyperglycemia. Myocardial infarction occurs frequently in patients whose diabetes was not manifest previous to the infarction. It is, of course, possible that blood sugar regulation is impaired (CLAWSON, 1949) many years before overt diabetes is diagnosed. The prognosis of myocardial infarction is worse in diabetics than in metabolically healthy subjects (SIEVERS, 1961; PARTAMIAN, 1965). We know no more about atheromatosis in diabetes mellitus than about the pathogenesis of atheromatosis in general. During hyperglycemia the artery produces sorbitol and fructose from glucose by the polyol pathway. The cells take up water and their O_2-consumption decreases. One of the noxious effects of hyperglycemia may be by way of intracellular sorbitol accumulation (MORRISON, 1972).

b) Diabetic Microangiopathy

In 1936, KIMMELSTIEL and WILSON described lesions of the glomerula specific to diabetes mellitus. They described hyaline globules in the glomerula and called it nodular intercapillary glomerulosclerosis. Later, the diffuse thickening of the basal membrane was described as a much more common sign of diabetes mellitus than the nodular form of the diabetic glomerulosclerosis. The basal membrane is focally or diffusely thickened to about ten times its normal thickness. The thickening of the basal membrane probably explains the reduced glomerular filtration. The footlike protrusions of the epithelial cells are altered in diabetes in a similar manner as in the nephrotic syndrome of different etiologies. Some authors hold that the diabetic lesion begins with a thickening of the peripheral basal membrane of the glomerula (GOETZ, 1960; SABOUR, 1962; BLOODWORTH, 1963; AZÉRAD, 1964; MACDONALD, 1964). Others localize the primary lesion in the mesangial region (MÉRIEL, 1962; FIASCHI, 1963; CAMERINI-DAVALOS, 1964).

The diabetic retinopathy also begins with a thickening of the basal membrane. Whereas the presence of a thickening of the basal membrane of the glomerula in newly discovered young diabetics has not been proven (ØSTERBY-HANSEN, 1965), SIPERSTEIN (1968) believes that such a change can always be demonstrated in the capillaries of the muscle. SÄVE-SÖDERBERGH'S findings do not support SIPPERSTEIN'S view (1966). On the contrary, these data show a good correlation between the duration of the diabetes and the thickening of the basal membrane.

The controversial question as to whether the thickening of the basal membrane and diabetic microangiopathy are due to hyperglycemia and its sequelae, or to another, independent, coexistent disease, cannot yet be answered with certainty. Even the staunch supporters of the hypothesis that another independent phenomen is involved acknowledge the fact that severe microangiopathy is seldom present before overt hyperglycemia has developed. Similar glomerular lesions to those found in the human have also been described in experimental diabetes in animals after a sufficiently long observation period (ØRSKOV, 1965).

In diabetes of long duration, microangiopathy is found in most organs, including the pancreas itself, the gastrointestinal tract, muscle, and the brain (FUNK, 1966; ANGERVELL, 1966; RESKE-NIELSEN, 1966; ZACKS, 1962).

The pathophysiological nature of the chemical changes in the thickened basal membrane is still unexplained (MUIR, 1964). According to WINEGRAD (1966), more glucose than normal could be metabolized by the glucuronic acid pathway. The basal membrane of the glomerula contains glucose and galactose bound to collagen and in the form of sialiofructohexosamine glycane (DISCHE, 1965). It is possible that the synthesis of these carbohydrate-containing components of the basal membrane is dependent on the activity of the glucuronic acid pathway, which is increased in diabetes.

c) Present Knowledge

The pathophysiology of the acute metabolic disturbance in diabetes, the diabetic coma, is more or less well understood. The intermediary metabolism and its regulation and disturbances are relatively well known since they can be investigated in the experimental animal. Relative or absolute insulin deficiency leads to hyperglycemia and glucosuria, because cell membranes are impermeable to glucose in the absence of insulin, so that glucose uptake ceases. The insulin action on hepatic glucose production is also lost: in spite of hyperglycemia, the liver continues to release glucose into the blood, thereby increasing hyperglycemia. Adipose tissue liberates free fatty acids into the blood from

triglyceride stores. Triglyceride lipase is no longer inhibited by insulin and the free fatty acids cannot be reesterified. Free fatty acids are oxidized to keto acids in the liver, which flood the organism and eventually lead to ketoacidosis. Insulin and the intravenous administration of hypotonic solutions can correct all acute diabetic disturbances. The pathogenesis of insulin deficiency and of the diabetic complications are much more difficult to investigate and are still not clear. Possibilities and hypotheses have been discussed. Definite conclusions have not yet been reached. Diabetes mellitus is inherited, but the exact mode of inheritance is still not known. How and where the diabetogenic gene(s) act, is still a mystery. A disturbance in the biosynthesis of insulin or its secretion must be present. This results ultimately in an inability of the islet cells to secrete sufficient amounts of insulin.

D. Morphology of Diabetes Mellitus

H. STEINER

1. General

The morphology of diabetes embraces three main forms which have some common traits and some particularities 1. labile juvenile diabetes ("lean diabetes"), 2. stable, mild diabetes with obesity, and 3. pancreatic diabetes.

Although large series allow determination of typical morphological patterns quantitatively and qualitatively, in an individual case it is often not possible to make a definite diagnosis on the basis of morphological criteria, since most of the findings can also occur, although much less frequently, in non-diabetics or prediabetics. Conversely, normal morphology may exceptionally be present in the diabetic (e.g. normal B-cell mass in individual cases of stable mild diabetes).

2. The Pancreas and the Islets of Langerhans

a) The Exocrine Pancreas

The pancreas, as a whole, is often considerably enlarged in adult obese-type diabetes, but as a rule, the increase in volume is due to deposition of fatty tissue parallelling the generalized obesity. There may, however, be a net reduction of the parenchymatous mass in such cases. Generally, pancreatic weight does not deviate from normal in cases of acute juvenile diabetes, whereas the weight of the pancreas is often greatly reduced during the chronic course of the disease (GEPTS, 1965), although increased weight is sometimes observed even in these cases.

The total islet volume also shows the same wide variation among individual cases as the proportion of islet volume to the total pancreas does (Fig. 9). These volumes are difficult to estimate, and careful planning of the measuring technique is required to exclude erroneous interpretation and false results. On average, the islet-cell tissue of the diabetic is reduced by over 50% in comparison to the volume in the healthy subject of the same age. However, the proportions may be within absolutely normal limits. This loss of islet parenchyma is definitely less pronounced in diabetes of the obese type than in juvenile "lean" diabetes (Fig. 9). This mass decrease in the latter group is demonstrable shortly after the onset of the disease, even if the islets are large and very active B-cells can be detected. The reduction is much less marked, if present at all, in pancreatic diabetes, where definitely hyperplastic islets can often be seen, in contrast to essential diabetes. This also applies for pancreatic cirrhosis associated with hemochromatosis (HEDINGER, 1953). In addition to the severe fat infiltration already mentioned, which occurs mainly in diabetes of the obese type, arteriosclerosis, a focal or diffuse interacinous fibrosis and lymphocytic infiltrations of the pancreas are very common in chronic diabetes. Foci of acute pancreatitis can be observed not uncommonly in acute cases (LAZARUS and VOLK, 1962).

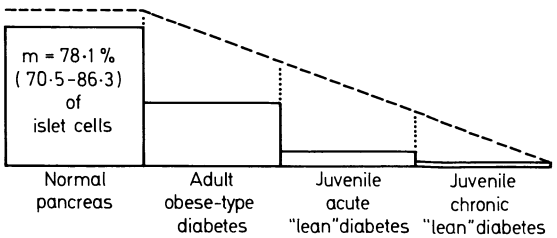

Fig. 10. Proportion of B-cells to the total mass of islet cells. Schematic representation. Strokes indicate the upper range limit (left border lining of the squares)

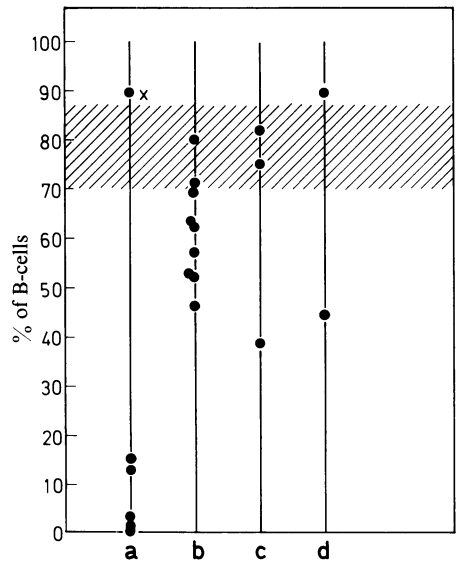

Fig. 11. Proportion of B-cells in the islets of Langerhans in 20 diabetics (staining after GOMORI-RUNGE). The hatched area indicates the range of healthy nondiabetics. (According to VON WATTENWYL, 1964)
a Labile juvenile diabetes; *b* stable adult obese-type diabetes; *c* peracute juvenile diabetes; *d* insulin-resistent diabetes; *x* 45-year-old uremic male with clinical juvenile diabetes of 16 years' duration: To be classified morphologically into the group of adult obese diabetes (insulin determinations not performed)

b) The Islet System

Deviation of the ratio of A-cells to B-cells in favor of the A cells is a fairly constant *quantitative change* (Figs. 10 and 11). This is due to a reduction of B-cells and not to an absolute increase of A-cells. This *relative* A-cell increase is due to the glucagon-producing A_2-cells in such cases. The decrease of B-cells is again very marked in chronic juvenile diabetes. In the acute form of the disease, the B-cells are usually reduced in number, but at this stage they still show signs of high secretory activity. The B-cells are often reduced by 40 to 50% of normal in adult obese-type diabetes, but individual variation is very wide (Figs. 10 and 11). Sometimes, small (newly formed) islets consisting almost entirely of strongly granulated B-cells, are seen in these patients (Fig. 12). In contrast to these findings, quite definite increases in the islet and B-cell masses have been observed in *animal experiments on the healthy animal* receiving continuous glucose infusions (KINASH and HAIST, 1954). Massive islet-cell proliferations can also be observed in several types of animals after immunization with heterologous insulin. The following findings are present in *newborn infants of diabetic women:* true hypertrophy of the islet

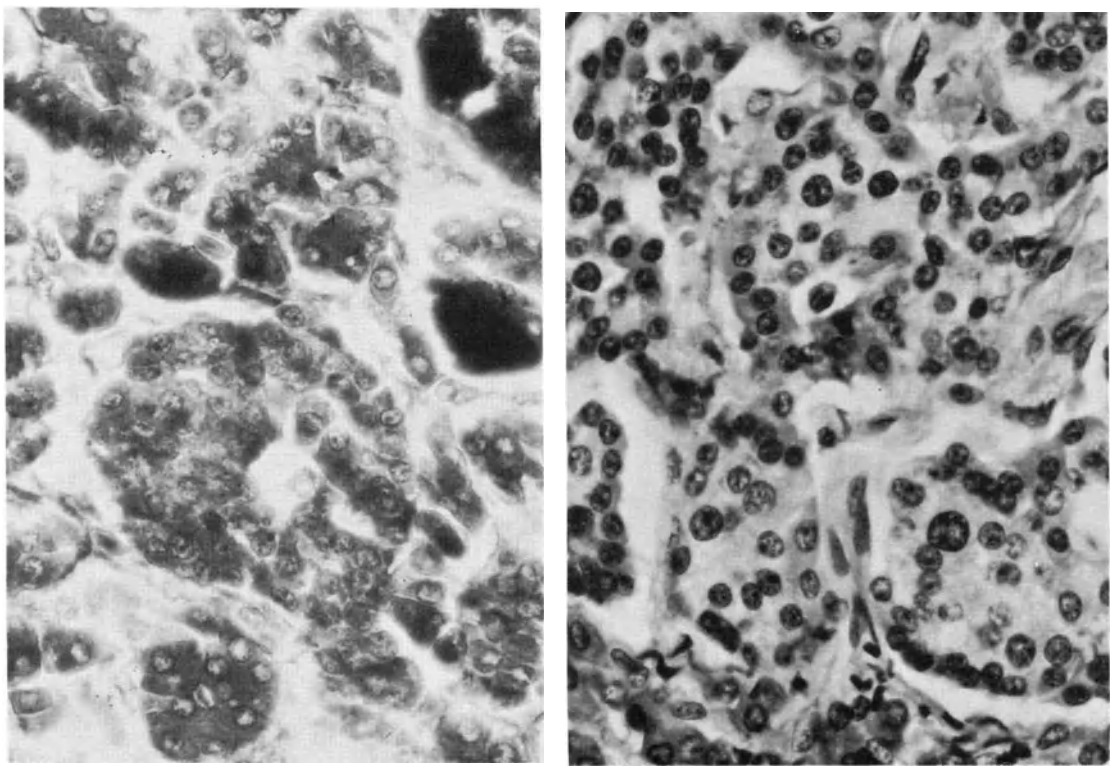

Fig. 12. Small islets of Langerhans with richly granulated B-cells (new formation) and large islets with strongly degranulated B-cells and nuclear hyperplasia in a 60-year-old female diabetic with stable, mild diabetes. Stain: Gomori-Runge; Scale 470: 1

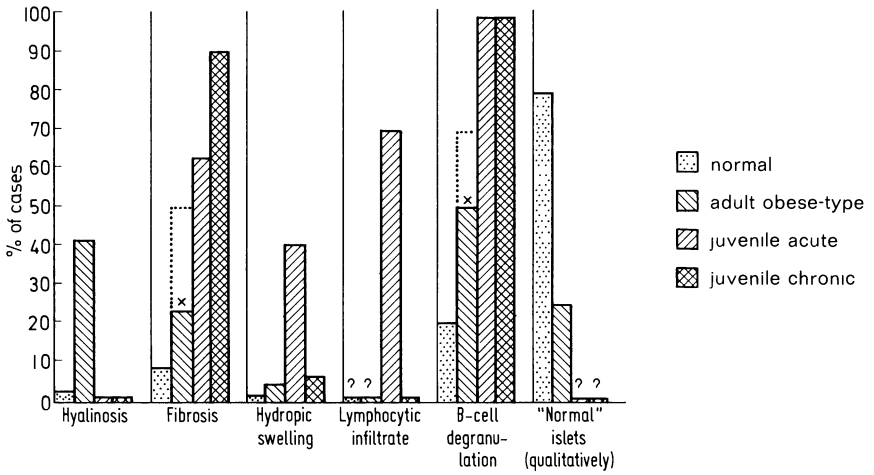

Fig. 13. Average frequency of typical histological changes in the islets in diabetics and healthy subjects. Schematic representation taking different sources into consideration. (Particularly WARREN and LE COMPTE, 1952; SEIFERT, 1958; LAZARUS and VOLK, 1962; GEPTS, 1965)

apparatus with polynesia (many islets), maccronesia (large islets) and a strong predominance of B-cells, so that the weight of the islet apparatus can be as much as 10% of that of the total pancreas. These changes have also been observed in children of women with latent diabetes. Pharmacologically-induced hyperglycemia (e.g. with corticosteroids) in animals causes a significant increase in the B-cell mass and islet volume (the latter increasing up to 4 times more than in controls; HELLERSTRÖM, 1963). The figures for an adult with steroid diabetes or acromegaly correspond closely to those for subjects with diabetes of the obese type. From this it can be deduced that diabetes mellitus only develops where a genetic predisposition does exist.

The islet tissue also undergoes numerous, but mainly nonspecific *qualitative changes*, which can differ with the various diabetic groups (Fig. 13). The majority are probably due to secondary factors (? vascular). *Lymphocytic infiltrations* of the islets of Langerhans (von Meyenburg's insulitis) (Fig. 14) is a very typical change in acute juvenile diabetes. It has a striking similarity to inflammatory features in an autoimmune disease (see also p. 762).

The B-cells are very active in the first phase of juvenile diabetes. The cells are mainly totally degranulated and reflect a high degree of synthetic activity which can be detected by the accumulation of Weichselbaum granules (structures in cytoplasm of very active B-cells developed through aggregation of ribonuclein, stainable with toluidine blue, and eliminable with ribonuclease), and enlargement of the nuclei.

Hydropic changes not uncommonly occur in the cytoplasm of B-cells in acute juvenile diabetes, where vacuolizations and glycogen infiltrations arise (GEPTS, 1965). These changes are very rare in chronic forms of diabetes. The few B-cells present in juvenile diabetes lasting for many years are atrophic, and B-cell granules are hardly demonstrable. Islet hyalinosis

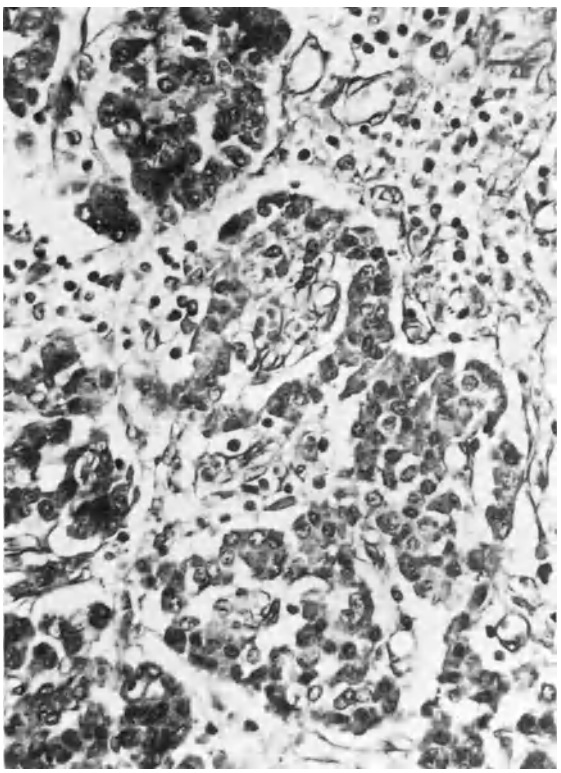

Fig. 14. Lymphocytic insulinitis and periinsulitis in a 9-month-old boy with peracute diabetes lasting 4 days. Insulin treatment started few hours before death. Stain: Gomori-Runge; Scale 350: 1

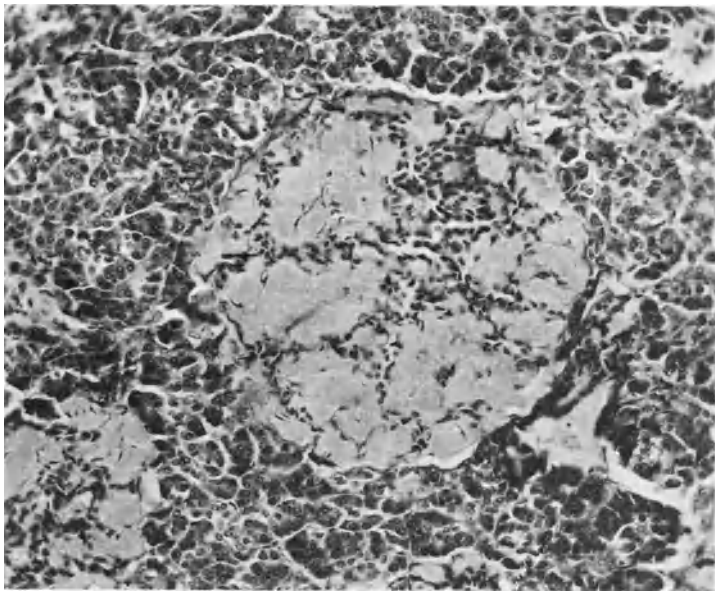

Fig. 15. Hyalinosis of the islets of Langerhans. Stain: hematoxyline-eosin; Scale 120: 1

is only rarely found in chronic lean diabetes, but is frequent in the obese type (Fig. 15). This change increases in frequency in the latter group with increasing age and is not uncommon in non-diabetics, whereas it can seldom be detected in the former group even after diabetes of 30 years' duration. The severity is by no means parallel to the degree of severity of the diabetes. On the other hand, *fibrosis of the islets* is a common finding in both groups. Investigations in the past few years have shown that this amorphous hyaline infiltration is due to fine fibrils of amyloid deposited between the basal membranes (LACY, 1964). Such amyloid deposits are, as a matter of interest, frequently encountered within B-cell insulomas (PORTA, 1962). The B-cells of obese diabetics are usually well granulated. The insulin content of the pancreas of these patients is relatively large, but the threshold for the release of insulin is higher.

To summarize: the manifold changes of pancreatic morphology are a reflection of an extensive and progessive hypofunction of the islet apparatus after initial high activity in juvenile diabetes. In the obese-type diabetes, however, there is only a moderate quantitative and qualitative insufficiency of the B-cells which, as in pancreatic diabetes, is compensated in part by increased activity of the cells present. The content of granules is high in this stable form of obese-type diabetes, but the threshold for insulin secretion is greatly raised. Thus, in addition to influences leading to reduction of B-cells, there are other noxious agents which impair the action of insulin (see p. 760). For these reasons, diabetics often require a larger amount of insulin than patients who have undergone pancreatectomy (see pp. 749 and 808).

3. Primarily Vascular Concomitant and Subsequent Symptoms (So-Called Late Syndrome)

a) *Arteriosclerosis of the great vessels* is more severe in diabetics and arises earlier than in nondiabetics. The lesions, however, are seldom specific. Thus for example a picture familiar to a clinician – Mönckeberg's media sclerosis – may also be encountered in the elderly nondiabetic. As a rule there is endothelial proliferative thickening through colloid, hyaline substances, deposition of lipids and splintering of the tunica elastica. These morphological changes can hardly be differentiated from those in the nondiabetic.

b) *Arteriolosclerosis* is also a nonspecific change which occurs more frequently in diabetics than in nondiabetics. It is often associated with hypertension.

c) *Diabetic microangiopathy* is a very characteristic change which must be held directly or indirectly responsible for many of the so-called late complications. It is a proliferative endarteritis with deposits positive to PAS (period acid, Schiff) and negative to colloidal iron. This contrasts to the reactions in common arteriosclerosis. The elastic internal membrane is usually intact in the arterioles. Not uncommonly there is an increased number of perivascular mast cells. The initial lesion is a pronounced thickening of the basement membrane in particular. This change appears as PAS-positive

homogeneous lesions (FUNK, 1965) in the capillaries and pre-capillaries. Antiimmunoglobulins can be fixed immuno-histochemically in these lesions (LARSSON, 1967). According to certain authors, this homogeneous thickening of the basement membrane can be found in the muscle capillaries in up to 50% of healthy subjects born of two diabetic parents (SIPERSTEIN, 1967). Others did not observe this finding. POMETTA, for example, was unable to reproduce several expected results.

Microangiopathy is dispersed in many organs. The lesions seem to lead to the manifest disease particularly when tissue function is lost in the end organs due to the reduction of blood supply. These organs are often fibrotic. Permeability of the vessels is increased due to impaired metabolism and thickening of the membrane. This in turn leads to further characteristic changes (see below).

Renal changes are of considerable practical importance:

d) *Diabetic nephropathy.* In addition to the changes in the small vessels, *glomerular sclerosis* is of particular importance (Fig. 16) in the kidney of diabetics. This nephropathy may take the form of nodular thickening in the intercapillary spaces, or of a diffuse PAS-positive thickening of the basement membrane, or of a combination of both. These ultrastructural changes can be detected quite early. Changes in the intercapillary spaces seem to precede the thickening of the basement membrane as a rule (KIMMELSTIEL, OSAWA, and BERES, 1966), and development in juvenile diabetes seems to be dependent on the duration of the disease. More recent investigations also indicate that the development of glomerular sclerosis is connected with the arteriolosclerosis of the kidneys (FISHER, 1967). Glomerular sclerosis in the nodular and diffuse forms is a very common complication of juvenile diabetes of long duration, and is the main cause of death in this group. In fact, nodular glomerular sclerosis has only very rarely been observed in nondiabetics, and may be considered as a specific diabetic complication. The importance of other forms of nephropathies is considerably less compared with that of glomerular sclerosis. The *Armanni-Ebstein* nephropathy (RITCHIE and WAUGH, 1957) con-

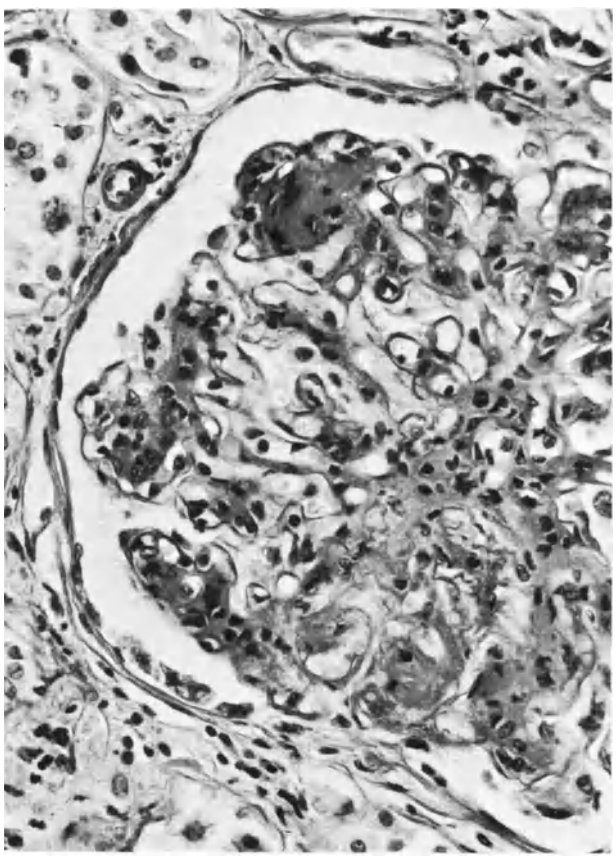

Fig. 16. Kimmelstiel-Wilson glomerular sclerosis with severe hilifugal, PAS-positive thickening of the glomerular loops. Stain: PAS; Scale 450: 1

sists of an extensive vacuolar deposition of glycogen in the cytoplasm of the contorted proximal part of the renal tubule. This change is observed particularly often in cases with severe changes in sugar metabolism leading to diabetic coma. It can also be produced experimentally in animals through severe hyperglycemia.

Acute papillary necrosis is a grave complication of pyelonephritis often found in diabetics (see p. 797). It is an ischemic necrosis of the renal papilla. It often leads rapidly to anuria. The lesion is not specific to diabetes.

diverticula of the capillary walls of the venous limb which are often thickened by hyaline masses containing lipids (Fig. 17). See p. 792 for the influence of hypophysectomy on diabetic retinopathy.

Refer to appropriate textbooks for treatment of other morphological changes in the eyes (in the iris, conjunctiva and lens) in diabetes mellitus.

f) The initial processes in *diabetic neuropathy* are partly attributed also to metabolic disorders due to changes in vascular permeability. The microangiopathy in small perineural vessels can

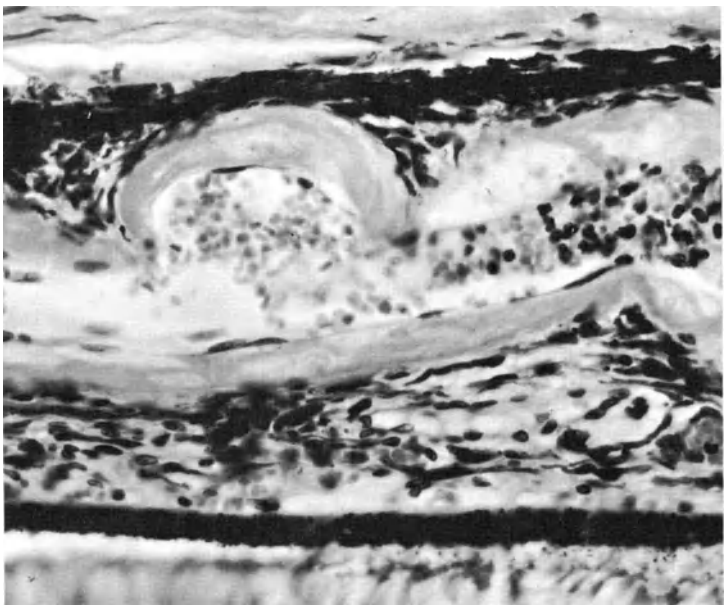

Fig. 17. Severe arteriosclerosis with aneurysmal protrusion of a vessel in the membrane choriocapillaris of the left eye. Stain: Van Gieson; Scale 250: 1. Same case as in Fig. 16

e) *Diabetic retinopathy*. This complication can be considered as a result of angiopathy. It is now the most common cause of blindness in the Western hemisphere. The early change is thickening of the basement membrane. Morphological findings include variations in the caliber of the vessels, microaneurysms, hard and soft exudates, hemorrhagia and *proliferative retinitis*. The last change can be described morphologically as capillary proliferations in hemorrhagic foci and ischemic areas. The soft exudates (cottonwool foci) are due to changes probably developed primarily because of metabolic disturbances which can partly be accounted for by the hypoxia secondary to capillary changes. The hard exudates are localized in the outer reticular retinal layer and represent serum exudated from the vessels (DIEZEL and WILLERT, 1963). These hard exudates can be absorbed under certain conditions. The microaneurysms are first be considered to play a significant role in the advanced form due to the poor vascularization of the tissue. Thickening of the basement membrane is the first detectable morphological sign of the disease. In addition to the classic form of *symmetric neuropathy*, the *ischemic mononeuropathy* is characterized by multifocal small infarctions of the nerves (circumscribed ischemic necroses). The vascular disorder in this disease is probably localized outside the nerve in small arterioles. Diabetic neuropathy also involves nerves of the autonomic system.

g) The microangiopathy of the heart in particular (myocardial infarction), the extremities (diabetic gangrene) and skin (diabetic dermatopathy, necrobiosis lipoidica) are of clinical importance. The morphology of the changes in the small vessels cannot be differentiated from that of the changes in other organs.

With the exception of Kimmelstiel-Wilson glomerular sclerosis, all these changes have in common that they also occur, though much less frequently, in nondiabetics. The changes are thus morphologically nonspecific. Thickening of the basal membrane is often the only finding in the initial stage. The raised permeability of the vessels resulting from this is held partly responsible for the morphological consequences. The microangiopathy and ordinary arteriosclerosis are usually localized in several organs. For example, retinopathy is almost always associated with a glomerular sclerosis.

h) *Hypophysis and diabetes mellitus.* It is of interest that microangiopathies are partly reversible by *hypophysectomy* (see Chap. V, p. 87). The thickening of the basement membrane in particular disappears. On the other hand, the arterioles remain unaffected.

For this reason, the interest in the hypophysis is evident. This gland is closely linked with sugar metabolism through the various hormone systems. A more or less significant infarction of the hypophysis is not a very uncommon finding in diabetes. The acidophils (producers and storers of growth hormone and prolactin) are greatly increased in the hypophysis particularly in juvenile diabetes with severe hypoglycemia. On the other hand, no significant deviation in the cellular picture is seen in diabetes in the elderly where the hyperglycemia is not severe (STEINER, 1965). (Juvenile diabetes: 59 ± 11.9% acidophils; adult obese-type diabetes: 43.5 ± 13.8%; normal: 34.8 ± 8.2% in the male; and 36.8 ± 6.3% in the female).

4. Other Common Morphological Changes in Diabetes Mellitus

Most changes are not specific to diabetes mellitus, as has been shown above, and can also arise in other metabolic disorders.

a) *Liver changes.* Glycogen inclusions and swelling of the nuclei of hepatic cells are often found in severe diabetes. These inclusions also develop in pancreatic diabetes produced experimentally with alloxan. Intensive investigation showed nuclear glycogen in the liver in 80% of a group of diabetics, and in 53% of the control group (SELLYEI and WALTON, 1969). Liver enlargement is not uncommon and is usually due to obesity. Enlargement associated with a large deposition of glycogen (Mauriac's syndrome) is seen in particular in the poorly controlled juvenile type. Liver enlargement and glycogen depots disappear again when the diabetes is restabilized.

b) *Lesions due to treatment.* A whole series of changes is directly or indirectly connected to treatment of the disease: complications due to development of resistance and allergy, typical appearance of lipodystrophy (disappearance of fat in the region of the injections), and local fibrosis and swelling in the regions of the injections (see p. 790).

c) *Infections.* These differ only in frequency and course in the diabetic. The morphological picture is hardly different from that of the same infection in the nondiabetic.

E. The Clinical Features of Diabetes Mellitus

G. R. CONSTAM

Diabetes mellitus is defined as a chronic metabolic disorder leading to incomplete utilization of the absorbed carbohydrates and to a rise in the blood sugar, usually associated with the excretion of pathologic amounts of glucose in the urine.

It is to be expected that better knowledge about the pathogenesis and the etiology of this disease will soon necessitate alterations in the definition, in the diagnosis and in the differential diagnosis of diabetes millitus.

1. Incidence

Diabetes mellitus occurs at any age and in all races. The diabetes *morbidity* was estimated to be 0.7% before the First World War, and 1.5% in 1950, in Europe and the U.S.A. These figures were based on the examination for urinary sugar in whole population groups. When the urine was examined for sugar 2 hours after an English breakfast, the proportion of diabetics rose to 4%, and even to 12% when extra sugar was given. In a large American city, the glucose tolerance test revealed a 15% incidence of diabetes, and in Mexico 13% of the age group over 60 years were diabetic. The uncommon occurrence of diabetes in younger age groups can be explained by the fact that the disease is very often still in the latent phase at this age.

Statistics from South Africa about Indian immigrants into Natal are not at all in keeping with the above figures. It was found that diabetes mellitus occurred 10 times more frequently in these Indians than in their original homeland, and that 40% of the population suffered from diabetes after 20 years of immigration.

All authors, including the experts of the World Health Organization, are of the opinion that the incidence of diabetes is increasing considerably. SCHÖFFLING (1965) found the same in Central Germany, OTT (1957) in

Switzerland. The Health Authorities of U.S.A. estimated the number of cases of overt diabetes to be around 2 million in 1949, and to be 3 million in 1964. They expect to have 4 million cases by 1970. It is not known to what extent the determined *increase* in *diabetes morbidity* represents a real increase and not only the result of greater life expectancy and of improved methods of investigation.

See p. 759 about etiology, inheritance and environment.

The relations between *diabetes mellitus and trauma* are of interest to both the physician and the specialist. To produce diabetes mellitus experimentally in an animal, the greater part of the pancreas must be removed, in the dog, for example, 9/10 of the pancreas. Experience gained from pancreatectomies confirms this for man. An accident involving the region of the pancreas can only cause diabetes if most of the organ is destroyed. Such a lesion must also result in insufficiency of the exocrine secretion, and such severe injuries always are fatal. Cases of diabetes caused by traumatic damage to the pancreas are therefore very unlikely.

Theoretically, sclerosis of the pancreas can occur as a result of injury or pancreatitis, but, so far, this has not been proven histologically. *Traumatic pseudocysts* of the pancreas do not cause diabetes, whereas pseudocysts after pancreatitis, calcifying pancreatitis and the late stages of mucoviscidosis (see p. 809) can.

Cerebral concussion, intracranial hemorrhage and, less often, injury of bones or soft tissues, can be followed by hyperglycemia and glycosuria. This is a temporary extra-insular *stress glycosuria* (see p. 774). Despite the enormous number of cranial injuries during the last wars, there was no increase in diabetes mellitus. Not a single case of diabetes of traumatic etiology was found by VON NOORDEN in 20000 diabetics, or by UMBER in 7000 patients or by JOSLIN in 40000 cases.

Even if trauma has been dismissed as the cause of diabetes, it can, however, act as a releasing factor, i.e. it can cause potential, chemical or latent diabetes to become clinical. In addition, reduced physical activity, overeating, infections, anxiety, worries or pain can cause a subclinical diabetes to become manifest. Probably, these cases would have developed clinical diabetes even without an accident (or releasing factors) if the subjects concerned had lived long enough.

For the same reasons, *deterioriation* of pretraumatic diabetes is also possible. On the other hand, preexisting diabetes can also influence the *results* of an accident, diabetics being predisposed to infections and slow healing processes.

Tumors as well as inflammations of the pancreas must be very extensive before they produce diabetes. In *acute pancreatitis*, the glucose tolerance is only temporarily diminished. The majority of pancreatic necroses as well as tumors of the pancreas progress without developing diabetes. *Chronic pancreatitis* with or without *calcifications* and formation of *calculi* is often considered a cause of diabetes. *Arteriosclerosis* can lead to hyaline degeneration and to fibrosis of the islets of Langerhans. The connection with diabetes is not clear, since we do not know if the latter is a result or the cause of vascular changes.

The development of hyperglycemia and glycosuria has been observed during treatment with *adrenocortical, anterior pituitary* and *thyroid preparations*, with *diuretics of the benzothiadiazine group*, with *chlorthalidone*, and also after severe extensive *burns* treated with a high caloric diet. Probably a previously potential diabetes has been activated in these cases.

2. Prevention

Prevention is hampered by our lack of knowledge about the cause of the disease and by our inability to diagnose it at an early stage. For the time being, the predisposition to diabetes mellitus cannot be detected clinically with sufficient certainty.

Usually, married couples are advised not to have children when both partners have overt diabetes. In practice, however, the majority of cases of conjugal diabetes are not detected until after they have already had children or even grandchildren.

Table 3. Classification of diabetes mellitus (see also Table 4)

	Causes
1. Essential, *familial* primary diabetes:	Unknown, perhaps inheritance and provocative factors
2. Non-essential *secondary* diabetes:	
a) Insular insufficiency diabetes:	Total or subtotal pancreatectomy, tumors, inflammations of the pancreas, mucoviscidosis, hemochromatosis.
b) Extra-insular diabetes:	Adrenaline- (stress-stimulating) diabetes, acromegaly, Cushing's syndrome, hyperthyroidism, Conn's syndrome
3. *Uncommon special forms of diabetes:*	
Lipo-atrophic diabetes (LAWRENCE)	
Myatonic diabetes (PRADER, LABHART, WILLI)	

Table 4. Stages of *essential* diabetes (World Health Organization 1965) (see also HAMURI, 1967)

1. *Potential diabetes:*
   Metabolic disturbance not detectable with the present-day laboratory methods. Diagnosis should be suspected in homologous twins if one is already diabetic, in children with both parents diabetic, children with father or mother and a sibling diabetic or cases of diabetes in the family of the non-diabetic parent (grandparent, uncle, aunt, cousin), in women delivered of a baby with a birthweight of 10 pounds or more or stillbirths with hyperplasia of the islands of Langerhans in the absence of rhesus incompatibility.
2. *Latent diabetes:*
   a) Normal oral glucose tolerance test which, however, had been abnormal under stress or when obese.
   b) Cortisone-glucose tolerance test abnormal.
3. *Asymptomatic = subclinical = chemical diabetes:*
   Oral glucose tolerance test abnormal, but no other diabetic symptoms.
4. *Clinical or overt diabetes:*
   Oral glucose tolerance test abnormal, diabetic symptoms or complications.

The diagnosis of a *pre-diabetes* can only be made in retrospect, when potential diabetes has progressed into latent, asymptomatic or clinical diabetes.

Table 5. Classification of essential diabetes (WHO)

	Age of manifestation	Characterization
a) Childhood (infantile) diabetes	0–14 years	Needs insulin early
b) Juvenile diabetes	15–24 years	Majority need insulin at an early stage
c) Adult diabetes	25–64 years	Begins less abruptly, needs for insulin vary
d) Diabetes of old age	65 years and over	Often long periods without insulin therapy

Table 6. Differential diagnosis of melliturias

A. *Normoglycemic*
   1. Renal glycosuria
      a) Primary, sometimes familial glycosuria with reduced renal threshold of varying degree
      b) Secondary renal glycosuria through damage of the proximal tubules
         α) Familial: de Toni-Fanconi-Debré syndrome
         β) Acquired
      c) Glycosuria during pregnancy
      d) Neonatal melliturias
   2. Glycurias
      a) Pentosuria (see p. 775)
      b) Fructosuria (see p. 775)
      c) Galactosuria (see p. 775)
      d) Lactosuria (see p. 775)
      e) Saccharosuria (see p. 776)
      f) Mannoheptulosuria (see p. 776)

B. *Hyperglycemic* (sometimes only of short duration)
   1. Primary essential diabetes mellitus, predisposition inherited
   2. Non-essential, secondary diabetes mellitus
      a) Pancreatogenic
         α) Acute pancreatitis
         β) Fibrosis of the pancreas
         γ) Pancreatectomy
         δ) Hemochromatosis
         ε) Hunger-diabetes (transitory)
      b) Extra-pancreatic
         α) Adrenaline ("irritant" "stress") glycosuria
         β) Acromegaly
         γ) Cushing's syndrome, glucocorticoid administration
         δ) Hyperthyroidism
   3. Oxihyperglycemic glycosuria, tachyalimentation, pseudo-diabetes
      a) Accelerated absorption
      b) Delayed or disturbed formation of glycogen

The alimentary cyclic glycosuria can be due to 1. early diabetes mellitus, 2. renal glycosuria, 3. oxihyperglycemia. The glycosuria in pregnancy can be the consequence of 1. early diabetes, 2. a fall in the renal threshold through increased glomerular filtration rate.

Prevention of diabetes tries to remove factors promoting the manifestation of the disease. Among these, avoiding overweight through increased muscular activity and corresponding adjustment of nutrition are of the greatest importance. Active foci of infection, especially of the biliary tract and of the pancreas must be eliminated, mental stress whenever possible avoided. Women with a family history of diabetes should not have more than two to three pregnancies.

Recognizing diabetes in its early stages is of great importance, since it seems possible that early onset of therapy can simplify the treatment and improve the long-term prognosis.

It is still controversial whether electronmicroscopic or histochemical vascular changes can occur prior to demonstrable metabolic disturbances and thus indicate potential diabetes. In the future, potential diabetes may become detectable by metabolic or morphological deviation which is not yet known.

3. Course of Diabetes Mellitus

The development of diabetes from the potential to the latent and finally to the clinical stage of the disease is rapid in some people and slow in others. Symptoms and clinical features may vary considerably, depending on whether the disease arose during growth or after maturity or at old age. This difference may be so great that some authors believe two different diseases are involved. This seems unlikely in view of the

fact that different forms can arise in the same family and that one form may change into the other. We, therefore, think that there is only one disease with different rates of evolution. When the disease develops rapidly, it becomes overt before or shortly after the termination of growth, leading relatively soon to failure of the islet system and to insular-insufficiency diabetes. On the other hand, when the disease develops slowly and remains for some time in the stages of latent or chemical diabetes plasma insulin may in some cases even be increased (see p. 761). In clinical diabetes *relative islet insufficiency* usually progresses so slowly into *absolute islet insufficiency* that the majority of diabetics die before reaching this stage.

The 2500-year-old classification of the "fat/sthenic" and the "thin/asthenic" (insulin-deficient) diabetes is for didactic reasons still justified today. The former type is predominantly found in the elderly, the latter usually in younger patients, in thin people mainly before their 46th year.

a) Subjective Symptoms

The *subjective symptoms* are: fatigue, polydipsia, polyuria, loss of weight, the last three being called the "cardinal symptoms of diabetes". In children weight loss despite polyphagia is striking. Before the disease becomes overt, some patients complain of weakness and tremor 4 to 5 hours after a meal. This *reactive hypoglycemia* (see p. 816) disappears after the ingestion of carbohydrates, which explains the increased longing for sweets, particularly for chocolate.

In small children, the reappearance of enuresis, in the adult a sudden development of myopia, and in the elderly dizziness are suggestive of diabetes.

The diabetes of elderly overweight persons causes little trouble for a long time and, with few exceptions, shows little tendency to ketoacidosis. On the other hand, during growth and in normal or underweight elderly persons polyphagia may rapidly change into loss of appetite, nausea, then vomiting, and later somnolence, possibly followed by coma.

b) Objective Symptoms

In the "*fat/sthenic*" *diabetes* rubeosis of the skin, especially of the face, disturbances of the coronary, peripheral and cerebral circulation, of the renal and central nervous systems are common. The retina may also be affected, and cataracts may be present. Glycosuria may be absent even in the presence of hyperglycemia which varies less quickly than in the "thin" diabetic. The tendency to ketosis and ketonuria is slight. The diabetes responds well to weight reduction and to sulfonylurea derivatives, at least at the onset of the disease, which is only slightly response to insulin. This form of diabetes is benign only in so far as its tendency to acidosis is concerned, and malignant on account of its susceptibility to vascular complications. The main goal of its therapy is to prevent, reduce or treat these vascular disturbances.

There are exceptions to this rule, and the "fat" diabetes can change its character within a few days, usually under the influence of some stress, and even develop ketoacidosis.

The "thin/asthenic" diabetic shows severe glycosuria at an early stage, sometimes even with moderate hyperglycemia. The blood sugar fluctuates, there is a strong tendency to ketonemia and ketonuria. It is sensitive to insulin, whereas the sulfonylurea derivatives are only temporarily effective in the very early stages. Here, the first purpose of treatment is to prevent the occurrence of ketoacidosis, the second the prevention of the long-term diabetes syndrome.

4. Diagnosis and Differential Diagnosis

For the time being, our diagnosis is still based on the demonstration of a *delayed or reduced ability to assimilate carbohydrates* in the presence of normal gastrointestinal function. This impaired carbohydrate assimilation is perhaps not the cause, but already a consequence of diabetes. Measuring carbohydrate assimilation by glucose tolerance tests does not furnish a sharp dividing line between diabetes and non-diabetic conditions. Thus, in some cases diagnosis has to be deferred and may be confirmed only after long observation and repeated investigations. In the early phases, the metabolic disorder appears irregularly, hyperglycemia with or without glycosuria may disappear spontaneously and reappear only after months or many years.

If the evidence is sufficient, we are able to diagnose diabetes, but in the absence of signs and symptoms, we can never exclude definitely the presence of potential diabetes.

The diagnosis of diabetes mellitus is based on the *family and personal histories, a thorough general examination and the determination of glucose in urine and blood.* Diabetes in a near relative strengthens the suspicion of diabetes and indicates diabetes mellitus even if a slight abnormality of the carbohydrate assimilation has been found which by itself would not be sufficient for diagnosis.

In the *typical personal history*, there are or were cardinal symptoms present at least in severe cases. The *clinical examination* of the diabetic patient has to exclude other causes for the symptoms, and to detect any late symptoms or complications.

Routine examination for glycosuria most often leads to the discovery of diabetes. Blood sugar estimations 1–2 hours after a carbohydrate-rich breakfast, repeated every year, in all direct relatives of each diabetic would permit earlier recognition of the disease in persons predisposed. See p. 811 about the laboratory methods of investigation.

a) Renal Glycosuria

The *familial renal glycosuria* has a limited capacity of tubular reabsorption of glucose alone. The morphology of the proximal tubules seems unchanged, but single tubules may be shortened. Depending on their number, the renal threshold for glucose can be so much lowered that even during fasting, and with perfectly normal blood sugar, glycosuria is constantly present, or with the renal threshold less depressed, glycosuria is intermittent only. The Tm_{GI}, the maximum capacity for the reabsorption of glucose, is not always reduced, but the amount of filtrated glucose always bears a definite relation to the amount of the reabsorbed glucose (REUBI, 1959; FROESCH, 1957; KRANE, 1966).

The innocuous anomaly is probably inherited through an autosomal dominant gene, the mild cases are possibly heterozygous, and the severe cases homozygous (FROESCH, 1957). No connection with diabetes mellitus has been confirmed.

The renal glycosuria due to congenital or acquired damage of the proximal tubules, the morphology of which can be usually demonstrated (SWAN'S neck tubule), is to be differentiated from the familial glycosuria. In the former two conditions, phosphate, amino acids and bicarbonate, in addition to glucose, are inadequately reabsorbed (de Toni-Fanconi-Debré syndrome).

As a rule, osteomalacia resistant to vitamin D predominates in the clinical picture.

The disorder may be congenital and inherited through an autosomal recessive gene. It may develop from a congenital metabolic disorder (cystinosis) or, reversibly or irreversibly, through exogenous (malate, lysol, heavy metals) or endogenous (Bence-Jones (myelom) protein, nephrosis) noxious agents (LEAF, 1966).

The physiological increase in glomerular filtration during pregnancy can lead to a fall in the renal threshold for glucose, and thus to renal glycosuria. This *glycosuria of pregnancy in the presence of normoglycemia* is today considered diabetes-suspect, even when it disappears with the termination of the pregnancy.

Glycosuria of the newborn occurs in the majority of infants during the first few days or weeks of life. Prematurity prolongs its duration. It is better described as *neonatal mellituria*, since, besides glucose, lactose, fructose and galactose are also found in the urine. Functional immaturity of the renal tubules and of the liver presumably are the cause of the excretion of glucose and galactose. Increased reabsorption of lactose from the intestine explains the concomitant lactosuria.

b) Cyclic or Alimentary Glycosuria

The result of the oral glucose tolerance test is normal in *cyclic or alimentary glycosuria*. Intermittent glycosuria is restricted to postprandial periods, whereas urine voided during the fasting state is sugarfree. This may be renal glycosuria with a slight fall in the renal threshold, which has a good prognosis, or an early stage of true diabetes mellitus with lowered renal threshold. The prognosis of the latter is uncertain and is influenced by medical supervision.

Primary essential diabetes with an inherited predisposition, with abnormally high and prolonged hyperglycemia after carbohydrate intake associated with the excretion of pathological amounts of glucose in the urine is the predominant cause of glycosuria. *Secondary diabetes* can be due to pancreatic or extrapancreatic factors.

Insular-insufficiency diabetes develops following damage or loss of the B-cells of the islets. It is reversible in acute pancreatitis and in prolonged starvation, and irreversible in advanced fibrosis of the pancreas, in hemochromatosis, and after pancreatectomy. See p. 748, 808 for pharmacological and experimental pancreatic diabetes.

Extra-insular diabetes is due to the mobilization of glycogen under the influence of hormones or to increased gluconeogenesis or to diminished breakdown of glucose in the periphery. It is primarily reversible, only progressing to true, irreversible diabetes in the presence of a predisposition.

A large release of *adrenaline* can occur with any somatic or mental stress, and in particular with CLAUDE BERNARD'S "piqûre", with brain injuries, brain tumors, encephalitis, meningitis, injuries to the soft tissues, fractures, and myocardial infarctions. It is due to increased glycogenolysis in the liver with the simultaneous inhibition of the secretion of insulin. A *pheo-*

chromocytoma which is active for a long time can lead first to intermittent and later to permanent diabetes.

Glycosuria is very rarely due to a *tumor of the A-islet cells* producing glucagon (see p. 823).

In *acromegaly*, the growth hormone probably leads to poor utilization of glucose in the periphery through the release of free fatty acids, if sufficient additional insulin cannot be liberated (see p. 113). See p. 86 for idio- and meta-pituitary experimental diabetes.

In *Cushings's syndrome* or during treatment with glucocorticoids (cortisone, prednisone), gluconeogenesis in the liver is increased (See p. 303, 351).

The reduced glucose tolerance of *primary aldosteronism* is rarely associated with glycosuria, and is due to potassium deficiency, which impairs the formation of glycogen and, above all, delays the release of insulin. We do not know whether *hyperthyroidism* can lead to clinical diabetes alone, or only when associated with potential diabetes.

In *oxi-hyperglycemic glycosuria* (LAWRENCE) [tachyalimentation (WILLIAMS), pseudodiabetes] the blood sugar rises quickly to high values after ingestion of food or glucose, on account of an accelerated absorption of carbohydrates, and then falls rapidly to normal or subnormal levels. This reaction is most striking in the oral glucose-tolerance test. Temporary glycosuria appears, and hypoglycemic symptoms are common. It occurs after gastroenterostomy or gastrectomy with the consequent accelerated emptying of the stomach, in hyperthyroidism and in vegetative dystonia. The intravenous tolerance test and the tolbutamide test yield normal results. Alimentary glycosuria may result from this disorder.

Similar oral glucose loading curves are met in the rare cases of glycosuria due to delayed or impaired deposition of glycogen. This is found only in combination with one form of *glycogen-storage disease* (Type 1, von GIERKE, glucose-6-phosphate deficiency) and also, very rarely indeed, with severe *liver dystrophia* (so-called hepatic glycosuria).

Though *glycuria* is infrequent, its diagnosis is of importance to avoid treatment of an incorrectly diagnosed diabetes and because the recognition of fructose or lactose intolerance or of galactosemia is of vital significance.

Every case of mellituria with normal or subnormal glucose tolerance tests must be further investigated, and the sugar or sugar-like substance in the urine must be identified. This can be done most simply with enzymatic methods or by paper chromatography (CONSTAM, 1957; CONSTAM and ISLER, 1957).

Pentosuria. Alimentary pentosuria, i.e. the excretion of arabinose or xylose, can occur intermittently in normal and in diabetic individuals after the intake of food rich in pentose. On the other hand, in *essential pentosuria*, *xylulose* (xyloketose) is continually lost in the urine, regardless of food intake. This anomaly is inherited on an autosomal, recessive gene and is due to defective TPN-xylite-dehydrogenase, an enzyme which activates the conversion of xylulose into xylite (HIATT, 1966). Both forms of pentosuria can occur alone or in combination with diabetes mellitus.

Fructosuria, levulosuria, is observed in normal persons after excessive intake of fructose. Such *alimentary fructosuria* is rare, since the limit of assimilation for this sugar is seldom exceeded. *Essential fructosuria* is the result of a deficiency of fructokinase. Apart from the polyuria following the intake of large amounts of fructose, these patients have no other symptoms. Their life expectancy is normal. Intake of fructose causes an abnormal rise of fructose in the blood and a reduction of blood glucose. *Fructose intolerance*, another disorder of the metabolism of fructose, is inherited on an autosomal, recessive gene. It is caused by a deficiency of the fructose-1-phosphate-aldolase and may lead to severe hypoglycemia, liver damage, and retarded growth. The diagnosis is made by carefully injecting fructose intravenously, which results in hypoglycemia and hypophosphatemia (FROESCH, 1966).

Galactosuria and galactosemia. Hereditary congenital galactosemia must be differentiated from the mild *physiological galactosuria* in normal babies and from the *secondary galactosuria* in liver diseases. Whereas amino acids and protein are excreted in the congenital type, lactose or glucose or even fructose sometimes are found in the urine in the other two conditions.

Galactosemia is a metabolic disorder, inherited on an autosomal recessive gene. The body is unable to convert a sufficient amount of galactose into glucose, due to a deficiency of galactose-1-phosphate-uridyltransferase. The toxic intermediate metabolic products lead to malnutrition, hepatic cirrhosis, cataract, debility and death. The diagnosis can be made by showing the absence of this ferment in the erythrocytes of these patients, even in the blood obtained from the umbilical cord. The damage is reversible, provided a galactose-free diet is instituted at the right time (INSELBACHER, 1966).

Lactosuria is met in normal women about 6 weeks before delivery, and persists until after lactation. It is also observed in healthy infants during the period of breast feeding. In both cases, galactosuria is an accompanying feature;

there are no subjective symptoms and treatment is not necessary.

The *lactosuria of lactation* must be differentiated from the lactosuria due to *lactose intolerance*, which causes diarrhea and occasionally is accompanied by lactosuria, glycosuria and intestinal malabsorption. Treatment involves the elimination or the reduction of lactose in the diet.

Saccharosuria results from a disturbance of one or several of the disaccharidases. It leads to an accumulation of saccharose in the intestine, to fermentation and diarrhea. Occasionally this may lead to the absorption of disaccharides and to their excretion in the urine. Here as well, all food containing saccharose must be avoided.

Mannoheptulosuria follows the intake of large amounts of certain Avocado pears. D-Mannoheptulose is excreted in the urine. The condition has no clinical importance, unless it is mistaken for diabetes.

5. Prognosis

As statistics from the Joslin Clinic in 1957 showed, before the discovery of insulin, six years was the average duration of diabetes from its diagnosis till death. In 1956/57 it had increased threefold and the present day figures are even more favorable. This is the result of insulin therapy particularly, but also of the modern improved methods for the treatment of infections and circulatory disturbances, earlier diagnosis, and better training of physicians and patients. The value of the oral hypoglycemic tablets cannot yet be definitely appraised; probably they are of importance too.

ROOT estimated the life expectancy of the diabetic to be at least 3/4 of the normal expectancy. Among 44000 diabetics, he found about 3000 had survived the average life expectancy reckoned from the time the first diabetic symptoms appeared.

According to the figures of WHO, the mortality due to diabetes in Germany has increased from 10.2 in 1950/52 to 13.6/100000 inhabitants in 1960/61. In Switzerland, these figures have risen from 13.4 to 14.7, and in U.S.A. from 16.3 to 16.7 per 100000 inhabitants.

As Table 6a indicates, *ketoacidosis* was the most common cause of death in diabetics before 1922, i.e. before the introduction of insulin. Today, *renal, cardiac and circulatory disorders* have taken over this position. The cases of death resulting from *infections*, in particular *tuberculosis*, are also on the decline, thanks to the combination of modern chemotherapeutic agents and antibiotics with insulin therapy. The increase of *cancer* among diabetics can be explained by the longer life expectancy of diabetics and by the improved diagnostic methods. Comparable investigations in the same age groups suggest that, with the exception of *carcinoma of the pancreas*, malignant tumors do not occur more frequently in diabetics than in the metabolically healthy population. The latter, according to OAKLEY and co-workers, has a frequency of 4% of all the carcinomas in the general population, amongst diabetics 14%. WARREN *et al.* reported in 1966 10.7% carcinoma of the endometrium amongst 214 autopsied diabetic women dying from cancer, compared with 5% in nondiabetic female patients. According to MEISSNER and LEGG and to MOSS, endometrial cancer is twice as common in diabetics. So far, we have not noticed a preponderance of this localization of carcinoma in diabetic women. *Hypoglycemia* as a cause of death can be avoided by dividing the daily insulin requirement into several smaller doses.

In infantile and juvenile diabetes, *ketoacidosis* is still a common cause of death. KRAINICH and STRUWE found this in 3/4 of their cases, and the Joslin Clinic in 44%. The majority of the patients who developed diabetes before the age of 20 and subsequently lived

[a] From JOSLIN *et al.*: The treatment of diabetes mellitus, 10th ed. Philadelphia: Lea & Febiger 1959.

for over 10 years died from *nephropathy. Coronary* and *cerebral circulatory disorders* were the causes of death in those developing diabetes later in life. Our own series of observations on patients who survived the first clinical manifestation of their diabetes for 20 years or more show that 48% died from myocardial infarction, 16% from cerebral ischemia and 16% from uremia. As already mentioned, the prognosis of diabetes is greatly influenced by the renal, cardiac and circulatory disturbances. These may be accompanied by changes in the nervous system, and are collectively termed the "*diabetic angio-neuropathy*" (see Chap. 9).

Investigations on patients observed for more than 20 years show that the severity of the metabolic disorder has little influence on the prognosis, providing ketoacidosis can be avoided, but that the late symptoms grow in severity and frequency with advancing age of the patient and duration of diabetes. Poor treatment promotes the development of diabetic angio-neuropathy, whereas correct treatment has the opposite effect (Table 7). The quality of control of diabetes during the first 5–10 years seems of particular importance for the long-term prognosis (CONSTAM, 1965, 1970; CAIRD, 1969). Early and good treatment gives to a diabetic the best chances for protection from vascular complications for 30 or even 35 years. He can preserve his working capacity for more than 40 years by keeping angio-neuropathy at bay.

Table 7. Relation between the quality of treatment and the further course of diabetes

	Quality of treatment								
	Always poor			Variable			Always good		
	Duration of diabetes in years								
	20	25	30	20	25	30	20	25	30
No late symptoms	3	2	2	31	6	2	74	39	14
1–2 late symptoms	10	4	0	83	37	15	33	29	19
More than 2 late symptoms	67	22	6	126	88	48	13	12	10
Total number of diabetics	80	28	8	240	131	65	120	80	43

There are rare cases of diabetes, less than 3% of our patients, who, in spite of poor control, remain free from renal or circulatory disturbances. They present a special, not yet well defined type of diabetes.

The working capacity, the periods of absence from work, and the efficiency of the diabetic are dependent on the age of the patient, the duration of diabetes, the quality of treatment, and the time at which an effective therapy was started. Intelligence and energy are indispensable to keep a diabetes well controlled, and for the very same reason well stabilized diabetics have proved to be excellent workers in various professions and arts. On the other hand, poorly regulated patients are irregular also in their professional performances and often compelled to interrupt their work.

Blindness, nephropathy with edema and hypertension with cardiac failure make young diabetics unfit for work. Gangrene, cardiac insufficiency, or cerebral palsy, and less often, neuropathy cause *incapacity for work* in the older diabetics.

6. Therapy

a) Aim and Principles of the Treatment of Diabetes

Treatment should not only aim at prolonging life, but at obtaining normal growth and development, normal efficiency and life expectancy, and physical as well as psychic well being of the patient.

The earlier treatment is started, the simpler and the better its long-term prognosis. Therefore, we should do our best to recognize the disease as early as possible and to arrest its further evolution, i.e. to prevent potential diabetes from becoming latent, latent from developing into clinical and clinical diabetes from progressing to complete insular insufficiency.

We try to achieve this by *reducing the endogenous insulin requirement.* If this is not sufficient, we may, in addition, *accelerate the release of endogenous insulin* or slow the *intestinal absorption of carbohydrates and increase the peripheral action of insulin* or *substitute exogenous insulin* for the endogenous hormone.

Complete control, i.e. normal blood sugar values at all hours of the day, is possible only in early recognized cases. An effort should be made to attain the blood sugar values presented in Table 8. The sugar in the urine should disappear whenever possible, and, in severe cases, should not exceed 10–20 g/24 hours. A glycosuria of even 30 g/day must be accepted in individual cases of labile diabetes, if severe hypoglycemia is to be avoided. Polyuria and acetonuria must be suppressed at all costs.

In exceptional cases, we are sometimes compelled to deviate from these rules, such as in professions with irregular meal times, patients with mental disease and in persons unwilling to follow the treatment. The "free normal diet" is the choice left open where there is a lack of intelligence, and also for children who are

Table 8. Guiding principles for "good" and "fair" control

Overt diabetes	Blood sugar in mg/100 ml			Glycosuria per 24 hours	Acetonuria
	Fasting	1 hour after breakfast or lunch	2 hours after breakfast or lunch		
With diet alone	< 1.20	< 1.60	< 1.30	0	0
Diet + tablets	< 1.20	< 1.80	< 1.30	0	0
Diet + insulin, good	< 1.20		< 1.50	< 5% of carbohydrate intake	0
Diet + insulin, fair	< 1.30		< 1.80	< 10% of carbohydrate intake	0

inadequately supervised at home. Treatment with insulin is then restricted simply to preventing ketonuria and loss of weight. The long-term prognosis in most of these cases is, however, unfavorable.

Drastic measures should be avoided in patients older than 65 years, except when there is a vital indication, such as an incipient coma, an unavoidable operation or a complication. When an overweight patient of more than 70 years has suffered from diabetes for more than 10 years and this caused no complaints nor late symptoms, this proves that the patient has adjusted his mode of living well to his illness, and it is advisable not to change the situation, at least not in a radical way. As long as there is no ketonuria, high blood sugar values of up to 260 mg/100 ml after meals are of little significance in the cases already in existence for a long time and without complications or complaints, provided glycosuria is relatively moderate.

The treatment must be applied constantly by the patient or his relatives. In addition to treating and supervising the patient, educating the diabetic is an important part of the treatment and, therefore, the duty of the physician. A severe psycho-organic syndrome, indifference, debility, or hypochondria can render education impossible, but it is indispensable for the great majority of diabetic patients.

The success of the treatment should not be based on the laboratory findings alone. The subjective symptoms of the patient, particularly his professional efficiency, are as important as the objective results of the medical examination.

b) General and Dietary Treatment

Treatment with diet, muscular activity, avoidance of infections and mental stress all serve to reduce the endogenous insulin requirement.

The *method of diet prescription* should be simple and adequate for use in infantile, juvenile and adult diabetics, for overweight, normal and underweight patients, and even for cases with labile diabetes.(Table 9).

Diet prescriptions are necessary (Table 10 gives an example) even in the stage of potential, and even more in that of latent diabetes, to protect the predisposed islet cells from overwork.

Table 9. Seven fundamentals for permanent dietary treatment

1. The *diet prescription* must be given in writing, contain not only what is forbidden, but also what is permitted, not only the daily amount of food, but also its distribution amongst the various meals of the day.
2. Adaptation of the diet as much as possible to the individual needs and possibilities.
3. No starvation diet!
4. Distribution into as many single meals as possible.
5. Carbohydrates are the main producers of sugar, fats the main suppliers of calories, proteins are indispensable for the formation of tissues and enzymes; they are partly converted into carbohydrates and fats.
6. Restrict the insulin requirement by avoiding "surplus caloric import" (exceptions; children and people over 65 years of age).
7. Prevent the rapid absorption of carbohydrates by eliminating food with highly concentrated carbohydrates, and by combining carbohydrates with proteins and/or fats in the same meal.

Table 10. Diet prescription for potential and latent diabetes

Avoid completely:

Sugar, food or drinks sweetened with sugar, beer, honey, liqueurs, malt-containing food such as ovaltine, syrup, sweet cider, sweet wines, pastry.

Use in moderate amounts and per meal only one of the following items:

Cereal, bread, potatoes, oats, barley, rice, corn, millet, flour, noodles, spaghettis.

Overweight persons have to omit also:

Butter, fat, oil, cream, egg yolk, bacon, nuts.

Between the 3 main meals (breakfast, lunch, supper) and before retiring, 3 snacks consisting of bread or fruit or milk are recommended.

The so-called "qualitative diet", in which only the food richest in carbohydrates is quantitatively fixed, usually is adequate for diabetics who are controlled by diet alone without the aid of hypoglycemic drugs (Table 11).

Table 11. "Qualitative diet" for diabetics controlled without hypoglycemic drugs

Fats in particular (butter, oil, cream, egg yolk, nuts) must be restricted or omitted for overweight patients, skimmed milk substituted for whole milk, lean cheese for cream cheese, lean meat for fat meat, salads made with vinegar or lemon juice, meat grilled or boiled, not roasted, sausages are to be avoided.

To be avoided completely:

Sugar, sweetened foods and drinks, beer, honey, liqueurs, ovaltine etc., syrups, apple juice, sweet wines, cakes, pastries, bananas, dates, figs, raisins, grapes, currants

Permitted without restrictions:

to sweeten:
Assugrin, disorb, saccharine, sionon, sucaryl

to season:
Vinegar, pepper, salt and other spices

Drinks:
Water, beef tea, meat broth, coffee, tea, mineral water without additional substances, completely fermented wines

Vegetables containing few carbohydrates:

Red cabbage, endives, cucumber, lettuce, cress, dandelion, silver beet, mushrooms, rhubarb, pickled cabbage, celery stalk and leaves, asparagus, spinach

The following recommended *distribution of the food* should be changed only with the permission of the physician.

1. *Breakfast:*	White bread ... grams, or dark bread ... grams Milk or yoghurt Butter Cheese Coffee or tea
2. *Mid-morning snack:*	Bread[a] Butter[a] Cheese Fruit (exceptions given above)
3. *Lunch:*	Vegetables (in particular those listed above) White bread ... grams, or dark bread ... grams, or ... medium size potatoes, or ... ounces of barley, or oats, or millet, or maize, or ... drachms of rice Meat, or fish, or sausages, or eggs, or cheese Fruit (exceptions given above) Butter, fat, oil, cream
4. *Tea:*	Like 1st or 2nd meal
5. *Dinner:*	Like lunch[a] Milk[a]
6. *Before retiring:*	Like mid-morning snack

[a] Cross out if not applicable, ... physician must fill in corresponding amounts. 20 g brown bread = 16 g white bread = 1 medium sized potato = 1 table spoon of oats, barley, millet, maize = 1 dessert spoon rice or noodles or fluor.

Reduction in weight is more essential than the limitation of carbohydrate intake in the overweight diabetic patient.

The diet poor in fat and limited in carbohydrates is nearly always successful. The patients do not feel hungry if their food intake is distributed amongst 5–7 meals a day (Table 11).

Patients who need drugs to lower the blood sugar, tablets or insulin, should eat about the same amount of blood sugar-forming food every day at about the same time. Otherwise, the hypoglycemic agents will have one day too much, another day too little action.

To obtain the necessary stability of the diet, foods are grouped as shown in Table 12, and *food equivalents* (Table 13) permit patients a satisfactory variation in their diet besides the uniformity in its composition.

Some of the foods rich in carbohydrates also contain proteins and fats, but only in relatively small amounts. In cases where the protein content cannot be neglected, glucose formation from proteins is considered in our exchange tables. Under *free foods* are listed items which either contain very little carbohydrates or are normally consumed in such small amounts that they have practically no influence on blood sugar.

In Germany and Austria, the carbohydrates are usually measured in *bread units*, one unit corresponding to 12 g of carbohydrates. The term *bread equivalent*, preponderantly used in Switzerland, implies the amount of bread, cereal, oats, barley, potato, rice which supply 10 g of carbohydrates, inclusive of the glucoplastic amino acids. One *vegetable equivalent* represents the corresponding amount of vegetables, one *fruit equivalent* that of fruit or berries. Bread-, vegetable- and fruit equivalents contain equal amounts of carbohydrates, but they are physiologically different. According to JOSLIN, from bread the sugar rushes into the blood, from fruit it flows and from vegetables it seeps.

One *milk equivalent* corresponds to the quantity of milk or milk products, with the exception of cream, which yields about 10 g of carbohydrates and 7 g of protein. A *protein equivalent* represents the amount of meat, fish etc. containing 10 g of proteins, a *fat equivalent* the portion of butter, fat, oil etc., which forms 10 g of fat, whereas a *cream-nut equivalent* furnishes 10 g of fat, 1–6 g of carbohydrates and 2–6 g of proteins.

The corresponding values of the usual food stuffs are presented in Table 13.

In practice, the dietary conditions are most simply arrived at by giving a basic diet to begin with, watching its effects, and adding corrections subsequently if necessary.

Table 12. Classification of foods according to their main nutritional content

1. Carbohydrates		2. Proteins	3. Fats	4. Free foods of unimportant nutritional value

240 g	Whey	200 cc
300 cc	Curdled milk	250 cc
240 g	Full milk	200 cc

e) Proteins

	1 protein equivalent corresponds to
Meat, uncooked	50 g
Meat, cooked	40 g
Brain	100 g
Tripe	50 g
Liver, cooked	40 g
Smoked meat	40 g
Ham, uncooked	60 g
Ham, cooked, smoked, salted	40 g
Tongue	50 g
Sausages of different types av. erage	60 g
Fish, without skin and bones, raw	60 g
Fish, without skin and bones, cooked	50 g
Eggs, hens', without shell	80 g
Cheese lean	35 g
Cheese, at	40 g

f) Fats

	1 fat equivalent corresponds to
Butter, fresh	12 g
Egg yolk	20 g
Bone marrow	12 g
Margarine	10 g
Olive oil	10 g
Lard	10 g
Bacon, smoked or salted	15 g
Bacon, cooked	20 g

Table 14 gives an example of a basic diet for an adult with sedentary occupation. The figures in small print below the carbohydrate, protein, fat and calories represent average values for 1 equivalent in order to permit an approximate estimation of the composition of the diet.

Patients who cannot be trusted with the simple multiplication in such a diet, can see from Table 15 how many grams of apple or orange etc. are allowed at a specific meal.

If the patient continues to excrete sugar despite the basic diet, the bread at lunch and dinner can be omitted. If this is not sufficient, then stronger hypoglycemic agents are needed. If, however, the blood sugar values have become almost normal, the diet may be extended to include more bread equivalents at lunch and dinner, and more fruit equivalents before retiring etc.

For adults performing heavy work, the bread equivalents of all meals have to be increased. If breakfast is very early, two mid-morning snacks may become necessary. Diabetics who must lunch at or near work need at least 4 bread equivalents for this meal, giving them the possibility of eating weighed sandwiches brought from home, in addition to their fruit equivalents.

The weighing of food appears cumbersome at the start. However, after some experience, this does not cause any considerable delay in preparing meals. Observant diabetics can develop the ability to estimate the amount of vegetables, fruit and meat correctly within a few weeks. It is important that the carbohydrate-rich bread equivalents are always correct. When eating in a restaurant or while travelling, or when not at home, the bread equivalents should be

Table 14. Average basic diet for an adult with sedentary occupation, under treatment with hypoglycemic agents

5. *Dinner:*	like lunch, in addition milk[b] ... cc, or yoghurt[b] ... cc

[a] Physician must indicate whether none, little, much, unrestricted.
[b] Physician must cross out the inappropriate.

c) Treatment with Antidiabetic Tablets (Oral Hypoglycemic Agents)

Two groups of drugs – the sulfonylurea derivatives including pyrimidine and biguanides are extensively used today.

Table 16 gives a survey of the sulfonylurea and pyrimidine derivatives in use.

All the sulfonylurea derivatives act in the same way. They differ only in their toxicities, their potency per gram of substance, the duration of action and their side effects.

The main action of the sulfonylurea drugs is to stimulate the release of insulin from the

Table 16. The most commonly used sulfonylurea and pyrimidine derivatives

Carbutamide	Alantin Antidiabeticum Bucrol Butasulfe Glucidoral Invenol Midosal Nadisan Norboral Retarden Sulfadiabet
Tolbutamide	Artosin Dolipol Orinase Rastinon
Chlorpropamide	Catanil Chloronase Diabinese Diabetoral Mellinese
Glybenclamide, glyburide	Daonil Diabeta Euglucon
Tolazamide	Diabetas Tolinase Tolisan
Acetohexamide	Dinetin Dimelor Ordimel
Glycodiacine	Gondafon Lycanol Redul

B-cells of the pancreas. In nondiabetics, the release of insulin is primarily regulated by the glucose content of the arterial blood in the pancreas. In the diabetic, however, the damaged B-cells can no longer react to the hexose stimulus or the reaction is delayed. Sulfonylurea derivatives can mobilize insulin reserves still present. The insulin in the B-cells may be bound to zinc, in the form of large conglomerations of insulin molecules. The splitting up of these molecular complexes by sulfonylurea promotes the liberation of insulin from the B-cells. The insulin thus liberated, acts primarily on the liver, where it inhibits the release of glucose. The sulfonylurea compounds also potentiate the action of small amounts of insulin even in the complete absence of the pancreas. In dogs fed on a carbohydrate-free diet, they increase the capacity of the B-cells to produce insulin. Whether this holds true for man is not certain. Tolbutamide can release insulin from the insulin-antibody bondage in vitro and can also prevent insulin from combining with antibodies. Sulfonylurea derivatives also have an antithyroid effect, and some of them are bacteriostatic, although this is of no practical importance. The temporary inhibition of individual hepatic enzymes is just as unimportant as the increased excretion of endogenous citric acid when large doses of tolbutamide are used.

Side effects are the more unpleasant, the longer the duration of action of the drugs. When these drugs were introduced, side effects were observed in 5–11% of the cases treated with carbutamide, and in 1–3.2% treated with tolbutamide. They were more common with chlorpropamide, but only when the daily dosage exceeded 0.5 g. Today, side effects are considerably less frequent, due to the more precise indications for the use of these drugs.

The side effects caused by sulfonylurea derivatives may be toxic or allergic reactions of the skin, the bone marrow and the nervous system. They appear as *morbilliform rash* with high fever, as *urticaria*, as *photoallergic eczema*, as *exfoliative dermatitis*, as *thrombocytopenic purpura*, as *agranulocytosis* or as *hemolytic* or *aplastic anemia*. *Headache* not associated with hypoglycemia or dizziness or peripheral neuropathy, which is to be differentiated from diabetic neuropathy, may be symptoms of intolerance of the sufonylurea compounds. Occasionally, heartburn, nausea and abdominal pains may occur, due perhaps to the increased gastric secretion. Reactivation of *gastric or duodenal ulcers* causes the typical pattern of pain, even hemorrhage and perforation. A few patients complain of *constipation*. *Cholostatic jaundice* is especially common with overdoses of chlorpropamide. Several cases of *porphyria*, and several of *myocardial changes* have been reported. We have not so far observed *hypothyroidism*, which is thought to develop after years of treatment with sulfonylurea.

Incompatibility with alcohol, an antabuslike effect, considerably lowers tolerance to alcohol. The action of barbiturates is prolonged, whereas salicylates, sulphamethizole and phenylbutazone can potentiate the hypoglycemic power of the sulfonylurea drugs. PAS taken at the same time is said to produce headaches.

It is important to realize that the action of tolbutamide can be increased by the anticoagulant agents of the dicoumarol group.

Overdosage is dangerous and may lead even to fatal hypoglycemia. Even normal doses endanger patients with renal failure and delayed excretion of the drugs. Further, individuals who break down these drugs only very slowly can also be endangered (SCHULZ). The diagnosis of hypoglycemia is easily missed, its symptoms: weakness, dizziness, ataxia and confusion being mistaken for cerebral thrombosis. Secondary failure of the treatment, i.e. the sudden loss of hypoglycemic action after a period with satisfactory effectiveness, may lead to ketoacidosis in an unobservant patient. The right moment for the start of insulin therapy should not be missed.

Tables 17 and 18 summarize the indications and contraindications for sulfonylurea compounds. Table 19 is for the information of patients under this treatment.

Table 17. Indications for the use of sulfonylurea derivatives

1. Adults who have never had insulin, who cannot be controlled by diet alone and who have no signs of ketosis.
2. Adults in whom diabetes started after age 40 and was treated by insulin for less than 5 years and was controlled by 30 units per day or less.
3. Overweight patients may try oral treatment even after larger doses and longer use of insulin, but only after preliminary reduction of body weight.
4. Cases of insulin resistance justify a trial.
5. In latent diabetes, when the blood sugar 1 hour after breakfast is above 120 mg per cent, cautious oral treatment may be used to prevent further deterioration of carbohydrate tolerance.

Table 18. Contraindications to sulfonylurea therapy

1. Diabetes which can be controlled by diet alone.
2. Overt infantile or juvenile diabetes.
3. Insufficient action of sulfonylurea compounds.
4. Diabetic women who might become pregnant.
5. Ketoacidosis
6. Diabetics under stress.
7. Renal- or hepatic insufficiency.
8. Infected gangrene or progressive retinopathy.
9. Insufficient medical supervision.

Table 19. Advice for patients on sulfonylurea therapy

1. The effect of alcoholic beverages is markedly increased by these blood sugar-lowering agents.
2. Besides these tablets no other medication is allowed unless your doctor approves. Drugs for rheumatic pains or urinary infection are particularly likely to alter the potency of the blood sugar-lowering tablets.
3. Stop taking the tablets and notify your doctor immediately if one of the following symptoms appears:
   a) raised temperature;
   b) skin rash;
   c) severe headache;
   d) bleeding from nose, intestine, bladder, genital organs;
   e) incipient acidosis, i.e. nausea, and possibly vomiting, combined with much sugar in the urine.
4. *Take 1/2 tablet less:*
   a) in case of "insulin reaction" i.e. headache or trembling with sweating and weakness;
   b) prior to an unusual exercise like swimming, hiking, sport.
5. *Take 1/2 tablet more:*
   a) if your urine test shows sugar 2 days in succession;
   b) if after this the morning urine is not sugar free in 2 days, blood sugar determination is necessary.
6. Thirst, large volume of urine and strongly positive sugar tests demand immediate notification of the doctor, even on Sundays.

The choice of drug depends on the action of the drug and its duration of action. It is advisable to try tolbutamide first; it is the least potent, but also the least toxic. It must be given in two daily doses since its half-life is 8 hours. It is excreted by the organism in the oxidized form in the urine, precipitating as a whitish sediment on acidification, thus simulating albuminuria. If this preparation is not effective enough, one of the stronger preparations, carbutamide, glyburide or chlorpropamide, can be tried, and since they have half-lives of 40 and 34 hours respectively, they need only be given once daily. In our opinion, the other preparations have no great advantages over the four drugs mentioned above.

Without reduction of the needs for endogenous insulin at the same time, i.e. without dietary measures, the oral antidiabetic agents are inadequate and not effective for very long. *They should only be used in combination with diet.*

To stabilize diabetics who are not treated with insulin, 0.5 g of carbutamide or 5 mg of glybenclamide (glyburide), or 0.25 g of chlorpropamide are given with breakfast on the first morning. The blood sugar is measured and the leucocytes are counted in the late afternoon, as also on subsequent days. If the blood sugar measured in the capillary blood does not fall to below 140 mg%, then 1.0 g of carbutamide, or 10 mg of glyburide, or 0.5 g of chlorpropamide is given again on the following day. If the blood sugar is below 120 mg%, however, the dose on the following day is reduced by 0.5 g carbutamide or 2.5 mg of glyburide, or by 0.25 g of chlorpropamide. This procedure is repeated during the next few days. If the blood sugar falls, the carbutamide, glybenclamide or chlorpropamide dosage can be reduced. If a satisfactory fall of the blood sugar is obtained with 1 g of carbutamide or 5 mg of glybenclamide or 0.5 g of chlorpropamide, these drugs are replaced by the less toxic tolbutamide. The daily dose of this drug, however, must be greater (by 0.5 g) than that of the other 3 preparations and must be divided between a morning and an evening dose.

Continuation of the treatment with sulfonylurea drugs has little chance of lasting and favorable action if the blood sugar does not fall to below 120 mg% by the fifth afternoon.

When the leucocytes fall to below 3000 the treatment must be discontinued at once and the patient observed for the possible development of *agranulocytosis.*

The *maximum maintenance dose* per day, is 1.5 g of carbutamide, 15 mg of glybenclamide, 2.0 g of tolbutamide and 0.5 g of chlorpropamide.

The *transition from insulin to oral hypoglycemic therapy* can be made in stages or abruptly. In the latter case, the insulin is fully discontinued in the morning, and instead the patient is given 1.5 g of carbutamide or 10 mg of glybenclamide, or 0.5 g of chlorpropamide with breakfast. The blood sugar is checked by a quick method at 11 a.m., and if necessary, insulin can then be injected before lunch. If the blood sugar has still not fallen in the late afternoon, insulin therapy must be resumed and the trial with tablets abandoned. However, if the patient responds, i.e. if the true blood sugar is under 120 mg% between 5 and 6 p.m., the following day the doses of carbutamide or glybenclamide or chlorpropamide are reduced in the same way as described above, and tolbutamide eventually substituted for these long-acting preparations.

If diet and sulfonylurea derivatives are inadequate, their hypoglycemic action can be considerably enhanced by giving a biguanide in addition. The sulfonylurea treatment is continued, and biguanide is administered in the usual way, the dosage being slowly increased.

A trial of sulfonylurea preparations in combination with insulin is only worthwhile in certain rare cases of insulin resistance.

Table 20 gives a survey of the biguanides in use.

The actions of biguanides demonstrated in vitro on muscular and liver tissues are: increased uptake of glucose, enhanced formation

Table 20. Survey of biguanides currently used

Chemical term	Structural formula	Commercial name
DBI Phenylethylbiguanide		*Phenformin*, DBI, Debinyl
W 37 n-butylbiguanide	$CH_3-CH_2-CH_2-CH_2-$	*Silubin*, Silubin, Silubin retard
LA 6023 Dimethylbiguanide		HCl *Glucophage*, Metformin

of lactate, with reduced utilization of oxygen and diminished storage of glycogen, inhibition of various enzyme systems. However, we still do not know what effect these actions have in vivo.

In a test using labeled glucose, it was shown that biguanides also promote the breakdown of glucose in the periphery of healthy subjects, but causes gluconeogenesis at the same time in the liver, so that the glucose turnover rises, while the blood sugar remains constant. In the diabetic, the release of glucose from the liver is already increased and is little increased by biguanide, whereas the action in the peripheral breakdown is predominant and the blood sugar consequently falls (SEARLE, 1966). Probably the liver absorbs more lactate and reconverts it into sugar. The biguanides appear to act peripherally only on the muscle cells, lowering the threshold for the uptake of glucose at the cell membrane. They slow the absorption of carbohydrates from the intestine. The mode of action is still not fully explained. These compounds have no direct influence on the B-cells of the pancreas, and do not increase the plasma insulin, as do the sulfonylurea derivatives.

The side effects of biguanides may take the form of diarrhea, heartburn, loss of appetite, nausea, or vomiting. They may occur early and promptly disappear if the dose is reduced. Later, only 1–2 months after the start of this therapy, tiredness, weakness, and loss of weight occur. Some patients have a sensation of a metallic taste when drinking alcohol. Allergic skin changes are exceptionally rare and may present urticaria or pruritic erythema. In the medical literature, one case of thrombocytopenia has been attributed to this therapy.

The biguanides can also lead to hypoglycemia, which, however, is never severe. The development of *ketonuria* in the presence of normal or only slightly elevated blood sugar is dangerous and can be fatal. It must not be treated by intravenous administration of lactate, since the biguanides, at least phenformin, have the tendency to elevate the levels of lactate in the blood. A number of cases of severe *lactacidosis*, some with fatal outcome, have been described in the last few years. Diabetics with acute circulatory failure seem to be particularly prone, as are elderly people with renal insufficiency, and young diabetics with too little insulin. *In acute complications, the tablets must be replaced by insulin*, even when the blood sugar levels were normalized by biguanides.

Here, as well, there is the danger that the right moment for starting treatment with insulin may be missed. It is better in doubtful cases to start with insulin therapy, and then subsequently to try tablets.

Tables 21 and 22 summarize the indications or contraindications for using the biguanides.

Table 21. Indications for treatment with biguanide

1. Adult, overweight diabetics, in whom the diet alone is inadequate. Here we prefer biguanides to the sulfonylurea derivatives. If only a fair stabilization is obtained with the biguanides, a sulfonylurea preparation is added.
2. As an additional therapy in diabetics inadequately stabilized with sulfonylurea compounds.
3. In labile diabetes, where the stabilization with insulin and diet is unsatisfactory (trial).
4. In insulin resistance (trial).

Table 22. Contraindications to treatment with biguanide

1. Gastrointestinal disease.
2. Infected gangrene.
3. Circulatory, renal, or hepatic insufficiency.
4. Underweight.
5. Operations.
6. Women who may become pregnant.

We choose the weaker preparations, dimethyl- and butyl-biguanide in preference to phenformin, since we have never observed a case of acidosis with the former two compounds. Butyl-biguanide is also on the market as tablets with prolonged action.

During the first days, 1 tablet of 500 mg dimethyl-biguanide is given three times daily before meals, or 1 tablet of 100 mg butylbiguanide retard twice daily, in the morning and in the evening. If the desired decrease of the blood sugar is not obtained within 5 days, the dose is

increased by 1 tablet every fifth day, until the blood sugar is stabilized as required, or side effects appear and demand that the dose be reduced again.

Combined treatment with biguanides and sulfonylurea derivatives has been mentioned on p. 784.

d) Treatment with Insulin

Treatment with insulin is an imperfect substitution therapy, since the exogenous insulin injected subcutaneously, intramuscularly or intravenously, reaches the systemic circulation, whereas the endogenous insulin first passes from the pancreas into the liver by the portal vein, and only then reaches the general circulation. In addition, commercial insulin is probably changed during the process of extraction from the pancreas and therefore not identical with the normal hormone.

Treatment with insulin is necessary in the vast majority of cases of growth-onset diabetes. It is also indispensible in maturity-onset diabetes if diet, adaptation of the mode of living and possibly the use of oral hypoglycemic drugs are not adequate to control the disease. It is also indicated in the presence of severe late symptoms (such as progressive retinopathy, or infected gangrene, see p. 792/95), since, in addition to its hypoglycemic action, insulin also seems to have other effects (see p. 794). Insulin therapy is urgent in pre-coma and in diabetic coma. An early and rapid start of combined insulin and dietary therapy allows interruption of the administration of insulin for shorter or longer periods in some growth-onset diabetics.

Insulin therapy should start before the islet system fails completely, while reserves of endogenous insulin are still sufficient to control the postalimentary hyperglycemia after exogenous insulin has reduced the basic blood-sugar level. Insulin treatment leads to complete islet insufficiency, i.e. a form of labile diabetes with all the inconveniences this involves for the patient if it is started too late or inefficiently managed.

There are no absolute *contraindications* to treatment with insulin. Severe allergy to insulin must first be corrected. In elderly patients, the blood sugar must be reduced slowly. Mental deficiency or pronounced irresponsibility render the treatment insulin difficult, and may even make it impossible.

The ferments of the intestinal tract inactivate insulin so that it must be given by injection.

The action of insulin is prolonged by combination with proteins such as protamine or globin, or other complex substances, such as surfen, from which it is gradually liberated. The insulins of the *lente group* are not bound to other bodies; their prolonged action is achieved partly by their delayed solubility and partly by their crystallization. They represent suspensions of amorphous or crystalline insulin.

Table 23 gives a review of the most common types of insulin in use. Insulin is measured in *international units*. One unit is the amount of insulin which has the same action as 1/24 mg of a crystallized standard insulin.

The action of insulin varies with the individual. The *glucose equivalent*, i.e. the amount of carbohydrates utilized by 1 unit of administered insulin, varies according to the dose of insulin and to the blood sugar level or the time at which the injection was made. It is greater with small than with high doses. Massive single doses of insulin are considerably less effective per unit. In the presence of high blood sugar, the action per unit of insulin is delayed and smaller than in mild hyperglycemia.

Start of Insulin Therapy: Without diet, the effects of the treatment with insulin are unpredictable and irregular. Stabilization with

Table 23. The most commonly used types of insulin

Type	Appearance	Addition	Buffer	Possibility of mixing	Duration
Rapid					
Regular, soluble	Clear	None	None	With all other insulins	5– 7 hours
Actrapid	Clear	None	Acetate	Lente group	
Intermediate					
Globin	Clear	Globin	None	Regular	12–18 hours
Lente	Turbid	None	Acetate	Lente group	18–24 hours
NPH	Turbid	Protamine	Phosphate	Regular	18–24 hours
Semilente	Turbid	None	Acetate	Lente group	12–16 hours
Rapitard	Turbid	None	Acetate	Lente group	4–20 hours
Slow					
Protamine zinc	Turbid	Protamine	Phosphate	Regular	24–36 hours
Ultralente	Turbid	None	Acetate	Lente group	24–36 hours

insulin and diet should begin in a suitably equipped hospital.

The first dose is: in the adult 10 U; in children 4 U soluble insulin and is given 30–45 min before breakfast. This rule does not apply to cases of ketoacidosis and extreme underweight.

The following doses are based on the results of the urine tests before the three main meals, according to the "0–8 rule" (Table 24). The urine is examined with BENEDICT's qualitative reagent or with Clinitest-tablets. One hour before the test is to be performed, the bladder is completely voided and the urine discarded. The test is done on the "second" urine.

Table 24. "0–8 rule"

Benedict or clinitest	Acetone negative	Acetone positive	Repeat test after
Increase the dose by soluble insulin:			
Blue	0 U	0 U	4–5 hrs
Green-cloudy	2 (1)	4 (2)	4–5 hrs
Yellow-green	4 (2)	8 (4)	4–5 hrs
Brown	6 (3)	12 (6)	1 hour
Red or orange	8 (4)	16 (8)	1 hour

( ) = Dosage for children weighing less than 40 kg.
If food intake stopped (p. 788) repeat test after.

Example: A diabetic who has never received insulin, is given 10 U of soluble insulin before breakfast. The test for sugar in the urine before lunch is brown and acetone is negative. The patient then receives 6 U. The test before dinner is yellow/green and acetone-positive; the patient, therefore, receives 8 U insulin. On the following morning, the test is again yellow/green and acetone is positive. He then receives another 8 U in addition to the 10 U of the previous day, making a total of 18 U insulin. The urine test is blue at midday, so the dose of the previous day is given, i.e. 6 U. In the evening the test is brown again, and acetone is negative. The patient therefore receives 8 + 6 units = 14 U.

The blood sugar is measured at the latest on the third day, before lunch and supper, and before breakfast on the following morning. The insulin dosage can then be adjusted more exactly.

Ambulant adult diabetics, who are neither resistant to insulin nor ketotic should not be given more than 40 U at once. Children under 40 kg should not be given more than 24 U in one dose. After one to two weeks of intensive treatment with insulin there is usually some improvement in tolerance, so that the insulin dose can be decreased, and in certain cases, treatment with insulin may even be stopped. As soon as the insulin requirement has been constant for 2–3 days the physician can change from the rapidly acting soluble insulin to an insulin with prolonged action providing the following rules are adhered to:

In diabetics who need 10–30 U insulin per day a single injection of a "depot" insulin is usually adequate, the choice of preparation being dependent on the time of day at which the need for insulin is greatest.

Diabetics with a daily requirement of 30–50 U of insulin usually need 2 injections given at the same time, before breakfast. A rapidly acting insulin is given separately from a "depot" insulin.

If 50–80 U of insulin are needed per day, it is best to give two injections of an intermediary insulin, one before breakfast and the other before dinner in the evening.

The treatment of *labile diabetes*, or of patients who are not compensated with 80 U, necessitates the advice of a specialist in this field. The same applies to children, even if their insulin requirement is below 40 U daily.

Adjustment of the Dose of Insulin to Changes in Tolerance. We advise intelligent diabetics to increase the insulin dose by 2 U, if the urine voided before breakfast contains sugar on two consecutive days. This rule applies only to patients who are not bedridden, but are capable of normal activity. If bed rest is necessary, regardless of whether on account of illness or injury, soluble insulin is substituted for the long acting one. Half as much insulin as used the previous day is injected before breakfast, a little less than a quarter as much before lunch, and a little more than a quarter as much before dinner, if the urine sugar tests before the 3 main meals are negative. If a test is positive, the insulin dose is increased at once by 4 U in adults, by 2 U in children.

Hypoglycemic manifestations despite adherence to the prescribed diet and normal physical activity always require a reduction of the dose of insulin which caused the hypoglycemia. If this dose was less than 16 U it must be reduced by 2 U, if it was greater, by 4 U. If the hypoglycemia led to loss of consciousness the dose must be reduced by 8 U. Reactive hyperglycemia with glycosuria usually follows hypoglycemia. Therefore, the dose of insulin must be reduced after a hypoglycemic attack, even if glycosuria is present. The dose should be reduced by 4–6 U per half day *before* any unusual physical exertion; 6 U applies to strenous physical exertions such as field work, skiing or competitive sports.

Interrupted food intake due to lack of food or indigestion or loss of appetite should not

lead to discontinuation of insulin therapy, but to the application of "*rule 0–8*", since loss of appetite may be a sign of precoma. Table 24 mentions the insulin doses. Urine tests have to be repeated and the insulin injections, if necessary, renewed every 4–5 hours if the urine test is blue-yellowish-green, every hour if it is brown, orange or red.

Hunger in a diabetic indicates poor control with significant loss of sugar in the urine, or inadequate diet or too high a dose of insulin.

e) Side-Effects of Insulin

α) Hypoglycemia, Insulin Shock, Insulin Reaction (see also p. 783)

The development of hypoglycemic symptoms does not only depend on the concentration of the blood sugar, but rather on the rate at which the blood sugar falls, and, in addition, on the amount of glycogen still in storage. Therefore, patients can be found who feel well with a blood sugar of 30 mg% or less and others have symptoms even when the blood sugar is still elevated at 180 mg%.

Hypoglycemia is due either to *insufficient formation of blood sugar* or to excessive blood sugar consumption. The former is caused by poor food intake or indigestion, or, very rarely, by insufficient or non-mobilizable glycogen or fat reserves. *Increased blood sugar consumption* may be due to physical exertion, to overdosage of insulin or reduction of the insulin requirement, for instance after childbirth or surgical drainage of an abscess. Occasionally, improved tolerance is met without any recognizable reason, perhaps due to blocked insulin being liberated.

Diabetics with untreated pituitary or adrenal insufficiency, are very sensitive to insulin and predisposed to hypoglycemic shock. This applies also to diabetics who have lost weight, and those suffering from diarrhea.

The possibility of an insulin reaction must always be considered in patients treated with insulin who do not feel well, particularly when the symptoms arise shortly before meal time and improve with food intake. The typical *cardinal symptoms*, due in particular to adrenaline are: tremor, sweating, weakness and ravenous appetite. They may be absent especially when slow-acting insulin is used, in which case nervous symptoms such as headache, paresthesia in the oral region, and visual disturbances are prevalent. Some patients complain of pain in the pancreatic area. Silly, euphoric behavior is mistaken for drunkenness. A state of apathy or semiconsciousness and epileptic seizures terrify the patient's family. Cerebral disorders with paralysis and bilateral Babinski's sign may be difficult to differentiate from encephalorrhagia. Lasting cerebral damage, a psycho-organic syndrome, epilepsy and even death are possible.

The prognosis of a hypoglycemic shock depends on the dose and type of insulin, on the state of nutrition and the cardiovascular system, and above all on how fast appropriate treatment is started. Even hemiplegia with pseudo-bulbar palsy can disappear within a few hours or days. Tolerance of severe hypoglycemia by brain and heart is poor, and insulin therefore must be carefully handled. Particular caution demands the use of long-acting insulin, since hypoglycemic shock can appear very suddenly with no previous warning.

Hypoglycemia must be differentiated from diabetic coma, epilepsy, eclampsia, encephalorrhagia, alcoholic intoxication, poisoning, hyperventilation, tetany and psychoses; in children from acute infections beginning with convulsions. Hypoglycemic symptoms are sometimes similar to those of severe hyperglycemia, because both are due to the inadequate supply of sugar to the brain and muscle cells.

The differential diagnosis between insulin reaction and diabetic coma is presented in Table 25.

Prevention is based on regular food intake, correct in time and quantity, adaptation of insulin to changes in insulin requirement, for instance sport, or work, and appropriate schooling of the individual patient. The recognition of mild signs of hypoglycemia and the appropriate changes in the dosage of insulin are important.

Treatment: as longs as the patient can still swallow, he should immediately eat rapidly absorbable carbohydrates, such as sugar or bread, no fruit nor fructose. If he is unconscious, 1–2 mg of *glucagon* are given subcutaneously, intramuscularly, or intravenously, or 40–50% glucose solution intravenously. In general, 20–40 ml of the glucose solution are sufficient. If the condition of the patient has not improved within 2 min after glucose administration, then the intravenous injection of glucose should be repeated, and the patient rapidly transferred to a hospital, where he should be treated according to the schedule on p. 816.

As soon as the patient is able to swallow again food is given by mouth. Hypoglycemia may recur, especially with the use of long acting insulins; therefore food intake is repeated e.g. 100 cc milk every 1/2 hour for 2 hours. See p. 815 for the so-called prolonged hypoglycemic coma.

Table 25. Differential diagnosis between insulin reaction and ketoacidosis

	Hypoglycemia after		Ketoacidosis
	Rapidly-acting insulin	Long-acting insulin	
1. Causes			
Food intake	Reduced, delayed or neglected	Reduced, delayed or neglected	Dietary mistake
Physical activity	Increased	Increased	Reduced
Infections			Common
2. Previous history			
Onset	Sudden	Usually sudden	Gradually
Loss of consciousness	Rapid, within minutes	Within seconds or after minutes of increased apathy	Gradual, over hours or days
Vomiting	Seldom, only as a cause	Seldom, also as a result	Often precedes unconsciousness
Polydipsia	Absent	Absent	Severe
Appetite	Usually increased	Usually good	Poor
Visual power	Diplopia common	Diplopia common	
Rapid. pass. blindness	Diplopia common	Diplopia common	
Abdominal pains	Seldom, then only as cause	Seldom, then only as cause	Often an accompanying feature
Thoracic tension	Absent	Absent	Frequent
Diarrhea	Only as cause	Only as cause	
Mood	Restless, irritable	rarely tired	tired
3. Findings			
Breathing	Normal or snoring, irregular	Normal or snoring, irregular	Regular and deep (Kußmaul)
Smell of acetone	Absent or faint	Absent or faint	Strong
Skin	Moist, pale, normal elasticity	Moist, pale, normal elasticity	Dry, often reddened, reduced elasticity
Sweat	Increased	Increased	Absent
Tongue	Moist	Moist	Dry
Pupils	Dilated	Usually dilated	Normal or constricted
Ocular pressure	Normal, seldom reduced	Normal, seldom reduced	Usually reduced
Tremor	Present	Not always present	Absent
Musculature	Rigid	Rigid	Flaccid
Babinski	Often pos. both sides	Often pos. both sides	Negative
Blood pressure	Normal-elevated	Normal-elevated	Decreasing
Sugar (urine)	None or little	None or little	Much
Acetone in urine	Seldom present	Seldom present	Much
Blood sugar	Usually < 60 mg% or falling quickly	Low	Usually > 400 mg%
Alkali reserve	Normal	Normal	Reduced, 20 Vol% at 40 mm Hg, $pCO_2 = 9.1$ mEq/l
Leucocytes	Normal	Normal	Increased
Reaction to administration of carbohydrates	Improvement within a few minutes	Improvement usually within a few minutes	No improvement

β) Allergy to Insulin

Redness and swelling of the skin and the subcutaneous tissue at the site of injection occasionally arise after several days of treatment with insulin. These symptoms disappear spontaneously within a few weeks if the therapy is continued. There are two different types of reaction, the *immediate reaction*, occurring within minutes of the injection, and the *delayed reaction* arising only after several hours. The question of whether these are really allergic or other phenomena is still not settled. It is also still unknown whether insulin or accompanying substances are responsible for these reactions. Severe generalized *allergy* to insulin, with generalized urticaria, angioneurotic edema or with thrombocytopenic purpura has now become rare, since the modern insulins are highly purified. Patients resuming insulin therapy after interruption are particularly at risk. Because of this, when insulin therapy is resumed, the initial doses given on p. 787, should be adhered to and can be supplemented if necessary with

higher doses after as little as 30 min (see below for insulin resistance and the formation of antibodies).

The therapeutic measures consist of giving up alcohol for disinfecting the skin, and substituting pure porcine, or pure bovine, or the highly purified Nipagin insulin for the preparation used before. Mixing an antihistamine, e.g. 0.1 ml antazoline, with every injection of insulin, has proved satisfactory. After about 10 days, the insulin will be tolerated without any additive substance. For very severe cases prednisone is used.

γ) Insulin Lipodystrophy

Local atrophy of the subcutaneous tissue at or near the site of injection, or an abnormal accumulation of adipose tissue, "*insulin lipomas*" are not uncommonly found in young diabetics of both sexes, and in adult women. They are seldom seen in adult men. They occur after the use of insulin of most types and their cause is not exactly known. *Insulinfibrosis*, a condition in which the site of often repeated injections becomes hardened by the formation of new fibrous tissue, is mentioned here because it needs the same treatment. These areas are hypesthetic and the patients therefore prefer precisely these places for their injections. The lipomas and fibrosis disappear almost completely after months or years if injections are made elsewhere. On the other hand, the atrophic areas need years to be corrected. The following points have proved to be satisfactory in preventing the lipo-atrophy: replacement of the 70% alcohol for cleaning the skin by some other disinfectant such as Desogene tincture, sterilization of the syringes and needles by boiling, use of small, fine hypodermic needles (No. 0.25), and proper distribution of the site of injections (CONSTAM, 1966).

δ) Presbyopia due to Insulin

Hypermetropia develops when the eye accustomed to high concentrations of blood sugar readjusts to normal blood sugar values. It is harmless but may be alarming to the patient. The refractive disorder disappears spontaneously after 2–4 weeks.

ε) Death due to Insulin

Cases of death are very rare in comparison to the large number of patients using insulin every day. The causes to be considered are oversensitivity to insulin, and hypoglycemic shock, whether erroneous or deliberate as in suicide or murder. A mere 5 units of insulin can cause a fatal outcome in a diabetic with an unsubstituted adrenocortical insufficiency.

Resistance to Insulin. Insulin resistance is assumed when over a long period of time 200 U insulin or more are needed daily to control diabetes with a diet of roughly 200 g carbohydrates. It is, however, advisable to start the appropriate measures at the stage when a patient needs more than 120 U insulin per day and not to wait until several hundreds or even a thousand units are necessary. In certain conditions, a severe resistance to insulin can spontaneously disappear within a few months or years. However, it can also lead to ketoacidosis and death.

The following factors impair the action of insulin:

1. Delayed absorption from the subcutaneous tissue. Mild resistance to insulin may be caused by local allergy to insulin, or injections into insulin lipomas, or into fibrous or edematous skin areas. Such patients react with a prompt fall of blood sugar after intravenous administration of insulin.

2. Increased amounts of contrainsular hormones as in acromegaly, Cushing's syndrome, pheochromcytoma, hyperthyroidism, and after treatment with ACTH or glucocorticoids; thiazine diuretics can also increase the insulin requirement. The insulin resistance occasionally observed in hemochromatosis is unexplained.

3. Inhibition of the peripheral utilization of glucose, e.g. by free fatty acids, β-oxybutyric acid in ketoacidosis.

4. Blocking of insulin by antibodies, though rare, is the most common cause of true insulin resistance.

Therapy. The cells capable of forming antibodies can produce different antibodies to one and the same antigen. By electrophoresis or ultracentrifugation these antibodies may be shown to be intracellular or humoral. The predisposition to forming antibodies is genetically determined and can vary greatly from one individual to another. Intracellular antibodies can first be formed, followed by humoral ones, or only one type is produced, or both types together.

Insulin is a weak antigen in most mammals, since its molecule is so small.

Intracellular antibodies to insulin lead to delayed allergy, whilst humoral ones produce immediate allergic reactions, rarely anaphylaxis, sometimes neutralization of the insulin of all mammals including the human, except for the

guinea pig. The insulin-antibody complex can partly be precipitated in the cold, and then at a strongly acid pH insulin may be reliberated from it. For reasons unknown, the antibody titer can rise at one time, and fall at another, and in addition its binding capacity for insulin can vary.

3 weeks to 3 months after treatment is started with bovine insulin, antibodies to insulin, which can bind in general about 10 U insulin/liter plasma are found in diabetics as well as in non-diabetics. This occurs less frequently with porcine insuline. In cases of insulin resistance, these antibodies can be greatly increased and can fix several thousands of units/liter plasma. The severity of the resistance, i.e. the insulin requirement, for unknown reasons does not run parallel to the levels of antibodies contained in the plasma. In the presence of high antibody titers, soluble insulin can be regained and steadily liberated again, so that it acts like a depot insulin over 24 hours or more (FANKHAUSER). However, in patients resistant to insulin large amounts of insulin can also be suddenly liberated again, for unknown reasons, and can lead to severe hypoglycemia.

If the diet is adequate, and both infections and an endocrine hyperfunctional syndrome, hyperthyoidism in particular, can be excluded, then porcine soluble insulin must first be used in cases of insulin resistance, instead of the bovine or mixed insulins, since it is less antigenic in the human. If this has no effect when given subcutaneously, 20 U are given i.v., which normally causes the blood sugar to fall by 50%, and which will confirm or exclude a disturbed subcutaneous absorption.

Oral antidiabetic agents, the sulfonylurea derivatives or biguanides, can be tried in combination with insulin, as a third measure. The molecular structure of altered insulins has a less antigenic effect, and recently a sulfated insulin (ARNOTT, 1965) has been recommended for use in insulin resistance. Only after all these measures have proved futile, a trial with prednisone is indicated, but this should only be done under the supervision of an experienced specialist. At first 60–80 mg of prednisone are given daily. Success usually becomes apparent only after a few weeks. In certain conditions a small maintenance dose of 5–10 mg must be continued for a very long time. When these measures fail, the insulin therapy must be continued boldly with massive doses of insulin; using preparations with concentrations of 100, and even 500 U per ml. Careful supervision is essential, since the insulin resistance may suddenly disappear any day.

7. Accompanying Symptoms and Complications of Diabetes Mellitus

Diabetes mellitus is accompanied by characteristic tissue changes, the majority of which do not become clinically apparent until 8–20 years after the first clinical manifestation of the disease. LUNDBAEK used the phrase "long-term diabetes syndrome" to summarize these changes. This syndrome is largely due to microangiopathy, which, on careful examination, can already be found in the early stages of diabetes. In a few cases, the corresponding clinical symptoms may even precede clinical diabetes, so we can appropriately replace the term "long-term diabetes syndrome" by "diabetic angiopathy" and "diabetic neuropathy".

The histologists differ in opinion about the question of whether this is a change specific to diabetes, or arteriosclerosis, modified by diabetes. The alterations in the retina, and the nodular form of glomerular sclerosis are recognized by the majority of pathologists as being characteristic of diabetes. Although the arterial changes show no histological differences, their location is typical in diabetes. In addition to retinopathy and nephropathy, peripheral angiopathy in the lower extremities seems to be typical. Histochemical investigations on the aorta, on coronary and peripheral vessels, have shown differences between arteriosclerosis and diabetes, but the significance of this is uncertain. According to GOLDENBERG and BLUMENTHAL, changes characteristic of diabetes are mainly found in the arterioles and venules with a diameter of less than 150 μm. Hypertrophy and hyperplasia of the endothelial cells, among which fine PAS-positive fibrils are embedded, are typical, as is thickening of the basal membrane.

Involvement of the smaller vessels with exemption of the larger arteries are clinically and pathologically considered indicative of diabetes, and not of arteriosclerosis. This suggests specific vascular changes in diabetes, but mixed forms are common.

Is diabetic angiopathy a result of diabetes mellitus, or is diabetes the consequence of vascular disease? The facts supporting the first view are: the vascular disorders increase in number and severity with the duration of diabetes, the long-term diabetes syndrome has been observed after pancreatitis, after pancreatectomy, in hemochromatosis, and development of the long-term syndrome can be delayed by early control of diabetes. The facts speaking against this view (which are, however, being questioned again) are: observations of retinopathy or peripheral angiopathy or necrobiosis

lipoidica, of microscopic vascular changes, before the diabetes becomes overt, and even in the conjunctivae of healthy children of diabetic mothers. Finally a still unknown factor X has been postulated, which produces both the vascular changes, and diabetes. However, in recent years it seems more and more probable that the angiopathy is the result of diabetes.

The micro-angiopathy occurs in all organs, but is clinically preponderant in the eyes, the kidneys, the peripheral, cerebral, and coronary vessels, and also in the nervous system.

In contrast to angiopathy, infections, allergies, tumors, and injuries may be incidental accompanying features not related pathogenitically to diabetes mellitus, although their courses are considerably influenced by diabetes.

a) Changes in the Eyes

Ptosis of the upper eyelid is not uncommon in diabetics, even without hypothyroidism. *Microaneurysms of the conjunctival capillaries* are significantly more frequent in diabetics and in the non-diabetic children of diabetic mothers, than in the healthy descendants of non-diabetics. A stripe-like clouding of the *cornea* occurs in particular with dehydration in diabetic coma. *This folding of the membrana Descemeti* is the result of reduced intraocular pressure. The loosening of the pupillary margin is characteristic of diabetes. *Diabetic iritis*, a toxic form of iridocyclitis, differs from the inflammation of the iris in the absence of precipitates. The rare *rubeosis iridis*, a red mottling of the iris produced by the expansion and new formation of capillaries is usually followed by malignant hemorrhagic glaucoma.

See p. 793, 794 for disorders of the pupils and the ophthalmic nerves.

Refractive changes are common. Every case of myopia starting after the age of 30 is suggestive of diabetes, whereas hypermetropia arising suddenly, during treatment of diabetes, indicates hypoglycemia. Insulin-induced presbyopia has already been mentioned on p. 790.

In diabetic coma, turbidity of the lens may arise as a result of dehydration, and disappears 1–2 days after the ketoacidosis has been corrected. *Thickening of the anterior fission area of the lens* may be found in young patients 2–3 years after the diabetes becomes overt. This rarely occurs in non-diabetics. The senile cataract possibly arises somewhat earlier in elderly diabetics than in non-diabetics. Treatment is the same. In contrast to this, the *diabetic cataract*, begins subcapsularly, and may occasionally develop within a few hours to days, especially in patients under 50 years. It is relatively infrequent and is encountered only in neglected cases of juvenile diabetes. Antidiabetic therapy may, but does not always, succeed in making this turbidity disappear. In some cases, it may, therefore, be necessary to remove the diseased lens surgically. Primary and secondary glaucoma appear to occur more frequently in diabetics, even in young patients, than in non-diabetics.

Diabetic retinopathy is often the long-term symptom which is first recognized, because it can be diagnosed by simple means. Regular examinations are an important part of long-term care of diabetic patients. The earliest changes and the evolution of the condition can best be demonstrated by repeated fluorescine angiography. Fortunately, central vision in the majority of cases is maintained for many years. The formation of new blood vessels, *proliferative retinopathy*, is an ominous sign, often followed by *hemorrhage into the vitreous body* leading to *detachment of the retina*. Even in the absence of visible retinopathy, diabetics appear to be more predisposed to detachment of the retina.

The development of the retinal changes depends on the duration of the illness but also, to a considerable degree, on the time of onset and quality of the treatment. The intermittent course of retinopathy – remissions are not uncommon during the early stages – makes it difficult to assess the effect of therapeutic measures in short-term studies. Careful treatment can lead to the disappearance of hemorrhage and exsudates in patients under 60 years of age. The *prognosis* for elderly patients and in cases with proliferative retinopathy is doubtful. The large series of statistics presented by White shows that of the 1000 or more diabetics, 6% were blind when the metabolic disorder had been present for 20 years or longer. Therefore, prevention is very important, and the judicious treatment of diabetes should be instituted as early as possible.

Hyper- and severe hypoglycemia are to be avoided since the latter is said to provoke hemorrhages into the vitreous body. The diet should be low in fat, particularly in saturated fatty acids. Exertions which increase congestion in the head, particularly straining while holding one's breath, are to be avoided. The large number of recommended vitamin flavonoid and lipocaic preparations have so far not proved very effective.

The action of drugs causing a fall in the blood lipids has not been confirmed, nor has treatment with sex hormones and anabolic androgens stood up to precise testing. Anticoagulants, corticoids and ACTH are contra-

indicated. The observation that the retinopathy disappeared with the development of Sheehan's syndrome led to the recommendation of hypophysectomy (see p. 115) or the division of the pituitary stalk in selected patients. The mode of action is unknown. Loss of growth hormone is, according to some authors, not responsible for the effect (POWEL, 1966). On the other hand, pooled findings indicate that 1/3 of the patients benefited from the procedure, but the indications were strict in these cases. 2/3 are improved, but spontaneous improvement or stillstand can also occur in 1/3 (RUCKER, 1967).

The situation must be carefully considered, before this procedure is recommended, as it necessitates life-long substitution with cortisone and eltroxine. A certain degree of intelligence and responsibility in the patient are required. The diabetes needs less insulin afterwards, but becomes more labile and more prone to severe hypoglycemia. The transnasal stereotactic electrocoagulation of the pituitary (see p. 116) does not cause much stress and the patient can get up on the 2nd day. Hypophysectomy is only indicated in patients with progressive retinopathy despite excellent diabetes control; the eye sight of the better eye must still permit sufficient vision for an active life, the patient must be intelligent enough to handle his diabetes despite its tendency to marked hypoglycemia, and the substitution for the loss of adrenal, pituitary and sometimes sexual functions. *Nephropathy* is a contraindication to this operation. Last but not least, the patient must be willing to take the risk of this complicated treatment, which does not improve life expectancy. A reliable presentation of the indications and contraindications will only be possible after more experience of this method of treatment.

Retinal lipemia is rare and found only in forms of lipemia and in severe ketoacidosis. It does not influence the visual power, and disappears after intensive treatment of the diabetes with insulin and a fat-restricted diet. All ophthalmologists recognize the specificity of the *diabetic pigmentopathy of the macula lutea. Retrobulbar neuritis* is not specific to diabetes. *Atrophy of the optic nerve* has occasionally been observed even in young diabetics.

b) Diseases of the Nervous System

α) Emotional Disturbances

Depression can be caused by the patient's realization that he has an incurable disease, by increasing fatigue and weakness and by the possible association of sexual impotence. On account of this, patients with severe diabetes often assume a hopeless attitude at the onset of treatment. However, after a few days of intensive therapy when strength and hope of surviving are restored, this mood changes.

Diabetes mellitus can be found combined with all types of functional and organic disorders of the nervous system. According to BLEULER, there is a positive correlation with manic-depressive illness, arteriosclerosis, and senile psychoses, and a negative correlation with schizophrenia, oligophrenia, and possibly also with epilepsy. In any case, depression occurs frequently, and we have the impression that the duration of the depressive phase can be shortened by good control of the diabetes.

β) Disturbances of the Sense Organs

The visual disturbances have been discussed in Sect. a. *Olfactory disturbances* are demonstrable in over 60% of long-lasting cases of diabetes. The *taste* threshold is elevated for glucose but normal for table salt. *Impaired hearing* without inflammatory changes in the ears have been confirmed even in young diabetics. The acoustic nerve is selectively involved, the vestibular nerve almost always spared.

γ) Diabetic Neuropathy

This term includes peripheral, central, radicular and medullary symptoms, as well as those of the autonomic nervous system. A really satisfactory classification is not possible, since this condition has an exceptionally polymorphous symptomatology, its pathogenesis is not clear and the histology is inconsistent. Depending on the predominant clinical features, the terms mono- or polyneuropathy, encephalopathy, enteropathy, radiculopathy and so on are used. The old description "diabetic pseudo-tabes" remains a fitting term for some cases.

Pains arise mainly in the lower extremities, often on both sides, sometimes symmetrically. They are described as dull, cramp-like, tearing or burning; they typically occur during the night and disappear when the patient gets up and walks. They are preceded long in advance by a phase of paresthesia, a feeling of coldness, numbness, prickling or burning. Hyperesthesia may become tormenting, and anesthesia can lead to severe burns.

The objective findings are diminution or loss of tendon reflexes, especially of the ankle and knee jerks, and reduction of the sensation for vibration, especially in the feet. There are also hypesthetic and anesthetic zones, mainly in the lower limbs, and in certain conditions

there is an increased sensitivity to pressure of all the muscles at their points of insertion. The ankle-jerk reflexogramm is retarded in the absence of hypothyroidism, and the conduction rate of the motor nerves is delayed even in young diabetics.

Weakness of the peroneal muscles is not infrequent, but paresis or paralysis of any other muscle or of any of the cranial nerves with the exception of I and XII do occur. The cranial nerves III and VI are involved most frequently. In contrast to pains and paresthesia, paresis and paralysis are usually unilateral.

The *amyotrophic form* of diabetic neuropathy causes atrophy of the pelvic and pectoral girdles in particular, but also of the muscles of hand and feet.

In exceptional cases, all these symptoms can precede the clinical manifestation of diabetes.

Pupillary disturbances are common, but a typical Argyll-Robertson reaction is rare. The atony of the stomach – *diabetic gastroparesis* – leads to delayed emptying of the stomach and to retention of food, making good control of the diabetes impossible. This is occasionally accompanied by *diabetic enteropathy*, with its nocturnal or postprandial diarrhea (*diabetic diarrhea*) or nocturnal incontinence of stools or severe chronic *constipation*. Objective findings are peripheral neuropathy, sometimes accompanied by symptoms involving the autonomic nervous system, such as *abnormal sweat secretion*, orthostatic or positional *hypotension* and *diabetic arthropathy*. Intestinal X-rays may show a so-called malabsorption picture and/or a large hypotonic stomach (gastroparesis diabeticorum). The differential diagnosis has to exclude atony of the anal sphincter, exocrine pancreatic insufficiency, and sprue.

Dystonia of the urinary bladder due to weakness of the detrusor muscle can be recognized cystometrically and may lead to atony of the organ. Early recognition of this condition is important in order to prevent secondary infections.

The neurogenic forms of impotence, sometimes associated with retrograde ejaculation, is another manifestation of diabetic neuropathy.

Callosities of the feet, usually localized over the heads of metatarsal bones, are generally painless. They develop even in feet with well preserved circulation. They often precede *trophic ulcera*, the so-called "mal perforans".

Neuropathic joint changes analogous to CHARCOT's arthropathy are found in the ankle, the tarsal and the tarso-metatarsal joints, rarely in the knee. They are clinically characterized by sometimes extensive destruction of bones and joints in the absence of osteoporosis, osteomyelitis or infection. The blood supply is sufficient. Swelling occurs in the absence of inflammation, with neither tenderness nor temperature changes prominent.

Diabetic osteopathy, mainly localized in the feet, reveals spontaneous fractures and/or atrophy of the phalanges on X-ray examination.

Minor injuries, repeated and unnoticed for a long time by the hypalgesic patient, are considered the *cause* of callosities, arthropathy and osteopathy (p. 799, 800).

Disturbances of the autonomic innervation can cause inactivation of the sweat glands, loss of vaso- and pilo-motor functions, reversal of temperature gradients of the skin, formation of *edema*, *orthostatic hypotension* with or without *orthostatic tachycardia*, and *night sweats*, in circumscribed areas of the body only.

Most patients with diabetic neuropathy present an increase in the protein content of the *cerebrospinal fluid* with normal cell count.

There are no pathognomonic signs for diabetic neuropathy, so that diagnosis must be reached by a process of elimination. Therefore, the differential diagnosis deserves close consideration.

The relations between the diabetic neuropathy and the severity of the metabolic disorder are not clear; with longer duration neurological changes increase in frequency.

The prognosis is good for the majority of patients with paralysis. Paralysis involving the cranial nerves generally recedes in 6–12 weeks. The amyotrophic forms of the pelvic and shoulder regions regress within 3–18 months, in contrast to those involving the distal parts of the lumbs, hands and feet, where there is little chance of recovery. The prognosis is unpredictable for neurogenic impotence and diabetic enteropathy. Urinary bladder atony in young diabetics may disappear when good control of the diabetes is achieved. In elderly people, cholinergic drugs, e.g. carbachol up to 16 mg daily, can be tried. If this fails, resection of the internal sphincter of the bladder seems indicated. Opium in the form of drops, or Reasec, and disinfection of the bowels with sulfonamides, neomycin or chloramphenicol have been recommended for diabetic diarrhea.

The effects of sodium dithiocaprylicum and vitamin B_{12} on the pains are still not clear. The former drug is injected intravenously in a dose of 40–50 mg twice daily for one week, and is repeated if indicated. 1000 γ of vitamin B_{12} are given intramuscularly for five days. Good control of the diabetes is perhaps the most important factor. Insulin also appears to be more effective here than the oral antidiabetic agents.

In addition to treatment with diet, insulin and vitamins, orthopedic measures may be necessary in some cases of arthropathy to obtain reasonable equilibrium.

c) Disorders of the Cardiovascular System

The larger arteries of diabetics present a more extensive and severe atherosclerosis than the vessels of non-diabetics of the same age group. Heavy calcifications are found more frequently in the medium-sized arteries, and the obliterative endothelial proliferation is most striking in the arterioles. Swelling of the endothelial cells and thickening of the basal membranes are typical findings in the capillaries. This microangiopathy seems to affect all tissues of the body.

The relations between diabetic angiopathy and arteriosclerosis and the development of vascular changes prior to clinical diabetes have been discussed on p. 791. The connections between fats, proteins, lipoproteins and glycoproteins of the blood, with diabetic angiopathy have still not been fully explained.

In young diabetics, the angiopathy generally first becomes clinically apparent in the eyes and kidneys; in elderly patients disorders of the heart, lower extremities, and brain are predominant.

α) Peripheral Vascular Disease

Every peripheral circulatory disorder demands a careful examination for diabetes. The clinical features, with the exception of a few peculiarities (frequency of gangrene and preference for the smaller peripheral vessels), do not differ from those of arteriosclerotic or endarteritic angiopathy. They can be found in monographs (RATSCHOW, 1959; KAPPERT, 1960). They are usually treated medically and surgically in the same way, with the exception of the optimal control of the diabetes.

The true form of diabetic angiopathy is found particularly in the lower extremities. It can also arise combined with or released by infections in the upper limbs, in the skin, in the face and in the vulva or penis when the diabetes is uncontrolled.

Tissues of an extremity with a poor blood supply are easily injured. This is true particularly in diabetics with diminished sensitivity for pain and heat as a consequence of their neuropathy. Slight injuries, foot mycosis, corn plasters, too hot a foot bath or exposure to cold can produce ulceration on the feet. As soon as the continuity of the skin is interrupted there is danger of infection.

Fissures, sometimes very painful, are mostly localized on the heels and are often produced by putting on shoes without unlacing them sufficiently.

Gangrene, the necrosis of tissue, follows the obliteration of a vessel, and may be precipitated by mechanical, chemical or thermal trauma, or by infection.

Prevention is better than cure. Prevention of diabetic angiopathy consists in establishing precise control of the diabetes as soon as possible, in maintaining this control and avoiding injuries. Protection from excessive heat and cold, good care of the feet, treatment of foot diseases and deformities are important prophylactic factors.

Since the introduction of insulin, gangrene arises on average 10 years later than previously. The importance of good treatment of the diabetes can not be overemphasized. Insulin appears to be more effective than oral antidiabetic drugs.

We use vasodilating drugs orally, intramuscularly or intravenously, to improve collateral circulation. Sometimes, these drugs are given as an intra-arterial injection or infusion. The value of the long-term treatment with anticoagulants has not yet been proven. Total abstinence from nicotine is important. When indicated, the patients are referred to a vascular surgeon for a unilateral lumbar sympathetic ganglionectomy which may be combined with excision of short sections of obliterated arteries or with endarterectomies. Diabetic neuropathy finally leads to suppression of the peripheral sympathetic function. In spite of this, we use lumbar sympathectomy in earlier stages, which then increases peripheral circulation considerably. The whole treatment of peripheral angiopathy is a fight for time; if we can postpone amputation for some years, a surgical intervention is justified. If the block lies in the femoral artery or higher, bypass operations have proved useful even in diabetic patients. The use of baths, massage, leeches and in particular local treatment with heat or electric currents must be avoided, since they can precipitate gangrene. In general, mummified tissue areas are not excised, and it is advisable to wait for spontaneous segregation. Chemotherapeutic agents and antibiotics are used in the usual dosage. In some conditions, they are applied intra-arterially and/or locally. The local application of trypsin helps to remove necrotic or indurated tissue. In general, we try to keep the affected area as dry as possible.

In infected gangrene major surgery has to be postponed until the diabetes is controlled and general resistance improved. Till then, surgical intervention is limited to draining an abscess or removing a superficial crust. With the help

of quick-acting insulin, antibiotics, and perhaps blood transfusions the patient's condition improves in a few days, whereupon surgical elimination of the entire infection becomes feasible.

However, in the presence of a fulminating, extensive infection, surgery cannot wait so long. A few hours of active insulin therapy, if necessary intravenously, by an experienced physician, and hypothermia to the affected area considerably improve the patient's chances in the emergency surgical intervention.

An amputation is only justified if gangrene is progressing despite all therapeutic measures, optimum control of diabetes with insulin, if the pain does not become tolerable within a few days, or if there is any danger of septicemia.

Any decision on amputation must be made in the knowledge that a patient with severe diabetic angiopathy usually has myocardial damage, which will make the use of an artificial leg difficult and perhaps impossible. Even after a small, partial amputation the other extremity will have to carry more weight. Will it be able to do this despite the angiopathy which is always bilateral? In our opinion, the *most restricted amputations* are only possible after the diabetes is well controlled, but even then we must be prepared to take the risk that further amputations higher up may later become necessary.

McKittrick's advice has stood the test, and atropine must be the only premedication, no local anesthesia, no tourniquet; the stump should be left entirely or partly open after amputation for infection, and a drain should be inserted only when the infection has not been removed. The stump should be closed without a drain after amputations for non infected arterial insufficiency.

Good control of diabetes by diet and insulin with sugar determinations at different times of the day is necessary and will permit good healing of the amputation stump. In addition, any anemia or hypoproteinemia must be corrected.

Thrombophlebitis in the diabetic is treated in the same way as in subjects with normal metabolism, providing the diabetes is well controlled.

β) Hypertension

Hypertension is more common in diabetics than in non-diabetics. Even in growth-onset diabetics, blood pressure is frequently found to be elevated after 20–25 years' duration. Hypertension appears earlier and more frequently when the diabetic treatment is inadequate. Elevation of blood pressure in a young diabetic should always suggest diabetic nephropathy, but one should also consider acute glomerulonephritis, Conn's syndrome and pheochromocytoma. Myocardial infarctions and gangrene are more common in hypertensive than in normotensive diabeties.

The use of salidiuretics of the benzothiadiazine group or of chlorthalidone to reduce blood pressure, may necessitate an increase in the dosage of insulin in some conditions. See p. 794 for orthostatic hypotension.

γ) Heart Disease

Diabetes is very often accompanied by aortic and/or coronary sclerosis. This occurs in diabetic men and women with equal frequency whilst it is rare in non-diabetic female patients.

The frequency of coronary sclerosis and thrombosis increases with the duration of diabetes and with poor quality of treatment. Myocardial infarction in a woman before the menopause suggests diabetes mellitus. *Coronary thrombosis* is the most common cause of death in elderly diabetics.

The *prognosis* of coronary sclerosis is greatly dependent on the quality of the antidiabetic treatment.

Reduction of weight in overweight patients, the exclusion of nicotine, and removal of infections, especially of the urinary tract, are important. Reduction of body weight and of blood sugar must be carried out cautiously. The diet should be poor in fats but relatively rich in carbohydrates. Hypoglycemia must be avoided, since severe falls in the blood sugar can precipitate myocardial infarction. Patients with heart disease often feel better with a slightly elevated than with normal blood sugar levels. Therefore, the insulin dosage must be carefully, adjusted considering also the subjective feeling of the patient.

d) Diseases of the Kidneys and the Urinary Tract

The collective term "*diabetic nephropathy*" appears to be appropriate since the renal changes found in diabetes mellitus are so polymorphous. It is now the most frequent cause of death in growth-onset diabetics.

Intercapillary glomerulosclerosis was described by Kimmelstiel and Wilson as characteristic patho-anatomical changes in the kidneys (see p. 768). Both glomerular and tubular functions are limited. Glomerulosclerosis is found in diabetics who have been treated with insulin and in others who have never received this hormone. The duration of diabetes, and possibly its intensity, the quality of treatment, the stage

at which it was started, and urinary-tract infections influence the development and course of glomerulosclerosis.

The *diagnosis* of glomerulosclerosis is a histological one. During life it can only be confirmed by renal biopsy. The condition can be suspected when there are clinical symptoms of a nephrotic syndrome, such as albuminuria without particular findings in the sediment (apart from the bi-refractive lipoids [Maltese crosses]), hypoproteinemia with edema and hyperlipemia, associated with hypertension, azotemia, and retinopathy; sometimes only a few of these symptoms are present.

The prognosis is bad. We know of no means which will halt this condition, which lasts for 2–12 years, on average 6–7 years.

Treatment is directed at trying to eliminate any accompanying infection. As long as there is no retention of nitrogen, one aims at compensating the protein loss as far as possible with a diet relatively rich in proteins and poor in sodium. In the presence of azotemia, the protein intake must be reduced, but not below 0.5 g/kg body weight. In uremia, numerous different methods of estimating the blood sugar give values which are too high.

The terminal phase of the condition is occasionally accompanied by a striking improvement of carbohydrate tolerance. Various factors have been suggested as the cause of this: delayed elimination of insulin through the urine, accumulation of the guanidine bodies, increased permeability of the cells, facilitating the transport of glucose into the tissues in the absence of insulin, increased excretion of proteins binding insulin, and reduction in the caloric intake.

Diabetics seem more susceptible to infections, which frequently involve kidneys and urinary tract. There may be inflammation of the renal pelvis, the ureters, the bladder, the ovaries, and the urethra, as well as the formation of abscesses in the perirenal tissues, in the kidneys, and the prostate etc. Some of the former infections may easily be missed if they cause no subjective symptoms.

The *necrosis of the renal papilla* is fairly typical of diabetes mellitus. It affects women more frequently. The diagnosis must be considered if severe renal symptoms suddenly arise or when a not very active pyelonephritis leads to high pyrexia, hematuria and renal colic, with no other apparent reasons. There may sometimes be particles of renal tissue in the urinary sediment. A retrograde pyelogram shows changes which are more or less characteristic. However, the patient's grave general condition often prevents radiological examination. The only therapeutic measure possible is to combat the accompanying infection with antibiotics.

When the urine is infected, the results of the tests for sugar in the urine are unreliable. *Pneumaturia* is occasionally seen in diabetes. The cloudy urine, looking like apple juice just off the press, contains gas. The patients complain of irritation of the bladder, and of inability to void urine while lying. If the pneumaturia does not disappear after the blood sugar is normalized, atony of the bladder and vesicovaginal or rectovesical fistulae have to be considered.

Dystonia and atony of the bladder: the interval between emptying the bladder increases until the patient must only void urine twice in 24 hours, and then under pressure. Examination reveals residual urine in the absence of obstruction and cystometric hypotension (see Sect. γ).

e) Infections

Diabetics are especially suspectible to infections, which usually increase the insulin requirement. On the other hand the tolerance may improve in extreme conditions with collapse and inanition. Poorly controlled patients are less resistent. With the exception of draining superficial abscesses without anesthesia, surgical procedures must be postponed until the diabetes is under control.

Furuncles and *carbuncles* are so common in untreated diabetics, that their occurrence in non-diabetics must lead to a test for diabetes.

Before insulin was introduced in the treatment of diabetes, many diabetics died of *pulmonary tuberculosis*. The incidence of pulmonary tuberculosis is still twice that in non-diabetics. The flaring up of a tuberculous infection is usually but not always followed by a deterioration of carbohydrate tolerance to the extent that ketoacidosis may develop. Sometimes, the latter precedes the former.

The prognosis of tuberculosis in diabetes has become considerably more favorable since the introduction of insulin, and in particular since chemotherapeutic agents and antibiotics have become available.

Mycosis of the foot is without doubt the most common infection which can precipitate or worsen gangrene. Candida albicans (thrush) is sometimes the cause of *vaginitis* or *balanitis* in diabetics. *Pruritus vulvae* in diabetes is suggestive of fungal infection.

f) Diseases of the Skin

See above about infections. They are treated in the same way as in non-diabetics. A rosy skin on the forehead and cheeks, and sometimes

also on hands and feet is von Noorden's *rubeosis*, an early sign of poorly controlled diabetes. It is caused by dilatation of skin capillaries.

Xanthomatosis, the diabetic xanthoma, may occur, as in any other form of hyperlipemia, in poorly controlled diabetics. They can appear as a dissemination of yellowish, sometimes also reddish, occasionally pruritic or even painful, papules and plaques, which are distributed symmetrically over neck, back, buttocks, elbows, and knees. A low-fat diet and insulin cause the diabetic xanthoma to disappear.

Xanthelasma, i.e. the deposition of lipoids in the eyelids has no connection with diabetic xanthoma. It may be more frequent in diabetics than in non-diabetics.

Tornblom was the first to discover, and Melin the first to describe *diabetic dermopathy* or *circumscribed diabetic skin atrophy*, or the "*spotted leg syndrome*". All these terms depict changes in the skin below the knees on the anterior and lateral aspects of the lower legs and very rarely on the extensor surfaces of other limbs. At first, multiple, reddish, flat papules arise, round to oval in shape, measuring 5–12 mm across and sometimes arranged in a line. Some papules show a central depression and blisters may form. Later, this skin eruption becomes crusted and the typical picture of the disorder does not develop until after a few months; the skin where the papules had been becomes brownish, slightly depressed and covered by an atrophic epidermis. These atrophic areas disappear spontaneously after 1.5 to 2 years.

The differential diagnosis includes freckles and pigmentation due to varicosis.

The cause of these skin changes is not definitely explained. No treatment is necessary.

Diabetic necrobiosis lipoidica occurs mainly in the younger diabetics and particularly in women. In this condition, there are round to oval-shaped plaques, sharply demarcated, with rather shiny atrophic centers. The peripheral areas have a yellowish or reddish colour. As a rule, the skin eruptions occur symmetrically on both sides, and are rarely unilateral. The plaques are sometimes preceded by a stage with reddish papules of only a few mm in diameter, which may increase to 2 cm and often undergo necrosis in the middle. The small ulcers heal after a few weeks and leave dark pigmented scars which may reopen from time to time. The cause of this disorder is unknown. The ulcers heal when the diabetes is well controlled, but not the plaques, which may increase in size. Isoniazid is used successfully in the majority of patients (DEGOS, 1966). If it fails, we use local cortisone creams and injections of diluted solutions of corticoids under the affected skin.

Gray or dark brown pigmentations of the skin suggest hemochromatosis. See Chap. XVIII for diabetes mellitus combined with Addison's disease.

Insulin-induced lipodystrophy has been discussed in Sect. d, and the skin changes during treatment with the sulfonylurea derivatives in Sect. c.

A thickening of the subcutis in the palm of the hands is rarely met in diabetes of long duration. There is a loss of the elastic fibers, but no signs of collagenosis. This *stiff-hand syndrome* (LUNDBAEK) inconveniences the patient especially in the early morning.

g) Diseases of the Digestive System, Including the Liver

Acute pancreatitis can give rise to transitory hyperglycemia and glycosuria with diabetes-like glucose tolerance tests. According to MILLER, 2% of the cases are followed by true diabetes mellitus. *Chronic pancreatitis*, on the other hand, is considered to cause diabetes mellitus more frequently – 13% of the cases of chronic pancreatitis without the formation of calculi, and 45% of the cases associated with calculi formation result in diabetes mellitus. If the period of observation is extended to more than 18 years, about 10% of cases of *necrosis of the pancreas* may develop diabetes (BERNHARDT). Conversely, acute pancreatitis can lead pre-existing diabetes to develop rapidly into keto-acidosis.

Carcinoma of the pancreas is 3–4 times more frequent in diabetics than in non-diabetics.

Hepatomegaly is a sign of poor control, especially in young diabetics. The histological findings reveal steatosis in the majority of the cases, and glycogen infiltration in a few cases. Good control of the diabetes results in the rapid regression of the enlarged liver. Overdosage of insulin for many years is said to produce glycogen infiltration.

h) Diseases of the Sexual Organs

Menarche arises about a year later in diabetics, and the *menopause* occurs a few years earlier than in non-diabetics. Hormonal *contraceptives* worsen the metabolic state only slightly, however, and perhaps only temporarily. Today, the *fertility* of well controlled diabetic young men and women is almost normal. However, there is a precocious loss of potency in the male, even during middle age, sometimes followed by loss of libido. A reduction of libido and of the

capacity to reach orgasm is met in diabetic women too, although much less frequently than in men.

Temporary impotence due to the loss of strength in uncontrolled diabetes disappears with proper antidiabetic treatment. We more frequently encounter *chronic impotence* on account of weakness or lack of erection. This usually occurs in diabetics with peripheral angiopathy. More rarely, so-called "retrograde ejaculation" is found as a consequence of diabetic neuropathy, i.e. an increasing amount of the ejaculate, and finally all of it, flows back into the bladder, due to insufficiency of the internal sphincter. Large numbers of sperms can be found in the urine voided thereafter. In addition to these vascular and neurogenic factors, psychic stress and hormonal disorders may also be of importance. SCHÖFFLING and his team found that the testes were reduced in size in almost 1/4 of the impotent diabetics, and that the prostate was enlarged in about a third. Hypogonadotropic hypogonadism, however, has not been confirmed with certainty. The prognosis of neurogenic impotence is poor, it is doubtful in angiogenic impotence in patients over 50.

The Klinefelter syndrome, though rare, is sometimes found combined with diabetes mellitus. The same applies to gonadal dysgenesis and to Turner's syndrome (see p. 713). The cause of these combinations is unknown.

Vulvitis or balanitis are often the first symptoms leading to the detection of diabetes.

i) Diseases of the Other Endocrine Glands

Refer to Chap. XVIII for diabetes in other endocrinopathies.

k) Diseases of the Blood and of Hemopoiesis

The pale face of many patients with diabetes of many years' standing is not due to anemia, but rather to narrowing of the cutaneous vessels. *Anemia* can, however, easily be overlooked due to rubeosis or xanthosis. There are no morphological changes of the blood picture typical to diabetes mellitus. *Pernicious anemia* is not uncommonly found combined with diabetes. This combination occurs too frequently to be explained by mere coincidence, and it is striking that both diseases can be familial and can also arise in combination with hypothyroidism and with the nontuberculous Addison's disease. This may indicate that the disease is an autoimmune illness (see Chap. XVIII). Diabetics more often suffer from a *normochromic macrocytic form of anemia* which is difficult to treat.

l) Diseases of the Bones and Joints

The term "*diabetic foot*" describes a swelling in the region of the ankle joint, which occurs infrequently, develops slowly without pain, and results in a typical valgus position of the externally rotated foot. Another form which develops acutely with pain and reddening of the skin and with a rise in temperature is considerably less frequent. The diabetic foot is due to a diabetic arthropathy and osteopathy of tarsal bones.

More frequently, the *diabetic osteopathy* is found in the metatarsals and the phalanges where the diaphysis joins the epiphysis. The distal regions of the metatarsal and the proximal areas of the phalanges are the most common sites for these changes. Often osteopathy is accom-

Fig. 18a. Diabetic foot

Fig. 18b. X-ray of the diabetic foot

panied by trophic ulcers, – mal perforant – or by its preceding stages, and by thickening of the skin areas exposed to great pressure. These concomitant features are not the cause but the results of the bony changes. The bones are osteoporotic and there are signs of osteolysis which leads to fragmentation or rupture of the cortex and to secondary changes in the joints, sometimes with incomplete dislocation. This displaces the toes, dorsally and backwards, leading to noticeable shortening of the foot. Reparative periosteal reactions with the formation of new bone by the periosteum or osteophytes are rare.

Clinically there is relatively little pain. Often these symptoms are combined with diabetic angio-, neuro- and retinopathies. Recurrences in the same or in the other foot, sometimes after years, are common.

The cause of the diabetic osteopathy is not quite clear and perhaps not always the same. Neurogenic disorders cannot explain all the symptoms. In the American medical literature, the term Charcot's joint is used, suggesting a neurogenic mechanism. In addition, angiopathic changes, and in some cases infections or repeated injuries of hypalgetic tissues may be involved. The fact that the condition is usually localized in the lower extremities stresses the importance of mechanical strain.

The diabetic foot is treated by orthopedic measures. Parsons has recommended lumbar sympathectomy. The bone fragments loosened by osteolysis are sometimes spontaneously cast off, leaving a healed but shortened toe.

Osteoporosis is frequently seen in adult diabetics, and at an earlier age than in healthy people. We suspect that a diet insufficient in calcium for many years may explain this.

m) Tumors

With the exception of carcinoma of the pancreas, which occurs 3–4 times more frequently among diabetics, the incidence of benign and other malignant tumors does not seem to be greater

in diabetics than in nondiabetics of the same age groups. Carcinoma of the endometrium is discussed on p. 776.

8. Marriage, Pregnancy, and Birth

Diabetes mellitus is no reason for staying single. If diabetics marry each other, or someone with a family history of diabetes, they should refrain from having children of their own.

Large babies (birth weight 4.5 kg or more), still births, and neonatal deaths suggest diabetes mellitus, since they are so often observed in women who later develop clinical diabetes, sometimes after 30 years or more.

Before the introduction of insulin, pregnancy was very rare indeed in diabetic women; it usually ended in fatal ketoacidosis. Today, diabetic women's fertility is normal. In our experience at least, the number of spontaneous abortions is not increased, but premature birth and intra-uterine death during the last quarter of pregnancy and neonatal deaths cause an increased loss of babies.

a) Effects of Pregnancy on Diabetes

Pregnancy has a diabetogenic effect, but only in the sense that a potential or latent or subclinical disease may become clinically apparent. This is supported by observations that diabetes is more common in married than in single women, and that its frequency increases with parity. In uniovular diabetic twins, the one with earlier and more pregnancies develops clinical diabetes before her twin sister. Organic hyperinsulinism improves during pregnancy.

Every growth process involves an increased insulin requirement. The higher number of granula, hyperplasia of the B-cells and the raised IRI in the blood during late pregnancy are signs of elevated insulin production. During pregnancy, in nondiabetic women too, the insulin content of the blood is found to be considerably higher in the fasting state and after an intravenous injection of glucose.

Why is the insulin requirement increased during pregnancy? Refer to p. 86 for the diabetogenic properties of growth hormone. The growth hormone produced by the pituitary is not increased during pregnancy; but a hormone with similar chemical and active properties is formed in the placenta (the human placental growth factor) and found in the blood (see Chap. V, p. 84, and Chap. XI, p. 677).

Growth hormone and the glucocorticoids are hormonal antagonists to insulin, which cause hyperglycemia and an increase of the IRI in the serum. Placental tissue also seems capable of binding and breaking down insulin. Insulin is essential for growth, the growth hormone having an anabolic effect only in the presence of insulin (see p. 88).

Probably, the diabetogenic action of pregnancy is due to the unknown placental growth factor and perhaps also to glucocorticoids. This would explain why latent diabetes is often recognized during pregnancy, and why it seems to "disappear" after delivery. However, diabetes is not cured, even if the fasting blood sugar values are normal and the urine contains no sugar. Suitable tolerance tests demonstrate a latent diabetes. Treatment is essential in these cases, as otherwise the diabetes will become overt within a few years. JOHN states that 60% of women showing temporary glycosuria during pregnancy, develop clinical diabetes 1–25 years later.

Pregnancy increases the intensity of preexisting clinical diabetes. Today, the raised insulin requirement can be checked by adaptation of the insulin dosage. The fact that the quantity of insulin often needs little or no adjustment, sometimes even a reduction, can be explained by intensified medical supervision and improved dietary discipline of the patient.

In addition to increasing the insulin requirement, pregnancy can also lead to a *fall in the renal threshold for glucose* and to *lactosuria*. During gestation, there is an increased risk of urinary tract infection and renal failure.

About a quarter of all women show glycosuria during the course of pregnancy (FLYNN). This can be a *renal*, i.e. *normoglycemic glycosuria*, a so-called glycosuria of pregnancy. It is characterized by the constant excretion of abnormal amounts of glucose in the urine, despite normal or subnormal blood-sugar levels in the oral glucose-tolerance tests. Pregnancy leads to a physiological increase of the glomerular filtration rate. If the tubular capacity to reabsorb the filtrated glucose is exceeded, renal glycosuria occurs in healthy subjects as well as in diabetics. After delivery, this glycosuria disappears.

Since MILLER observed 4 still births and 3 overlarge babies in 11 pregnancies with normoglycemic glycosuria and Pomeranze saw a woman with glycosuria of pregnancy who developed clinical diabetes 14 years later, the question has arisen of whether some of these patients, or perhaps all of them, should not be considered potential diabetics. This question is not yet settled, and so far, glycosuria of pregnancy remains suspect of potential diabetes, requiring long-term medical supervison.

A fall in renal threshold may, but does not necessarily, develop during pregnancy in women

with clinical diabetes. In this event, more blood-sugar estimations are needed to control the diabetes. Occasionally, the renal component of glycosuria is so strong that the carbohydrate intake must be increased to avoid ketoacidosis. After delivery, the renal threshold reverts to the previous level.

Lactosuria is found only during the last days of pregnancy and during lactation. It may affect urine tests. Chromatography can reveal small amounts of lactose in the urine even several weeks before delivery. In addition to lactose, galactose is also eliminated in the urine; if large amounts are present, even urine tests based on oxidase methods (e.g. testape), become unreliable.

The tendency to infections of the urinary tract is especially high in pregnant diabetics. They are treated in the same way as in nondiabetics.

The majority of growth-onset diabetics die of renal failure. Pregnancy is very dangerous in women with renal damage, and especially for diabetics with impaired renal function.

Diabetes mellitus as such is no indication for termination of pregnancy, nor even is ketoacidosis, which would only be exacerbated by surgery. Diseases of the kidneys or heart may render the continuation of pregnancy dangerous or impossible in diabetic and nondiabetic women alike. The stress of pregnancy weighs more in a diabetic than in a normal woman. Therefore, the number of pregnancies should be limited to 2, in favorable circumstances to 3 in diabetic women.

The *treatment of diabetes during pregnancy* is based on a diet of 180–250 g of carbohydrates and 1.5–2 g of protein per kg body weight, with so little fat that the weight increase remains within the physiological limits, i.e. at the beginning 1 kg per month, and 1.5 kg per month during the last trimester. Table salt is reduced or omitted in case of water retention. Acetonuria is treated by an increase in carbohydrates and reduction of fats in the diet and if necessary an augmentation of insulin.

In early diabetes, when diet and exercise alone are insufficient to control the diabetes, insulin is used. During the first 3 months of pregnancy, insulin is adjusted cautiously to avoid hypoglycemia. Later we try to keep the blood sugar as close as possible to normal limits. Oral hypoglycemic drugs are eliminated (see p. 783).

Signs of a *late toxicosis* (preeclampsia) must be treated by bed rest, a salt-free diet, and when necessary, hypotensive drugs and salidiuretics. It may sometimes be necessary to increase the dosage of insulin.

As soon as delivery is imminent, the daily or twice-daily insulin injections are replaced by 3 injections of soluble insulin. If labor starts while the patient is still under the influence of long-acting insulin, an intravenous dose of fructose must be substituted for the missed meal.

There is usually a pronounced but temporary decrease in the insulin requirement immediately after delivery, whether delivery is vaginal or by cesarian section. This seems to be due to the loss of the placental growth factor.

b) The Influence of Diabetes on Pregnancy

Before the insulin era, the *mortality rate of the mothers* was as high as 45% (GILBERT and DUNLOP), whereas today, the lowest mortality figures are 0.3–0.7%, in comparison to those of 0.32–0.37 for nondiabetic women.

According to WHITE, only one in three untreated diabetics has a chance of producing a live child. The *mortality rate of the children* largely depends on the experience, knowledge and cooperation of the team consisting of diabetologist, obstetrician, anesthesist and pediatrician.

The course of the pregnancy to the 30th week is usually normal, with the exception of the susceptibility to infections. Hyperemesis in the early stages of pregnancy does not appear to be particularly severe or frequent. It usually requires adaptation of insulin to the irregular food intake.

The main obstetric difficulties occurring during the last 6–9 weeks are:

1. increased tendency to hydramnios;
2. increased tendency to toxemia;
3. macrosomia or microsomia of immature infants;
4. intra-uterine death (RUST).

The frequency of *hydramnios* in normal pregnancy is estimated at 0.5–1%, in diabetics at 19%. As mentioned above, WORM and SIEGELER showed how hydramnios can be avoided by adequate insulin therapy.

The frequency of toxemia in nondiabetic women is reported to be about 10%; in diabetics, according to the literature, it is 8–48%. Prevention, i.e. avoid of abnormal increase in weight, seems very important. A gain of 400–500 g per week suggests toxemia and calls for admission to hospital. If bed rest does not lead to increased urine volume and to weight loss, diuretics are indicated, even if they increase the requirement of insulin still further.

Nephropathy present before pregnancy considerably increases the risk of toxemia. The infants of diabetic mothers with nephropathy

are small whilst those of diabetic mothers with good renal function are generally considerably larger and heavier, but more immature than children of healthy women with the same duration of pregnancy.

The most frequent and the most deceptive complication is intra-uterine death. According to HAGBARD, this occurs before the 35th week in 3% of cases, but the risk increases with every week and reaches 25% after the 37th week. Neonatal mortality, however, decreases from 19% in infants delivered between the 33rd and 34th week to 11% with delivery during the 35th and 36th week. *Placental insufficiency* is considered the main cause of intra-uterine death.

If fetal movements decrease in intensity and frequency this is a sign for alarm. If the time intervals between the fetal activity felt by the mother grow longer, the life of the child seems to be in danger. Bed rest for the mother, if necessary combined with inhalations of oxygen, up to 8 liter/min for 10–15 min, 2–8 times daily, seem to help the fetus, but this is a clinical impression only and we do not know the mode of action of oxygen therapy.

Some indication of placental function is obtained by measuring urinary estriol elimination. If it falls below 8 mg/24 h during the 35th week or later, the life of the fetus is in danger; according to KYLE, values below 4 mg were always followed by fetal death within 48 h.

The value of ovarian hormone therapy is controversial. We have never used the doses indicated by WHITE, because the effectiveness of this treatment has not been proven and damage to the fetus not definitely excluded. If the estrial excretion diminishes, we give 40 mg of estrogen daily per os and up to 250 mg hydroxyprogesterone i.m.

Choosing the optimal time and the best mode of delivery is the main obstetric problem in diabetic women, i.e. the time when the risk of postnatal immaturity of the newborn is about equal to that of intra-uterine death. Before the 35th week, the chances for neonatal survival are small, after the 38th week, intra-uterine death becomes frequent.

The following factors should be taken into consideration in determination of the time of delivery:

1. obstetric history of the mother;
2. the evolution of the present pregnancy in regard to complications and diabetes. A sudden drop in the insulin requirement during the last weeks, for instance, may indicate impending intra-uterine death;
3. comparison of the risk of intra-uterine death against postnatal prematurity. To evaluate this, fetal movements, excretion of estriol in the urine examination of the amniotic fluid and changes in insulin requirement give valuable hints.

The most frequent time of delivery is three weeks before the normal term. We allow young women whose diabetes has been discovered during the course of the current pregnancy, who have never before had any perinatal loss and whose pregnancy is progressing normally to go on to term, but never past the 40th week. However, an obstetric history with one or more stillbirths calls for induction of labor before this, as does diabetes with vascular damage, since these women are obstetrically older than their age and therefore more prone to fetal loss.

The determination of the duration of the pregnancy is much more reliable in women who know the date of conception exactly, because they have recorded their morning rectal temperature regularly. In such cases, we consider 268 days the normal duration of pregnancy.

An indication of sufficient maturity of the fetus is given by the appearance of the distal femoral ossification centers on X-ray examination. If possible, we postpone the delivery until they are visible, usually 3–4 weeks before term. We have never lost a newborn baby delivered after the ossification centers had become recognizable.

Normal delivery, if proceeding without complications, involves the least stress for both mother and child. Cesarean section involves the risks of any major surgical procedure, which have been reduced considerably by experience and modern anesthesia. The uncertainty of prognosis for delivery per vaginam increases with the severity and duration of the diabetes and with the prematurity of the infant, whilst the duration of cesarean section and the stress involved are known beforehand.

We consider a cesarean section indicated:

1. if the mother has previously lost a child before or during labor;
2. if the relative positions of head and pelvis are unfavorable or the position of the fetus is abnormal;
3. in primiparae aged 28 or ever;
4. if rapid delivery is urgent;
5. if delivery is necessary 4–5 weeks before term or earlier. Table 2 summarizes our personal experience.

Early vaginal delivery is started by oxytocin drip, often combined with surgical rupture of the membranes. Delivery should be completed within 12 hours.

Before cesarean section, the only premedication is atropin. No opiates or barbiturates are given. General anesthesia is started by Pentothal (penthiobarbital sodium); after delivery of the

child, usually 6–8 min after the beginning of general anesthesia, we give nitrous oxide and oxygen.

The *puerperium* is the same in diabetic as in nondiabetic women. Breast-feeding is more difficult for the former.

c) Influence of Maternal Diabetes on Fetus

Diabetic embryopathy must be differentiated from diabetic fetopathy in the children of diabetic mothers.

Malformations resulting from diabetic embryopathy are three times more frequent than similar malformations in the general population. The incidence of fetal malformations is 6 times higher. The rate of congenital abnormalities in our own observations was 12.8%. They are not uniform in character. Those affecting the heart seem to be preponderant. We have seen several cases of deformations of the ear lobes and preauricular appendices, which, in two children, were combined with a congenital facial paralysis. The teratogenic agent of the embryopathia diabetica is unknown; we do not know whether too much or too little sugar is of any importance.

The frequency of intra-uterine death in children of diabetic mothers during the last weeks of pregnancy and the increased occurrence of stillbirths in the same family underline the importance of the fetopathia diabetica. If such children are delivered in a macerated state, pathologico-anatomical investigations yield little information. Often children may be born alive, but have little resistance and die within a few hours or during the first two days. Some are born in a condition resembling hydrops congenitus, they are swollen, flaccid, adynamic, cyanotic, dyspneic and hepatomegalic. Another group, in which prognosis is considerably better, shows macrosomia with a cushingoid hydropic appearance, which may be seen also in macrosomia with normal or even subnormal weight. These newborn infants have a tomato-coloured bluish red and thick face with flaccid cheeks and double chin; the neck is hidden by an accumulation of adipose tissue on chin and chest; hair is highly developed, covering the skull like fur extending down to the frontal and temporal regions.

Some authors attribute the macrosomia to maternal hyperglycemia. During the last weeks of pregnancy, fetal blood sugar is only a little lower than the maternal value. The high blood sugar of the fetus stimulates the β-cells of the pancreas, thus increasing their number and insulin production. This leads to an increased formation of glycogen in the liver and in the musculature and enhances fat and protein synthesis. There may be other factors contributing to macrosomia, such as adrenal activity. In a child who died 3 hours after delivery, WILLI observed suprarenal glands which were almost the size of the kidneys and weighed 17 g. This perhaps explains the Cushing-like appearance. However, the hypertrophy of the adrenal glands may also be a consequence of hyperglycemia.

Only a minority of the children of diabetic mothers are exempt from macrosomia. The birth of a small baby to a diabetic mother may indicate maternal nephropathy.

Immaturity and decreased vitality are typical of children of diabetic mothers. They are more immature than their weight and the duration of pregnancy would suggest. The discrepancy between anatomical oversize and functional weakness is a striking feature of macrosomia (WILLI, 1965).

Erythroblastosis in the blood, and extramedullary hematopoiesis in various organs, mainly in liver, spleen, lymph glands and kidneys, are typical signs of immaturity. The same is true of the delay in the development of ossification centers.

Immatury and reduced vitality make adaptation to extra-uterine life more difficult. Birth injuries are more frequent on account of immaturity and macrosomia.

The respiratory distress syndrome, due to the formation of *hyaline membranes*, is a relatively common cause of postnatal death. Its pathogenesis has not yet been fully elucidated. It is always accompanied by respiratory and metabolic acidosis. A pH value of less than 7.15 is an ominous sign.

During the first 6 hours after delivery, the blood sugar of the newborn falls, sometimes to as little as 20 mg%, without causing hypoglycemic symptoms. In spite of glucose administration, the blood sugar of these premature infants may remain below 40 mg%.

Another remarkable feature is the fall of the blood calcium level which frequently reaches pathological levels 6–8 hours after delivery, thus causing hypocalcemic tetany; this, however, generally remains latent. It is recognizable clinically by tremor and excessive mechanical irritability of the peripheral nerves.

About one third of our children develop *hyperbilirubinemia* of over 15 mg%, which is due to the inability of the immature liver to conjugate bilirubin during the first days of extra-uterine life. In contrast to morbus hemolyticus, hyperbilirubinemia reaches its maximum only after 3–4 days.

During the first day, edema may develop, although the newborns urinate abundantly,

lose weight and take little fluid. Apparently, much water moves from the intracellular to the extracellular space, causing hypervolemia, a great strain on the heart which may show considerable dilatation. All these difficulties during the change from intra- to extra-uterine life are transient and generally subside within 8 days.

Treatment of Newborn Infants of Diabetic Mothers. Immediately after delivery, whilst the umbilical cord is tied, the head is kept low and the body wrapped in warm towels; nose, mouth, throat and upper respiratory tract are vigorously aspirated. After a cesarean section, the stomach must be emptied. In case of cyanosis, oxygen is administered. Then the infant is placed naked in an incubator and treated like a premature baby. However, this is not necessary for children who are mature or have been delivered only 1–2 weeks before term.

If no respiratory distress syndrome develops, the infant is taken out of the incubator 12–24 hours later. If cyanosis and dyspnea increase, oxygen administration is increased to 30%, maximum 40%, but never for longer than is absolutely necessary, since too much oxygen may favor the formation of hyaline membranes. The humidity of the air in the incubator is increased to 90–100%, because oxygen therapy leads to exsiccation of the mucous membranes.

The presence of severe metabolic acidosis (base excess more than −10 mEq) demands i.v. injection of sodium bicarbonate in 10% glucose and repeated checks of pH and base excess in the arterial blood. In very severe cases, prolonged and controlled artificial respiration may prove lifesaving.

General conditions permitting, food intake begins at the latest 8 hours after delivery; it is delayed in case of respiratory distress syndrome. At first, the infants receive 5% glucose orally, 10 ml 5 times during the first 12 hours, and later breast milk. Early and abundant glucose intake is believed to prevent severe hyperbilirubinemia and metabolic acidosis.

If hyperbilirubinemia exceeds 20 mg%, exchange transfusion is necessary.

Hypocalcemic cramps are treated by i.m. injections of 3–5 ml of 10% calcium gluconate, acute *dilatation of the heart* by i.m. injection of 0.5 ml Cedilanid 1–3 times, or oral administration of 4 drops 3 times, during the first day, later on 2 drops 3 times daily.

9. Infantile and Juvenile Diabetes Mellitus

Diabetes mellitus which develops in the still immature organism, is characterized by its tendency to develop ketoacidosis and by the lability of blood sugar. It easily leads to hepatomegaly, retarded growth, and the relatively early appearance of the long-term diabetes syndrome. Gastrointestinal disorders and infections are quite common at this age and cause significant variations in carbohydrate tolerance. It is surprising how easily children can adjust themselves to the necessities of the disease. Difficulties most commonly start at puberty.

In contrast to *neonatal glycosuria*, *congenital diabetes* is very rare. It is claimed that 80% of newborn infants show glycosuria before the first feed (see p. 774). Towards the end of the second week, in premature babies a little later, neonatal glycosuria disappears.

Clinical diabetes may appear at any age. Periods of rapid growth between the 5th and 7th, and the 10th and 14th year are preferred. Girls develop the disease rather earlier than boys.

After an infectious disease or an immunization, but usually quite unexpectedly, children lose their appetite, start to wet their beds again or develop severe constipation, symptoms followed within a few days by polyuria, polydipsia, weakness, weight loss and the signs of precoma.

Temporary glycosuria, postprandial hyperglycemia and abnormal glucose tolerance tests can be detected months or even years in advance. The renal threshold for glucose is often decreased, while the fasting blood sugar may remain normal for a long time. The diagnosis must therefore be made with the aid of *blood sugar determinations after meals.*

According to their height, their formation of ossification centers and their dental development, the majority of diabetic children show advanced growth compared to normal ones at the time clinical diabetes is discovered. As the illness progresses, this situation is reversed, unless early good control assures continuation of growth.

Without treatment, the majority of growth-onset diabetics die within a few days to weeks from ketoacidosis. When treatment is started early, the diabetes is usually successfully under control within a few weeks with the help of diet and insulin. The following improvement of tolerance sometimes enables patients to maintain normal blood sugar values with diet alone. However, this remission does not occur in all the cases and lasts only a few weeks or months, rarely years, before the carbohydrate tolerance deteriorates again. Insulin therapy must then start again, this time permanently. It is not yet possible to state definitively whether oral hypoglycemic agents will prolong the remission.

As in the adult, treatment includes diet, insulin, adjustment in the way of living, and the

education of the patient and his relatives. Useful as a low calory diet is in the adult, it is detrimental in children. During childhood, the diet should not be adapted to the lowest possible dose of insulin, but rather to normal growth and well-being, and the prevention of diabetic angiopathy.

The diet differs in four principal points from that of healthy children of the same age groups:

1. The carbohydrate and protein contents must be about constant, but adapted to age.
2. Foods with a high concentration of carbohydrates, such as sugar, sweetened foods, and drinks, honey and grapes, are generally excluded (exceptions see below).
3. If possible, proteins are given in addition to the carbohydrates with the three main meals, so as to slow down the absorption of the latter.
4. The protein content is higher than for the healthy child, since we cannot avoid a loss of nitrogen through the urine.

We discard the "free or normal diet", since it considerably reduces life expectancy! The statement that irregular intake of food can be compensated for by constant adjustment of the insulin dosage, has not yet been proved in unhospitalized children. In our experience it is not correct and endangers the children concerned. The feeds of even healthy babies are specified and the diabetic babies are continued on normal feeds, but extra sugar and malt products are omitted. Rules for feeding for the first 6 months (WILLI and KOLLER):

Milk: 1/10 body weight, maximum 600 g = 3 milk equivalents.

Carbohydrates: 1% of body weight, rounded off to 5 or 10 g, given as gruel or farinaceous foods (a child weighing 4200 g receives 45 g carbohydrates = $4\frac{1}{2}$ bread equivalents).

From the 2nd to 3rd month, 1–3 ounces of fruit juice are given in addition, the nutritional value of which is not taken into account. Later, vegetables are also added, in small harmless quantities to begin with. As soon as potatoes are introduced, usually from the 5th month, these are measured in bread equivalents (see Sect. 7b).

The nutritional requirements of children and juveniles vary greatly from one child to another and for the same child, depending on whether he is in a phase of intensive growth and on his physical activity. On account of this, no absolute values for carbohydrates, fats, or proteins can be given. The dietary regimen summarized in Table 26 for diabetic children and juveniles, is used as "basic diet". We begin treatment with this diet and it is continually adjusted to the individual needs and the development of the child.

In diabetic children who are not overweight, we leave the fat allowance open. Fats are used to meet the caloric requirements which, at this age, vary considerably from hour to hour.

Any attempt to treat a diabetic child in the beginning without insulin or with sulfonylurea derivates carries the risk of losing the reserves of endogenous insulin and of approaching the stage of complete islet insufficiency.

Diabetic dwarfism is characterized by a retardation of more than 10 cm below average height, and by the infantile psyche in the presence

Table 26. Basic diet for diabetic children and juveniles

of normal intelligence. The moon-shaped face is explained by thickening of the skin. The abdomen is unusually large, the ossification centers develop late, and sexual maturation is often delayed. In the early stages, the size of the liver varies. Later, it becomes quite large and its anterior border is felt below the umbilicus (Mauriac syndrome). There is no splenomegaly. The abdominal cutaneous veins are distended. Diabetic dwarfism is probably due to a wrong or deficient diet and to inadequate administration of insulin. The Mauriac syndrome has become much less common in recent years.

The intelligence of diabetic children used to be labeled as above average. Whether this is true is difficult to decide, since unintelligent diabetic children die earlier than gifted ones.

10. Surgical Procedures in Diabetics

Today, diabetes mellitus is no longer a reason for refraining from an essential operation; it is at most a reason for postponing surgical intervention. However, it is a technical mistake to operate on a diabetic without treating the diabetes pre- and postoperatively.

An operation makes preexisting diabetes worse and may provoke ketoacidosis. On the other hand, uncontrolled diabetes increases the risk of operation due to its tendency to hemorrhage, delayed healing and infection.

The preoperative treatment is aimed at increasing resistance by eliminating dehydration, by replenishing the glycogen stores, by preventing acidosis, and by lowering the blood-sugar concentration to normal or almost normal values. The insulin requirement and the insulin sensitivity should, if possible, be established before the patient undergoes surgery.

Whenever feasible, the diabetes must be controlled before an operation. If surgery is urgent, intravenous injections of soluble insulin every half to one hour will permit sufficient control over diabetes and dehydration in a few hours. Complications during and after surgery are less frequent when there is sufficient time to eliminate ketoacidosis, to reduce the blood sugar to below 160 mg per cent before meals, not only before breakfast, and the urine sugar to below 10 g per 24 hours. Cooperation between surgeon, diabetologist and anesthetist is important.

The diet should contain relatively ample amounts of carbohydrates (180 to 250 g carbohydrates for an adult). Preoperative undernourishment must be avoided, since it increases the tendency to acidosis and depletes glycogen depots.

Treatment with hypoglycemic tablets is only continued if control of diabetes is perfect and food intake unchanged by the operation, e.g. cataract operation. Treatment with insulin is preferable for all other cases, since the surgical stress increases the insulin requirement to an unpredictable extent. Long-acting insulins are replaced by soluble insulin. Three daily examinations of the urine, as described on p. 787 permit the insulin dosage to be adjusted to the existing metabolic situation. Blood-sugar measurements before meals prevent overdosage of insulin.

Prolonged fasting must be avoided by parenteral administration of carbohydrates.

During an *emergency operation*, which does not permit proper preparation of the patient, intravenous administration of whole blood or of 5% fructose is started and soluble insulin added to the tube of the infusion every $\frac{1}{2}$–1–2 hours, according to the blood-sugar level determined by a rapid method every hour before and during the operation, and every two hours after it. During anesthesia, hypoglycemia should be avoided at all costs.

Operations should be postponed in case of ketoacidosis, with the exception of draining an abscess.

Modern general anesthesia is the same for diabetics and non-diabetics. If adrenaline is combined with local anesthetics, the insulin dosage must be adjusted accordingly. No local anesthesia is permitted on feet or toes of diabetics with peripheral angiopathy.

During the operation, hypoglycemia is more dangerous than hyperglycemia.

A solution of 40% dextrose and of glucagon should always be ready during anesthesia of a diabetic patient.

In order to assure normal healing of wounds, the post-operative treatment tries to prevent acidosis and hyperglycemia, but also hypoglycemia with its strain on the myocardium. In older patients, e.g. after prostatectomy, normalization of blood sugar may lead to oliguria which will disappear when we permit a small rise of the blood-sugar level.

As long as the patient cannot drink or eat, we give 1–$1\frac{1}{2}$–2 liters of 5% fructose or 2.5% fructose and 2.5% glucose, or 2 parts of physiological glucose and 1 part of physiological saline solution by intravenous drip.

When fluid intake per mouth is permitted, we first give tea with 1–2 teaspoons of fructose per glass of tea.

With the help of 2–4 blood sugar determinations per day, the insulin dose is adjusted to the need, until the patient can resume his ordinary diet.

Draining of an abscess is usually followed by a sudden reduction of the insulin requirement,

permitting reduction of the insulin dosage. Hypoglycemia must be avoided during operations on the eye, since it causes an increase in the intraocular pressure.

11. Special Forms of Diabetes Mellitus

a) Diabetes Mellitus after Pancreatic Failure

α) After Pancreatectomy

The operation only results in diabetes mellitus if at least 90% of the pancreas is removed. Carcinoma of the pancreas, organic hyperinsulinism and chronic recurrent pancreatitis are indications for pancreatectomy. The subsequent diabetes needs remarkably little insulin for its control, only 10–50 units per day. This may be partly explained by the simultaneous loss of the exocrine enzymes of the pancreas and of glucagon. Retinopathy was found in a few patients who survived the operation long enough.

β) After Pancreatitis

Hyperglycemia and glycosuria which are present during the course of acute pancreatitis almost always disappear after the inflammation has subsided (see p. 798). On the other hand, chronic pancreatitis, especially in the recurring form, leads to progressive destruction of the exo- and endocrine tissue and finally to calcification.

This type of diabetes is characterized by its fluctuations. The insulin requirement increases considerably during painful phases and falls during remission. The terminal malabsorption syndrome fakes "improvement" of the diabetes.

This form of diabetes is often followed by neuropathy, later retinopathy, whilst nephropathy is rather rare.

γ) Due to Hemochromatosis

Hemochromatosis damages the islet tissue of the pancreas, and thus causes diabetes mellitus. We distinguish *primary, idiopathic, inherited hemochromatosis* from *secondary hemochromatosis*, and *hemosiderosis*, which is found in alcoholic liver cirrhosis, in blood diseases after repeated blood transfusions, in rare liver diseases, in porto-caval anastomoses, in inanition, after excessive intake of iron preparations and in protein deficiency of Bantu Africans.

Idiopathic hemochromatosis is now looked upon as a hereditary diseases with dominant inheritance. It is often met in the latent form, i.e. without tissue changes, in other members of the family. The disturbed regulation of iron absorption leads gradually to an excessive accumulation of iron in the tissues. It is 10–20 times less common in women (menstruation!) than in men. The predominant clinical features are the grey-brown pigmentation of the skin (bronze diabetes), liver cirrhosis, diabetes mellitus, cardiac failure, and in the male hypogonadism (see 799).

The diabetes mellitus develops relatively late. In the early phases, it is usually mild, later more severe, and sometimes even very severe. There is a tendency to acidosis, but the diabetes can unexpectedly become latent again. The blood sugar is labile and the insulin acts in spurts, so that severe hypoglycemic shock may arise, which must be treated by the intravenous administration of dextrose. On the other hand, resistance to insulin has been reported relatively often. The long-term diabetic syndrome has also been observed in hemochromatosis, but less frequently than in the usual form of diabetes mellitus, on account of the short duration of diabetes, the rarity of hypertension, hypercholesterolemia and obesity, and due to moderate or poor nutritional status as well as to pituitary hypofunction.

The *diagnosis* of hemochromatosis is simple in the presence of all the clinical features. In the early stages, when one or two of three typical symptoms are missing or not yet evident, the diagnosis may be difficult and sometimes it is not possible until a post-mortem examinations is performed.

The diagnosis can be confirmed by the following methods: estimation of the iron and copper contents of the blood, measurement of the iron-binding capacity of the blood, the histological examination of the skin or, more reliably, of the liver tissue, and further presence of hemosiderin in the sternal puncture and in the urinary sediment. The last two symptoms are also present in hemosiderosis.

The prognosis of hemochromatosis has improved since insulin has been introduced, combined with phlebotomies.

The most common *causes of death* are hepatic insufficiency, hemorrhage from esophageal varicose veins, diabetic coma, primary carcinoma of the liver, cardiac failure or intercurrent infections, seldom a severe state of shock associated with flooding of the organism with ferritin.

The *therapy* aims at delaying the development of cirrhosis of the liver, at compensating the diabetes, and, above all, at removing iron from the body.

The *diet* should be relatively high in proteins, vitamins and carbohydrates, but low in fat. Wine must be avoided!

There are two ways of *eliminating the iron* – repeated phlebotomy or desferrioxamine B. The former is the treatment for primary hemochromatosis, since a large amount of iron is withdrawn rapidly in this way (2 liters of blood contain approx. 1 g of iron). Desferrioxamine B (Desferal), on the other hand, would, at the most, be considered in cases with anemia.

The indications for treatment with insulin are similar to those for the ordinary form of diabetes mellitus, but it may be necessary to give the insulin intramuscularly due to poor absorption from subcutaneous tissue. Sulfonylurea derivatives appear to have no effect, whereas biguanides sometimes reduce the blood sugar.

δ) Due to Fibrosis of the Pancreas

Mucoviscidosis or *fibrocystic disease* of the pancreas is an inherited familial disease, in which the function of all the exocrine glands is disturbed, especially those producing mucus. The disease often results in chronic bronchitis, bronchiectasis, and finally in chronic pulmonary insufficiency. In children meconium ileus, cirrhosis of the liver with congestion of the portal veins and prolapse of the rectum are common concomitant features. Insufficiency of the exocrine pancreatic glands can occur alone or combined with disturbances of the respiratory tract. It may lead to a malabsorption syndrome in spite of the increased appetite and ample food intake. The sodium and chloride contents of sweat, and to a lesser extent of saliva and tears, are definitely increased. The activity of the pancreatic ferments in the duodenal juice and in the feces is reduced. Recently, a glycoprotein which may be characteristic for the condition has been demonstrated in the mucus, in the epithelial cells of the mucous glands and in the stool. The progressive fibrosis of the pancreas can destroy the islets and consequently lead to labile diabetes mellitus in its late stages.

b) Diabetes Mellitus Resulting from Disorders of Other Endocrine Glands and from Hormone Therapy

α) Pituitary

See p. 113 about diabetes in acromegaly.

β) Adrenal Glands

See p. 335 about diabetes in primary aldosteronism, p. 432 in pheochromocytoma, and p. 349 in Cushing's syndrome.

γ) Thyroid Gland

It is not known to what extent hyperthyroidism can produce diabetes. It can give rise to oxyhyperglycemia, and it makes preexisting diabetes worse. Hyperthyroidism must be considered in every case of acidosis without obvious cause and in every case of insulin resistence. Correction of the hyperthyroidism improves associated diabetes mellitus, but does not cure it. Refer to p. 187 for more details.

c) Diabetes due to Deficiency of Adipose Tissue

Lipoatrophic diabetes (LAWRENCE), *the diffuse, diabetogenic lipoatrophy*, or *lepercaunismus* is very rare and affects predominantly young people. The loss of fatty tissues of the skin and internal organs makes the conversion of carbohydrates into fats impossible and deprives the insulin of one of its end-organs. It leads to an increase in growth, which, however, in contrast to acromegaly, stops with puberty. The diabetes mellitus becomes overt when growth ceases and there is a fall in the protein requirements. The inability to deposit fats in the adipose tissue explains the hyperlipemia and the liver steatosis. The "fat-mobilizing" substance recently found in the urine will probably explain lipoatrophy and diabetes mellitus, but this still awaits further confirmation (HAMWI).

The characteristic clinical features of the disease are disappearance of the adipose tissue, hyperlipemia, hepatomegaly, and an elevated basal metabolic rate, as long as this is calculated in the usual way according to the body surface and not to the total body weight. Splenomegaly is not very uncommon, and it has been observed several times in combination with *acanthosis nigricans*. Children have a strongly developed musculature (Hercules boys), large prominences, and crinkly hair which gives them an elf-like appearance (leprecauns). Insulin and growth hormone in the blood are normal. This form of diabetes has no tendency to ketoacidosis and is resistent to insulin, perhaps since one of its main sites of action is missing and/or the excessive mobilization of fatty acids inhibits the action of the islet hormone. A low-fat diet causes a regression of hyperlipemia and of diabetes.

The relation to *progressive lipodystrophy* (BARAQUER-SIMONS) is not yet clear. This may be an early stage of diffuse diabetic lipoatrophy. In contrast to the latter illness, the disappearance of adipose tissue begins in the face and spreads gradually over the upper part of the body. It is often combined with diabetes, which sometimes proves resistent to insulin, and with hepa-

tomegaly. Progressive lipodystrophy is much more common in women than in men.

d) Diabetes in the Prader-Labhart-Willi Syndrome – Myatonic Diabetes ("Flour-Bag Dwarf")

In 1956 PRADER and his team described 9 children with obesity, acromicria, hypogonadism and myatonia in the early years of life, associated with retardation in mental and physical development, and also with disorders of carbohydrate metabolism. In the newborn, myatonia was predominant, and later obesity and oligophrenia. In boys, hypogonadism was the prevailing clinical feature. The myatonia was obvious from birth since the movements of the infants were absent or very weak.

The muscular hypotonia decreases somewhat after birth, so that the children can walk from the second year on wards. The obesity usually develops during the first year, the abdomen being particularly involved. The acromicria and the short neck, knock knees, and pallor of the skin all combine to give the appearance of a flour bag. The hypogonadism – small, ectopic or absent testicles with a rudimentary scrotum – leads to delayed and incomplete puberty.

In the first years of life, there is hypersensitivity to exogenous insulin, and later a reduction in carbohydrate tolerance. Finally, a form of diabetes develops, which differs from the usual infantile diabetes in the absence of ketosis and the good response to dietary treatment and sulfonylurea derivatives. A severe case of this form of diabetes can be considerably improved by the reduction of overweight, which is often enormous. With the exception of diabetes, the syndrome appears to be the exact opposite of lipoatrophy.

The nature of the disorder is unknown. Familial occurrence indicates an inherited disease, and the advanced age of the mother at the time of the patient's birth suggests a chromosomal anomaly in the baby.

e) Young Diabetics Independent of Insulin

In Europe, juvenile diabetes which can be controlled for decades by diet alone or in combination with oral hypoglycemic agents, and does not need insulin even during pregnancy is very rare indeed.

In Natal, there appear to be many young overweight diabetics among the Indians who do not need insulin (CAMPBELL). These observations stem entirely from developing countries, where the nutritional conditions are difficult to assess. On the other hand, this form of diabetes may have a different pathophysiology. The type of diabetes in Natal Indians differs from the K-type described by SHAPER in Campala, Uganda. In the latter type, the diabetes becomes overt between the 16th and 35th year and in spite of the thinness and the typical classic beginning of the metabolic disorder, the patients seem able to manage without insulin. In contrast to the K-type, there is the J-type described by HUGH-JONES among young underweight Africans in Jamaica. This type necessitates large amounts of insulin, but the patients show only slight ketotic tendencies. Such cases have also been described in other warm countries. The J-type could be explained by undernourishment and deficiency of animal proteins and of fats.

F. Diagnosis of Diabetes Mellitus

E. R. FROESCH

The correct diagnosis of diabetes mellitus is of utmost importance to everyone and so are the consequences. In spite of the frequency of the disease, criteria for the diagnosis of diabetes mellitus are still poorly defined. The reasons for this unsatisfactory state of affairs are multiple:

1. Glucose tolerance decreases with age, so that the criteria for a normal glucose tolerance curve vary for each age group.

2. The so-called "normal" curves are probably subject to an inherent error. The group of so-called normal control subjects undoubtedly contains some individuals with potential diabetes.

3. In U.S. and in England venous blood is usually used for estimating blood sugar, whereas in Europe capillary blood, the glucose content of which corresponds to that of arterial blood, is mostly used. In the fasting state the arteriovenous difference of blood glucose is very small, but during the glucose tolerance test it may rise up to 60 mg%. One hour after ingestion of 50 g of glucose orally, this difference is 30 mg% on the average.

4. Glucose tolerance is altered by the following factors: severe, acute illness, physical inactivity or rest, prolonged fasting. A normal diet with at least 200 g of carbohydrates for three days should precede a glucose tolerance test. Glucose tolerance decreases during pregnancy. About 50% of all patients with cirrhosis of the liver have a "diabetic" glucose-tolerance curve. The majority of syndromes of endocrine hyperactivity are associated with carbohydrate intolerance. Hypokalemia of any etiology causes

glucose intolerance. The following commonly used drugs also decrease glucose tolerance: glucocorticoids, diuretics and contraceptive drugs.

Polyuria and polydipsia are usually the first symptoms of diabetes mellitus. Examination of the urine for sugar, therefore, is the first diagnostic test for diabetes.

1. Urine Examination for Glucose

Quantitative or semi-quantitative estimations of urinary glucose are essential for the treatment and control of diabetes. For the diagnosis, however, specificity is more important than quantitation.

a) Glucose Oxidase Methods (Tes-Tape, Clinistix)

These tests are based on the specific oxidation of glucose to gluconic acid by the enzyme glucose oxidase. The indicator paper is impregnated with glucose oxidase, peroxidase and orthotolidine (indicator dyes). Glucose oxidase reacts with glucose and oxygen to form gluconic acid and hydrogen peroxide. The latter converts orthotolidine into a blue indicator. The paper strips are dipped into the urine and the colour reaction is read after one minute. If there is no blue coloration, the test is considered negative. Concentrations of glucose up to 0.01% can be detected with glucose oxidase test strips. Normal glucose excretion may reach values of up to 200 mg per day or 15 mg%. A slightly positive reaction with glucose oxidase does not necessarily imply the diagnosis of diabetes mellitus. In such a case, a semi-quantitative test such as a clinitest must be carried out, from which more quantitative conclusions can be drawn about the amount of glucose present in the urine. Samples of urine voided after a meal are suited for detection campaigns for diabetics, since they contain glucose also in cases of latent diabetes, whereas the urine obtained in the fasting state is often devoid of glucose. Apart from this, these specific and easily handled glucose oxidase strips are very well suited for the occasional control of urine in old people with "mild" diabetes.

b) Benedict's Semi-Quantitative Test

Benedict's solution contains sodium bicarbonate, sodium citrate and copper sulfate. Copper sulfate is reduced by glucose under the influence of heating and a blue color develops. Eight drops of urine are mixed with 5 ml of qualitative Benedict's solution in a test tube. The mixture is then kept boiling over a flame for 3 min, or heated in a boiling water bath for 6 min. The color changes give a fairly exact measurement of the sugar present in the urine: blue: no sugar; green clear: 0.1%; green cloudy: 0.3%; green with a yellow sediment: 0.5–1%; yellow: 1%; orange: 2%, red to brown: over 2%. Benedict's test is less specific than the glucose oxidase methods. All pentoses, hexoses and both disaccharides maltose and lactose, also give a positive Benedict's test. When the Benedict's test is positive and the glucose oxidase test strip negative, the sugar present in the urine must be identified by means of paper chromatography.

c) Clinitest, the Tablet Modification of Benedict's Test

Clinitest tablets contain the same ingredients as Benedict's solution plus sodium hydroxide. 5 drops of urine and 10 drops of water are mixed with one tablet in a test tube. The sodium hydroxide present in the tablet causes the mixture to boil. The solution can be shaken 15 sec after boiling has ceased and the reaction read off from a color scale. This test is preferred to Benedict's test by most patients since it is much easier to carry out wherever the patient happens to be. The tablets are hygroscopic and must, therefore, be stored in a dry place. The cost of the tablets is considerably higher than that of Benedict's solution.

d) Quantitative, Polarimetric Examination of Urine Sugar

Naturally occurring D-glucose deflects the plane of polarized light to the right, fructose, protein and beta-oxybutyric acid to the left. Provided that no other optically active substance is present in the urine, the glucose content can be quantitatively measured. During the phase of the stabilization of the blood sugar this method is very useful in hospitalized diabetics, provided that false results due to the substance mentioned above and interfering drugs are excluded.

2. Qualitative Estimation of Ketone Bodies in the Urine

The presence of ketone bodies in the urine is not strictly diagnostic for diabetes mellitus. Ketone bodies are always excreted in small amounts, and particularly during fasting. As a rule, there is no glucose in the urine during fasting, so that the presence of glucose together with ketone bodies is quite specific for diabetes mellitus. Semi-quantitative estimations of ketone bodies in the urine are of great importance for the initial stabilization of diabetes mellitus.

Rothera's or Galat Test. Urine is added to ammonium sulfate and sodium nitroprusside, both in the form of dry powder. Ammonia is then added. A purple-red color, the intensity of which increases with rising concentrations, is formed in the presence of ketone bodies. A concentration as low as 3 mg% gives a weak positive reaction. *Acetest tablets* make use of the same principle. They also contain sodium nitroprusside. A drop of urine is put on a tablet. A purple color forms when more than 10 mg% acetoacetic acid or 25 mg% acetone are present in the urine. The paper strips, *Ketostix,* make use of the same principle. The strips are quickly dipped in the urine and the reaction read off within 15 sec. A weak purple-red color is formed in the presence of a concentration of 10 mg% acetoacetic acid.

3. Methods of Estimating Blood Sugar, and their Use in Diagnosing Diabetes Mellitus

Precautions mentioned in the introduction must be observed in interpreting the blood sugar and glucose tolerance. Apart from this, correct collection and storage of blood are also of considerable importance and the method used for estimation of glucose must be specific. The glucose concentration in blood left to stand at room temperature rapidly diminishes and is approximately halved within 3–4 hours. Addition of sodium fluoride prevents glycolysis in the red cells. 20 mg of a mixture of 1 part of sodium fluoride and 2 parts of potassium oxalate are used for 5 ml of blood and not only prevent coagulation of blood, but also guarantee that the glucose concentration remains constant. Immediate deproteinization of the blood is even better. Today, only those methods of estimating blood sugar which guarantee a high degree of specificity through the quality of deproteinization or through the specific measurement of glucose itself should be in use. HAGEDORN-JENSEN'S, HOFFMANN'S and the orthotolidine methods have been adapted to the autoanalyzer and are, therefore, most commonly used. Glucose oxidase methods are very good and are employed in nearly all laboratories. The hexokinase method which is absolutely specific and most reliable, is expensive and, therefore, used only for particular research purposes.

a) Fasting Blood Sugar

The fasting blood sugar is elevated in manifest diabetes mellitus. In the healthy control subject, the fasting blood sugar lies between 60 and 105 mg%. Values between 105 and 130 mg% are suggestive, but not yet diagnostic, of diabetes mellitus. Values over 130 mg% are usually diagnostic. In spite of this, diabetes mellitus must not be diagnosed on the basis of a single laboratory observation, since there are many sources of laboratory errors. Moreover, it is always possible that the patient was not fasting. Therefore, the diagnosis of diabetes mellitus is not based on a single blood-sugar value, but on several estimations of fasting blood sugar or on a glucose-tolerance curve in borderline cases.

b) Tests which Indirectly Determine the Dynamics of Insulin Secretion

α) Oral Glucose Tolerance Test (Fig. 19)

This test is usually carried out with 100 g of glucose per os in U.S.A., and with 50 g or 1.75 g/kg ideal body weight on the continent. The large dose of 100 g carries the disadvantage of occasional nausea and vomiting or diarrhea.

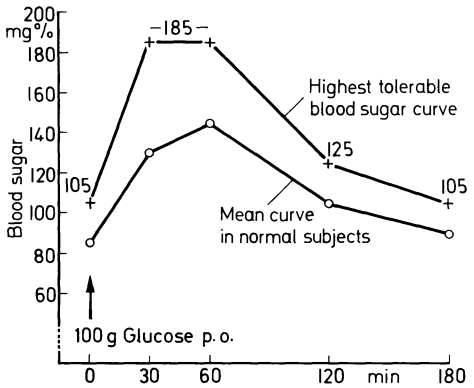

Fig. 19. Oral glucose tolerance test with 50 or 100 g and capillary (arterial) blood sugar determination

In children, 1.75 g of glucose/kg are usually given. Glucose is dissolved in 250 ml (50 g) or 500 ml (100 g) of water and is administered to the patient after a period of 12 hours of fasting. Blood sugar is estimated in the fasting state, 1/2, 1 and 2 hours after glucose intake. The person under investigation sits or lies still, drinks and eats nothing during the test and does not smoke. Diabetes is probable if the value after 30 min or after 1 hour is above 185 mg% and if the value after 2 hours is above 125 mg% (capillary blood). As was mentioned in the introduction, the age of the patient must be taken into consideration in the interpretation of these values. The values quoted are absolutely normal for a person between 60 and 80 years, whereas they are suggestive of prediabetes in someone between 20 and 30.

β) Intravenous Glucose Tolerance Test (Fig. 20)

The intravenous glucose tolerance test is a simple rapid test. In addition, it has the advantage over the oral glucose tolerance test that one

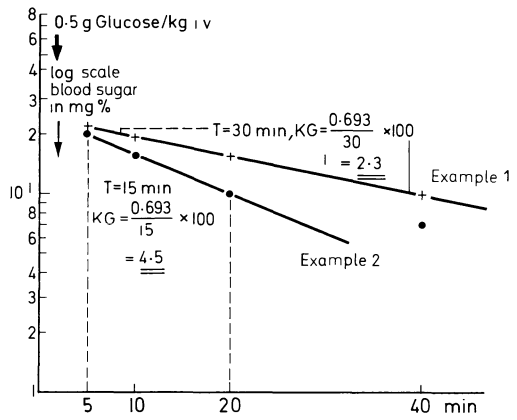

Fig. 20. Intravenous glucose tolerance test according to CONARD with two practical examples and the calculation of the glucose assimilation coefficient (KG)

factor of uncertainity, i.e. glucose absorption, is excluded. However, since it is known that glucagon, secretin and other intestinal factors also affect insulin secretion, it has become questionable whether the intravenous glucose tolerance test really has so many advantages over the oral test. However, it appears that the results of the two tests agree very well. As with the oral tolerance test, a normal diet with at least 200 g of carbohydrates during the 3 days prior to the test is required. The test is carried out in the morning in the fasting state. Capillary blood is collected at the start and then 0.5 g glucose per kg of body weight in a 40 or 50% solution is rapidly injected intravenously (approximately 2 min). Further blood collections are made after 10, 20 and 40 min. The blood-sugar levels are then plotted on semi-logarithmic paper. The glucose-assimilation coefficient (KG) may be calculated with the aid of logarithm tables. It is simpler to use semi-logarithmic paper, on which the blood sugar is plotted on the ordinate and the time in minutes on the abscissa. The line obtained from the three blood-sugar values may be extended and the biological half-life (T) is read from the curve. For this, one chooses 2 fixed points on the line, e.g. the blood sugar value of 200 and 100 mg%, and from the abscissa (T) reads off the minutes required for this decrease in blood sugar. The glucose assimilation coefficient (KG) may then be calculated as follows:

$$KG = \frac{0.963}{T \text{ in min}} \times 100 .$$

Normal Values. Normal values are still rather poorly standardized for different age groups. Glucose assimilation decreases with increasing age. The mean KG value is 1.80. A KG value of less than 1.40 is very suggestive of diabetes (= average value of a large group − 2 standard deviations). Whereas we have to interpret 3 figures in the oral glucose tolerance test (blood sugar at 30, 60 and 120 min), we obtain a single value (KG) with the intravenous tolerance test, which may be interpreted without taking any other values into consideration.

γ) Tolbutamide Test

When given intravenously, sulfonylureas cause a rapid release of insulin and a fall in blood sugar. In the diabetic, less insulin is secreted and the fall of the blood sugar is less marked and slower. The blood sugar reaches its lowest value after 60 min or even later. A specimen for the fasting blood sugar is collected and then 1 g of tolbutamide is given intravenously over a period of 2–3 min. Blood-sugar estimations are made after 20, 30, 40 and 60 min. In healthy subjects, the blood sugar falls rapidly and reaches a minimum between 20 and 40 min. Unfortunately, this test is not quite as reliable as the glucose tolerance test. In general, it can be taken that after 20 min the blood sugar value should be less than 75% of the original value. If it is higher than 90%, diabetes can be diagnosed with certainty. Further tests to detect the presence of diabetes mellitus must be employed in patients with values between 75 and 90% of the fasting blood sugar value after 20 min. A value higher than 75% of the fasting value at 30 min is considered definitely abnormal.

δ) Cortisone Glucose Tolerance Test

Glucocorticoids are some of the diabetogenic factors which can convert prediabetes into latent or subclinical diabetes. The test is carried out as follows. The diet should contain at least 200 g of carbohydrate in the last three days before the test. The patient receives 50 mg of cortisone acetate $8\frac{1}{2}$ and 2 hours before the glucose tolerance test. 100 g of glucose are given orally for the glucose tolerance test. The test can be interpreted as being positive for diabetes when the value after 1 hour (venous blood) rises above 160 mg%, and the value after 2 hours exceeds 140 mg%. These values exceed the glucose values normally found in the venous

blood during the normal oral glucose tolerance test with 100 g of glucose by 20 mg%. The cortisone glucose-tolerance test has not become a routine test and remains a research instrument.

ε) Estimation of Insulin in the Plasma (Fig. 21)

Insulin was the first peptide hormone in the plasma to be measured by the radioimmunoassay, and BERSON and YALOW are to be credited with this success. The method is based on the isotope-dilution principle. A predetermined limited amount of insulin antibodies is mixed with serum containing insulin and a certain amount of insulin labeled with iodine 131. Insulin antibodies of the guinea pig bind insulin labeled with iodine 131. More labeled insulin is bound if there is little insulin in the serum. The antibodies cannot distinguish between insulin labeled with iodine 131 and human unlabeled insulin. At the end of the reaction, when an equilibrium is reached between labeled insulin, unlabeled insulin, antibodies and antibody-insulin complexes, the free insulin labeled with iodine 131 is separated from antibody-bound insulin. This separation is achieved either by means of paper electrophoresis or by a second antibody reaction in which guinea pig antibodies against insulin are precipitated by anti-guinea pig serum. A standard curve is made with human unlabeled insulin. The insulin concentrations in serum with unknown insulin contents are read off from the curve. The concentration of the so-called immunoreactive or immunological insulin in the serum lies between 10 and 20 μU/ml of plasma in the normal fasting human. The average concentration is about 15 μU/ml of plasma. During the intravenous glucose tolerance test, the insulin levels rise rapidly within 5 min and reach a maximum of 50–100 μU. They then fall to the original values after 20–40 min. After oral intake of glucose, the insulin values in the blood do not reach a maximum until after 30–60 min, and they fall much more slowly. After 120–150 min they are back to the fasting value. Insulin secretion does not react uniformly to glucose loads in diabetes. The fasting values are diminished in juvenile ketotic diabetes, and the insulin concentration does not rise after glucose administration. In the elderly diabetic where the disease is manifest but ketosis is absent, the fasting insulin values are often within the normal range. The rise in insulin concentration is delayed, but in obese subclinical diabetics it can occasionally reach values exceeding those found in normal controls after 2–3 hours. In young prediabetic persons who demonstrate a normal glucose tolerance but are genetically diabetics, the rise in insulin concentration during the glucose tolerance test is on an average less than in normal controls. The differences are, however, slight. They are of statistical value for groups of patients, but are of no diagnostic value for individuals. Insulin estimation in the plasma has, therefore, remained a research instrument rather than a diagnostic tool.

G. Hypoglycemia

E. R. FROESCH

1. Definition

The blood sugar varies from 70 to 130 mg% according to the nutritional state. By definition, one speaks of hypoglycemia when the blood sugar falls below 50 mg%. The true fasting glucose lies between 70 and 105 mg% when measured by a specific enzymatic method. The blood sugar may fall below 70 mg% during prolonged fasting, but usually not below 50 mg%. The symptoms of mild hypoglycemia are nonspecific and cannot be distinguished from

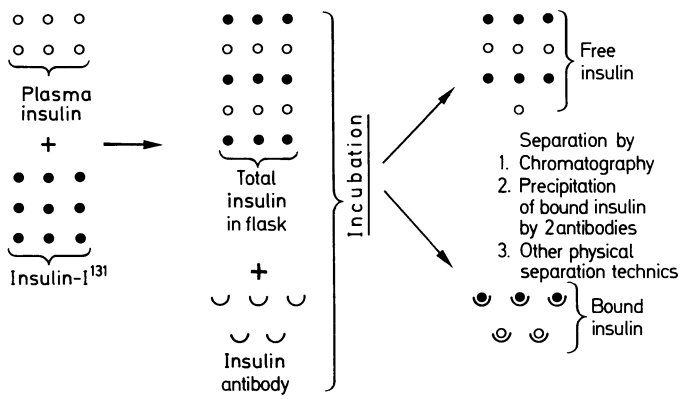

Fig. 21. Principle of the radioimmuno assay of insulin in serum

those of neurovegetative dystonia. It is therefore not permissible to diagnose hypoglycemia on the basis of symptoms such as sweating, trembling, palpitations, and giddiness alone. The diagnosis is based on at least one, or better several, blood sugar levels below 50 mg%.

2. Symptoms of Hypoglycemia

The symptoms of hypoglycemia are almost entirely cerebral in origin, since the brain is primarily dependent on glucose for its energy supply, whereas most other tissues turn to other sources of energy when glucose is scarce. Myocardial infarction occasionally described as having occurred during hypoglycemia is not due to nonavailability of glucose in itself, but rather to the endocrine counterregulation and particularly to increased levels of blood catecholamines. The sensitivity of different areas of the brain to hypoglycemia seems to vary. The hypothesis that the cerebral centers suffer from hypoglycemia in the reversed order of their phylogenetic development is interesting but should not be interpreted literally. The bizarre and varying symptoms of hypoglycemia make such a strict order of successive failure of one brain center after another during hypoglycemia seem unlikely. As a rule, however, the function of the cerebral cortex is always lost first, whereas the respiratory center, for example, may continue to function long after the complete loss of cortical function. The clinical picture of hypoglycemia depends on the rate at which the blood sugar falls. The signs of catecholamine release are often much more pronounced during rapidly developing hypoglycemia than during hypoglycemia which arises slowly. Symptoms due to adrenaline are cold sweating, trembling, uneasy feeling, nausea, occasionally hunger, palpitations and a striking pallor of the skin. The cerebral disturbance varies and is again dependent on the type and manner of the fall in blood sugar. Common neurologic symptoms are disorders of coordination leading to ataxia, sensory and motory disturbances and diplopia. Hemiparesis may be seen. The parts of the brain with a poor blood supply appear to fail first. Hypoglycemia often begins with apathy and inadequate reactions, clouding of consciousness and finally ends in deep coma with a characteristic retrograde amnesia. Not uncommonly, the patients are first irritated and excited, with outbursts of anger or with peculiar unintelligible behavior leading to the diagnosis of schizophrenia. Hypoglycemia may provoke any type of epileptic seizure and many patients with organic and other forms of hypoglycemia reach the internist in a roundabout way via the psychiatrist. In hypoglycemic shock of short duration no permanent brain damage remains. The prognosis becomes critical when the coma lasts for half an hour, one hour or longer. The patients then no longer awake promptly when the blood sugar level is normalized. A physician should never give up when the patient does not awake readily from the hypoglycemic shock or within an hour after correction of hypoglycemia. There are many examples of patients with prolonged coma whose cerebral function was restored to normal only after 24, 48 hours or even after weeks. In this respect, hypoglycemia may be compared with ischemia of the brain, in which several weeks may be needed for complete recovery. If a patient regains consciousness after an injection of glucose but becomes unconscious later on, the blood sugar has probably fallen to hypoglycemic values again due to the prolonged action of insulin. In most cases of hypoglycemia, the glucose injection should be followed by an intravenous drip of 5 or 10% glucose. The so-called protracted hypoglycemic shock is an extremely dangerous complication of hypoglycemia. The coma is described as protracted when consciousness is not regained within an hour after normalization of the blood sugar. The longer hypoglycemia lasts, the greater is the danger of irreversible cerebral damage. Patients with panhypopituitarism and cortical adrenal insufficiency are particularly liable to develop protracted hypoglycemic shock; since such patients often respond very well to treatment with glucocorticoids, prednisone has been included in the therapeutic scheme for protracted hypoglycemic shock. The prognosis is poor but not utterly hopeless. One observes again and again that patients who have already been given up wake up from hypoglycemic coma which has lasted for several days and that they recover completely or almost completely.

3. Treatment of Hypoglycemic Shock

Since the prognosis of hypoglycemic shock worsens within minutes, adequate amounts of glucose should be given at once without waiting for laboratory results. A single intravenous injection of 20–40 g of glucose is frequently sufficient to correct hypoglycemia. If the patient does not wake up at once, glucose is administered by slow intravenous infusion and the blood sugar is measured hourly. The treatment can be combined with administration of glucagon, 1–2 mg being given intravenously or intramuscularly. A blood sugar stabilized between 150 and 300 mg% is the only criterion indicating that therapy is adequate.

Therapeutic Scheme for Hypoglycemic Shock

1. 20–40 g of glucose (50–100 ml 40% glucose) intravenously.
2. Intravenous drip of 5–10% glucose so that blood sugar is kept constant between 150 and 300 mg%.
3. Crystalline glucagon, 1–2 mg every 2 hours, intramuscularly or by slow i.v. infusion
4. 30 mg of water soluble prednisone every 6 hours intramuscularly or in the drip.

Hypoglycemia in the presence of panhypopituitarism and adrenal insufficiency must be treated with physiological saline as well as glucose. An aqueous glucose solution leads to severe water intoxication and hyponatremia.

4. General Pathophysiology of Hypoglycemia

Hypoglycemia is due to an imbalance between exogenous glucose intake and endogenous glucose formation on one hand, and glucose utilization on the other hand. Diminished gluconeogenesis nearly always results in hypoglycemia, whereas increased glucose utilization is often compensated for a long time by increased hepatic glucose release. Hypoglycemia may be subdivided into fasting and reactive types, depending on whether it develops in the fasting state, after food intake or after the action of a certain agent (see Table 27).

5. Reactive Hypoglycemia

Reactive hypoglycemia hardly comes into the differential diagnosis of organic hyperinsulinism. Leucine stimulates not only normal B-cells, but also B-islet cell adenomas (FLOYD, 1964, 1966). This amino acid causes hypoglycemia more or less regularly in such patients. Patients with *familial leucine hypersensitivity* (COCHRANE, 1956) also react to leucine with excessive secretion of insulin (YALLOW, 1960) which leads to hypoglycemia in these children in the absence of histologically detectable changes of the islets of Langerhans. These children often show a slight tendency to fasting hypoglycemia (COCHRANE, 1956). The mode of action of leucine is unknown, as is the biochemical substrate for the dysfunction of islet cells in leucine-hypoglycemia. A qualitatively normal, but quantitatively excessive response of the islet cells to a physiologic stimulus seems to be involved.

There are two distinct types of *glucose-induced reactive hypoglycemia.* Reactive hypoglycemia in the non-diabetic is characterized clinically by a feeling of weakness, giddiness, trembling, hunger, nervousness, nausea, headache and other unspecific symptoms 1 to 2 hours after breakfast and less commonly after lunch and dinner. Symptoms last between 10 and 30 min and disappear spontaneously. Many of these patients are emotionally labile. Although the blood sugar seldom reaches values below 60 mg%, these patients often react promptly to glucose administration. Many respond well to a diet low in carbohydrate and rich in protein. Meals should be small but frequent. The pathogenesis of reactive hypoglycemia is not uniform and in most cases not understood. Since no measurable disorder of glucose metabolism is

Table 27. Classification of hypoglycemia by pathogenesis

Fasting hypoglycemia

detectable in most patients, it is assumed that nervous, neurovegetative and psychological factors play an important role. A therapeutic trial with frequent meals with low carbohydrate content and psychopharmacological drugs is indicated in every case. A critical and complete survey of the problem of reactive hypoglycemia is that by MARKS and ROSE (1965, pp. 136–154).

The symptoms of reactive hypoglycemia occuring 1–2 hours after meals in gastrectomized patients cannot usually, as was previously assumed, be explained by truly low blood-sugar levels or a particularly rapid fall in blood sugar (STALKER, 1959; SMITH, 1953). Personality changes seem to be of importance in these cases too.

The other form of reactive hypoglycemia is typical of diabetics. In our experience, reactive hypoglycemia in early stages of diabetes is uncommon. It occurs mainly in overweight diabetics in the stage of prediabetes or subclinical diabetes (SELTZER, 1956). The blood sugar rises slowly, remains elevated for a longer period than normal and induces a delayed and prolonged release of insulin (PERLEY, 1967; BAGDADE, 1967), which infrequently results in mild hypoglycemia 3 to 6 hours after glucose intake. This form of hypoglycemia is never dangerous. It is temporary and clears up spontaneously. Treatment consists of frequent, small meals with low carbohydrate content.

In *hereditary fructose intolerance,* fructose-1-phosphate aldolase is absent in the liver. Fructose-1-phosphate accumulates in the liver after fructose intake. This intermediate blocks glycogenolytic and gluconeogenetic enzymes, so that the liver loses its property to replace the glucose that is utilized by other tissues. Hypoglycemic episodes in patients with hereditary fructose intolerance are severe and last for hours when large amounts of fructose are absorbed. Plasma insulin is not increased and even decreases during hypoglycemia. Patients with hereditary fructose intolerance develop a very strong distaste for sweet foods since they regularly vomit after fructose intake. In this way they protect themselves from the ill effects of the noxious agent which kills infants who are forced to take fructose over prolonged periods of time (FROESCH, 1972).

Fructose-1,6-diphosphatase deficiency may present itself with hypoglycemia as the leading symptom. Often lactic acidosis is more prominent. These children maintain normal blood sugar during fasting for as long as glycogen is available. When gluconeogenesis should set in they rapidly develop severe hypoglycemia. Fructose also induces acute hypoglycemia, probably by fructose-1-phosphate inhibition of phosphorylase. Children with this disease grow normally despite of fructose intake for which they do not develop a distaste, in contrast to subjects with hereditary fructose intolerance.

In contrast to hereditary fructose intolerance, hypoglycemia after galactose intake by *galactosemic children* is mild and usually symptomless. In these patients, galactose-1-phosphate accumulates in liver cells and inhibits the hepatic release of glucose, although to a lesser extent than fructose-1-phosphate (ISSELBACHER, 1966).

Sulfonylureas stimulate insulin secretion. Even in reasonable doses they occasionally induce severe and sometimes fatal hypoglycemia. Individual disturbances in their breakdown in the liver, renal insufficiency and stimultaneous administration of other drugs may be responsible for an excessive response to sulfonylureas (MARKS and ROSE, 1965). *Biguanides,* whose mode of action is still unexplained, are much less potent and hypoglycemic incidents are unknown after these agents. Salicylic acid itself has a weak hypoglycemic effect, but can potentiate the action of insulin and sulfonylureas. *Hypoglycine* is consumed with the fruit Blighia sapida in Jamaica, which contains other psychotropic agents. Hypoglycine and its metabolites, shortchain, unsaturated fatty acids, with terminal vinyl groups, react with coenzyme A. These peculiar fatty acids are not oxidized but block the oxidation of normal, endogenous fatty acids. Thus, glucose becomes the main source of energy and glucose utilization increases. In addition, gluconeogenesis is inhibited so that hypoglycemia develops (JELIFFE, 1954; CORREDOR, 1967). The reaction to *alcohol* differs according to the nutritional state of the individual. Large amounts of alcohol inhibit gluconeogenesis in fasting subjects and can cause severe hypoglycemia (FREINKEL, 1965; ARKY, 1966).

6. Fasting Hypoglycemia

Fasting hypoglycemia denotes clinical conditions in which a fall in blood sugar is in no way connected with the intake of food or drugs. Hypoglycemia develops during fasting or during work, when glucose utilization is increased and no glucose is absorbed from the gut. In normal subjects, the blood sugar does not fall below 70 mg% during the night. It may fall further, to 50–60 mg%, if fasting is continued for several days. Values below 50 mg% are not found in metabolically healthy people and are suggestive of an endocrine or metabolic disorder. Complete starvation leading to severe cachexia in the terminal stage may result in serious impairment of gluconeogenesis and hypoglycemia, even in subjects with previously sound metabolism.

Intense physical exercise can lead to a temporary fall in blood sugar which is rapidly compensated and, at the most, results in subjective symptoms of hypoglycemia, such as a feeling of emptiness and weakness.

Decreased levels of endocrine antagonists to insulin frequently lead to hypoglycemia. Hypoglycemia is most severe in panhypopituitarism and may often be the cause of death. In patients lacking both growth hormone and adrenal cortical hormones, prolonged fasting regularly results in hypoglycemia. Hypoglycemia occurs less frequently and is less severe in Addison's disease, where pituitary function is intact.

It is interesting that hypoglycemia never develops in adrenalectomized patients who have lost the adrenal medulla but are substituted with cortisone. In these patients, small amounts of adrenaline are still formed by the sympathetic ganglia. The adrenaline response to hypoglycemia is decreased and delayed in the patients (VAN EULER, 1961).

In contrast to the classical opinion, according to which adrenaline is the main endocrine regulator of glycogenolysis, it is now thought that physiological doses of adrenaline may be ineffective and that glycogenolysis is mainly controlled by glucagon (SOKAL, 1966). Nevertheless, adrenaline is one of the major physiologic stimuli of lipolysis in adipose tissue and may hence promote gluconeogenesis through increased levels of free fatty acids. Free fatty acids are converted into acetyl coenzyme A in the liver. The ratio of acetyl coenzyme A to coenzyme A changes in favor of the former. Pyruvate now is mainly converted to oxalacetate instead of acetyl coenzyme A and oxalacetate is available for the formation of new glucose. BROBERGER and ZETTERSTRÖM (1961) assume that failure to release adrenaline may be the cause of some cases of spontaneous hypoglycemia in children. No single hormone deficiency can be held responsible for all cases of "*idiopathic infantile hypoglycemia*" (MCQUARRIE, 1954). Symptoms usually begin before the 6th month and disappear at the latest during puberty. Ephedrine, small doses of glucocorticoids and diazoxide can be therapeutically helpful in these patients. Diazoxide is certainly the most effective of these drugs, but has also some side effects (MARKS and ROSE, 1965). Infantile hypoglycemia in the congenital *adrenogenital syndrome* with 11-β-Hydroxylase deficiency is rare.

Hypoglycemia is a regular concomitant symptom of glycogenosis type I and is occasionally found in types III and VI. *Type-I glycogenosis* is inherited as an autosomal recessive trait. There is no glucose-6-phosphatase in the liver. This is the crucial enzyme for glucose production by the liver, since it is responsible for the hydrolysis of glucose-6-phosphate. These patients' mental development is more or less normal, provided that frequent small meals are given to prevent severe hypoglycemia (FIELD, 1966). The differential diagnosis between organic hyperinsulinism and the above-mentioned diseases presents no difficulties. Only leucine-hypersensitivity and idiopathic infantile hypoglycemia could be mistaken for organic hyperinsulinism.

Large extra-pancreatic tumors are rarely associated with hypoglycemia and they present greater problems in the differential diagnosis. The differential diagnosis between organic hyperinsulinism due to a B-cell adenoma and hypoglycemia due to an extrapancreatic tumor cannot be made on the basis of measurements of immunoreactive plasma insulin alone, since normal insulin values may sometimes be encountered in rare patients with islet-cell adenoma. Often, however, these extrapancreatic tumors are so large that they can hardly be overlooked. Two-thirds of the tumors are of mesenchymal origin, mainly fibrosarcomas, and lie within the retroperitoneal space or in the mediastinum (PAPAIOANNOU, 1966). Liver cell carcinomas come next in frequency of tumors causing hypoglycemia. They often lead to fulminating and severe hypoglycemia which may lead to death within a short time. The prognosis of hepatomas with hypoglycemia is, therefore, very bad. In contrast to this, mesenchymal tumors, although usually malignant, often grow rather slowly. Long remissions and even total cures after surgical treatment and irradiation of such tumors have been described. Carcinomas of the gastrointestinal tract, bronchus and adrenals rarely go along with hypoglycemia.

The pathogenesis of tumor hypoglycemia has not been fully explained (UNGER, 1966; FROESCH, 1968). On one hand, glucose utilization by the tumors is increased, on the other hand, glucose release from the liver into the blood is partly or completely blocked despite otherwise normal liver function and normal glycogen content of the liver (FROESCH, 1963; JAKOB, 1967). Pharmacologic doses of glucagon result in rapid glycogenolysis and in a rise in blood sugar. However, glucose cannot be mobilized spontaneously in adequate amounts. Furthermore, lipolysis, i.e. the release of free fatty acids from adipose tissue is partially or totally blocked so that free fatty acids do not increase during hypoglycemia. The tissues, therefore, continue to use glucose as their only available source of energy. This can result in severe hypoglycemia (FROESCH, 1963; JAKOB, 1967). In the normal subject, only about 20% of the total

calories are covered by glucose during fasting, whereas glucose remains the chief substrate in these patients with tumor hypoglycemia even during very severe hypoglycemia. The contribution of glucose to total CO_2-production during hypoglycemia was found to be 40–60%, and therefore greatly increased in two patients with tumor hypoglycemia. The relation between the block of hepatic glucose release and lipolysis has not yet been clarified in patients with tumor hypoglycemia. SILVERSTEIN, WAKIM, and BAHN (1965) found increased urinary excretion of tryptophane in patients with tumor hypoglycemia. L-tryptophane causes inactivation of phosphoenol pyruvate carboxykinase in the liver and thus blocks gluconeogenesis (RAY, 1966). On the other hand, L-tryptophane is partly decomposed to nicotinic acid which inhibits lipolysis in adipose tissue. This might explain both metabolic abnormalities, the deficiency of hepatic glucose production as well as inhibition of lipolysis. This hypothesis, however, has not yet been confirmed experimentally.

Treatment of these patients entails regular glucose administration. Glucose requirements can rise to 600 or even 800 g per day, so that 20 to 30 g of glucose must be administered hourly. These patients must be wakened and fed regularly at night, otherwise they will fall in deep hypoglycemia and may die. Whenever possible, the tumor should be radically removed and postoperative irradiation be carried out, although these tumors are not particularly X-ray sensitive. An operation is worthwhile even when radical removal of the tumor is not possible, since reduction of the tumor mass can result in an improvement in the metabolic state. Hypoglycemic attacks may disappear completely or become less frequent and less severe. Long-term treatment with glucocorticoids or glucagon has not proved useful. Diazoxide appears to have no favorable influence on hypoglycemia in this condition.

7. Hyperinsulinism, B-Islet-Cell Adenoma

Hyperinsulinism is difficult to diagnose. Sometimes, hypoglycemic symptoms or shock may occur only once to three times a year, so that the patient does not consult the physician at all or the physician may not consider further investigations necessary. Hypoglycemia usually develops slowly without any signs of adrenaline secretion so that the patient is not warned and is taken by surprise by very severe hypoglycemic shocks. About half the patients with organic hyperinsulinism are first referred to the psychiatrist or neurologist before the internist is consulted. B islet-cell adenomas are still being misdiagnosed as psychosis or epilepsy. The following sequence of diagnostic measures is to be used in diagnosing hyperinsulinism as quickly as possible (MARKS, 1968):

a) Diagnosis of B Cell Adenoma

1. Glucose tolerance test with 50 or 100 g of glucose orally, with additional blood sugar estimation after 4 hours to detect reactive hypoglycemia in diabetics. This test must be carried out at the beginning of the investigations for practical reasons, since glucose tolerance may become abnormal after subsequent diagnostic measures. The glucose tolerance curve in these patients paradoxically shows a diabetic pattern in about 50% of the patients (MARKS, 1961). Fasting plasma-insulin values are elevated in about half the patients. Their rise following glucose administration may be normal, excessive or not uncommonly less than normal (SAMOLS, 1963; LUNDBAEK, 1966). Thus, the diagnostic value of the glucose tolerance test is questionable but it should still be placed at the beginning of the diagnostic measures.

2. Tolbutamide test using 1 g intravenously. This test should only be carried out when the fasting blood sugar lies above 50 mg%. In patients with B islet-cell adenoma, the blood sugar falls below 30 mg% within 30 to 60 min and, in contrast to the curve for the normal subject, does not return spontaneously or in due time to normal levels (FAJANS, 1961). In this test a cannula, or better still a slow infusion with physiologic saline should be set up so that glucose and glucagon can be administered intravenously at any time. Insulin values must be measured before and then 2, 5, 10, 30 and 60 min after tolbutamide administration. They usually rise above 200 μU/ml in cases of islet-cell adenoma and remain elevated for 30 min or longer.

3. 72-hours fasting test. When the tolbutamide test is negative and no hypoglycemic symptoms are elicited, a 72-hours fasting test may directly follow the tulbutamide test. In cases of islet-cell tumors, hypoglycemic attacks occur between the 12th and 36th hour after the last meal in more than two-thirds of all patients. However, this test must be carried through to 72 hours in order to absolutely exclude B-cell adenoma. An important safety measure is the close surveillance of the patients during the night. When hypoglycemic symptoms are experienced, the blood sugar should be determined, and the test should be discontinued when the blood sugar value falls below 40 mg%.

4. Glucagon test. Glucagon strongly stimulates insulin secretion, and MARKS and SAMOLS (1967) made use of this to develop a convenient test for the diagnosis of hyperinsulinism. Insulin secretion is stimulated to a greater extent by glucagon in patients with B islet-cell adenoma than in normal subjects (MARKS, 1968). These authors consider the glucagon test as one of the best and least dangerous for the diagnosis of B islet-cell adenoma.

As already explained, two-thirds of all patients with organic hyperinsulinism can be diagnosed by determination of immunoreactive plasma insulin. Since the insulin concentration in the blood varies considerably, at least 3 to 5 fasting insulin levels should be determined in order to exclude or confirm hyperinsulinism. Plasma-insulin values must be interpreted with caution. Insulin secretion is controlled primarily by the blood glucose. Therefore, the ratio of plasma insulin to blood glucose is more meaningful than the insulin values themselves. It is characteristic of B-cell adenomas that plasma insulin stays elevated between 20–40 μU/ml at blood-sugar levels below 40 mg% when they should be below 10 μU/ml as in the normal subjects. Since we have no possibility of producing low blood-sugar levels other than with insulin, it is difficult to establish this correlation for low blood-sugar levels in metabolically healthy subjects.

The diagnosis of a B-cell adenoma in a diabetic, an extremely rare coincidence, presents special difficulties. In 1960, MOSS and RHOADES collected 23 such cases from the literature. The diagnosis was made only post mortem in 16 of these 23 cases. Insulin requirements generally diminish. In addition to severe hypoglycemia, reactive hyperglycemia with ketosis may also develop. Increased plasma-insulin concentration is of no diagnostic value, since such patients already have circulating insulin antibodies due to previous treatment with insulin. Theoretically, the fasting test should gradually lead to hypoglycemia in the diabetic with a B-cell adenoma, making the diagnosis possible.

b) Incidence, Frequency and Localization of B-Islet-Cell Adenomas (MARKS and ROSE, 1965)

The incidence of B islet-cell adenomas is in no way sex-linked. They are most often found in the age group between 20 and 50, but children may also be affected. In one case, the adenoma was claimed to be present from birth on. Several cases of B-cell adenomas in one family are not rare. These patients usually belong to the group of endocrine adenomatosis. Most adenomas have a diameter between 1 and 2 cm. Smaller adenomas may also cause hypoglycemia. B-cell adenomas are found in all portions of the pancreas with no predelection. Those on the surface of the pancreas can be distinguished from lymph nodes by their brown, blue or blueish-black colour.

5% of all B-cell adenomas are located outside the pancreas. They occur with decreasing frequency in the duodenum, stomach, jejunum, Meckel's diverticulum, ileum, and extremely rarely in the gallbladder, excretory biliary ducts, mesentery, omentum, transverse colon and other structures in the neighbourhood of the pancreas. Multiple, benign adenomas are rare. They often are not much larger than normal islets, but may occasionally reach a diameter between 1 and 3 cm. These adenomas are not hyperplastic islets (previously termed polynesia) but are true multiple neoplasms. Most of these cases belong to the syndrome of endocrine adenomatosis.

10–20% of all insulin-secreting pancreatic tumors are malignant. There are no definite histologic criteria for malignancy. Metastases confirm malignancy. The clinical course is very variable. Hypoglycemia is often the first symptom of an islet carcinoma. Sometimes the rapidly increasing severity and frequency of hypoglycemic attacks suggests a carcinoma rather than an adenoma. The illness can also progress slowly and may then not be differentiated from an islet-cell adenoma. Occasionally, anorexia and tumor cachexia precede hypoglycemia. B-islet cell carcinomas produce insulin, proinsulin and proinsulin-like material.

c) Pathophysiology of Hypoglycemia in Active B-Islet-Cell Adenoma

Hyperinsulinism produces hypoglycemia during fasting, due to increased glucose assimilation and an inhibition of hepatic glucose production. As explained above, glucose tolerance and glucose assimilation coefficient may be in the diabetic range (MARKS, 1961). What are the mechanisms leading to hypoglycemia in these patients? Obviously, there is an imbalance between the formation of new glucose in the liver and glucose consumption in peripheral tissues. In patients with B islet-cell adenomas presenting a diabetic glucose tolerance curve, insulin secretion is usually not stimulated by glucose. These adenomas are often unresponsive to glucose. The decreased glucose assimilation coefficient is in part due to a failure of the pancreas to increase insulin secretion after glucose administration. Insulin secretion is relatively constant, and higher than in normal fasting subjects. Hypoglycemia occurs during prolonged

fasting because the plasma insulin level remains slightly elevated and inhibits glucose release from the liver. Not uncommonly, the imbalance between glucose production and glucose consumption comes to a new equilibrium at a blood sugar of 40 mg% which may last for several hours before the blood sugar decreases further and hypoglycemic shock develops.

A relative insulin resistance of the peripheral tissues in patients with hyperinsulinism has already been discussed. Diabetic glucose assimilation coefficients may be found in patients with organic hyperinsulinism at a time when plasma-insulin values are greatly elevated. We still cannot say with certainty whether humoral insulin antagonists are responsible or whether a true tissue resistance to insulin is present.

d) Treatment of the B-Islet-Cell Adenoma

When a case of organic hyperinsulinism has been diagnosed, an attempt should be made to localize the islet-cell adenoma. The tumor can be visualized by a celiacography in the pancreas in 10–20% of all cases. As a rule, adenomas with a diameter of 1–2 cm are detected by this procedure. Smaller adenomas may be missed. Scintigraphic methods for localizing insulinomas have so far been unsuccessful. The correct diagnosis of B islet-cell adenoma is absolutely imperative for the surgeon. The surgeon must find the islet-cell adenoma by means of careful dissection of the whole pancreas. Unfortunately, about 5% of islet-cell adenomas are ectopic and lie outside the pancreas, so that they are usually missed by the surgeon. Previously, when exploration of the pancreas was negative, four-fifths of the pancreas was removed. This procedure can no longer be recommended. If the adenoma cannot be localized, no portion of the pancreas should be removed. The adenoma may well be found during a second exploration one or two years later, when the tumor has grown larger (STEINKE, 1968). Besides, a four-fifth resection of the pancreas involves a high risk. An operation according to Whippel, with total pancreatectomy and partial resection of the small intestine should not be carried out since such patients become invalids afterwards. β-cytotoxic substances may make a cure possible for these patients in the near future (Streptozotocine) (BRODER, 1973).

e) Symptomatic Treatment of Organic Hyperinsulinism

At present, there is no ideal symptomatic treatment for organic hyperinsulinism. Surgery stands unchallenged at the top of the list of possible therapeutic measures. Only when it fails, i.e. when the islet-cell adenoma is not found or is inoperable, should pharmacotherapy be tried. The drug of choice is diazoxide (FAJANS, 1966). A daily dose of 150–300 mg increases the blood sugar by an average of 10 mg%. Symptoms of hypoglycemia may be delayed for hours so that the majority of patients may be symptom-free. Unpleasant side effects of diazoxide are sodium retention, palpitations, and high blood pressure. These symptoms are usually prevented by rather large doses of a hyperglycemic saliuretic drug. There are, however, other unavoidable side effects of diazoxide, of which growth of lanugo-type hair on the face is one of the most distressing. It always develops in children and female patients and is found to be extremely unpleasant. Gastrointestinal symptoms can, but need not arise and usually do not necessitate discontinuation of diazoxide therapy. The appetite decreases in most patients. Regular glucose administration is no longer necessary and overweight patients regularly lose weight in the first months of diazoxide therapy. Glucagon raises the blood sugar only temporarily and for this reason it is unsuitable for long-term treatment of organic hyperinsulinism. In contrast, treatment with glucocorticoids has proved successful since glucose formation in the liver is stimulated over a long period of time and blood sugar is increased. The risks of prolonged administration of glucocorticoids in high doses are wellknown. Streptozotocine should be restricted to cases of B-cell carcinoma. Some rather striking improvements of hypoglycemia and tumor growth have been reported after Streptozotocine therapy.

H. Glucagon: The Second Pancreatic Hormone

E. R. FROESCH

MCLEOD (1922) was the first to notice that intravenous administration of certain insulin preparations caused an initial rise in the blood sugar. MURLIN and his team (1923) separated a substance with a hyperglycemic action from insulin preparations and named it "glucagon", since it mobilized glucose from the liver.

Glucagon was later concentrated from insulin preparations and pancreas extracts. STAUB, SINN, and BEHRENS succeeded in crystallizing glucagon in 1953, and in 1956 BROMER succeeded in determining its structure. After ACTH and insulin, glucagon is the third polypeptide hormone which has been synthetically produced in the test tube.

1. Chemistry of Glucagon

The pancreas contains only about 5–10 mg of glucagon per kg wet weight, or about one twentieth to one tenth of its content of insulin (SAMOLS, 1966). Glucagon is highly insoluble at a pH of 4–9. These were probably the main reasons for the long delay in the purification of the hormone. Glucagon which has been recrystallized repeatedly still contains small traces of insulin and vice versa. These small traces of insulin cannot be removed from glucagon preparations by ordinary methods of protein chemistry.

Glucagon consists of a chain of 29 amino acids without disulfide bonds. The isoelectric point lies between pH 7.5 and 8. Glucagon is soluble at pH 3–4 and is very stable. Insulin contaminants can be removed by incubation with alkali or with reducing chemicals containing SH-groups, such as glutathione or mercaptoethanol.

2. Physiology of Glucagon

a) Site of Origin

Glucagon is formed in the A-cells of the islets of the pancreas. Ligation of the pancreatic duct and atrophy of the exocrine tissue do not result in the loss of A-cells. Glucagon can still be extracted from the pancreas after the B-islet cells have been destroyed with alloxan (PINCUS, 1950). In the dog, there are no A-cells in the uncinate process, and glucagon is also absent in this area of the pancreas (BENCOSME, 1956). A substance similar to glucagon can also be obtained from the gastrointestinal tract. Intestinal glucagon is immunochemically and biologically related to, but not identical to pancreatic glucagon (UNGER, 1968). It is assumed that the argyrophilic cells in the gut, which are similar in appearance to the A-cells of the pancreas, secrete intestinal glucagon. Intestinal glucagon appears to have a greater molecular weight than pancreatic glucagon (UNGER, 1968). It reacts with antibodies of most animals immunized with pancreatic glucagon. However, there are already antibodies which can distinguish the two types of glucagon and which react with only one or the other.

b) Metabolism

The existence of two or more different substances in the serum with glucagon-like activity sheds some doubt on previous findings which were collected and interpreted under the assumption that there is only one pancreatic glucagon. The glucagon concentration in the peripheral blood lies between 0.5 and 6 ng/ml serum when measured by the most recent immunochemical methods (WEINGES, 1968). Glucagon in a concentration of as low as 1.0 ng/ml has a glycogenolytic action on the liver (SOKAL, 1966). Thus, concentrations of this hormone found in the blood are also effective on the liver.

Glucagon action on the perfused liver *in vitro* is of short duration. It appears to be rapidly degraded and inactivated by the liver. It seems to have a short half-life which has not been exactly determined. Blood sugar rises for 20–30 min after an intravenous injection of glucagon and then falls again. The duration of action is quite similar to that of insulin.

Glucagon has three main sites of action in the organism. The most important is the stimulation of glycogenolysis in the liver. Glucagon converts the inactive phosphorylase-b into active phosphorylase-a, so that glycogen is rapidly broken down and released as glucose from the liver into the blood (SUTHERLAND, 1951, 1965). It appears that pancreatic glucagon is the true physiological antagonist of insulin (FOA, 1968). When the blood sugar falls, pancreatic glucagon rises in the pancreatic veins and in the peripheral blood and causes the blood sugar to return to normal values (UNGER, 1968). According to SOKAL (1966), glucagon is much more effective than adrenaline and noradrenaline, which also have a glycogenolytic action and work through the same mechanism as glucagon.

According to the interesting observations of SAMOLS and others in the last few years, glucagon is not only an antagonist of insulin, but also in some way a synergist. When glucagon is given by rapid intravenous injection, insulin concentration in the blood rises rapidly and before the blood sugar increases (SAMOLS, 1965). Furthermore, again according to these authors, there is first a rise in the glucagon concentration in the blood and then a release of insulin following the administration of glucose (SAMOLS, 1965). It would now appear that glucagon is no longer an antagonist to insulin, but rather a stimulator of insulin secretion. This view is supported by the observation that glucagon also stimulates insulin secretion *in vitro* (VECCHIO, 1966). Since it has become possible to differentiate between pancreatic and enteral glucagon, evidence accumulates that the rise in glucagon in the blood following administration of glucose is due to an increase in the secretion of enteral glucagon rather than pancreatic glucagon (UNGER, 1968). This is also supported by the observation that glucagon rises only after oral administration of glucose and not after intravenous administration. It is plausible that liberation of enteral

glucagon is responsible for the considerably greater release of insulin after intake of glucose by the oral route than after the intravenous administration of glucose. It is not known whether this enteral glucagon released after glucose administration has a physiological action different from that of pancreatic glucagon. It seems that the glycogenolytic action of enteral glucagon is less potent than that of pancreatic glucagon (UNGER, 1968). The third action of glucagon in the organism involves adipose tissue. Glucagon is a lipolytic hormone. In physiologic concentrations it stimulates the liberation of free fatty acids from adipose tissue. Here as well, glucagon appears to be an antagonist to insulin, which has a definite antilipolytic action. Insulin promotes the storage of absorbed food in the form of glycogen and fat, whereas glucagon stimulates the mobilization of these substances as glucose and free fatty acids (WEINGES, 1968; LEFEBRE, 1967).

The mechanism of action of glucagon on adipose tissue, liver and islet cells appears to be the same. The mode of action of catecholamines and of glucagon has been thoroughly investigated, in particular by SUTHERLAND and his team (1965). According to these investigators, glucagon promotes the formation of cyclic 3′,5′-AMP from ATP through the activation of adenylcyclase. The cyclic AMP then converts inactive phosphorylase-b or inactive lipase into the active form of the enzyme by phosphorylation of serine residues in the enzyme. Protein kinases are responsible for this phosphorylation.

3. Overproduction of Glucagon

Overproduction of glucagon is sometimes held responsible for the development of diabetes mellitus (WEINGES, 1968). The prevalence of A-cells over B-cells in the pancreas of the diabetic was quoted in support of this hypothesis (FERNER, 1953). However, permanent diabetes mellitus has been successfully produced in experimental animals only in a few instances and with extremely high doses of glucagon. Glucagon levels in the blood of diabetics are usually slightly elevated or within normal limits. This is further evidence against the pathogenetic significance of glucagon in diabetes mellitus (WEINGES, 1968).

Although it is highly probable that overproduction of glucagon has nothing to do with essential diabetes mellitus, there have been a few reports of pancreatic tumors associated with hyperglycemia and glycosuria (UNGER, 1964; MCGAVRAN, 1966; YOSHINAGA, 1966). Usually these tumors are diffusely growing neoplasms of the A-cells which lead to destruction of the pancreas and to metastases in the liver. The estimation of glucagon content of the serum, and when possible of the tumor, is the only safe means of substantiating that these tumors really secrete glucagon and are responsible for the diabetic state. In the few cases described, the blood sugar showed very large swings and there was no ketosis. In addition, the cases were characterized by failure to respond to intravenous administration of glucagon.

4. The Glucagon-Deficiency Syndrome

Pancreatectomy results in diabetes and not in hypoglycemia. There is no satisfactory method, neither surgical nor chemical, to selectively eliminate the A-cells. Cobalt chloride, phenolsulfonphthalein and syntaline A are only partially effective. In certain types of birds, islets containing A-cells are separated from those containing B-cells. In these animals, fatal hypoglycemia can occasionally be produced by complete removal of the islets containing A-cells. It is assumed that this type of hypoglycemia is due to glucagon deficiency (FOA, 1968). There is still no good evidence that certain forms of spontaneous hypoglycemia during infancy are due to a glucagon deficiency.

XIV. The Parathyroids

M. WERNLY

With Contributions by

B. COURVOISIER and J. A. FISCHER

A. Historical Dates

1880 The parathyroids were described for the first time in man by SANDSTRÖM.
1895 KOHN added to SANDSTRÖM's description and recognized for the first time that the parathyroids were independent of the thyroid gland.
1896 VASSALE and GENERALI showed that removal of all four parathyroids produced severe tetany in dog.
1903 ASKANAZY found an adenoma of the parathyroid gland at the post mortem of a case of skeletal disease and suspected a connection between the two. This is the first reported case of hyperparathyroidism.
1906 ERDHEIM suspected the connection between the parathyroids and mineral metabolism.
1907 ERDHEIM described hyperplasia of several or all parathyroids in osteomalacia in man.
1908 MCCALLUM and VÖGTLIN successfully demonstrated that hypocalcemia arose after parathyroidectomy.
1914 ERDHEIM described hyperplasia of several or all the parathyroids in spontaneous rickets in rat. This is the earliest report of compensatory hyperplasia of the parathyroids, i.e. secondary hyperparathyroidism.
1926 MANDL successfully cured a clinical case of primary hyperparathyroidism by removing an adenoma of the parathyroid.
1925 COLLIP and HANSON, working independently, discovered parathyroid hormone and its hypercalcemic effect.
1934–1948 ALBRIGHT (Boston) described the biochemistry and diagnosis of primary hyperparathyroidism. He discovered that primary hyperparathyroidism was frequently an endocrine disorder, with nephrolithiasis as the most important symptom.
1959 RASMUSSEN and CRAIG and AURBACH succeeded in isolating and purifying parathyroid hormone and it was recognized as a polypeptide hormone.
1962 COPP isolated a hormonal factor with a hypocalcemic action from the parathyroids.
1963 HIRSCH showed that this hormone originated in the thyroid in mammals.
1963 BERSON described a radioimmunological method for the estimation of parathyroid hormone in serum, with which he was able to measure elevated values.
1965 TENENHOUSE showed that the hypocalcemic factor was also a polypeptide hormone. In birds and reptiles it is found in the ultimobranchial body. It is now generally called calcitonin rather than thyrocalcitonin.
1967 RAISZ succeeded in estimating the calcitonin concentration in plasma in several patients by recording the decrease in the number of osteoclasts in bone cultures *in vitro*.
Immunological methods introduced by TASHJIAN, DEFTOS, and ARNAUD have simplified the estimation of calcitonin.

B. Normal Anatomy and Histology

M. WERNLY

Weight. The 4 parathyroids in the unfixed state have a combined weight of 170 mg on average. The superior glands are somewhat smaller and each weighs 40 mg, as against the inferior glands, each of which weighs 45 mg (WERNLY, 1946).

Shape. The normal parathyroid is almost the size and shape of a lentil. It is flattened on both sides and is usually longitudinally oval. It is brownish red in color and has a yellow tint in the presence of an increased fatty penetration. The consistency is softer than that of a lymph node of the same size, and more compact than that of a fragment of fat.

Number. Normally, 4 parathyroid glands are formed in man. However, there have been reports of 2 or 3 glands. The possibility of congenital hypoplasia or aplasia cannot be excluded, but it is more likely that inadequate anatomical

preparation is the reason. We have demonstrated and histologically verified more than 4 glands in 50 cases among 450 post mortems. There are a few reports of even 8–12 glands (ERDHEIM and WERNLY, 1946).

Ontogenesis. The upper parathyroids arise from the 4th pharyngeal pouch and the lower parathyroids from the 3rd. The two pairs of glands cross each other during the developmental migration. The lower parathyroids move an especially long way, together with the thymus which also arises from the 3rd pharyngeal pouch. Occasionally their progress is arrested during this process or they descend further than usual. The numerous variations in the position of the lower parathyroids are thus due to the development.

Normal Topography. The superior parathyroids are usually situated on the posterior surface of the thyroid gland. They are generally connected with one of the hilus-like depressions in the middle of the two lobes of the thyroid gland, which is entered by a branch of the inferior thyroid artery. The lower parathyroids are normally embedded in a pyramid-shaped piece of fat at the lower pole of the thyroid gland. The base of this pyramid faces upwards and is formed by the thyroid gland. The two lateral surfaces are formed by the carotid artery and the trachea, and the anterior and posterior surfaces by the superficial and deep fasciae of the neck.

Arterial Blood Supply. Each parathyroid has its own artery, the parathyroid artery, which enters at the hilus and passes into the center of the gland from where it supplies the entire parenchyma via several branches. There are no anastomoses connecting the parenchyma with the surrounding tissues. The parathyroid artery is thus an end artery. Generally all four parathyroid arteries arise in the inferior thyroid artery, but occasionally the upper pair arise in an anastomosis between the inferior and superior thyroid arteries. There is a further anastomosis between the upper and lower thyroid arteries and the arteries of the pharynx, the esophagus, and the trachea, so that an adequate blood supply to the parathyroids is ensured in all circumstances. During radical neck surgery, and less frequently during operations on the thyroid, one or more of the parathyroids may be inadvertently removed or their blood supply endangered. Ligation of the small arterial branches in the region of the surface of the thyroid gland is thought to be especially dangerous. The branch which gives rise to the parathyroid artery can also be involved in this process. Ligation of this branch proximally instead of distally to the origin of the parathyroid artery, may cause necrosis of the parathyroid gland. HALSTED has therefore advocated that the small arterial branches be ligated near to the surface of the thyroid gland. The value of this suggestion is not known. It is more important to ligate the trunk of the inferior thyroid artery immediately after it leaves the carotid artery, where the procedure is harmless. It is also important that the connection between the posterior thyroid capsule and the surrounding tissues is preserved during the wedge-shaped resection of a single adenoma next to the posterior capsule of the thyroid gland and during total thyroidectomy. In this way, both the parathyroids and their blood supply remain intact.

Variation in Position. It is sometimes very difficult to find the parathyroids when they are not in the usual position. The upper glands must then be systematically searched for on the entire posterior surface of the thyroid gland, at its upper pole, between the trachea and the esophagus, and higher up, along the carotid artery. The lower glands are occasionally displaced cranially against the posterior surface of the thyroid gland, but more often distally against the jugular vein, in which case the parathyroid gland lies either in the tip of the thymus or free in the retrosternal space. The presence of a goiter makes it much more difficult to find the parathyroids. Occasionally, one gland may not only be displaced by a nodule of a goiter but also compressed and pushed out of shape into a long, flat, oval band on the surface of the nodule. In some animal species, it has frequently been reported that it is normal for the parathyroids to be completely embedded in the thyroid gland. This rarely occurs in man (p. 931, intrathyroidal adenoma of the parathyroid).

Topography of Mediastinal Adenomas. Adenomas of the parathyroid glands can be displaced into the anterior or posterior mediastinum or onto the anterior surface of the pericardium by negative intrathoracic pressure since the glands are not fixed to any cervical organs. A vascular stem is often found running towards the thyroid in such cases. The surgeon can use the vascular stem as a guide to the correct position in the retrosternal space. When a mediastinal adenoma is suspected, every downward branch of the inferior thyroid artery should be dissected out to decide whether a vascular stem of this type is present or not.

Cytology. Light microscopy allows division of the parenchymal tissue of the parathyroids into 3 cell types: the chief cells, the water-clear cells (GETZOWA), and the oxyphil cells (WELSH). Chief cells and water-clear cells are connected by numerous intermediary forms. We differentiate between small dark chief cells and large clear chief cells, and between small and large water-clear cells. The small dark and the large clear chief cells make up the main part of the normal parathyroid. The water-clear cells have strongly vacuolized protoplasm with sharply demarcated cell borders. The large water-clear cells can be 2–3 times as big as the large clear chief cells.

From the microscopic findings in inactive, active and hyperactive glands it can be concluded that parathyroid hormone is formed primarily in the large chief cells. Since these large chief cells are the predominant element in the gland of the young subject, they were also called young chief cells earlier. Other authors name them the clear chief cells or the water-clear transitional cells. The small, dark chief cell with a small nucleus appears to be the chief cell in the resting phase. The functional significance of the water-clear cells, which occur only infrequently in the parathyroids of a healthy subject, is not clear. All the chief cells as well as the water-clear cells contain large amounts of glycogen, the inactive dark chief cells containing the least and the water-clear cells the most. The pronounced vacuolar aspect of the water-clear cells, making the protoplasmic space look empty, is due to a multitude of small membrane-limited vacuoles originating from the Golgi apparatus. They do not contain glycogen.

The protoplasm of the oxyphil cells has a very strong affinity for acidic stains in particular, but also for basic substances. Some of them are found scattered diffusely in the parenchyma, and some as goups of cells or as microadenomas. Very few of these cells are found in the parathyroids of newborns and adolescents. They increase greatly in number with increasing age, and in the female after the menopause they account for up to 10% of the total mass of parathyroid glands, or 90% of a single gland. More recent electron microscope and histochemical investigations have shown that a large part of the protoplasm of these cells is composed of mitochondria closely packed together and of mitochondrial enzymes. The significance of these oxyphil cells is still largely unknown (HAMPERL).

Synthesis of parathyroid hormone, secretion granules, and cellular organelles on electron microscope examinations (MUNGER, 1963; LANGE, 1961; ROTH, 1971) have shown that parathyroid hormone, like other polypeptide hormones such as insulin and pituitary hormones, is probably found in secretory granules in the cells. The pro-secretory and secretory parathyroid hormone granules are oval and round. They are enclosed by a membrane and have a diameter of 100–220 μm. They are developed in the region of the Golgi apparatus and later released into the protoplasm, probably leaving the cells via exocytosis.

Active chief cells of the normal human parathyroid contain a well-developed Golgi zone, abundant ergastoplasm (site of protein synthesis), many secretory granules, a few mitochondria and little glycogen. Inactive chief cells of inactive glands have all the opposite features. The oxyphil cells and the uncommon water-clear cells of the normal gland contain only very few and only small secretory granules. Their Golgi zones and their ergastoplasms are difficult to demonstrate and are small. The oxyphil cells contain a large amount of mitochondria, and the water-clear cells contain much glycogen.

The parenchymal cells of the parathyroid adenoma in primary hyperparathyroidism invariably behave like hyperactive cells. They contain a great abundance of large secretory granules, as well as a strong ergastoplasm, ring lamellae, a precursor of the ergastoplasm, and a Golgi apparatus. It is striking that the cells of the oxyphil and of the water-clear adenomas behave in exactly the same way as long as these adenomas are really associated with the clinical features of primary hyperparathyroidism, which is a definite difference from the oxyphil and water-clear cells of the normal parathyroid, in which all these cellular organelles are only poorly developed.

The parenchymal cells of the hyperplastic parathyroid assume an intermediate position between the normal gland and the adenoma. This applies in particular to the secretory granules, the Golgi apparatus and the ergastoplasm. In cases of severe hyperparathyroidism with highly increased parathyroid hormone concentrations in the blood, the parathyroid cells look depleted of secretory granules, whereas in moderate hyperparathyroidism a considerable number of granules is visible. ROTH (1971) suggests that the release of parathyroid hormone can be suppressed without a concomitant decrease of the synthesis of parathyroid hormone.

Structure, Fat Cells, Colloid Cysts. The parathyroids have a trabecular-acinous structure. Small glands in the functionally inactive state show wide connective tissue septa. With increased activity, the number of the parenchymal

cells is increased, and there is usually also a marked increase in the number of individual cells, the very small chief cells developing into large chief cells or into small water-clear cells. As the activity increases, the full picture of hyperplasia of the parathyroid gland develops (p. 934). Due to this increase in the volume of the parenchyma of the parathyroid, the connective tissue septa in the hyperactive glands are lost entirely or reduced to narrow strands. The gland ultimately assumes the fully compact structure of the hyperplastic parathyroid.

Fat cells are scattered in the interstitial spaces and in the parenchyma. They are numerous in inactive glands and also in glands of obese subjects. They decrease steadily with increasing activity and are completely absent from hyperplastic glands. The adenomas of primary hyperparathyroidism are also almost entirely free of fat cells. During childhood and youth the glands contain only a small number of fat cells. The number of fat cells can be valuable in assessment of the functional state of a gland or of a glandular biopsy. It must, however, be borne in mind that the number of fat cells can vary greatly from one part of a gland to another, or from one gland to another. Furthermore, the number of fat cells can be greatly increased in the parathyroids of obese subjects, regardless of the degree of activity of these glands (WERNLY, 1946).

Not uncommonly, colloid granules are found scattered in the parenchyma of a normal, hyperplastic, or adenomatous parathyroid. True colloid vesicles with cuboid or cylindrical epithelium lining the walls are also found. In addition, there are alveoli without colloid, which can be small or large. True cysts can also be present. It is not unusual for colloid vesicles to arise in groups, giving a thyroid-like appearance. Large parathyroid cysts can only be distinguished from ordinary branchiogenic cysts if they can be related to the clinical diagnosis of primary hyperparathyroidism.

C. Physiology and Biochemistry of Calcium and Phosphate Metabolism

JAN A. FISCHER

1. Calcium Metabolism

Calcium and phosphate are the main constituents of the skeleton. Calcium is also a regulator of electrical and biochemical processes. In man, its concentration in the plasma is kept within narrow limits. As far as is known, the concentration of the ionized calcium changes little in the course of the evolution of the vertebrates. The regulation of enzyme reactions, transmission of electric impulses in the nervous system, muscular contraction, lactation, the secretion of gastric juices, and renal concentrating ability are all dependent upon the concentration of the ionized calcium in the plasma. Calcium is also necessary for blood coagulation.

Death probably results from cardiac failure in patients with a total plasma calcium above 18–20 mg/100 ml or below 4 mg/100 ml. In hypercalcemia, the ventricle is in a state of contraction at the time of death, and in the past the development of the contraction was even used as an assessment of the concentration of the ionized calcium in an unknown solution. There are at least four points of action in muscle: the conducting nerve, the muscle end plate, the electrically charged membrane of the myofibrils and the actomyosin. In addition, there are biochemical sites of action in numerous enzyme reactions. It is not known precisely what process brings about cardiac arrest in acute hypercalcemia. As a rule, the patients die of renal failure in chronic hypercalcemia.

This chapter deals chiefly with abnormal regulation and disorders of calcium metabolism. The molecular processes in which calcium is an important trace element have not been dealt with. The reader is referred to p. 856 for a discussion of its function as a supporting mineral in the bones.

a) Distribution

More than 99% of the body calcium is found in the skeleton and the teeth (p. 856). The remainder is distributed in the extra- and intracellular fluids.

Plasma. The calcium concentration is most easily measured in the plasma, and this estimation is clinically the most important. The calcium concentration in the plasma is 8.5–10.5 mg/100 ml, depending on the method used. When the same method is used the variations do not exceed $\pm 5\%$ in normal control persons, and $\pm 1\%$ in the same subject when measured at the same time of day. The concentrations are kept within the narrow limits mentioned above predominantly by parathyroid hormone and calcitonin (Table 1). In addition to parathyroid hormone, vitamin D and thyroxine cause a rise in the serum calcium concentration, whereas calcitonin, cortisone and glucagon cause a fall. A deficiency of parathyroid hormone may be present if recovery of the normal calcium concentration in the plasma is delayed after an intravenous infusion of EDTA, which

chelates calcium. The rise of the calcium concentration in the plasma is accelerated by the administration of growth hormone, which presumably causes increased calcium mobilization from bone (GERSHBERG, 1967).

Calcitonin causes a fall in the calcium concentration in the plasma. Calcitonin deficiency arises in patients after thyroidectomy, and these patients show a delayed return of the calcium concentration to normal values after intravenous administration of calcium (MAZZUOLI, 1966). Cortisone also causes a fall in the serum calcium concentration. One exception to this, however, is the elevated calcium concentration in the plasma in hyperparathyroidism. This difference provides a way of differentiating hypercalcemia due to hyperparathyroidism from that due to other factors (DENT, 1962) (p. 926).

Table 1

Factors increasing the serum calcium concentration
Parathyroid hormone
Vitamin D (oversensitivity in sarcoidosis)
Calcium
Thyroxine
Growth hormone
Vitamin A
Paraneoplasia (parathyroid hormone-like substances)
Bone metastases (predominantly osteolytic)
Factors lowering the serum calcium concentration
Calcitonin
Cortisone
Phosphate
Vitamin-D deficiency (? resistance)
Paraneoplasia (?)
Bone metastases (predominantly osteoplastic)
Glucagon

A normal serum calcium concentration can only be attained in the presence of a minimum intake of vitamin D and/or of calcium, and of a maximum intake of phosphate. An increase of the plasma phosphate is associated with a fall in the concentration of the serum calcium. Parathyroid hormone and vitamin D (and its metabolites) are necessary for regulation of the serum calcium concentration, and their release into the plasma is in turn dependent on the concentration of the ionized calcium (p. 871). Methods for determining ionized calcium are not yet generally applied, since measurement of the total calcium concentration is usually sufficient for clinical purposes. The concentrations of diffusible and ionized calcium are dependent on the pH and on complexing agents such as phosphate, citrate, other organic anions, and variations can thus remain unobserved if only the total calcium concentration is measured. Conversely, variations in the concentration of serum proteins lead to hyper- or hypocalcemia in the presence of unchanged concentrations of ionized calcium. This occurs in an extreme form in the hen, where the serum calcium can rise to 30 mg/100 ml in the presence of an ionized calcium concentration of about 6 mg/100 ml. Of the calcium in the serum, 60.5% is in a diffusible form (46.9% ionized, 13.6% as bicarbonate, phosphate and citrate complexes, and 39.5% bound to proteins (MOORE, 1970) (Fig. 1). Similar values can be found in WALSER (1961). The differential diagnosis between hyper- and hypocalcemia is described on p. 926. The calcium concentration in the extracellular fluid is 7 mg/100 ml. In the *cerebrospinal fluid*, it is 4.5–6 mg/100 ml. These values correspond approximately to the concentration of ionized calcium, since the calcium bound to the plasma proteins cannot diffuse freely.

The concentration of intracellular calcium can only be roughly estimated. In the liver and the kidney, calcium is found predominantly in subcellular particles. The calcium in the cytoplasm, defined as cell sap free of organelles, amounts to 10^{-6} to 10^{-7} M (THIERS, 1957). There is a steep concentration gradient between the extracellular fluid and the cytoplasm. Calcium is stored intracellularly in the mitochondria, the microsomes and the cell nuclei. No absolute concentrations can be given for the intracellular fluids because of the inhomogeneous distribution in the cell, and there is no point of reference, particularly since the volume, the pH, and the concentrations of the proteins and anions of the individual compartments cannot be measured accurately. As a rule, the concentrations are deduced from the nitrogen content or the

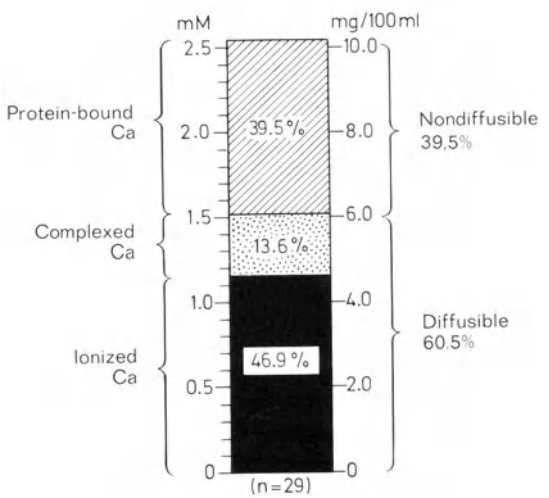

Fig. 1. Fractions of total serum calcium as obtained by ultrafiltration and determination of the ionic calcium concentration in 29 normal sera (percentages are mean values of the group). (After MOORE, 1970)

nucleic acid content of the cell or from the subcellular particles. In addition, there is an inhomogeneous distribution in individual organs and it is difficult to obtain an insight into the complex distribution and compartmentalization of calcium. It is easier to measure the calcium concentration in erythrocytes, which contain only small amounts (0.634 µg/ml) (HARRISON, 1968). Myocardial function can partially be judged by the ECG since the Q-T duration varies inversely to the serum calcium concentration.

Hypercalcemia and a rapid intake of large amounts of phosphate can result in nephrocalcinosis and in the calcification of organs and blood vessels. The calcifications arise preferentially in alkaline regions in the kidneys and occasionally in the gastric mucosa. Furthermore, calcifications arise in necrotic areas, and possibly for the same reasons also in the liver following poisoning with carbon tetrachloride. Calcification of the basal ganglia is found in idiopathic hypocalcemia (p. 899). DANOWSKI (1962) gives a detailed account.

b) Balance

Calcium is absorbed from the small intestine and is excreted in the gut, urine and sweat. It is also excreted through the placental circulation and in the milk (Fig. 2). The determination of the calcium balance is inexact and time-consuming since an equilibrium between the multiple compartments of the bone with variable calcium intake can be obtained only over a period of weeks and months.

α) Calcium Intake

The daily requirement of calcium is about 0.5–1.0 g for the adult, 1.0–1.5 g during growth and pregnancy, and at least 1.5 g during lactation. The daily intake is 0.5–1.5 g in West European countries and in North America. Intake may very well be below the minimum requirements, especially in advanced age and during pregnancy, and it is certainly below the minimum in some developing countries.

With an increased nutritional intake of calcium, the amount of calcium absorbed in the small intestine decreases steadily, as the intestinal mucosa becomes saturated. Maximum absorption is achieved with an intake of 3–5 g/24 h, and is 1–1.5 g/24 h (NORDIN, 1968).

Calcium Absorption. Calcium absorption is limited to the upper small intestine, the duodenum and the jejunum. The methods available for the measurement of calcium absorption are preeminently of academic interest. The simplest method, which is rather inaccurate, is limited to the comparison of the calcium intake and the fecal calcium excretion. The calcium intake can easily be measured providing the calcium content of the drinking water is considered in the calculation. Measurement of the calcium excretion in the stools is time-consuming and must be carried out over balance periods of 3–7 days. Chromium is given constantly to the patient by mouth and the calcium excretion is related to the chromium content in the stools (HARGREAVES, 1965). With a daily intake of 1 g, or 15 mg/kg body weight, the fecal excretion is about 700 mg or 11 mg/kg body weight (Fig. 2). The error in the measurement can be as high as 1000 mg/24 h in isolated cases, and the measurements sometimes have to be continued over 4-day periods for over 100 days (ISAKSSON, 1967). This method is not suitable for determining differences of less than 100–200 mg/24 h in the balance.

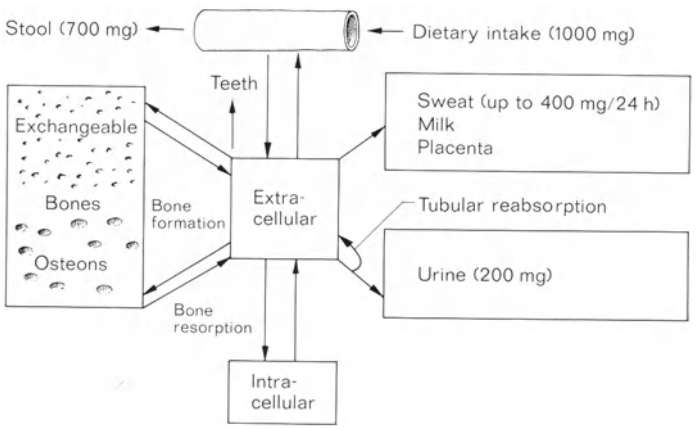

Fig. 2. The metabolism of calcium. The schematic representation of the osteons and the exchangeable calcium pool reflects the autoradiographic picture. For explanations see text.

Calcium absorption is estimated more simply with radioactive ^{47}Ca after oral intake of 5–20 μCi ^{47}Ca (half-life 4.7 days). The rise in the concentration can be measured in the plasma, or the retention is determined with a whole-body counter or with a scintigraph over specific parts of the skeleton such as the radius (AVIOLI, 1965; SODE, 1968). This method is easy to use. Measurement of the specific activity in the plasma has the disadvantage that it is impossible to allow for secretion through the intestine, the calcium excretion in the urine, the plasma volume and the flow rate of the calcium from the plasma to other compartments of the body, especially in pathologic cases. With the whole-body counter method and scintigraphy, a homogeneous distribution in the skeleton is assumed. This disadvantage can be counteracted by using radioactive ^{47}Ca in combination with ^{45}Ca, which has a longer half-life. Both isotopes are administered orally and intravenously at the same time. The ratio of the two isotopes excreted in the urine is measured 24 hours later, and the amount of calcium absorbed from the small intestine is calculated. The rapid decay of ^{47}Ca and the formation of the less energy-rich ^{47}Sc must be taken into account in the measurement of ^{47}Ca and correspondingly screened off (DE GRAZIA and RICH, 1965).

Transport mechanisms of calcium through the intestinal mucosa are dealt with in the section on vitamin D (p. 882). In the intestine, calcium deficiency leads to increased absorption of magnesium. Magnesium deficiency results in increased calcium absorption (ALCOCK, 1962). It is still uncertain whether there are transport routes common to both magnesium and calcium through the intestinal mucosa of whether magnesium is simply a requirement for calcium absorption. Magnesium promotes calcium absorption in the intestine and leads to elevated retention of calcium and magnesium in the bones (CLARK, 1967, 1968). Extreme magnesium deficiency leads to hypocalcemia in rats (MCMANUS, 1969). Intestinal calcium absorption and calcium release from the bones are dependent on a minimum magnesium concentration.

Increased Calcium Absorption. Vitamin D, parathyroid hormone and growth hormone promote the absorption of calcium. It is also increased in the presence of an acid pH, by an increase in the ionized calcium concentration, and by lactose. A protein-rich diet with increased amounts of basic amino acids, pregnancy, the growth period, calcium-deficient nutrition and phosphate deficiency also promote calcium absorption. Calcium absorption is increased in sarcoidosis, possibly due to elevated sensitivity to vitamin D. The effects of vitamin D and parathyroid hormone occur only after some hours, whereas inhibition of calcium absorption by intravenous calcium infusions can be measured within minutes (BIRGE, 1969).

Reduced Calcium Absorption. Calcium absorption is reduced in the presence of adrenocortical steroids, thyroxine, vitamin-D deficiency and rickets. It is also reduced in the malabsorption syndrome with steatorrhea due to the reduced absorption of vitamin D and of calcium. Calcium absorption is diminished in hyperthyroidism, in hypoparathyroidism, and after administration of alkalis, oxalate, phytate or phosphate. In inflammatory processes in the region of the intestine, calcium absorption is sometimes increased after the administration of cortisone, if it influences the basic disease.

β) Calcium Excretion

Calcium is excreted into the intestine, and in the urine, sweat, and breast milk.

Intestine. The daily excretion into the intestine is 150–450 mg or 2–6 mg/kg body weight, and is approximately the same as the calcium excretion in the urine.

Calcium excretion in the feces is measured after the intravenous injection of ^{47}Ca. Assuming that the specific activity ($^{47}Ca/^{40}Ca$) of the calcium excreted in the urine is the same as that of the calcium excreted in the stools, the excretion of the total calcium in the stools can be calculated from the excretion of the ^{47}Ca and ^{40}Ca in the urine and from the radioactive ^{47}Ca in the feces (LAZOR, 1963).

Kidneys. The urinary calcium excretion is dependent on the calcium concentration of the ultrafiltrable calcium (about 60 % of the total calcium) in the glomerular filtrate and on the tubular reabsorption of calcium. Calcium excretion is increased by an increased nutritional intake and/or intestinal absorption such as occurs in sarcoidosis, and by an elevated bone breakdown such as occurs in hyperthyroidism and in acidosis. The urinary excretion is also increased in hyperparathyroidism because of a direct inhibition of calcium reabsorption in the proximal tubules. Small differences in the ultrafiltrable calcium can lead to considerable variations in the urinary calcium without remarkable changes of the total serum calcium concentration.

Calcium is filtered through the glomeruli, and about 99 % is reabsorbed in the tubules.

Providing renal function is normal, the excretion threshold through the kidneys lies at a serum concentration of about 8 mg/100 mg. When the serum concentration falls below 8 mg/100 mg, practically all the calcium is reabsorbed and less than 30 mg is excreted in 24 hours. With normal nutrition, the daily excretion is 150–450 mg, or 2–6 mg/kg body weight. With a calcium-free diet the excretion is below 200 mg. The maximum excretion in the urine is about 1 g/24 h. When this concentration is exceeded, calcium is deposited as renal stones or in the tissue until the glomerular filtration is so limited that calcium can no longer be excreted in large amounts. In such cases it is not always possible to determine whether primary hyperparathyroidism was originally present or whether the results are due to secondary hyperparathyroidism, resulting from the hypocalcemia of renal insufficiency, or even autonomic tertiary hyperparathyroidism. Since the calcium clearance never exceeds the creatinine clearance, secretion of calcium in the tubules cannot be confirmed or excluded. The tubular reabsorption, like the absorption in the small intestine, is promoted by parathyroid hormone and inhibited by cortisone (LAAKE, 1960).

Calcium, magnesium and sodium are presumably reabsorbed in the renal tubules by a common carrier mechanism. The details are unknown. Calcium infusion leads to increased excretion of magnesium (COBURN, 1967). Increased magnesium intake results in an elevated excretion of calcium in the urine, which may be due partly to increased calcium absorption in the intestine (CLARK, 1968). The micropuncture method has been used to demonstrate that calcium and sodium are reabsorbed in the same region of the proximal tubule (DUARTE, 1967).

Calcium and magnesium reabsorption is diminished by an increased sodium intake with an expansion of the extracellular space, and the excretion into the urine is increased, while calcium excretion is decreased in response to a diminution of the extracellular space by thiazides. Administration of desoxycorticosteroids such as 9-fluorohydrocortisone with simultaneous intake of sodium leads to expansion of the extracellular space and only then to an increase in the excretion of calcium and magnesium into the urine (MASSRY, 1968; SUKI, 1968). The tubular reabsorption of calcium is maximally increased in hyperparathyroidism. An additional loading of the renal tubules by an infusion of sodium chloride, leads to a rise in the calcium excretion, in contrast to the result in normal control subjects (AXELROD, 1966). A sodium-deficient diet, however, causes an increase in the tubular reabsorption of calcium in idiopathic hypercalciuria (EDWARDS, 1965).

Calcium excretion in the urine is increased in the presence of complexes such as citrate, in phosphate deficiency, and in acidosis. Furthermore, calcium excretion is increased by saliuretics such as ethacrinic acid, in osmotic diuresis and by carbohydrates. Carbohydrates produce a higher calcium excretion in patients with calcium oxalate stones and in their relatives than in control subjects (LEEMAN, 1969).

Hypercalciuria can result in nephrocalcinosis and nephrolithiasis, but calcium is not the only factor involved in these disorders. Stone formation is favored by an alkaline pH, which is usually found in hyperparathyroidism, in Cushing's syndrome, in primary hyperaldosteronism and in urinary tract infections. Renal stones are most frequently found in hyperparathyroidism, in idiopathic hypercalciuria, in Paget's disease, in Cushing's disease and in immobilization osteoporosis, which may also be found with weightlessness in astronauts.

Calcium and phosphate are present in the urine in an oversaturated solution, so that protective substances which prevent the formation of renal stones must be assumed. Phosphonates, which differ from pyrophosphate in that they cannot be metabolized by renal pyrophosphatases, inhibit nephrocalcinosis (FLEISCH, 1968). A different substance is a peptide, which has not yet been successfully purified (HOWARD, 1968).

Hypercalciuria leads to water diuresis with diminished water reabsorption and to increased excretion of sodium in the urine. Inhibition of water reabsorption in the ascending Henle's loop can be assumed (BINSWANGER, 1967; SUKI, 1969). Selective perfusion of the proximal and distal tubules of the rat with calcium inhibits water reabsorption in the distal tubules. These are morphologically altered in dog following calciuria, which explains vasopressin resistance (LASSITER, 1965; EPSTEIN, 1959).

Hypocalciuria develops in particular with a fall in the calcium concentration in the serum, and with diminished calcium uptake in the intestine, in intestinal malabsorption syndromes or following oral administration of phytates and phosphate. Thiazides and a sodium-deficient diet lead to increased reabsorption of calcium by the renal tubules. These drugs are therefore used for the treatment of idiopathic hypercalciuria (YENDT, 1966).

Sweat. The calcium excretion is 20–365 mg/24 h, depending on the temperature and the humidity

of the air. The average excretion is 120 mg/24 h (ISAKSSON, 1967). Excretion in the sweat is measured on the arm and is related to the potassium excretion, which in turn is calculated from the exchangeable potassium and the potassium balance of the total body surface. The calcium concentration varied, depending on the author, between 0.3 and 15 meq/liter. Between 0.1 and 0.7 meq/liter, it is mainly proportional to sweat excretion (VELLER, 1968).

Fetus. Calcium excretion through the placenta corresponds to the calcium content of the fetus, which contains 30 g calcium and 22 g phosphorus at term. With a calcium content of 1200 g in the adult, the 30 g correspond to a loss of 2.5% during pregnancy. This is partly compensated for by a greater calcium absorption in the intestine with a corresponding rise in the parathyroid hormone concentration (CUSHARD, 1972); during the last quarter of pregnancy, about 250 mg calcium is incorporated daily into the fetus (CUSHARD, 1971; HYTTEN, 1964).

Lactation. About 50–70 g calcium is excreted in the milk. When lactation is prolonged about 500 g is excreted. The World Health Organization therefore recommends a daily calcium intake of 1200–1500 mg between the fourth and ninth months of pregnancy and about 1200–2000 mg during lactation.

Summary. Determination of the calcium balance is inexact and time-consuming, particularly because the fecal excretion and the loss in the sweat are not easily determinable. After an alteration of the calcium intake, weeks or months may be required before equilibrium between the different compartments of the bone is attained. Intestinal calcium absorption can be estimated with isotopes, but this only permits comparisons between patient groups with increased, diminished or normal calcium absorption. The most important single measurement is the estimation of the serum calcium concentration.

2. Phosphate Metabolism

Phosphate and calcium are the main bone minerals. Phosphate is found in higher concentrations than calcium in the intracellular fluid where it is an important anion and component of the nucleic acids and of the energy-rich compounds such as adenosine triphosphate. Phosphate is a regulator of oxidative phosphorylation and a buffer in cells, plasma and urine.

a) Distribution

About 80% of the phosphate is found in the bones and teeth. The remainder is distributed throughout the intra- and extracellular fluids, and half of it is found in the musculature.

Plasma. In contrast to the calcium concentration in the plasma, which is kept within the same narrow limits throughout life, the phosphate concentration in the plasma is age-dependent. In the adult the concentration of inorganic phosphorus is 2.5–4.5 mg/100 ml. During youth, it is 4.0–7.0 mg/100 ml, and it rises to 4.5 mg/100 ml during the menopause. Of the inorganic phosphate in the plasma, 88% is ultrafiltrable (WALSER, 1961). Phosphate acts as a buffer substance in the plasma and the urine, although the total buffering capacity in the blood is only 5.5% (ELLISON, 1958). In addition to inorganic phosphate, there is about 1 mg/100 ml phosphorus in the form of phosphate esters and 8 mg/100 ml as phosphates bound to lipids. The total phosphorus concentration in the plasma is about 12 mg/100 ml. The concentration of inorganic phosphate in the plasma shows considerable diurnal variations and is dependent on nutritional intake (Fig. 3) (STANBURY, 1958). The serum phosphate is lowest in the morning and highest in the evening. This rhythm is approximately parallel to fluctuations in the concentration of parathyroid hormone in the serum (ARNAUD, 1971). The normal rhythm of the phosphate concentration in the plasma and of the phosphate excretion in the urine disappears after removal of the adrenals or of the pituitary gland. The changes

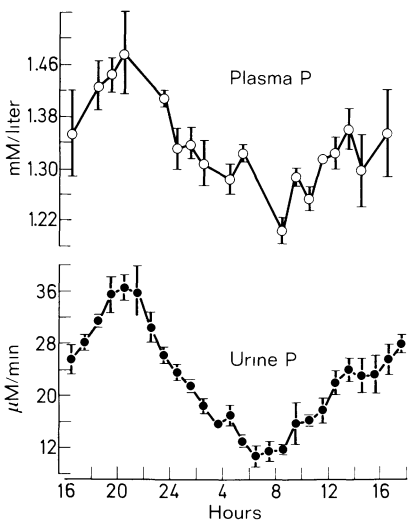

Fig. 3. Diurnal variation of the serum phosphorus concentration and the urinary phosphate excretion in three normal subjects. (After STANBURY, 1958)

in the serum are paralleled by those in the urine and cannot therefore be related to changes in the urinary phosphate excretion. There may be some interrelationships between the diurnal fluctuations of the cortisol levels and of the phosphate levels in the plasma (GOLDSMITH, 1965). The phosphate concentration is measured in the morning in the fasting state. Serum proteins and erythrocites must be separated within two hours of the blood collection, so that organic phosphates are not measured as well.

The phosphate concentration in the plasma is influenced by the nutritional intake of phosphate, by intestinal absorption, by the incorporation and release of phosphate in the bones and in the intracellular fluid, and by its excretion through the kidneys. Vitamin D, parathyroid hormone, thyroxine and acidosis accelerate bone metabolism and thereby the release of calcium and phosphate into the plasma. Growth hormone promotes the reabsorption of phosphate in the renal tubules and leads to an elevated phosphate concentration in the serum during growth and in acromegaly (CORVILAIN, 1964). Parathyroid hormone and calcitonin reduce the serum phosphate concentration by increasing the excretion through the kidneys. Furthermore, calcitonin inhibits bone resorption, and insulin and glucose increase the uptake of phosphate into the intracellular fluid. For reasons which have still not been explained, the serum phosphate concentration is diminished in the presence of septicemia caused by gram-negative organisms (RIEDLER and SCHEITLIN, 1969).

The differential diagnosis of hyper- and hypophosphatemia is discussed on p. 940.

The concentration of inorganic phosphate in the *extracellular fluid* corresponds to the serum concentration.

It is 1–2 mg/100 ml in the *cerebrospinal fluid*, where it is increased in hypoparathyroidism.

Most of the phosphate in the *intracellular fluid* is in an organic form. Phosphate is a component of nucleic acids, of energy-rich compounds such as adenosine triphosphate (ATP), hexose phosphates, and creatine phosphate. Transport of phosphate through the intracellular membranes, such as the mitochondrial membrane, is increased under the influence of parathyroid hormone. Phosphate acts as a regulator of ATP synthesis and of additional energy-rich compounds which, together with oxidative phosphorylation and the respiratory chain, facilitate the transport of ions through the mitochondrial membrane. ATP is an important source of energy for muscular contractions, for the synthesis of cell constituents and for glandular secretions. Phosphate deficiency leads to muscular weakness, nausea, and anorexia (LOTZ, 1968).

In *the urine*, phosphate forms an important buffering system for the excretion of hydrogen ions, after bicarbonate and ammonia. Phosphate is excreted predominantly as $H_2PO_4^-$ at pH 4.8, and as HPO_4^{--} at pH 7.8.

b) Balance

Phosphate is absorbed in the intestine and is incorporated into the bones and the intracellular fluid. About 80% is excreted in the urine and sweat. Some is presumably excreted into the intestine.

α) Phosphate Intake

The daily requirement of phosphate corresponds to that of calcium and is about 1 g (calculated as phosphorus). Only organic phosphates are absorbed. Elemental phosphorus is highly toxic.

Absorption. The regulatory mechanism for the absorption of phosphate in the intestine is not well known. Phosphate is presumably absorbed by passive diffusion. Vitamin D, parathyroid hormone and growth hormone accelerate the absorption of calcium and thus also that of phosphate. These substances presumably have no direct effect on the absorption of phosphate.

Increased absorption is found with a calcium-deficient diet, following the administration of fats and of cations, and in the presence of an acid pH.

Reduced absorption is found with reduced calcium absorption or a predominance of cations such as calcium, strontium, magnesium and aluminum, which form complexes with phosphate. Aluminum hydroxide gel is used for the treatment of renal insufficiency to reduce phosphate absorption. Organic phosphate compounds such as phytates cannot be hydrolyzed and therefore cannot be absorbed.

β) Phosphate Excretion

Phosphate is excreted in the urine, stool and sweat. Further, about 22 g phosphorus are incorporated into the fetus during pregnancy. The loss in the maternal milk during a lactation of average duration is about 40 g.

Kidneys. Like the plasma concentration, the excretion of phosphate demonstrates a circadian rhythm which is less obvious in the absence of parathyroid hormone. The phos-

phate clearance must therefore always be measured at the same time of day or, better still, over 24 hours (STANBURY, 1958) (Fig. 3). Theoretically, the most accurate measurement of the phosphate excretion is obtained by measuring the maximum tubular reabsorption (T_{mP}) while the phosphate intake is changed by means of intravenous infusions of phosphate. This investigation is complicated by the fact that infusions of phosphates cause the ionic calcium concentration to fall within minutes, with a corresponding increase of the parathyroid hormone concentration and a reduction of the T_{mP} (FISCHER, 1973). Furthermore, a potassium loss may also be produced, which in itself causes a reduction of the T_{mP} (STANBURY, 1958). The phosphate excretion is measured primarily as the tubular reabsorption (TRP) or as the maximal tubular phosphate reabsorption (BIJOVET, 1970). Phosphate is filtered through the glomeruli and about 85–95% is reabsorbed in the tubules. When serum phosphate levels are increased with phosphate infusions, even in hypoparathyroidism, only 38% is reabsorbed (FAIRHURST, 1963). The ratio of the phosphate clearance to the creatinine clearance gives an indication of the tubular phosphate reabsorption (TRP) (the calculation is given on p. 944). The maximum tubular phosphate reabsorption can be measured directly, or, more conveniently, read from a nomogram (BIJOVET, 1969).

There is probably a transport mechanism common to glucose and phosphate in the proximal renal tubules. Increased amounts of glucose are reabsorbed under the influence of parathyroid hormone. An increase in the maximum glucose reabsorption (Tm) is thus interpreted as a sign of hyperparathyroidism in the differential diagnosis of hypercalcemia (TRANSBOL, 1967).

Apart from being reabsorbed in the proximal tubules, phosphate is also secreted in the distal tubules in amphibians and in birds. This is also true of man during the administration of high doses of phosphate, when phosphate clearance may exceed the glomerular filtration rate (WEBSTER, 1967).

The excretion of phosphate in the urine is dependent on the nutritional intake, on the plasma concentration, and on factors which influence the tubular reabsorption or secretion. Renal phosphate excretion is increased by various factors: parathyroid hormone, calcium administration, cortisone, estrogens, thyroxine, increased protein intake, hypokalemia, hypomagnesemia, acidosis, bicarbonate administration and expansion of the extracellular fluid volume (SUKI, 1969). As a rule, the excretion of phosphate in the urine is elevated in primary hyperparathyroidism, providing renal function is not seriously impaired. It is elevated in secondary hyperparathyroidism, in rickets, in osteomalacia, in hyperthyroidism, in acidosis (intensive muscular activity, diabetes, hunger), with the intake of large amounts of phosphate, in gout, in acute immobilization osteoporosis, in the presence of predominantly osteolytic bone metastases, especially after treatment with estrogens, in vitamin-D intoxication, in sarcoidosis, in tubular lesions (renal tubular acidosis, pyelonephritis) and in vitamin D-resistant rickets. The urinary excretion of phosphate is difficult to evaluate in certain cases for the diagnosis of hyperparathyroidism, since it can be elevated in all forms of hypercalcemia.

In uremia renal osteopathy develops, which is associated with a decrease in the serum calcium concentration. This leads to secondary hyperparathyroidism with a reduction in the tubular phosphate reabsorption. The urinary phosphate excretion is only suppressed in the presence of a greatly reduced glomerular filtration rate (FALLS, 1966) (p. 871).

Angiotensin diminishes the excretion of phosphate, sodium, chloride, calcium and magnesium, presumably by inhibiting the renal blood flow (BRODEHL, 1966). The excretion of phosphate is reduced by growth hormone, insulin and hydrocortisone. Thus, it is decreased during growth and in hyperinsulinism. It is also reduced during pregnancy and lactation, vitamin-D deficiency and intestinal malabsorption, with reduced renal function, in hypoparathyroidism, after parathyroidectomy, in certain cases of idiopathic hypocalcemia, in Addison's disease and in the presence of predominantly osteoplastic bone metastases.

A small proportion of the phosphate is excreted in the urine in the form of pyrophosphates which probably originate from the bones (p. 889). The excretion of phosphate, pyrophosphate and hydroxyproline is correspondingly elevated in hyperparathyroidism (AVIOLI, 1966).

Sweat. Phosphate excretion in the sweat has not yet been directly measured. The calcium and nitrogen excretion is estimated in the sweat. The phosphate excretion is estimated on the assumption that the ratio between the phosphate and calcium or nitrogen excretions does not differ from the whole body balance. The excretion in the sweat is 125 mg/day on average (ISAKSSON, 1967).

Intestine. The amount of phosphate presumably secreted together with calcium into the intestine is not known.

3. Bone Metabolism

a) Structure and Biochemistry of Bones

The skeleton consists of cells, the organic bone matrix (mainly collagen, mucopolysaccharides) and the bone mineral (chiefly calcium and phosphate). When bone is formed, bone matrix is synthesized and calcium phosphate is subsequently deposited. Amorphous calcium phosphate is transformed into hydroxyapatite. The skeleton consists of inorganic bone mineral (about 70%) and of the organic bone matrix (about 30%).

Macroscopically the bones are composed of *spongiosa* and *compact* parts. The spongiosa consists of trabeculae, and the compact bone of concentric lamels. It is found in the subperiostal regions of the skeleton and in the diaphyses of the long bones. The segmentation in *osteons* is characteristic of the structure of the compact bone. These osteons are histogenetically, trophically and mechanically determined units. They consist of a narrow Haversian canal layered with osteoblasts, and undifferentiated cells, arteries, capillaries, veins and nerve fibers. Around the Haversian canal the bone substance is deposited in concentric lamels. Between these layers the osteocytes are found. The reader is referred to the appropriate textbooks for the detailed description of the anatomy of the bones.

α) Bone Cells

Bone is probably separated from the extracellular fluid by a cellular membrane. NEUMANN (1969) found six times more potassium in the so-called bone-water than in the extracellular fluid. The exchange of fluids, salts and nutrients is regulated by cells which control the formation and the resorption of bone.

The osteocytes orignate from osteoblasts which, in turn, are formed from undifferentiated mesenchymal cells. This series of events can be demonstrated autoradiographically with the aid of thymidine labeled with tritium. It can be shown that thymidine is incorporated into desoxyribonucleic acids and cell division occurs in undifferentiated mesenchymal cells, from which osteoblasts and osteocytes, and osteoclasts develop.

The osteoblasts are only present in growing osteons. They are responsible for the formation of new bone. The cytoplasm of the osteoblasts is rich in ribonucleic acids which regulate protein synthesis. They also contain large amounts of enzymes such as the alkaline and acid phosphatases which can be demonstrated histochemically. The osteoblasts excrete the organic *bone matrix* and have a well-developed Golgi apparatus (YOUNG, 1964). Increased osteoblastic activity can be demonstrated in the presence of a rise in the concentration of the *alkaline phosphatase* in the plasma. It runs parallel to an increase of the accretion as measured by isotopic-kinetic analysis (p. 863). There is no correlation with bone resorption, however (KLEIN, 1964).

It is possible to separate the alkaline phosphatases from the placenta, the leukocytes, and the small intestine on electrophoresis. Alkaline phosphatase of the bone – but not of the liver – is inactivated by heat. For practical purposes the results are disappointing (POSEN, 1967). The heat-stable alkaline phosphatase is slightly elevated during pregnancy.

When the liver function is normal, an elevated serum alkaline phosphatase concentration serum usually indicates increased osteoblastic activity. A familial deficiency of alkaline phosphatase (*hypophosphatasia*) leads to impaired bone formation with a pronounced increase in osteoid. This deficiency shows that an alkaline phosphatase is important in bone formation (BARTTER, 1966). *Hyperphosphatasia* or familial osteoectasia is associated with a pronounced increase in osteoblasts and in bone formation, as demonstrated by means of labeling with tetracycline (THOMPSON, 1969). The mineralization of the bones is also inadequate.

Immature osteons are surrounded by osteoblasts, whereas mature osteons are enveloped by endosteal lining cells. Osteocytes are found between the lamellae of the compact bone. They are connected by means of long processes passing through narrow canals. As in the case of the osteoblasts, it has been demonstrated histochemically that alkaline phosphatase and numerous hydrolases are present in the osteocytes. No acidic phosphatase has been demonstrated. The osteocyte is not very different from the osteoblast from which it originates (VAES, 1967). Osteocytes regulate new bone formation and breakdown (BELANGER, 1969), while plurinuclear osteoclasts stimulate bone resorption (Fig. 6a, p. 860).

β) Bone Matrix

90–95% of the bone matrix consists of collagen, a protein which contains amino acids, predominantly glycine (about 30%), proline (12%), and hydroxyproline (10%). The osteoblasts initiate the synthesis of the collagen. Free amino acids are taken up by the osteoblasts and are deposited on the ribosomes, where protocollagen is formed. At this point only proline incorporated into the protocollagen is hydroxylated into hydroxyproline. This reaction requires the presence of ascorbic acid. The protocollagen is

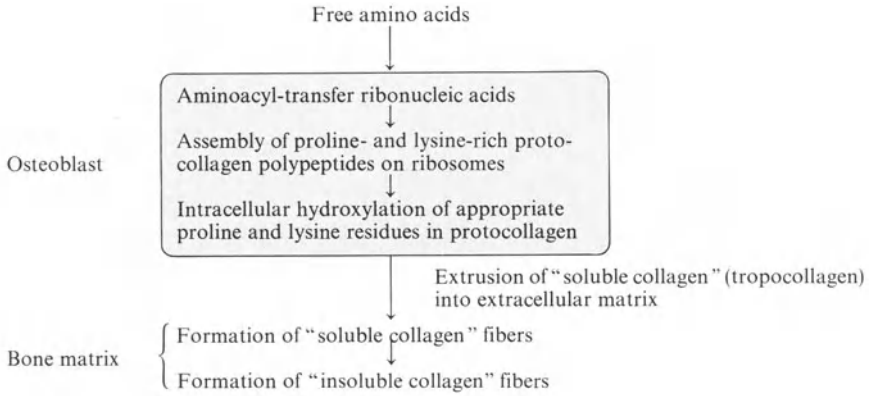

Fig. 4. The biosynthesis of collagen in the osteoblasts and in the bone matrix. (After PROCKOP, 1967)

secreted into the intercellular fluid where it is first converted into "neutral salt-soluble" and then to "insoluble" collagen fibrils which are then connected to form a network (PROCKOP, 1967) (Fig. 4). Collagen is composed of three helical polypeptide chains with a molecular weight of over 350000. Amino acids such as glycine and proline, which have been demonstrated autoradiographically, are the main components of collagen. Proline is first selectively incorporated into the osteoblasts within 30 min. From there it passes into the unmineralized osteoid within 4 hours, and appears later in the mineralized bone matrix (CARNIERO, 1959). In addition to collagen, 1–2% of the bone matrix is formed by the *ground substance* of the bone, which is made up predominantly of mucopolysaccharides such as chondroitin sulfate.

The architecture of the matrix probably determines the size of the skeleton and the orientation of the bone crystals.

γ) Bone Mineral

The main bone minerals are calcium and phosphate. They are present in the form of amorphous calcium phosphate and of hydroxyapatite (POSNER, 1969). Tetracycline is deposited in the transitional zones between osteoid and apatite. The area of the surface marked with tetracycline gives an indication of the rate of the mineralization of the skeleton and thus of the formation of new bone (FROST, 1963) (p. 860). Furthermore, the bones contain small amounts of carbonate (6%), nitrate (1%), sodium (0.7%), magnesium (0.7%), and fluoride (traces) (NEUMANN, 1958). The apatite crystals measure about 50–100 × 200–250 × 450–500 Å. They correspond to synthetic hydroxyapatite in X-ray and infra-red spectroscopy. The combination of the phosphate with the side chains of collagen molecules appears to be important for the beginning of the nucleation process (GLIMCHER, 1962). The details of the precipitation of calcium and phosphate in the net of collagen fibrils are not definitively known. Calcium phosphate is normally precipitated on the collagen of the bones and in the teeth. It is only visible macroscopically in organs such as the liver and the spleen, in the blood vessels or the skeletal musculature in pathologic conditions. The reason for this is only partially known. FLEISCH (1961, 1968) has shown that pyrophosphate plays some part in the process. Pyrophosphate *in vitro* inhibits the precipation of calcium phosphate on apatite crystals (FLEISCH, 1961) and it has been demonstrated in the plasma and in the bone. Administration *in vivo* prevents calcification of the skin and of the aorta (FLEISCH, 1966a; SCHIBLER, 1968; CARTIER, 1959). Alkaline phosphatases are also pyrophosphatases in most tissues, and particularly in the skeleton (RUSSELL, 1968). It is possible that a pyrophosphatase in the bone favors the accelerated breakdown of pyrophosphate which inhibits calcification. Precipitation of calcium and phosphate can then occur (FLEISCH, 1968).

A normal serum calcium and/or phosphate concentration is necessary for bone mineralization. NEUMANN (1958) showed *in vitro* that calcium and phosphate are present in the serum in a solution oversaturated with hydroxyapatite, and that precipitation is therefore favored. Calcification is impaired if calcium and phosphate are decreased. A fall in the calcium concentration in the extracellular fluid is observed in the presence of an increased bone formation, as for example in rachitic children treated with vitamin D, in whom the skeleton suddenly becomes more mineralized. About 500 mg calcium daily are incorporated from the extracellular fluid into the bones and correspondingly about the same amount of old bone is resorbed. In addition, there is a constant exchange of

calcium between the apatite lying on the bone surface and the extracellular fluid. These two exchange processes were estimated separately over more than 30 years with autoradiographic techniques involving exposure to ^{226}Ra or ^{90}Sr. Radioactive ^{226}Ra is bound, to a great degree irreversibly, to the skeleton (ROWLAND, 1960). The "hot spots" are clearly visible and correspond to the areas of bone formation already formed at the time the isotopes were taken up by the body. At the same time, radioactive radium is diffusely distributed over the entire surface of the bone minerals. Most of the diffusely distributed radium is presumably exchanged independently of the metabolism of the bones. The sum of the calcium ions in the extracellular fluid and in the bones remains relatively constant at least for short periods of time. About 50% of the radium is diffusely distributed after 20–30 years (MARSHALL, 1959; ROWLAND, 1960).

With advancing age, apatite replaces water in the skeleton so that bones ultimately contain no more than 3–5% water.

b) Formation and Resorption of Bone

Hormones and/or vitamin D regulate bone formation and resorption via cellular mechanisms which, in turn, regulate mineralization and demineralization. The formation of new bone and its resorption occur simultaneously in different parts of the bone. Bone remodeling is the sum of both processes, which are frequently both increased or reduced. They are regulated by hormones and require the presence of vitamins A and D, ascorbic acid, and an adequate protein intake (p. 888) (Table 3).

Bone Formation. The formation of new bone in the embryo is preceded by the formation of cartilage (endochondral) or the bones are formed directly from specialized mesenchymal cells (membranous). Remodeling of bone continues throughout life. Bone formation is regulated by osteoblasts and osteocytes and is defined by the synthesis of bone matrix and subsequent incorporation of bone mineral. This has been discussed with reference to the structure and the biochemistry of the bone (p. 856).

Bone Resorption. Bone resorption is controlled partly by osteoclasts and partly by osteocytes. They liberate substances which dissolve the bone matrix, releasing calcium and phosphate. Thus, the product of calcium × phosphate in the plasma is elevated. The calcium arises either from old bones which are destroyed by cellular resorption, or from the exchangeable calcium pool, in particular from the osteons which are not fully mineralized. When the calcium × phosphate product in the plasma falls, calcium is immediately released from the exchangeable portion of the bones (ROSENBAUM, 1964). Bone resorption begins only later, when apatite crystals are dissolved by osteoclasts and osteocytes under the influence of parathyroid hormone, and calcium is released predominantly from the old, nonexchangeable parts of the bone.

The rapid incorporation and release of calcium from the bones may be regulated by the *osteocytes*. The processes of the osteocytes are separated from the bone by a layer of amorphous calcium phosphate (BAUD, 1968). A halo around the osteocytes indicates an increased bone resorption and increased release of calcium (BÉLANGER, 1969) (p. 856). The multinuclear *osteoclasts* are produced only within hours to days under the influence of parathyroid hormone and cause dissolution of bone mineral. This process was described by KOLLIKER as early as 1873. Acid phosphatase is the predominant histochemically demonstrable enzyme in osteoclasts. It can be elevated in the plasma in hyperparathyroidism. The question as to whether the osteoclasts are principally phagocytic cells or whether they initiate and regulate bone dissolution has been asked over the years. KOLLIKER'S assumption that the formation of the osteoclasts precedes bone dissolution has been confirmed histologically, by electron microscopy (HANCOX, 1963) and in cultures of bone cells *in vitro* (GAILLARD, 1961). Osteoclasts predominantly dissolve the bone and phagocytize the bone minerals only temporarily. This has been demonstrated in autoradiographic experiments with plutonium, which can be observed first on the bone surfaces and later in the cytoplasm of the osteoclasts (ARNOLD, 1957). The osteoclasts have a brush-border and numerous vacuoles and vesicles which are demonstrable by electron microscopy (GONZALES, 1961). The dark grains in the mitochondria are presumably calcium phosphate crystals (PEACHEY, 1964).

Dissolution of apatite occurs when there is a fall in pH, formation of complexes with calcium or exchange of calcium ions with cations such as sodium. The local pH would have to fall below 6.8 for dissolution of bone minerals to occur, but no such fall has been demonstrated. The calcium balance becomes definitively more negative when the pH of the arterial blood falls, but it has not been confirmed whether increased bone destruction and/or increased calcium excretion through the kidneys is the primary cause of the negative calcium balance (LEMANN, 1966; REIDENBERG, 1966). Citrate, the best chelator of calcium, occurs

only in insufficient concentrations in plasma and bones. There is still no explanation or evidence of an ionic exchange which would have a significant effect on the disintegration of the bone surfaces.

It is possible that pyrophosphate influences bone resorption. In addition to bone formation, it may also inhibit the dissolution of apatite crystals. Since pyrophosphate is normally present in the bones, this property could be of importance *in vivo*. According to this view, the pyrophosphate covering the bone crystal must be destroyed during bone resorption (FLEISCH, 1966b, 1968) (p. 889).

In analogy to the dissolution of the bone minerals, the bone matrix could also be dissolved by acids or by ionic exchange. Results are inconclusive. It is more likely that the bone matrix is dissolved by proteases formed in the osteoclasts or osteocytes. Parathyroid hormone promotes the enzymatic breakdown of collagen, although it has not been demonstrated whether this is a primary site of action (VAES, 1967). Bone resorption is enhanced particularly by parathyroid hormone, thyroxine, and vitamins A and D. It is inhibited by calcitonin.

c) Methods

Bone formation and resorption can be estimated histologically (morphometrically) and radiologically. Determination of calcium, phosphate, citrate, and alkaline and acid phosphatase concentrations in the plasma and of the urinary hydroxyproline excretion can be useful in assessment of bone formation and resorption, as can physical and chemical analyses of the bones and kinetic analysis based on the use of isotopes or stable strontium. Some methods described in this chapter are still at the experimental stage, but they have contributed considerably to the understanding of the pathogenesis of metabolic bone disease.

α) Morphometry of the Bones

Bone formation and resorption can be measured histologically at autopsy, or by means of biopsies from the iliac crest or from a rib. The biopsy findings have been found to agree with the postmortem findings. Withdrawal of a bone cylinder from the iliac crest is simple and the procedure can be performed in outpatients. It is suitable for assessing the course of a metabolic bone disorder since it can be repeated several times. A suitable set of instruments has been developed by BURCKHARDT (1966). An adequate number of normal control cases from all age groups is obviously necessary for the exact morphometric assessment of bone biopsies.

A massive increase of unmineralized osteoid is even visible in decalcified bone sections. However, undecalcified sections must be examined by a quantitative morphometric method for an accurate assessment of bone biopsies (FROST, 1963; MERZ and SCHENK, 1970a; JOWSEY, 1966).

The formation of new bone is evaluated either microradiographically or with the aid of tetracycline labeling. The two methods give similar results. Microradiography is based on the fact that radioopaque (calcified bone) can be distinguished from radiolucent (osteoid) regions

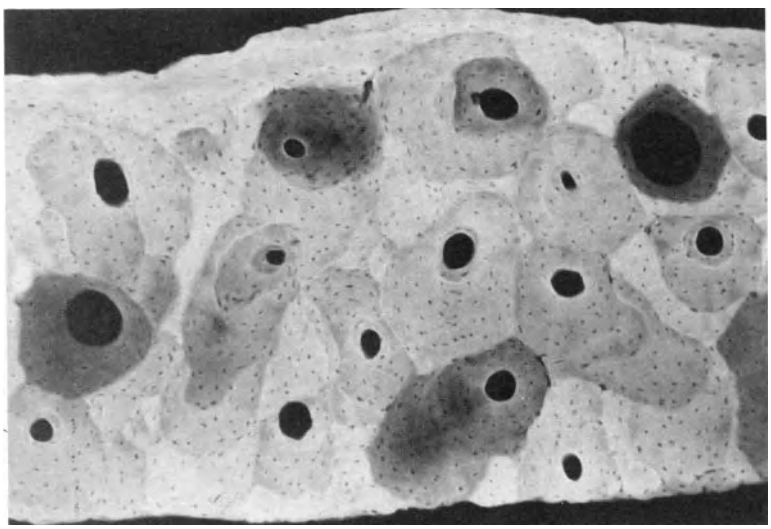

Fig. 5. Microradiograph of an undecalcified section of rib cortical bone. 80 : 1. The less radioopaque, darker parts are young, partly mineralized bones and the light areas represent the old parts of the skeleton. (Kindly supplied by Professor ROBERT SCHENK)

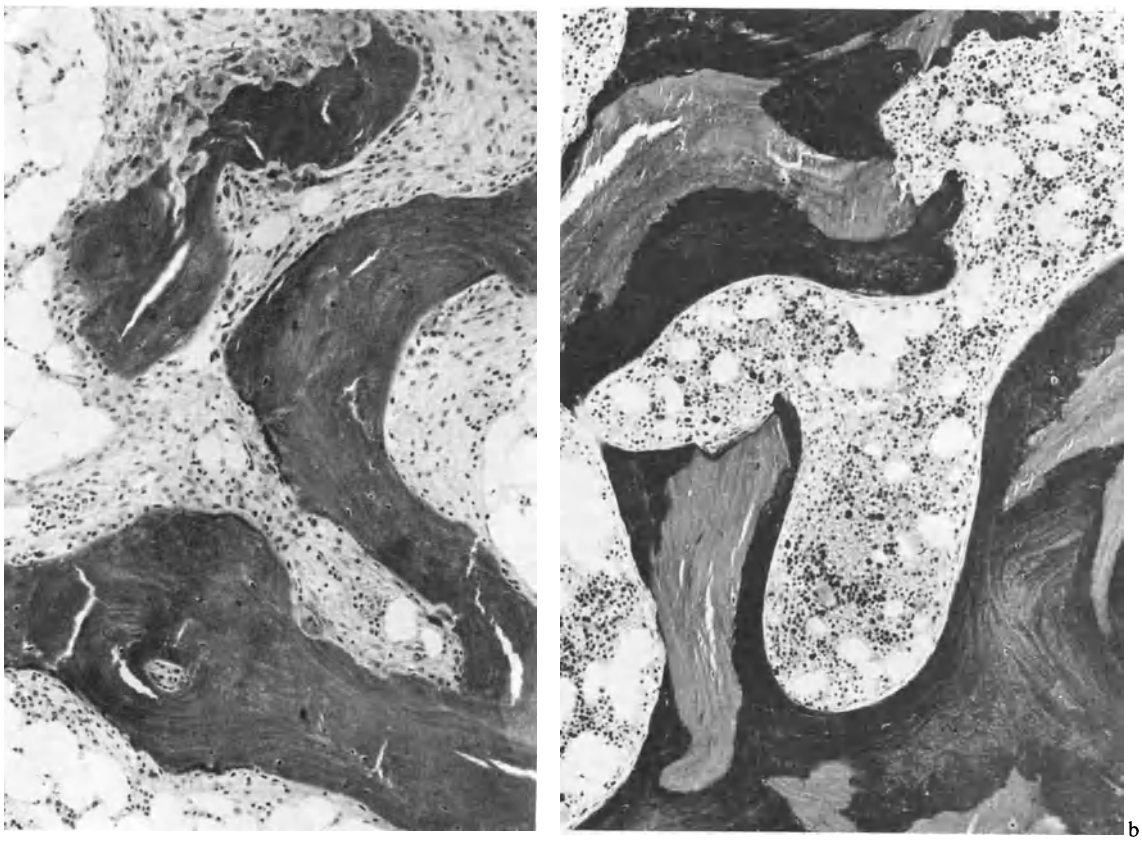
on a microradiophotograph of a bone section (JOWSEY, 1966) (Fig. 5). The microradiophotograph gives a measure of the size of the surface covered with osteoid. It reveals little about whether an increase of the osteoid is due to a rise of the formation of new bone or to decreased mineralization of the skeleton.

Labeling of the skeleton with tetracycline allows better differentiation between the two processes. Tetracyclines are only incorporated into metabolically active bone at the transitional zones from osteoid to apatite; from there tetracyclines are transported into the calcified bones (FROST, 1963; MÜLLER and SCHENK, 1966). The patient is given 1 g tetracycline per day (4 × 250 mg) for 4 to 6 days and if possible 10–30 days before the bone biopsy. The shift of the tetracycline from the surface of the bone into the calcified bone can be measured in a bone biopsy from a rib, and the volume of newly formed bone can be calculated as the newly formed volume per volume bone per year.

With the aid of tetracycline, active osteoid seams labeled with tetracycline can be differentiated from inactive, unlabeled areas in a biopsy taken from the iliac crest. The number of osteoblasts per osteoid surface can also be of aid in the assessment of new bone formation. If the number is increased relative to the amount of osteoid present, bone formation is increased, whereas in the absence of osteoblasts bone cannot be mineralized (MERZ, 1970a). This can be particularly well demonstrated in patients with osteomalacia due to intestinal malabsorption, in whom the number of osteoblasts is inadequate before treatment with vitamin D, causing a defect in mineralization. Treatment with vitamin D leads to increased numbers of osteoblasts and to subsequent deposition of bone mineral (FISCHER, 1970).

Bone resorption is assessed by measuring resorption surfaces. Furthermore, Howship's lacunae with osteoclasts are distinguished from those without osteoclasts. The osteoclast index (the number of osteoclasts per 100 mm^2 trabecular bone surface in the iliac crest) gives so far the best estimate of osteoclastic resorption. The osteoclast index according to SCHENK (1969) is 2.6 $\pm$ 1.1 in over 100 random autopsies on controls between 20 and 80 years of age.



a b

Fig. 6a and b. Undecalcified sections of bone biopsies from the iliac crest, 5 µm, Goldner stain, 110 : 1. a) Primary hyperparathyroidism with fibroosteoclastic bone resorption (female, 52 years). b) Osteomalacia in intestinal malabsorption (idiopathic sprue) (male, 57 years), the red-stained osteoid, which is present in large amounts, appears dark. (Kindly supplied by Professor ROBERT SCHENK)

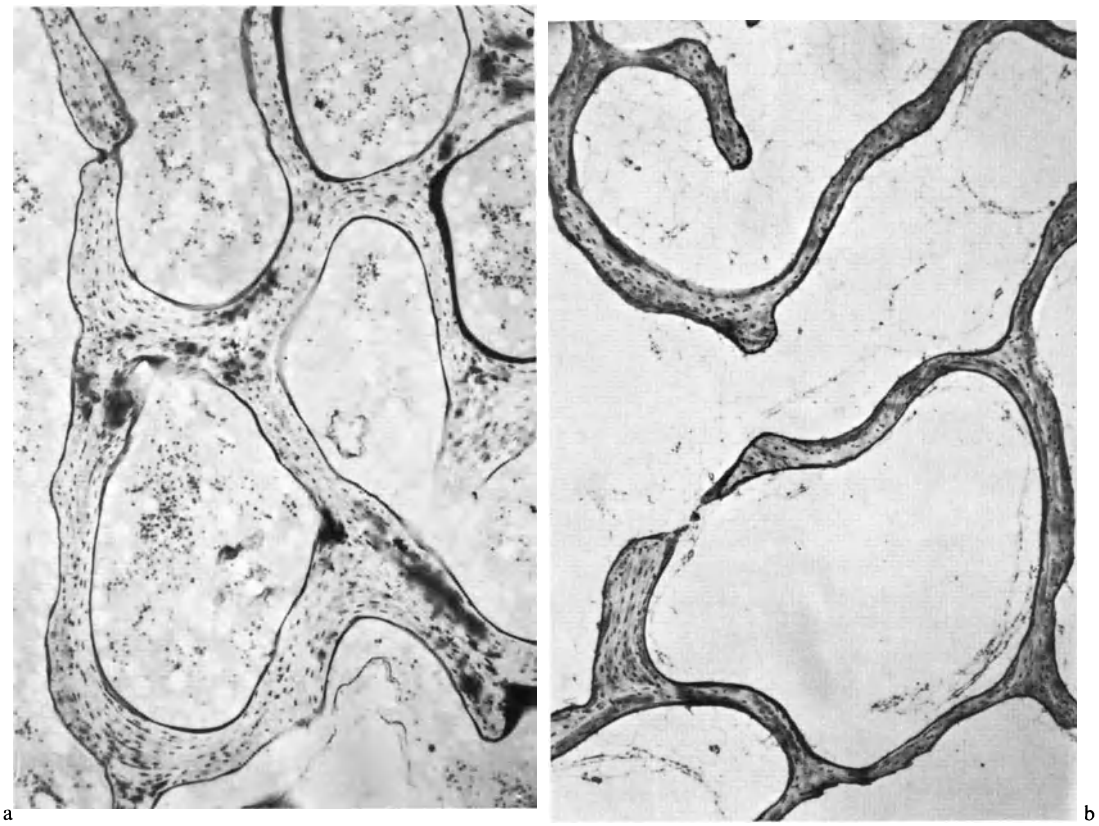


Fig. 7a and b. Undecalcified sections of bone biopsies from the iliac crest. Basic Fuchsin stain 45 : 1. a) Normal trabecular bone (male, 43 years). b) Osteoporosis with a decreased total bone mass (male, 75 years). (Kindly supplied by Professor ROBERT SCHENK)

The osteoclast index can be elevated or normal in hyperparathyroidism. Fibro-osteoclasia is qualitatively visible in about 10–20% of the cases with primary hyperparathyroidism (Fig. 6). As a rule, these patients also have radiologically visible subperiostal resorption zones in the phalanges of the fingers (p. 911). There are also surgically verified cases of primary hyperparathyroidism with a normal number of osteoclasts, in whom calcitonin may inhibit bone resorption (BINSWANGER, 1968a).

The volumetric *density* of the spongiosa is measured as the percentage of the bone trabeculae in a histological section. Regardless of the rate of bone formation or resorption *osteoporosis* is defined as a loss and *osteopetrosis* as an increase in volumetric density (FROST, 1963; MERZ, 1970b) (Fig. 7). Osteoporosis can be caused by decreased bone formation or by increased bone breakdown.

Hyperthyroidism and Cushing's disease have been chosen as examples, since the value of the morphometric assessment of the histology of the bones is demonstrated in these two disorders. A loss of bone substance, i.e. osteoporosis, is common to both. Hyperthyroidism causes more rapid remodeling of the skeleton with increased bone formation. The osteoid mass is sometimes increased. In contrast to the mineralization defect in rickets or in osteomalacia the major part of the osteoid tissue stores tetracycline and is covered by osteoblasts. It is therefore metabolically active. The bone resorption is also increased and exceeds the formation of new bone. The end result is osteoporosis and a loss of bone mass. In Cushing's disease or cortisone medication, however, bone remodeling is slowed down. Bone resorption is dominant in all these conditions. The end results are clinically and radiologically very similar, although the pathogenesis of the two forms of osteoporosis is fundamentally different.

β) Bone-Cell Cultures

The synthesis of the bone matrix and possible sites of action of hormones can be observed in in-vitro cultures of bone cells (PROCKOP, 1967). As a rule, embryonic bone splinters from the vault of the skull or from the metaphysis of the long bones are used; bone biopsies from

patients with hyperparathyroidism have also been compared with those of normal controls (FLANAGEN, 1965).

Triiodothyronine *in vitro* causes a promotion of the uptake of amino acids into embryonic cartilage cells (ADAMSON, 1967). Morphometric and kinetic results indicate that bone resorption is promoted in particular, and bone formation to a lesser extent. Undifferentiated mesenchymal cells can imitate the function of osteoblasts, osteocytes or osteoclasts. The results of metabolic investigations are therefore only partly applicable to the conditions *in vivo*.

γ) Kinetic Studies of Bones

In this section, kinetic investigations depict the measurement of the movement of isotopes and of strontium, which are primarily exchanged with and incorporated into bones (BAUER, 1961; AUBERT, 1960; EISENBERG, 1961; HEANEY, 1958, 1964; PROCKOP, 1967). The diagnostic value of the kinetic investigations is still limited. They are of value in understanding the pathophysiology of the skeleton, especially when used in combination with other methods.

Hydroxyproline labeled with ^{14}C is used to investigate the metabolism of collagen. The mineral exchange in the bones is measured with radioactive calcium and strontium and also with cold strontium, since it occurs only in traces in bones.

Collagen. PROCKOP (1967) has promoted investigations with ^{14}C-labeled proline. The increased excretion of hydroxyproline peptides in the urine is a reflection of an accelerated collagen metabolism. Proline is incorporated into collagen and subsequently hydroxylated into hydroxyproline in the osteoblasts. Kinetic methods using ^{14}C-labeled proline can show whether the raised excretion of hydroxyproline peptides into the urine is due to increased collagen synthesis, to a block in the conversion of the "soluble" collagen into the "insoluble" collagen fibrils, or to an increase in the breakdown of collagen or hydroxyproline into CO_2 and urea (PROCKOP, 1967) (Fig. 4). The major reason for increased urinary hydroxyproline excretion is an elevated collagen breakdown (soluble and insoluble collagen), e.g. during growth, in hyperthyroidism and in hyperparathyroidism. During growth and after the administration of growth hormone there is an additional increase in collagen synthesis which is responsible for the increased excretion of hydroxyproline into the urine. In lathyrism and in Marfan's syndrome this is due to a disturbance in the incorporation of hydroxyproline into the bone matrix with a retardation of the conversion of the "soluble" collagen into "insoluble" collagen. Cortisone reduces the excretion of hydroxyproline, mainly by inhibiting collagen synthesis. Additional histological and kinetic investigations with radioactive calcium permit localization of the cause of an elevated hydroxyproline excretion. In hyperthyroidism and in hyperparathyroidism, increased bone resorption is the dominant feature. The hydroxyproline excretion is reduced postoperatively in hyperparathyroidism, reflecting the decreased bone destruction, although the alkaline phosphatase rises at the same time with a compensatory increase of the formation of new bone (MACDONALD, 1965). Urinary hydroxyproline excretion correlates better with bone resorption as measured by isotopic kinetic methods than with bone accretion (KLEIN, 1964, p. 864). The clinical importance of the urinary excretion of hydroxyprolines is discussed on p. 942.

Bone Mineral. In most methods a single intravenous injection of radioactive calcium or strontium or stable strontium is given, and subsequently the loss in the plasma and the excretion in the urine and feces are measured (Fig. 8). Calcium and strontium behave similarly towards the skeleton, and the discussion is therefore limited to calcium. In about 48 hours, the calcium reaches a state of equilibrium with the extracellular fluid and with the pool of the rapidly exchangeable calcium (abbreviated calcium pool). At the same time, the substitution of the rapidly exchangeable radioactive calcium in the bones through stable calcium and its excretion in the urine, feces and sweat cause a steady fall in the concentration of the isotope in the plasma. The amounts excreted can be measured in the stools and urine and the difference from the amount injected gives an indication of the amount incorporated into the bones. Some of the exchange processes are related to the metabolically active, growing osteons and are irreversible during the investigation. At the same time, an exchange occurs at the bone surfaces. This has also been observed in isolated hydroxyapatite crystals *in vitro* (PAK, 1967). A portion of the incorporated calcium is again released by bone resorption, presumably after a few days to a few weeks. The *retention* is obtained by subtracting the amount of radioactive calcium excreted in the urine and stools from the amount administered. A more accurate measurement is achieved by using a whole-body counter. The results obtained with this method are somewhat lower (NORDIN, 1965), since the excretion in the sweat is not

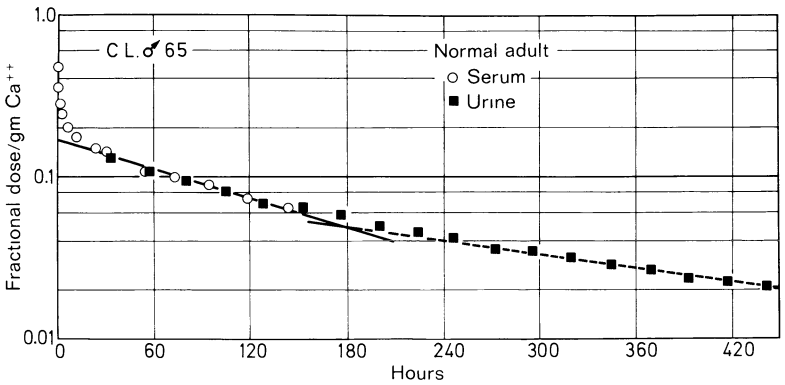

Fig. 8. Fractional dose of $^{45}Ca/g\ ^{40}Ca$ in the plasma and in the urine following a single intravenous injection of radioactive ^{45}Ca in a normal adult. (After HEANEY, 1958)

taken into account. The retention can be followed over weeks and months with a whole-body counter after one or several intravenous injections of radioactive ^{47}Ca or ^{85}Sr. The classic calcium balance (p. 850) gives similar information to the measurement of calcium retention. The curve obtained with a whole-body counter gives additional information about the rates of incorporation and removal of the calcium from the skeleton, insofar as the usual present-day models correspond to reality. The method is still in the experimental stage.

The calcium pool gives the theoretic distribution volume of calcium at the time of the injection. It is calculated from the ratio of the amount of isotope injected (Ri) to the theoretic plasma concentration at time zero (Rs_0). These quantities are obtained from the retrograde extrapolation of the fall in retention or the plasma concentration between the second and third and sixth and seventh days. The calcium pool is the sum of the extracellular distribution volume and the rapidly exchangeable calcium. The significance is controversial. The calcium pool is especially enlarged during growth. In rats, calcium administration has no influence on the size of the calcium pool (BRONNER, 1965). It is used in the estimation of bone turnover and accretion in the skeleton.

$$E = \frac{Ri}{Rs_0} \qquad (1)$$

E = calcium pool
Ri = amount of isotope injected
Rs_0 = concentration of the isotope at time zero
$T/2$ = half-life of the radioactive calcium in the plasma after intravenous injection, between the second and third and the sixth and seventh days
U = calcium turnover
Ca_U = excretion of calcium in the urine
Ca_F = excretion of calcium in the stools
R = resorption
B = calcium balance

The *turnover* (U) of the calcium between the calcium pool and the bones is calculated from the rate of fall of the calcium in the plasma or in the urine, multiplied by the calcium pool. $T/2$ is the half-life of the radioactive calcium in the plasma after the intravenous injection between the second and third days and the sixth and seventh days. 0.693 is an experimentally derived constant.

$$U = \frac{0.693}{T/2}\ E\,. \qquad (2)$$

The accretion or deposition (A) is calculated from the difference between the turnover and the excretion in the stools (C_F) and in the urine (Ca_U).

$$A = U - Ca_U - Ca_F\,. \qquad (3)$$

It is assumed that the metabolically regulated release of radioactive calcium occurs after 8–10 days at the earliest, as otherwise the accretion would be mainly a measurement of the retention of the calcium in the bones (p. 862). Turnover and accretion are increased during growth, in hyperthyroidism, in acromegaly and in Paget's disease. They are reduced in Cushing's disease. An increase in the accretion is paralleled by a rise in the concentration of the alkaline phosphatase in the plasma and indicates increased bone formation (KLEIN, 1964).

The *resorption* (R) can be calculated from the difference between the accretion and the calcium balance (B) (difference between calcium uptake and calcium excretion).

$$R = A - B\,. \qquad (4)$$

There is a good correlation between accretion and alkaline phosphatase, and between bone

resorption and the hydroxyproline excretion in the urine (KLEIN, 1964). Calcium administration inhibits bone resorption in rats, presumably by inhibiting the release of parathyroid hormone (BRONNER, 1965).

The kinetics measurements can be related up to a point to the formation of new bone, which can be demonstrated histologically. There is no strict relationship between accretion and the number of osteoid seams labeled with tetracycline or bone formation measured microradiographically (LEE, 1965; RIGGS, 1967). There is a better correlation in the young than in the adult dog, since during growth a large part of the calcium given is incorporated into the bones by metabolically active osteons, whereas in the adult the exchange between isotope and bone surfaces becomes a dominant feature. The results obtained in osteomalacia are contradictory. Histological examination after tetracycline labeling shows that bone formation is slow, whereas the turnover measured with strontium can be increased up to two-fold (FROST, 1963; FRASER, 1960). The osteoid borders labeled with tetracycline represent newly formed osteons. These osteons are autoradiographically visible as black spots ("hot spots"), in contrast to the diffusely distributed radioactive calcium (MARSHALL, 1959). The diffuse exchange processes cannot be determined histologically with tetracycline labeling. These processes may be important, particularly in adults, for the rapid regulation of the serum calcium concentration and for calcium homeostasis. The histological and kinetic investigations give additional and independent information. A great disadvantage of kinetic investigations is that the models used are crude simplifications and cannot be regarded as true reflections of pathologic conditions. A biopsy specimen is only a small part of the skeleton and may not be representative. Furthermore, purely morphological criteria are used, which do not allow measurement of the rates of bone formation or resorption.

δ) Physical Examinations

The breaking strength and the percentage deformation associated with fractures are dependent on the ash content per bone volume. This decreases with advancing age. However, the bone mineral remains qualitatively unchanged during adulthood (BELL, 1967).

ε) Radiographic Densitometry

In addition to the visual assessment of the form, structure and density of the skeleton, the bone density can be measured with the aid of strictly standardized conditions related to the intensity of the X-rays, geometry, and film properties. The density of the bone is measured at the vertebra in the hand and in the foot, and information can be obtained about the hydroxyapatite content of the bone. An aluminium hydroxyapatite scale with increasing density is laid alongside for comparison. The depth of the soft tissues is a hindrance in the assessment of bone density (KROKOWSKI, 1966). The measurement of the γ-absorption with ^{125}I gives superior results in thin bones (JOHNSTON, 1968).

The bone mass can also be estimated by measuring the depth of the compact bone in the bones of the hands, and by visual assessment of the bone density (GARN, 1967; BERNSTEIN, 1966). Structural alterations are discussed in the clinical section (see index).

ζ) Analytical Methods

Estimation of the ash content or the weight of the bone related to bone volume gives some indication of osteoporosis (ARNOLD, 1964; TROTTER, 1960). The calcium and phosphate contents can be referred to the wet or dry weight or to the nitrogen or nucleic acid content (p. 849). However, a disturbing factor is the absence of any point of reference. The nitrogen content gives a measure of the cell activity and of the size of the bone matrix. The nucleic acid content is related to the number of cells and the mitotic rate. The ash weight again takes no account of the bone matrix which is important for the assessment of the metabolic activity of the skeleton.

Radiological diffraction spectra and infrared absorption spectrophotometry allow investigation of the quality of the apatite. Bone minerals consist chiefly of hydroxyapatite and amorphous calcium phosphate. Traces of pyrophosphate are also present (POSNER, 1967).

4. Metabolic Bone Disease

Metabolic bone disorders indicate *generalized* involvement of the skeleton, in contrast to localized disorders due to a fracture or in osteomyelitis. Nevertheless, the involvement often only becomes clinically obvious in localized parts of the skeleton which are especially subject to strain and traction.

This section gives a general survey on alimentary and hormonal influences (except parathyroid hormone and calcitonin) and the effects of age and immobilization on the skeleton. Detailed descriptions are given in the appropriate chapters (see index).

a) Alimentary Influences

α) Calcium

A calcium-deficient diet can cause osteoporosis, particularly in growing and undernourished persons and in old age. An inadequate intake of calcium probably leads to an increased secretion of parathyroid hormone and a rise in bone resorption. In man, a calcium-deficient diet leads to increased intestinal calcium absorption, to an increase in bone resorption as measured by isotopic-kinetic analysis, and to the excretion of increased amounts of calcium and hydroxyproline in the urine. All these factors can be explained by an increased parathyroid hormone secretion rate (PHANG, 1968; SMITH, 1964). Conversely, in some cases an elevated intake of calcium leads to a positive calcium balance with a reduction of the isotopic-kinetically measured bone resorption, and possibly to inhibition of the release of parathyroid hormone (SCHWARTZ, 1965).

In cases with microradiographically visible increased bone resorption and decreased bone formation calcium infusions produce a normalization of these findings which may be due to inhibition of the parathyroid hormone secretion (PAK, 1969).

The density of the compact bone in the bones of the hands, measured radiologically in subjects receiving a calcium-deficient diet (< 300 mg/day) and others receiving a diet rich in calcium (> 1 500 mg/day), however, does not differ from that found in comparable population groups in Central and North American (GARN, 1967).

In adult cats, a calcium-deficient diet leads to osteoporosis which can be prevented by the administration of calcium or by parathyroidectomy (JOWSEY and RAISZ, 1968a). In rats, an elevated calcium intake causes inhibition of the isotopic-kinetically measured bone resorption, and possibly also of the release of parathyroid hormone, without any alteration of the serum calcium concentration (BRONNER, 1965). Intestinal calcium absorption is sometimes reduced in idiopathic osteoporosis during youth and old age (DENT, 1956; SPENCER, 1964). In these cases treatment with vitamin D and/or calcium leads to an improvement in the bone findings, without disclosing anything about the pathogenesis of the osteoporosis.

β) Vitamin D, Vitamin-D Resistance and Phosphate

Osteomalacia is characterized by an increase in unmineralized osteoid due to a defect in the mineralization of the bone matrix. Pathognomonic findings are pseudofractures and Looser's zones. Amorphous calcium phosphate is deposited into the osteoid, which is only slowly converted into apatite (POSNER, 1967). The osteoid mass can only be quantitatively assessed in undecalcified sections.

An increase of the osteoid mass alone is no proof of a vitamin-D deficiency. It can also occur in hyperthyroidism or in hyperphosphatasia, when it is a reflection of increased bone formation. The rate of collagen synthesis is normal or increased in both conditions. Osteoblasts and tetracycline deposits in osteoid seams are indications that bone formation is increased. Their absence suggests a mineralization defect such as occurs in vitamin-D deficiency (MÜLLER, 1966; BAYLINK, 1970; FISCHER, 1970).

Bone formation as measured by tetracycline labeling of osteoid seams, is retarded in osteomalacia (RAMSER, 1966). The fibro-osteoclasia is not always very extensive, especially in severe hypocalcemia, in intestinal malabsorption and in azotemia, since the permissive action of vitamin D on bone resorption is probably absent (RASMUSSEN, 1963; FISCHER, 1970).

The pathogenesis of the osteomalacia cannot be explained by the absence of a single factor, with the exception of vitamin-D deficiency in infantile rickets and of nutritive vitamin-D deficiency, which rarely occurs alone (DENT, 1969). The different forms of osteomalacia are therefore discussed separately.

Osteomalacia develops in vitamin-D deficiency in children (rickets), or as a result of resistance to the action of vitamin D (renal insufficiency, vitamin D-resistant rickets). It also arises in steatorrhea, after gastrectomy, in liver cirrhosis, with a phosphate-deficient diet or with a phosphate loss through the kidneys. Vitamin-D deficiency is the dominant feature in infantile *rickets*. At first the serum calcium concentration is usually only slightly reduced; the reduction later becomes severe, causing tetany. The serum phosphate concentration is low, and the phosphate excretion in the urine is elevated due to secondary hyperparathyroidism. The alkaline phosphatase in the plasma is raised before and immediately after treatment with vitamin D. It is a sign of increased osteoblastic activity.

Vitamin-D deficiency leads to osteoporosis in growing rats on a calcium-deficient diet. An increase of the osteoid mass only arises when the animals' diet is also deficient in phosphates (STEENBOCK, 1955). Parathyroid hormone deficiency alone, in contrast to vitamin-D deficiency, does not lead to a massive increase

in the osteoid mass. In the malabsorption syndrome with steatorrhea, osteoporosis sometimes precedes the osteomalacia, and can be treated successfully with vitamin D (GARNER, 1966; MUNCK, 1963; FISCHER, 1970).

Steatorrhea prevents normal intestinal absorption of the fat-soluble vitamin D, and furthermore, phosphate absorption is reduced, since a significant proportion of the phosphate is delivered to the organism in the form of fats. Finally, protein absorption is decreased, which is of importance in the synthesis of the bone matrix. In rare cases, there is no steatorrhea, and in one case only a reduction of the xylose absorption was demonstrable (MOSS, 1965).

Osteomalacia rarely occurs following *gastrectomy*. An elevation of the serum alkaline phosphatase may be related to an increased release of an intestinal phosphatase, especially from a blind loop. Osteomalacia was found in only 6 out of 1228 patients, and it was improved by treatment with vitamin D (MORGAN, 1965). In another series the vitamin-D concentration, measured biologically in the plasma, was reduced in 10 out of 28 patients and the osteoid seams widened at the same time (THOMPSON, 1966). In some patients, particularly the elderly, the bone density, measured radiologically in the metacarpal bone, is reduced (MORGAN, 1966). Mild, but frequent changes suggesting osteomalacia are reported by EDDY (1971).

In *renal insufficiency* the reduction of the calcium concentration in the plasma is the predominant feature at first. The osteoid surface is generally increased and tetracycline storage is limited to a few seams (BINSWANGER, 1968). When bone chips are incubated, calcium phosphate is deposited when certain concentrations of calcium and phosphate are reached. The calcification is impaired by the addition of plasma from uremic patients (YENDT, 1955). The acidosis occurring in uremic patients probably also contributes to the inhibition of the mineralization of the skeleton. Bicarbonate leads to a reduction of the calcium excretion in the stools and urine when serum calcium and phosphate are unaltered (LITZOW, 1967).

The intestinal absorption of calcium is reduced even when concentrations of vitamin D in the plasma are normal. This is corrected only with pharmacological doses of vitamin D. BELL (1964) observed a patient with sarcoidosis before and after the development of acute nephritis with azotemia: The calcium absorption, which was elevated at first, was reduced, while hypersensitivity to vitamin D was replaced by resistance. The hypocalcemia is not due to increased excretion of calcium in the urine. The calcium excretion through the kidneys is reduced, as is glomerular filtration. Resistance to vitamin D is thought to be the main cause of hypocalcemia (STANBURY, 1966).

The phosphate concentration in the plasma is elevated due to the reduced glomerular filtration rate. The hyperphosphatemia also leads to hypocalcemia and sustains the secondary hyperparathyroidism. Parathyroid hormone levels are elevated. They can be reduced with aluminium hydroxide gel or a phosphate-deficient diet (SLATOPOLSKY, 1970). During prolonged azotemia the osteomalacia disappears, but bone resorption increases and the serum calcium is normalized during stimulation of the parathyroid hormone secretion (STANBURY, 1966).

Osteomalacia connected with widening of the osteoid seams appears not only in vitamin-D deficiency, but also with a *phosphate-deficient diet* or with *phosphate loss through the kidneys*. In man, a massive increase of the osteoid tissue is produced in phosphate deficiency by the binding of the phosphate with aluminium hydroxide gels in the gut, and in rat by a phosphate-deficient diet (COLEMAN, 1950; LUDWIG, 1967; LOTZ, 1968). Vitamin D-resistant rickets results from a loss of phosphate through the kidneys. The calcium concentration in the plasma is normal. Calcium absorption from the gut and excretion through the kidneys are reduced. The phosphate loss is due to a defect in the renal tubules. The parathyroid hormone concentration is in the normal range (ARNAUD, 1971).

Treatment with vitamin D in doses which would normally lead to vitamin-D intoxication improves the mineralization of the skeleton. Calcium administration does not lead, as would be expected, to improvement of the osteomalacia. Calcium cannot be incorporated into the bones in the presence of a phosphate deficiency. Additional evidence that the rate of bone formation is slow comes from kinetic measurements, which show that the deposition rate is reduced, and from a decrease of the alkaline phosphatase in the plasma and the excretion of hydroxyproline in the urine (LAFFERTY, 1964; NAGENT DE DEUXCHAISNES, 1967).

Even treatment with *phosphate* alone improves the absorption of calcium and phosphate in the gut and the mineralization to some extent. This is associated with a rise in the calcium deposition, measured with ^{47}Ca. Furthermore, there is a decrease in the calcium concentration in the plasma and the calcium excretion in the urine, and an increase in the alkaline phosphatase level in the plasma and in the urinary hydroxyproline excretion, reflecting secondary hyperparathyroidism; the parathyroid hormone con-

centration in serum is increased following treatment with phosphate (NAGENT DE DEUXCHAISNES, 1967; ARNAUD, 1971).

γ) Fluoride

In North Dakota, subjects over 45 years of age who are exposed to drinking water with a high fluoride content have been found to have significantly higher bone density and less frequent compression fractures of the spine than comparable subjects living in South Dakota, where the fluoride content of the drinking water is lower. These findings are more common in women, although both sexes are subjected to the same environment (BERNSTEIN, 1968).

Fluoride can inhibit or stimulate bone resorption depending on the dose used (FACCINI, 1967; BAYLINK, 1970). In rats with immobilization osteoporosis, the calcium content of the bones is increased and the serum calcium reduced, which indicates that bone resorption has been reduced and formation of new bone is probably being promoted (GEDOLIO, 1966). Studies in growing rats, however, reveal an increase in periosteal bone formation, an inhibition of mineralization, and an increase in bone resorption (BAYLINK, 1970). In man, osteosclerosis with increased osteoid formation arises first, and after a latent period of a few months this is converted into apatite (JOWSEY, 1968 b). This delayed calcification is explained by an inhibition of the formation of bone matrix and of collagen synthesis by fluoride *in vitro* (PECK, 1965). The calcium balance becomes positive only after two to three months, and this is possibly related to the delayed calcification of the bone matrix (RICH, 1964).

A chronic fluoride intoxication leads to osteosclerosis and to increased fragility of the bones.

δ) Proteins

The *protein intake* influences the collagen synthesis and thus the extent of the bone matrix. Malabsorption causes osteoporosis as well as osteomalacia.

b) Age

Senile osteoporosis is the physiological loss of bone minerals with advancing age. Osteoporosis is characterized by a morphometrically measurable decrease in the volumetric bone density of the spongiosa, by a reduction of the thickness of the corticalis and by an enlargement of the Havers' compartments in the compacta (Fig. 7b). The radiologically measured thickness of the corticalis and the ash content or the bone weight per bone volume are decreased (ARNOLD, 1964; TROTTER, 1960). The thickness of the compact bone, measured radiologically, decreases slowly in the metacarpal bones from the beginning of the fifth decade. No definite connection with menarche and menopause in the woman is demonstrable, especially since the loss of minerals begins at about the same time, at the age of 40, in Central America (menopause at 40) and in North America (menopause at 50) (GARN, 1967). Senile osteoporosis is about four times more frequent in women than in men, (WHEDON, 1968). The mineral content of the bones at the end of the growth period is seldom known, and therefore little can be said, especially in individual cases, about the action of the menopause on the increased bone loss. Senile osteoporosis arises independently of the onset of the menopause and develops at the same time in the male and female. Senile osteoporosis cannot be discussed without mentioning alimentary osteoporosis, since this is implicated in the pathogenesis and in the treatment. Successful treatment discloses nothing about the pathogenesis of the senile osteoporosis. The same is applicable to the action of calcium, of estrogens and of androgens, which inhibit bone resorption in individual cases without causing any radiologically detectable improvement of the osteoporosis. As a rule, reduced bone formation can be demonstrated in senile osteoporosis. The number of newly formed osteons per year is reduced in these patients (VILLANUEVA, 1966). Two groups of patients with a reduced or compensatory increased number of osteoblasts and presumably formation of new bone become evident (MERZ, 1970). There may be some connection with immobilization osteoporosis, since muscular contraction could promote compensatory new bone formation in the presence of increased bone breakdown. In effect, histological morphometric examination of bone biopsies and kinetic studies using redioactive calcium reveal increased bone resorption as well as decreased formation of new bone (FROST, 1963; HEANEY, 1965). The findings in these bones presumably differ only quantitatively from those in hyperparathyroidism. Calcium deficiency promotes increased bone resorption due probably to increased parathyroid hormone secretion. The pathogenesis of senile osteoporosis is still largely unknown.

c) Immobilization and Gravity

In the absence of muscular contraction, bone formation is impaired and bone resorption

increased, leading to hypercalciuria, nephrolithiasis and occasionally in acute cases to increased serum calcium. The hydroxyproline excretion is higher during the night than during the day, reflecting increased bone breakdown at rest (MAUTALEN, 1970). The weights of the left psoas muscle and the third lumbar vertebral body are proportionally decreased or increased regardless of body weight and body length (DOYLE, 1970). Muscular contraction leads to an increase in the formation of new bone, possibly regulated through local piezo electric current changes at stressed bone surfaces (BASSETT, 1966). Movement is thus the best therapy for most forms of generalized osteoporosis. Increased bone resorption can lead to compensatory formation of new bone, a process which is best supported by movement and physiotherapy. An impressive example of immobilization osteoporosis is seen in astronauts in whom the action of gravity is also absent (LUTWAK, 1969). In rats, immobilization osteoporosis can be prevented by thyroidectomy or parathyroidectomy (BURCKHART, 1967).

d) Cortisone

Bone remodeling is retarded in Cushing's disease and following treatment with cortisone. The osteoporosis and the reduction in body length in children are caused primarily by a decrease in the formation of new bone. The osteoid mass is diminished and only small parts store tetracycline, indicating delayed mineralization of the skeleton. The excretion of hydroxyproline in the urine is decreased, reflecting the retarded collagen synthesis (HARTMANN, 1966). The uptake of radioactive ^{45}Ca by the bones *in vivo* is delayed (CLARK, 1959), as is the release of radioactive calcium from bone-cell cultures (STERN, 1969). In Addison's disease and after the removal of the adrenals in rats, the situation is reversed, and hypercalcemia with increased bone resorption arises, which can be prevented by thyroidectomy (JOWSEY, 1968c). *In vitro*, synthesis of polysaccharides and cartilage growth are retarded (BARRETT, 1966). The uptake of uridine labeled with ^{14}C of the ribonucleic acids, and the uptake of proline labeled with ^{14}C of the collagen are retarded in isolated bone cells by cortisone. It is probable that cortisone inhibits primarily the synthesis of collagen and of mucopolysaccharides, possibly at the site where the synthesis of ribonucleic acids is controlled by desoxyribonucleic acids.

Less bone matrix is formed when protein synthesis is inhibited, and osteoporosis then arises. It is not definitely known whether cortisone has an influence on bone resorption. The release of ^{45}Ca from the bones and collagen breakdown are not influenced *in vitro*. A reduction of bone resorption can be only poorly demonstrated in isotopic-kinetic and morphometric investigations. Hypercalcemic patients with multiple myeloma who are treated with prednisone show a reduction in the previously enlarged calcium pool, and in accretion and resorption rates (BENTZEL, 1964). The osteoporosis in Cushing's disease and following medication with adrenocortical steroids is due primarily to inhibition of the new bone formation with retarded synthesis of bone matrix. In addition to the retarded bone metabolism cortisone produces decreased intestinal calcium absorption and hypercalciuria, which could contribute to the negative calcium balance (KIMBERG, 1969).

e) Sex Hormones

Estrogens and androgens primarily inhibit bone resorption, and are therefore used for the treatment of senile osteoporosis. Castration causes a slight rise in the serum calcium and in the calcium excretion in the urine in man, which can be explained by increased bone breakdown (SZYMGNENDERA, 1967). The morphometrically measured bone formation and resorption, as well as the hydroxyproline excretion in the urine are reduced in the presence of estrogens (FROST, 1963; KATZ, 1968).

Isotopic-kinetic investigations and microradiographic findings in bone biopsies show that bone resorption is diminished by estrogens and androgens (GORDAN, 1963; RIGGS, 1969). The best possible result is a temporary increase in calcium and phosphate retention. Accretion is inhibited by a longer treatment. In addition, estrogens inhibit the growth of the epiphyseal cartilage and longitudinal growth of the bones in mouse, rat and rabbit (SIMMONS, 1966; BERNBER, 1968). The calcium balance remains uninfluenced (LAFFERTY, 1964; EISENBERG, 1966). ALBRIGHT'S theory (1948), which assumed from the findings of positive nitrogen balances following treatment with androgens that there was a promotion of bone formation, has not been confirmed.

The fact that estrogens and androgens produce a questionable inhibition of the increased bone resorption during the treatment of senile osteoporosis, says nothing about its pathogenesis. It is more likely that osteoporosis during the menopause is senile osteoporosis with a different course in the male and in the female (p. 867). The mode of action of estrogens and androgens is similar to that of the adrenocortical steroids. Bone resorption is retarded.

Estrogens and androgens primarily inhibit bone resorption and can retard the osteoporosis in some patients, whereas the adrenocortical steroids inhibit the formation of new bone and lead primarily to osteoporosis.

f) Thyroxine

Thyroxine causes an increase in bone remodeling. Bone formation and resorption are increased, the latter exceeding the former. The result is a reduction in the bone mass, i.e. osteoporosis. Bone formation is increased and this is occasionally reflected by an increase in the osteoid mass. In contrast to rickets and osteomalacia, the osteoid seams are narrow, they store tetracycline along the demarkation line and therefore do not show a mineralization defect. Mineralization of the skeleton is delayed in osteomalacia, whereas bone formation is increased in hyperthyroidism, as in the growth period and in acromegaly (FROST, 1963). The accretion, measured isotopic-kinetically, and the number of osteoclasts are sometimes increased in hyperthyroidism. They are usually below normal limits in hypothyroidism (BELL, 1967a; FROST, 1963). There is a good correlation between the hydroxyproline excretion in the urine and the concentration of protein-bound iodine in the plasma (KIVIRIKKO, 1965). The increased turnover of collagen becomes apparent in the skeleton and the skin, hence the thin skin of the patients with hyperthyroidism. The increased excretion of hydroxyproline and of calcium in the urine, and the increase in the osteoclasts as well as the hypercalcemia, which arises rarely, are indications of increased bone resorption. The possible inhibition of the release of parathyroid caused by the slight hypercalcemia could explain the inhibition of calcium absorption in the gut. Intestinal calcium absorption can also be inhibited by the rapid passage of the food through the small intestine. The inhibition of parathyroid hormone release also explains the hypercalciuria with an inhibition of the calcium reabsorption in the renal tubules. Hypercalciuria thus arises much more commonly than hypercalcemia in hyperthyroidism.

In rats, thyroidectomy prevents the development of immobilization osteoporosis (p. 867).

g) Growth Hormone

Growth hormone primarily promotes bone formation, with an increase in the mitotic rate of the osteoblasts. In cartilage-cell cultures, there is an increased incorporation of tritium-labeled thymidine into desoxyribonucleic acids under the influence of growth hormone after a latent period of 48 hours. Later, there is an increase in cell division (DAUGHADAY, 1966). The increased number of osteoblasts causes a rise in the formation of osteons in acromegaly (FROST, 1963). In acromegaly, bone resorption is sometimes increased, with a slight elevation of the serum calcium concentration leading to a negative calcium balance (BELL, 1967b; NADARAJAH, 1968).

h) Unexplained Causes

In addition to the decreased calcification of the bone matrix a high increase in the number of osteocytes with an increased bone breakdown can be observed in *osteogenesis imperfecta* (ROBICHON, 1968).

In *osteopetrosis* bone resorption is decreased and both the calcium absorption in the intestine and the calcium retention in the skeleton are increased. This could be caused by overproduction of calcitonin (p. 882).

In *idiopathic hypercalciuria*, accretion and bone turnover, as measured with radioactive calcium, are increased and the intestinal calcium excretion is relatively low compared with the excretion in the urine. The total calcium excretion i.e. into the urine and into the intestine, is not elevated. Increased bone remodeling could be the primary reason for idiopathic hypercalciuria (LIBERMANN, 1968).

5. Regulation of the Calcium and Phosphate Metabolism

Parathyroid hormone is the most single important regulator of the serum calcium concentration. The presence of vitamin D is necessary for parathyroid hormone to be able to exert its full effect on the intestine and the skeleton. Calcitonin causes a fall in the serum calcium concentration and serves as a rapid-onset counter-regulator. Skeletal growth and bone remodeling are further regulated by growth hormone, thyroxine, cortisol, and the sex hormones (see index, p. 868).

a) Parathyroid Hormone

α) Occurrence, Isolation, Secretion, and Metabolism of Parathyroid Hormone

Parathyroid hormone is formed in the parathyroids in all known animal species.

In addition to the highly purified parathyroid hormone (PTH), parathyroid extract (PTE, Lilly) is used in clinical medicine. PTE has a potency of about 100 units (USPU)/ml, or

10 units/mg dry weight. In contrast, the potency of highly purified parathyroid hormone is 2000–3000 units per mg dry weight. PTH was isolated in 1959 by counter-current distribution (RASMUSSEN and CRAIG; AURBACH). For later purification procedures gel filtration was extensively used (RASMUSSEN, 1964b; AUERBACH, 1967). Parathyroid hormone consists of a single polypeptide chain with a molecular weight of about 10000. The chain contains 84 amino acids. The total sequence of bovine PTH was derived in 1970 (BREWER; NIALL) (Fig. 9a). The first 34 amino-acid residues have been synthesized and the chain is still biologically active (POTTS, 1971a). The ability of bovine PTH to form antibodies remains intact after oxidation with a methionine or after treatment with cyanide bromide, while the biological activity is destroyed at the same time (POTTS, 1965).

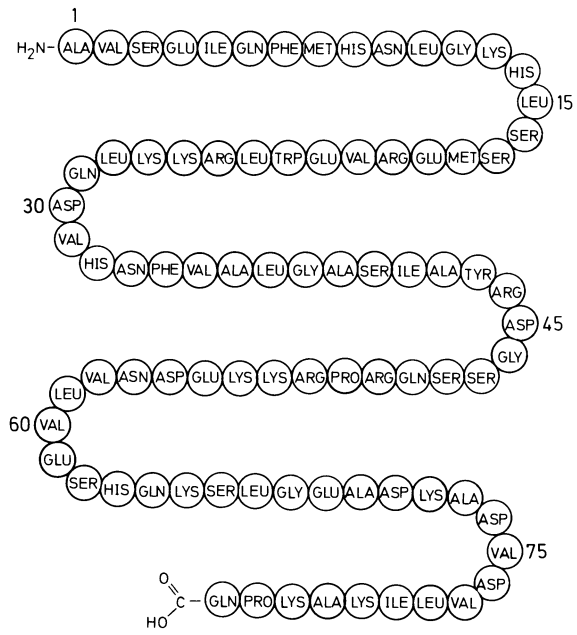

Fig. 9a. Amino-acid sequence of bovine parathyroid hormone (After BREWER, 1970; NIALL, 1970)

The sequence of the first 34 amino acid residues starting with the amino terminus of human PTH has been elucidated (BREWER and ARNAUD, 1972) (Fig. 9b). The synthesis has been accomplished and the chain is still biologically active (ANDREATTA, 1973). Antibodies have been raised against this peptide and the presence of immunoreactive PTH demonstrated in human serum using this system (FISCHER, 1974). Alternative structures for human PTH have been proposed by POTTS (1973).

Purified parathyroid hormone always leads to increased mobilization of calcium from the bones and thus to a rise of the serum calcium concentration of calcium. At the same time PTH promotes the excretion of phosphate through the kidneys and thus a fall in the serum phosphate concentration. The two actions cannot be separated. At least five peptides have been found in the parathyroids, and they show different biological effects, particularly *in vitro* (RASMUSSEN, 1964b).

The potency of parathyroid hormone is examined by its action on the mobilization of calcium from the skeleton (MUNSON, 1955) and by the phosphate excretion through the kidneys. The most frequently used assay is performed in the parathyroidectomized rat, in which the rise of the calcium concentration is measured after an injection of an extract of unknown potency. The increase in the serum calcium concentration and the phosphaturic action can also be tested in men. In order to prevent anaphylactic shock, which is theoretically possible, the extract must be given subcutaneously and applied on to the conjunctiva first. An intravenous injection of 200 units PTE does not normally cause any symptoms. One

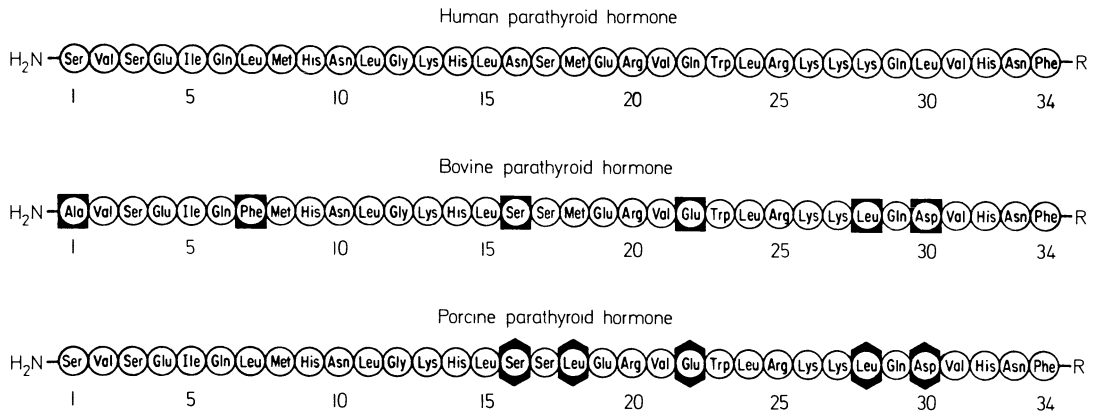

Fig. 9b. Comparison of the amino acid sequences of amino-acid residues 1–34 of human, bovine, and porcine parathyroid hormone. (After BREWER, 1972, 1970; O'RIORDAN, 1971)

thousand units PTE given over 12 hours in an infusion occasionally gives rise to shivering, fever and headaches. To our knowledge, severe complications have never occurred. Unpurified PTE is not used therapeutically as it leads to the formation of antibodies after a relatively short time. These antibodies have been demonstrated by radioimmunological methods (MELICK, 1967).

The concentration of the parathyroid hormone is measured in the plasma, urine and extracts of the parathyroids or of paraneoplastic tumors such as bronchial carcinoma and hypernephroma (GOLDBERG, 1964; SHERWOOD, 1967). Biological methods are sensitive enough for estimation of the hormone activity in organs and in the urine (ELICE, 1965). BERSON's radioimmunological methods are the most suitable for measurement of the concentration of PTH in serum (1966), and permit normal subjects to be differentiated from patients with hyperparathyroidism (REISS, 1968a; ARNAUD, 1971) (Fig. 10). At present bovine and porcine PTH are used as antigens. Their cross-reactivity with human PTH is not known quantitatively (BERSON, 1966; ARNAUD, 1971).

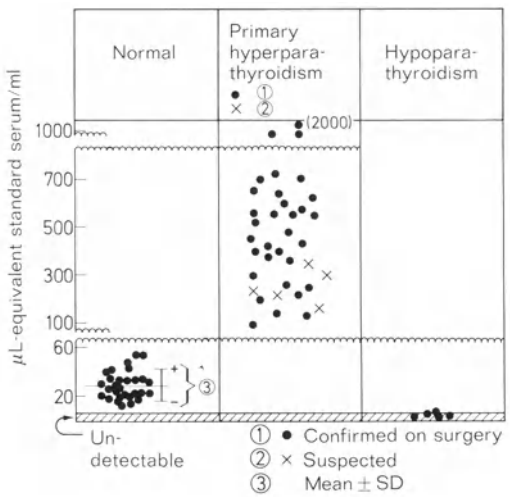

Fig. 10a. The concentration of parathyroid hormone in the serum of normal subjects and in patients with hypo- and hyperparathyroidism (After REISS, 1968a)

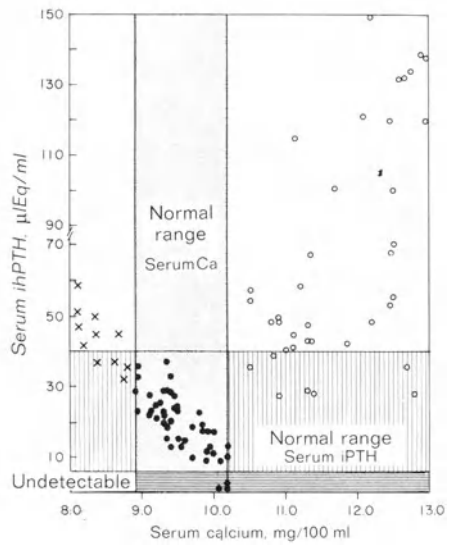

Fig. 10b. Relation between concentrations of serum calcium and immunoreactive parathyroid hormone (iPTH) in normals (●), in hypocalcemic patients (×) and in patients with surgically verified primary hyperparathyroidism (⊙). (After ARNAUD, 1971)

The level of PTH in serum can be estimated by indirect methods for clinical purposes. The assessment of hyperparathyroidism is based on the summation of the biological sites of action, and the single most important measurement is an accurate determination of the serum calcium concentration. The *parathyroid hormone concentration* in the plasma varies inversely to the serum calcium and magnesium concentrations. A fall in the serum calcium results in an increased secretion of parathyroid hormone (Fig. 11). It is the concentration of the ionic fraction rather than the total serum calcium concentration which regulates the PTH secretion. This has been clearly shown with phosphate infusions in the cow, where a lowering of the ionic calcium concentration preceded a decrease in total calcium. In this situation a rise in PTH concentration occurs within minutes of the fall in ionic calcium, while the total calcium concentration remains unchanged (FISCHER, 1973). Infusion of a parathyroid of the goat with blood rich in calcium or magnesium leads to inhibition of the secretion of parathyroid hormone (CARE, 1966). The quantity of parathyroid hormone which can be extracted from parathyroid glands is relatively small. If it can be assumed that most of the hormone is extracted by the usual procedures, this would suggest that the content of parathyroid hormone in the parathyroids is renewed 3 to 15 times per hour by synthesis in cows (SHERWOOD, 1966, 1968; BUCKLE, 1968). In normal control subjects the concentration of parathyroid hormone in the serum is inversely proportional to the calcium concentration in the serum. The serum calcium and PTH concentrations have to be taken into account in the assessment of borderline cases of primary hyperparathyroidism (ARNAUD, 1971).

The parathyroids are hyperplastic in rats fed on a calcium-deficient diet, although the serum calcium concentration may remain in the normal range. Acromegaly can be connected with hyperplasia of the parathyroids. Presumably the rise in the phosphate concentration

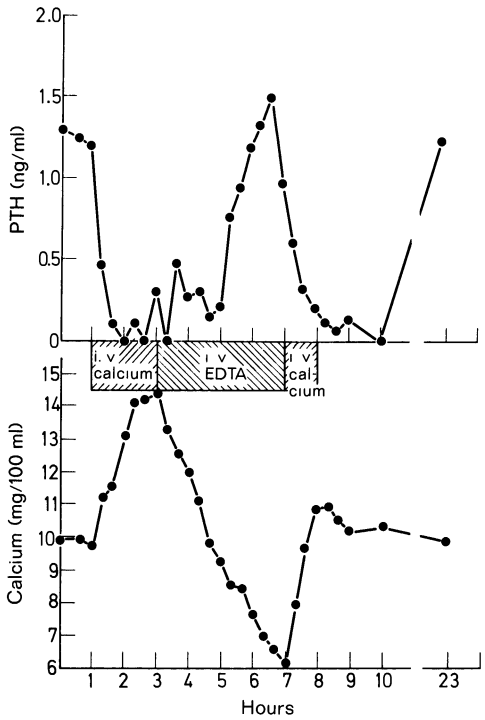

Fig. 11a. Concentrations of parathyroid hormone and calcium in bovine plasma in response to alternate infusions of calcium chloride (196.4 mEq/h) and disodium EDTA (115 mEq/h). (After SHERWOOD, 1966)

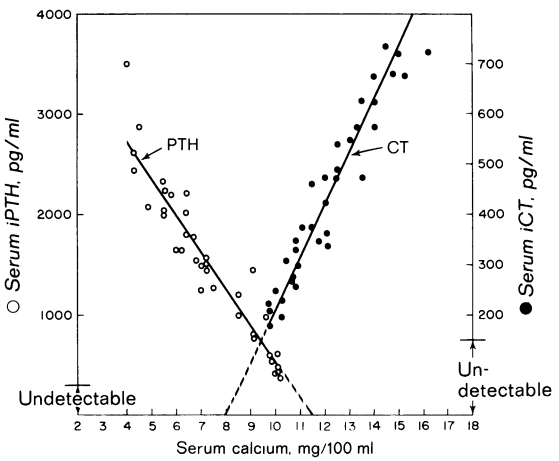

Fig. 11b. Relation between concentrations of serum calcium and immunoreactive parathyroid hormone (iPTH) and calcitonin (iCT) in pigs. r for iPTH = −0.942, for iCT = 0.964; p for both 0.001. (After ARNAUD, 1970)

in the plasma leads to frequent unmeasurable falls in the ionic calcium concentration, which cause secondary hyperparathyroidism. Rats on a high-calcium diet show decreased bone resorption, as measured isotopic-kinetically, with an unchanged serum calcium concentration (BRONNER, 1965). The parathyroid hormone concentration in the plasma in sarcoidosis is lowered in normocalcemic subjects, reflecting inhibition of the parathyroid hormone secretion with increased liberation of calcium from bone (REISS, 1968b; CUSHARD, 1972). A similar mechanism is assumed to be the cause of the normocalcemic secondary hyperparathyroidism with a decreased calcium absorption due to malabsorption. In addition to the hypocalcemia, frequent small unmeasurable falls in the serum calcium concentration are probably sufficient to act as a stimulus for an increased release of parathyroid hormone (FISCHER, 1970). Rats fed on a magnesium-free diet develop hyperparathyroidism with hypercalcemia, which can be prevented by parathyroidectomy (GITELMAN, 1968). A rise in the calcium and magnesium concentrations in the plasma leads to inhibition of the release of parathyroid hormone (CARE, 1966). A rise of the phosphate concentration in the plasma itself probably does not influence PTH secretion, except when it leads to a fall in the serum calcium concentration and subsequently to a rise in PTH secretion. The central nervous system and the pituitary have no demonstrable influence on the parathyroids. *In vitro*, a reduction in the calcium or magnesium concentration in the incubation medium leads to a rise in parathyroid hormone secretion and also to an increase in the uptake of amino acids and in the synthesis of nucleic acids and of proteins. An elevated calcium concentration leads to inhibition of these processes (RAISZ, 1969; SHERWOOD, 1970; OLDHAM, 1971).

Besides decreased serum calcium and magnesium concentrations, epinephrine is also potent stimulator of PTH secretion that might be of physiological importance (FISCHER, 1973).

The PTH is regulated by the serum calcium concentration in primary hyperparathyroidism. It is not autonomous. As shown by POTTS (1971b) and confirmed by BINSWANGER and FISCHER (1972), reduction of the serum calcium concentration produces an increase in PTH in the serum, whereas calcium infusions inhibit PTH secretion. In chronic hypocalcemia with normal kidney function (intestinal malabsorption, pseudohypoparathyroidism) the PTH is increased in relation to the decrease in serum calcium. The PTH concentrations are in the same order of magnitude as in primary hyperparathyroidism. However, in patients with azotemia and severe renal insufficiency the PTH concentrations are usually higher because the metabolism of PTH in the kidney is retarded (MELICK, 1969; ARNAUD, 1971).

The *metabolism* of PTH was not investigated until recently. Subsequent to BERSON's (1968)

discovery of the immunoheterogeneity of PTH in serum, ARNAUD (1970) has demonstrated that the PTH in peripheral serum and in tissue culture medium from parathyroid slices *in vitro* is immunologically different from glandular PTH, whose sequence is known in the bovine species (BREWER, 1970; NIALL, 1970). It appears at present that PTH is probably secreted in its glandular form *in vivo* and subsequently converted into lower-molecular-weight species, which are primarily found in peripheral serum and in tissue culture medium (ARNAUD, 1970; SHERWOOD, 1970; HABENER, 1971). The lower-molecular-weight forms are biologically active (FISCHER, 1972a; REISS, 1972). A converting enzyme has been extracted from parathyroid glands, liver and other tissues, which facilitates the conversion of PTH from its glandular form into the form which primarily occurs in serum. This conversion is stimulated in the presence of EDTA or EGTA, and the converting enzyme is a possible site of action for the regulation of PTH secretion by calcium. Furthermore, a calcium-binding protein has been isolated from parathyroid tissue with a high affinity (log K_f 5.5) for calcium. This is another possible site for the regulation of PTH secretion by calcium (OLDHAM, 1971b).

There is convining evidence that PTH circulating in the serum of patients suffering from paraneoplastic hyperparathyroidism, which has different immunological properties from the PTH circulating in patients with primary hyperparathyroidism, has a different molecular structure (RIGGS, 1971).

The metabolic *breakdown* of PTH occurs within hours in the plasma. The half-life of the bovine glandular hormone is 10–20 min in man, and 20–30 min in the cow, regardless of the serum calcium concentration (ARNAUD, 1967; SHERWOOD, 1968). MUNSON (1955) demonstrated hypocalcemia after two hours in parathyroidectomized rats on a calcium-deficient diet. DAVIS (1960) found that parathyroid transplants were more effective in the testes than in the spleen, and concluded therefore that the hormone was destroyed in the liver. These transplantation experiments exclude a nervous control over the liberation of parathyroid hormone from the parathyroids. ORIMO (1965) and MARTIN (1969) demonstrated that the breakdown of iodine-labeled parathyroid hormone is higher in the kidneys *in vitro* than in the spleen, skeletal muscle and liver. The half-life in the plasma is prolonged in patients with renal insufficiency or after nephrectomy (MELICK, 1969). Parathyroid hormone, which can be immunologically demonstrated, disappears from the plasma more slowly in uremic patients following parathyroidectomy than in hyperparathyroid patients (BERSON, 1968).

β) Sites of Action of Parathyroid Hormone

The most important sites of action are the bones, the kidneys and the small intestine.

Bones. Parathyroid hormone causes an initial fall followed by a rise in the calcium concentration in the plasma. Immediately after an injection of parathyroid hormone the serum calcium concentration decreases. This decrease is followed by a sustained rise. The initial decrease is explained by a sequestration of calcium phosphate in bone and in soft tissues. The initial decrease was usually attributed to calcitonin, until this effect was confirmed by PARSONS (1971) with homogeneous parathyroid hormone. The hypercalcemia is produced primarily by an increased mobilization of calcium from the bones and increased bone resorption, with an increase in osteoclastic and osteocytic activity. It is presumably the osteoclasts that are responsible for the long-term action of parathyroid hormone in bone remodeling, whereas the promotion of tubular calcium reabsorption by the kidneys, the calcium absorption in the gut, and the antagonistic action of parathyroid hormone and of calcitonin on the osteocytes are essential for the regulation of the serum calcium concentration (RASMUSSEN, 1967b). The significance of the action of parathyroid hormone on the osteocytes is further supported by the fact that the activity of osteoclasts can be suppressed by ^{239}Pu or by paraaminosalicylic acid, without significantly interfering with the mobilization of calcium from the bones, which occurs under the influence of parathyroid hormone (DOTY, 1965). Parathyroid hormone promotes the release of calcium from around the osteocytes which are then surrounded by a halo (BÉLANGER, 1968; FEINBLATT, 1970). The destruction of the bone matrix around the osteocytes by gelatinase can be demonstrated photographically on the surface of a film.

Parathyroid hormone causes an increase in the alkaline phosphatase in osteocytes (BÉLANGER, 1963). This can be demonstrated histochemically. Pyrophosphates protect bone crystals from dissolution *in vitro*. The alkaline phosphatase might be a pyrophosphatase, which would stimulate the metabolism of pyrophosphates and the dissolution of bone minerals under the influence of PTH (FLEISCH, 1970; RUSSEL, 1968) (p. 889).

The promotion of osteolysis via osteoclasts is one of the chief actions of parathyroid hor-

mone. Since BARNICOT (1948) observed that fibroosteoclasts were demonstrable after parathyroid tissue was transplanted over the bone *in situ* there has been no doubt that parathyroid hormone acts directly on bone, resulting in increased bone breakdown. In a similar manner, a direct action of parathyroid hormone has been demonstrated *in vitro* in bone cell cultures: there was an increase in the number of osteoclasts, and in the amounts of acid phosphatase released from osteoclasts. Prelabeled ^{45}Ca and hydroxyprolines were liberated, indicating the simultaneous dissolution of mineral and collagen (GAILLARD, 1961; RAISZ, 1965; SUSI, 1966). Calcium is primarily mobilized from the older parts of the bone. The increased release of calcium is only observed if the bones of the experimental animals have been labeled with radioactive ^{45}Ca three weeks prior to the administration of parathyroid hormone. When parathyroid hormone and ^{45}Ca are injected simultaneously, radioactive calcium is not mobilized from the newly formed parts of the skeleton (TALMAGE, 1965). A sudden fall in the serum calcium concentration leads to an immediate release of calcium from the bones, which is similar in parathyroidectomized rats and in normal controls. This sudden release of calcium from the bones is not regulated by parathyroid hormone (ROSENBAUM, 1964). A similar process also arises immediately after an injection of parathyroid hormone – the phosphate concentration in the plasma falls and there is an increase in the calcium released into the serum before the differentiation of osteoclasts or of osteocytes begins.

The action of parathyroid hormone on the bones consists predominantly in an increase in the mitotic rate, followed by an increase in the number of osteoclasts. An increased incorporation of thymidine into bone cells *in vitro* indicates a new synthesis of desoxyribonucleic acids and more frequent cell divisions (YOUNG, 1964). This effect is characteristic of parathyroid hormone and cannot be obtained in parathyroidectomized rats by means of peritoneal fluid rich in calcium. On the other hand, incorporation of ^{3}H-cytidine into ribonucleic acid can be stimulated by parathyroid hormone or calcium-rich peritoneal fluid (PARK, 1968). The increased release of calcium from bone cells cultures and the formation of osteoclasts is prevented *in vitro* by actinomycin-D. It inhibits protein synthesis at the level of the formation of messenger-nucleic acids (Fig. 9, Chap. I) (RAISZ, 1965 b; GAILLARD, 1965 a). Calcium mobilization from the bones, which occurs under the influence of parathyroid hormone, is also inhibited to a large extent *in vivo* in animals treated with actinomycin D (Fig. 12) (RASMUSSEN, 1964 a).

Experiments by TENENHOUSE (1966) provide further evidence of a cellular site of action for parathyroid hormone. PTH leads to an increased release of ^{45}Ca from bone chips incubated with ascites tumor cells. After centrifugation of the cells incubated with parathyroid hormone, a factor with different chemical properties from parathyroid hormone was isolated from the incubation fluid. This factor in itself leads to the release of calcium from the bone chips, whereas parathyroid hormone cannot exert its influence in the absence of cells. PTH stimulates the activity of an alkaline phosphatase in osteocytes. It is possible that this factor is the alkaline phosphatase, mentioned above, which as a pyrophosphatase accelerates the dissolution of the protective layer of pyrophosphate around the osteocytes, and thus promotes bone breakdown (p. 889). The connection is still hypothetical. Nevertheless, the fact that parathyroid hormone possesses a cellular receptor and that cells (osteoclasts or osteocytes) promote bone resorption, presumably through the release of enzymes, appears to be confirmed. VAES' results support this view (1967). He demonstrated an increased liberation of acid hydrolases such as beta-glucoronidase and of hyaluronidase from lysosomes which primarily dissolve mucopolysaccharides in bone-cell cultures under the influence of parathyroid hormone. The optimum pH for these hydrolases is an acid one. The concentration of the acid phosphatase is elevated in the plasma in a few cases of hyperparathyroidism and can be diminished with calcitonin *in vivo* and *in vitro* (DOTY, 1968; HEERSCHE, 1969). The synthesis of hydrolases precedes the action of parathyroid hormone. Actinomycin-D, which inhibits protein synthesis, also reduces the increased release of acid hydrolyses. This action is similar to the dissolving action of vitamin A on cartilage or to the phagocytosis of the leukocytes. In contrast to parathyroid hormone, the action of vitamin A can only be demonstrated in isolated lysosomes (FELL, 1962).

The release of proteolytic lysosomic enzymes through the action of vitamin A *in vitro* is inhibited by cortisone in a dose which has no influence on the increase of the number of the osteoclasts and the loss of bone minerals. Furthermore, calcitonin has no effect on the release of lysosomic enzymes *in vitro* despite its inhibitory action on calcium release and the formation of fibroosteoclasts. The increased release of hydrolases is therefore apparently not a direct effect of parathyroid hormone on lysosomes. The significance of these results

is also doubtful, since no collagenase has been demonstrated in lysosomes and collagen is the main constituent of the bone matrix (p.). A collagenolytic factor has been successfully demonstrated in bone-cell cultures, and this factor is activated by parathyroid hormone. The cellular site of origin of the factor is unknown (WALKER, 1964). Parathyroid hormone not only induces release of calcium from the bones, but also leads simultaneously to desintegration of the bone matrix. The increased excretion of *hydroxyproline* in the urine is an indication of the desintegration of the bone matrix. In hyperparathyroidism this rise is due to increased bone resorption rather than to raised collagen synthesis. The excretion of hydroxyproline decreases immediately after parathyroidectomy, although bone formation and the alkaline phosphatase in the plasma are increased postoperatively (MCDONALD, 1965). An infusion with calcium, which suppresses parathyroid hormone secretion and promotes the release of calcitonin, leads to inhibition of bone resorption as well as of the excretion of hydroxyproline in the urine (KEISER, 1964).

The dissolution of apatite into calcium and phosphate is promoted by the destruction of a protective layer of pyrophosphate, presumably under the influence of a pyrophosphatase (FLEISCH, 1966) (p. 889). NEUMANN (1958) further assumed that the dissolution of bone minerals could be promoted by an increase in hydrogen ions, as is found with the increased release of lactic acid under the influence of parathyroid hormone. Acetazolamide (Diamox), which inhibits carbonic anhydrase and thus also acidification, prevents a rise in the mobilization of calcium released by parathyroid hormone in the hen (SIEGMUND, 1965). A definite fall of pH to under 6.8 has not so far been demonstrated *in situ* at the bone surfaces.

Parathyroid hormone and vitamin D together lead to a rise in the citrate concentration in the plasma in the presence of an increased serum calcium concentration. Aconitase is inhibited by calcium, and the increase in citrate is possibly principally a result of the hypercalcemia. The hypothesis that the increase of citrate, and to a lesser degree of lactate dissolves the bones by acting as chelators of calcium is attractive but must be abandoned since the concentration of citrate in the bones is probably not even locally adequate for production of an increased calcium mobilization. A rise in the serum calcium concentration is also observed in rats treated with cortisone and under the influence of vitamin D without any simultaneous increase in citrate formation (HARRISON, 1957). An increase of citrate and lactate in the plasma in vivo and in bone-cell cultures in vitro merely indicates that increased amounts of glucose are metabolized with a liberation of lactate, citrate and CO_2. The increase of citrate is sometimes secondary to increased calcium uptake by osteoclasts with inhibition of aconitase activity and citrate breakdown (VAES, 1967; COHN, 1965). PTE inhibits isocitrate dehydrogenase *in vitro* in bone-cell cultures; the effects of calcium and/or parathyroid hormone cannot be differentiated (HEKKELMAN, 1963; HERRMANN-ERLEE, 1966). Increased oxygen consumption has been observed in isolated mitochondria incubated with parathyroid hormone and an oxidizable substrate (RASMUSSEN, 1966).

RIGGS (1965) demonstrated increased bone resorption in all the bone biopsies taken from patients with surgically verified primary hyperparathyroidism by microradiography. BINSWANGER (1968 a), in contrast, found an increased number of osteoclasts per trabecular surface in only half his cases of primary hyperparathyroidism which were confirmed by surgery. The number of osteoclasts remains constant throughout life in normal persons. It is justifiable to assume that in some patients with hyperparathyroidism with no increase in fibroosteoclasts, the counterregulation by calcitonin causes the disappearance of the osteoclasts, (p. 880).

New bone formation can be elevated or reduced in hyperparathyroidism. In some patients, increased bone resorption can lead to a compensatory increase in bone formation, as has been described in the case of immobilization osteoporosis (p. 867). WHITEHEAD (1959) found a reduced uptake of radiolabeled phosphate by the bones of rats treated with PTE. He deduced that bone formation was suppressed in this way. The compensatory new formation of bone does not occur in bone cell cultures *in vitro*, and an inhibitory action of parathyroid hormone on bone formation of bone appears probable.

The osteoblasts disappear from bone-cell cultures treated with parathyroid hormone within three to four days (GAILLARD, 1961). Morphological cell differentiation is difficult to observe in cell cultures. The inhibition of collagen synthesis and the uptake of proline and of glycine into the osteoblasts and into the bone matrix is a reflection of reduced osteoblastic activity (GAILLARD, 1965 b; YOUNG, 1964; OWEN, 1968; FLANAGAN, 1969). This effect cannot be explained by parathyroid hormone alone, since incubation in a calcium-rich medium can also inhibit collagen synthesis (PARK, 1968). Proline uptake into collagen is decreased in bone-cell cultures from patients with hyperparathyroidism with no radiologically

visible bone involvement and with a normal urinary hydroxyproline excretion. In cases with radiologically visible skeletal involvement and with an elevated hydroxyproline excretion in the urine, the proline uptake into collagen is increased, indicating increased compensatory new bone formation. The oxygen consumption is always raised (FLANAGAN, 1965). There is no definite demonstrable action of parathyroid hormone on bone formation.

Kidneys. In contrast to the action of parathyroid hormone on bone, which causes calcium to be mobilized within some hours, its action on the kidneys takes place within minutes. There is an increased excretion of phosphate which is independent of any alteration in the glomerular filtration rate. An injection of parathyroid hormone into a renal artery has the same effect (PULLMAN, 1960). In addition to the inhibition of phosphate reabsorption in the proximal tubules, the secretion from the distal tubules may also be increased since the phosphate clearance exceeds the creatinine clearance in some cases (WEBSTER, 1967). Selective destruction of the distal tubules by means of mercuric chloride leads to inhibition of the hormone-dependent excretion of phosphate. Stop-flow experiments in the dog indicate an inhibition of phosphate reabsorption in the proximal tubules (NICHOLSON, 1959; LAMBERT, 1963). There is still no unified concept as to whether parathyroid hormone has one or several sites of action in the kidney tubules.

Furthermore, reabsorption of calcium and of magnesium is increased under the influence of parathyroid hormone (RASMUSSEN, 1963a; MACINTYRE, 1963; NAMY, 1969). PTE causes an initial reduction of the excretion of calcium and magnesium in parathyroidectomized patients. After one to four days, this reduction gives way to an increase in calcium excretion (GILL, 1967). The hypercalciuria and the increased amounts of bicarbonate excreted at the same time, resulting in an alkalinization of the urine, sometimes lead to nephrocalcinosis and to the formation of kidney stones.

The increased tubular reabsorption of glucose which arises under the influence of parathyroid hormone has been used in some cases for the diagnostic investigation of hypercalcemia of unknown origin (HALVER, 1967). In addition, increased amounts of potassium, sodium, chloride, citrate, sulfate, bicarbonate, water and amino acids are excreted and more hydrogen ions and ammonia are reabsorbed. It is difficult to differentiate whether a disturbance is due to the primary action of parathyroid hormone or to the secondary tubular damage resulting from the hypercalcemia. This is especially applicable to the hyposthenuria due to hypercalcemia, which can arise from a disturbance of the counterflow system in the presence of a reduction of the sodium content of the renal medulla, or from vasopressin resistance in the distal tubules, or as the result of a direct action of parathyroid hormone on the renal tubules (EPSTEIN, 1959; FOURMAN, 1963).

Gut. Parathyroid hormone promotes the absorption of calcium, magnesium and phosphate by the intestinal mucosa. This effect can be demonstrated *in vivo* and *in vitro* in isolated intestinal villi following the injection of parathyroid hormone into the whole animal. PTH has no direct effect on indestinal villi *in vitro*. The uptake of ^{45}Ca is delayed in parathyroidectomized rats (RASMUSSEN, 1963; WINTER, 1970)

Ulcers develop in the stomach and the duodenum in about 10% of cases of hyperparathyroidism, regardless of the presence of islet cell adenomas of the pancreas, which occur frequently in familial polyglandular adenomatosis (ZOLLINGER, 1955; SCHMID, 1961). The ulcers usually regress after parathyroidectomy. Following administration of calcium, acid secretion of the stomach can rise before and after parathyroidectomy (BARRERAS, 1967; 1970). Calcium can cause increased liberation of gastrin in Zollinger-Ellison syndrome (TRUDEAU, 1969). A chronic increase of the serum calcium is not always associated with a rise in the gastric acid secretion (MURPHY, 1966).

γ) Mechanisms of Action of Parathyroid Hormone

The action of parathyroid hormone takes place in different phases at various sites of action. The increase of the phosphate excretion and of the calcium reabsorption in the renal tubules begins within minutes and is independent of any preceding protein synthesis. It also occurs in the absence of vitamin D. Presumably inhibition or promotion of a transport mechanism is involved. The elevated bone resorption which arises under the influence of parathyroid hormone, with increased release of calcium from the bones and raised hydroxyproline excretion in the urine, develops within hours and is preceded by an increase in protein synthesis, since bone resorption is raised only insignificantly in the presence of actinomycin-D (Fig. 12) (p. 874) (RASMUSSEN, 1964a). Vitamin D is essential to the action of parathyroid hormone on the bones (Fig. 13) (RASMUSSEN, 1963b). Calcium absorption from the small intestine takes an intermediary position. It

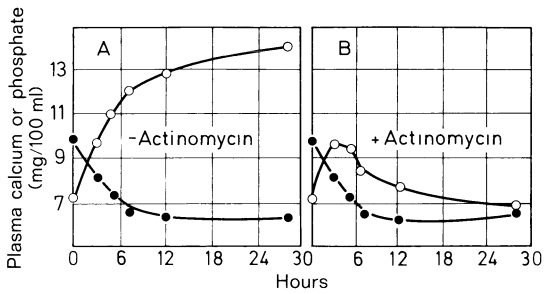

Fig. 12. The sequential alterations in plasma calcium (open circles) and phosphate (closed circles) after an intraperitoneal injection of 200 µg purified bovine parathyroid hormone into parathyroidectomized rats. Control values on left; values on right recorded in animals given 1 µg actinomycin-D/g body weight 2 h prior to injection of parathyroid hormone. (After RASMUSSEN, 1964)

comes into effect more slowly than the action on the kidneys and more rapidly than the calcium mobilization from the bones. On the other hand, the action on calcium absorption by the intestine is more quickly exhausted than the action on the bones (RASMUSSEN, 1961). The release of calcium from isolated intestinal villi is accelerated under the influence of parathyroid hormone only in the presence of vitamin D (RASMUSSEN, 1963a). PTE leads to increased synthesis of ribonucleic acids in the intestinal mucosa (HAMILTON, 1968).

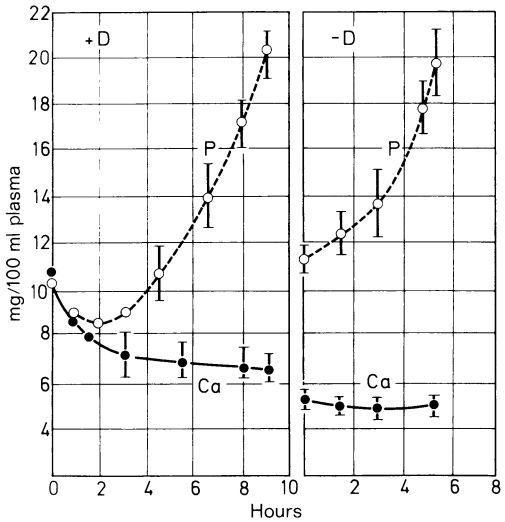

Fig. 13. Sequential changes in serum calcium and phosphate concentrations after parathyroidectomy by electrocautery in vitamin D-fed rats on a low-calcium diet (left) and of vitamin D-deficient rats on a normal-calcium diet (right). The decrease in serum phosphate 2 h after parathyroidectomy in vitamin D-fed rats (left) is significant ($p < 0.01$) compared with the initial value. The initial decrease in the serum phosphate in vitamin D-fed rats does not occur in thyroparathyroidectomized rats (in the absence of calcitonin) and the fall in the serum calcium is less steep. (Kindly supplied by Professor H. RASMUSSEN; after RASMUSSEN, 1963)

Increased administration of lactose leads to a rise of the calcium absorption by the intestine which is independent of parathyroid hormone and of vitamin D. Parathyroid hormone causes a rise in the serum calcium *in vivo*. This can be demonstrated even in the absence of vitamin D in animals treated with lactose and with calcium. *In vitro*, parathyroid hormone causes an increase in the calcium released from bone-cell cultures (AU, 1967).

Failure to respond to the administration of parathyroid hormone in cases with intestinal malabsorption does not definitely indicate vitamin-D deficiency or resistance of the skeleton to PTH, since the amounts of hormone administered can be too small to elicit a response in the presence of secondary hyperparathyroidism. The increase in osteoid mass found in hypocalcemia and in vitamin-D deficiency is at the most only a relative and not an absolute hindrance to the action of the osteoclasts on the skeleton.

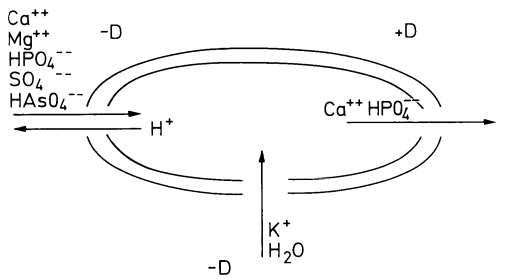

Fig. 14. Schematic representation of the action of parathyroid hormone on mitochondria *in vitro*. For some actions (+D) vitamin D is a requirement, others (−D) occur in the absence of vitamin D. For detailed explanations see text. (After RASMUSSEN, 1963, 1967)

The *mitochondrial membrane* is a subcellular site of action of parathyroid hormone. There is a close relation in the mitochondria between oxidative phosphorylation and ionic transport mechanisms under the influence of PTH. *In vivo*, the kidneys excrete increased amounts of phosphate, sulfate, potassium and water, and diminished amounts of hydrogen ions (Fig. 14). In mitochondria the uptake of phosphate, potassium, sulfate and water is promoted and the uptake of hydrogen ions suppressed (Table 2, Fig. 14). These effects can also be seen in the absence of vitamin D as they occur in the renal tubules. Some of the actions on the renal tubules are probably due to the hypercalcemia and to nephrocalcinosis, which cannot always be detected macroscopically. In spite of this, the analogy between the action on the renal tubules and on the mitochondria is impressive.

Table 2. Similarities between the actions of parathyroid hormone on the renal tubules and on mitochondria

	Excretion by the renal tubules in vivo		Uptake by the mitochondria *in vitro*	
	Stimulation	Inhibition	Stimulation	Inhibition
PO_4	+		+	
SO_4	+		+	
K	+		+	
H		+		+
Ca		+	+	+ (Release)
Mg		+	+	
H_2O	+		+	

The *magnesium concentration* probably holds a key position as an activator of the oxidative phosphorylation and of alkaline phosphatase or pyrophosphatase, which possibly accelerates the bone mineral dissolution around the osteocytes under the influence of parathyroid hormone. The uptake of magnesium into the mitochondria is increased under the influence of parathyroid hormone. Calcium is released from the mitochondria under the influence of parathyroid and/or of vitamin D. Like the calcium mobilization from bone, this release has only been demonstrated in mitochondria from rats previously treated with vitamin D (Fig. 15). These examples are meant to illustrate that mitochondria are suitable for the study of the mode of action of parathyroid hormone. A detailed description of possible sites of action of parathyroid hormone on the respiratory chain has been given by RASMUSSEN (1967a, 1966).

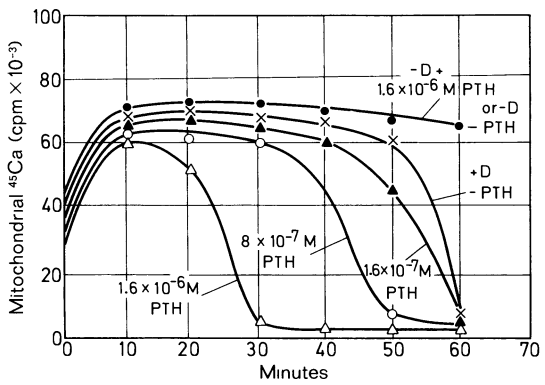

Fig. 15. The effect of parathyroid hormone and of vitamin D on the release of radioactive ^{45}Ca from mitochondria *in vitro*. (After DE LUCA, 1962)

A further possible site of action of parathyroid hormone is the *adenylcyclase*. After an injection of parathyroid hormone, the excretion of cyclic 3′,5′-adenosine monophosphate (cyclic 3′,5′-AMP) is increased prior to the onset of phosphate diuresis (CHASE, 1968) (Fig. 16). It has been demonstrated in labeling experiments that cyclic 3′,5′-AMP originates from the kidneys. A similar rise in the excretion of the cyclic 3′,5′-AMP and phosphate has also been achieved with high doses of vasopressin. Parathyroid hormone activates an adenylcyclase from the renal cortex *in vitro*; vasopressin, in contrast, an adenylcyclase from the renal medulla (CHASE, 1968). The activation of adenylcyclase is also promoted in bones under the influence of parathyroid hormone (CHASE, 1970). Most of the actions of parathyroid hormone can be imitated by an infusion of cyclic-dibutyryl-adenosine 3′,5′-AMP to the rat or of cyclic 3′,5′-AMP into the renal artery of the dog. The result is an increase in the serum calcium concentration

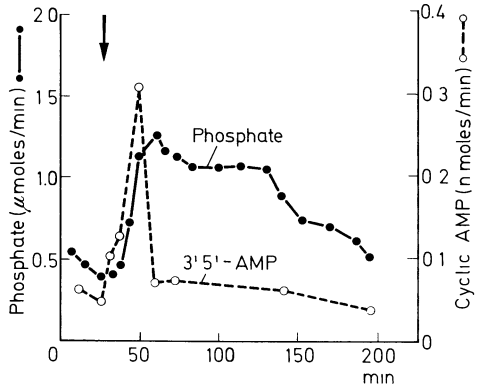

Fig. 16. Subsequent stimulation of urinary 3′5′-AMP and phosphate excretion by parathyroid hormone in vivo. (After POTTS, 1971)

and of the urinary hydroxyproline excretion and phosphate excretion (RASMUSSEN, 1968; RUSSELL, 1968b). There is suggestive evidence that cyclic adenosine monophosphate is the effector and second messenger of the action of parathyroid hormone. In patients with pseudohyperparathyroidism the parathyroid hormone concentration in the serum is increased; an infusion of parathyroid hormone leads neither to an increase of the renal phosphate excretion nor to an excretion of cyclic AMP; an adenylcyclase deficiency is postulated as the reason for the tubular resistance of parathyroid hormone (LEE, 1968; CHASE, 1969). Another explanation, however, is that in view of the raised endogenous serum parathyroid hormone concentrations, the amount of parathyroid hormone injected into these patients was insufficient to cause an increase in the urinary phosphate excretion.

In isolated renal tubules, parathyroid hormone stimulates the formation of 3′,5′-AMP and gluconeogenesis. In the absence of calcium in the incubation medium 3′,5′-AMP only is formed.

The effect on gluconeogenesis requires calcium (NAGATA, 1970). Parathyroid hormone promotes the calcium uptake in isolated renal cells (BORLE, 1970). The intracellular calcium concentration is crucial for the transmission of the parathyroid hormone action (RASMUSSEN, 1970).

In the kidneys and possibly in osteocytes the primary site of action of parathyroid hormone is probably a membrane which depends on metabolic processes (mitochondria, respiratory chain, adenylcyclase). In osteoclasts, the desoxyribonucleic acids of the cell nucleus probably play a major part in the control of the parathyroid hormone action and the synthesis of proteins or enzymes which stimulate the dissolution of bones. The exact mechanisms of action of parathyroid hormone remain to be elucidated.

b) Calcitonin (Thyrocalcitonin)

Calcitonin (CT) is a polypeptide hormone which causes the concentrations of calcium and phosphate in the serum to fall. The existence of a calcium-lowering principle, calcitonin (CT), was first suspected by COPP in 1961 (COPP, 1962). Calcitonin was then extracted by HIRSCH (1963) from the thyroid and named thyrocalcitonin. Thyrocalcitonin and calcitonin are identical. In most mammalian species including man CT is primarily a thyroid hormone. As a calcium-lowering hormone CT is the most important counterregulator of parathyroid hormone.

α) Occurrence, Isolation, Secretion, and Metabolism of Calcitonin

CT originates from the parafollicular or C cells (PEARSE, 1966a). The C cells were probably mentioned for the first time by BABER in 1877, but until recently no physiological importance was attached to them. On immunofluorescent examination C cells selectively bind antibodies to CT (BUSSOLATI, 1967). They are histochemically similar to the islet cells of the adenohypophysis (PEARSE, 1966). C cells are found in all cervical organs, in the thyroid gland, in the ultimobranchial body, in the parathyroids, in the thymus, and free in the neck (CARVALHEIRA, 1968). In pigs, CT has been extracted from the adrenal medulla (KAPLAN, 1970). In shark (*squalus suckleyi*) and hen CT has been extracted from ultimobranchial bodies. A small amount is found in the thyroid gland in hens, whereas equal amounts have been isolated from the thyroid gland and the ultimobranchial body of pigeons. Separate perfusion of the thyroid and the parathyroid glands of goats with calcium-rich blood has shown that CT arises from the thyroid (FOSTER, 1964). With the exception of the anteater, which has a separate ultimobranchial body, calcitonin primarily arises from the thyroid gland in mammalian species (COPP, 1967; MACINTYRE, 1967). In man, CT was demonstrated in the thyroid as well as in the thymus and in the parathyroids (GALANTE, 1968). Isolation and synthesis of porcine CT give evidence of a single polypeptide chain of 32 amino acids (RITTEL, 1968; GUTTMANN, 1968). Isolation and synthesis of CT from a medullary thyroid carcinoma in man also revealed a single chain with 32 amino acids; the structure, however, is markedly different. There are eighteen amino-acid residues in which human CT is diffent from porcine CT (Fig. 17) (NEHER, 1968; SIEBER, 1968). The structure of CT from the normal human thyroid is not yet known. The potency of CT is biologically tested in the rat or in the mouse by measurement of the fall in the serum calcium concentration. Growing animals with increased bone remodeling are more sensitive to CT than adult animals; a diet rich in phosphate promotes the calcium lowering effect (HIRSCH, 1968). In the rat bioassay, human and porcine CT do not significantly differ. However, salmon CT is biologically 20 to 30 times more active in man and rat (KEUTMANN, 1970).

The CT concentration in the plasma was first measured in the rat bioassay (STURTRIDGE, 1968). The use of a radioimmunoassay allows more accurate and reproducible determination of the CT concentration in the serum (LEE, 1969; CLARK, 1969; ARNAUD, 1970). Because of the

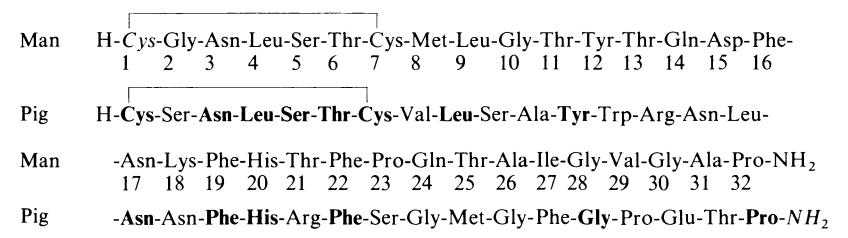

Fig. 17. Comparison of the amino-acid sequences of human calcitonin M (medullary carcinoma of the thyroid) and of porcine α-calcitonin. The amino-acid residues in heavy type are common to the human and porcine calcitonin. The first seven amino-acid residues are similar and the C terminals identical. (After NEHER, 1968)

different structures of human and porcine CT, which was exclusively used until 1968, the cross-reaction was, as expected, poor (TASHJIAN, 1969). CT from medullary carcinomas and synthetic human calcitonin M (SIEBER, 1968) were used for the generation of high-affinity antibodies to human CT (CLARK, 1969; TASHJIAN, 1970).

The *regulation of the CT concentration* in the serum by the thyroid is similar to the regulation of the parathyroid hormone concentration. Calcium and magnesium stimulate the secretion of CT directly, without the interposition of a feedback loop such as the pituitary or the central nervous system. A rise in the serum calcium leads to an increase in the CT concentration in the venous effluent of the thyroid (FOSTER, 1964; CARE, 1967). The CT concentration in the serum is proportional to the calcium concentration (LEE, 1968; ARNAUD, 1970). Isolated perfusion of the parathyroids with EDTA, which binds calcium, in contrast, leads to a rise of the parathyroid hormone concentration in the venous effluent from the parathyroids (CARE, 1966; ARNAUD, 1970).

Glucagon and cyclic adenosine monophosphate increase the secretion of calcitonin *in vivo* and *in vitro* (AVIOLI, 1969; CARE, 1969; BELL, 1970). The half-life of CT in the serum is similar to that of parathyroid hormone, lying between 4 and 12 min (LEE, 1969). The half-life of salmon CT in the circulation of the dog is much longer than the half-life of porcine CT, which explains the unusual potency of salmon CT in man (HABENER, 1971). The CT concentration in the thyroid is increased in chronic hypocalcemia. The parafollicular cells of the dog show an enlargement of the nuclei, an increase of intracellular vacuoles and a change in enzyme concentrations which can be histochemically demonstrated (PEARSE, 1966; HACHMEISTER, 1967; CAMERON, 1968). The CT content of the thyroid is slightly reduced in chronic hypercalcemia. Hypocalcemia probably causes an inhibition of the release of CT from the thyroid and the storage of secretory granules containing CT in the thyroid gland of rat (GITTES, 1968).

There is no fall in the CT concentration in the plasma of thyroidectomized patients, as measured in the rat bioassay, since CT is also synthesized in other organs (GUDMUNDSON, 1969; KAPLAN, 1970). The thyroid protects rats from hypercalcaemia and nephrocalcinosis resulting from lethal amounts of parathyroid hormone (RASMUSSEN, 1967). Oral administration of calcium causes a temporary calcium increase only in thyroidectomized rats (GRAY, 1969). Parathyroidectomized rats have lower serum calcium concentrations than rats in which both the thyroid and the parathyroids have been removed. These results in rats provide evidence that CT in the serum is effective as a regulator of the normal serum calcium concentration (TALMAGE, 1965).

In contrast to the situation in parathyroidectomized rats, a perfusion of CT over 6 hours in intact rats leads to an increase of the fibroosteoclasts, presumably due to secondary hyperparathyroidism in the presence of hypocalcemia (EVANSON, 1967). The same situation can be produced *in vitro* in bone-cell cultures; parathyroid hormone and CT first inhibit and later even stimulate the release of calcium (FRIEDMAN, 1968).

In contrast to parathyroid hormone, the onset of the action of CT is rapid, but also quickly exhausted even when more CT is infused. Presumably CT is necessary for the regulation of rapid alterations in the serum calcium concentration, whereas parathyroid hormone is constantly released to maintain a normal calcium concentration in the serum.

Parathyroidectomy leads to a reduction in the serum calcium, whereas the removal of the thyroid, the major CT-producing organ in man, is not followed by hypercalcemia. Growth hormone promotes the calcium-decreasing action of CT. CT is more effective in growing rats. Hypophysectomy inhibits the action of CT (COPP, 1968). If bone remodeling, and in particular resorption, is increased, CT has a greater hypocalcemic effect. MILHAUD (1965) noted that the uptake of 131-iodine in the thyroid was barely measurable two weeks after hypophysectomy, whereas the CT concentration remained unchanged.

β) Sites of Action of Calcitonin

Bones: The most important action is the inhibition of bone resorption. In parathyroidectomized rats fed on a calcium-rich diet, CT causes a reduction in the number of fibroosteoclasts. The bone trabeculae become thicker, and the changes are accompanied by a corresponding increase in bone density on X-ray examination (FOSTER, 1966a). The loss of strontium and of hydroxyproline from the skeleton and the urinary excretion of hydroxyproline are reduced in rats treated with CT *in vivo* (KLEIN, 1968; KAHLER, 1966; MARTIN, 1966; RASMUSSEN, 1967). Perfusion of the isolated tibia with CT leads to an increase in the calcium retention in the bones (PARSONS, 1968).

In-vitro inhibition of the bone resorption was demonstrated in bone-cell cultures pretreated with parathyroid extract (ALIAPOULIOS, 1966; FRIEDMANN, 1968). Calcitonin and para-

thyroid hormone influence bone resorption via cellular sites of action. The inhibition of the release of ^{45}Ca from bone-cell cultures under the influence of CT or the stimulation by parathyroid hormone is lost after heat inactivation (RAISZ, 1967).

The formation of osteocytic lacunae under the influence of PTH in rats is lost if the animals are simultaneously perfused with CT (RASMUSSEN, 1967). The osteocytes are probably a site of action in the bone for CT and PTH (p. 856).

The dominant feature of CT is the inhibition of bone resorption. Stimulation or inhibition of bone formation has not been definitively found. Inhibition of bone resorption alone can result in increased retention of calcium in the bones, which can lead to hyperostosis. If bone resorption is suppressed calcium cannot be released into the plasma, and this leads to hypocalcemia.

Kidneys. CT increases the urinary excretion of phosphate even in hypoparathyroid patients without changing the glomerular filtration rate (HAAS, 1971; ARDAILLOU, 1967). The injection of CT in high concentrations into the renal artery of the dog does not lead to an increase of the phosphate excretion into the urine (CLARK, 1969). In contrast to parathyroid hormone, which leads to a prolonged rise in the phosphate excretion, CT only produces a temporary effect. The phosphaturic action may reflect a direct effect of CT on the kidney tubule or it may be caused by a lowering of the serum calcium concentration. The latter alternative is supported by the fact that EDTA, which lowers the serum calcium, produces an increase in phosphate excretion in parathyroidectomized rats (RASMUSSEN, 1967). The fall of the plasma phosphate and calcium can be demonstrated in nephrectomized and eviscerated animals, which shows that the major action of CT is the inhibition of bone resorption (GUDMUNDSON, 1966). CT does not produce a fall in the serum calcium in parathyroidectomized hypocalcemic rats, whose bone resorption is suppressed. The elevated serum phosphate does fall, however, and this can be prevented by previous nephrectomy (ROBINSON, 1967). These results could explain the changes in urinary phosphate excretion in patients with hyper- and hypocalcemia and varying concentrations of PTH and CT in the serum. They also offer an explanation for the changing phosphate excretion after the infusion of calcium in hyperparathyroid patients, and for the resulting uncertainties associated with the interpretation of the calcium infusion test (p. 943). In addition to the actions of CT on the bones and on the kidneys, CT also has other effects which are probably secondary to the lowering of the serum calcium concentration. These effects include the fall in the calcium concentration in the myocardium and in the kidneys (GUDMUNDSON, 1966; KENNY, 1965). A similar reduction of the intracellular calcium concentration has been described in hypocalcemia after parathyroidectomy, where, in contrast, there is a reduction of the CT concentration in the serum (WALLACH, 1966). The calcium absorption in isolated loops of the small intestine is not affected by CT (ROBINSON, 1968).

γ) Calcitonin in Man

The structure and synthesis of CT from medullary thyroid carcinomas are discussed on p. 879. The biological activity of human CT does not differ greatly from porcine CT in man. In the presence of increased bone resorption (Paget's disease and/or hypercalcemia) CT produces a rapid fall of the calcium and phosphate concentrations in the plasma (FOSTER, 1966c; HAAS, 1968). An intravenous injection of even 1 M.R.C. (Medical Research Council) unit of CT produces a significant calcium-reducing activity in the plasma of patients with hypercalcemia (FOSTER, 1966b) (Fig. 18). In normal control subjects calcium, magnesium, potassium, and phosphate excretion are increased in the absence of any lowering of the serum calcium concentration (SINGER, 1969). The CT concentration of normal human plasma can be measured by radioimmunoassay. It is elevated after an infusion of calcium in normal subjects and in patients with medullary carcinomas of the thyroid (STURTRIDGE, 1968; TASHJIAN, 1970). Thyroidectomy does not alter the bioassayable CT concentration in the serum, and the human

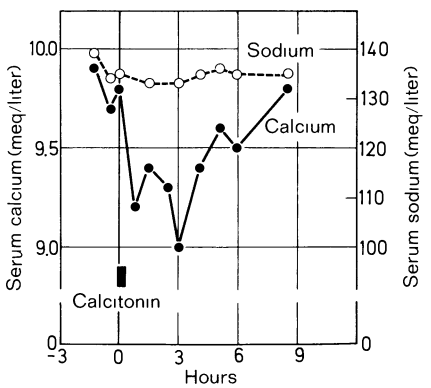

Fig. 18. Serum calcium and sodium concentrations after an intravenous injection of 1 MRC unit of porcine calcitonin in a patient with hypercalcemia resulting from skeletal metastases. (After FOSTER, 1966c)

thyroid is therefore thought not to be the only site of synthesis for CT (GUDMUNDSON, 1969). The clinical features of overproduction or deficiency of CT do not include any striking findings. Thyroidectomy does not lead to hypercalcemia in man. Deficiency of CT can be suspected in thyroidectomized patients if the half-life of calcium given by infusion proves to be 200 min, in contrast to 48 min in control subjects (WILLIAMS, 1966; MAZZUOLI, 1966).

An elevated concentration of CT in the thyroid and in the plasma has now been demonstrated in most cases with medullary carcinoma of the thyroid gland, which often occurs together with pheochromocytomas. The serum calcium concentration is lowered only in a few cases. These patients usually suffer from diarrhea, so that intestinal malabsorption must be taken into account (TASHJIAN, 1968; CUNLIFFE, 1968). Medullary carcinoma of the thyroid can also be associated with mucosal neuromas, Marfanoid features, myopathy, and pigmentation, making the patients look like Giacometti sculptures (CUNLIFFE, 1970). Occasionally the disease is associated with Cushing's syndrome caused by ectopic production of ACTH (KEYNES, 1971). Elevated histaminase concentrations have been found in serum and in the tumor tissue, which accounts for the absence of any histamine reaction in some patients suffering from medullary carcinoma of the thyroid (BAYLIN, 1970; BAUM, 1971). In most of these patients hyperplasia of the parathyroids or an increased level of parathyroid hormone was recorded, which can be caused either by a minimal lowering of the serum calcium concentration or by a possible direct stimulation of parathyroid hormone secretion by CT (FISCHER, 1971). Medullary carcinomas are frequently familial with an autosomal dominant mode of inheritance. The life expectancy in patients subjected to surgery is good, and the single best laboratory examination in otherwise healthy subjects is radioimmunological determination of the CT concentration in the plasma (MELVIN, 1971). With the particular mode of inheritance half a family can be affected with the disease. Surgery is certainly the treatment of choice.

Overproduction of CT could be the cause of some cases of idiopathic "hypoparathyroidism" (FISCHER, 1967). An increased concentration of CT in the thyroid gland of these patients can be explained by the hypocalcemia and an inhibition of the release of CT into the plasma. Thyroidectomy does not cause any lasting correction of the hypocalcemia in patients with pseudohypoparathyroidism (LEE, 1968). Hyperostosis is demonstrable in one third of cases with idiopathic or pseudohypoparathyroidism. The hyperostosis is even more pronounced in hereditary osteopetrosis, which is occasionally associated with hypocalcemia and thus possibly with overproduction of CT or with hypersensitivity to CT (WHITE, 1965). The osteopetrosis was characteristic in the mice described by WALKER (1966) in which hypocalcemia, hypophosphatemia and a large number of parafollicular cells in the thyroid were indirect signs of overproduction of CT. There may be some connection between the CT and PTH secretions in patients with hyperparathyroidism with and without hypercalcemia and/or fibroosteoclasia. They can be explained by a dominance of parathyroid hormone and/or CT secretion (BINSWANGER, 1968).

In summary, the physiological importance of CT is still debatable. Thyroidectomy does not change the serum calcium concentration. In the absence of CT the serum calcium remains elevated for quite long periods following a calcium infusion; the thyroid protects rats from lethal effects due to parathyroid hormone (RASMUSSEN, 1967; WILLIAMS, 1966). Thyroidectomy does not alter the CT concentration in the human plasma (GUDMUNDSON, 1969). Animals entirely free of calcitonin have not been described. Nevertheless, CT is probably important for the rapid regulation of the serum calcium concentration. In patients with medullary carcinoma of the thyroid excess CT does not alter the histological or the radiological appearance of the skeleton.

c) Vitamin D

Vitamin D differs from parathyroid hormone and calcitonin (half-life 10–30 min) in that it has a half-life varying from days to months. According to conventional definitions, parathyroid hormone and calcitonin are *hormones* with a short half-life; they are excreted in inverse or direct proportion to the calcium concentration in the plasma. Vitamin D, however, must be supplied with the diet, and it is stored in the body. Parathyroid hormone and calcitonin are polypeptide hormones with a similar number of amino-acid residues and with molecular weights of the same order of magnitude. Their structure is species-specific, whereas this is not the case with vitamin D, a steroid vitamin or hormone effective in all the known vertebrates.

Vitamin D has several features in common with hormones, e.g. the stimulation of the synthesis of the biologically active 1,25-dihydroxycholecalciferol from vitamin D by low serum phosphate concentrations and para-

thyroid hormone (TANAKA, 1973; RASMUSSEN, 1972).

Vitamin D has two important sites of action, the small intestine and the skeleton. Hypocalcemia is normalized by the administration of vitamin D regardless of the pathogenesis, via increased absorption of calcium in the gut and probably via increased bone resorption. Vitamin-D deficiency leads to rickets in the child and in the adult to osteomalacia, which is often associated with oesteoporosis (WERNLY, 1952; GARNER, 1966). The main causes of osteomalacia in the adult are renal insufficiency and steatorrhea with malabsorption, which are associated with a reduction of protein absorption and of collagen synthesis. Severe osteomalacia rarely develops after gastrectomy. In renal insufficiency and in phosphate diabetes a resistance to the action of vitamin D is considered a cause of the osteomalacia. An isolated deficiency of vitamin D has only been demonstrated in the adult in severe nutritional deficiency, and has been connected with the lack of sunlight in England. No isolated disorder of vitamin-D absorption in the gut has been demonstrated so far (p. 865).

α) Uptake and Metabolism

The vitamins of the D group are steroids used in clinical practice in the form of ergocalciferol (vitamin D_2), cholecalciferol (vitamin D_3), or as dihydrotachysterol (calcamin, AT-10). The physiological properties of vitamin D_2 and D_3 and dihydrotachysterol are not very different.

Dihydrotachysterol has a shorter half-life than ergocalciferol (HARRISON, 1967). The different preparations are not discussed individually (p. 903). Unless otherwise stated, the properties of vitamin D_3 are described.

Vitamin D_3 is absorbed in the small intestine and subsequently transformed in the liver into 25-hydroxycholecalciferol (25-HCC) (PONCHON, 1969). 25-HCC is subsequently converted to the biologically active 1,25-dihydroxycholecalciferol (1,25-DHCC) in the kidney (FRASER and KODICELE, 1970). DELUCA and his collaborators (1972) have isolated and synthesized 25-HCC and 1,25-DHCC. Their clinical activity is being tested. Following the administration of 25-HCC and 1,25-DHCC the onset of action in the small intestine is earlier than that of vitamin D_3, since vitamin D_3 has to be transformed to 1,25-DHCC to become biologically active. The action of 1,25-DHCC on calcium absorption from the intestine in the rat starts several hours earlier than the action of vitamin D_3 (DELUCA, 1972). Infusion of 25-HCC into the mesenteric artery increases calcium absorption within the same time period, whereas vitamin D_3 in much higher doses remains ineffective (OLSON, 1969). In bone cell cultures 25-HCC and 1,25 DHCC increase calcium release, whereas vitamin D_3 produces only doubtful effects (RAISZ, 1972). Most of the experiments reported have been performed with vitamin D_3 as 1,25-DHCC is not yet easily available.

Vitamin D is absorbed in the small intestine. The minimum amount required to normalize the serum calcium in a growing rat fed on a diet with no vitamin D is less than 1 USP unit. The minimum requirement for man is not known. It is probably about 10 units per day. Vitamin D is also administered parenterally, particularly in intestinal malabsorption. It is poorly absorbed in the absence of bile in cases of bile obstruction, such as primary biliary cirrhosis and in steatorrhea, since it is a fat-soluble vitamin. The concentration of vitamin D in the plasma can only be roughly estimated biologically. It is determined by the measurement of the absorption of radioactive calcium by the gut, the increase in the serum calcium concentration, or the ash content and mineralization of the skeleton in rats or hens with rickets. Competitive protein-binding assays have been introduced for the measurement of vitamin D and 25-HCC in human serum (BELSEY, 1971; BAYARD, 1972).

Radioactive vitamin D_3 has a short half-life of 12 hours in the plasma but is converted into 25-hydroxycholecaliferol, whose half-life is 19.6 days (SMITH, 1971).

Vitamin D is stored for months in the liver and in the skin. Because of the long half-life there is a danger of vitamin-D accumulation and intoxication leading to hypercalcemia and nephrolithiasis, and of generalized deposition of calcium in blood vessels and soft tissue. 7-Dehydrocholesterol is converted to active vitamin D in the skin by the action of ultraviolet light. For this reason, patients with hypocalcemia and hypoparathyroidism need less vitamin D in summer than in winter. Exposure to sunlight can lead to hypercalcemia in patients with sarcoidosis since the compensatory fall of the calcium concentration in the plasma due to calcitonin is presumably not sufficient to normalize the serum calcium. Patients with sarcoidosis show increased sensitivity to vitamin D. The concentration in the plasma, measured biologically for its antirachitic activity, is within normal limits (THOMAS, 1959). Small amounts of vitamin D that are inactive in normal persons lead to hypercalcemia in patients with sarcoidosis (TAYLOR, 1963; BELL, 1964). In idiopathic hypercalcemia, the antirachitic activity is still elevated 14 months after discontinuation of

treatment with vitamin D; the breakdown is probably delayed (FELLER, 1958). The serum calcium and the intestinal calcium absorption are increased by 1,25-DHCC in patients in advanced renal failure (BRICKMAN, 1972), even if it is administered in a dose ineffective for vitamin D_3.

β) Sites of Action of Vitamin D

The most important sites of action are the small intestine and the bones, where vitamin D accumulates rapidly after a single injection (DELUCA, 1968). Physiological amounts (thought to be 10 units/day in man) primarily promote calcium absorption in the small intestine. Larger amounts (≃1 000–10 000 units/day) stimulate the mobilization of calcium from bones and lead to a rise in the serum calcium concentration. Toxic amounts of vitamin D or parathyroid hormone cause hypercalcemia, nephrocalcinosis, and azotemia. An exception is vitamin D-resistent rickets, which can be treated with over 500 000 units daily without necessarily giving rise to hypercalcemia.

Gastrointestinal Tract. Vitamin D in physiological concentrations primarily increases the uptake of calcium by the small intestine. The action of parathyroid hormone is less obvious than that of vitamin D. The calcium and phosphate absorption are directly stimulated by vitamin D. The maximum calcium absorption occurs in the duodenum, the maximum phosphate absorption in the jejunum (KOWARSKI, 1969). Calcium is necessary for vitamin D-dependent phosphate transport (HARRISON, 1961). calcium transport *in vivo* does not depend on the presence of phosphate (WALLING, 1969).

Increased calcium absorption under the influence of vitamin D can be demonstrated *in vitro* on isolated segments of the gut. The absorption is more pronounced when the segments are incubated with oxygen (SCHACHTER, 1961). However, a partial effect of vitamin D is still demonstrable at low temperatures and in the presence of cyanide or in a nitrogen atmosphere when oxidative metabolism is minimal (HARRISON, 1965). Part of the action of vitamin D is due to a rise in the permeability of the small intestine to calcium, but it is also actively absorbed under the influence of vitamin D depending on the presence of oxygen (SCHACHTER, 1966; WASSERMANN, 1968 a).

The primary sites of action of vitamin D in the intestinal mucosa may lie in the cell nucleus, since 1,25-DHCC is stored in the cell nuclei of the small intestine (TSAI, 1972). The synthesis of ribonucleic acids precedes the delayed onset of action of vitamin D on calcium absorption in the gut. The formation of ribonucleic acids is in turn followed after 16 hours by the release or synthesis of calcium-dependent adenosine triphosphatase and a calcium-binding protein (MELANCON, 1970; WASSERMANN, 1968 b). This action is probably regulated in the cell nucleus since the stimulation of the calcium absorption produced by the action of vitamin D and by parathyroid hormone is inhibited with actinomycin-D (CORRADINO, 1968) (p. 874).

The physiological importance of the calcium-binding protein or calcium-dependent adenosine triphosphatase for intestinal calcium absorption *in vivo* has not yet been demonstrated because selective inhibition is not possible.

Bones. Vitamin D probably leads to an increase in bone formation and in higher doses to increased bone resorption. In vitamin-D deficiency an increase of the osteoid mass and osteoporosis develop in association with pseudofractures or Looser's zones. In contrast to hypocalcemia caused by parathyroid hormone deficiency, vitamin-D deficiency or phosphate deficiency leads to a marked increase of osteoid, and it appears probable that vitamin D has a direct effect on the formation of new bone. This increase of osteoid results from accelerated collagen formation and reduced mineralization of the skeleton in the rachitic rat (ROHR, 1965; PATERSON, 1968). A similar increase in collagen synthesis is encountered in hyperparathyroidism. It may also be a sign of secondary hyperparathyroidism in patients suffering from osteomalacia (FLANAGAN, 1965).

In osteomalacia, there is a discrepancy between kinetic data measured with strontium or radioactive calcium and the histological findings (p. 864). The accretion and the calcium pool can be increased, whereas the rate of bone formation measured with tetracycline in bone biopsies is retarded (FRASER, 1960; FROST, 1963). The accretion or deposition of calcium and phosphate, measured isotopic-kinetically, is increased after treatment with vitamin D (BAUER, 1956; HARRIS, 1965). In rats, vitamin D leads to an increased incorporation of radioactive ^{45}Ca and radiolabeled phosphate into the bones (CARLSON, 1952) and stimulates growth, particularly the growth of the skeleton. The conversion of the epiphyseal cartilage into calcified apatite is taken as a biological measurement of the vitamin D activity of an unknown solution.

Administration of vitamin D to patients with chronic azotemia or intestinal malabsorption results in an increase in the number of osteo-

blasts, the storage of tetracycline, and the calcification of osteoid seams (BINSWANGER, 1968; BORDIER, 1968). In addition, vitamin D also causes an increased incorporation of phospholipids into the bones. This can be demonstrated histochemically at the transitional zones between osteoid and apatite (CRUESS, 1967; IRVING, 1959).

Vitamin D in higher doses leads to increased bone breakdown with a rise of the serum calcium concentration. This occurs even with a calcium-deficient diet. It is preceded by an elevated release of citrate, which can be interpreted as an indication that citrate in the plasma binds the calcium, thus leading to an increase in the calcium mobilization (CARLSON, 1954). The rise of citrate in the plasma is not a mandatory finding, since the liberation of calcium is also raised in rats treated with cortisone and vitamin D, without a change in the citrate concentration in the plasma (HARRISON, 1957). It is possible that the increased release of calcium inhibits aconitase and retards the citrate metabolism (p. 875).

The increased bone breakdown under the influence of vitamin D and parathyroid hormone is, like the increased calcium absorption in the small intestine, inhibited by actinomycin D and is probably under the control of the cell nucleus (HARRISON, 1966) (p. 11). Vitamin D *in vitro* causes an increase in the number of osteoclasts and in the demineralized bone matrix around osteocytes (GOLDHABER, 1965; BÉLANGER, 1965). The release of calcium from bone-cell cultures is accelerated by 1,25-DHCC whereas 25-HCC is effective in higher amounts only and vitamin D is ineffective (RAISZ, 1972).

Parathyroid hormone and vitamin D synergistically stimulate bone resorption. Parathyroid hormone leads to an increase in bone resorption only in the presence of vitamin D, whereas in rats, vitamin D leads to an increased excretion of hydroxyproline in the urine only when combined with parathyroid hormone (RASMUSSEN, 1963; PECHET, 1967).

Vitamin D stimulates bone breakdown and leads to the release of calcium into the plasma. At the same time, there is an improvement in the skeletal mineralization. The question as to whether the bone mineralization is increased secondary to an elevated calcium supply, or whereas in rats, vitamin D leads to an increased of new bone directly is still open. The latter view is supported by the fact that hypocalcemia alone, such as is found in hypoparathyroidism, is not asscociated with any considerable increase of the osteoid mass, in contrast to the findings in vitamin-D deficiency.

Kidneys. It is not known whether vitamin D in physiologic concentrations has a direct action on the renal tubules. During treatment of rickets or osteomalcia with vitamin D, there is a reduction of the phosphate excretion (HARRISON, 1941), associated with inhibition of parathyroid hormone secretion by the rise in the serum calcium concentration. In the absence of parathyroid hormone vitamin D leads to a slight rise in the phosphate excretion through the kidneys, but the phosphate clearance remains within normal limits (ALBRIGHT, 1948). The rise is in the same order as that obtained by EISENBERG (1965) during the treatment of hypoparathyroidism with calcium infusions and may be a result of the increased serum calcium concentration. In thyroparathyroidectomized dogs, vitamin D, 25-HCC and 1,25-DHCC cause a fall in fractional phosphate, sodium and calcium excretion (PASCHETT, 1972).

Vitamin-D intoxication leads to hypercalciuria in man, and in severe cases to hypercalcemia, nephrocalcinosis, nephrolithiasis and soft-tissue calcifications. A direct stimulatory effect on urinary calcium excretion is debatable. It might be the result of inhibition of parathyroid hormone secretion by a rise in the calcium absorption in the gut, of bone resorption and of a rise in the serum calcium concentration.

An increase in the magnesium excretion is observed in rats, together with a fall in the magnesium concentration in the plasma. This effect is in contrast to the action of parathyroid hormone, which inhibits the magnesium excretion (LIFSHITZ, 1967).

Apart from nephrocalcinosis, which arises in vitamin-D intoxication, no other actions of vitamin D on the kidneys can be demonstrated with certainty.

Mitochondria. Vitamin D promotes calcium uptake. This effect is inhibited by cortisone *in vitro* as it is *in vivo* (KIMBERG, 1969). Like parathyroid hormone, vitamin D stimulates the release of calcium from liver and kidney mitochondria (ENGSTROM, 1964) (p. 877).

6. Bones, Calcium and Phosphate

(Interrelationships and Conclusions)

There is a constant exchange of calcium between the bones and the extracellular fluid. Part of the calcium is exchanged according to physicochemical laws, and the remainder is incorporated into or released from the bones under the regulation of specific cells. Some of the bone mineral is not exchanged with the extracellular fluid for years. In adulthood, the formation of new bone is equal to its breakdown.

The serum calcium concentration is maintained within narrow limits under the influences of parathyroid hormone, calcitonin, and vitamin D. Bone formation and bone resorption are influenced by the homeostatic requirements of the plasma for calcium. An elevated serum calcium concentration is produced primarily by an increased release of calcium from the bones. When the calcium concentration falls, bone resorption is inhibited and/or increased amounts of calcium are incorporated into the bones. Small and rapid changes in the serum calcium concentration, which are important for the minute-by-minute regulation of the serum calcium concentration, are effected by alterations of the calcium absorption in the small intestine and by the reabsorption of calcium in the renal tubules (NORDIN, 1970).

a) Bones

Regulation of the serum calcium concentration is independent of the bone mass. Since the calcium reserves in the bones are unlimited, a calcium deficiency (osteoporosis) or increased calcium retention (hyperostosis) only becomes clinically and radiologically manifest after some months or even years. The most important sites for the regulation of the bone mass are the collagen synthesis, the mineralization of the bone matrix and bone resorption.

Vitamin D is necessary for bone growth, for skeletal mineralization, and to some extent for the release of calcium from the bones under the influence of parathyroid hormone. High concentrations of vitamin D stimulate bone breakdown. Amino acids must be available primarily for the formation of bone matrix. Calcium and phosphate are necessary for the mineralization of the skeleton. A sodium-deficient diet or diminished intestinal calcium absorption leads to osteoporosis in the growing rat and in patients with intestinal malabsorption. Phosphate and vitamin-D deficiency lead to a delayed mineralization of the skeleton with increased osteoid.

Skeletal growth and skeletal remodeling are affected by parathyroid hormone, calcitonin, vitamin D, and also by thyroxin, the adrenocortical steroids, the sex hormones and growth hormone. Thyroxin promotes bone remodeling, whereas the adrenocortical hormones inhibit it. Both produce osteoporosis, since the bone resorption exceeds the formation of bone. With estrogens, bone formation is usually inhibited to a lesser extent than bone resorption. Estrogens can thus prevent the osteoporosis from progressing at the most. Growth hormone increases the longitudinal growth of the bones by activating osteoblastic activity and bone resorption. An increase in the calcium concentration in the plasma indicates primarily an elevated bone resorption (Table 3). Hydroxyproline excretion in the urine parallels the formation of new bone and bone resorption. In most cases, a rise in hydroxyproline excretion in the urine is a sign of increased bone breakdown. Reduced and normal values overlap in groups of adult subjects; the excretion can only be compared in the same individual. Whenever possible, the calcium concentration in the plasma is maintained within normal limits and calcium is released from the bones, even when the skeleton can no longer tolerate the physical strain and bone pains or fractures develop.

b) Solubility of Calcium and Phosphate in the Plasma and Bones

There is a constant exchange of calcium between the bone surfaces and the extracellular fluid, and the sum of the calcium molecules in the two compartments remains unchanged. When the serum calcium falls, bone resorption, calcium absorption in the gut, and the reabsorption of calcium by the kidneys are increased and adjusted to the new conditions. Bone resorption and intestinal calcium absorption are inhibited in hypercalcemia, whereas the calcium excretion in the urine is increased. Compensatory processes independent of hormonal regulation come into action rapidly but are rapidly exhausted. The same is true to a lesser degree of the hormone-regulated processes in the renal tubules and the gut. Hypocalcemia or hypercalcemia of long duration is compensated by a cell-mediated, hormone-regulated incorporation or release of calcium from the bone. In the absence of parathyroid hormone and calcitonin the calcium concentration in the plasma is 4–7 mg/100 ml. When the parathyroids alone are missing in rats, the fall in the calcium concentration is greater than when the thyroid and parathyroids have been removed. This indicates that a minimal release of calcitonin continues in spite of the hypocalcemia. When the serum calcium falls below 6 mg/100 ml the exchange between the bone and plasma is chiefly a physicochemical process. Normalization of the serum calcium to 10 mg/100 ml involves metabolic regulation such as is produced by parathyroid hormone and/or vitamin D (MCLEAN, 1961).

In vitamin-D deficiency, the calcium phosphate product in the serum falls. Vitamin D is necessary for the increased release of calcium from the bones under the influence of parathyroid hormone. Parathyroid hormone has

no effect on the calcium × phosphate product as long as the urinary phosphate excretion remains normal in the absence of renal insufficiency. A rise in the serum calcium concentration leads to inhibition of parathyroid hormone secretion. A rise in the phosphate concentration in the plasma leads to a simultaneous fall in the calcium concentration and, together with an increased release of parathyroid hormone, to an increased renal phosphate excretion. This fact is important in potentially fatal hypercalcemia since an infusion of phosphate causes a prompt fall in the calcium concentration (HERBERT, 1966; KISTLER, 1966). This fall has also been demonstrated in parathyroidectomized patients. If parathyroid hormone is constantly administered to parathyroidectomized rats, the hydroxyproline excretion in the urine and the histologically detectable osteolysis around osteocytes are not altered by phosphate administration, so that improved mineralization is a possible effect (FEINBLATT, 1970). The calcium is not excreted in the urine or gut, but is retained or at least temporarily sequestered in the bones and in the intracellular fluid (EISENBERG, 1970) (Fig. 19). Phosphate infusions can lead to the precipitation of calcium phosphate at the infusion site and in soft tissue such as in the liver and the myocardium, especially in patients with renal insufficiency. Phosphate deficiency leads to osteomalacia and to hypercalciuria. Phosphate administration leads to increased retention of calcium in the bones (LOTZ, 1968; LUDWIG, 1967; GOLDSMITH, 1967; NAGENT DE DEUXCHAINES, 1967).

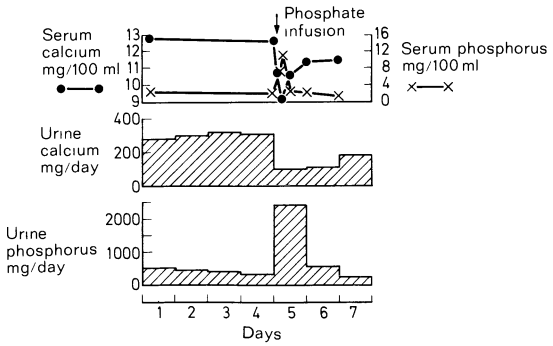

Fig. 19. Serum calcium and phosphate concentrations, and urinary calcium and phosphate excretions following an infusion of 3.065 g phosphorus over 6 h in a patient with primary hyperparathyroidism. (After KISTLER, 1966)

Phosphate and calcitonin may lead to inhibition of alkaline phosphatase or pyrophosphatase activity in bone, and thus lead to inhibition of the release of bone minerals and of bone resorption via a diminished dissolution of pyrophosphatases (Fig. 20) (FERNLEY, 1968; FLEISCH, 1970; RUSSELL, 1970) (p. 889). Calcium release from bone-cell cultures and bone resorption are inhibited by an increased phosphate concentration in the incubation medium (RAISZ, 1969). Bone resorption is also inhibited *in vivo* in the presence of phosphate even in parathyroidectomized animals, ruling out a stimulation of parthyroid hormone secretion in hypocalcemia (BINSWANGER, 1971; BAYLINK, 1971). Conversely, an extreme phosphate deficiency can make a fall in the serum calcium after parathyroidectomy impossible (COBURN, 1970). Phosphate is also used therapeutically for reducing the calcium excretion in the urine and for preventing renal stone formation.

Calcium administration leads to a fall in the serum phosphate concentration in thyroid- and parathyroidectomized patients, and increased amounts of calcium and phosphate are excreted through the kidneys (EISENBERG, 1968). A calcium infusion into the renal artery of the dog leads to a decrease in urinary phosphate excretion. A massive administration of calcium, particularly when vitamin D is given at the same time, leads to a rise in the calcium × phosphate product in the plasma and to precipitation of calcium phosphate in the reticuloendothelial system of the liver and spleen and in the kidneys, with a consequent decrease in glomerular filtration (LAVENDER, 1963; BINSWANGER, 1966). The calcification of soft tissue is also possible after administration of phosphate and calcium, particularly in the presence of impaired renal function. The precipitation is favored in alkaline regions, such as in the renal tubules and occasionally in the gastric mucosa.

In *in-vitro* conditions ressembling the situation in the plasma, calcium phosphate is precipitated when the solubility product of calcium × phosphate is increased. With a fall in the serum calcium concentration following phosphate infusions, calcium is not excreted in the urine or in the stools. The maximum solubility product *in vitro* corresponds to the situation in vivo (HERBERT, 1966). An excessive solubility product of calcium × phosphate leads to deposition of calcium and phosphate in the bone and in soft tissue, while a fall in the calcium × phosphate product leads to a release of calcium and phosphate from the bones. The mechanisms underlying the fall of the calcium concentration following the administration of phosphate and those responsible for the fall of the phosphate concentration following calcium administration are presumably partly physicochemical, since they are not influenced by thyroparathyroidectomy. Physicochemical processes regulate the serum calcium concentration in the plasma continuously, whereas

the metabolic and the endocrine regulatory mechanisms come into action within minutes or days, depending on the degree of compensation required. The later mechanisms are less rapidly exhausted.

Parathyroid hormone increases the calcium concentration and leads to a fall in the phosphate concentration in the plasma via an increase in urinary phosphate excretion. An impairment of renal function usually causes a rise in phosphate and a fall in calcium in the plasma. This leads to an increase in osteoid mass for known (acidosis, vitamin-D resistance) or unknown reasons, even in the presence of a normal calcium × phosphate product.

The administration of calcitonin causes the calcium × phosphate product to fall by inhibiting bone resorption and stimulating the urinary phosphate excretion. A considerable fall can be seen in vitamin-D deficiency in intestinal malabsorption, where the absorption of calcium and phosphate is reduced. The hypocalcemia leads to secondary hyperparathyroidism and thus to an additional fall of the phosphate concentration in the serum. Growth hormone increases the calcium × phosphate product. It is raised in children and in acromegaly.

c) Regulation of the Serum Calcium Concentration

Vitamin D and calcitonin have been demonstrated in all vertebrates including fish, whereas parathyroid hormone appears for the first time phylogenetically in the amphibians (Copp, 1970). Seawater contains 10 mMol/liter calcium, as against a concentration of 2.5 mMol calcium in the plasma. It is reasonable to assume that parathyroid hormone is not necessary for the mobilization of calcium from the skeleton in the sea, whereas in the amphibians, which leave the water environment, calcium is stored in the bones and must be released under the influence of parathyroid hormone for the maintenance of a normal calcium concentration in the plasma. Calcitonin is necessary in fish for protection from the high-calcium environment occurring in the sea. In higher vertebrates, parathyroid hormone is important in the maintenance of the calcium concentration in the plasma, whereas vitamin D is essential for the mineralization of the skeleton and calcitonin for the fall and rapid changes in the serum calcium concentration. Although only a small proportion of the calcium is found in the plasma, this is maintained within the same narrow limits in the presence of a changing intake and excretion. A rise in the serum calcium concentration is observed with an increase in bone resorption caused by thyroxin and parathyroid hormone. A fall is encountered when bone resorption is inhibited by calcitonin. Hypocalcemia can also be a sign of an increase in the skeletal mineralization at the beginning of the treatment of rickets with vitamin D or as an initial effect of parathyroid hormone (Table 3). The significance of glucagon as a calcium-lowering hormone is still questioned because pharmalogical amounts have to be used: glucagon leads through an increased release of calcitonin to a fall in the calcium and phosphate concentrations in the plasma (Avioli, 1969). Independently, glucagon inhibits bone resorption *in vitro* and leads to hypocalcemia in thyroidectomized rats (Skin, 1970). Like calcitonin, it appears to have a direct effect on bone. Vitamin D leads to normalization of the calcium concentration in the plasma in hypocalcemias of any etiology. Precise physiologic regulation of the serum calcium concentration is achieved by the counteraction of the calcium-increasing para-

Table 3. The bones and the regulation of the serum calcium concentration

thyroid hormone and the calcium-lowering calcitonin. The action of parathyroid hormone is *qualitatively* similar to that of vitamin D. Parathyroid hormone has a rapid onset of action (within minutes) in comparison to vitamin D and its biologically active metabolites (within hours). Intestinal calcium absorption is promoted primarily by vitamin D, whereas the release of calcium from bones is increased prodominantly by parathyroid hormone. A rise in the serum calcium (due to calcium, parathyroid hormone, or vitamin D) inhibits the phosphate reabsorption in the renal tubules (EISENBERG, 1968). Calcitonin stimulates the renal excretion of phosphate despite the hypocalcemia. Phosphate excretion is inhibited in renal insufficiency or when calcium is infused directly into the renal artery of dogs (LAVENDER, 1963).

Parathyroid hormone is the single most important agent in the regulation of the serum calcium concentration. Parathyroid hormone deficiency after parathyroidectomy leads to hypocalcemia, whereas thyroidectomy and calcitonin deficiency cause no rise in the calcium concentration in man.

Regulation of the calcium concentration in the plasma is accomplished by means of variations in the calcium absorption by the small intestine and in the calcium reabsorption in the renal tubules, and also by means of changes in the rates of incorporation and release of calcium around the osteocytes and the formation of osteoblasts and osteoclasts. Parathyroid hormone causes a rise in the serum calcium concentration via an increase in the calcium absorption through the gut, the reabsorption in the renal tubules, and raised phosphate excretion. The incorporation and release of calcium in the bones may be regulated by osteocytes; a halo is characteristically formed around the osteocytes, reflecting increased bone breakdown and thus a release of calcium. The osteocytic bone resorption is increased under the influence of parathyroid hormone and inhibited by calcitonin (RASMUSSEN, 1967). The osteocytes may thus be partly responsible for the regulation of the calcium level in the plasma. Presumably, alkaline phosphatase in the osteocytes corresponds to the pyrophosphatase which promotes the dissolution of pyrophosphates. Pyrophosphates protect apatite from dissolution (FLEISCH, 1966). Parathyroid hormone causes a histochemically demonstrable increase of the alkaline phosphatase in the osteocytes, which may correspond to the pyrophosphatase. It has been postulated that there is an increase in pyrophosphatase activity and in the breakdown of pyrophosphate under the influence of parathyroid hormone, which favors the dissolution of bone mineral (RASMUSSEN, 1967; FLEISCH, 1970; RUSSELL, 1970) (Fig. 20).

If this hypothesis is correct, the administration of pyrophosphates should lead to a fall in the calcium concentration in the serum, but this has not been observed, since pyrophosphates are immediately metabolized by a pyrophosphatase. Because of this, analogous compounds have been synthesized, such as the phosphonates, which are not broken down by pyrophosphatase. Phosphonates inhibit osteolysis stimulated by parathyroid hormone *in vitro* in mice calvariae and they also lead to a fall in the calcium concentration in parathyroidectomized rats treated with parathyroid hormone (FLEISCH, 1968b, 1969).

The calcium-lowering action of calcitonin occurs within minutes. It can only be seen

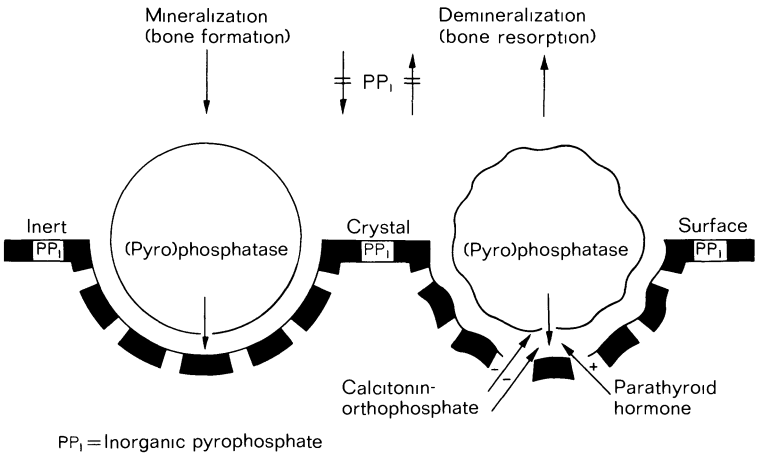

Fig. 20. Hypothetical role of pyrophosphate and pyrophosphatase, and parathyroid hormone, calcitonin, and phosphate in bone mineralization and resorption. It is proposed that mineralization and resorption occur more readily after hydrolysis of the pyrophosphate layer by pyrophosphatase. (After RUSSELL, 1970)

when the bone resorption is increased. It is possible that calcitonin is necessary for the rapid regulation of the serum calcium concentration, as a rise of the serum calcium above the normal level under the influence of parathyroid hormone is seen only after one hour. Calcitonin and parathyroid hormone act independently of each other. Calcitonin is effective in parathyroidectomized animals, and parathyroid hormone in thyroidectomized animals (GUDMUNDSON, 1966). Calcitonin inhibits an increase in the serum calcium concentration regardless of the cause (e.g. parathyroid hormone, 3′,5′-AMP, vitamin D). It does not have to be an antagonist acting at the same biological site. Calcitonin causes a rapid fall in the calcium concentration in the serum ($t_{\frac{1}{2}} < 30$ min); a slow fall is seen following parathyroidectomy ($t_{\frac{1}{2}} > 2$ hours), although the concentration of parathyroid hormone in the serum falls by 50% even after as little as 10–20 min (TASHJIAN, 1966; MELICK, 1965).

Actinomycin-D, an inhibitor of the messenger ribonucleic acids and thus of protein synthesis, impairs the release of calcium from the bones which occurs under the influence of parathyroid hormone and vitamin D. Vitamin D is essential for the full effect of parathyroid hormone. In contrast, vitamin D and actinomycin-D have no effect on the calcium-lowering action of calcitonin or on the rise in urinary phosphate excretion resulting from the action of parathyroid hormone (TASHJIAN, 1965; ARNAUD, 1966; DELUCA, 1968). These effects occur in the absence of previous protein synthesis, and are thus of rapid onset (within minutes), but they are also rapidly exhausted. The increase in osteoclasts due to parathyroid hormone requires time (some hours) and the previous synthesis of proteins. When protein synthesis and calcium release are in progress, the unlimited calcium reserves of the skeleton are utilized. Maintenance of a serum calcium concentration at a level of 10 mg/100 ml requires the constant secretion of parathyroid hormone and an adequate nutritional intake of vitamin D.

D. Hypoparathyroidism

B. COURVOISIER

1. Etiology and Pathogenesis

a) Postoperative Hypoparathyroidism

The most common cause of hypoparathyroidism is damage to one or more of the parathyroid glands during operations on the thyroid gland. Even with a flawless technique, this occurs in around 1–4% of cases. Damage results either from inadvertent removal of one or more of the glands or from ligation of an artery. From experiments in animals it has been deduced that more than half the parathyroid tissue must be lost before lasting insufficiency arises.

The parathyroids are endangered mainly during removal of large goitrous nodules because of their small size and also because they are often atypically situated. Topography of the arterial vascular supply and the possibilities and risks of arterial damage have been dealt with on p. 846. Postoperative hypoparathyroidism is observed considerably more frequently in females. It is assumed that there is some connection with the fact that thyroidectomies are performed more frequently in women than in men (hyperthyroidism is more common in females) or with the increased stress on the parathyroids associated with the variations of estrogen production during the menstrual cycle and pregnancy.

b) Hypoparathyroidism Following Treatment with Radioactive Iodine

Possibility of damage of this nature has been considered and examined both clinically and experimentally, but appears rather unlikely (EIPE, 1968).

c) Reactive Hypoparathyroidism after Removal of a Parathyroid Adenoma

The parathyroid adenoma leads via hypercalcemia to inactivity and atrophy of the remaining parathyroids. Removal of the adenoma can but need not necessarily lead to the development of temporary hypocalcemia. It may be that the atrophic parathyroids are incapable of producing sufficient hormone, or recalcification of the skeleton commences, or the compensatory excessive secretion of calcitonin leads to hypocalcemia. The fact that postoperative hypocalcemia is almost exclusively observed in primary hyperparathyroidism with skeletal involvement and practically never in the absence of skeletal involvement supports the idea of skeletal avidity for calcium and phosphate and thus suggests "recalcification tetany". The fact that the level of the serum phosphate is usually not elevated but lowered fits in with this interpretation.

d) Hypoparathyroidism in Newborns Associated with Hyperparathyroidism in the Mothers

Reactive, transitory parathyroid insufficiency is observed occasionally in the newborn due

to primary hyperparathyroidism in the mother. In a few cases, the condition in the mother is diagnosed for the first time when the disorder is found in the newborn.

e) Transitory, Congenital Hypoparathyroidism in Newborns

This form of parathyroid insufficiency arises between the 2nd and 19th days of life and is also observed in the absence of maternal hyperparathyroidism; according to FANCONI (1967, 1970) it may be due to a functional insufficiency of the parathyroids which are subjected to particularly severe stress during this phase of life (immaturity of parathyroid function, immaturity of glomerular function resulting in insufficiency of phosphate glomerular filtration, increased supply of phosphates from cow's milk). Hyperparathyroidism must always be carefully searched for in the mother and excluded, if necessary by observation over several years.

f) Idiopathic Hypoparathyroidism

This term applies to conditions which show all the biochemical and clinical symptoms of postoperative parathyroid insufficiency although no cause can be found. Pathogenesis and diagnosis of these disorders are discussed later on p. 899. In contrast to pseudohypoparathyroidism, where the immunoreactive parathyroid hormone concentration in the serum (IPTH) is usually elevated, IPTH is not measurable in idiopathic or surgical hypoparathyroidism.

2. Symptoms

a) Tetany

This is the best known and most important manifestation of hypocalcemia of parathyroid insufficiency. Clinically, it is a syndrome embracing neuromuscular overexcitability. Three subtypes are differentiated, each of which can appear in isolation, but all three can occur simultaneously in the same subject. These are: 1. the tetanic attack, 2. the tetanic equivalent, and 3. latent tetany.

b) The Tetanic Attack

This is associated with sensory-motor excitability and has a specific topographic and chronological course. The attack can arise spontaneously or can be precipitated by a mechanical, acoustic, or psychological stimulus or by hyperventilation. In the child, it is often observed following a febrile infection. The onset can be sudden and unexpected, but as a rule an aura precedes the event, the most common signs being fear, general malaise, muscular pains, paresthesias in the face and limbs and vasomotor disturbances. The duration of the aura varies widely from individual to individual. During the actual attack, there is tonic contraction of separate groups of muscles. The thumb and fingers are usually the first to be affected. The thumb is usually forced into the adduction position, the fingers are pressed together with the metacarpophalangeal joints flexed and the distal joints extended (obstetrician's hand). The hand is sometimes even maintained in complete flexion (tight fist) however; this is observed particularly in children. During the main crisis, the spasm extends from the hands to the arms, which lie adducted against the body with the elbows flexed. The legs are fixed in complete extension in the varus position with flexion of the foot and toes. The face often shows contraction of the upper lip accompanied by drooping of the corners of the mouth (carp mouth). A common symptom which PRADER describes in the child is the inability to show the teeth. Strabismus is occasionally also observed. The muscular cramps are usually extremely painful. They are accompanied by feelings of fear and paresthesias.

The autonomic nervous system can be involved during the crisis. This involvement can present, for example, as laryngospasm, which is particularly dangerous in the baby and young infant, and as spasm of the bronchi, cardia and sphincter of the bladder. In a similar manner, blood vessels are also sometimes affected by the crisis, causing RAYNAND's phenomenon, migraine, angina pectoris, etc. to occur. Autonomic and vascular tetanic features can completely dominate the clinical picture (visceral, vascular tetany) and in such cases the diagnosis is often rather difficult. Generalized convulsions and loss of consciousness are common in the child.

The crisis lasts for a few seconds, hours, or days, during which there are quite long remissions of the acute features. When the crisis stops, symptoms disappear in the reverse order to that in which they appeared: peripheral spasm is the last to recede.

c) Tetanic Equivalent, the Epileptic Seizure

The visceral and vascular forms of tetany mentioned above actually belong here when they arise in isolation. It is, however, more justifiable to speak of a tetanic equivalent with an epileptic seizure within the field of

tetany. It can be the only symptom of parathyroid insufficiency or it can arise with other tetanic manifestations. It cannot be differentiated from epilepsy clinically or by means of an electroencephalogram. Tetany occurring exclusively as part of the epileptic picture is most commonly observed in idiopathic hypoparathyroidism and idiopathic hypocalcemia, less frequently with postoperative hypoparathyroidism, but only rarely with hypocalcemia of any other etiology (D-hypovitaminosis, malabsorption). Signs of the aura and sphincter insufficiency can be present or absent. Occasionally, discrete features of latent tetany follow the attack. In the literature, cases are described which progressed as classic epilepsy for years and were treated as such until hypoparathyroidism was finally diagnosed either by chance or from the development of other tetanic symptoms. From this, it can be seen that routine estimation of calcium is essential in every case of epilepsy.

d) Latent Tetany

Latent tetany signifies a state in which a partial or complete acute attack can readily be provoked by diagnostic measures. This state of latent tetany embraces a series of neurovegetative and neuropsychiatric symptoms. They vary widely from one individual to the next and are not only seen with hypoparathyroidism but also with other forms of tetany. A long list of diagnostic procedures has been suggested for the recognition of latent tetany, and the most important of these are presented here.

α) Chvostek's Sign

Tapping of the facial nerve immediately below and in front of the ear (root of the facial nerve) results in twitching of the corner of the mouth, the nostril and the orbicularis oculi in latent tetany. Similar twitching can be elicited by percussion below the zygomatic arch at the midpoint between the corner of the mouth and the ear. Only simultaneous twitching of all three muscles after tapping the root of the facial nerve can be interpreted as a sign of tetany (Chvostek I). Twitching which can be released only in the region below the zygomatic arch or in the region of the cheek, or which appears only in two muscle groups after tapping the root of the facial nerve (defined as Chvostek II and III by different authors) can also arise in healthy subjects. Thus, such twitching is only of slight diagnostic value and must be used with caution. Occasionally, however, when the diagnosis of tetany has been confirmed, it can be useful in assessment of the course of the ilness, e.g. for estimating a therapeutic measure. Occasionally, Chvostek's facial phenomenon cannot be released in confirmed cases of hypoparathyroidism with greatly reduced serum calcium levels.

β) Trousseau's Sign

A sphygmomanometer is applied to the upper arm and a pressure just above the systolic blood pressure is exerted for 3 min. In tetanic subjects, a typical carpal spasm usually arises. Occasionally, this sign fails to occur in confirmed cases of tetany. In other cases the spasm can be induced by a presure much lower than the systolic pressure or simply through pressure on the nerve root in the medial bicipital groove. Finally, the spasm may be observed only after removal of the sphygmomanometer.

γ) Hyperventilation Test

Any form of latent tetany can become manifest in the presence of hyperventilation. After a few minutes, typical carpal spasm arises. A hyperventilation test carried out over 5 min may occasionally be negative, however, in mild forms of hypoparathyroidism, and is more commonly positive in nonendocrine, normocalcemic hyperventilation tetany. Carpal spasm can be evoked particularly easily by using Trousseau's arm constriction in combination with the hyperventilation test. It is best to apply the sphygmomanometer after the hyperventilation.

δ) Electrical Investigations (no longer used for practical purposes)

The excitability of motor nerves is raised in tetany of every etiology. With modern electromyographic methods, which, however, are available only to specialists, a series of changes more or less specific to tetany can be differentiated. Characteristic changes of the so-called twitching form are described as Erb's sign.

e) Course of Tetany

There are numerous individual variations. A tetanic attack can be solitary or can recur at more or less regular intervals. Between attacks, the patient usually shows subjective and objective signs of neuromuscular overexcitability, which are termed as latent tetany. In a few cases, the tetany remains latent and never progresses into acute tetany.

f) Pathology, Physiology, and Pathogenesis of Tetany

In spite of numerous investigations, the pathogenesis of tetany still remains uncertain. There is even controversy about the true site of origin of the tetanic phenomenon. From close analysis of the symptoms, it can be deduced that nervous overexcitability is present, involving the cerebral centers to a large degree, as well as the spinal cord and peripheral nerves. The role of calcium and/or magnesium and other electrolytes important for neuromuscular excitability has been discussed in the chapter on Physiology on p. 848. It has now been definitely established, however, that hypocalcemia is observed not only in hypoparathyroidism but also in a series of other disorders. This question has been dealt with under differential diagnosis (p. 897). It must be emphasized that tetany is a syndrome that can have very different reasons. Thus, tetany is *not* equivalent to parathyroid insufficiency, but only one of its manifestations. The habit of naming an illness after its main symptom (tetany = parathyroid insufficiency etc.) should be avoided.

Since tetany also occurs in the absence of parathyroid insufficiency, it is also important to know that the syndrome of nervous overexcitability is most marked in parathyroid insufficiency. This becomes manifest as severe tetanic attacks, and also as the epileptic seizure (which is not seen with normocalcemic tetany and with hypocalcemia due to D-hypovitaminosis or malabsorption), and as diverse neurological and psychopathologic features. Finally, the duration of the latent tetany can be prolonged, extending over decades.

g) Mental Changes

Mental changes occur in chronic hypocalcemia much more commonly than was suspected in the past. They are now usually recognized from their unspecific character even were other tetanic symptoms are absent, however. Thus, in the presence of vague mental disorders, the diagnosis of hypoparathyroidism should be considered more frequently that it has been in the past, and features of latent tetany should be searched for and serum calcium and phosphorus estimated.

In the child, untreated hypoparathyroidism and other forms of hypocalcemia (rickets, malabsorption, uremia) often lead to tetanic spasm (spasmophilia) but tetanic symptoms may sometimes be completely absent. In such cases, more definite neurological and mental symptoms are found, generalized malaise, photophobia and blepharospasm being the features most commonly observed. These children very often also show retardation of mental development, disorders of emotional adjustment and irritability and poor concentration in school. All symptoms disappear rapidly after correction of the hypocalcemia. The great responsibility incumbent on the doctor to recognize these cases early is obvious. It can without hesitation be ranked in importance with the problem of early diagnosis of infantile hypothyroidism with mental developmental disturbances.

Acute tetany and symptoms of latent tetany occur less frequently in adults with hypoparathyroidism than in children. Such patients are noticed because of their lability, anxiety, irritability, and lack of compensation. They are generally somewhat depressed and very often complain of chronic headaches. These are features of the endocrine psychosyndrome, which is dealt with in more detail in the section on hyperparathyroidism (BLEULER). In severe tetany, features of the acute exogenous reaction type (BONHÖFFER) are rarely observed, and "neuropathic crises" have been reported in the literature. As is true of all psychopathologic disorders occurring with endocrine illnesses, these symptoms are not specific or particularly characteristic of hypoparathyroidism. In contrast to previous opinions that psychic disorders occurred predominantly with idiopathic hypoparathyroidism, it has been shown in the last few years that these disturbances arise more frequently than was suspected in a discrete form after thyroidectomy also, and may occasionally develop into acute psychotic crises.

h) Neurologic Changes

As a rule, neurologic findings are normal in parathyroid insufficiency. There are, however, known cases of idiopathic or postoperative hypoparathyroidism with cerebral edema, increased intracranial pressure, papilledema and symptoms of a unilateral focal lesion which can simulate a brain tumur. Headache without neurologic findings is very common. In addition, extrapyramidal symptoms with Parkinsonism have been described in idiopathic hypoparathyroidism. Such disturbances can occasionally be accentuated or be caused by phenothiazine preparations (e.g. prochlorperazine). Mild features of Parkinsonism can even arise after oral treatment, whereas intramuscular injection (e.g. 10 mg prochlorperazine) can produce very severe neurodysleptic (dystonic) attacks. The attack begins with painful stiffness of the neck, paresthesia, fascicular muscular twitching, sweating and tachycardia, followed shortly after-

wards by tonic muscular cramps in the neck, jaws, tongue and extremities. Visual spasm and laryngospasm also develop and in addition, a series of "typical tetanic" features, such as obstetrician's hand, carpal spasm, Trousseau's and Chvostek's phenomena, may be found. This picture shows very marked similarities to the tetanic attack, but differs in that it does not respond at all, or at least not promptly, to treatment with calcium and magnesium but is arrested at once on intravenous administration of barbiturates. Refer to the next section for possible connections with cerebral calcifications.

i) Cerebral Calcifications

X-rays of the skull often show symmetric and small calcified foci irregularly distributed in the ganglia of the brain stem, particularly in the putamen and the nucleus caudatus. These calcifications can be distinguished from those of the choroid plexus by the fact that they extend further frontally in the brain, whereas those in the choroid plexus are limited to the region around the genu of the lateral ventricle. Their localization can be more precisely traced by means of sterographic X-rays. When they are very pronounced, they form opaque stripes or spots. Small calcified foci are occasionally also found in the cerebellum or in the deeper regions of the cortex of the brain. About 40 such cases of cerebral dystrophy have been observed and they have been encountered predominantly in idiopathic hypoparathyroidism and less commonly in chronic parathyroid insufficiency after thyroidectomy. They are not specific to hypoparathyroidism and are also observed in various congenital disorders of the nervous system including mongoloid idiocy and a familial form of oligophrenia. Finally, they account for some of the characteristic brain lesions found in endemic cretinism. The histological structure consists of predominantly perivascular hyaline masses, with secondary deposition of calcium and iron salts (pseudocalcium concrements). These changes are thus quite different from calcium metastases localized elsewhere and associated with hyperparathyroidism and hypercalcemia of any other etiology. It is not certain whether these dystrophic calcifications affect brain function. Nevertheless, it is suspected that the extremely severe reaction of certain patients with hypoparathyroidism to phenothiazine drugs (Parkinsonism, neurodysleptic attack, p. 893), could be due to irreversible damage to the extrapyramidal centers which cannot be influenced by treatment with calcium.

j) Cataract and Other Changes in the Eye

The cataract is the best known dystrophic manifestation of hypoparathyroidism. It is a direct sequela of chronic hypocalcemia and is observed in the idiopathic as well as the postoperative form of hypoparathyroidism. It is also seen, but less commonly, in chronic hypocalcemia of other etiologies. It is seen both in adults and in children. Often it is the key to diagnosing hypoparathyroidism in the age groups where cataracts are not normally found. In the early stages, it can be differentiated with no difficulty from other forms of cataracts, with the exception of those found in dystrophic myotonia; it is always bilateral, and is situated in the anterior and posterior cortical layers of the lens in the adult. Zonular and central cataracts are occasionally also observed in children. In advanced stages, clouding of the lens becomes diffuse and the nucleus of the lens also becomes involved, so that differentiation from other cataracts, e.g. senile cataract, is no longer possible. The rate of development varies greatly. Cases of bilateral tetanic cataracts have been described where blindness has resulted within months. In other cases, mild changes remain almost constant for years. A cataract, once formed, can cease to grow with suitable treatment, but it can never be cured. Sometimes further progress is observed even despite correct treatment. Every case of hypocalcemia should be examined for cataracts by a specialist early, to avoid recognition of the tetanic cataract only after loss of vision. At this stage, it is too late for effective therapy.

Up to now, there is no satisfactory explanation for the pathogenesis of the cataracts.

Papilledema, keratitis, strabismus, diplopia, lid ptosis, conjunctivitis, blepharitis etc. (Pohjola, 1962) are uncommon symptoms in idiopathic hypoparathyroidism.

k) Trophic Disorders of the Skin, Nails and Hair

These disorders are found predominantly in idiopathic hypocalcemia but have also been observed in long-standing untreated cases of postoperative hypoparathyroidism.

Hair. In hypoparathyroidism, tufts of hair can be lost, or complete alopecia may develop or the growth of hair may be sparse. In addition to the hair on the head, the entire body hair and the eyebrows and eyelashes are sometimes lost. Acute tetanic attacks are occasionally preceded by acute loss of hair.

Skin. In hypoparathyroidism, the skin is dry, split and scaly. Eczema can heal within a short time after correction of the hypocalcemia.

Nails. The nails show transverse furrows and are brittle. The skin often covers the nail fold and cornification is disturbed. This sometimes causes the nail to be rejected, and subsequent growth is incomplete.

Moniliasis. Infection with monilia albicans is very common in hypoparathyroidism. The nails and the corners of the mouth are the most frequent sites, but in severe cases the infection spreads over the whole of the skin and the buccal cavity and intestinal tract may also be affected. Changes in the hair, skin and nails can usually be corrected with adequate treatment of the hypoparathyroidism, but monilia infection of the nails does not respond to this sort of treatment.

l) Dental Damage

If hypoparathyroidism arises during growth, changes in the dental enamel are possible. The teeth then show transverse grooves with hypoplasia of or faults in the enamel, each groove corresponding to a tetanic episode during the phase of development of this part of the tooth. In addition to the faults in the enamel, the whole process of development and growth of the teeth can be disturbed. The pulpa is abnormally extensive, the root is shortened and conical, dental eruption is delayed or fails to occur, and dental stumps showing no true formal differentiation are occasionally found enclosed within the jaw bones. The cortex of the alveolae is sometimes thickened (lamina dura) (in constrast to the findings in hyperparathyroidism where it has been known to disappear).

Like cataracts, the faults in the enamel are due to the hypocalcemia, as is borne out by the fact that similar defects are seen in children with rickets due to hypocalcemia, but it is still not known for certain whether the other irregularities of dental formation and growth are a result of the parathyroid insufficiency or are malformations.

m) Bone and Joint Changes

Hyperostosis of the skeleton is observed in one third of cases of idiopathic hypoparathyroidism and very occasionally in postoperative hypoparathyroidism (MARTIN, 1966) in contrast to the bone atrophy in hyperparathyroidism. Localization and extension vary widely: hyperostosis can occur exclusively on the long bones, jaw bones and skull (generalized thickening of the cranium) or it can involve the entire skeleton, including extremities, vertebral column and pelvis. The change usually takes the form of periostosis and seldom that of full hyperostosis (periostosis and endostosis). Radiologically, the skeleton appears abnormally dense and the periosteum is thickened due to bone apposition. These skeletal changes are never very marked and they do not tend to progress rapidly. There is never a state of overmineralization such as is found in osteopetrosis. Histological examination reveals thickening of the corticalis and spongiosal trabeculae without signs of increased activity. More frequently, there are signs of reduced osteoclastic activity.

In some cases, bone changes are characterized by the combination of periostal hypertrophy and endostal "pseudoatrophy", where the spongiosal trabeculae, although larger in diameter, are reduced in number.

Painful joint changes are often found in hypoparathyroidism whether osteopathy is present or not. They arise in the vertebral column and in the ileosacral and hip joints. Inflammatory features do not arise, but osteophytic formation with calcification is often severe in the capsules, tendons and surrounding soft tissues. Changes in the ileosacral joints can be distinguished from those in Bechterew's disease by the extensive para-articular hyperostosis.

n) Biochemical Changes and Laboratory Findings

Radioimmunological methods have made it possible to demonstrate elevated parathyroid hormone levels in the blood of patients with hyperparathyroidism (p. 871). Unfortunately, this test cannot yet be used for the detection of diminished hormone levels in the blood. However, pseudohypoparathyroidism with an increased concentration of immunoreactive parathyroid hormone (IPTH) can be clearly differentiated from idiopathic or postoperative hypoparathyriodism; in these conditions the IPTH level is too low for assay. The diagnosis of hypoparathyroidism must thus be made indirectly for the time being, on the basis of biochemical effects caused by the hormone deficiency.

The classic humoral syndrome of hypoparathyroidism is characterized by the triad hypocalcemia, hyperphosphatemia and hypocalciuria. Hypocalcemia is the most constant and important change which is almost exclusively responsible for the clinical and morphological symptoms. The serum calcium rarely falls below 6 mg/100 ml. Serum phosphate is elevated to above 5 mg/100 ml in adults and above

7 mg/100 ml in children. Finally, the 24-hour urinary excretion of calcium is reduced to 10–50 mg. The 24-hour urinary excretion of phosphate, on the other hand, can vary so widely (p. 854) that it is of no use for the diagnosis. The serum alkaline phosphatase is always normal. This is important in the differentiation from malabsorption and rachitic hypocalcemia, where the phosphatase is increased in the majority of cases. Hyperuricemia is found in a few cases of idiopathic hypoparathyroidism.

ECG. A Q-T segment with a prolonged isoelectric S-T and very short T wave is characteristic of every form of hypocalcemia.

EEG. The EEG is frequently changed in chronic hypoparathyroidism. The most common deviation consists of long waves (2–5 per sec) arising in groups or singly, accompanied by detached scatterings of spikes. During tetanic attacks, spastic potentials, often of cirumscribed localization, are sometimes recorded. All changes are accentuated by hyperventilation, and terminated by correction of the hypocalcemia. We have seen that the epileptic seizure is a symptom of tetany but it is impossible to differentiate it from more common forms of epilepsy either by the clinical findings or by means of the EEG. Cerebrospinal fluid is normal, but the pressure is occasionally raised.

o) Onset and Course of the Disorder

The clinical features of hypoparathyroidism are multiple. Postoperative hypoparathyroidism usually sets in as early as 24–48 hours after surgery (thyroidectomy or removal of a parathyroid adenoma) and usually starts with a typical attack of tetany. The hypocalcemia is usually marked at this point. If the case is not treated, latent tetany then develops, with occasional mild or severe attacks of acute tetany, which disappear spontaneously after a few weeks providing only ischemia of the parathyroids or relative parathyroid insufficiency after removal of a parathyroid adenoma is present. When there is severe damage to the parathyroids, latent tetany becomes chronic. Although much is known about the symptoms of chronic postoperative parathyroid insufficiency, very little is known about the epileptic seizure which occasionally arises as the only symptom. On the other hand, investigations on a large number of thyroidectomized patients in the last few years have shown that latent or partial parathyroid insufficiency without tetany can be demonstrated by means of suitable methods (p. 945) more frequently than expected. There is always a multitude of more or less severe functional and psychic symptoms. This clinical picture is often not recognized.

Idiopathic hypoparathyroidism (p. 899) is definitely a chronic disorder. It is seldom diagnosed in the newborn or infant. The first symptoms usually appear during the second decade. Attacks of spasm almost always occur in infantile idiopathic hypoparathyroidism and sometimes have a fatal outcome. Forms of the disorder with epileptic seizures as the only symptom are particularly common at this age. If the children survive, their mental and physical development is usually severely impaired.

Idiopathic hypoparathyroidism not uncommonly causes few symptoms and goes unnoticed in adults too. Tetany can remain latent without an acute attack ever occurring in spite of a very low serum calcium. This is probably due to a relative adaptation of the neuromuscular receptors to chronic hypocalcemia, and hypocalcemia is certainly not the only cause of tetany. Thus, mental (endocrine psychosyndrome) and dystrophic (cataract and osteoarticular syndrome) disorders are in the foreground. The question of the onset of the disorder arises in every newly diagnosed case of hypoparathyroidism in adulthood. Many years can pass between the onset of the first symptoms and the diagnosis. The diagnosis is often not made until adulthood although the case history shows that the first symptoms went as far back as infancy. The state of the teeth is a particularly good indicator of the time of onset. Some cases of idiopathic hypoparathyroidism may very well arise during adulthood; there is then no history of early symptoms. From post-mortem observations, it can be concluded that the vast majority of cases begin before the 16th year of life. The frequency declines in the 2nd and 3rd decade and increases again slightly in the 4th decade.

The diagnosis is even more difficult in advanced age. The advanced hypocalcemic cataract can no longer be differentiated from a senile cataract, and mental changes can be attributed to senility. Few cases of idiopathic hypoparathyroidism have been diagnosed for the first time between the 60th and 80th years of life.

It is important to realize that the course can be very variable. Clinical symptoms and biochemical findings can vary over long periods of time. Occasionally, serum calcium falls to a yearly minimum in spring following the dark winter months, indicating D-hypovitaminosis (p. 884). The cyclic variations in mineral

and bone metabolism in the female under the influence of estrogens suggest that estrogens also have some effect on the long-term course of hypoparathyroidism.

3. Diagnosis

The diagnosis is obvious if a hypocalcemic attack of tetany follows thyroid or parathyroid surgery. The clinical diagnosis can be difficult otherwise, due to the multiplicity of signs and symptoms, the varying severity of the hormone insufficiency, the varying duration of the disorder, and the wide variation in the sensitivity of the receptors to hypocalcemia. We have seen that age plays an important role in the symptomatology, e.g. in neurologic changes. Because of this, the clinical picture in the child differs greatly from that in the adult.

Diagnosis is particularly difficult when hyperthyroidism is superimposed on existing hypoparathyroidism. Hyperthyroidism causes a rise in calcium excretion in the urine and a lowered calcium level is sometimes normalized. Thus, hypoparathyroidism can be overshadowed clinically and biochemically by the development of hyperthyroidism. This is especially important for the choice of treatment of recurrent thyrotoxicosis.

It is easier to investigate suspect cases than to pick them out more or less by intuition from the patients in a practioner's consulting room or a hospital clinic. General features of hypoparathyroidism can be so variable and so confusing that the diagnosis is not made for years. The symptoms can simulate angina pectoris or other vasomotor circulatory disorders and even gastrointestinal disorders. It can also be similar to a psychoneurosis or even a psychosis. The doctor should therefore at least consider the possibility of hypoparathyroidism in all vague circulatory disorders, spastic illnesses of the gastrointestinal tract, nonspecific headaches, all neurotic and psychotic conditions, and in every case of laryngospasm or epilepsy. The condition must be suspected in every patient who has undergone thyroid surgery. Occasionally the ophthalmologist is the first to diagnose hypoparathyroidism on discovery of a tetanic cataract.

Laboratory investigations and functional tests are discussed on p. 940.

4. Differential Diagnosis

Difficulty in differential diagnosis can arise not only with cataract, cerebral calcifications, changes of the skin, hair and nails, dental changes and the osteoarticular syndrome, but with every physical symptom. Hypoparathyroidism is characterized by hypocalcemia, atypical behavior of the alkaline phosphatase, hypocalciuria, very low concentration of immunoreactive parathyroid hormone, and neurological symptoms.

a) Differential Diagnosis of Hypocalcemia

Hypocalcemia is one of the biochemical symptoms of D-hypovitaminosis due to malabsorption or other alimentary disorders. It is always accompanied by hypocalciuria (as is hypoparathyroidism), by hypophosphatemia (in contrast to hypoparathyroidism) and by a rachitic-osteomalacic osteopathy with elevated levels of alkaline phosphatase in the blood (in contrast to normal alkaline serum phosphate levels in hypoparathyroidism). Hypophosphatemia and the elevated serum phosphatase constitute the most important criteria for the differential diagnosis between hypocalcemia due to D-hypovitaminosis and that due to parathyroid insufficiency.

Hypocalcemia can, however, also have *renal causes*. In certain tubular nephropathies, the hypocalcemia is accompanied by hypophosphatemia and a rachitic-osteomalacic osteopathy with hypercalciuria (Albright-Lightwood syndrome) or with hyperphosphaturia (vitamin D-resistent rickets). Glomerular, azotemic renal insufficiency of very long duration can produce hyperphosphatemia and hypocalcemia as well as hypocalciuria and a mixed osteopathy (osteomalacia and ostitis fibrosa). In such cases, however, the disorders of calcium and phosphate metabolism are dominated by the symptoms of renal insufficiency. Tetanic symptoms due to hypocalcemia are almost always absent due to the coexisting acidosis (the reader is also referred to the section on secondary hyperparathyroidism). Hypocalcemia of entirely different etiologies is observed in acute pancreatitis and in certain forms of metastatic skeletal carcinomatosis (chronic leucopathia, carcinoma of prostate, breast and bronchus (HALL, 1966), and also in medullary carcinoma of the thyroid secreting calcitonin.

Concentration of Immunoreactive Parathyroid Hormone in the Serum (iPTH). iPTH is elevated in all other forms of hypocalcemia leading to secondary hyperparathyroidism. iPTH concentrations are elevated in pseudohypoparathyroidism, nutritional rickets of infancy, intestinal malabsorption, and renal insufficiency. iPTH may be undetectable in some normocalcemic, normal subjects, depending on the sensitivity of the radioimmunoassay used. However, in

hypocalcemia iPTH is usually elevated, and every form of secondary hyperparathyroidism can thus be clearly differentiated from hypoparathyroidism (REISS, 1968; ARNAUD, 1971; FISCHER, 1973).

b) Differential Diagnosis of the Neurologic Syndrome

We have seen that the clinical picture of hypoparathyroidism is dominated by tetany but that tetany with all its features of neuromuscular overexcitability also occurs in numerous other pathologic conditions. A distinction must be made between hypocalcemic and normocalcemic tetany. The most common causes of hypocalcemia are discussed above (p. 890). Tetany is observed in all these conditions, but is not a mandatory feature. It is absent in hypocalcemic nephropathies accompanied by acidosis.

Normocalcemic tetany is observed in different conditions which may not be related to calcium and phosphate metabolism and parathyroid function and in which there are no dystrophic changes of hypoparathyroidism. The most common cause of normocalcemic tetany is alkalosis arising after hyperventilation, prolonged vomiting, after oral and parenteral administration of alkaline salts (bicarbonate) and in primary aldosteronism (p. 333). The ionized calcium concentration is clearly decreased, whereas the total serum calcium, phosphorus, and phosphatase, and the urinary excretion of calcium are normal. Tetany following hyperventilation is encountered mainly in females and can present as acute tetany as well as less characteristic chronic disorders such as depression and paresthesia. Vegetative circulatory disorders (angina pectoris, extrasystoles, tachycardia) can also be a manifestation of hyperparathyroidism. The attack and the chronic state are both characterized by anxiety as the predominant symptom. The fear is psychic in nature and is maintained by the physical symptoms of tetany. Hyperventilation can provoke acute tetany and other chronic symptoms which complicate the diagnosis. Tetanic symptoms disappear when exhalation of carbon dioxide is interrupted by closing the mouth and nose or by breathing into a paper bag or inhaling carbon dioxide. The diagnosis is usually not difficult in most cases if the psychoneurotic element of the personality is taken into account.

Tetany is induced by a reduction in the concentration of ionized calcium, but this may not be the only cause.

So-called idiopathic tetany (not to be confused with idiopathic hypoparathyroidism) was first described during World War I, and the term is still used occasionally. It can be defined as an illness with symptoms of latent and manifest tetany in normocalcemic individuals of poor social standing. Current views class some of these cases under hypocalcemic tetany in D-hypovitaminosis and others as alkalotic tetany.

One form of tetany is caused indirectly by a rise in the level of serum phosphorus and a fall in the concentration of serum calcium and less frequently of magnesium.

Unless there is antagonism between serum calcium and serum phosphorus, hyperphosphatemia does not cause tetany.

Magnesium Deficiency. In man, a fall in the level of serum magnesium is observed in primary hyperparathyroidism after resection of an adenoma of the parathyroid. This is applicable particularly to cases of hyperparathyroidism with marked bone involvement, especially if vomiting occurs at the same time. Magnesium deficiency also occurs after infusions of large quantities of fluid devoid of magnesium, in chronic alcoholism, liver cirrhosis, malabsorption, intensive diuretic treatment with thiazides, tubular acidosis, renal insufficiency and primary hyperaldosteronism. Extreme magnesium deficiency presents, especially in children, as tremor, athetotic-choreiform movements, muscle weakness, giddiness, and irritability. Convulsions reminiscent of a grand-mal attack are dangerous but rarely fatal. Treatment of magnesium deficiency is discussed on p. 932.

c) Differential Diagnosis of Epilepsy

We have already seen that the grand-mal epileptic seizure, or occasionally petit-mal epilepsy, can be the presenting symptom of idiopathic hypoparathyroidism and less commonly of postoperative hypoparathyroidism. The symptomatology of this form of epilepsy completely hides that of genuine epilepsy. The EEG does not help in the differentiation. Relevant conclusions can be drawn only from the therapeutic test. Anticonvulsive treatment which inhibits true epilepsy has no effect on epilepsy associated with hypoparathyroidism, whereas treatment which corrects the hypocalcemia clinically cures parathyroid epilepsy as well as normalizing EEG findings. Although these cases are uncommon, they are of great practical importance. Clinical symptoms of latent tetany should be routinely searched for and serum calcium estimated whenever possible in epileptic institutions. The same applies to disorders of mental development, retardation and character

changes in children, and in adults, illnesses with vague psychological features and Parkinson's disease.

E. Idiopathic Hypoparathyroidism and Pseudohypoparathyroidism

B. COURVOISIER

1. Clinical Definition

a) Idiopathic Hypoparathyroidism (IHP)

This term embraces a chronic syndrome with the following clinical criteria:

1. biochemical syndrome: hypocalcemia, hyperphosphatemia, hypocalciuria;
2. tetany (latent or manifest);
3. dystrophies (facultative): cataract, cerebral calcifications, enamel hypoplasia and anomalies of dental formation, osteoarticular syndrome, dystrophies of skin, hair and nails (p. 894);
4. no history of surgery or ^{131}I therapy in the parathyroid region;
5. no other causes for the hypocalcemia, i.e. no D-hypovitaminosis, no intestinal malabsorption and no renal insufficiency.

IHP is an uncommon condition. About 200 cases have been described in the literature. Both sexes are equally affected. The first symptoms usually arise during late childhood or in adolescence. Many years can go past before the diagnosis is made.

In a review of 22 autopsied cases of IHP the parathyroids were atrophied, replaced by fatty tissue or not found (ZELTNER, 1969). Familial incidence has been observed in many cases, especially when the parents were consanguineous (BUCHS, 1955–1957; PEDEN, 1960; ZELTNER, 1969). These facts suggest that IHP is sometimes the result of a sex-linked or autosomal genetic defect with expression in early or late life. The etiology of sporadic IHP is obscure.

Autoimmune Endocrinopathies, Simultaneous Occurrence of Idiopathic Hypoparathyroidism with Addison's Disease and Pernicious Anemia. This syndrome is discussed in more detail in Chap. XVIII (p. 1009) (pluriglandular syndrome) where the coexistence of IHP with primary chronic adrenocortical insufficiency and of Hashimoto's thyroiditis with hypothyroidism are dealt with, together with BLIZZARD'S investigations demonstrating the presence of antibodies to parathyroid tissues in a large percentage of these cases. There is a familial incidence of IHP and moniliasis (SUTERKIN, 1943). Pernicious anamia is often found associated with IHP. In addition, in several cases, Addison's disease was found to be present and antibodies to the "intrinsic factor" and adrenocortical tissue were demonstrated. Pernicious anemia usually begins late in the course of the IHP.

b) Pseudohypoparathyroidism (PSHP)

ALBRIGHT coined this term (1942) for an illness which in addition to the 5 criteria mentioned is also characterized by the following 4 criteria:

6. dwarfism and round face;
7. brachydactylia;
8. subcutaneous calcifications;
9. negative Ellsworth test (no phosphaturia after intravenous injection of parathyroid extract) (p. 945).

In this Ellsworth test, the reaction of renal excretion of phosphate to an intravenous injection of a parathyroid extract is examined. In postoperative hypoparathyroidism, the test causes a marked rise in renal phosphate excretion which is normally diminished. ALBRIGHT demonstrated a similar reaction in idiopathic hypoparathyroidism, except in a few cases in which renal excretion of phosphate reacted only insufficiently or hardly at all to the injection of parathyroid hormone.

ALBRIGHT assumed that the last criterion in the list was due to primary renal resistance to parathyroid hormone (PTH). With this assumption in mind, be put forward the hypothesis that PSHP was not to be considered the expression of a hormone insufficiency, but much more as a failure of the receptor organs to respond to PTH. This interpretation was confirmed by his findings in parathyroid biopsies in three cases, one biopsy showing normal parathyroid tissue and two showing parathyroid hyperplasia.

MARTIN (1940) gave the first detailed description of this syndrome; all significant criteria are summarized here without any theory about the pathogenesis.

PSHP is also a rare disorder (less than 50 cases in the literature). It occurs more frequently in females than in males. The onset usually dates back to late childhood or adolescence, but the diagnosis is often made much later. Clinical symptoms coincide with the principal features of IHP. In addition there are numerous constitutional anomalies and subcutaneous calcifications. Usually the patient's appearance is conspicuous. Stature is small and stocky, the dwarfism being proportional or the extremities conspicuously short. The hands are short and broad. The face is round and the features quite expressionless.

Mild obesity is rarely observed. Oligophrenia is common. Bones of the hands and feet are disproportioned, the phalanges, particularly metacarpals and metatarsals 1, 4, and 5, being shortened due to impaired endochondral growth. The rest of the skeleton shows the same osteoarticular changes as are found in IHP. Calcifications in the soft tissues can occasionally be palpated as small, hard, movable and indolent subcutaneous nodules. Usually they are first detected on X-rays. They are found mainly on the extremities and are para-articular, subcutaneous, intratendinous or intramuscular.

The basal metabolic rate is frequently found to be reduced in PSHP. Recent investigations have not shown this to be due to primary hypothyroidism or to a peripheral resistance to thyroid hormones, but rather to insufficient secretion of thyrotropic hormone (WINNACKER, 1967; ZISMAN, 1969).

In PSHP the renal (and perhaps skeletal) resistance to PTH is the basic metabolic defect. The constitutional anomalies and the subcutaneous calcifications appear to be separate, unrelated inherited defects (FRAME, 1972). The PTH resistance is therefore independent of these abnormalities.

c) Brachymetacarpal Dwarfism without Hypocalcemia (Pseudopseudohypoparathyroidism after Albright)

Examination of the families of patients with PSHP has revealed relatives with brachydactylia, round face and subcutaneous calcifications but no hypocalcemia. Furthermore, there are isolated cases as well as many familial cases where only constitutional anomalies and subcutaneous calcifications are found and no hypocalcemia or other symptoms of hypoparathyroidism. This syndrome was given the bizarre name of pseudopseudohypoparathyroidism by ALBRIGHT (1952). This term is questionable, and attempts have been made to replace it by other terms (dysplasia with calcification of soft tissues, Albright's dystrophy, brachymetacarpal dwarfism). It is now certain that the simultaneous occurrence of so many polymorphic dysplasias cannot produce a uniform picture, particularly since other types of malformations are found at the same time in the skin, skeleton, cardiovascular, urogenital and endocrine systems: anomalies of skin pigmentation, hypertrichosis, bone malformations, gonadal dysgenesia, pheochromocytomes etc. New dysplasias belonging to this group are continually being reported in the literature at the moment.

The occurrence of PSHP and brachymetacarpal dwarfism without hypocalcemia in the same family indicates that both disorders have a common genetic basis.

The discovery of constitutional abnormalities or subcutaneous calcifications without endocrine malfunction is of practical interest, since other members of the family could be affected by PSHP.

2. Pathogenesis

ALBRIGHT's hypothesis that PSHP is not a hormonal deficiency but a nonresponse of the

a b c

Fig. 21a–c. Three patients with round face and undifferentiated features characteristic of pseudohypoparathyroidism (a: from MARTIN, 1940; b: from SCHÜPBACH, 1949; c: a case from Zurich, a 33-year-old imbecile female patient)

receptors seems to be confirmed. In fact, three different forms of PSHP can be established (FRAME, 1972).

a) Renal and Skeletal Resistance to PTH

The absence of increased urinary phosphate excretion after PTH administration is considered a major diagnostic feature. The hormone is incapable of inhibiting phosphate tubular resorption. CHASE and AURBACH (1967, 1968) showed that the adenyl cyclase-3′-5′ cyclic AMP system in the tubular cells is activated by PTH and in normal subjects the hormone increases the urinary excretion of 3′-5′ cyclic AMP. In PSHP the renal tubular resistance to PTH is demonstrated by the absence of increased urinary phosphate and cyclic AMP excretion in response to parathyroid hormone administration (CHASE, 1969). Thus the primary fault in PSHP is the inability of the renal tubule cyclic AMP system to be activated by PTH. The consequence is increased phosphatemia that is partially responsible for the hypocalcemia. The extent to which the adenyl cyclase-cyclic AMP anomaly lowers the distal tubular calcium reabsorption which is normally stimulated by PTH has yet to be determined. Hypocalcemia increases PTH secretion: immunoreactive PTH concentrations in the serum are usually elevated (LEE, 1968; CHASE, 1969; FISCHER, 1973). Hypocalcemia together with clinical or X-ray and histologic evidence of hyperostosis, as in IHP, implies not only renal but also skeletal resistance to PTH. PTH normally activates the adenyl cyclase-cyclic AMP system in both kidney and bone (CHASE, 1969; FEDAK, 1969). However, a nonresponse of this kind has not yet been demonstrated in bone. One indirect argument for this case is the absence of increased amounts of hydroxyproline in the urine after PTH administration in PSHP in contrast to the rise in normal subjects and/or IHP (MCDONALD, 1972).

b) Skeletal Resistance to PTH with Normal Kidney Response

It is possible in some cases for only the skeletal adenyl cyclase-cyclic AMP system to be unresponsive to PTH, while activity in the kidney is normal (FRAME, 1972). This would explain the cases observed in which PSHP is associated with hyperostosis, hypocalcemia and a constant (SCHÜPBACH, 1949; COURVOISIER, 1963) or increased urinary phosphate response to PTH (FRAME, 1962). A change of this kind has also been observed in a case with clear-cell hyperplasia (FRAME, 1962).

c) Renal Resistance to PTH with Conserved Skeletal Receptivity

Several cases of biochemical hypoparathyroidism combined with renal resistance to PTH (absence of increased urinary phosphate and/or cyclic AMP excretion), as well as X-ray and histologic signs of osteitis fibrosa cystica have been reported in the literature (FRAME, 1972). This suggests that the renal resistance to PTH brings about hyperphosphatemia partially responsible for the hypocalcemia, thereby stimulating the parathyroids, as in group a). Some of these cases of secondary hyperparathyroidism were confirmed by radioimmunologic hormonal assay and/or histologic evidence of parathyroid hyperplasia. The osteitis fibrosa cystica is proof of the normal bone receptiveness to PTH. The mobilized bone calcium should correct the hypocalcemia, but it is possible that the calcemic effect is blocked or blunted by the hyperphosphatemia and also that there is a defect in osteocytic osteolysis (FRAME, 1972). As in the first group, the extent to which the adenyl cyclase-cyclic AMP anomaly lowers the distal tubular calcium reabsorption has yet to be established.

Finally these observations show that some patients have constitutional abnormalities, as described by ALBRIGHT, while others have a normal phenotype.

Other hypotheses have been suggested to explain PSHP: impaired biosynthesis of PTH, resulting in the *secretion of a biologically inactive hormone*, has been postulated, as has the presence of a *substance inhibiting PTH* in the blood or tissues (MANN, 1962). The detection of a very high concentration of calcitonin in the thyroid gland of some patients with PSHP (50–100-fold increase) (ALIAPOULIOS, 1966; TASHJIAN, 1966) gave rise to the speculation that the hypocalcemia is due to an *excessive secretion of calcitonin*. However, the concentration of calcitonin was found to be increased only in the thyroid gland and not in the peripheral blood of these patients. An increase in the concentration of calcitonin in the thyroid does not necessarily reflect an increased secretion but can also result from a diminished secretion. The ineffectiveness of total thyroidectomy on the plasma level of calcium in these patients contradicts the view that hypercalcitonism of thyroid origin is the cause of this syndrome (SUH, 1969).

3. Hereditary Factors

The condition can also be looked upon as a heredopathia (familial incidence and occurrence

in identical twins). Inheritance seems to occur through a dominant gene. Transmission is irregular and the localization of the gene is unknown. The women : men ratio of 2 : 1 suggests that the disorder is connected with the X chromosome (MANN, 1962). ELRIK and ALBRIGHT (1950) postulated some time ago that a three-fold genetic anomaly might be present embracing the following 3 groups of symptoms: 1. failure of the receptor organs to respond to PTH, resulting in the same changes as are found in IHP; 2. constitutional anomalies, a type of dyschondroplasia, particularly of the metacarpals and metatarsals; 3. tendency to development of subcutaneous calcifications.

F. Treatment of Hypoparathyroidism

B. COURVOISIER

a) General Facts

Treatment of parathyroid insufficiency involves 2 types of drugs:

1. calcium salts for intravenous and oral use;
2. the steroids, vitamin D and dihydrotachysterol.

Parathyroid hormone cannot be used therapeutically in the form now available. The commercially available extract induces the formation of antibodies and leads to "hormone resistance". Antibodies to bovine parathyroid hormone have recently been demonstrated for the first time in man.

There are two types of vitamin D; vitamin D_2 is of vegetable origin and vitamin D_3 of animal origin.

Vitamin D_2, or calciferol, is derived from egosterol, which is contained in ergot and barm, by means of a photochemical reaction under the influence of ultraviolet light.

Vitamin D_3, or cholecalciferol, is the natural vitamin D of animal origin and is derived from 7-dehydrocholesterol. In man, endogenous vitamin D_3 is synthesized in the skin under the action of ultraviolet light. Exogenous vitamin D_3 is obtained from food, being found predominantly in certain fish oils, and in smaller amounts in milk, butter and egg yolk. Synthetic vitamin D_3, which is identical to the naturally occurring substance, has been in therapeutic use for the past few years. The recently detected more active metabolites 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol (p. 883) are not available for therapeutic purposes and probable will not be, whereas therapeutic interesting analogues may be found.

Dihydrotachysterol is obtained by irradiating ergosterol and is used for the treatment of hypocalcemia as AT 10 (antitetanic factor 10).

Chemically pure vitamin D_2 and D_3 are, however, quite as suitable as dihydrotachysterol for the treatment of hypocalcemic states. JESSERER compared both vitamins with dihydrotachysterol and detected only insignificant pharmacological differences: aqueous solutions of all 3 substances are equally effective when given by i.m. or i.v. injection. An oily solution of vitamin D given by the i.m. route is effective, whereas an oily solution of dihydrotachysterol has no effect. In contrast, when the preparations are given orally dihydrotachysterol is more potent than vitamin D. All preparations can be used for the treatment of hypocalcemic states. It is important to know that the individual reactions to vitamin D and dihydrotachysterol vary and can do so in the same person at different times. The correct dose must therefore be chosen with care in such a case. The biological half-life of vitamin D_2 and D_3 is some weeks or even months, and vitamin-D intoxication is a serious problem in the treatment of hypoparathyroidism. According to KAYE, the biological half-life of dihydrotachysterol is shorter and may therefore be more useful in the treatment of hypoparathyroidism than vitamin D.

b) Treatment of Acute Tetany

Acute tetany is most commonly observed in postoperative hypoparathyroidism, the first attack usually arising as soon as a few hours after thyroidectomy or removal of a parathyroid adenoma. Acute tetanic attacks are, however, also seen in idiopathic hypoparathyroidism. Treatment consists of an intravenous injection of calcium salt: an injection of 20 ml 10% solution of calcium gluconolactonate (= 180 mg calcium) given slowly intravenously is most suitable. Blood for the estimation of serum calcium and phosphate must be taken before the injection is given. It is not necessary to wait for the results of these estimations since treatment with calcium is harmless and produces no ill effects in normocalcemic tetany. If the patient's response to the first injection is inadequate or only temporary the injection should be repeated once or twice hourly for the next few hours until the result of the serum calcium estimation is available. It must be stressed that the effect of intravenous injection of calcium is only short due to rapid fixation of calcium in the skeleton and rapid excretion through the kidneys. Because of this it may be necessary to start an intravenous infusion with calcium (15 mg Ca^{++}/kg body weight in

500 ml physiological saline). As soon as the diagnosis of hypocalcemic tetany is confirmed, and depending on the severity of the hypocalcemia, treatment is supplemented by a steroid promoting a rise in serum calcium. Crystalline vitamin D_3 in an aqueous solution is most potent and has the fastest onset of action. Depending on the serum calcium level, which is often very low (6 mg/100 ml and even lower), 4–6 ampoules (1 ampoule contains 7.5 mg = 300000 units)) are given. The full effect of this treatment cannot be expected until after 1–3 days, in spite of the intravenous route of administration. Meanwhile, an uninterrupted infusion with calcium is maintained. Repeated serum calcium estimations are essential for an adequate dosage. Sedation with a barbiturate can also be useful during this phase. Phenothiazine compounds of any sort must be avoided, since as was seen above (p. 893) extrapyramidal features of hypoparathyroidism can occasionally be accentuated or severe neurodysleptic attacks induced. When tetanic symptoms do not cease even after normalization of serum calcium in spite of continuous treatment and high doses of vitamin D, the possibility of magnesium deficiency must be considered, particularly in postoperative hypoparathyroidism following the removal of a parathyroid adenoma, though this does occasionally happen with other forms of hypocalcemic tetany. After serum magnesium has been estimated, substitution therapy must be started at once, following the schedule described in the chapter dealing with the postoperative course and treatment of primary hyperparathyroidism (p. 932). The hypocalcemia is generally corrected within 1–8 days following intravenous injection of vitamin D. If correction fails to occur, a further 7.5 mg vitamin D_3 must be given intravenously, and if repeated administrations of vitamin D are still required after a few weeks, long-term treatment adhering to the principles given below must be introduced. Not uncommonly, however, the serum calcium level becomes normal spontaneously after a few weeks or, more infrequently, months in postoperative hypoparathyroidism due to compensatory hyperplasia of the still intact parathyroids. The patient can then be considered cured providing estimations of serum calcium every 3–6 months for the following 2 years give favorable results.

c) Treatment of Chronic Postoperative and Idiopathic Parathyroid Insufficiency

Vitamin D and dihyrotachysterol given by the oral route are the drugs of choice. The most important aims of treatment are normalization of serum calcium at a level between 9 and 11 mg% and the prevention of hypercalciuria. The dangers of hypercalcemia and hypercalciuria (nephrolithiasis, nephrocalcinosis etc., p. 918) and of hypocalcemia (tetany, neurologic changes, cataract and other changes, p. 893) have been discussed in detail above. Serum calcium can vary spontaneously over several months, rising without warning to normal values or falling to very low levels.

Thus, with the exception of cases of transient postoperative parathyroid insufficiency, hypoparathyroidism can never be considered cured. Patients need treatment for the rest of their lives, serum calcium must be checked regularly and normalized with vitamin D when necessary. No fixed daily dose can be given due to the marked individual variation. The dosage must be adjusted continually from estimations of the serum calcium. Serum calcium and the 24-hour excretion of calcium in the urine must be measured once to twice monthly at first, and later every 3 to 6 months. It must be remembered that the variations in the dosage in individual cases can be associated with the facts that a lower dose is needed during the sunny summer and autumn months than in winter and spring, and that vitamin-D requirements are increased by mobilization and decreased by immobilization. Vitamin-D requirements are increased by hypothyroidism and decreased by hyperthyroidism. *Treatment must be discontinued when serum calcium exceeds 10.0 mg/100 ml and urinary excretion of calcium is more than 300 mg in 24 hours.*

The dosage depends of the seriousness of the disorder and should be adapted to each individual patient. The following dosage schedule for vitamin D or dihydrotachysterol will serve as a guide:

Initial dose: 1–2 mg daily for several days.
Average maintenance dose: 0.5–1.0 mg.

Vitamin D and dihydrotachysterol have a cumulative action. For this reason treatment can also be intermittent: 1.0–3.0 mg twice weekly.

The diet for patients with chronic hypoparathyroidism should contain adequate amounts of calcium. The maintenance doses of vitamin D and dihydrotachysterol can be reduced by regular administration of calcium (1.0 g calcium daily). Postoperative hypoparathyroidism is occasionally associated with hypothyroidism. Since thyroid hormones cause calcium mobilization, i.e. raise a reduced serum calcium level and increase urinary excretion of calcium, substitution therapy for thyroid insufficiency is strongly indicated. Resistance to vitamin D and dihydrotachysterol has occasionally been observed in postoperative hypo-

parathyroidism. In one such case, it was observed that pregnancy terminated the vitamin-D resistance. In another case, the normal response to vitamin D, which had previously been present, was restored by giving 25 mg cortisol orally, twice daily.

G. Primary Hyperparathyroidism

M. WERNLY

1. Definition

Primary hyperparathyroidism is caused by excessive synthesis and release of parathyroid hormone in the absence of an elevated hormone requirement of the organism. The most common morphological findings in the parathyroids are 1. the solitary parathyroid adenoma, and less commonly, 2. multiple parathyroid adenomas or 3. multiple parathyroid adenomas associated with the syndrome of the endocrine adenomatosis ("chief-cell hyperplasia"); 4. primary hyperplasia of the water-clear cells and 5. carcinoma of the parathyroid gland may be responsible.

Secondary and tertiary hyperthyroidism are discussed below (p. 934, 939).

2. Etiology, Incidence and Frequency

Etiology. With the exception of endocrine adenomatosis, which is most probably due to a gene mutation, nothing is known about the etiology of primary hyperparathyroidism. Adenomas of the parathyroids are independent of the functional state of the pituitary gland. Contrary to earlier suspicions, the serum phosphorus does not directly influence the formation of an adenoma. However, an increase in the serum phosphorus concentration always leads to hypocalcemia and thus to an increased parathyroid hormone secretion.

The term "tertiary hyperparathyroidism" describes a pathogenic form of primary hyperparathyroidism. It has arisen from a small number of clinical cases associated with the development of parathyroid adenoma causing hypercalcemia from hypocalcemic secondary hyperparathyroidism. This rare occurrence has been observed so far in a few cases of intestinal malabsorption and chronic renal failure, which presented clinically for years as secondary hyperparathyroidism with hypocalcemia. During the clinical course there was a slow change to normo- and hypercalcemia, and at the same time the clinical picture of secondary hyperparathyroidism was replaced by that of primary hyperparathyroidism. The morphological changes causing this condition are found at operation to be a diffuse or microadenomatous hyperplasia of all 4 parathyroids, sometimes associated with a well-defined large parathyroid adenoma. The removal of this adenoma cures the primary, alias tertiary, hyperparathyroidism in the classic way. In addition to the usual course of development of the autonomic adenoma, there is thus a less common type of development of a reactive adenoma, in which the adenoma is preceded by secondary hyperplasia of the parathyroid glands due to hypocalcemia or hypomagnesemia. Tertiary hyperparathyroidism is discussed on p. 939.

It is not known whether there is any etiological or pathogenic connection with intercurrent sarcoidosis or gout.

Most parathyroid adenomas develop for no apparent reason. However, in a few cases, hyperplasia of the parathyroids related to renal or some other disease may precede the adenoma. The parathyroid adenoma in endocrine adenomatosis is most probably due to a genetic mutation (WERNER).

Incidence. In adulthood, primary hyperparathyroidism due to a parathyroid adenoma is at least twice as frequent in the female as in the male. There is no sex-linked difference in incidence before puberty or for the rare carcinoma of the parathyroid glands. Nor is it yet certain whether primary hyperplasia of all four glands is also more common in the female sex. Primary hyperparathyroidism is uncommon before the 2nd year of life. The 20–40 age group accounts for 30% of cases, and the 40–60 age group for 50%.

Frequency. Primary hyperparathyroidism used to be considered a rare disease, but the number of cases diagnosed is increasing continually with growing medical interest and the possibility of measuring parathyroid hormone in the blood directly by radioimmunoassay. The knowledge that 5% of all patients with nephrolithiasis suffer from primary hyperparathyroidism has contributed to the early diagnosis of cases of hyperparathyroidism. The true frequency of primary hyperparathyroidism, however, is deduced from the routine estimation of the serum calcium in a series of subjects chosen at random. Thus, BOONSTRA found 31 cases of hyperparathyroidism confirmed at operation in 26000 hospital admissions (8 presented clinically as nephrolithiasis, 13 had gastrointestinal symptoms, 17 suffered from fatigue to the point of exhaustion, 3 patients had mental depression, none had skeletal involvement). Thus there was at least one clinically unrecognized case of

primary hyperparathyroidism in 850 hospital patients, corresponding to a frequency of 1.2‰. However, it must be borne in mind that these figures for the frequency relate to patients admitted to hospital, who have some significant symptoms of disease, and not to a healthy population. The percentage incidence is considerably higher if parathyroid hormone concentrations are systematically measured even in normocalcemic subjects (PURNELL, 1971).

3. Pathologic Anatomy and Histology

A histologist experienced in work on the parathyroid glands should be present at every operation on the parathyroids. He should examine all the pieces of tissue excised by the surgeon throughout the operation and should identify them as being parathyroid tissue or tissue from other cervical organs. He should also make the differential diagnosis between the normal, hyperplastic, adenomatous or carcinomatous parathyroid tissue.

a) Frequency of the Various Findings in the Parathyroids in Primary Hyperparathyroidism

These data have been derived from four series of statistics (Table 4). The differences between one series and the other are due to the various ways of interpreting the histological findings by the different authors.

b) Solitary and Multiple Adenomas

Adenomas can be little larger than the normal glands but can also reach the size of an almond, of a cherry, or of a hen's egg. The weight varies between 25 mg and 100 g. The solitary adenoma does not differ macroscopically or microscopically from multiple adenomas. The adenomas are somewhat darker than the normal gland, which often has a pronounced yellow fatty appearance, and may be red-brown to red-yellow in color. In comparison with thyroid tissue, the parathyroids appear brighter and pink. Anatomists and surgeons also consider the parathyroids have a characteristic consistency, which is softer than that of the thyroid tissue, or of a lymph node, but considerably firmer than that of fat or thymic tissue. Every parathyroid adenoma possesses a clearly recognizable capsule. This capsule is only exceptionally penetrated by one or two pseudopodialike parenchymal processes. When they reach a certain size, most adenomas show a well-differentiated vascular stem, which is of great importance to the surgeon when the adenoma is situated in the mediastinum (p. 846). The possibility of a parathyroid adenoma within the thyroid must be taken into account (p. 931).

The sectioned surface is usually slightly darker than the outer surface. During sectioning, one or several cysts with bright yellow or hemorrhagic contents are sometimes opened. Adenomas with a completely regular appearance on the outside sometimes show a large number of microadenomas on being sectioned.

The histological preparations of parathyroid adenomas involving only a part of the glandular parenchyma show a globular, oval form. Their tendency to expand causes compression of the surrounding tissue. In medium-sized adenomas the compressed part of the normal parathyroid tissue shows up as a narrow stripe. Usually no more normal parathyroid tissue is found in the presence of larger adenomas. The presence of a stripe of normal parathyroid tissue is important for the histological diagnosis during an operation. Some fat cells are usually also

Table 4. The frequency given as a percentage of the different findings in the parathyroid glands in primary hyperparathyroidism

	Mayo Clinic Rochester (BLACK) up to Dec. 1959	Massachusetts General Hospital Boston (ROTH) up to Aug. 1959	Armed Forces Institute Washington (ROTH) up to Aug. 1959	Karolinska Syukhuset Stockholm (HELLSTRÖM) up to 1960
Solitary adenoma	89.1%	79 %	83.1%	84.8%
Multiple adenomas	2.9%	4.7%	2.8%	2.2%
Multiple parathyroid adenomas in endocrine adenomatosis	2.6%	–	–	–
Primary hyperplasia of the chief cells	–	6.7%	5.6%	2.9%
Primary hyperplasia of the water-clear cells	4.9%	6 %	2.8%	9.4%
Carcinoma	0.5%	3.6%	5.7%	0.7%
Number of cases	385	352	142	138

recognized in the stripe of normal parathyroid tissue, whereas fat cells are extremely rare in the adenoma. The behavior of the fat cells is also of diagnostic importance and is discussed on p.

The adenomas of primary hyperparathyroidism are composed of small and large chief cells, water-clear cells of all sizes, or of atypical oxyphil cells which are often larger and brighter than the usual oxyphil cells. As a rule, however, an adenoma contains not only one cell type but several. One cell type usually dominates the picture. The parenchymal cells of a functioning adenoma are analogous to normal cells or similar but never quite the same as those in secondary hyperplastic glands. They differ from normal cells in the following cytological properties: peculiar color tinges of the protoplasm with the usual methods of staining, which are not observed in normal cells, tendency to syncytial arrangement of the cell types; abnormally large nuclei of bizarre form (Fig. 22), numerous amitoses (50 nuclei or more in a narrow syncytial space). True and atypical mitoses are never found in this condition, in contrast to carcinomas of the parathyroids.

Parathyroid adenomas often show signs of secondary degeneration, which is probably due to the enormous cellular proliferation without the simultaneous formation of an efficient vascular network. This results in hypoxemic necrosis, hemorrhage and focal softening with cystic formation. Even subtotal or total necrosis of the adenoma sometimes occurs, in which case there may be a spontaneous clinical cure of the hyperparathyroidism. There are also cases of corresponding clinical observations with the typical "postoperative" hypocalcemic tetany (HOWARD, 1953; JOHNSTON, 1961).

The lipoid adenoma is considered as a parathyroid adenoma presenting clinically as primary hyperparathyroidism. Abundant, edematous fibrous tissue stroma with numerous fat cells is found between the chief cells, which are arranged in loose strands (OBER, 1958; ABUL-HAJ, 1962). A similar picture is occasionally found in a part of the gland in the presence of a classic parathyroid adenoma. Cystic parathyroid adenomas are discussed on p. 847 and p. 924.

Not every parathyroid adenoma is associated with primary hyperparathyroidism. There are adenomas which are not active, including predominantly the pure oxyphil adenomas seen in elderly persons (p. 847). They must be strictly differentiated from the active oxyphil adenomas in primary hyperparathyroidism, which are predominantly or exclusively composed of atypical oxyphil cells (p. 906). The fundamental difference between the functionless adenoma and the functioning oxyphil adenoma has recently been confirmed by electron microscope studies which showed that the cellular organelles of the oxyphil cells of the former adenoma type are inactive, while those of the second adenoma type are hyperactive (p. 847). Differentiation on histological grounds only can be difficult.

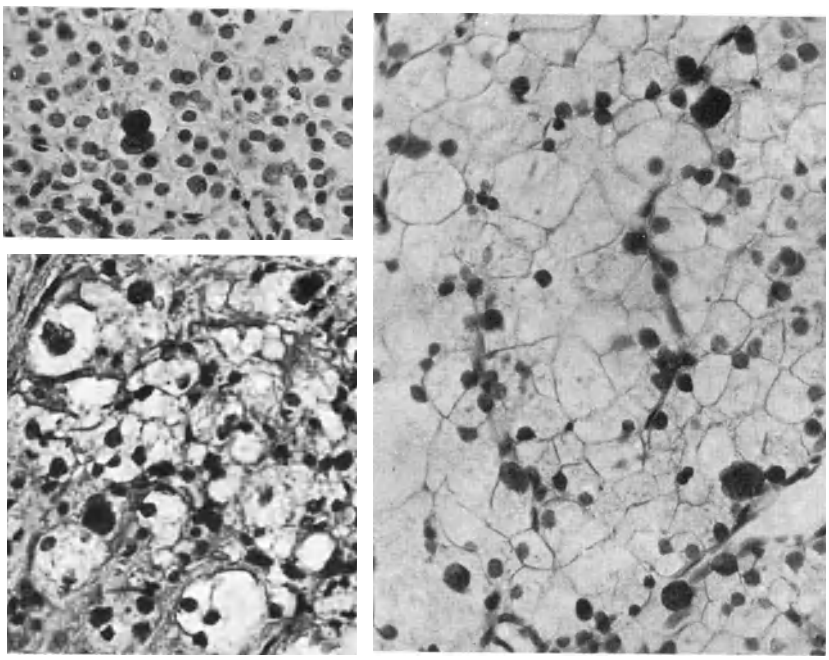

Fig. 22. Primary hyperparathyroidism. Abnormaly large nuclei with atypical form in three benign adenomas

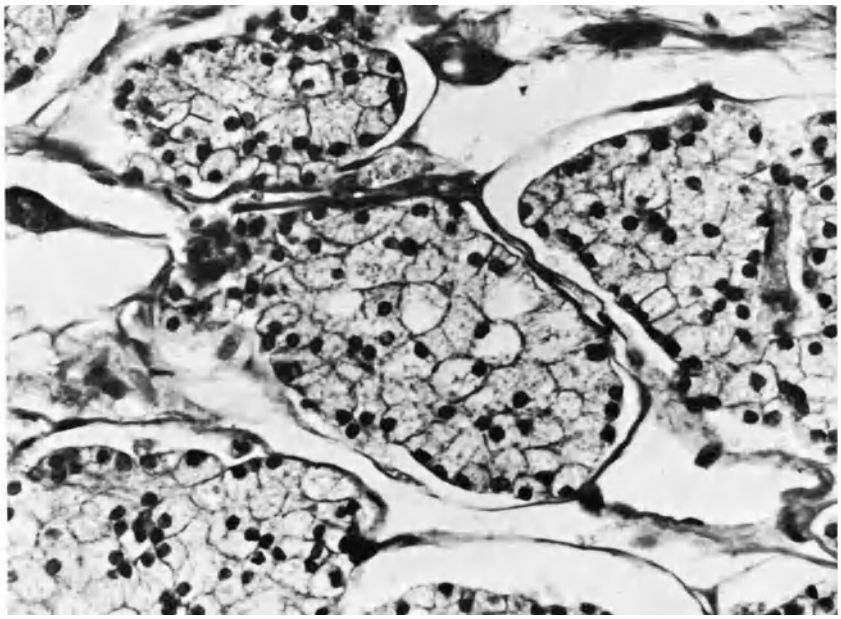

Fig. 23. Primary hyperplasia of water-clear cells in primary hyperparathyroidism

Recently, BLACK (1961) and RAMSDELL (1960) have also described parathyroid adenomas discovered incidentally during operations on the thyroid. These adenomas do not differ at all, morphologically, from functioning parathyroid adenomas. The subsequent, very precise clinical investigation revealed no clinical symptoms of hyperparathyroidism in most of these patients. In a few cases, there was hypercalcemia, or borderline hypercalcemia. There was no hypercalcemia in 7 of 21 cases. Whereas the cases of clinically silent hypercalcemia were assessed with no particular difficulty (chemical hyperparathyroidism without clinical symptoms, p. 911), assessment of normocalcemic cases is possible only with the aid of a sensitive radioimmunoassay for parathyroid hormone in the blood (chemically and clinically silent parathyroid adenomas are discussed on p. 911).

c) Primary Hyperplasia of the Water-Clear Cells

This condition is observed in one in 20 cases of primary hyperparathyroidism, and is characterized by a pronounced increase in the volume of all 4 glands. The weight of two or three of the 4 glands is usually over 10 g. One or two glands sometimes retain the normal weight. According to BLACK the total weight of all 4 glands is 760 mg–132 g, and according to ROTH 3–60 g. In contrast to the parathyroids in normal subjects, the upper glands are usually

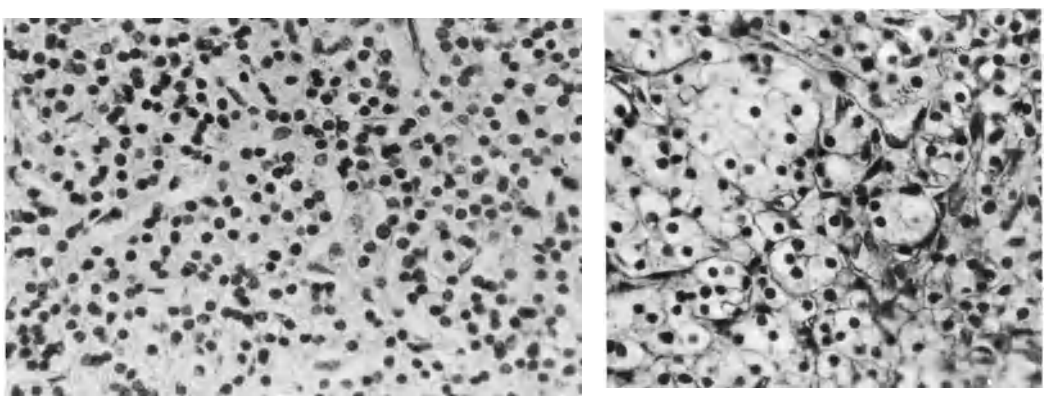

Fig. 24. Secondary hyperplasia of water-clear cells in secondary hyperparathyroidism. Left: chronic nephritis; right: osteomalacia

larger than the lower glands. The surface is very irregular in comparison with that of an adenoma, and numerous lobes and recesses as well as pseudopodia-like processes are seen. In spite of this the capsule is thin and transparent, and is easily separable from the surrounding tissue. The color is often a striking chocolate brown. These special properties of the surface and the color are only recognizable when the glands are grossly enlarged.

All 4 glands contain only one cell type, very large water-clear cells (Fig. 23). Even if one gland has retained its normal size, it consists entirely of these cells. Chief cells, small water-clear cells or oxyphil cells are only rarely discovered even with the most thorough inspection of the preparation. A stripe of normal parathyroid tissue is never found. Irregular parenchymal processes of the water-clear cells are not uncommonly seen in histological preparations, extending from the surface of the gland into the surrounding adipose tissue. Since a water-clear solitary adenoma can give a histological picture compatible with these findings, the diagnosis of primary hyperplasia of the water-clear cells is possible only in the presence of evenly distributed hyperplasia of the water-clear cells in all 4 glands.

The differentiation of this characteristic picture from that of secondary hyperplasia of all four glands in secondary hyperparathyroidism, as encountered in cases of chronic renal insufficiency or intestinal malabsorption, is of practical importance. The reader is referred to p. 934 for a discussion of the histology of this condition. The finding that the entire parenchyma is composed exclusively of large, water-clear cells is the decisive feature of the picture of primary hyperplasia of the water-clear cells.

The surgeon performing a subtotal resection of the total tissue of the gland, leaving a small, well-vascularized remnant of 50–100 mg, can often suspect primary hyperplasia of the water-clear cells from the chocolate brown color alone, but the histological findings in all 4 glands are essential for a definitive diagnosis. Difficulties can arise when 2 greatly enlarged glands on one side merge into one unit, as the surgeon cannot be quite certain whether he has found all 4 glands, and cannot carry out the intended subtotal resection.

d) Parathyroid Adenomas in Endocrine Adenomatosis

Multiple adenomas of the parathyroids are a form of endocrine adenomatosis (adenomas of the parathyroids, adenohypophysis, islet cells of the pancreas, adrenal cortex and medulla). They cause primary hyperparathyroidism about as frequently as hyperplasia of the water-clear cells. The adenomas of the parathyroids are always multiple in this syndrome, and in most cases every parathyroid gland reveals several small adenomas. Some of the cases recognized so far have been described as "primary hyperplasia of the chief cells" in the literature (p. 909). The frequent familial occurrence is probably an expression of a genetic mutation, and is characteristic of endocrine adenomatosis (Chap. XVIII, p. 1007).

All the parathyroids are considerably enlarged. ROTH gives the total weight of all 4 glands as 1–25 g. The upper glands are usually more enlarged than the lower. On several occasions one of the lower glands has proved to be situated in the mediastinum. The surface of the gland is irregular, and usually devoid of pseudopodia-like processes. The color is reddish-brown and not chocolate brown as in primary hyperplasia of the water-clear cells. A structure consisting of small nodules is macroscopically visible. The histology shows either a solitary chief-cell adenoma or microadenomatous hyperplasia of the chief cells. The size of these chief cells varies from field to field or from one microadenoma to the other. Their size, however, usually remains within normal limits. Fields with small water-clear cells are rarely found, and fields with larger water-clear cells are even rarer. In two cases, the glandular parenchyma was composed almost entirely of small and large clear oxyphil cells. Giant nuclei and amitoses are more uncommon in microadenomatous hyperplasia than in a solitary adenoma. A stripe of normal parathyroid tissue has never been observed. Fat cells are occasionally scattered in individual areas.

The picture described here is very similar to that of microadenomatous hyperplasia of secondary hyperparathyroidism (p. 934). Sometimes it is even impossible to differentiate between the two conditions from the histological picture of a single gland or of a glandular biopsy. In such cases, only the total clinical findings together with the histological findings of all 4 glands can be of any further help.

The following factors must be taken into account during surgical treatment: in every case of primary hyperparathyroidism in which clinical or histological examination suggests an endocrine adenomatosis all 4 glands should be very carefully examined during the operation. As a rule three glands are totally removed, and 30–50 mg of the smallest gland left behind. BLACK advocates the precaution of marking the residual parathyroid with a black silk

suture, so that in case of recurrence, which is not uncommon, the gland can be easily identified. The total excision of all four glands is the treatment of choice in theory, but this procedure will be permissible only when a substitution therapy better than the present method becomes available.

e) Primary Hyperplasia of the Chief Cells

The morphological findings in the parathyroids in this disorder are very similar to those in endocrine adenomatosis (p. 908). There are different opinions about whether the term hyperplasia or adenomatosis should be chosen. We prefer adenomatosis for of the following reasons: changes in the islet cells of the pancreas, in the adenohypophysis, and in the adrenal cortex are all termed adenoma or multiple adenomatosis and the same term should therefore be applied to changes in the parathyroids. However, the term "primary hyperplasia of the chief cells" has now become so well-established that it can no longer be excluded from the clinical and patho-anatomical terminology.

Most cases of primary hyperplasia of the chief cells or multiple parathyroid adenomas have been observed and described in association with endocrine adenomatosis. In a few cases, however, multiple adenomas of all four parathyroids have been the only findings, with no clinical or morphological evidence of involvement of the pituitary gland, the islet cells, or the adrenals. It is striking that there is an increased familial incidence in these cases (in 14 of 30 cases according to CUTLER), as there is in endocrine adenomatosis. Familial frequency, however, is one of the characteristic features of the syndrome of endocrine adenomatosis, and this therefore indicates that isolated, multiple parathyroid adenomatosis, or isolated primary hyperplasia of the chief cells, should also be included in the syndrome of endocrine adenomatosis.

f) Carcinoma of the Parathyroid

This is extremely rare. Many authors in the past, however, repeatedly referred to carcinomas of the thyroid gland as parathyroid carcinomas when the cellular picture of the tumor was similar to that of the parathyroids. However, the symptoms of hyperparathyroidism were absent, and the classification of such tumors as parathyroid tumors was not confirmed.

A few cases of parathyroid carcinomas have nonetheless been reported. They all showed clinical and biochemical features of primary hyperparathyroidism. The tumor in the parathyroids shows local malignant properties with infiltrative growth into the surrounding tissues, namely into the capsule of the adenoma, the thyroid gland, the large blood vessels, the muscles and the esophagus. Metastases occur frequently and are found in the regional lymph nodes, the lungs, liver, bones, and spleen. During surgery, the strong adherence of the tumor to the surrounding tissues is striking, and in direct contrast to the situation in cases of benign adenomas. The histological findings are less definitive. In most but not all cases (v. ALBERTINI), mitoses which are sometimes atypical are recognized, as well as distinct tumor invasion into the surrounding tissue. Amitosis and capsular invasion by themselves, on the other hand, cannot be interpreted as signs of malignancy, since they have also been observed in benign adenomas and in primary hyperplasias. The existence of endocrine-active metastases and recurrence of the tumor after surgical removal are the only features which can be considered criteria of malignancy.

The theoretical question of the existence of endocrine-inactive carcinomas of the parathyroids cannot yet be answered. It is not possible to make a diagnosis from the clinical features and the findings in the blood, and the local findings do not allow a distinction from the carcinoma of the thyroid gland. There is an unspoken rule that only tumors related to primary hyperparathyroidism by the clinical features and the findings in the blood are described as carcinomas of the parathyroids.

Carcinoma of the parathyroids has a typical clinical course. Hypercalcemia with more than 14 mg/100 ml is usually present.

Excision of the carcinoma results in the disappearance of all the symptoms of the disease but the cure is not lasting. There is always the possibility of a recurrence of the clinical symptoms and the pathologic findings in the blood, which can be associated with the formation of a recurrent tumor locally or with metastases. A second radical operation sometimes produces a cure lasting some months, and occasionally years. Finally, the terminal recurrence appears with the fully developed picture of hyperparathyroidism with all the clinical and biochemical findings. Death is due to renal insufficiency (nephrocalcinosis, renal vein thrombosis, renal hypertension and renal failure) or pancreatitis. An intercurrent illness can also have a fatal outcome. Autopsy reveals metastases of the carcinoma of the parathyroids in one of the organs mentioned. Carcinoma of the parathyroids and its metastases are resistent to radiotherapy.

4. Pathophysiology

The parathyroids are not controlled by any other known endocrine organ, such as the pituitary, in normal or pathologic conditions. A fall in the serum calcium and/or magnesium levels in the serum are the recognized stimuli for the secretory activity of the parathyroids. Conversely, their most important function is to regulate the concentration of calcium in the serum (p. 869, p. 889).

The clinical symptoms of primary hyperparathyroidism are entirely attributable to the autonomous elevation of the parathyroid hormone activity. The following changes have been observed in primary hyperparathyroidism due to the action of the parathyroid hormone at the three sites – the bones, the kidneys and the intestine.

1. Increased activity of the osteocytes, osteoblasts, and osteoclasts throughout the skeleton. In contrast to the normal physiological situation, the osteocytic osteolysis and the osteoclastic resorption dominate bone formation in primary hyperparathyroidism. This leads to an increased release of calcium and phosphorus into the extracellular space and into the serum. An elevated turnover of calcium and phosphorus is seen in the skeleton. This can be domonstrated by kinetic methods. Only a few patients, however, lose such large amounts of bone minerals that clinically recognizable osteopathy results. In most cases, the skeletal involvement is termed generalized osteitis fibrosa cystica (v. RECKLINGHAUSEN), while in a smaller number of cases there is a mixed osteopathy, consisting of generalized osteitis fibrosa cystica and osteomalacia.

2. Elevation of the phosphate clearance and reduction of the calcium clearance. The increased amounts of phosphate obtained from bone resorption are eliminated from the organism via the elevated renal clearance of phosphorus. Serum phosphorus remains normal or tends to fall. The reduced renal clearance of calcium favors hypercalcemia, as do the increased amounts of calcium released by destruction of the bones. Thus, hypercalcemia, normo- or hypophosphatemia, hypercalciuria and hyperphosphaturia are the four mandatory symptoms of primary haperparathyroidism (p. 924).

3. Increase in intestinal absorption of calcium. A third, intestinal hypercalcemic factor joins the osseous and renal factors producing hypercalcemia. More calcium is excreted by the kidneys than by the intestine. In healthy subjects on a normal diet, 80% of the calcium is excreted in the feces and 20% through the kidneys. In primary hyperparathyroidism the intestinal excretion falls, sometimes to 10%, with an increase of the renal fraction to 90%.

In addition to the changes in serum calcium and phosphorus levels, serum citrate may rise above 3.5 mg/100 ml in primary hyperparathyroidism, while the magnesium in the urine can be increased and the serum magnesium normal or slightly decreased (SUTTON, 1970). In some cases, the magnesium balance is negative.

Neuromuscular excitability is suppressed in hypercalcemia and increases in hypocalcemia, which accounts for the hypotonia of the striated muscles with asthenia and the atonic constipation found in hypercalcemic patients.

Extreme hypercalcemia as observed in acute hyperparathyroidism leads to polyuria, vomiting, dehydration and renal insufficiency with hyperphosphatemia. Metastatic calcification in numerous organs arises when the serum calcium and phosphorus are greatly increased at the same time (cf. acute hyperparathyroidism, p. 923). The development and assessment of additional indirect results of hypercalcemia (gastric ulcer, pancreatitis, mental and neurologic changes) are discussed in the clinical section.

Hypercalciuria related to or independent of hypercalcemia is the cause of the nephrolithiasis which occurs frequently in primary hyperparathyroidism. Nephrocalcinosis is seen predominantly but not exclusively in severe hypercalcemia of long duration. The diminished renal excretion of hydrogen ions with an alkaline urine in the presence of hypercalcemia has an additional effect on the nephrocalcinosis and the nephrolithiasis. The nephrocalcinosis can lead to a progressive, irreversible impairment of the renal function. It is thus the most important feature of primary hyperparathyroidism, as it is potentially fatal.

The polyuria observed in primary hyperparathyroidism is due to the direct effect of hypercalcemia on the distal tubules. The water reabsorption is suppressed and the free water clearance increased. The polyuria is always associated with hyposthenuria demonstrable even in the early phase of the illness.

Hypocalcemia, hypophosphatemia and hypomagnesemia have been observed after removal of a functioning parathyroid adenoma with pronounced skeletal involvement. These features are caused by a rapid deposition of calcium phosphate in the skeleton. The so-called recalcification tetany is caused partly by the hypocalcemia, and partly by the hypomagnesemia.

The immunoreactive parathyroid hormone concentration (IPTH) is not always elevated in cases of primary hyperparathyroidism. Except

for the unique experience of REISS (1971), the literature reports a considerable overlap between normal and elevated levels (BERSON, 1966; ARNAUD, 1971). However, ARNAUD (1971) finds that when the serum calcium concentration is measured as well as IPTH, it is practically always possible to discriminate between normal and pathologic cases. In other words, when the serum calcium concentration is in the high normal range IPTH is low or undetectable in normal subjects, in contrast to the level in patients with primary hyperparathyroidism, where it is elevated. In secondary hyperparathyroidism of renal insufficiency IPTH can be in the same range as in primary hyperparathyroidism in some assays and much higher other assays. These differences are caused by the occurrence of at least two different molecular forms of parathyroid hormone in peripheral serum and site-specific antibodies. IPTH can be suppressed with calcium infusions in all cases of primary hyperparathyroidism, thus ruling out complete autonomy of parathyroid hormone secretion (POTTS, 1971). This is in contrast to the results of REISS (1971) and BUCKLE (1971), who seemed to be able to suppress IPTH in primary chief-cell hyperplasia of the parathyroid glands but not in parathyroid adenomas. In renal insufficiency IPTH is lowered following an increase of the calcium concentration in the dialysis bath (FOURNIER, 1971). IPTH has been suppressed with calcium in two cases of tertiary hyperparathyroidism (BRICKER, 1972; VOSIK, 1972). In conclusion, IPTH secretion can be suppressed with calcium in primary hyperparathyroidism, thus ruling out complete autonomy of PTH secretion. The pathogenesis of tertiary hyperparathyroidism (from secondary hyperparathyroidism) remains unknown.

5. Clinical Features and Symptoms

a) Presentation and Course

The *clinical picture* and the *course* of primary hyperparathyroidism are extremely variable. As well as the classic type with VON RECKLINGHAUSEN'S osteitis fibrosa, there is a form presenting with predominantly renal symptoms, and other forms with gastric ulcers, pancreatitis, gout, pseudogout, and band keratitis. There are other forms which show no signs of organic changes, but present clinically with functional symptoms only (hypercalcemic syndrome).

Finally, there is a symptomless form with hypercalcemia (chemical hyperparathyroidism). In addition, parathyroid adenomas discovered incidentally at thyroidectomy show all the morphological signs of a functioning adenoma without giving rise to clinical symptoms or hypercalcemia. The interpretation of these "silent" adenomas is still speculative, because of the lack of sufficient data (estimation of parathyroid hormone in the blood) (p. 907).

The course is chronic in most cases. Exceptionally it is short and peracute or there are acute phases during the chronic course (acute hyperparathyroidism). There have been reports of spontaneous necrosis of the parathyroid adenoma (p. 906). The frequency of these spontaneous healings is not known.

b) Skeletal Changes (Osteitis Fibrosa Cystica Generalisata von Recklinghausen)

The skeletal involvement was the predominant feature in the first recognized cases of primary hyperparathyroidism which were identified beyond doubt, but the skeletal changes are now considered quite an uncommon feature. Pronounced osseous changes can be seen clinically in about 15% of all cases of primary hyperparathyroidism (KEATING, HELLSTRÖM and RASMUSSEN, 1952). A considerably higher percentage is obtained, however, when more sensitive methods of skeletal examination are used. Skeletal involvement is found in 20–30% of cases by systemic X-ray examination (STEINBACH, 1961), and in 80% with the aid of bone biopsies after labeling with tetracycline (VAN DER SLUYSVEER, 1964). Quantitative microradiography of bone biopsies (JOWSEY) and biochemical methods with "bone-seeking" elements can detect involvement of the skeleton in all patients with primary hyperparathyroidism (radioactive calcium: BAUER, 1955; stable strontium: HARRISON, 1959).

Primary hyperparathyroidism occasionally presents clinically with bone symptoms only. They are, however, much more often associated with other symptoms of hyperparathyroidism, such as nephrolithisasis.

α) Clinical Symptoms of the Skeletal Involvement

The beginning of the skeletal disturbance is usually marked by the development of vague pains in the back, the sacral region, the hips and the limbs after prolonged exertion. Deformations results over some months, the most common being dorsal kyphosis, or kyphoscoliosis with the simultaneous formation of a pigeon chest. Shortening and widening of the neck so that the collar becomes too tight is very characteristic. Further characteristic changes are shortening of the trunk, with loss of the physiological lumbar lordosis, and the forma-

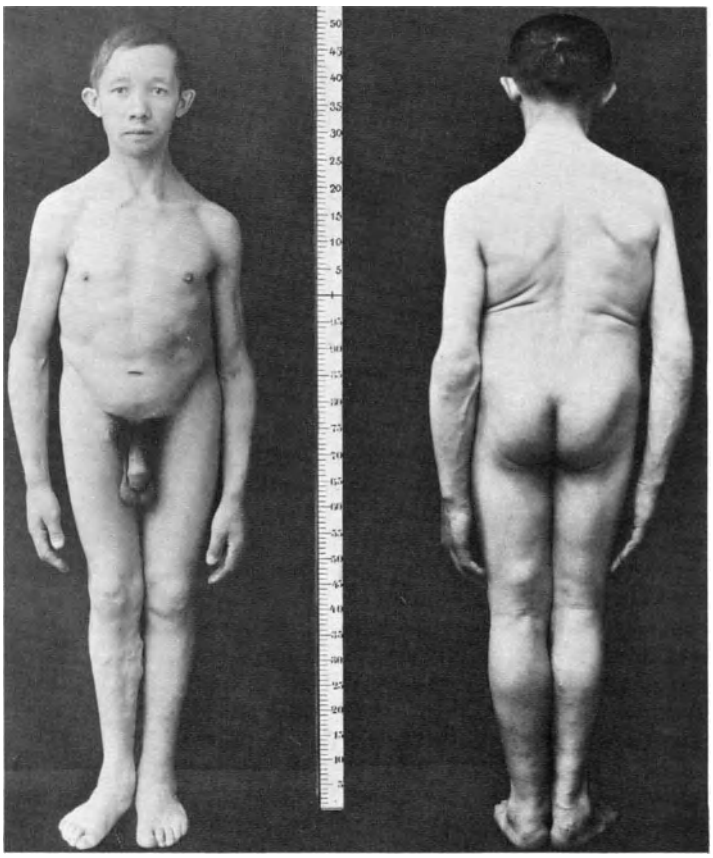

Fig. 25. Kyphoscoliosis, shortening of body and consecutive folding of the skin of the trunk in primary hyperparathyroidism. The hands reach down to the knees

tion of compression folds across the skin on the trunk. These patients appear to have arms which are much too long in relation to the trunk (Fig. 25). The ratio of half the arm span: the length of the upper part of the body: the length of the lower half of the body is no longer 1:1:1. Shortened, thickened fingers with an appearance reminiscent of clubbed fingers are also typical. In contrast to true clubbed fingers due to hypertrophy of the soft tissue, the cause in these cases is compression of the soft tissue due to acro-osteolysis (X-ray findings, p. 915). Slight thickening of the skeletal structures is also noted occasionally and is due to cysts in the bones and to osteoclastomas (X-rays, p. 915). An osteoclastoma can develop with no other demonstrable features as a circumscribed tumor of the jaw, in which case it is called an epulis. Not all epulides are due to hyperparathyroidism, but a thorough examination for hyperparathyroidism should be made nonetheless in every case with an epulis. Much too frequently an epulis is known about for years and is treated surgically as a giant cell tumor or by irridation. It may even be cured, while the fundamental disorder progresses further and in some cases develops into irreversible nephrocalcinosis (HELLSTRÖM and WELTI). In rare cases, the involvement of the jaw bones leads to sudden loosening of the teeth with subsequent loss of healthy teeth. The skeletal disturbance exceptionally presents first as a spontaneous fracture at the site of a bony cyst or of an osteoclastoma, or also away from such a focus. The tendency to heal, however, is good. When the fracture penetrates a thin-walled cyst, consolidation is sometimes possible only after the removal of the parathyroid adenoma (Fig. 29).

All these skeletal changes can be detected clinically, providing they are looked for. It is important to diagnose them, since they allow the exclusion of joint diseases, intervertebral disk disorders, and inflammatory and tumor-like disorders of the locomotor system. It must be remembered, however, that gout or pseudogout (chrondocalcinosis), i.e., a joint disease, is seen in about 5% of cases of primary hyperparathyroidism. The idea that a painful disorder of the locomotor system is due to either a skeletal

or a joint disease, but not to both at the same time, is not always correct.

The bone pains become very acute during the night in some advanced cases. In these cases they are not limited to the site of healed or badly consolidated fractures, but involve the whole skeleton. The stability of the skeleton can be reduced to the extent that the long bones and the pelvis become bent even in the absence of fractures. Nursing is thus made difficult, since every contact with the patient causes him intolerable pain. The patients usually die of the advanced nephrocalcinosis present at the same time.

β) X-Ray Examination of the Skeleton

This reveals primarily the generalization of the disorder (osteitis generalisata), and allows differentiation of circumscribed skeletal disorders (Sudeck syndrome, Jaffe-Lichtenstein disease, Paget's disease) from most metabolic disorders of the skeleton (osteoporosis, osteomalacia, primary hyperparathyroidism). In severe cases, the atrophy of the bone can be recognized at almost any part of the skeleton. The cortex appears to be rarified and porous. It may even be completely perforated and corroded. The spongiosa is not well defined. It looks like cotton wool and the radiological contrast is poor. X-ray of the lumbar vertebrae shows the typical biconcave fish vertebrae, and the bodies of the thoracic vertebrae are wedge-shaped and deformed. Fractures of the bones are common, and bending of the bones is less often observed. They can give rise to heart-shaped deformation of the pelvis.

In addition to the severe, generalized atrophy of the bones, a series of other symptoms are known to be specific to hyperparathyroidism: subperiosteal resorption, acro-osteolysis, bony cysts, osteoclastoma, and a ground-glass appearance of the skull. Occasionally they are also seen in a milder form in renal osteitis of secondary hyperparathyroidism (p. 936f.).

X-Ray Examination: Subperiosteal Resorption. This is an early symptom and one of great importance in the differential diagnosis from osteoporosis and osteomalacia in particular. In osteoporosis, even in the advanced stages, the cortex is rarified but still sharply defined. In osteomalacia, involvement of the cortex begins relatively late and is only slight (Fig. 26), while in hyperparathyroidism, subperiostal resorption zones and atrophy of the cortex can be ob-

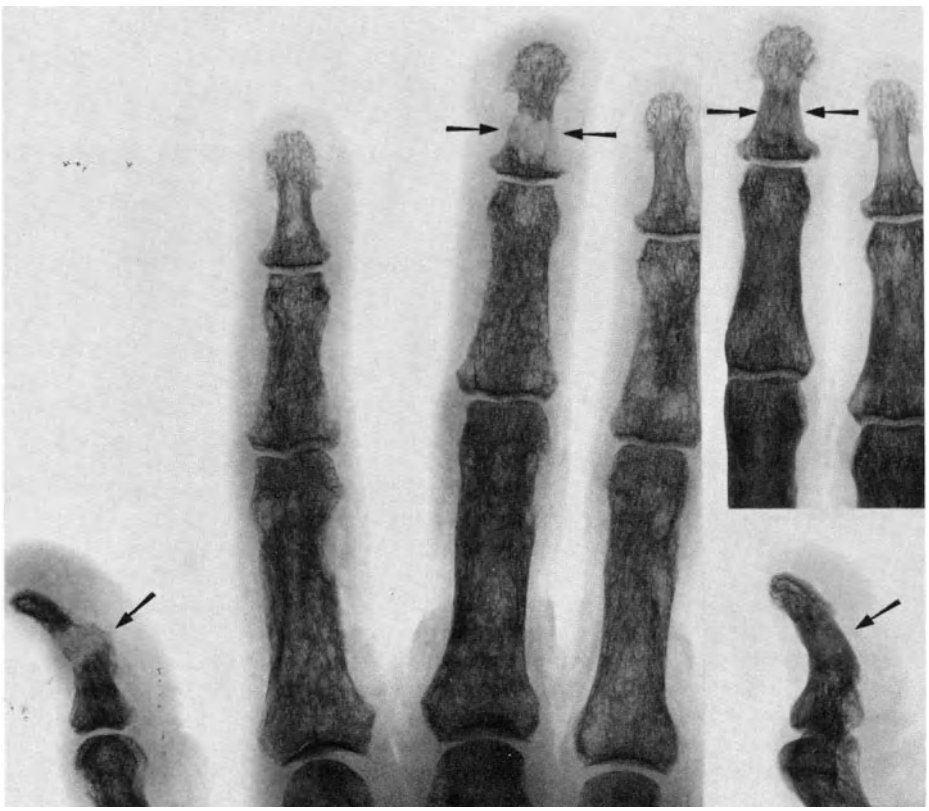

Fig. 26. General atrophy of bone and multiple zones of Looser in osteomalacia. Healing after treatment with Vitamin D.

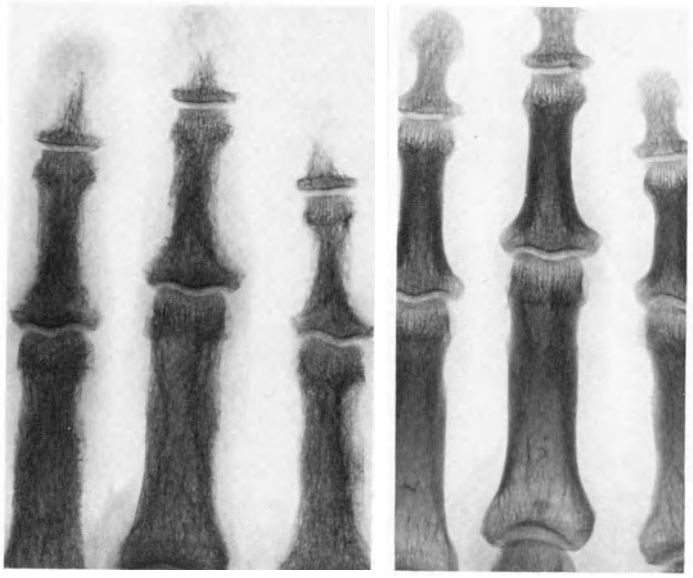

Fig. 27. Subperiosteal resorption and acro-osteolysis of the end phalangi of the fingers in primary hyperparathyroidism. Healing after extirpation of parathyroid adenoma

served at an early stage. The cortical atrophy is most impressive in the middle phalange of the middle finger (Fig. 27). The cortex appears to be very rarified or even finely granulated. The outer silhouette of the bone is no longer recognizable in many places, so that the spongiosa appears to form the edge. This phenomenon is referred to as spongio-

a b

Fig. 28. a) Acro-osteolysis of the acromioclavicular joint in primary hyperparathyroidism. b) Healing after extirpation of parathyroid adenoma

sation of the cortex. In other places, the cortex immediately below the periosteum is sometimes still present in parts but fully resorbed over other parts. These particularly typical, ribbon-like narrow defects sometimes extend for several millimeters parallel to the outer contour and are described as subperiosteal resorption (Fig. 27). Subperiosteal resorption can also be recognized in the cortex of the alveola of the teeth, where it is termed as loss of the lamina dura. Great stress used to be laid on this symptom, but it is unreliable since it is too dependent on the occurrence of paradentosis. A disappearance on porosity of the cortex can be seen in the bony walls of the paranasal sinuses (Fig. 31) and furthermore in the outer borders of the pubic and ischiopubic rami.

X-Ray Examination: Acro-Osteolysis. This term describes pronounced cortical resorption of multiple terminal bone structures. It is most severe in the distal phalanges of the fingers, where it can lead to the complete disintegration of the bony structures, so that only a few traces of the spongiosa scattered in the soft tissues are still recognizable (Fig. 5). The changes lead to clubbed fingers, with distension and deformation of the terminal phalanges, as has been mentioned already. Acro-osteolysis is occasionally also seen at the upper ends of the fibula and tibia, the pubic symphysis, at the sacroiliac joints and in a severe form in the acromioclavicular joints. The articular ends of the clavicle and the acromion appear disintegrated and corroded, their contours have a finely serrated appearance (Fig. 28). This feature is particularly valuable for diagnosis, since it is occasionally discovered at a routine chest X-ray in the absence of clinical symptoms or any suspicion.

X-Ray Investigations: Bone Cysts and Osteoclastomas (osteitis cystica). These are not mandatory findings, but their presence is an important diagnostic index of hyperparathyroidism. Differentiation between osteoclastomas and true cysts is not possible on X-ray plates, and they are often collectively termed as bone cysts. Bone cysts are sometimes found in the epiphyses of the long bones situated in the

Fig. 29. Bone cyst and fracture due to cyst of the distal end of the femur; osteoclastoma of proximal end of tibia. Healing of the cyst, eburnization of osteoclastoma after extirpation of parathyroid adenoma

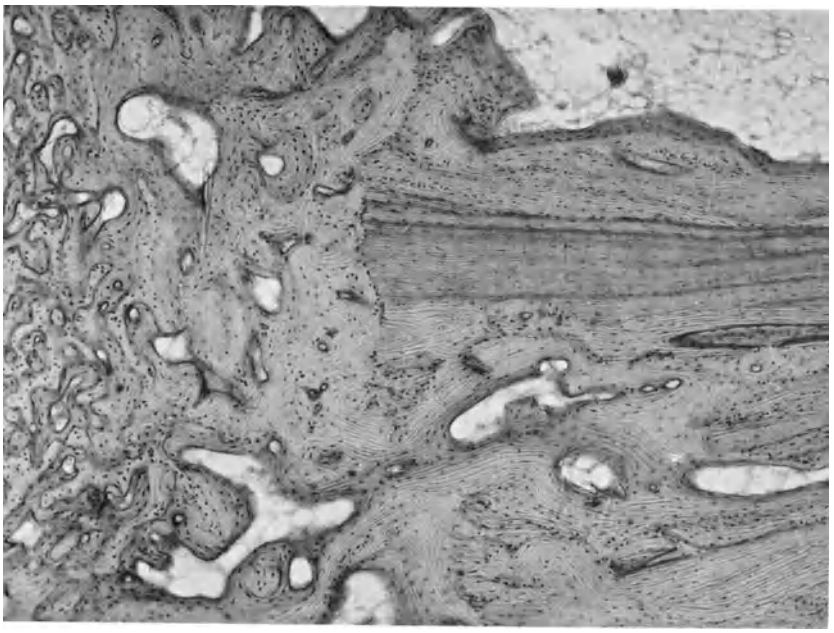

Fig. 30. Healing of a bone cyst in primary hyperparathyroidism after extirpation of parathyroid adenoma. Edge of cyst in middle of picture, right: old lamella, left: irregular zones of repair, new formation of bone

cortex or centrally. The most frequent localizations are the shoulder, the elbow, the distal end of the radius, the femoral head, the trochanter and the knee. Osteoclastomas are also found in the form of epulides in the jaw, in the cortex of the diaphyses of the long bones, in the ribs and in the phalanges. Traumatic cysts containing fluid due to hemorrhage of the marrow cannot be definitely differentiated from osteoclastomas by radiological examination. Both appear as sharply defined, round or polycyclic recesses in the structure of the bone, and can be uni- or multilocular. A tumor-like penetration is sometimes demonstrable in the cortex at the site of the bone cyst or of the osteoclastoma. During healing, which can occur spontaneously or after surgical removal of the functioning parathyroid adenoma, the osteoclastoma usually shows us an opaque eburnation (Fig. 29), whereas with true cysts only the margin of the cyst is seen at all clearly (Figs. 29, 30). Osteoclastomas and cysts can both be lost in the general faint pattern of the osseous tissue, and remain undetected during the active phases. After removal of the parathyroid adenoma, however, they are easily recognizable.

X-Ray Investigation: Ground-Glass Appearance of the Skull. The ground-glass appearance of the skull is due to the subperiosteal resorption as well as to multiple (microscopically) small osteoclastomas. Radiological examination shows a scattering of fine granules, and in advanced cases a coarse perforation of the spongiosa, giving a moth-eaten appearance. The internal and external cortex are almost completely lost (Fig. 31). Not uncommonly, the skull appears to be thickened, giving the impression of osteosclerosis. This process of sclerosis of the cranium is found predominantly during healing after removal of the parathyroid adenoma, but has also been observed in chronic advanced cases of hyperparathyroidism. The picture of cranial sclerosis in the active and healing stages has often been mistaken for Paget's disease. Differentiation is possible, however, if it is borne in mind that foci of patchy thickening are almost always observed as well as resorption in Paget's disease, in contrast to hyperparathyroidism (LIEVRE, 1959).

X-Ray Investigation: Osteosclerosis. Osteosclerosis occurs, as mentioned above, in the skull, and also sometimes in larger skeletal areas such as the pelvis (AITKEN). It can be difficult to differentiate from osteosclerosis of Paget's disease (PLATTNER). Generalized osteosclerosis, or so-called banded sclerosis of the lumbar vertebral bodies, is more often seen in secondary than in primary hyperparathyroidism (p. 937).

γ) Histology of the Skeletal Changes (Osteitis Fibrosa, Osteomalacia)

In primary hyperparathyroidism affecting the skeleton, the most important morphological

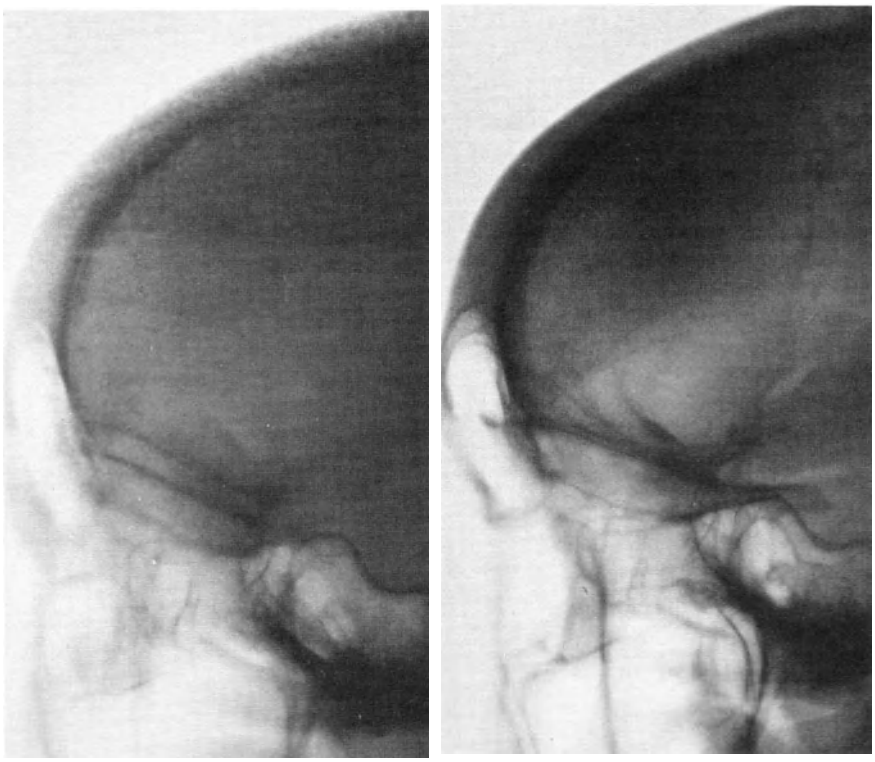

Fig. 31. Ground-glass appearance of skull. Rarification of corticalis of septs of sinuses in primary hyperparathyroidism. Healing after extirpation of parathyroid adenoma

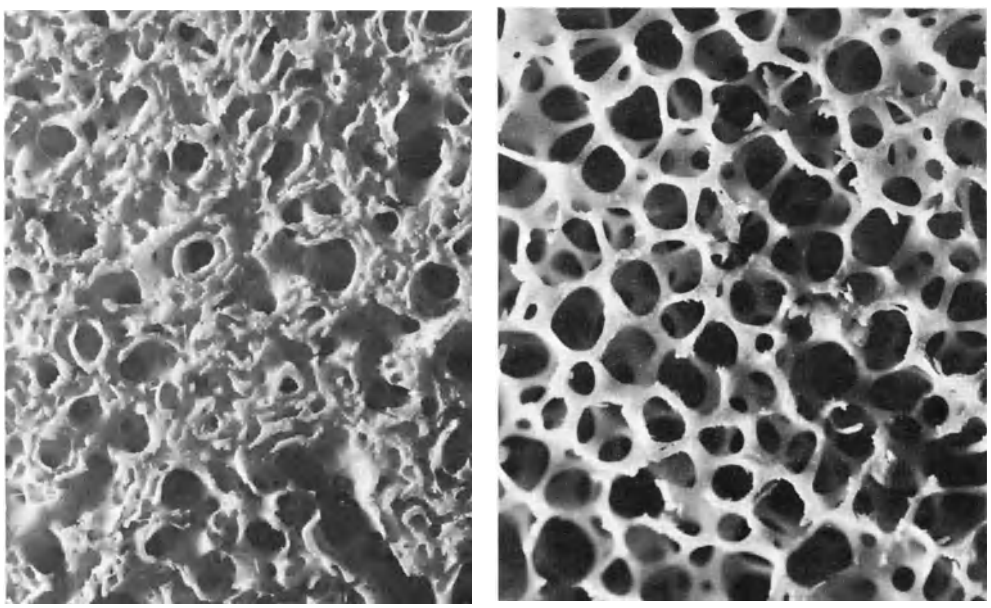

Fig. 32. Left: dissecting resorption in primary hyperparathyroidism. Magnified picture of cross-section of vertebra (maceration preparation). Right: normal vertebra

feature is osteitis fibrosa. A gross increase in osteoid tissue (osteomalacia) is only rarely observed.

Osteitis fibrosa begins in the endosteum, surrounding all the trabeculae of the spongiosa, and filling the Havers' canals in the cortex. The endosteum grows steadily from a layer which is hardly visible microscopically into a thick broad band of connective tissue. A large number of osteoblasts and osteoclasts are found

on the surface of the bone. In the advanced stages, all the osseous trabeculae are covered by a thick layer of connective tissue. This fibrous tissue then penetrates right into the center of the osseous trabeculae by fine recesses of resorption. Osseous trabeculae become excavated to form tunnels over long stretches. This process of tunnel formation is called dissecting resorption (Fig. 32). In some places, the skeletal tissue becomes completely dissolved; irregular fields of connective tissue in which numerous osteoclasts are scattered are then found. When the fields with no skeletal substance are very extensive, osteoclastomas ranging from microscopic size to the size of an apple develop. The space of the hematopoietic marrow is encroached by endosteal fibrosis, so that anemia can develop.

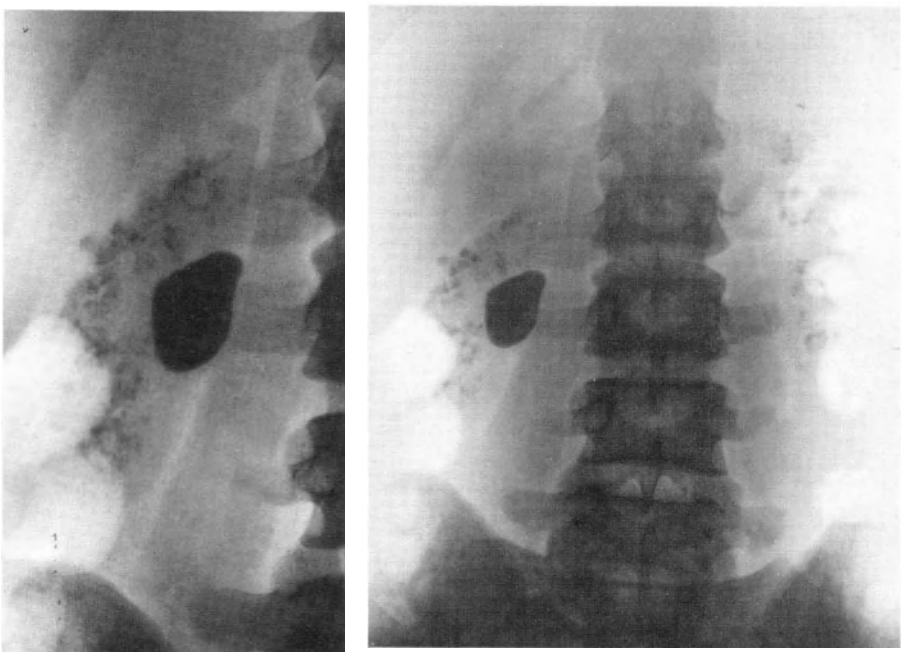
The osteomalacic component of the osteopathy is less often observed. Slightly widened osteoid margins are often seen corresponding to the greatly accelerated bone metabolism. Severely widened osteoid margins, indicating clinical osteomalacia, are only rarely observed (LICHTWITZ, 1957). They are always found in association with osteitis fibrosa as a mixed osteopathy.

There is still little known about the pathogenesis of the fibro-osteoclastic, osteomalacic and mixed osteopathies of primary hyperparathyroidism. It involves the interaction of numerous factors, which is partly synergistic and partly antagonistic. These factors are 1. the severity and the duration of the parathyroid hyperactivity, 2. the exogenous intake of calcium, 3. the intestinal absorption of calcium, 4. the impairment of the glomerular filtration of calcium or of the tubular reabsorption of calcium due to the hypercalcemia (Chap. XIV, p. 852, p. 910), 5. frequently renal insufficiency, resulting in a fall of the serum calcium, and 6. possible counterregulation by calcitonin.

c) Nephrolithiasis

Nephrolithiasis is by far the most frequent clinical symptom in primary hyperparathyroidism, both in the earliest stages and in the later course. It is found in about 75% of cases of hyperparathyroidism. The figures reported vary widely according to the classification of the patients (medical, urological, psychiatric, outpatients or inpatients). KEATING gives a frequency of 76.8% in the 380 cases seen at the Mayo Clinic. Solitary renal stones were found in 14.7%, multiple renal calculi in one kidney in 28.2%, and bilateral renal stones in 33.9%. In many cases nephrolithiasis is the only symptom of hyperparathyroidism. In addition, nephrolithiasis can occur in combination with any other signs of the hypercalcemic syndrome and with skeletal involvement.

The proportion of cases of primary hyperparathyroidism among unselected cases of



a b

Fig. 33a and b. Nephrocalcinosis and nephrolithiasis in primary hyperparathyroidism

nephrolithiasis is also the subject of speculation. Figures given vary a great deal. Most authors accept 5% as the minimum, and even 12% in cases of recurrent nephrolithiasis. McGeown in Belfast has indicated 18%, but this has not been confirmed in other regions.

Any attack of renal colic can be an early symptom of primary hyperparathyroidism. The second attack of renal colic or additional clinical symptoms of the disease may not occur for some years. However, renal colic sometimes recurs at short intervals. The renal calculi formed in primary hyperparathyroidism consist of calcium oxalate or calcium phosphate. Concretions of ammonium and magnesium phosphate can be observed in the presence of an intercurrent urinary infection. This is rare in the early stages of the illness. Urate stones are found at the same time as or alternating with stones containing calcium (Howard, 1954). The renal calculi range in size from simple gravel in the urine to solitary stones. They may also form casts, or multiple caliciform stones.

The outcome of nephrolithiasis varies widely from one individual to the other. Patients with history going back over decades sometimes show no signs of renal damage at the time of the parathyroid operation. In other cases, the condition progresses to bilateral infection of the kidneys with pyonephrosis. The prognosis of the nephrolithiasis is in general good after a parathyroid adenoma has been successfully removed. Regression of the calculi is possible after the hypercalciuria has been corrected. In many cases, numerous renal stones are excreted over the years, and any concretion remaining in the renal pelvis usually remains silent even in the presence of urinary tract infection. Recurrences or the further growth of existing stones have rarely been observed. Lithotomy should be performed only after parathyroid surgery.

d) Nephrocalcinosis

Nephrocalcinosis is much less common than nephrolithiasis (7.1%, Mayo Clinic), but the prognosis is much more serious. It has been stated that nephrocalcinosis is observed only rarely in association with nephrolithiasis. This, however, is not an absolute rule (p. 918, Fig. 33). The clinical diagnosis is made on radiological examination, which shows a few scattered or numerous dots of calcium lying very close together in the renal shadow, predominantly in the renal pyramids (Fig. 33). The comparison of X-rays made during life with those of the isolated organ at autopsy shows, however, that the nephrocalcinosis is already advanced before it can be detected on a straight abdominal X-ray or a tomogram. The early stage of the condition is not even indicated by the histological demonstration of calcification, since in experimental nephrocalcinosis the histological deposition of calcium is preceded by a very definite increase in the content of the chemically measurable calcium in the kidney. It must therefore be assumed that the first stage in the renal disorder is represented by a submicroscopical change in the tubular epithelium and in the basal membrane of the tubule. All the other stages up to complete calcification of all the epithelial tubules, the basal membranes and large areas of interstitial tissue occur after this (Engfeldt). Radiological evidence always means that the condition is at an advanced stage. We have often observed that polyuria associated with hyposthenuria is usually present at an early stage in primary hyperparathyroidism (p. 910). This loss in concentrating capacity sometimes disappears completely after the parathyroid adenoma has been removed, but sometimes it continues, especially if nephrocalcinosis is present, so that the cure obtained in primary hyperparathyroidism is only partial or temporary in some cases. It can progress to tubular disturbances and to severe glomerular insufficiency with uremia and malignant hypertension. The morphological changes causing late renal damage can be obstruction of large tubular areas and compression of the medium-sized arteries by the calcium deposition. Death follows from uremia or from a vascular complication of the hypertension. Too many cases of hyperparathyroidism are diagnosed too late and lead to fatal uremia or malignant hypertension, in spite of a successful parathyroidectomy. Only early diagnosis can avoid this.

e) Gastric Ulcer

A peptic ulcer of the duodenum or of the stomach is found in about 15% of cases of primary hyperparathyroidism. Hyperparathyroidism is therefore associated with an increased predisposition to the development of ulcers. The course of gastric ulcers occurring in hyperparathyroidism appears to be more severe than that of gastric ulcers occurring otherwise. As a rule, the clinical and radiological findings disappear rapidly after the removal of a parathyroid adenoma. It appears that the increase of the gastric secretion is due to the hypercalcemia (Barreras). The association of an ulcer with a parathyroid adenoma is of practical importance, and the possibility of primary hyperparathyroidism must always be considered in every case of peptic

ulcer which is difficult to treat (FRAME). In exceptional cases hyperparathyroidism may even be discovered because of a peptic ulcer. Treatment of an ulcer with milk and alkaline salts is not only useless but also dangerous in the presence of primary hyperparathyroidism as it can lead to hyperparathyroid crisis by the summation of two hypercalcemic factors: hyperparathyroidism + milk-alkali syndrome. Primary hyperparathyroidism must always be considered when short-term treatment of an ulcer with milk and alkaline salts causes an unfavorable reaction with nausea and vomiting.

Peptic ulcers in the Zollinger-Ellison syndrome are discussed in Chap. XV (p. 971).

f) Pancreatitis

Pancreatitis is observed more frequently in primary hyperparathyroidism than among healthy individuals chosen at random. KEATING found it 10 times among 380 cases at the Mayo Clinic (2.6%). More recent investigators give higher figures (MIXTER 7%, KYLE 12%, LUDWIG 19%), which may possibly be due to the fact that even patients with mild forms of pancreatitis are very carefully examined for hyperparathyroidism. All forms of pancreatis can be present in primary hyperparathyroidism: acute recurrent, subacute recurrent, chronic with abdominal pains, or chronic without pain, but with nausea, vomiting, diabetes and steatorrhea. During the course of acute pancreatitis, hypocalcemia and hypophosphatemia develop almost regularly during the first or second day, reaching the lowest levels between the fourth and seventh days. So far, hypocalcemia has been attributed to the binding of large amounts of calcium in the region of the necrotic adipose tissue, and also to activation of trypsinogen due to the elevated serum calcium ions concentration. Recently, however, PALOYAN has put forward the view that the massive release of glucagon demonstrated during attacks of pancreatitis is responsible for the hypocalcemia (the action of glucagon causing a fall in the serum calcium and a release of calcitonin). It is important to diagnose hypocalcemia after pancreatitis, since it may mask the hypercalcemia of primary hyperparathyroidism. Primary hyperparathyroidism must be considered in every case of pancreatitis, and the serum calcium should not only be estimated during the acute phase but several times 1–3 months afterwards.

PALAYON considers the hypocalcemia which has been postulated but never confirmed in chronic pancreatitis is a cause of secondary hyperparathyroidism.

g) Band Keratitis, Conjunctival Calcification

Superficial deposition of calcium in the Bowman's capsule of the cornea has been observed in all forms of hypercalcemia, including primary hyperparathyroidism. As a rule, the calcifications are seen only in the lateral region of the palpebral fissure, in the form of ill-defined, patchy grey opacities, usually in a sickle-shaped formation along the margin of the cornea. This condition can be differentiated from arcus senilis by the very superficial localization of the lesions. The initial stages can only be recognized with the aid of a slit-lamp. Occasionally, subepithelial, superficially situated, round glass-like particles consisting of calcium are also found in the conjunctiva in the region of the palpebral fissure. The conjunctiva is nearly always inflamed in the region of the particles, and the patient complains of conjunctival irritation.

Very intensive marginal keratitis, with identical morphology, involving the entire palpebral fissure like opalescent glass, is occasionally found in the absence of hypercalcemia. It occurs as a dystrophic calcification in intraocular inflammation of different types.

h) Hyperuricemia and Gout

Hyperuricemia and gout are more frequently observed in patients with primary hyperparathyroidism than in the average population (hyperuricemia in approximately 50–60% of all cases of hyperparathyroidism, gout in 5–25% depending on the author). However, it is still not known whether the hyperuricemia and the gout are results of the renal insufficiency in primary hyperparathyroidism (SCOTT), or whether there is a genetic relation between gout and hyperparathyroidism (MINTZ, TURRIAN). It is also possible that the transport of uric acid through the renal tubules is impaired by the calcification, as is supported by the fact that cases of gout have also been described in hypercalcemia of sarcoidosis, and in pseudohypoparathyroidism with calcification of the soft tissues (SCOTT, 1964). In the differential diagnosis, it must be remembered that the articular changes cannot be interpreted as an argument against primary hyperparathyroidism, since attacks of gout and chronic gout of the joints are to be expected in a certain number of cases of hyperparathyroidism. Systematic investigation of every case of hyperuricemia and of gout for primary hyperparathyroidism has so far proved disappointing, however: SCOTT (1964) for example, did not detect a single of hyperparathyroidism in 100 cases of gout.

i) Pseudogout (Articular Chondrocalcinosis)

Like gout, pseudogout is found more frequently in patients with primary hyperparathyroidism than in the average population (in 2.5–7.5% of all cases of hyperparathyroidism, McCarty). The acute form of this clinically uncommon condition shows great similarity with an attack of monarticular gout, but it is the knee joint and not the big toe which is most often involved, and colchicin has no therapeutic value. In addition to the acute form, there is a chronic, polyarticular course. The fluid obtained from the joint during the acute phase contains numerous small crystals of calcium pyrophosphate, which almost proves the diagnosis (Mc Carty). The same crystals can also be demonstrated scattered diffusely or localized in articular cartilages (Aitken), ligaments, tendons and menisci. On radiological examination, they appear as a fine punctate haze, as bands, or as lines. Pseudogout does not only occur frequently in primary hyperparathyroidism, but also in diabetes mellitus (40–60%), whereas classic gout occurs in 4% and hyperuricemia in 35% of cased. It an be concluded that the deposition of calcium crystals is only partly due to the hypercalcemia of primary hyperparathyroidism (McCarty).

j) The Hypercalcemic Syndrome

This term includes a series of clinical symptoms arising directly from hypercalcemia, which are not associated with marked morphological changes, and usually disappear rapidly after correction of the hypercalcemia. The hypercalcemic syndrome does not only develop in primary hyperparathyroidism, but has also been observed in hypercalcemia of different etiologies. The clinical symptoms are: mental and neurologic changes, polydipsia, polyuria, loss of appetite, meteorism, vomiting, constipation, muscular weakness, and bradycardia. According to general opinion, skeletal and renal changes, peptic ulcers, gout, pseudogout and pancreatitis are not part of the hypercalcemic syndrome. However, symptoms of hypercalcemic syndrome usually are associated with the classic symptoms of primary hyperparathyroidism, i.e. the skeletal and renal changes, but they can also occur on their own, and according to Keyne's estimate, do so in 15% of all cases. Mild hypercalcemic symptoms are not noticed by many hyperparathyroid patients. Only after successful surgical treatment with the re-establishment of normal conditions, do they notice in retrospect that numerous symptoms have disappeared.

α) The Hypercalcemic Syndrome: Psychic and Neurologic Changes

The accounts in the medical literature are limited to case histories or enumeration of single symptoms such as depression, apathy, agitation, hallucinatory phenomena, and paranoia.

Bleuler was the first to attempt to classify the various mental changes in endocrine diseases. He found initially that mental changes could arise with almost all endocrine disorders, and also showed that these mental changes were on the whole similar to each other, regardless of the underlying endocrine pathology. He divided them into two well-defined forms according to their psychopathologic picture. The first form is a chronic type, the so-called localized psychosyndrome in the brain. Bleuler called it an *endocrine psychosyndrome*. There is considerable evidence that the mental changes observed in this condition are due to localized metabolic disturbances in the brain (similar psychic pictures are seen after psychosurgery, after localized cerebral inflammation, in inherited systemic degeneration, and in experimental investigations on the localized effects of hormones on different parts of the brain). The clinical picture takes the form of changes in mood, and changes in initiative and the individual drives. The second form of the endocrine psychic disorder is observed much less frequently and is due to diffuse brain damage. Its psychopathology is of the *acute, exogenous reaction type* (Bonhöffer). It presents clinically as a state of confusion or somnolence progressing into pre-coma or coma, or as a state of excitement or confusion with exaggerated emotions, hallucinations, dreams and delusions.

In primary hyperparathyroidism, it is usually the changes associated with the endocrine psychosyndrome which are observed. Its incidence is difficult to estimate. Petersen, a student of Bleuler, made a thorough investigation of 54 cases, and found significant disturbances in one third, mild psychic peculiarities still within normal limits in another third, and no deviations from normal in the last third of his hyperparathyroid patients. In general, severe changes are predominantly observed in the presence of highly elevated serum calcium concentrations (Petersen). The patients do not really appear to be ill, but seem affected, depressed, peculiar or childish. The changes in their mood and drive can be chronic, but they characteristically arise without warning, and disappear after some time just as unexpectedly. The patients are occasionally euphoric, irritable and spiteful, but more often they are depressive. The patient feels he is not fit to live, loses all

motivation, gives up fighting for his existence and say he wishes to die. From here onwards, all intermediate stages up to severe depression are found. The patients often also complain of mild symptoms such as tiredness, headaches, and confusion. In other cases, exaggerated sensitivity and irritability are the predominant features. These deviations usually all disappear a few weeks to 6 months after removal of a parathyroid adenoma. Changes in individual drives, such as hunger, thirst and aggressivity, are relatively frequent in primary hyperparathyroidism. It must be assumed that the polyuria and the polydipsia are also due to a renal mechanism (p. 910). Loss of appetite can be considered a disturbance in the drive, and also a result of the meteorism and constipation, which are common in primary hyperparathyroidism. The disturbance of the emotional state is thus much more pronounced than the changes in the individual drives in the endocrine psychosyndrome.

KIND, an associate of BLEULER, has already described several typical cases of the *acute, exogenous reaction type* (BONHÖFFER), which generally occurs only if the serum calcium concentration is over 16 mg/100 ml, in primary hyperparathyroidism. The main symptoms are memory disturbances, clouding of consciousness, drowsiness, disorientation and confusion. Most reports in the medical literature relate the organic confusion and disorientation to paranoia and schizophrenia. This is incorrect. These psychic changes, although due in general to severe, diffuse brain damage, can also disappear rapidly after treatment of the hypercalcemia.

Finally, some patients suffering from hyperparathyroidism with slight psychic disorders go through a hypocalcemic phase after removal of the parathyroid adenoma, and can be precipitated into a severe state of confusion. The reactions of these patients to treatment are quite variable. The emotional disturbance can disappear instantaneously after the serum calcium has been normalized. In some cases, the disappearence is only temporary, and the condition recurs after a short time. The further course of the condition is unpredictable. The state of confusion varies without any clear connection with the treatment carried out, and even without any correlation with the level of the serum calcium. Recovery may occur suddenly for no obvious reason (KIND and WERNLY, 1942). According to BLEULER, either hyperparathyroidism and hypoparathyroidism lead to similar psychic symptoms, or the psychic changes are related to the magnesium and not to the calcium levels, as hypomagnesemia also occurs in the postoperative state.

In addition to the mental changes, neurological disturbances have been observed in primary hyperparathyroidism, predominantly headaches and muscular weakness accompanied by sensory and motor disturbances of the peripheral nerves. The headaches occur frequently and are not always related to intercurrent hypertension. They do not respond to conventional analgesics but usually disappear quickly after removal of a parathyroid adenoma. The muscular weakness is restricted to generalized flaccidity, asthenia and increased fatigability on physical exertion, but exceptionally it becomes very severe, so that use of the extremities and in particular the ability to walk may be greatly impaired. The tendon reflexes are normal or slightly diminished, and diffuse muscular atrophy is occasionally found. GERSTER (1969/70) describes neuralgic pains, disturbances of the deep sensibility, of the conductance of peripheral nerves, and of the electromyogram. All these features, which are characterized mainly by severe hypercalcemia, can be cured if the parathyroid adenoma is removed within some few days or weeks, and the disturbances can disappear completely.

The increase of the protein content of the cerebrospinal fluid is of interest. It occurs in hypercalcemia of various etiologies, including primary hyperparathyroidism. In addition to primary hyperparathyroidism, the following pathologic conditions have been given as causes: idiopathic hypercalcemia, carcinoma without metastases in the brain, vitamin-D intoxication, milk-alkali syndrome (EDWARDS, 1959; KRAWITT, 1965). Only a small number of observations have been recorded, and changes in the CSF have not been seen in every case of hypercalcemia.

β) Polyuria, Polydipsia

Mild polyuria and polydipsia are frequently seen in primary hyperparathyroidism, but are rarely so severe that the patient complains of pronounced thirst. If the patient does experience thirst it is more tormenting than most other forms of thirst. It continues day and night. The patient declines milk, tea and lemonade, and requests cold water. However, no amount of fluid quenches the thirst and the feeling of discomfort remains. In contrast to this condition, the thirst encountered in diabetes insipidus is reduced by an adequate fluid intake. The polyuria in the hypercalcemic syndrome can reach 10 liters, and can be confused with diabetes insipidus. The polyuria, however, is resistant to vasopressin, and is sometimes associated with a loss of the sweat secretion.

Removal of the parathyroid adenoma reestablishes normal sweating.

The etiology of the polyuria and polydipsia has been dealt with on p. 876 and p. 910. The reader is referred to p. 932 for the effect produced on them by removal of a parathyroid adenoma.

γ) Anorexia, Flatulence, Vomiting, Constipation

Discrete forms of meteroism and constipation are almost always present in primary hyperparathyroidism. The patients often mention loss of appetite and nausea. There is a history of periodic attacks of vomiting, occurring relatively often for no apparent reason. The patients also complain of abdominal pains, even in the absence of an ulcer (p. 919) or pancreatitis (p. 920). The gastrointestinal symptoms are related to the reduction in neuromuscular excitability and are thus a direct result of the hypercalcemia. However, it has not been confirmed that cases with severe hypercalcemia suffer from intestinal disorders more frequently than those with less severe hypercalcemia. Nevertheless, nausea, loss of appetite, vomiting and loss of weight are never absent in severe hypercalcemia. Severe vomiting always implies the onset of the very dangerous acute form of hyperparathyroidism (p. 923 f.).

δ) Circulatory Symptoms

Bradycardia is observed most frequently and must be mentioned first, followed by the electrocardiographic findings. The typical ECG findings for hypercalcemia, with a shortening of the Q-T interval, are less often encountered than the prolongation of the Q-T found in hypocalcemia. The hypercalcemia can therefore rarely be diagnosed from the ECG alone. The fact that an increase in the calcium ion concentration in the extracellular space enhances the effect of digitalis is of practical importance. Great caution must therefore be exercised in using digitalis and strophantine in hyperparathyroid patients with hypercalcemia. The same is true of adrenaline.

k) Acute Hyperparathyroidism

A very dangerous, acute exacerbation of hyperparathyroidism may suddenly arise without apparent cause. This acute phase is similar to the state caused by experimental poisoning with parathyroid hormone, and is known as acute hyperparathyroidism or parathyroid crisis. An excessive concentration of calcium in the blood is the initial characteristic biochemical finding. In the later course of the crisis, severe hyperphosphatemia also develops. The parathyroid crisis can develop from the chronic cases of previously existing primary hyperparathyroidism slowly or unexpectedly. Sometimes, however, it occurs suddenly without any premonitory symptoms. The situation usually becomes serious when the calcium level exceeds 17 mg/100 ml. The highest recorded values are about 21 mg/100 ml. Shortly before the crisis, there is vomiting or polyuria, or both. In the acute condition, there is severe generalized dehydration. Circulatory collapse, renal failure, hyperpyrexia, confusion, hallucinations, somnolence and coma have been observed. Hyperphosphatemia develops as a result of the renal failure. The simultaneous oversaturation of the serum with calcium and phosphate in a state of severe dehydration leads to the deposition of calcium in almost all the tissues, kidneys, lungs, gastric mucosa, arteries, periarticular tissues, conjunctiva, cornea, tympanic membrane, myocardium and skeletal muscles, parotids, pancreas, thyroid and liver. Thromboses are occasionally found, most often in the arcuate and interlobular veins of the kidneys; according to STEMPL, this is another factor in the etiology of the terminal uremia. Hemolysis and parenchymatous jaundice have been reported, as has intravascular clotting.

It has been postulated that an acute rise in the release of parathyroid hormone is the cause of the acute crisis. In this light, the clinical picture is identical to that of experimental parathyroid hormone poisoning. It has also been repeatedly observed that crude palpation of a parathyroid adenoma can precipitate a parathyroid crisis. In recent years, however, it has become apparent that the excess parathyroid hormone is not the only factor and probably not even the most important cause of a parathyroid crisis. More frequently acute hypercalcemia arises in the presence of known or unknown primary hypercalcemia when a second pathogenic mechanism favoring the development of hypercalcemia is introduced, such as the administration of vitamin D. Parathyroid hormone and vitamin D act synergistically to produce mobilization of calcium from the bones, and the calcium mobilization is potentiated by the presence of elevated concentrations of both parathyroid hormone and vitamin D. A similar potentiation can be caused by the following pathogenic factors: postoperative immobilization, BLACK warns that surgery should never be performed in patients with primary hyperparathyroidism unless the patients are well hydrated and the serum calcium lowered if possible. Hyperparathyroidism can be potentiated by high doses of oral calcium (COLLIP),

by chlorothiazides and treatment with milk and alkaline. The unfavorable effect observed in the treatment of peptic ulcers in primary hyperparathyroidism and all other factors which can be considered as possible causes of hypercalcemia are summarized in Section α, p. 927.

Treatment of the parathyroid crisis has been dealt with on p. 933.

6. Diagnosis

The diagnosis of primary hyperparathyroidism is based largely on laboratory findings, but clinical diagnosis is sometimes possible: the clinical suspicion gives the first impetus, the laboratory investigations confirm or contradict the clinical suspicion. There are no serious difficulties in recognizing the advanced forms of the illness with extensive skeletal and renal involvement. Care and thoroughness are necessary for early diagnosis of the disease, which is only possible if the doctor considers the possibility of primary hyperparathyroidism when faced with a series of apparently trivial symptoms such as renal colic, spontaneous fractures, vague abdominal symptoms, gastric ulcer, and tiredness, headaches and depression. Special attention should be given to patients who present with several suggestive symptoms. Table 8 gives a survey of the clinical, radiological and laboratory features considered as positive evidence.

Finally, there are cases of clinically symptomless hyperparathyroidism, which can only be detected by systematic estimation of the serum calcium and parathyroid hormone concentrations. The conclusive investigations carried out by BOONSTRA have already been mentioned above (p. 904). It is thus advisable to estimate the serum calcium at least once in every patient admitted to hospital.

Laboratory Tests. Repeated demonstration of hypercalcemia is the most important step in the diagnosis of primary hyperparathyroidism. The existence of a normocalcemic form of primary hyperparathyroidism with recurrent nephrolithiasis as an isolated clinical symptom is discussed in the section on the differential diagnosis of idiopathic hypercalciuria on p. 929. The detection of hypophosphatemia or hypercalciuria is considerably less reliable. Up to now, the only single test of parathyroid function which also allows a conclusive diagnosis is radioimmunologic determination of the parathyroid hormone concentration in the serum. A critical account of these tests is given on p. 941. The tests measuring the phosphate clearance must be used cautiously. In many cases, the diagnosis of hyperparathyroidism is made by a process of elimination when no other cause for hypercalcemia can be found. The cortisone test after DENT is the best method for differentiating between hypercalcemia due to hyperparathyroidism and that due to some other factor, but this method is not infallible.

Table 5

Clinical evidence
Renal colic, concretions containing calcium
Polyuria, polydipsia
Sacral and limb pains
Thoracic kyphosis, compression folds on the trunk
Spontaneous fractures
Clubbed fingers
Tumors of mandible and maxilla (epulis)
Anorexia, meteorism, intermittent abdominal pains or dyspepsia
Peptic ulcers refractory to therapy
Vomiting after milk-alkali treatment
Recurrent pancreatitis
Asthenia, muscular adynamia
Tiredness, malaise, headaches
Depression, irritability, aggressiveness
Confusion, hallucinations
Somnolence, apathy, coma with hyperpyrexia
Band keratitis, subconjunctival calcifications
Gout, hyperuricemia, pseudogout
Tetany in newborns (maternal hyperparathyroidism)
Radiological evidence
Generalized skeletal demineralization
So-called osteoporosis
Spongiosation of the cortex
Subperiosteal resorption of the phalanges
Acro-osteolysis (fingers, acromioclavicular joints)
Bone cysts
Epulis
Ground-glass appearance of the skull
Nephrolithiasis
Nephrocalcinosis
Laboratory evidence
Elevated level of immunoreactive parathyroid hormone in the serum
Hypercalcemia
Hypophosphatemia
Elevation of the alkaline phosphatase
Hypercalciuria (24-hour urine)
Unexplained uremia
Unexplained isosthenuria
Shortening of the Q-T interval in the ECG

The localization of a parathyroid adenoma can rarely be determined by palpation, and a thyroid node cannot be excluded. Most intrathyroidal parathyroid adenomas are situated in the lower pole of the thyroid, which can be significantly enlarged on palpation. The radiological identification of a parathyroid adenoma is rarely sucessful, mostly in cases of large cystic adenomas in the mediastinum.

Arteriographic and scintigraphic methods are equally unsuccessful so far. Better results were obtained, however, by preoperative cathe-

terization and radioimmunological measurement of the parathyroid hormone concentrations in 8 large veins of the neck and of the superior aperture of the thorax (REITZ, 1969). REISS and CANTERBURY (1969) used the immunoassay for parathyroid hormone, introducing a different method for the lateral localization of parathyroid adenomas, which is easier but less reliable. First, the basal value of the parathyroid hormone concentration in serum is determined. Then one side of the neck is squeezed from the clavicle and along the trachea for 10–20 sec, and two hours later the same procedure is repeated on the other side. The parathyroid hormone concentration is checked in two further serum samples 1 min after the squeeze on each side. On the side of the parathyroid adenoma, there is usually an increase in the parathyroid hormone concentration, while on the other side the parathyroid hormone concentration does not vary from the basal value.

Recent experience suggests that cervical thermography may be a very useful method of localizing parathyroid disease and of differentiating parathyroid hyperplasia from adenomatous disease (SAMUELS, 1972).

7. Differential Diagnosis

Typical primary hyperparathyroidism is not difficult to diagnose. It is more difficult to evaluate poorly defined symptoms, noncharacteristic generalized disorders or gastrointestinal symptoms, and mental changes. It has already been stressed that it is essential that primary hyperparathyroidism be considered in the presence of symptoms of this kind.

Other diseases which have symptoms suggestive of hyperparathyroidism must also be taken into account. This applies mainly to nephrolithiasis, but also to certain skeletal conditions or radiological changes in the skeleton, nephrocalcinosis, and finally to idiopathic hypercalciuria. The single most important measurements are the determination of the serum calcium and the immunoreactive parathyroid hormone concentration.

a) Differential Diagnosis of Skeletal Involvement

The radiological findings in fully developed generalized osteitis fibrosa cystica are typical in primary hyperparathyroidism, which can hardly be confused with other skeletal disorders. The distinction from other metabolic skeletal disturbances can, however, be more difficult in milder forms and in the initial stages. This is true of renal osteopathy due to secondary hyperparathyroidism, and of the osteomalacia and the osteoporosis to a lesser extent, as well as of other nongeneralized skeletal disturbances.

α) Generalized Osteitis Fibrosa Cystica of Secondary Hyperparathyroidism

This has been observed particularly in chronic uremic renal diseases, in intestinal malabsorption, in vitamin-D deficiency of rickets in infancy, and in a very few cases of pseudohypoparathyroidism. The pathogenesis, the clinical symptoms which patients rarely complain of, the histology, biochemistry and radiological findings corresponding to those in primary hyperparathyroidism are discussed below (p. 936f.). The differential diagnosis is based on the chemical findings in the blood and on discovery of the underlying condition.

β) Rickets and Osteomalacia

These two skeletal conditions are also generalized and are characterized by the almost pathognomonic Looser's zones. Subperiosteal resorption is rarely observed (Figs. 26 and 27, p. 913f.). Acroosteolysis, bone cysts and osteoclastomas hardly ever develop. A reliable diagnosis can be made on radiological examination in many cases, based on these characteristic signs. The differentiation between renal osteopathy and intestinal malabsorption can be more difficult, since they are both mixed osteitic-osteomalacic diseases (p. 936f.). The findings in the bone biopsy, the hypocalcemia, hypophosphatemia and the elevated serum phosphatase are important for the diagnosis of osteomalacia.

γ) Osteoporosis

Radiological examination allows differentiation between this generalized skeletal affection and primary hyperparathyroidism: predilection for the vertebral column, pelvis, ribs and skull, slight involvement of the long bones, absence of subperiosteal resorption (on the contrary: well-maintained, sharply defined cortex), absence of bone cysts and osteoclastomas. Primary hyperparathyroidism mainly affects the 40–60 age group, whereas the age distribution is quite different for osteoporosis: post-menopausal osteoporosis, 5–8 years after the menopause, senile osteoporosis in the male sex in the 7th or 8th decade, idiopathic osteoporosis in the male sex (idiopathic hypercalciuria is discussed on p. 929) in the 3rd and 4th decades. The main symptoms in osteoporosis are lumbosacral pains and spontaneous fractures at typical sites (vertebral bodies, neck of femur, distal end of radius, proximal end of humerus). The

calcium, phosphate and alkaline phosphatase levels in the blood are normal in osteoporosis.

δ) Osteitis Deformans (Paget's Disease) and Polyosteitic, Fibrous Dysplasia (Jaffe-Lichtenstein Disease)

These conditions are monoosteitic or polyosteitic disorders focal but never generalized skeletal diseases. The pseudocystic changes can arise in a single place in fibrous dysplasia. When multiple pseudocysts are present, they are unilateral or segmental. The difficulties encountered in differentiating the skull in Paget's disease from the osteosclerotic skull in primary hyperparathyroidism have already been mentioned on p. 916. Alkaline phosphatase is discussed on p. 940.

ε) Multiple Myeloma

The diffuse infiltrative form of this disease sometimes simulates generalized metabolic atrophy of the bones, but the osteolytic foci of the myeloma can easily be mistaken for bone cysts or osteoclastomas. The possibility of a myeloma should always be considered in every case of a skeletal disease in advanced age. In every unexplained skeletal disorder, routine X-rays of the skull, thorax, the thoracic and lumbar vertebrae, pelvis and hand should be taken in addition to those of the affected part of the skeleton. Clinically silent lesions can thus be detected, e.g. osteolytic foci in the skull in multiple myeloma. The hematological findings and the serum proteins on electrophoresis are decisive factors in the diagnosis of multiple myeloma. The serum calcium is often elevated and rarely lower than normal; serum phosphate is normal, rarely elevated, and exceptionally reduced; the alkaline phosphatase is often normal.

ζ) Metastatic Skeletal Carcinomatosis

This condition is found particularly in carcinoma of the prostate, breast, thyroid, kidney and bronchus. Carcinomas of the gastrointestinal tract do not metastasize to the skeleton, with the exception of carcinoma of the rectum. As in multiple myelomas routine X-rays of the entire skeleton are important. Changes in the calcium and phosphate metabolism are often found in carcinoma of the prostate and of the breast (p. 927) but rarely in other types of carcinoma. In carcinoma of the prostate, the preferred localization is the pelvis. The X-ray findings can be similar to those in Paget's disease but in contrast to this disease, the osteoplastic metastases often extend beyond the cortical margin and can be seen on X-rays as-penetrations into the surrounding tissues. Another feature of Paget's disease with involvement of the pelvis is that the sacrum is practically always a site of lesions. This rarely the case in other similar skeletal disorders.

η) Solitary Bone Cysts and Giant Cell Tumors of Bones

These are circumscribed skeletal lesions. The biochemical findings are always normal. Confusion with the epulis does occur, but can be avoided if the normal biochemical findings are taken into account.

b) Differential Diagnosis of Nephrocalcinosis

Discrete depositions of calcium in the renal pyramids are quite often found on histological examination. They are of no clinical importance and cannot be detected on radiological examination. Fully developed nephrocalcinosis can be recognized even on a straight abdominal X-ray, and even better on a tomogram (Fig. 33, p. 918). Apart from primary hyperparathyroidism, vitamin-D intoxication, tubular acidosis and every form of hypercalcemia can also lead to severe nephrocalcinosis. Milder forms of nephrocalcinosis can also occur in the Franconi's syndrome, occasionally in idiopathic hypercalciuria, and in rare cases of poisoning with uranium, mercury, and oxalates. It also occurs occasionally in interstitial nephritis. The X-ray findings may sometimes be confused with depots of thorotrast, a contrast medium no longer in use, which was formely used for the retrograde pyelogram.

c) Differential Diagnosis of Hypercalcemia

Hypercalcemia is the most important diagnostic criterion for primary hyperparathyroidism, but it is not pathognomonic of this condition. It has been observed in a series of different illnesses, which are listed roughly in order of frequency below. Several hypercalcemic factors can be combined in individual cases. An example of this type is immobilization, which by itself only exceptionally causes hypercalcemia, but which in combination with metastatic skeletal carcinomatosis, Paget's disease, bone fractures, orthopedic surgery, poliomyelitis, and vitamin-D therapy sometimes produces hypercalcemia. In principle, analogous combinations of all the factors listed are possible, and some are very well known (p. 923).

α) Causes of Hypercalcemia

1. Malignant tumors, with or without skeletal metastases;
2. Primary hyperparathyroidism;
3. Hyperthyroidism;
4. Sarcoidosis;
5. D-hypervitaminosis;
6. Multiple myeloma and other hemoblastoses;
7. Estrogen and androgen treatment in malignant tumors;
8. Immobilization, e.g. after bone fracture, orthopedic surgery;
9. Paget's disease;
10. Primary bone tumors;
11. Milk-alkali syndrome;
12. Addison's disease, withdrawal of adrenocortical steroids;
13. Idiopathic hypercalcemia of childhood;
14. Thiazide diuretics.

β) Malignant Tumors

Hypercalcemia found incidentally, is due to a malignant tumor approximately as often as to primary hyperparathyroidism. Carcinoma of the breast is the most common malignant tumor giving rise to hypercalcemia, particularly during treatment with estrogens and androgens. However, other malignant tumors, such as multiple myeloma, hypernephroma, carcinoma of the prostate, bronchus, thyroid and ovary, neuroblastoma, and various sarcomas can also cause hypercalcemia. Hypercalcemia also occurs in leukemia during childhood. The serum calcium is considerably elevated in many cases, whereas the serum phosphate is only slightly elevated, normal, or reduced. Hypercalcemia is usually caused by the skeletal metastases, but occasionally it can also occur in the absence of skeletal metastases, and can disappear after removal of the malignant tumor. This is seen particularly with hypernephromas and bronchial carcinomas, which sometimes secrete parathyroid hormone (RIGGS, 1971). SHERWOOD was able to demonstrate by radioimmunological methods that parathyroid hormone levels can be elevated in serum and in tumor tissue in patients with hypercalcemia caused by various tumors. Very rarely, osteoplastic metastases of carcinomas lead to hypocalcemia (p. 897; Table 1, p. 849). Osteoclastic resorption zones are seen around skeletal metastases of paraneoplastic parathyroid hormone-producing tumors, as described by BARNICOT in 1941 with a parathyroid gland transplantation onto the surface of the skeleton (p. 874) (MELVIN, 1971).

γ) Hyperthyroidism

Hypercalciuria is almost a frequent symptom of hyperthyroidism, whereas slight hypercalcemia is found only occasionally, and marked hypercalcemia only exeptionally. An injection of parathyroid hormone produces more pronounced hypercalcemia in hyperthyroid patients than in healthy subjects, due to the summation of two hypercalcemic factors (HARRISON, 1964). Marked hypercalcemia can be expected when primary hyperparathyroidism and hyperthyroidism occur at the same time. The differential diagnosis in this case is not easy and must be based on determination of the parathyroid hormone concentration in the serum.

δ) Sarcoidosis

As in hyperthyroidism, hypercalciuria is often observed, whereas hypercalcemia is rare. Cortisone suppresses the hypercalcemia in sarcoidosis promptly and almost without exception. Patients with sarcoidosis are highly sensitive to vitamin D (danger of a hypercalcemic crisis). Sunlight alone can lead to hypercalcemia in sarcoidosis, which is still frequently mistaken for primary hyperparathyroidism. A diagnosis of primary hyperparathyroidism should thus not be made until sarcoidosis has been excluded. The situation is further complicated by the fact that there have been several reports of sarcoidosis occurring at the same time as primary hyperparathyroidism, proof of the latter condition being provided by the surgical removal of a parathyroid adenoma and radioimmunologic determination of elevated parathyroid hormone levels (p. 904).

ε) D-Hypervitaminosis

This condition was previously often observed in association with large doses of vitamin D used in the treatment of primary chronic polyarthritis, lupus vulgaris and sarcoidosis. To-day severe hypercalcemia with the full-blown picture of the hypercalcemic syndrome is encountered much less frequently, sometimes when repeated doses of vitamin D are given intermittently without sufficient indication, or with vitamin-D therapy in cases with elevated sensitivity to vitamin D. Every patient with an additional hypercalcemic factor must be considered as being oversensitive to vitamin D (p. 927). It has recently been demonstrated that hypersensitivity to vitamin D is possible not only in sarcoidosis but also in tuberculosis (SHAI, 1972). In these cases normal doses of vitamin D can produce severe hypercalcemia. A history of previous treatment with vitamin D or the more or less unnoticed intake

of vitamin D in food or as multivitamin is a deciding factor in the differential diagnosis between overdosage with vitamin D and primary hyperparathyroidism, due to the close similarity of the two clinical conditions.

Administration of average doses of vitamin D occasionally makes the diagnosis of primary hyperparathyroidism difficult. Since therapeutic doses of vitamin D remain active for some weeks or even months, the biochemical diagnosis of primary hyperparathyroidism is only possible when increased immunoreactive parathyroid hormone concentrations are measured in the serum. The differential diagnosis can also be made from the clinical features and the possible cause of the hypercalcemia. If this fails in cases of mild hypercalcemia, it is permissible to wait until the action of the vitamin D has disappeared. In cases of severe hypercalcemia, however, the procedure recommended for the treatment of the acute hyperparathyroidism must be used (p. 933).

ζ) Idiopathic Hypercalcemia in Childhood

It should not be too difficult to differentiate the various forms of this syndrome from primary hyperparathyroidism, since primary hyperparathyroidism has never yet been described in children less than two years old. Idiopathic hypercalcemia is also associated with typical facial changes, debility, and multiple changes in the large arteries (WILTSE, 1966), such as supravalvular aortic stenosis.

η) Milk-Alkali Syndrome (Burnett Syndrome)

The intake of alkaline powders together with large amounts of milk over some months for the treatment of gastric ulcer can lead to symptoms very similar to those seen in vitamin-D overdosage and in hyperparathyroidism. Extensive calcium depositions, band keratitis, and calcifications of the periarticular tissue occur. In addition, there is usually severe renal failure. The metabolic picture is characterized by hypercalcemia, hyperphosphatemia, and hypocalciuria, the last being an important diagnostic feature. The condition is usually easily distinguished from hyperparathyroidism by the behavior of the calcium in the urine and the phosphate in the blood, and also by the clinical history. Difficulties can arise, however, when renal failure develops in primary hyperparathyroidism due to nephrolithiasis or nephrocalcinosis. In a case of this kind, the metabolic picture can be similar to that in the milk-alkali syndrome. Further difficulty is encountered when a gastric or duodenal ulcer arises during the course of primary hyperparathyroidism and is then treated with milk and alkaline salts. The differentiation between the Burnett syndrome and hyperparathyroidism associated with the Burnett syndrome can then be very difficult. Immunoreactive parathyroid hormone should be determined in the serum. A diagnostic exploratory operation of the cervical organs is then indicated in doubtful cases with severe hypercalcemia refractory to therapy. The treatment for acute hyperparathyroidism should otherwise be followed (p. 933).

ϑ) Immobilization

It has already been mentioned that immobilization alone very rarely leads to hypercalcemia. However, hypercalcemia occurs more frequently when an additional, even minor, factor promoting calcium mobilization occurs. As well as the factors given in section α (p. 927), the following situations have also been implicated: bone fractures in young subjects, Paget's disease, bone metastases; previous long-term treatment with vitamin D for vitamin D-resistant rickets at the time of the immobilization, e.g. after an orthopedic operation.

ι) Addison's Disease

It has been known for some years that the Addisonian crisis can cause hypercalcemia. Chronic hypercalcemia in ADDISON'S disease is rare and occurs predominantly during childhood (PRADER). Mild hypercalcemia is found in about one third of untreated Addisonian patients. Hypercalcemia can also arise after total adrenalectomy and after sudden withdrawal of treatment with cortisone or ACTH.

κ) Paget's Disease

In the presence of extensive skeletal involvement, hypercalcemia can arise due to immobilization following a fracture. Previous treatment with vitamin D may even favor this complication. Hypercalcemia due to immobilization is uncommon in Paget's disease (GORDAN and LIÈVRE).

λ) Thiazide Diuretics

It has been known for some time that diuretics of the thiazide group almost always produce hypocalciuria by inhibition of the tubular reabsorption of sodium (amount of calcium excreted in the urine in 24 hours decreased by 30% or more, LICHTWITZ). The fact that the same diuretics can produce severe hypercalcemia

in the presence of a preexisting mild elevation of the serum calcium is less well known; it does, however, occur, but less frequently. VAN DER SLUYS VEER (1965) has observed this feature repeatedly in primary hyperparathyroidism. Thiazide diuretics are not known to produce an acute hypercalcemic syndrome by themselves. It is important to know about the mechanism of this type of hypercalcemia since dangerous hypercalcemia can be prevented by withdrawal of these drugs.

d) Differential Diagnosis of Hypercalciuria

Changes in the serum calcium level and in the amount of calcium excreted in the urine are generally parallel. There are two important exceptions to this rule: the milk-alkali syndrome, in which the hypercalcemia is associated with normo- or hypocalciuria, and multiple myeloma, in which hyper- normo- or hypocalciuria can be present. The absence of hypercalciuria is due to renal failure in both cases. Primary hyperparathyroidism also exceptionally runs a course without or with only mild hypercalciuria, due to the stimulation of the calcium reabsorption in the renal tubules by parathyroid hormone, or to renal failure. In spite of this, hypercalciuria is an important feature in the diagnosis of primary hyperparathyroidism (p. 941). Since hypercalciuria has been observed in numerous clinical conditions and often in association with nephrolithiasis, as in primary hyperparathyroidism, however, the differential diagnosis must be made in every case of hypercalciuria. The table below gives the various forms of hypercalciuria with or without hypercalcemia.

Hypercalciuria resulting from hypercalcemia is due to elevated glomerular filtration of calcium, while hypercalciuria in the absence of hypercalcemia is due to impaired tubular reabsorption of calcium (p. 852). In some cases, e.g. after the administration of high doses of vitamin D, both factors can function at the same time, producing an additive effect.

Table 6

Causes of hypercalciuria

A. Hypercalciuria resulting from hypercalcemia
1. Malignant tumors with or without skeletal metastases
2. Primary hyperparathyroidism
3. Multiple myeloma and other hemoblastoses
4. Estrogen and androgen treatment of malignant tumors
5. Idiopathic hypercalcemia of childhood
6. Addison's disease

B. Hypercalciuria with facultative hypercalcemia
1. Hyperthyroidism
2. Sarcoidosis
3. Vitamin D overdosage
4. Immobilization
5. Bone fracture, orthopedic operation
6. Paget's disease
7. Primary bone tumor

C. Hypercalciuria with normocalcemia
1. Idiopathic hypercalciuria
2. Acute osteoporosis
3. Cushing's syndrome
4. Cortisone therapy
5. Vitamin-D therapy (isolated cases)
6. Tubular acidosis (isolated cases)
7. Pyelonephritis

D. Hypercalciuria with hypocalcemia
1. Vitamin-D therapy for hypocalcemic conditions occasionally early in the treatment
2. Tubular acidosis
3. Pyelonephritis

Causes of hypocalciuria

E. Hypocalciuria with hypercalcemia
1. Milk-alkali syndrome
2. Multiple myeloma

F. Hypocalciuria with normocalcemia
1. Multiple myeloma
2. Hypothyroidism
3. Growth
4. Vitamin-D deficiency
5. Intestinal malabsorption

G. Hypocalciuria with hypocalcemia
1. Hypoparathyroidism
2. Other forms of hypocalcemia

H. Hypocalciuria independent of the concentration of the serum calcium
1. Renal insufficiency

Idiopathic Hypercalciuria. It is often difficult to differentiate this condition from primary hyperparathyroidism. Idiopathic hypercalciuria is found in about 10% of patients with renal stones (MELICK). It is characterized by hypercalciuria, normocalcemia, and sometimes mild hypophosphatemia. The following clinical features are worth mentioning: recurrent nephrolithiasis (oxalate, phosphate or mixed oxalate and phosphate stones), infrequent idiopathic osteoporosis (beginning in the 3rd or 4th decade, a rare type of osteoporosis of the male sex), a strong predominance in the male sex. Idiopathic hypercalciuria can also occasionally be observed alone, in the absence of nephrolithiasis or of skeletal disturbances.

Idiopathic hypercalciuria with recurrent nephrolithiasis is the first condition to be considered in the differential diagnosis of hyperparathyroidism with nephrolithiasis. All forms of symptomatic hypercalciuria must be excluded initially in both these conditions (Table 6, p. 929). It is also advisable to estimate the immunoreactive parathyroid concentration and the serum calcium at weekly intervals for some time. In some cases, the parathyroid suppression test

after HOWARD, KYLE and HAAS (p. 943), or the parathyroid hormone test after BECKER (p. 944) can be helpful. The cortisone test after DENT is not helpful in cases of mild hypercalcemia. Some authors (MATHER, 1953; WILLS, 1969) suggest the existence of rare cases of primary hyperparathyroidism with bilateral recurrent nephrolithiasis as an isolated clinical symptom with normal laboratory findings. Since differentiation from idiopathic hypercalciuria would not be possible in these circumstances, they recommend exploratory revision of the neck if the clinical findings are alarming despite the laboratory findings. Whether this concept is correct will be demonstrated when a large number of well-documented cases with reliable radioimmunologic measurements of the parathyroid hormone concentration and perfect parathyroid histology is reported in the literature. Thiazide or phosphate can be used in the treatment of idiopathic hypercalcemia, since they reduce the calcium excretion by the kidneys (YENDT, 1966). Thiazides may cause hypercalcemia mainly in cases of preexisting mild hypercalcemia (cf. section on the differential diagnosis of hypercalcemia, p. 927). Primary hyperparathyroidism can become evident following the treatment of idiopathic hypercalcemia with chlorothiazides (DUARTE, 1971; ADAMS, 1971). Furosemides are the only diuretics which lower serum calcium.

8. Prognosis

The prognosis of primary hyperparathyroidism is determined by the extent of the irreversible limitation of renal function. Early diagnosis and treatment are therefore desirable. It is questionable, however, whether the sinister picture of uremia in the terminal stages of nephrocalcinosis or bilateral pyonephritis is applicable to most cases of hyperparathyroidism, or only to a small number of patients. We are inclined to accept the second, more optimistic, prognosis. We know of exceptional cases of primary hyperparathyroidism which have been cured spontaneously due to spontaneous necrosis of the parathyroid adenoma (p. 906). Furthermore, statistics show that primary hyperparathyroidism is a relatively common condition (5% of all cases of renal calculus according to MELICK, p. 919, 1.2% of all hospital patients according to BOONSTRA, p. 905). Only a small proportion of these cases are diagnosed, treated surgically, and cured in most hospitals all over the world. If, however, only half the unknown cases have a fatal outcome because of nephrolithiasis or nephrocalcinosis such illnesses should be observed frequently, clinically and at autopsy. We conclude that the course of the illness is more favorable than assumed and may extend over years, and that spontaneous healing of primary hyperparathyroidism occurs more frequently than was thought earlier, due to spontaneous necrosis or other unknown causes. It is impossible to give even a vague figure for the frequency of the favorable outcome.

9. Therapy

Surgical removal of the parathyroid adenoma is almost the treatment of choice for primary hyperparathyroidism (the medical treatment of hypercalcemia is described on p. 932 and p. 933). Radiation of the parathyroid adenoma has proved ineffective. A high serum calcium must be lowered preoperatively if possible.

The removal of a parathyroid adenoma requires an experienced surgeon, and patients should be referred to an adequate clinic. ALBRIGHT has expressed the opinion that the most important step in obtaining successful results in the treatment of hyperparathyroidism is the choice of the right surgeon. It is particularly dangerous when a surgeon with little experience decides "to have a look". Two results are then possible; either the removal of the parathyroid adenoma is easy and the intervention ends successfully even when performed by an inexperienced surgeon, or location of the adenoma is exceptionally difficult and the surgeon with little experience does not succeed in locating it and causes a large number of fibrous adhesions which greatly handicap a second surgical procedure. As is typical in surgery, success is only seen after the surgeon has had experience with 50 of the same sort of cases.

This very pointed statement from ALBRIGHT describes a delicate problem in hard words. It may be absolutely justified in large surgical centers, but a compromise must be made in smaller centers. In general, it is recommended that parathyroid operations should be left to the few surgeons who have had the opportunity to perform these operations frequently. In any case, it is essential for the surgeon to study the literature, even if he is not a specialist in this field. We mention here the works published by CHURCHILL and COPE and in particular the exceptionally thorough and critical monograph by BLACK.

A few fundamental points about the surgical technique will be quoted from BLACK's work at thispoint. The possibilities and limitations of preoperative localization of the adenoma have been discussed on p. 924. The surgeon must be convinced of the correctness of the

diagnosis before the operation. He must have sufficient time at his disposal for the procedure, since though the parathyroid adenoma can become visible in the field of operation within a few minutes, it can take several hours of careful dissection to find it. If an adenoma cannot be found, the surgeon must make use of the intactness of the operation field in the first operation to inspect the positions of the normal parathyroids, to mark them, and if possible to perform a biopsy. The parathyroid biopsy must be performed with the greatest care. The presence of a pathologist experienced in the histology of the parathyroids is therefore indispensable throughout the operation.

The upper parathyroids should be looked for in the following positions: on the posterior surface of the thyroid gland, in the upper and posterior parts of the mediastinum between the trachea and esophagus, and in the connective tissue around the large vessels. The lower parathyroids must be searched for at or behind the lower pole of the thyroid gland, in the upper posterior mediastinum, and in the anterior region of the mediastinum. It is important to expose the way to the lower thyroid pole by ligating the inferior thyroid vein or the ima vein when necessary. If the parathyroid adenoma is located some distance from the thyroid, there is almost always a distinct vascular stalk arising from the inferior thyroid artery and leading to the parathyroid adenoma. Some adenomas of the anterior mediastinum are an exception to this, when they develop in a primarily abnormally located parathyroid. In this case, there is no vascular stalk running up from below (cf. p. 846). The size of parathyroid adenoma expected can only be prophesied with reservations. Statistics, however, show that the severity of the hypercalcemia and the increase in parathyroid hormone concentrations are in direct proportion to the weight of the adenoma. The adenomas in cases of hyperparathyroidism with skeletal involvement are usually larger than in cases with only renal complications. The variation between these two rules, however, is too wide for the surgeon to be guided by them during the operation. Parathyroid adenomas are small in some cases, e.g. only 100–250 mg. BLACK indicates that the small adenoma can present more difficulties to the surgeon than an abnormal location, but he is more optimistic than other surgeons about the abnormal position. Among 200 operations performed for parathyroid adenomas at the Mayo Clinic, BLACK only had to search for the adenoma in the anterior mediastinum after dividing the sternum in three cases. He performs the operation under local anesthesia supplemented with nitrous oxide. Other surgeons prefer a general anesthetic. Intubation anesthesia without curare is used at the Urology Clinic at Zurich University Hospital (MAYOR). Local anesthesia, especially with adrenaline added to the anesthetic fluid, has been rejected because of the danger of ventricular fibrillation. All cardiac glycosides are forbidden in hyperparathyroid patients for the same reason (p. 923). The Kocher collar incision is made in the usual way, the thyroid gland is exposed, and the parathyroids are searched for in turn. When a parathyroid adenoma is discovered during this process, it is totally removed. Partial resections used to be carried out because of the danger of the postoperative tetany but are no longer necessary. The removal of a normal parathyroid instead of an unfound parathyroid adenoma should never be permitted (p. 890), although it is not always easy to differentiate macroscopically between hyperplastic and normal glands. If three or four normal parathyroids are located, and still no adenoma is found, intrathyroidal localization of the adenoma must be considered. Usually an adenoma of this type is enclosed in the lower pole of one lobe of the thyroid and can be recognized by a slight bulge in the thyroid at this site. If there is the slightest indication of an intrathyroidal adenoma, examination of the cervical organs must be followed by partial resection of the thyroid. MAYOR even recommends subtotal thyroidectomy, leaving the upper part of the pyramid median lobe intact in cases where the exploration of the cervical organs is negative. Inspection of the anterior mediastinum is carried out at a second operation, not less than 1–3 months after the first. In the interval it would become obvious whether the hyperparathyroidism persists, or whether it has been cured by unrecognized removal of the adenoma or by ligation of the vascular supply to the parathyroid adenoma. The calcium and phosphorus abnormalities then return to the normal state. Before the second exploratory operation is undertaken, immunoreactive parathyroid hormone concentrations in the serum should be measured and special attention paid to a possible overdosage with vitamin D or other causes of hypercalcemia. The anterior mediastinum is inspected through a division of the sternum from the manubrium to the xyphoid process, or through a transverse incision opening the thorax in the 4th intercostal space and dividing the sternum transversely. If no adenoma is found after careful dissection of the whole region, the thymus must then be removed. This is done as an ultimate procedure, after the arch of the aorta with its branches, the pulmonary artery,

the left anonymous vein and the surface of the pericardium have been exposed. If a procedure involving division of the sternum is essential, the removal of a bone biopsy must never be neglected.

A special procedure is recommended for cases of primary hyperplasia of the water-clear cells. The surgeon recognizes this condition from the gross enlargement of all four parathyroids. In some cases, one gland can be much larger than the others, simulating a solitary adenoma. In these cases the diagnosis is possible only from the biopsy, which shows the same characteristic picture in all four glands (p. 907). If the diagnosis is confirmed, all the parathyroid tissue except a small well-vascularized tissue residue of about 100–200 mg must be radically excised. It seems that it is not always easy to decide what is a well-vascularized piece of tissue. BLACK observed postoperative tetany several times among 15 of his own cases.

The problem of the risk of recurrences of multiple parathyroid adenomas (primary hyperplasia of the chief cells) has already been discussed above. Again no more than 100–200 mg of well-vascularized tissue should be left behind. BLACK recommends marking the residual tissue with a black suture, because of the danger of recurrences entailing a second operation (p. 908).

Cases in which exploration of the cervical organs and mediastinotomy yield no positive findings, and those in which hyperparathyroidism persists after removal of a parathyroid adenoma, present a difficult problem. In such cases, the diagnosis must be minutely revised, taking all the possibilities into consideration in the differential diagnosis. If the diagnosis of hyperparathyroidism is confirmed, a surgeon with wide experience in the field of parathyroid surgery should be consulted for a second operation. At this point we should like to recall the classic case of Captain Martell; a parathyroid adenoma in the anterior mediastinum was removed by CHURCHILL at the 7th operation (COPE, 1966).

The first object of any treatment adopted in the interval before a second operation must be the prevention of renal complications and of acute, excessive hypercalcemic hyperparathyroidism, because these complications are dangerous. The first and most important measure is to encourage the intake of very large amounts of fluid. This is best done by distributing the fluid over the 24 hours, e.g. by taking 600–1000 ml approximately every 6 hours, waking up once during the night as well. When excessive hypercalcemia seems imminent, the phosphate infusion which is always ready or furosemide treatment should be started without delay (p. 933).

Patients who refuse surgery or are not cured by an operation must be treated with intravenous infusions of phosphates given at regular intervals. Oral phosphate treatment can be tried in less severe cases (p. 933). There is still no experience of the results achieved with long-term calcitonin treatment. In cases of hyperparathyroidism where the diagnosis is uncertain, an attempt to reduce the elevated calcium concentration with cortisone is worthwhile.

10. Postoperative Treatment

After successful removal of the adenoma, postoperative oliguria, and an immediate reduction of the urinary excretion of calcium, magnesium and of phosphorus are usually observed at first (GOLDSMITH, 1966). The values for serum calcium and phosphorus return to normal ranges within two to three days, but it is often much longer before the hypophosphatemia becomes normal; weeks and months can elapse before it occurs, or it may even fail to occur, without causing the success to be evaluated as incomplete. If the operation is unsuccessful, the serum calcium and the other metabolic changes fail to become normal or are only partially normalized.

Postoperative tetany develops in a few cases after successful removal of the adenoma. Hyperparathyroidism without apparent skeletal involvement is rarely associated with this complication, and then only mildly, but severe tetany lasting for weeks can develop in cases with extensive skeletal involvement and elevated serum phosphatase. The etiology of the two forms of tetany is not the same. The mild, transient form associated with the extra-osseous hyperparathyroidism is probably explained by parathyroid insufficiency due to atrophy of the nonadenomatous glands remaining in the organism. Severe postoperative tetany of hyperparathyroidism with skeletal involvement is due to the excessive recalcification of the bones in addition to parathyroid insufficiency. The skeleton is deprived of mineral substances and shows a great avidity for calcium, phosphorus, and magnesium after the parathyroid adenoma has been removed. Serum calcium, magnesium and phosphorus fall to extremely low levels. The more severe the skeletal changes are with high preoperative values of the serum phosphatase, the more severe this form of the postoperative "recalcification tetany" can be.

Treatment of severe postoperative tetany should not be postponed until the full tetany syndrome develops. Tetany must be expected postoperatively in patients with a high serum phosphatase. The serum calcium must be estimated several times on the first day. Intravenous calcium and vitamin D are then given according to the method of treatment described in p. 902. As soon as oral feeding is possible, the patient receives 30–50 g calcium lactate or calcium gluconate and 50–100 mg magnesium oxidate p.o. The dose of calcium is later reduced to 10–15 g while the magnesium dose remains unaltered. When the serum magnesium falls very low, down to 0.8 mEq/liter or less, magnesium can be given intravenously in a dose of 2 mEq/kg body weight over four hours, or up to 4 mEq magnesium/kg body weight daily. This dose can later be reduced to 0.25–0.5 mEq magnesium/kg body weight/day (MACINTYRE, 1967). Prophylactic use of intravenous vitamin D immediately after the operation in cases with an elevated phosphatase is not without danger. Even the surgeon experienced in parathyroid surgery can sometimes find only one of several parathyroid adenomas which may be present, with the result that the metabolic changes of primary hyperparathyroidism persist; in a case of this type, a single large dose of vitamin D could precipitate a parathyroid crisis. If there is still a tendency towards hypocalcemia after the first acute symptoms have subsided, vitamin D in a dose of 1.25–2.5 mg (= 50000–100000 units) or dihydrotachysterol (AT 10) in a dose of 8–10 drops can be given orally each day. It may take months for the skeleton to become recalcified. Until then, treatment with oral vitamin D combined with calcium and magnesium salts should be continued.

The bone pains usually disappear rapidly after successful operations, often even within hours. The recalcification of the skeleton, however, takes several months, during which there is still a higher predisposition to fractures.

Paresis of the recurrent laryngeal nerve developing with postoperative tetany is dangerous. An intravenous calcium injection should therefore always be kept ready. In doubtful cases, tracheotomy should not be postponed too long.

Postoperative psychosis of the acute exogenous reaction type has been dealt with above (p. 922).

11. Treatment of the Parathyroid Crisis

Measures must be taken at once to ensure adequate fluid intake at the first signs of an acute hypercalcemic crisis (p. 923). The administration of calcium and vitamin D in any form is to be avoided, as is treatment with thiazide diuretics. Administration of phosphates by the i.v. route has proved the most effective treatment. They should be given as recommended by GOLDSMITH: 1 liter of a sodium and potassium phosphate buffer solution at pH 7.4, containing 0.081 mol Na_2HPO_4 + 0.019 mol KH_2PO_4, to be given over 6–20 hours depending on the renal function. In severe hypercalcemia the renal function is rarely normal and extreme caution must be applied in the intravenous administration of phosphates. The most important element in the treatment of a parathyroid crisis is a high fluid intake, which may be combined with diuretics such as furosemide, which increase urinary calcium excretion (p. 851). The serum calcium begins to fall even during the phosphate infusion and sometimes reaches normal limits on the first day. The infusion can be repeated every 24 hours or whenever the serum calcium begins to rise again. The duration of action of the phosphorus administered varies widely. The same hypocalcemic effect can be achieved with oral phosphorus in less severe states. WILSON and YENDT recommend the following mixture for the oral treatment: 2.1 g $NaH_2PO_4 \cdot H_2O$ + 30.0 g $Na_2HPO_4 \cdot 12H_2O$ in one liter of calcium-free water. 100 ml of the solution contains 300 mg phosphorus. The daily dose is 300–600 ml or 0.9–1.8 g phosphorus, divided into 4 doses. This has recently been produced commercially in the form of sugar-coated tablets, under the name of "Reducto". In the recent past, there have been objections to the treatment with i.v. phosphates (BREUER and SCHACKNEY, 1967), but there have been few cases of death occurring during or after the infusion among the numerous cases benefited by this method (KISTLER), and the cause of death was not fully clarified in any of them. These authors have recommended that i.v. phosphates not be given in renal failure. The dose can be reduced to 500–250 ml and the phosphate given more slowly. The serum calcium, phosphorus, creatinine, and urea have to be monitored at short intervals. Caution is also indicated in hypercalcemia of multiple myeloma, since renal failure is often already present. In summary, it appears that intravenous administration of phosphates is the best available treatment of acute hypercalcemia at present when carried out correctly. The most important treatment in a parathyroid crisis is a high fluid intake. This may be combined with i.v. phosphate or diuretics, such as furosemide, which increase urinary calcium excretion. Furosemide (Lasix) can be given after the patient has been hydrated with 1–2 liters

of saline. The intravenous dose amounts to 80–100 mg every 1–2 hours leading to an average daily dose of 1240 mg (160–3200 mg). This results in an increased urinary excretion of calcium, sodium, and water. It is therefore essential to check the water balance (intake and excretion) every hour, to determine the concentrations of calcium, sodium, potassium, and magnesium in the serum, and if necessary replace the sodium, potassium, and magnesium lost in the urine (SUKI, 1970). A favorable hypocalcemic effect has also been observed with sodium sulfate ions, but very large amounts must be given, which can endanger the circulation (an isotonic solution with 116.7 g sodium sulfate in 3 liters water over 9 hours, after CHAKMAKIJAN). In desperate cases, peritoneal dialysis or hemodialysis can be used. Whether calcitonin (COPE and FOSTER) or mithramycin (SINGER) will solve the problem of the treatment of hypercalcemia is not known. Trials have shown only partial lowering of the elevated blood levels of calcium of different etiologies following calcitonin (HASS, 1967). The cytostatic antibiotic mithramycin (MITHRACIN and PFIZER) has recently been introduced to lower serum calcium especially in tumor hypercalcemia or if all other therapeutic measures have failed. The drug has been used in the treatment of metabolically active Paget's disease, despite possible side effects. If the diagnosis of primary hyperparathyroidism has been confirmed or is very likely, no time should be lost in operating immediately after rehydration and reduction of the hypercalcemia.

H. Secondary Hyperparathyroidism

M. WERNLY

1. Definition

In secondary hyperparathyroidism parathyroid hormone secretion is increased secondary to various stimuli such as a lowered calcium or magnesium concentration in the serum. Synthesis and release of parathyroid hormone into the blood are increased and there is generalized hyperplasia of the parathyroid glands.

2. Morbid Anatomy and Histology

The generalized hyperplasia of the parathyroids in secondary hyperparathyroidism involves all four glands and is termed *secondary* parathyroid hyperplasia because of the special etiological factors and because it contrasts with the primary hyperplasia of the chief cells (p. 909) and the water-clear cells (p. 907). A diffuse and a microadenomatous form are differentiated histologically.

The term microadenomatous hyperplasia implies only the morphological picture and not the functional state of the glands. Microadenomas are found in morphologically indistinguishable forms in primary as well as in secondary hyperparathyroidism.

1. Diffuse hyperplasia is characterized by uniform, compact enlargement of all four glands, in which nearly all the parenchymal cells are converted into large chief cells or into small water-clear cells. There are few fat cells. The structure is compact and homogeneous. The weights of the different glands can vary widely (cf. p. 848).

2. Microadenomatous hyperplasia is due to a focal proliferation of the smaller and middle-sized chief cells. Only a few large chief cells and water-clear cells are found. Multiple proliferations arise in all sections of the glands and grow to form microadenomas of different sizes, while the original glandular lobules become compressed to narrow cellular bands during the process. There are no fat cells in the microadenomatous regions, though they may be present in the original lobules. The weight of the different glands varies widely. The total weight of the glands is higher in the microadenomatous form than in diffuse hyperplasia.

It is not possible to differentiate between the two forms of hyperplasia etiologically or functionally. Clinical data indicate that microadenomatous hyperplasia is associated with a more intensive increase in the hormonal activity than the diffuse form. The difficulties in differentiating secondary microadenomatous hyperplasia from primary hyperplasia of the chief cells have been discussed above (p. 908).

3. Incidence

As parathyroid hormone in the serum is not estimated routinely, the conditions leading to secondary hyperparathyroidism remain insufficiently explained. We can only suspect a secondary hyperparathyroidism where patho-anatomical evidence of a secondary parathyroid hyperplasia is found. This unsatisfactory criterion has now been replaced by the demonstration of increased levels of parathyroid hormone in the serum in renal insufficiency, intestinal malabsorption, infantile rickets and pseudohyperparathyroidism, which are the most common forms leading to secondary hyperplasia (BERSON, 1966; POTTS, 1969; LEGUIN, 1970; FOURNIER, 1971; HACKENS, 1972). Clinical tests, such as the measurement of the phosphate

clearance, or preferably the TmP, the measurement of the urinary hydroxyproline excretion and the morphometric evaluation of bone biopsies are valuable indications of an increased parathyroid hormone secretion in parathyroid hyperplasia. In conclusion, there is a good correlation between the pathologic-anatomical evidence of parathyroid hyperplasia and increased parathyroid hormone concentration in the serum in secondary hyperparathyroidism.

Parathyroid hyperplasia is observed in chronic renal failure and in vitamin-D deficiency. It is seen considerably less frequently and in only a small proportion of cases of leukemia, multiple myeloma, skeletal metastases, Paget's disease, liver cirrhosis and certain gangrenous infections (WERNLY, 1946).

Secondary hyperparathyroidism can also be clinically diagnosed in the presence of a typical osteopathy (subperiosteal resorption), or metabolically or morphometrically from elevated bone resorption. Clinically, secondary hyperparathyroidism can be demonstrated in rare cases of pseudohypoparathyroidism. Furthermore, increased bone destruction can be demonstrated in certain forms of osteoporosis with the aid of bone biopsies and of kinetic methods. It is not certain whether an increased release of parathyroid hormone is associated with this process.

4. Etiology

In the majority of cases, parathyroid hormone secretion is stimulated by a lowered serum calcium concentration lasting for months or years in chronic uremic renal disorders and in intestinal malabsorption. The importance of the hypocalcemia for the stimulation of the parathyroid glands has been demonstrated experimentally; perfusion experiments with thyroid-parathyroid preparations, using extracorporeal circulation, have shown that hypocalcemic perfusing blood (EDTA-hypocalcemia) results in the release of parathyroid hormone, whereas the blood draining away has hypercalcemic effects (COPP) and a radioimmunologically elevated parathyroid hormone concentration (CARE). Recently, BERSON and YALOW have even demonstrated radioimmunologically a rise in the parathyroid hormone level after EDTA- induced hypocalcemia.

Hypomagnesemia can also cause secondary hyperparathyroidism and hypermagnesemia can suppress parathyroid hormone secretion. Using parathyroid explants *in vitro*, SHERWOOD (1971) has demonstrated that the parathyroid hormone secretion is inversely proportional to the magnesium concentration in the incubation medium. Furthermore, CARE was able to suppress the parathyroid hormone secretion *in vitro* by perfusing the parathyroids with hypermagnesemic blood. Clinically, little is known about the importance of magnesium in secondary hyperparathyroidism. It is possible that hypomagnesia is the cause of the secondary parathyroid hyperplasia observed in liver cirrhosis.

It is still undecided whether there are other factors besides hypocalcemia and hypomagnesemia which cause secondary hyperparathyroidism. We cannot entirely exclude this possibility because of the only very mild hypocalcemia encountered in certain cases of chronic renal insufficiency and intestinal malabsorption, and because of the difficulty in explaining certain uncommon forms of parathyroid hyperplasia (in leukemia, multiple myeloma, metastatic skeletal carcinomatosis, Paget's disease, liver cirrhosis, and gangrenous infections). It is certain, however, that a rise in the serum phosphate alone does not lead to secondary hyperparathyroidism, because it is always associated with a lowering of the serum ionized calcium concentration (FISCHER, 1972). It appears, however, that hypocalcemia is the most important stimulus, because if phosphate and calcium are given together no increase in parathyroid hormone concentration in the serum is seen (SHERWOOD, 1968; REISS, 1971).

5. Pathophysiology

Primary hyperparathyroidism is a disease of the parathyroids, whereas secondary hyperparathyroidism is a combination of a primary disease and of a parathyroid disorder.

Secondary hyperparathyroidism due to vitamin-D deficiency is caused by the hypocalcemia found in all forms of osteomalacia. Accordingly, there is almost always parathyroid hyperplasia (WERNLY, 1946), elevated phosphate clearance, an increased urinary excretion of hydroxyproline and an increase in the number of osteoclasts, reflecting the raised parathyroid activity (NORDIN, 1956; CRABBÉ, 1965; FISCHER, 1968). The increased release of parathyroid hormone into the blood corrects the hypocalcemia, depending on the severity of the vitamin-D deficiency or resistance. At the same time it causes the hypophosphatemia characteristic of most forms of osteomalacia. The action of parathyroid hormone may be determined by the loss of the permissive action of vitamin D in osteomalacia with a strongly reduced concentration of vitamin D in the blood and the tissues (p. 876). In extreme vitamin-D deficiency, parathyroid hormone no longer acts on the bones (ARNAUD, 1966). In most cases, the

increased parathyroid hormone activity is expressed as the known, specific changes in the skeleton, associated with fibrous osteitis (TORRANI, 1924; BALL, 1960; FISCHER, 1968) together with the changes of osteomalacia.

The pathophysiology of the *renal form of secondary hyperparathyroidism* is more complex. We have already shown that hypocalcemia of long duration is the cause. Renal disorders in existence for years or going back to youth are the main cause of the severe form of renal hyperparathyroidism. These include congenital malformations of the urinary tract with chronic renal insufficiency and urinary tract infection, or chronic pyelonephritis. As in osteomalacia, the hypocalcemia is either inadequately or almost completely corrected by the increased release of parathyroid hormone. The elevated phosphate level resulting from glomerular insufficiency remains uncorrected – there is no raised phosphate excretion since the parathyroid hormone succeeds in acting only inadequately on the diminished number of renal tubules. The effects of secondary hyperparathyroidism on the bone tissue are identical to those of primary hyperparathyroidism. They are, however, complicated by osteomalacia, which is usually quite severe, although it varies widely from case to case, and which is seen together with the changes brought about by fibro-osteoclastic osteitis (MACH, FOLLIS, BERNER, and BALL). Osteoid is occasionally seen in primary hyperparathyroidism (p. 917), whereas this is always present in renal secondary hyperparathyroidism. The osteomalacia of chronic renal insufficiency is probably due to suppression of the hydroxylation of 25-hydroxycholecalciferol into 1,25-dihydroxycholecalciferol by the kidney, leading to a state which resembles nutritional vitamin-D deficiency.

Intestinal absorption of calcium and phosphorus is greatly reduced even in the early course of chronic renal insufficiency (STANBURY). The osteomalacia of chronic renal disorders is identical to the changes seen in nutritional vitamin-D deficiency. It can thus be assumed that the chronic hypocalcemia of the chronic renal failure is due in the first place to calcium malabsorption. In addition, extremely low amounts of calcium and phosphates are usually excreted in the urine, and there is an increase in the serum phosphatase depending on the severity of the secondary hyperparathyroidism. The insufficient vitamin-D activity results in deficient calcification of the newly formed bone matrix with an accumulation of large uncalcified osteoid masses.

In conclusion, the bone changes accompanying the renal manifestation of secondary hyperparathyroidism are a mixed form with fibrosis and osteomalacia. The osteomalacic components of the renal osteopathy can be therapeutically influenced by high doses of vitamin D (p. 938), although there is considerable danger of vitamin-D intoxication and soft-tissue calcification.

Parathyroid hormone secretion is highly stimulated in some cases of renal secondary hyperparathyroidism, which can cause the original hypocalcemia to give way to normocalcemia and finally to hypercalcemia. This increase of the serum calcium due to the mobilization of calcium from the skeleton is accompanied by a similar rise in serum phosphates, also due to an increase in bone resorption. The phosphate cannot be removed by the damaged renal tubules. In such cases, extensive fibrous osteitis with bone pains develops, with radiologically severe subperiosteal resorption. In addition to this, when the Ca × P product exceeds 70, metastatic calcification can occur. This represents hyperfunction of the parathyroids which has become apparently autonomous. This hypothetical assumption has recently been supported by new evidence obtained from the findings with renal transplants. It has been shown that after successful renal transplantations, the pre-operative hypocalcemia not infrequently reverts to an often temporary hypercalcemia with values of 11–13.5 mg/100 ml, with the clinical picture of the skeletal hyperparathyroidism with calcification of the soft tissues and associated with the danger of renal damage due to nephrocalcinosis (MCPHAUL and MCINTOSH). In some cases, spontaneous correction of the hypercalcemia has occurred after several weeks or months, indicating the regression of the parathyroid hyperfunction. In other cases, however, hypercalcemia has lasted months or years and subtotal parathyroidectomy has had to be performed, thus curing the clinical and radiological symptoms of the fibrous osteitis and normalizing the serum calcium concentration (MCPHAUL, p. 938). The hypothesis that fully autonomous (tertiary) hyperparathyroidism can develop from secondary hyperparathyroidism is questionable, since all forms of primary and secondary hyperparathyroidism can be suppressed with calcium infusions (POTTS, 1971; BINSWANGER, 1972). Subtotal parathyroidectomy is discussed on p. 938 and tertiary hyperparathyroidism on p. 939.

6. Clinical Features and X-Ray Findings

The bone changes in secondary hyperparathyroidism are rarely clinically evident, mainly in cases of chronic uremia. Depending on

the pathogenesis fibroosteoclasia or osteomalacia is predominant (cf. section on the pathologic histology of primary hyperparathyroidism, p. 916). Pains in the extremities are the most frequent symptom, associated with deformations in adolescents (genu valgum and varum, pectus carinatum with rachitic rosary, kyphoscoliosis, epiphysiolysis or necrosis of the femoral head). The growth in children is retarded (renal dwarfism, renal rickets). The extensive osteopathy occasionally leads to severe bone pains with difficulty in walking, and exceptionally to invalidity. In severe osteomalacic osteopathy, tetany and muscular weakness are occasionally observed in the regions of the deltoids, the supraspinatus, and the iliopsoas, and can be associated with the characteristic waddling gait. Vitamin D often brings about an impressive correction of this osteomalacic myopathy (STANBURY). A painful form of pruritus is occasionally associated with secondary hyperparathyroidism of renal insufficiency.

The radiological findings present a combination of the changes of osteitis fibrosa cystica generalisata and/or of osteomalacia. The osteitis fibrosa is visible as subperiosteal resorption and cannot be differentiated from that occurring in primary hyperparathyroidism (p. 913). The acro-osteolysis and the ground-glass appearance of the skull are also identical to the findings in primary hyperparathyroidism (p. 915). Even bone cysts and epulides have been observed in rare cases of renal osteitis. Focal osteosclerosis alone is more frequently encountered in secondary hyperparathyroidism than in primary hyperparathyroidism (p. 916). The banded sclerosis of the vertebral bodies is considered especially characteristic. It is a ribbon-like thickening of the spongiosa along the upper and lower plates of the lumbar vertebrae. Each sclerotic band thus partly borders a clear intervertebral disc and a clear central part of the vertebral body, thus producing zebra-like transverse stripes (rugger-jersey spine). Where the osteomalacia predominates, typical Looser's zones can be found in all the possible localizations of classic osteomalacia. Bending of the bones also occurs in some cases, e.g. heart-shaped deformation of the pelvis. Changes in the epiphyseal regions have been observed in young subjects and in children. These changes are similar to those found in nutritional rickets. In some cases, acro-osteolysis of the metaphyseal end of the diaphysis can develop in addition to rachitic metaphysis, so that the diaphyseal ends appear to have a moth-eaten, perforated structure. In rare cases where the Ca × P product is above 70, X-rays reveal periarticular, subcutaneous, and arterial calcifications and nephrocalcinosis.

7. Differential Diagnosis

Although primary hyperparathyroidism differs from secondary hyperparathyroidism in the early stages, differentiation between the two conditions can be difficult in advanced cases. Primary hyperparathyroidism with nephrocalcinosis, uremia and skeletal involvement is often clinically, biochemically and even pathoanatomically similar to advanced secondary hyperparathyroidism due to chronic renal insufficiency. The histological findings in the parathyroids in secondary hyperparathyroidism (microadenomatous hyperplasia, p. 934) are indistinguishable from those in primary hyperparathyroidism due to primary haperplasia of the chief cells (p. 908). As has already been mentioned, the histological skeletal findings are identical in both conditions.

A few clinical characteristics which can be used for differentiations in individual cases are outlined here. A history of nephrolithiasis is very common in primary hyperparathyroidism, whereas it is hardly ever found in secondary hyperparathyroidism. Chronic renal insufficiency, when present, is almost always connected with severe nephrocalcinosis in primary hyperparathyroidism; nephrocalcinosis rarely arises in secondary hyperparathyroidism resulting from chronic uremic nephropathy. If the symptoms date back to youth, the secondary hyperparathyroidism is usually associated with rachitic deformations. This is not seen in primary hyperparathyroidism since this disorder is rare in children. Pruritus, subcutaneous and periarticular calcifications, osteosclerosis (rugger-jersey spine), and highly elevated immunoreactive parathyroid hormone levels (depending on the antibody used) are rarely seen in primary hyperparathyroidism, but are present quite often in secondary hyperparathyroidism.

8. Therapy

The therapy of secondary hyperparathyroidism in chronic uremia is restricted to cases with clinical skeletal symptoms, tetany, myopathy or metastatic tissue calcifications. However, the cause of the secondary hyperparathyroidism, chronic uremia, has to be treated first, including the nephrogenic anemia.

Before treatment with vitamin D can be started the serum phosphorus must be lowered or brought back into the normal range with oral aluminium hydroxide (Amphojel). The purpose is to reduce the calcium × phosphate

product to less than 70 and if possible to avoid soft tissue calcifications. Only then the patients receive vitamin D orally, in an initial daily dose of 0.25–0.5 mg (1 mg = 40000 IU). If no beneficial effect is seen after several weeks, the dose is gradually increased to 12.5 mg daily. The therapeutic success can be recognized from the normalization of the serum calcium concentration, the disappearance of skeletal pains, improvement of the general condition and normalization of the radiological findings. However, since vitamin D acts slowly and accumulates in tissues such as the liver, the dose must be increased cautiously. In order to avoid any risk of vitamin-D overdosage it is essential to check the serum levels of calcium, phosphorus and phosphatase regularly. An increase of the serum calcium above the normal range should be avoided, as should high serum phosphate levels, which result in a Ca × P product of over 70.

The fall of the alkaline phosphate to normal values can be considered a sign of an established cure. When there is the slightest suspicion of vitamin-D overdosage, the treatment must be interrupted for several weeks and the clinical course observed. Because of the accumulation of vitamin D in tissues, interruption of the treatment is perfectly permissible as a precaution even if there is no special suspicion of overdosage. With the onset of recovery, the vitamin-D therapy can be discontinued while the patient remains under clinical observation, or maintenance therapy with 0.25 mg daily or 3 times weekly is introduced.

In hyperphosphatemia the serum phosphate must first be lowered with aluminium hydroxide (see above). This is even more important if the serum calcium is normal or increased and the serum phosphorus is also high, thus causing an elevated Ca × P product. Here, vitamin D would also have a favorable effect on the osteopathy, but this cure must be purchased at the price of hypercalcemia with soft tissue calcification, nephrocalcinosis and progressive renal failure. If the condition is incurable, subtotal or total parathyroidectomy may be indicated in such cases. Conditions necessary for this procedure are relatively good general health and normal or not highly elevated blood pressure. In severe renal insufficiency renal dialysis must be started first. After subtotal parathyroidectomy in which several grams of parathyroid tissue can be removed and according to WILSON a residue of 200–300 mg or 7/8 of the total glandular tissue is left behind, the levels of the serum calcium and phosphorus fall alarmingly. Vitamin D in relatively high doses of 2.5–6.25 mg per day can now be administered. The osteopathy heals clinically and radiologically, the metastatic calcifications may disappear, and the general condition improves considerably. Any doubts about the justification of subtotal parathyroidectomy in cases of chronic uremic renal disorders with a favorable prognosis have been removed by convencing reports of successful cures with considerable improvement in the skeletal pains and the general condition.

When patients in chronic renal failure are dialyzed, the calcium concentration in the dialysis bath is critical for the maintenance of secondary hyperparathyroidism. FOURNIER (1971) has demonstrated that the immunoreactive parathyroid hormone concentrations can be lowered if a calcium concentration of 8 mg/100 ml rather than 5–6 mg/100 ml is used. However, the serum phosphate must first be lowered and kept in a normal range in order to avoid soft tissue calcifications. This is achieved by oral administration of aluminium hydroxide (Amphojel). Thus a highly successful conservative treatment of severe secondary hyperparathyroidism is possible and subtotal parathyroidectomy is avoidable in a certain number of patients on chronic dialysis.

9. Normocalcemic Secondary Hyperparathyroidism

JAN A. FISCHER

The increased secretion of parathyroid hormone in the presence of hypocalcemia has already been described on p. 872 as a cause of secondary hyperparathyroidism.

When patients with steatorrhea and hypocalcemia are treated with vitamin D for short periods, the serum calcium becomes normal within days. Hyperparathyroidism persists although the stimulus for the fall in serum calcium is absent. This can be supported by the rise in the phosphate excretion index, the hydroxyproline excretion in the urine and by the increased number of osteoclasts in bone biopsies. One patient remained normocalcemic for at least 9 months before dying of encephalomalacia. The post mortem revealed generalized fibroosteoclasia and hyperplasia of the parathyroid glands. Another patient showed clinical signs of hyperparathyroidism after having been normocalcemic for over 18 months.

The phosphaturia cannot be due to vitamin D since the doses used do not produce a pathologic increase of the urinary phosphate excretion even in patients who have undergone parathyroidectomy. When the parathyroids are intact the phosphate excretion is usually reduced due to suppression of the parathyroid

glands by the simultaneous rise in the serum calcium concentration (ALBRIGHT, 1948). In contrast to the action of parathyroid hormone, vitamin D reduces hydroxyproline excretion (KLEIN, 1963).

FISCHER (1968) has described this condition as normocalcemic secondary hyperparathyroidism. It is presumably a special form of secondary hyperparathyroidism with an altered feedback mechanism in the parathyroids. In spite of the normalized serum calcium concentration, the intestinal malabsorption persists with a reduction in calcium absorption. Lowering of the serum magnesium concentration as a possible additional cause of the increased release of parathyroid hormone in spite of the normocalcemia cannot always be excluded.

The differentiation from tertiary apparently autonomous hyperparathyroidism is not always easy. The homeostatic regulation of the calcium concentration in the serum is intact in the presence of a normal serum calcium concentration.

The normocalcemic form of secondary hyperparathyroidism is also seen in nutritional rickets of infancy. As a rule the phosphate concentration in the serum is diminished and immunoreactive parathyroid hormone concentrations increased (ARNAUD, 1972). It is possible that vitamin-D deficiency independent of the normal serum calcium concentration is the cause of normocalcemic secondary hyperparathyroidism (FISCHER, 1973).

In summary, this is a form of hyperparathyroidism in which hypocalcemia, the usual stimulus for an increased release of parathyroid hormone, is absent and in which no hypercalcemia is seen, suggesting that factors other than the serum calcium concentration stimulate parathyroid hormone secretion.

I. Tertiary Hyperparathyroidism

M. WERNLY

This condition has already been discussed on p. 904 in the etiology of primary hyperparathyroidism, where it was mentioned that a parathyroid adenoma can sometimes develop from secondary hyperparathyroidism, giving rise to the clinical picture of primary hyperparathyroidism. This condition was given the name tertiary hyperparathyroidism by ST. GOAR in 1963, and DAVIS in 1956 was the first to remove a parathyroid adenoma from a patient with malabsorption. It must be added that this condition cannot be sharply differentiated from the clinical picture of severe secondary hyperparathyroidism, which STANBURY and others treat with subtotal parathyroidectomy (p. 938). In both conditions autonomous ("primary") hyperparathyroidism develops from reactive (secondary) hyperparathyroidism.

Table 7. Diagnosis of normocalcemic secondary hyperparathyroidism. CaS = serum calcium; PEI = phosphate excretion index (immunoreactive parathyroid hormone increased)

Hyperparathyroidism	CaS	OH-proline in urine	Fibro-osteoclasts	PEI
Primary	↑(→)			
Secondary	↓	↑(→)	↑(→)	↑(→)
Secondary normocalcemic	→			
Tertiary	↑			

In some cases all four parathyroids are hyperplastic, reflecting secondary hyperparathyroidism. There are, however, confirmed cases of tertiary hyperparathyroidism due to a solitary adenoma after kidney transplantation. Tertiary hyperparathyroidism can only be differentiated clinically from secondary hyperparathyroidism, and not by the histological findings in the parathyroids. There are transitional stages between normocalcemic secondary hyperparathyroidism and tertiary hyperparathyroidism. They are characterized by hypercalcemia, a rise in the phosphate excretion index, and increased hydroxyproline excretion in the urine. An increase in the number of osteoclasts is almost always demonstrable. The parathyroids secrete parathyroid hormone seemingly autonomously, independent of any regulation by the serum calcium, and it can therefore only be differentiated from primary hyperparathyroidism by a previous history of secondary hyperparathyroidism. It often arises after renal transplantation (HERDMAN and MCINTOSH).

In most patients the serum calcium concentration becomes normal after some weeks or months. When it remains elevated subtotal parathyroidectomy is necessary.

The suppressibility of the immunoreactive parathyroid hormone concentrations by calcium infusions in primary hyperparathyroidism and in secondary hyperparathyroidism of renal insufficiency (p. 911) makes it appear likely that tertiary hyperparathyroidism is not autonomous either. However, the few patients with secondary renal hyperparathyroidism who develop hypercalcemia after renal transplantation have not been fully investigated.

K. Laboratory Investigations and Function Tests in Disorders of the Parathyroids

B. COURVOISIER

BERSON and YALLOW introduced a radioimmunoassay for estimation of the parathyroid hormone concentration in plasma or serum (p. 870). Since then the sensitivity and the precision of the measurement of the immunoreactive parathyroid hormone concentration in the serum (IPTH) has been considerably improved (REISS, 1968; POTTS, 1969; ARNAUD, 1971). The principles of radioimmunological estimations of hormones have been discussed elsewhere (estimation of insulin, p. 814). The reader is referred to the literature for other methods of investigation which are of particular importance for research purposes. These include balance investigations, quantitative morphometric evaluation of bone biopsies after labeling with tetracycline, and dynamic investigations of bone metabolism with trace substances, such as stable strontium, radioactive calcium (^{45}Ca, ^{47}Ca) and radioactive strontium (^{85}Sr). They have opened up new aspects in research into bone metabolism. Only clinically applicable methods in current use are discussed below (p. 873). It must be emphasized that measurement of the immunoreactive parathyroid hormone concentration in the serum (IPTH) is essential in the diagnosis of all doubtful cases of hyperparathyroidism. The detailed clinical evaluation of IPTH is discussed on p. 897.

1. Diagnosis of Primary Hyperparathyroidism

a) Hypercalcemia

The normal range for serum calcium is 9.0–10.5 mg/100 ml. Values vary according to the methods used and from one laboratory to the other, so that it is essential that the normal range is known in each laboratory.

Hypercalcemia is a very important biological finding in the diagnosis of primary and tertiary hyperparathyroidism (several recent reports in the literature have, however, emphasized the occurrence of normocalcemia in primary hyperparathroidism (p. 904)). The serum calcium must be estimated by a very accurate chemical method. The levels of the serum proteins must be taken into account in the interpretation of the results obtained (the serum calcium is decreased in the presence of a low blood level of protein). The acid-base balance must also be considered (ionized serum calcium is raised in acidosis and reduced in alkalosis). Prolonged venous constriction must be avoided when the blood sample is taken since the calcium can rise due to hemoconcentration (DENT, 1962). Apart from this, cork stoppers must not be used to seal containers with blood samples because they contain calcium.

Ultrafiltration of plasma and estimation of the free diffusable (ionized and complex-bound) calcium are necessary for calcium clearance investigations. In doubtful cases the estimation of the ionized calcium concentration is indicated.

b) Hypophosphatemia

The normal range for serum phosphate is 4.0–6.0 mg/100 ml in children and 2.5–3.5 mg 100 ml in adults. Like hypercalcemia, hypophosphatemia is a mandatory symptom of primary hyperparathyroidism. Its value, however, is limited by the fact that phosphate is not adequately excreted in renal insufficiency which is often found in primary hyperparathyroidism. In these patients the serum phosphate concentration can be normal or increased. In the presence of normal renal function, hypophosphatemia is frequently seen in primary hyperparathyroidism.

The *combination of hypercalcemia and hypophosphatemia* used to be considered almost pathognomonic for the diagnosis of hyperparathyroidism; it has now been shown, however, that in hypercalcemia of other etiologies, serum phosphate is usually normal or slightly elevated, but that this is not a constant finding, since hypercalcemia can also be combined with hypophosphatemia in some circumstances, e.g. metastatic skeletal carcinomatosis and hypercalcemia following carcinoma without skeletal metastases. Since the levels of parathyroid hormone and an immunoreactive substance similar to parathyroid hormone in the blood have been found to be elevated in several cases of tumor hypercalcemia (p. 927), the above combinations appear understandable, at least in these cases (RIGGS, 1971).

c) Alkaline Phosphatase

The level of this enzyme in the serum appears to be an index of osteoblastic activity. Numerous methods of measurement are reported, whose results are given in different units. The normal ranges are generally well defined for each method. An increase in alkaline phosphatase is a common but not mandatory finding in primary hyperparathyroidism. Elevated levels are found almost exclusively in cases with

demonstrable skeletal involvement. The alkaline phosphatase may also be elevated in numerous other conditions with skeletal involvement, e.g. Paget's disease, osteomalacia, rickets, renal osteopathy, osteogenic sarcoma, metastatic skeletal carcinomatosis, etc. Elevated values of alkaline phosphatase can only be interpreted as the result of a skeletal disorder if hepatobiliary disorders have been excluded. See above, p. 856 for information on special forms of alkaline phosphatase.

Acid serum phosphatase can be elevated in primary hyperparathyroidism (GRUNDIG, 1965).

d) Hypercalciuria

Estimation of the urinary excretion of calcium in 24 hours is important in the diagnosis of primary hyperparathyroidism. Since this investigation is thought to reveal the endogenous calcium turnover, i.e. the endogenous calcium loss, it should be carried out while the patient is receiving a calcium-deficient diet.

The patient receives a calcium-deficient diet containing about 150 mg calcium/day for at least 4 days. The 24-hour calcium excretion is measured on the last 2 or 3 days. Hydroxyproline can also be measured in the same urine samples providing the diet is deficient in collagen as well (Table 8). As urinary calcium is influenced by the quantity of sodium ingested in the diet and excreted by the kidney (the renal tubular handling of calcium is similar to that of sodium), the sodium content in the diet and urine must be taken into account if the clinical significance of urinary calcium is to be appreciated. In cases where strict dietary restrictions are impossible, as for example in outpatients, a low-calcium diet can be limited to the omission of milk and cheese (butter permitted) and a collagen-deficient diet limited to the omission of meat and gelatine. The 24-hour urine should be collected in a clean container and bacterial infection prevented by the addition of a few crystals of thymol. Before a sample is removed for analysis, the urine should be acidified and well stirred (to dissolve precipitates containing phosphates and oxalates).

Interpretation: With a calcium-deficient diet, not more than 200 mg (strict diet) or 250 mg (diet avoiding milk and cheese) calcium should be excreted in the urine in 24 hours. Hypercalciuria ranging between 200 and 600 mg is found in primary hyperparathyroidism, depending on the degree of hypercalcemia. Hypercalciuria is not a constant finding, however, because parathyroid hormone increases the tubular reabsorption of calcium. Hypercalciuria is more frequently seen in vitamin-D intoxication, or in hypercalcemia not caused by parathyroid hormone, where parathyroid hormone secretion is suppressed.

Table 8. Quantitative low-calcium and low-hydroxyproline diet

1600 calories 160 mg calcium 600 mg phosphorus	40 g proteins 2 g collagen 280 mg hydroxyproline
Breakfast:	
Tea or coffee	
Bread	50 g
Butter	10 g
Sugar	20 g
Jam	50 g
Lunch:	
Beef or veal	100 g
Artichoke hearts	50 g
or Canned asparagus	110 g
or Grated carrots	50 g
or Canned French beans	50 g
or Tomatoes	200 g
Potatoes	150 g
Oil	20 g
Bread	25 g
or Bananas	100 g
or Canned peach compôte	150 g
or Apples	150 g
or Canned pears	75 g
Dinner:	
Egg (not to be replaced by meat)	1
Noodles	40 g
Butter	10 g
Salad	25 g
Oil, salt, pepper, vinegar	10 g
Same fruits as lunch	
Salt, pepper. Sugar: ad libitum	
Drinks:	
Distilled water, no other mineral water, juice of one lemon per day, tea, black coffee, tea made with distilled water	

e) Estimation of Hydroxyproline

Measurement of the urinary excretion of hydroxyproline permits an approximate quantitative assessment of bone turnover and especially of bone resorption (C, 3, b, p. 863). Hydroxyproline is an end product of the metabolic breakdown of collagen. About 50% of it arises from the skeleton.

Interpretation: The mean 24-hour urinary excretion of hydroxyproline is 30 mg in healthy subjects (range 10–40 mg). During growth, hydroxyproline excretion is higher (50–90 mg/24 hours). Abnormally high values are found in numerous conditions with skeletal involvement, as well as in primary hyperparathyroidism with marked skeletal involvement.

f) Renal Phosphate Excretion Tests

These tests are based on the fact that parathyroid hormone increases the renal phosphate excretion by inhibition of the tubular reabsorption. Except for the estimation of the phosphate clearance, which does not require the measurement of the creatinine clearance, the method is identical, but the calculations for obtaining the various indices discussed below are not.

Method. The phosphate intake must be adequate for several days immediately before the test. The patient therefore receives a normal diet containing 700 to 1 400 mg phosphorus/24 hours. The test starts at 8 a.m. in a fasting patient, and lasts four hours. The patient empties his bladder just prior to the test, and collects the urine 4 hours later. A blood specimen is taken in the middle of the test. The phosphate and creatinine levels are determined in both serum and urine. The phosphate excretion can be expressed in various ways.

Phosphate Clearance.

$$C = \frac{\text{P urine} \times V}{\text{P serum}}$$

V = volume of urine

The normal phosphate clearance is 10.8 ml ± 2.7 ml/min. It usually exceeds 15 ml/min in primary hyperparathyroidism. The measurement of the phosphate clearance allows only poor discrimination between normal and hyperparathyroid subjects and it also varies widely with the phosphate intake.

Tubular Reabsorption of Phosphate (TRP). The creatinine clearance corresponds approximately to the glomerular filtration rate. The ratio between phosphate and creatinine clearances thus indicates the proportion of filtered glomerular phosphate not reabsorbed by the tubules. The ratio is calculated as follows:

$$\frac{C_p}{C_{cr}} = \frac{\text{P urine} \times \text{creatinine serum}}{\text{P serum} \times \text{creatinine urine}}$$

C_p = phosphate clearance
C_{cr} = creatinine clearance

Usually these results are expressed as the proportion of the glomerular filtrate reabsorbed by the tubules: *Tubular reabsorption of phosphate (TRP)*

$$TRP = \left[\left(1 - \frac{C_p}{C_{cr}}\right) \times 100\right] \%$$

$$= \left[\left(1 - \frac{\text{P urine} \times \text{creatinine serum}}{\text{P serum} \times \text{creatinine urine}}\right) \times 100\right] \%$$

Interpretation: The normal range for TRP is 85–95%. In primary hyperparathyroidism it is frequently lowered although there is significant overlap between the two groups.

Phosphate Excretion Index (PEI). NORDIN and FRASER (1965) include the serum phosphate level in their calculations to take into account the phosphate load of the kidney filtration. The PEI is calculated from the following formula:

$$PEI = \frac{C_p}{C_{cr}} - 0.055 \times \text{P serum} + 0.07 .$$

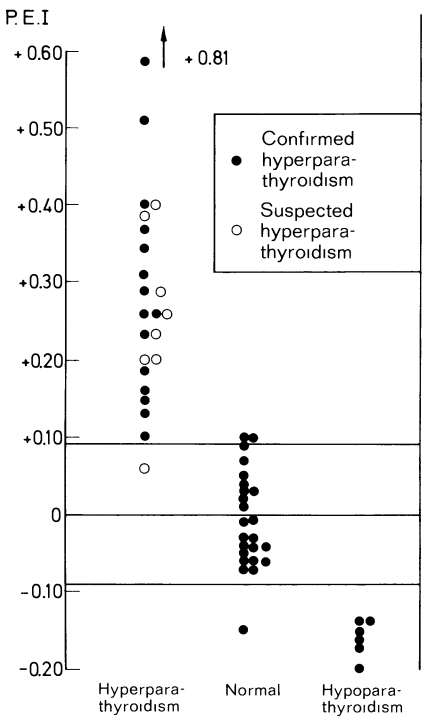


Fig. 34. Phosphate excretion index in hyperparathyroidism, hypoparathyroidism and in normal subjects (NORDIN, 1965)

The normal range is −0.09 to +0.09. Regardless of the serum phosphate level, a PEI lower than −0.09 or higher than +0.09 indicates an abnormal urinary phosphate excretion. In most of their cases of primary hyperparathyroidism, NORDIN and FRASER (1965) found the PEI to be above +0.09. However, overlaps do occur with normal subjects with the PEI and the TRP.

Index of Phosphorus Excretion (IPE). This is a modified phosphate excretion index (PEI), which appears to allow better discrimination between hyperparathyroid and normal subjects (NORDIN, 1968).

The IPE is calculated from the following formula:

$$IPE = \frac{P\ urine \times creatinine\ serum}{creatinine\ urine} - \frac{P\ serum - 2.5}{2}$$

The normal range is -0.5 to $+0.5$.

Maximal Tubular Reabsorption of Phosphate (Tm/GFR). The Tm/GFR can either be measured directly with the infusion of phosphate, or calculated and read off from the nomogram of BIJOVET (1969) (Fig. 35).

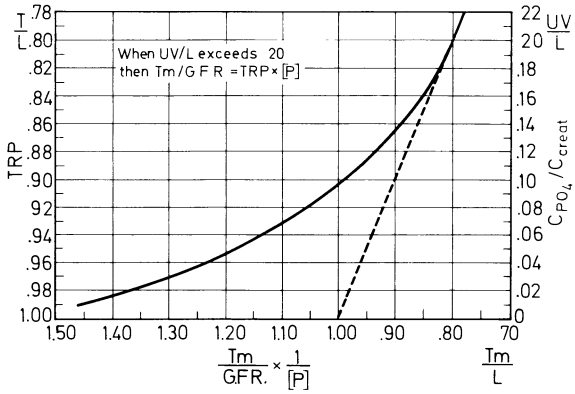

Fig. 35. Nomogram for the estimation of the $\frac{Tm}{GFR}\ \frac{18}{p}$ from the TRP or the C_{PO_4}/C_{Creat}. (After MORGAN, 1972)

The TRP and the C_p/C_{cr} have to be calculated, and the $\frac{Tm}{GFR} \times \frac{1}{P\ serum}$ read off from the nomogram of BIJOVET. This value has then to be multiplied by the serum phosphate concentration and the result is the *Tm/GFR*.

The normal range of the Tm/GFR is 22–42 mg/liter. It is lower in hyperparathyroidism and higher in hypoparathyroidism. The discrimination between normal and hyperparathyroid subjects appears to be better than with any other renal phosphate excretion test used.

g) Parathyroid Inhibition by Induced Hypercalcemia

Parathyroid activity is controlled by the concentration of calcium ions in the plasma. In healthy subjects, induced hypercalcemia thus causes temporary inhibition or suppression of parathyroid activity which becomes apparent as a sudden fall in the phosphate clearance. It used to be thought that the parathyroids acted autonomically and their activity could not be suppressed in primary hyperparathyroidism. If this were so, exogenous hypercalcemia would be followed by only a very slight change in phosphate clearance or none at all. Since sensitive methods for the determination of parathyroid hormone have been available, it has been demonstrated repeatedly that in hyperparathyroidism the parathyroids or their adenomas are not autonomous and their secretion is influenced by the concentration of the calcium ions in the blood (POTTS, 1972; BINSWANGER, 1973), so that both the following tests have lost their theoretical basis. However, in hyperthyroidism the influence of a further rise in calcium seems to produce a less pronounced fall in the phosphate clearance, and the tests might have some empirical value if no better criteria are available.

KYLE *and* HAAS *Method.* Phosphate and creatinine clearances are measured on the first day of the test between 8 and 10 a.m. Blood is taken at 9. An intravenous drip containing 15 mg Ca^{++}/kg body weight in 500 ml physiological saline is set up on the evening of the first day (10 ml 20% calcium gluconate = 180 mg Ca^{++}). The infusion is started at 9 p.m. and stopped at midnight. Blood is taken before and after the insfusion. On the second day, phosphate and creatinine clearances are measured under exactly the same conditions as on the previous day. This procedure of spreading out the test over 2 days is thought to eliminate a false interpretation due to variations of phosphaturia at different times of day (p. 854). This test is only of value when the serum calcium rises by at least 3 mg during the infusion.

Interpretation: Normal phosphate clearance is 10.8 ± 2.7 ml. Following hypercalcemia, the phosphate clearance can fall by more than 50% in healthy subjects. This fall is less than 25% in some patients with primary hyperparathyroidism.

Pak's Method. It has been shown that during a calcium infusion the change in the renal phosphate excretion is not dependent only upon the parathyroid inhibition. The calcitonin secretion is stimulated by the hypercalcemia and acts directly on the kidney to increase phosphate excretion. Calcium infusion also acts directly on the phosphate clearance independently of the PTH and calcitonin levels.

The stimulated endogenous calcitonin and the direct hypercalcemic action oppose the parathyroid inhibition. False-positive values are thus obtained in normal subjects by this test. PAK *et al.* have noticed that these two mecha-

nisms are active only for the first 12 hours after a four-hour calcium infusion. The inhibition of parathyroid hormone lasts 24 hours or longer. If phosphate clearance is determined over 12 hours (12th to 24th hour) after the calcium infusion, the source of error can be eliminated and the parathyroid response to hypercalcemia tested.

The patient is given a constant diet for three days; the daily intake of calcium, phosphorus and sodium is approximately 400 mg, 1000 mg, and 100 mEq respectively. The first day on the diet is the equilibrium day; the second is the control day for calcium infusion. At 9 a.m. on the third day of the diet the infusion of calcium is begun: 15 mg calcium (as calcium gluconate)/kg of body weight diluted to 500 ml with normal saline and administered intravenously over four hours. Amounts of sodium and fluid equivalent to those in the infusion are removed from the diet on the day of the infusion to keep the intake constant. Food, medication and fluid are given at the same time each day.

Urine is collected every 12 hours for two days beginning at 9 a.m. of the control day. Phosphorus and creatinine levels are measured in each specimen. The urinary phosphorus level is expressed as the ratio (by weight) to urinary creatinine level (mg phosphorus/mg creatinine).

The urinary excretion of phosphorus during the second half of the day of the calcium infusion is compared with that of the corresponding time period of the control day.

In normal patients, the ratio P/C_2 is decreased between -29% and -80% (mean value -52.7%); in hyperparathyroid patients this ratio varies between -25% and $+26\%$ (mean -7.7%).

h) Changes in the Reabsorption of Phosphate after Administration of Parathyroid Hormone (Becker)

(This test should be avoided if parathyroid hormone determinations are available, because of parathyroid antibody formation.) An injection of parathyroid hormone administed to healthy subjects causes a fall in the index of tubular reabsorption of phosphate. This fall is much more striking in the presence of hypoparathyroidism than in the healthy individual (Courvoisier). There is, however, a slight resistence to exogenous parathyroid hormone in cases with an elevated endogenous parathyroid hormone secretion.

Method: After supper, the subject to be tested receives nothing more to eat or drink until the following morning. The bladder is emptied at 8 p.m. and the urine discarded. A slow intravenous infusion of 1000 ml of 5% glucose is set up immediately afterwards. All urine is collected during the subsequent 12 hours, and phosphorus and creatinine measured. The infusion is regulated to last until between 7 and 8 a.m. At 8 a.m. blood is taken for the estimation of phosphorus and creatine. The patient is then discharged and instructed to pursue normal activities. At 8 p.m. on the second day, a similar infusion is given, this time, however, with the addition of 200 USP units of Lilly parathyroid extract (1 ml = 100 USP U = 20 U after Collip). The parathyroid extract must always be tested in a healthy subject (same method). An intracutaneous test should be performed on the person beforehand as a precaution to prevent allergic reactions to the parathyroid extract. (An intracutaneous injection of the extract diluted to 10 times its volume with physiological saline is given.) The index of tubular reabsorption (% TRP) is calculated on both days of the test.

Interpretation: The injection of parathyroid hormone causes a significant fall in tubular reabsorption of phosphate in healthy subjects and in hypercalcemia not due to primary hyperparathyroidism (11.5–27.6% fall in TRP). In primary hyperparathyroidism the reabsorption falls by a maximum of 6.8%.

i) Cortisone Test after Dent *for the Differential Diagnosis of Hypercalcemia*

This test is used by Dent for the differentiation of hypercalcemia due to primary hyperparathyroidism from hypercalcemia of other etiologies. Shulman was the first to notice that hypercalcemia in sarcoidosis can be corrected by glucocorticoids. Later, the same observation was made in vitamin-D intoxication. Glucocorticoids inhibit bone resorption and the release of calcium into the serum.

Method: 150 mg cortisone or 30 mg prednisone is given daily for 10 days. The serum calcium is determined before the test and on the 5th, 8th and 10th days.

Interpretation: From Dent's work, it can be concluded that cortisone and its derivatives do not affect hypercalcemia associated with primary hyperparathyroidism, whereas they cause a fall in serum calcium in hypercalcemia of other etiologies. Other authors, however, have occasionally demonstrated exceptions in both directions (Thomas and Gwinup). In spite of this, the cortisone test can be recommended

for the differential diagnosis of hypercalcemia because of its simplicity.

2. Diagnosis and Differential Diagnosis of Hypoparathyroidism

a) Calcemia and Phosphatemia

(Hypocalcemia; Hyperphosphatemia)

Measurements used in the diagnosis of primary hyperparathyroidism are also used for this purpose (p. 943).

b) Alkaline Phosphatase

This parameter is normal.

c) Urinary Calcium Excretion

Hypoparathyroidism is characterized by a very low urinary excretion of calcium. The calcium excretion depends to a large extent on the serum calcium concentration. The urinary calcium excretion allows no clear-cut discrimination between hypoparathyroid and normal subjects, one reason for this being that the tubular calcium reabsorption is inhibited in the absence of parathyroid hormone. It appears that in normocalcemic control subjects on a calcium-deficient diet the 24-hour urinary calcium excretion always exceeds 50 mg.

d) Phosphate Excretion Measurement

In contrast to hyperparathyroid patients, only a poor discrimination between normal and hypoparathyroid subjects is possible, whatever phosphate excretion test is used.

e) Ellsworth-Howard Test

The phosphaturic effect of parathyroid hormone or extract is used to differentiate pseudohypoparathyroidism from other forms of parathyroid insufficiency.

Method: On the first day of the test, hourly samples of urine are collected for 6 hours. Volume, phosphate and creatinine are measured in each sample. This investigation should be carried out at the time of day when phosphaturia is most stable, i.e. during the afternoon (after lunch). On the second day, 6 samples of urine are collected at the same time intervals, and 200 USP U Lilly parathyroid hormone (1 ml = 100 USP U) are injected at the end of the third hour. If possible, the same test should be performed at the same time in a healthy subject, using the same brand of parathyroid extract with the same production number to examine its phosphaturic potency. To prevent allergic reactions to the parathyroid extract, an intracutaneous test is performed beforehand with a solution of the extract diluted to 10 times its volume with physiological saline; 0.1 ml is used for the intracutaneous injection.

Interpretation: In healthy subjects, there is a 100% increase in the excretion of phosphate in the first hour after the injection of the parathyroid extract. This rise is even more pronounced in postoperative hypoparathyroidism and in certain cases of idiopathic hypoparathyroidism. Pseudohypoparathyroidism, however, is thought to be characterized by the fact that there is only a slight response to parathyroid extract or none at all.

f) Parathyroid Stimulation Tests

These tests should allow diagnosis of undected, latent, or partial hypoparathyroidism. Investigations of this type have been performed in thyroidectomized subjects with a normal serum calcium concentration. The method is described below, although it is of more theoretical than practical interest.

g) Artificial Hypocalcemia with EDTA (JONES *and* FOURMAN)

Ethylene-diamine-tetra-acetate (EDTA) chelates calcium. This chelate has a high affinity for calcium and makes it unavailable to the system. Thus, this salt causes hypocalcemia.

Method: Na_3-EDTA is given by intravenous infusion: 70 mg/kg body weight in 500 ml 5% glucose. The infusion is given over 2 hours (20 ml 2% procaine is added to prevent or alleviate pain which may be caused by the infusion). Blood is taken before and 2, 4, 8, 12, and 24 hours after the start of the infusion. Serum calcium not bound to EDTA is measured by titration.

Interpretation: In healthy subjects, the level of calcium not bound to EDTA falls by 2–3 mg/100 ml towards the end of the infusion (after 2 hours) and reaches normal levels again after 12 hours. It is assumed that this rapid correction of the hypocalcemia is due to mobilization of calcium caused by stimulation of the parathyroid hormone secretion. In parathyroid insufficiency, the fall is often more pronounced after 2 hours than in healthy subjects. The slow return to normal is particularly striking. It is 12 hours, or sometimes more than 24 hours, before normal levels are restored. This is thought to be due to an insufficiency of the parathyroid hormone secretion.

XV. Tissue Hormones

A. LABHART

With Contributions by

CHR. HEDINGER and J. MÜLLER

A. Definition

Endogenous organic transmitter substances not formed in glands but in individual cells, which may be contained within organ tissues or scattered throughout the entire body, are described as tissue hormones (FELDBERG, 1955). They can reach their end organs either by the blood stream as in the case of gastrointestinal hormones, or by diffusion into their immediate surroundings (local hormones) (GADDUM, 1955). The term "cellular hormones", however, indicating substances which regulate metabolic processes within the cell, is still inadequately explained and it is better to use a different term. According to the definition, neurohormones are also tissue hormones. For practical reasons they are dealt with here in the chapters on the corresponding endocrine systems.

Finally, the hormones which are formed in tumors and produce the paraneoplastic syndromes are considered either as pathologic tissue hormones or as ectopically formed hormones (Chap. XVI).

The science of the tissue hormones today extends for the main part beyond clinical endocrinology and forms a special field of pharmacology and physiology. Those tissue hormones which are of no importance in clinical endocrinology are therefore only mentioned here in connection with more recent pertinent literature.

Three well-defined hyperfunctional syndromes of tissue hormones are known and are discussed below. Hypofunctional syndromes may also occur (COHEN, 1973), but need to be confirmed by further studies.

The tissue hormones can be divided according to their chemical nature into the following groups:

I. Polypeptide

1. Gastrointestinal hormones:
   a) Gastrin,
   b) Secretin,
   c) Cholecystokinin-pancreozymin,
   d) Cerulein,
   e) VIP (vasodilator intestinal peptide),
   f) GIP (gastric inhibitory peptide),
   g) Motilin.
   h) Intestinal glucagon
2. Kinins:
   a) Bradykinin,
   b) Kallidin,
   c) Methionine-kallidin.
3. Angiotensin II.
4. Substance P.
5. VDM, VEM.

II. Glycoproteins:

Erythropoietin.

III. Amines:

Serotonin, melatonin, dopamine.

IV. Fatty acids:

Prostaglandins.

The list of chemically identified gut hormones is almost certain to grow. The prime candidates are gastric inhibitory hormones from the intestine (enterogastrones) other than secretin and GIP. For other as yet hypothetical hormones see CROXATTO (1960).

B. Polypeptides

1. Gastrointestinal Hormones

Peristalsis and secretion in the digestive system are regulated partly by nervous influences, and partly by the mechanical, chemical and physicochemical effects of the chyme on the gastrointestinal mucosa. Signals from the receptors of the gastric and intestinal walls are transmitted to the glands involved in digestion mainly by way of the gastrointestinal hormones. These are formed in the gastrointestinal mucosa by cells which appear to have a common origin in the neural crest (APUD-cells, PEARSE, 1971) and

reach their end organs via the blood stream. They are all polypeptide in character.

Among the gastrointestinal hormones which are suspected and known, the structure of gastrin, secretin, cholecystokinin and pancreozymin (CCK-PZ), which seem to be identical, and GIP (gastric inhibitor polypeptide) have been clarified; the first two have been synthesized. The amino-acid composition and sequence of cerulein are known, and synthesis has been accomplished. The term entero-gastrone is now used for a group of gastrointestinal hormones with an inhibiting effect on gastric secretion.

A second glucagon ("enteroglucagon") which appears to be formed in the duodenal mucosa and not in the A cells of the islets is discussed in Chap. XIII (p. 822).

a) Gastrins

EDKINS suspected the existence of gastrin in 1905. KOMAROV demonstrated it in 1938, GREGORY and his team purified and synthesized it in 1964. Human gastrin I is a polypeptide of 17 amino acids. Gastrin II has the same actions, and is esterized with sulfuric acid at the 12th tyrosyl residue. Gastrin of pig, dog, and sheep differ from each other only in the 5th amino acid and perhaps the sixth. The end-terminal tetrapeptide, tyr–meth–asp–phe–NH_2, has the same qualitative action, although to a slighter degree, as the heptadeca polypeptide.

Gastrin is formed in the mucosa of the antrum and is released through mechanical stimuli (distension), chemical stimuli (proteins and their metabolites, alkaline pH), and indirectly through vagal stimulation and peristalsis. An acidic pH, below 1.5, and other, as yet unexplained, influences from the gut inhibit the secretion of gastrin.

Besides human gastrin I and II, at least three other types of gastrin have been described in man. The "big gastrins" (MW about 3900) contain the heptadeca peptide amide as a C-terminal sequence linked to the remainder of the molecule by a peptide bond (GREGORY, 1972; YAPON, 1971). They have a relatively slow turnover and – when compared on the basis of blood levels – less effect on gastric secretion than heptadeca gastrins (WALSH, 1973). An important source of big gastrin is the intestine. A rise of serum levels is observed after meals.

"Big big gastrins" have a molecular weight of about 20000. These gastrins constitute the major fraction of fasting gastrin in serum. They are elaborated by the gut and not released in response to a meal (YALOW, 1973). The biological actions of big gastrins are unknown.

Still another type of gastrin is found in patients with pernicious anemia. It may be determined by radioimmunoassay but is biologically inactive (HANSKY, 1973). Biological activity of gastrins is mainly determined by the end terminal tetrapeptide (tyr–meth–asp–phe–NH_2). The remainder of the molecule modifies the strength but not the type of this activity.

Recently the fasting concentration of gastrin in the serum has been determined radioimmunologically. Normal values differ in different laboratories, but the concentration is in the range of 20–150 pg/ml. Patients with ulcus duodeni have a significantly higher fasting value for gastrin than normals, patients with ulcus ventriculi, or patients in whom complete vagotomy has been performed (BYRNES, 1970). The same is true of patients with pernicious anemia (MCGUIGAN, 1970).

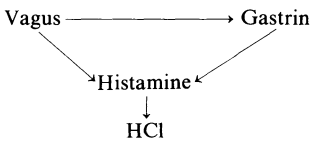

Fig. 1. Neural and humoral regulation of gastric acid secretion

When gastrin is given in physiological doses the following effects may be observed (GROSSMAN, 1970): stimulation of acid secretion and to a lesser extent pepsin secretion by the gastric mucosa, stimulation of water and enzyme secretion by the pancreas (this action probably does not occur in man), stimulation of bile flow, inhibition of water and electrolyte absorption in the intestine, contraction of the gastroesophageal sphincter, relaxation of the sphincter of Oddi, relaxation of the ileocecal sphincter, increased gastric mucosal blood flow, increased protein synthesis and growth in the gastrointestinal tract, contraction of gastric smooth muscle and release of insulin. There is still controversy as to which of these actions are of physiological importance and may also be observed following gastrin release by a meal. Pharmalogical actions following very high doses of exogenous gastrin include inhibition of gastric secretion, contraction of gallbladder and uterus and transient hypotension.

It has been proposed that the stimulatory effect of gastrin on acid secretion is mediated by histamine (CODE, 1965) (Fig. 1), which in turn stimulates adenyl cyclase. This may be true for amphibia but not for mammals (HAKANSON, 1971). Here, histamine might be one but is

certainly not the only mediator of gastrin action. Inactivation of gastric histamine receptors in man leads to a decrease but not to an abolition of gastrin stimulated acid secretion (BLACK, 1972).

Little is known about the mechanism of inactivation of gastrin. Liver and kidney seem to have a role in the degradation of gastrin. Serum gastrin rises proportionally in chronic renal failure with the serum creatinine. Whereas hemodialysis does not significantly alter gastrin levels, renal transplanation tends to return it to normal (KORMAN, 1972).

The synthetic pentapeptide, pentagastrin (butyloxycarbonyl–β-ala–tyr–meth–asp–phe–amide), can be used in a dose of 6 µg/kg body weight subcutaneously or 6 µg/h/kg by intravenous infusion or as snuff (1 mg every 10 minutes for 1 hour) (WORMSLEY, 1968) to produce the maximum stimulation for examination of the HCl production of the stomach. It has less side effects than histamine (multicenter pilot study 1967).

Other polypeptides found in animals with the same C-terminal pentapeptide as cerulein are even more active on the gastric secretion than gastrin (see p. 974). "Antigastrin" (2-phenyl-2-(2-pyridil)-thioacetamide) seems to be a competitive antagonist of gastrin (BEDI, 1967; OTTENJANN, 1968). In addition, antibodies against gastrin can be produced by crude gastrin extracts or gastrin coupled to a gamma-globulin (MC GUIGAN, 1968).

α) The Zollinger-Ellison Syndrome

The syndrome described in 1955 by ZOLLINGER and ELLISON includes the triad:

1. Severe, therapy-refractory ulcer disease, often with multiple (10%) ulcers, sometimes atypically located (25%), and with frequent complications.
2. Massive hypersecretion and hyperacidity of the gastric juice.
3. Non-B islet cell tumor of the pancreas, usually multiple, sometimes situated ectopically, and often (60%) malignant.

Watery diarrhea or steatorrhea often occurs in addition. The Zollinger-Ellison syndrome (ZES) results from overproduction of the tissue hormone gastrin. This syndrome must be differentiated from that of islet-cell tumors with diarrhea but no hyperacidity (see p. 974). Both syndromes have the same genetic basis. The ZES has recently been reviewed by ISENBERG (1973).

1. Frequency and Incidence. Up to 1964, 250 cases had been described. It is difficult to estimate the frequency, since individual cases are now seldom reported. At a rough estimate, 10% of unusually severe ulcer diseases are due to ZES (ZOLLINGER, 1964). The syndrome is more frequent in men (3:2) and occurs in every age group, but especially often in the 4th, 5th, and 6th decades; about 25% of cases of ZES are associated with adenomatosis (see Chap. XVIII). The combination of non-B islet cell adenomas and peptic ulcers in autopsy material chosen at random is more frequent than can be explained by the coincidence of probability (v. PLANTA, 1957).

Since multiple or atypical ulcers occur only in roughly one third of cases of ZES, tests for ZES should be performed in every case in which ulcer disease is refractory to therapy or has an atypical course, as also in cases with inexplicable diarrhea (HALLENBECK, 1968).

2. Morbid Anatomy and Histology. The tumors can be any size, from nodules visible only microscopically to tumors 8 cm in diameter, and are multiple in over 50% of cases. They are evenly distributed over the whole pancreas, but they can also arise ectopically (25%) in the duodenal mucosa or in the gastric antrum. Finally, development of the syndrome may also be due to adenomatosis or hyperplasia of the non-B islet cells (10%). Histologically, the cells are non-B islet cells. They probably arise from the argyrophil-metachromatic D cells (CAVALLIERO, 1967) although a few A-cell tumor have been described. There are signs of malignancy in over 50% of cases, and metastases are not uncommon, especially in the lymph nodes and liver (Fig. 2 from ZOLLINGER, 1964). The cells may have a trabecular, ribbon-like or an acinar-canalicular arrangement in which some authors see similaraties with pancreatic duct cells (CREUTZFELDT, 1973).

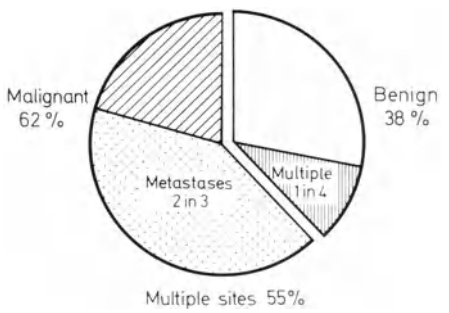

Fig. 2. Ulcerogenic tumors of the pancreas. Incidence of malignant, metastasizing multiple types (ZOLLINGER, 1964)

In the stomach there is hyperplasia of the parietal cells (MIEHER, 1962) which also extend to the antrum and are found in practically every

part of the stomach, probably due to chronic stimulation by gastrin. Hyperplastic glandular rods are demonstrable in the broadened hyperplastic folds of the gastric mucosa, which is reminiscent of Ménétrier's syndrome. Differentiation is, however, possible, as Ménétrier's syndrome is often associated with hyposecretion. Recently it seems that two types of ZES may be differentiated: type 1 with a short history, very high levels of serum gastrin, hyperplasia of G-cells in the gastric antrum and no pancreatic tumor, and type 2 less extreme hypergastrinemia and a tumor in the pancreatic islets (POLAK, 1972; Editorial, 1973). Still another type of ZES has been described where a gastric tumor arising from the antral G-cells producing gastrin caused the syndrome (ROYSTON, 1972).

3. Clinical Features. Ulcer symptoms dominate the picture in nine-tenths of cases and the remainder suffer from diarrhea. In the acute course the ulcers with complications are the presenting features. The disease can, however, also begin with diarrhea and loss of weight which may persist for some years before the ulcers become manifest (20%).

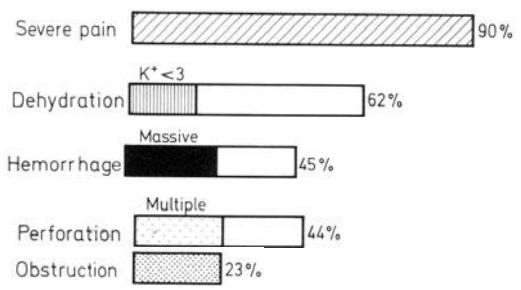

Fig. 3. Symptoms and complications of ZES

The ulcer most frequently (65% of cases) lies in the first two-thirds of the duodenum, and in a quarter of these just below the TREITZ's ligament. The pain is often constant and it does not respond to antacids. Ventricular ulcers are next in frequency, occurring in 20%. Jejunal peptic ulcers are characteristic of ZES, and ulcers are occasionally found in the esophagus. The ulcers are multiple in 12–15% of cases and all the complications, such as massive hemorrhage, perforation and obstruction, are common (Fig. 3, from ZOLLINGER, 1964). Ulcers regularly recur after conventional surgery. Although the symptoms of the ulcers in ZES are especially pronounced, they are not different in nature from those of the usual peptic ulcer.

Serum gastrin levels rise in proportion as the serum calcium increases. In the Zollinger-Ellison syndrome gastrin levels decrease after parathyroidectomy and rise again during calcium infusions, but do not respond to administration of parathormone (TRUDEAU, 1969).

Diarrhea in ZES (40%) is due to hypersecretion and hyperacidity and the direct stimulus is irritation of the small intestine by large amounts of acidic gastric juices. The diarrhea ceases if the gastric juices are continuously suctioned off. When the gastric juices are aspirated and neutralized and then given intraduodenally, they no longer cause diarrhea. The diarrhea is watery and reaches a volume of 5–10 liters/24 hours. It is refractory to opiates and leads to severe dehydration and in particular to hypokalemia, with grave or even fatal consequences.

The steatorrhea is also due to the hyperacidic hypersecretion and inactivation of the pancreatic lipase. As much as 30 g or more of fat may be excreted in the feces, and sometimes the full picture of a malabsorption syndrome can be present.

Islet-cell tumors rarely give rise to clinical symptoms. Even if malignancy is present the growth is slow and the course relatively benign.

4. Diagnosis. Before it was possible to estimate gastrin in the blood, the diagnosis of ZES was mainly based on the demonstration of HCl hypersecretion. The basal secretion, which is independent of vagal stimulation, is considerably raised in ZES, and is only slightly stimulated by histamine or appropriate stimulants. Estimation of the 12-hour secretion by continuous suction must produce a volume of more than 2 liters, with more than 100 mEq of free acid. One can never be certain that all the secretion has been obtained with a 12-hour estimation. A more reliable test is that of hourly basal secretion, which must yield a volume of more than 200 ml and an HCl content of over 20 mEq/h. The comparison of the basal secretion to the secretion after the maximum histamine test (Kay test) is of particular value. The production of acid after maximum histamine stimulation is proportional to the number of the parietal cells. The rise after maximum histamine or histalog stimulation should not be more than 60% and the ratio of the basal secretion to the maximum secretion in mEq HCl should be higher than 0.6. However, this test can also only give an indication of ZES since the basal secretion can vary considerably over the course of time, and the test may give false-positive or false-negative results (WINSHIP, 1967).

The most reliable diagnostic procedure now available is radioimmunological determination

of the fasting level of gastrin in the serum. The mean value differs from one laboratory to the other but is in the range of 20–150 pg/ml. In ZES the concentration is 10 times higher than normal, or even more (McGuigan, 1968). However, an increasing number of ZES with serum values below 300 pg/ml has been reported (Isenberg, 1973). Gastrin has been found in an islet-cell carcinoma with ZES in a concentration 16 times higher than in the serum of the patient, but there are gastrinomas which do not store gastrin to any significant degree.

Radiological examination of the gastrointestinal tract can detect the following characteristic findings in ZES:

1. Greatly increased fasting secretions, especially in the stomach, duodenum and proximal jejunum.
2. Frequently multiple ulceration, atypically situated (duodenum distal to the bulbus 19%, proximal jejunum 23%, several ulcers 10%).
3. Greatly hypertrophic stomach folds, edema in the duodenum and jejunum.
4. Megaduodenum.
5. Hypomotility of the stomach and duodenum with hypermotility of the small intestine (Amberg, 1964).

The tumors can sometimes be demonstrated angiographically by means of selective pancreas-arteriography (Clemett, 1967).

Detection of parietal cells in a biopsy specimen from the gastric mucosa in the antrum is further evidence of ZES.

The diagnosis is not difficult when there is a classic familial history, evidence of multiple and atypical ulcers, acid hypersecretion and hypergastrinemia. Surgery is definitely indicated in such cases. If, however, these pathognomonic features are not found in the history and radiological examination does not reveal adequate evidence for the disease, the following procedures may help in establishing a diagnosis:

1. Calcium infusion test (Passaro, 1970). In patients with ordinary duodenal ulcer, infusion of calcium (12–15 mg/kg over 3 hr period) produces an increase in acid secretion which is far below maximal acid output (MAO). In ZES, secretion may rise to MAO values.
2. Calcium injection test (Passaro, 1972). Rapid intravenous injection of calcium (2 mg/kg) produces an immediate and prolonged rise of acid secretion in ZES but not in other ulcer patients.
3. Secretin infusion test (Isenberg, 1972). Secretin (3 U/kg per hr) usually inhibits acid secretion. In ZES, it may lead to increased acid secretion and hypergastrinemia far above basal levels. Similar observations have been reported with glucagon.

5. Therapy. If the diagnosis is certain or highly probable surgical intervention is definitely indicated. Although individual cases have been cured by the removal of a solitary non-B islet cell tumor, excision of the visible and palpable pancreas tumors is not, as a rule, sufficient in the face of the frequent multiplicity, malignancy, and ectopia of the tumors. Tumors or metastases which are overlooked give rise to recurrences. Combination with a conventional ulcer operation is also pointless, since in ZES the border cells are found throughout the stomach, and even a gastric stump will lead to hypersecretion under the influence of gastrin and thus to recurrences. If a single tumor is found on exploration of the pancreas this can be removed, and if the basal secretions measured during the operation before and after removal of the tumor show a regression and biopsy of the lymph nodes is negative, it is reasonable to end the operation there and to await developments. In the case of multiple pancreatic tumors or of recurrences, the only certain measure to be considered is total gastrectomy and perhaps resection of the tail and body of the pancreas. Zollinger has been advocating this procedure since 1958.

It is not yet known whether competitive antagonists such as antigastrin, GIP (see p. 971 and p. 975) or gastrin antibodies have potential therapeutic applications.

6. Etiology and Pathogenesis. ZES is a group of symptoms of endocrine adenomatosis. This is an autosomal dominant hereditary disease with high penetration and varying expressivity and is pleiotropic. There is associated endocrine adenomatosis in only a quarter of the cases of ZES. However, endocrine adenomatosis is found frequently among siblings, antecedents, and descendants of patients with ZES (see Chap. XVIII, p. 1007).

The symptoms of ZES have been explained by the demonstration of gastrin in the non-B islet-cell tumors of ZES (Gregory, 1960). ZES is due to the ectopic formation of gastrin, which is normally produced by the mucosa of the antrum and not by the pancreas.

Overproduction of gastrin is observed after gastric operations in which the antrum is removed from the rest of the stomach but is left attached to the pylorus (Billroth II modification after Finsterer). The gastrin production of the antrum can then no longer be inhibited by contact with the acidic contents of the stomach. This results in a maximum secretion by the remaining part of the stomach, hyperacidity, and ulcers at the anastomoses.

β) The Syndrome of Watery Diarrhea with Hypokalemia with Non-B Islet Cell Tumors (*WDHA* – *W*atery *D*iarrhea, *H*ypokalemia, *A*chylia) Syndrome, Verner-Morrison Syndrome, Pancreatogenic Cholera).

There is one variant of endocrine active non-B islet-cell adenoma which does not produce gastrin, but apparently does produce a substance which stimulates the gut to an abnormally copious secretion particularly rich in potassium and may inhibit the gastric secretion at the same time (MARKS, 1967). This substance is at present hypothetical. Glucagon, secretin (ZOLLINGER, 1968) GIP (ELIAS, 1972; Editorial 1973) or VIP (BLOOM, 1973) have been suspected. It must be postulated since the diarrhea disappears after the removal of these tumors, and gastric secretion resumes. Exclusion of HCl hypersecretion is essential for the diagnosis. Usually there is hypo- or achlorhydria. This syndrome also has the same genetic basis as endocrine adenomatosis, and these tumors may be benign or malignant.

1. Clinical Features. Massive watery diarrhea refractory to the usual treatment usually begins abruptly, and 10–20 liters are lost in up to 20 evacuations in 24 hours. The excreta are especially rich in potassium and bicarbonate, so that hypokalemia with metabolic acidosis, as well as dehydration, azotemia, and shock arise. Hypercalcemia is seen in about half the patients.

2. Therapy. Strangely, the diarrhea is considerably improved by 15–20 mg of prednisone daily. (Inhibition of kinin-activation? See p. 977). The only causal treatment is complete removal of the tumor. In contrast to ZES, a gastrectomy is useless in this syndrome. Whether other syndromes, such as that with hyperglycemia, are variations of this one has still to be confirmed or denied (LEGER, 1962; KNAPPE, 1966; RAPANT, 1965). Hypokalemia itself leads to reduced glucose tolerance.

b) Secretin

Secretin was the first gastrointestinal hormone to be found. BAYLISS and STARLING created the term "hormone" for it in 1902. It has recently been purified and its structure clarified (JORPES, 1962). It is a one-chained polypeptide of 27 amino-acid residues of the following sequence (Fig. 4): It is strikingly similar in structure to glucagon (see p. 822), also having 14 identical amino-acid residues. It has recently been successfully synthesized (MUTT, 1967).

His—Ser—Asp—Gly—Thr—Phe—Thr—Ser—Glu—Leu—Ser—Arg—Leu—Arg—Asp—Ser—Ala—Arg—Leu—Glu—Arg—Leu—Leu—Glu—Gly—Leu—Val · NH_2

Fig. 4. Porcine secretin structure formula (MUTT, 1967)

Secretin stimulates the pancreas and the bile ducts to secrete water and bicarbonate. It inhibits gastric secretion of gastrin and peristalsis, but stimulates pepsin secretion. It also causes the release of insulin (see p. 748). It has a lipolytic action and some effects on the kidney and the cardiovascular system. Secretin is formed in the mucosa of the upper small intestine and is released in response to chemical stimuli [hydrogen ions, fatty acids (MEYER, 1972)]. Its clinical importance is limited at present to the pancreas function test (DREILING, 1958). It is still too expensive for trials in the treatment of ulcers.

c) Cholecystokinin-Pancreozymin (CCK-PZ)

In 1928 IVY and OLDBERG extracted cholecystokinin from the mucosa of the upper sections of the small intestine. In 1943, HARPER and RAPER showed that an extract of the same mucosa stimulates the secretion of amylase, trypsinogen, and lipase in the pancreas. They called this gastrointestinal hormone pancreozymin. It releases the enzymes from the acinar cells and promotes enzyme synthesis (MORISSET, 1971). Later, as more purified extracts became available it was possible to state that cholecystokinin and pancreozymin were the same intestinal hormone (MUTT, 1967). The only CCK-PZ so far isolated and investigated is porcine cholecystokinin. It may be that there are several species-specific cholecystokinins. It is composed of 33 amino-acid residues and has a molecular weight of 3900. The C-terminal octapeptide of porcine CCK-PZ is

Asp–Tyr(SO_3H)–Met–Gly–Trp–Met–Asp–Phe–NH_2.

In addition to its effects on the pancreas, CCK-PZ leads to the contraction and evacuation of the gallbladder as well as to the relaxation of the sphincter of Oddi. It inhibits gastric secretion probably competitively to gastrin (BROOKS, 1970). It is released when the intestinal mucosa comes in contact with fats, peptones, and dilute hydrochloric acid.

A rather crude preparation is used for radiological and clinical diagnosis of conditions affecting the gallbladder, and in surgery of the bile ducts (JORPES, 1964).

d) Cerulein

ERSPAMER and his group detected in the skin of different species of frogs a decapeptide and

a nonapeptide, which they named cerulein and phyllocerulein respectively, with the following structure:

Pyr–Gln–Asp–Tyr(SO_3H)–Thr–Gly–Trp–Met–Asp–Phe–NH_2.

Phyllocerulein lacks –Asp– in the third position. There is a striking resemblance in chemical structure between the ceruleins and the C-terminal octapeptide of porcine cholecystokinin-pancreozymin and the C-terminal hexapeptide of the gastrin. The chemical similarity corresponds with a striking resemblance in the pharmacological effects, which are very similar or even identical to those of cholecystokinin-pancreozymin. This latter might be simply a carrier polypeptide from which a smaller hepta- or octapeptide is split off and liberated into the circulation when the flow of bile and pancreatic juice as well as intestinal movements are necessary for digestive processes. It has a very strong effect on the contraction of the gallbladder, which is estimated at least 3 times more potent than that of CCK-PZ. In doses of 5–30 ng per kg i.v. it has been used for cholecystographic studies in patients. As CCK-PZ, it has a relaxant effect on the sphincter of Oddi.

In human subjects, cerulein inhibits duodenal motility and stimulates jejunal and colonic motility and tone.

In addition, it is a potent stimulator of pancreatic secretion, not only of pancreatic juice but also of amylase and bicarbonate. In the endocrine pancreas it stimulates the release of insulin.

In the liver it stimulates the flow of hepatic bile.

It has a similar but more potent effect than gastrin in stimulating acid secretion of the stomach; however, it can also inhibit the action of gastrin, probably in a competitive way.

In addition, it seems to have a hypotensive action on the cardiovascular system, which, however, differs widely from species to species.

Untoward side effects in man occasionally consist of a sensation of heat in the face with sweating, abdominal discomfort, and nausea of short duration.

e) Hypotensive Polypeptide of Said and Mutt (VIP), Vasodilating Intestinal Polypeptide

Recently, a new intestinal hormone of polypeptide character has been extracted from porcine small intestine by SAID and MUTT (1970). The polypeptide has 28 amino-acid residues whose composition, but not the sequence, is known. In contrast to the kinins, the substance P, and other vasoactive peptides, it has no glycine or proline.

The biological activity consists mainly in arterial vasodilatation with a hypotensive effect but with an increased total cardiac output. There seems to be no direct effect on the heart muscle although a stimulation effect on respiration has been observed.

In addition, it has a hyperglycemic effect corresponding to about two-thirds of that of glucagon.

The hormone is inactivated in the liver, and thus probably has no effect on the peripheral circulation. The physiological function might be regulation of the intestinal blood flow and the blood sugar. It might have pathogenetic importance in liver cirrhosis early dumping syndrome and WDHA-syndrome (BLOOM, 1973).

f) "Gastric Inhibitory Polypeptide" (GIP)

BROWN and PEDERSON purified GIP from a crude gastrointestinal extract containing CCK-PZ which inhibits the acid secretion of the stomach. Pentagastrin, stimulated H^+ secretion and secretion induced by hypoglycemia are also inhibited. This substance could be the gastrointestinal hormone released when fat is instilled into the duodenum. Porcine GIP is a polypeptide of 43 amino-acid residues, the sequence of which has been clarified by BROWN and DRYBURGH (1971). 15 of the first 26 amino acids occur in the same position as they do in porcine glucagon and 9 of the first 26 in the same position as in porcine secretin. The calculated molecular weight is 5105.

g) Motilin

BROWN and co-workers (BROWN, 1971) isolated a polypeptide from a side fraction produced during the purification of secretin, which produced increased motor activity in the antrum and an increased pepsin output. This polypeptide was purified and is composed of 22 amino-acid residues with an N-terminal of phenylalanine. The composition of the amino-acid residues is entirely different from that in the other gastrointestinal hormones (BROWN, 1972).

h) Intestinal Glucagon (Enteroglucagon)

It seems probable that glucagon extracted from A-islet cells of the pancreas and the one extracted from the duodenal mucosa are different polypeptides (see Chap. XIII, p. 822).

2. Kinins

More recent reviews can be found in ERDÖS (1966), MELMOM (1967), WERLE (1967) and STURMER (1966).

WERLE in 1937 considered the kinins as a substance in the plasma activated by the saliva and responsible for releasing the contraction of smooth muscle. The kinins were isolated by ROCHA E SILVA in 1956, and were synthesized by BOISSONNAS in 1963. The term "kinins" is today applied to the following three biologically active polypeptides of 9 to 11 amino-acid residues.

a) Bradykinin or kinin 9.
b) Kallidin (lysyl-bradykinin, kinin 10).
c) Methionyl-lysyl-bradykinin (methyionyl-kallidin, kinin 11).

Over 70 analogues have been synthesized and their actions been examined, so that the amino-acid residues responsible for the action are known.

The kinins are the most potent known vasodilators and need neither alpha- nor beta-receptors for their action. They produce pain and cause the contraction of smooth muscle fibers (bronchospasm, increased tone and motility of the gastrointestinal tract). They increase capillary permeability and promote the migration of leukocytes.

The kinins are liberated from kininogen, an α_2-globulin which is specific to the species and is produced in the liver. They are liberated by kallikrein, a group of enzymes which occurs in the plasma, granulocytes, and different glands (salivary, tear, and sweat glands, pancreas, kidney, gut). The plasma kallikrein can be activated by various physicochemical stimuli, but usually the presence of the Hageman factor, also essential for blood coagulation, is also necessary. Trypsin, however, can also activate kallikrein, that is, convert kallikreinogen into kallikrein. Inactivators of kallikrein also appear to be normally present in the plasma.

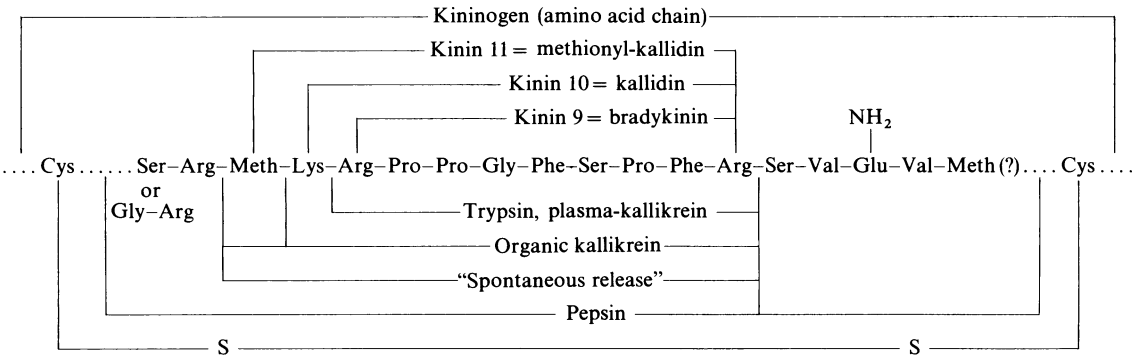

Fig. 5. Formation of kininogens and kinins released by different enzymes. (According to WERLE, 1967)

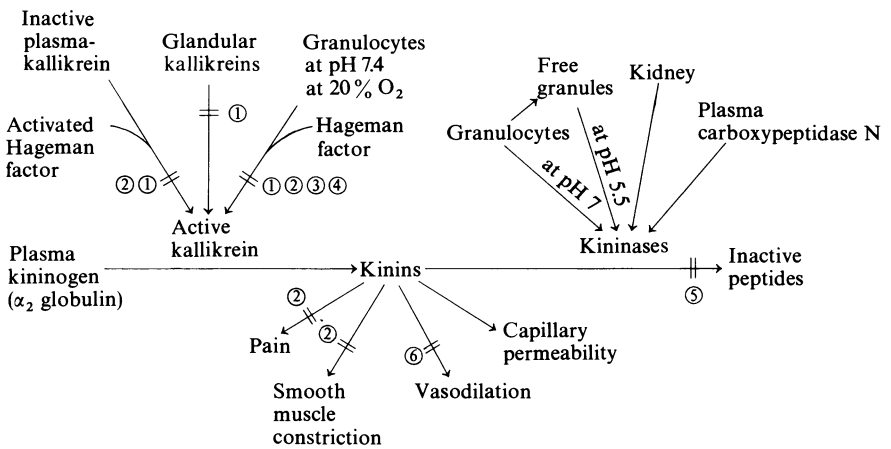

Fig. 6. Interactions of the kallikrein-kinin-kininase system, illustrating the various sources of kallikrein, the participation of Hageman factor, the sources of kininases, and the steps at which the synthesis, breakdown and effect of the kinins are influenced by pharmacologic agents. *1* glucocorticoids; *2* salicylates; *3* colchicine; *4* low oxygen, cyanide, EDTA; *5* EDTA, ε-amino caproic acid; and *6* phenothiazines = blocking.

The polypeptide trasylol, obtained from bovine lungs, inactivates kallikrein in particular, and also trypsin, chymotrypsin, and plasminogen. Apart from kallikrein, trypsin and plasmin can also liberate kinins, but to a lesser degree. It is not yet certain to what extent the β- and γ-globulins PF (the permeability factors) are similar to kallikrein or to what extent they can activate this substance (ERDÖS, 1966). Snake venom, bacterial enzymes, and pepsin can mobilize kinins. The active kinins have an exceptionally short half-life. They are inactivated within seconds by the plasma granulocytes and kidney kininases at the C-terminal end so that their concentration in the plasma normally lies below 2.5 ng/ml.

The kininase in human plasma is activated by epinephrine. Chymotrypsin inactivates bradykinin. Carboxypeptidase-B inhibits exogenous bradykinin. Kininases of the plasma are further inhibited by EDTA; ε-aminocapronic acid inactivates the carboxypeptidases (for literature see KELLERMEYER, 1968).

The physiological importance of the kinins is still unknown. They can have an effect on the change-over from the fetal to the neonatal circulation. Furthermore, they probably regulate the blood flow to the active glands and muscles. Kinins increase the blood supply to the brain, the coronary vessels, and the skin. In the kidneys, plasma flow, diuresis, sodium-potassium excretion, and the free water clearance are increased. On the other hand, the kinins are thought to cause the release of vasopressin. There is a relationship with the catecholamines which together with histamine are liberated by the kinins. Catecholamines are in turn mobilized through histamine.

The important characteristics of inflammation (rubor, calor, tumor and dolor) can be pathophysiologically explained by the action of the kinins. They are involved in endotoxin shock and in Quincke's edema, and are responsible for the flush in the carcinoid syndrome (see p. 986).

In addition, the kinins are probably involved in the pathogenesis of pancreatitis, arthritis, foreign-body granulomas, transfusion accidents, burns and in shock (for literature see KELLERMEYER, 1968).

The activation of the kinin system is related to the coagulation of the blood – both are dependent on the Hageman factor. On the other hand, immunological processes in which kinins are liberated are also connected with kinin activation.

Salicylic acid and glucocorticoids interfere with the activation of the kinins at different sites. This would partly explain their anti-inflammatory actions.

3. Renin-Angiotensin II

J. MÜLLER

a) Definition

Renin is an enzyme which can be extracted from kidney tissue. As a result of its interaction with a plasma protein, the *renin substrate* (angiotensinogen), the decapeptide *angiotensin I* is split off, which in turn is converted to the active octapeptide *angiotensin II* by a peptidase, the so-called *converting enzyme*. Angiotensin II itself is split into inactive peptide fragments by the action of different peptidases for which the collective term "*angiotensinases*" is used.

Whereas renin is exclusively or predominantly formed in the kidney, all the other reactions of angiotensin metabolism can occur in the peripheral blood. It is, however, not yet known whether in the intact organism angiotensin is produced predominantly in the kidneys, in the peripheral circulation, or in other organs under the action of stored renin. Nor do we know exactly which organs are responsible for the conversion of angiotensin I to angiotensin II and for the breakdown of angiotensin *in vivo*. From our present-day knowledge we can assume that changes in the concentration of angiotensin II in the plasma are due mainly to changes in renin secretion, whereas the remaining components of the renin-angiotensin system are usually present in excess. However, some findings have indicated that the concentration of

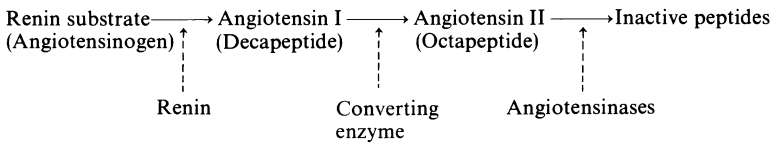

Fig. 7. Formation and degradation of angiotensin II

the renin substrate in the plasma is also under a physiological control, and it is possible that the conversion and breakdown of angiotensin are also variable.

Only angiotensin II has the properties of a hormone and is biologically active. It is not known whether the other components possess further physiological functions in addition to their effects on the production of angiotensin.

b) Biochemistry

α) Renin

The exact structure is at present still unknown. Studies with gel-filtration chromatography and ultracentrifugation indicate that the molecular weight of renin lies between 40000 and 50000. Renin is a thermolabile protein with an isoelectric point between pH 6.5 and 7.5.

From experiments with artificial substrates it can be assumed that renin splits the peptide bond between two leucine groups. The velocity with which purified renin liberates angiotensin from a standard substrate is linearly dependent on the renin concentration over a wide range and remains constant for a long period of time. Renin is also active in an electrolyte-free medium.

The species-specificity of renin activity is limited. Human, canine, rabbit and rat renin also act on a bovine substrate. By contrast, human renin does not react with porcine substrate.

Injection of renin of a foreign species leads to the formation of inactivating antibodies. Renin which is inactivated by acetylation remains antigenically active. Amazingly, it appears to be possible to provoke the formation of antibodies inactivating the endogenous renin in animals by treatment with renin of a foreign species (DEODHAR, 1964).

β) Renin Substrate

In the plasma, the renin substrate is found in the α_2-globulin fraction. SKEGGS (1963) succeeded in isolating three protein fractions from porcine plasma from which angiotensin-like peptides were split off during incubation with porcine renin. Three of these protein fractions could be purified to a high degree. These were glycoproteins with a molecular weight of about 57000 and an almost identical amino-acid composition. The organ of origin of renin substrate is still not definitely known.

According to animal experiments by CARRETERO and GROSS (1967) the renin substrate concentration in the plasma is not only dependent on the utilization but is possibly subject to a physiological regulation. Unilateral or bilateral nephrectomy, experimental renal hypertension, treatment with mineralocorticoids or excessive salt intake led to increased renin substrate levels. By contrast, low substrate concentrations were found following adrenalectomy and during sodium restriction. In humans, the plasma renin-substrate concentration is increased during pregnancy (GOULD, 1966), whereas it is decreased in the rat (CARRETERO, 1967). An increased renin substrate level in the plasma may be of clinical importance in women in whom hypertension and hyperaldosteronism occur during treatment with oral contraceptives (LARAGH, 1967).

γ) Angiotensin I and Angiotensin II

Structure:

Angiotensin I (bovine)

H_2N–Asp–Arg–Val–Tyr–Ileu–His–Pro–Phe–His–Leu–COOH

Angiotensin II (bovine)

H_2N–Asp–Arg–Val–Tyr–Ileu–His–Pro–Phe-COOH

Synthetic-β-angiotensinamide II

H_2N–β Asp(NH_2)–Arg–Val–Tyr–Val–His–Pro–Phe–COOH.

Naturally occurring angiotensin II probably has a helical structure. The amino-acid composition of human angiotensin is unknown. Porcine angiotensin II (5-valine) and bovine angiotensin II (5-isoleucine) are almost equally potent in man. The peptide most commonly used for therapeutical purposes is synthetic β-angiotensinamide II which has a prolonged effect, possibly due to increased resistance against angiotensinases.

On isolated smooth muscle, angiotensin I is about 10 to 20 times less active than angiotensin II. On the other hand, it is not certain whether angiotensin I itself has any effect on blood pressure.

The structural basis of biological activity of angiotensin II has been established by many experiments with numerous analogues. A hexapeptide with amino acids 3–8 is still weakly active. Phenylalanine must be in the terminal position and its carboxyl group must be free. A tyrosine in position 4 is obligatory (PAGE, 1962).

δ) Converting Enzyme

The chemical nature of this factor is totally unknown. Chloride ions are necessary for the conversion of angiotensin I to angiotensin II in

the plasma. The experiments of NG and VANE (1967) indicate that in the intact animal conversion does not occur diffusely in the blood but mainly during circulation in the lungs.

ε) Angiotensinases

This collective term includes several known proteolytic enzymes, such as trypsin, chymotrypsin, leucine-aminopeptidase, carboxy-peptidase, pepsin and numerous unknown enzymes from tissue and erythrocytes. The angiotensinase activity of human plasma is very high. It is, however, not sufficient to account for the short biological half-life of the pressor effect of angiotensin II. Therefore, degradation probably occurs in part extravasally, in organs such as the liver, kidney, spleen or muscles.

In the plasma, angiotensinase activity is found mainly in the α_1-globulin fraction. Aminopeptidase activity accounts for 60% of the total activity. A significant rise in the plasma angiotensinase activity has been observed by different authors in acute and chronic liver diseases (BIRON, 1967). Plasma angiotensinases are only active in the presence of calcium ions and can be inactivated by EDTA.

ζ) Methods of Determination

For methodology of plasma renin and angiotensin determinations and their normal values see Chap. VII, p. 378.

c) Physiology

α) Origin of Renin

In the mammalian organism, the major part of renin originates from the kidneys. The kidneys can secrete renin into the blood, the lymph or the urine. Renin-like substances have been isolated from the placenta, uterus and submandibular glands, but it is not definitely known whether they are identical to the renal renin.

It is generally accepted that renin is predominantly formed in the vascular pole of the glomeruli. However, it is still controversial whether renin is produced by the juxtaglomerular epitheloid cells of the afferent arterioles, or rather by the neighboring macula-densa cells of the distal renal tubules. At present, there is no definite direct evidence supporting one theory or the other. In many experimental situations the granulation of the juxtaglomerular cells is parallel to the renin content of the kidneys and it is assumed by different investigators that these granules are representative of the production or storage of renin. Under normal conditions, renin is only produced in the outer third of the renal cortex. Increased amounts of renin, however, are found in the deeper layers in renal artery stenosis.

β) Regulation of Renin Production and Secretion

At present, renin production cannot be quantitatively measured in an intact animal. Our present-day theories about the regulation of renin secretion are based on the estimation of renin concentration in the plasma or in renal tissue. Since the renin content in the kidneys changes in the same direction as the renin concentration in the plasma under most long-term experimental conditions it is assumed that production and secretion are controlled by the same regulating mechanisms.

1. Receptors and Mediators

Production and secretion of renin are influenced by renal and extrarenal factors. At present two theories of renal regulation are under discussion. They are based predominantly on morphological observations and on the assumption that the receptors of renin regulation are either identical to the renin-producing cells or in their immediate vicinity.

Baroreceptor Theory. According to this theory, renin production is mainly regulated by changes

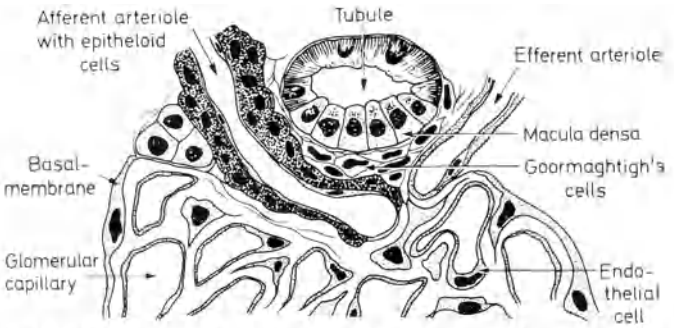

Fig. 8. Morphology of the juxtaglomerular apparatus. (From WOLFF, 1964)

in pressure. The receptors are situated in the wall of the afferent glomerular arteriole and register changes in arterial blood pressure, in vascular tone or in interstitial renal pressure.

Macula-Densa Theory. According to the opinion of other authors, renin production changes predominantly in response to changes in the composition of the urine in the distal tubule. According to this theory, the macula densa cells are chemoreceptors registering changes in sodium flux.

Neural Regulation. It is certain that renin production is influenced by the sympathetic nervous system. However, we do not know whether this is by direct stimulation of the renin-producing cells or by indirect amplification of the stimuli acting on the two postulated intrarenal receptors. The juxtaglomerular apparatus is richly supplied with non-myelinated nervous fibers. Denervation of the kidney leads to a fall in its renin content. Infusion of catecholamines, tyramine or dimethylphenylpiperazine into the renal arteries induces increased renin secretion.

Hormonal Regulation. Angiotensin exerts a negative feedback effect upon renin production. This suppression of renin production is independent of the plasma aldosterone level or of renal arterial blood pressure. Infusion of aldosterone into the renal artery of a sodium-deficient animal does not suppress renin secretion. It is uncertain whether hormones other than catecholamines and angiotensin can directly influence renin production.

2. Variations in Renin Secretion under Physiological and Pathological Conditions

Biological Rhythms. In normal humans, there is a circadian rhythm of plasma renin concentration which is independent of posture and food intake. In recumbent subjects, the highest values were found between 2 and 8 a.m., the lowest values between noon and 6 p.m. (GORDON, 1966).

Upright posture leads to a steep increase in plasma renin concentration, but the increment is larger in the morning than in the afternoon. The rise of renin can be suppressed by bandaging the lower half of the body.

In normal women, plasma renin concentration increases during the luteal phase of the menstrual cycle.

Sodium Balance. Acute or chronic sodium deficits due to a sodium-deficient diet, saliuretics, tubular sodium loss, Addison's disease or adrenalectomy lead to a marked increase in plasma renin concentration, excessive oral or parenteral sodium intake or treatment with mineralocorticoids to decreases in renin concentration.

Alterations of Circulating Blood Volume. Hemorrhage or hypotension lead to an increased secretion of renin whatever the etiology. An increase in renin production in thirst and in edematous diseases (cirrhosis of the liver, nephrosis) is probably also due to a decrease in circulating blood volume. Elevated renin concentrations are not usually found in patients with untreated congestive heart failure.

Hypertension. Normal or low plasma renin values are found in benign essential hypertension. In renal or malignant hypertension, the plasma renin concentration is often but not always elevated. There is no correlation between hypertension and the renin concentration; on the other hand, there is a reversed correlation between the sodium concentration and the renin concentration in the plasma. However, it is not certain whether the low plasma sodium concentrations found in some patients with renal hypertension are the cause or a consequence of the elevated renin level.

Pregnancy. Plasma renin concentrations are within the normal range in approximately 50 percent of normal women throughout pregnancy. In the others, plasma renin concentration increases during early pregnancy, stays at a high level until delivery and then decreases rapidly to normal values. The renin may be formed partly by the placenta. Normal or decreased renin values are observed in preeclampsia.

γ) Physiological and Pharmacological Effects of Angiotensin II

1. Effects on the Circulation

Blood Vessels. Angiotensin II has a marked vasoconstrictive effect mainly on the precapillary vessels, whereas its constrictive effect on the postcapillary vessels and the veins is only weak. Its predominant effect is on the vessels of the skin, of the splanchnic area and of the kidney, resulting in an acute reduction of the blood supply of these organs. Its effects on the vessels of skeletal muscles and on cerebral, coronary and pulmonary circulation are considerably less pronounced.

Heart. In vitro, angiotensin exerts a positive inotropic effect on the cardiac muscle (KOCH-

WESER, 1964). However, it is very questionable whether it exerts the same activity *in vivo*.

Blood Pressure. Angiotensin II is one of the most potent hypertensive agents. On a molar basis, it is 40 times more active than noradrenaline. Even a dose of 2 ng/kg/min can lead to a considerable rise in blood pressure. After an intravenous injection of angiotensin II the blood pressure reaches a maximum within one minute and becomes normal again within five minutes without a secondary fall below normal. Since the pressor activity of angiotensin is still demonstrable after adrenalectomy, sympathectomy, and cordotomy, as well as during treatment with atropine, ganglion blockers and adrenergic blockers, it is assumed that it acts directly on the vascular muscles. However, a stimulatory effect on the symphathetic nervous system may contribute to its overall effect on blood pressure.

Adrenal Medulla. Angiotensin acts directly on the chromaffin cells and leads to the release of catecholamines.

2. Effects on the Kidneys

Angiotensin causes an acute decrease in the renal blood supply and thus decreases the glomerular filtration rate. As a result, there is a decrease in water and electrolyte excretion. This antidiuretic effect has been observed mainly in humans and dogs. On the other hand, angiotensin inhibits sodium reabsorption in the distal tubules and thus leads to sodium and water diuresis. This diuretic action has been observed mainly in rabbits and rats. However, it is also demonstrable in man under certain conditions. Certain forms of renal hypertension lead to sodium loss. Administration of angiotensin in patients with cirrhosis of the liver and ascites leads to a marked salt-and-water diuresis.

3. Effects on the Adrenal Cortex

Angiotensin in small doses specifically stimulates the biosynthesis and secretion of aldosterone. In many cases of so-called secondary aldosteronism, an elevation in aldosterone secretion rate appears to be directly related to an increased renin production. Alterations of aldosterone secretion in response to alterations in sodium balance are at least partly mediated by the renin-angiotensin system.

4. Effects on Smooth Muscles

Angiotensin not only provokes contractions of vascular smooth muscles, but has a similar effect on the smooth muscles of the gut, uterus, gall bladder, seminal vesicles and ureters. These effects, however, are at least partly mediated by the autonomic nervous system. Thus, the effect of angiotensin on guinea-pig ileum can be partly suppressed by atropine.

d) Hyperfunctional and Hypofunctional Clinical Syndromes of the Renin-Angiotensin-System

Recently, 6 cases of renin-producing renal tumors, "hemangiopericytomas", originating from the juxta glomerular cells have been observed. The patients had hypertension and in a late phase hypokalemia as patients with primary aldosteronism. However, renin activity in the serum was high and especially elevated in the venous plasma from the affected kidney. After operations, the patients were cured, and renin-like enzyme could be extracted from the tumors. Also other, more common tumors as Wilms's tumor, may occasionally be associated with "primary reninism" and hypertension in children (Leading article, 1973; CONN, 1972).

On the other hand, isolated hypoaldosteronism with recurrent weakness and blurring of consciousness with hyperkalemia can be due not only to blocked biosynthesis of aldosterone, but apparently also to a deficiency of renin. Infusion of angiotensin II corrects plasma aldosterone, and the patients are successfully treated with fludrocortisone (Leading article, 1973; BROWN, 1973).

4. Substance P

In 1931 EULER and GADDUM described a new type of substance, probably of peptide structure, in extracts of the brain and gut. This substance, even in the smallest amounts, stimulated smooth muscle, salivary secretion and caused a fall in blood pressure.

This substance P, has now been purified, it's amino-acid sequence clarified; and recently it has been synthesized (CHANG, 1971; TREGEAR, 1971). It is a one-chain hendecapeptide.

Substance P is found in the intestinal tract and in the nervous system of man and of all the vertebrates examined (HAEFELY, 1962; LEMBECK, 1962; ZETLER, 1963).

Substance P causes most of the organs with smooth muscle to contract and causes the blood pressure to fall as a result of peripheral vasodilatation (PERNOW, 1953). Based on the grounds of occurrence of substance P in the central nervous system and on certain actions of poorly purified preparations, it has been postulated that the polypeptide has some function as an inhibitory transmitter substance at cen-

tral synapses (LEMBECK, 1962; ZETLER, 1963). Experiments with highly purified preparations, however, did not provide evidence of the specific neurotropic property of the substance (HAEFELY, 1962; BAILE, 1967). The assessment is, however, encumbered by the exceptional instability of the purified substance. An enhancement of intestinal peristalsis seems to be its most probable physiological action.

The hendecapeptides *Eledoisin*, extracted from Salivary glands of cephalopods and *Physalaemin*, isolated from amphibian skin, have a similar constitution and similar effects.

5. VEM and VDM (Vasoexcitor and Vasodepressor Substances)

In 1945, SHORR, MAZUR, and BAEZ discovered the vasoactive substances VEM and VDM during their studies of experimental shock. There is still a difference of opinion about whether these substances should be termed "tissue hormones", and this can only be settled after the physiological importance of these substances has been finally determined.

VDM is formed in the liver, spleen, and skeletal musculature. VEM is formed by the kidneys. The VDM produced in the liver has been identified as the Fe-containing protein, ferritin. Its hypotensive action is bound with its reduced sulfhydryl-ferro form. It loses its effect in the oxidized state. This is thus dependent on the prevailing oxygen tension. Apart from this, the adrenocortical hormones, protein intake, and ascorbic acid influence its activity. Ferritin reduces the reactivity of the capillaries to adrenaline, especially in the splanchnic area. In addition, it is thought to have an antidiuretic effect via the release of vasopressin and also has a function in the storage and liberation of iron. Very little is known about the nature of the VDM of muscular origin and of the hypertensive VEM.

6. Parotin

It is still uncertain whether a protein extracted from the glandula parotis and glandula submaxillaris, which stimulates calcification of the connective tissue in certain mammals, especially the teeth, lowers the serum calcium, and favors leukocytosis, is a hormone or not (ITO, 1960). Further, a protein NGF has been extracted from submaxillary glands of mice, which stimulates the growth of sympathicus nerve cells in the mammal (COHEN, 1960; LEVI-MONTALCINI, 1968). Other factors from the same source are said to stimulate the erythropoietin and the granulocytes (LEVI-MONTALCINI, 1968).

C. Glycoprotein: Erythropoietin

In 1906 CARNOT and DE FLANDRE observed that serum of anemic rabbits promoted the production of erythrocytes in the normal animal. This substance, now named "erythropoietin", has received intensive attention only in the past 20 years.

Erythropoietin is a glycoprotein, or a polypeptide with carrier protein. It is probably an alpha-globulin with a molecular weight of 28000–33000, containing neuraminic acid, 7–8% hexoses, hexosamine and sialinic acid. Despite a 50000-fold concentration from serum of anemic sheep, especially by means of ionic exchange chromatography, the hormone has still not been produced in purified form. In spite of weak antigenic properties, antibodies are retained which neutralize erythropoietin *in vivo* and *in vitro*. The antigen-antibody reactions are not species-specific (SCHOOLEY, 1962).

There might be a renal erythropoietic factor which converts a substance formed in the liver to active erythropoietin.

An insufficient oxygen supply is an adequate stimulus for the formation or release of erythropoietin. Thus, hypoxia and severe anemia can cause a rise in the plasma content, whereas the erythropoietin level falls with over-transfusion or with the return to sea level after adaptation to heights. The daily production, according to the urinary excretion, is estimated to be 4.0 U (WHO Standard B) with variations of 1.2–9.5 U (ADAMSON, 1966).

Hormones of the pituitary, gonads, thyroid, adrenal cortex and medulla are nonspecific stimulators of erythropoiesis. Androgens promote the formation of erythropoietin directly, whereas estrogens inhibit it.

Erythropoietin acts on the parent cells of the bone marrow and stimulates their differentiation into erythroblasts. It also seems to govern the rate of hemoglobin synthesis in the erythroblasts already differentiated. Further Cobalt ions increase the formation of erythropoietin. The erythropoietin content of the blood falls after nephrectomy and can no longer be stimulated by cobalt. Erythropoietin is formed mainly in the renal tissues, probably in the juxtaglomerular apparatus. It is possible that a small amount is also produced extra-renally.

Erythropoietin in the plasma is increased in all sufficiently severe cases of anemia. Erythropoietin is excreted in the urine in amounts definitely dependent on the severity of the anemia.

The erythropoietin is demonstrated by measurement of the ^{59}Fe incorporated into the erythrocytes in the overtransfused mouse after

administration of the serum or urine extract to be examined.

Renal tumors which give rise to polyglobulism contain and produce more erythropoietin. Erythropoietin is also accumulated in the fluid of renal cysts, in the cysts of cystic kidneys, and in hydronephrosis. This can lead to polycythemia probably secondary to partial ischemia of kidney tissue (ADAMSON, 1968). There is a series of other tumors known to lead to secondary polyglobulism.

D. Amines

1. Serotonin (5-hydroxytryptamine, enteramine)

Serotonin is formed in the enterochromaffin or argentaffin cells of the gastrointestinal tract as well as in the central nervous system. Mast cells form serotonin in the rat and mouse, but not in man. Serotonin probably acts as a local hormone (parakrinial), and can exert distant effects by means of the bloodstream in which it is transported predominantly by the thrombocytes. The blood platelets can concentrate serotonin from the plasma by more than a thousand fold, the uptake capacity being dependant of an intact energy metabolism with a normal ATP content. The abundance of serotonin in the spleen is probably due to the accumulation of thrombocytes. In the central nervous system, the hypothalamus in particular contains large amounts of serotonin and catecholamines, whereas the pineal body also forms the serotonin derivative, melatonin (see Chap. IV, p. 73).

a) Biochemistry

The biosynthesis of serotonin from tryptophane occurs by processes similar to the synthesis of the catecholamines from phenylalanine. Some of the same enzymes are employed. The dopa-decarboxylase also decarboxylates hydroxytryptophane to hydroxytryptamine. 5-Hydroxylation by tryptophane-hydroxylase is the first step. Under normal conditions, about 1% of the tryptophane taken in with the food is converted to serotonin. This percentage can rise to 60% under pathologic conditions such as the carcinoid syndrome.

Breakdown occurs in the first place through the actions of monoamine oxidase, which converts the serotonin into hydroxy-indole acetic aldehyde. Monoamine oxidase is also involved in the breakdown of a series of other amines but shows a preference for serotonin. 5-Hydroxy-indole acetic acid is formed from the aldehyde through an aldehyde dehydrase and is then excreted through the kidneys. The individual

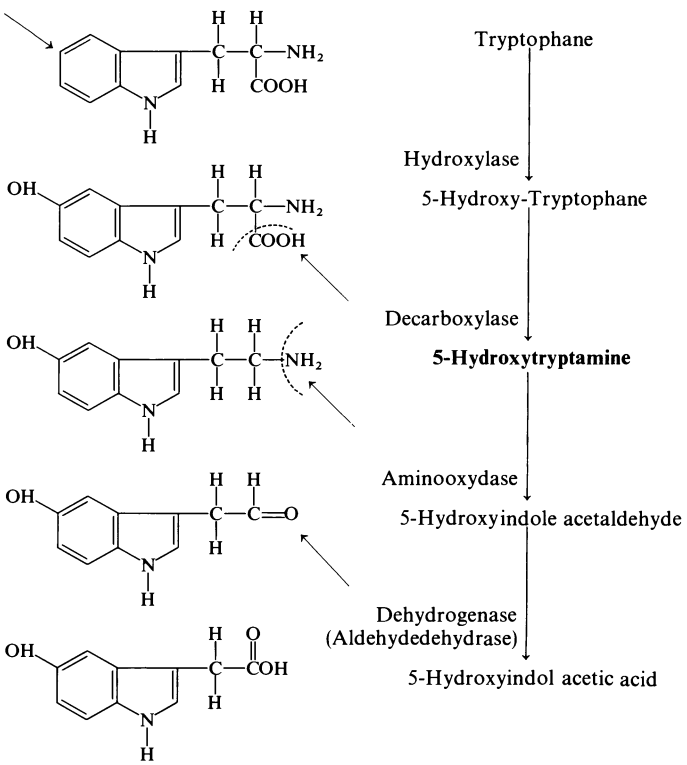

Fig. 9. Biosynthesis and metabolism of 5-hydroxytryptamine (serotonin). (From CERLETTI, 1958)

Table 1. Inhibitors of formation and degradation, releasing factors and antagonists of serotonin. (According to LEMBECK, 1962)

Inhibitory substances	Enzymes		Liberators	Antagonists
		Tryptophane		
		↓		
		Hydroxytryptophane		
α-Methyl-Dopa, Phenyl acetic acid	Decarboxylase	→		
		Hydroxytryptamine (Serotonin)	Reserpine *et al.*	LSD, Deseril, Medomin, etc.
Iproniacide, Niamide *et al.*	Monoamine oxidase	→		
		Hydroxyindole acetic acid		

stages of the building up and breaking down processes can be inhibited by enzyme inhibitors. This, however, is only of theoretical interest and cannot be used therapeutically (see p. 970).

b) Physiology

In 1966 a handbook of 724 pages on hydroxytryptamine was published. Although the pharmacological research of serotonin is very advanced, little is known about its physiology. Reserpine and similar compounds liberate serotonin from the brain and the thrombocytes, yet they have only a slightly similar effect on the enterochromaffin cells of the intestinal tract. Almost nothing is known about the physiological releasing mechanism. Adrenaline and noradrenaline can liberate serotonin. The only probable physiological action of serotonin known today is the increase in the motility of the gut. i.e., a fall in the stimulus threshold for mechanical influences acting on the Meissner's plexus to release peristaltic waves.

It is not known whether serotonin has any effect on blood coagulation through the destruction of the thrombocytes which is associated with the liberation of large amounts of serotonin. Depletion of serotonin stores through large amounts of reserpine does not produce a prolonged bleeding time. It is possible that in the case of a pulmonary embolus, the serotonin liberated through the destruction of platelets increases the pressure in the pulmonary circulation slightly. Only unphysiologically high doses of serotonin have an antidiuretic action, probably because they release vasopressin. It has no effect in diabetes insipidus (REBER, 1956). The renal blood supply is not influenced by physiological doses. The physiological significance of serotonin in the brain is still unexplained. Depletion of the stores by means of reserpine or para-chlorophenylalanine leads to depression, insomnia and hallucinations. The insomnia can be counteracted in animal experiments by the administration of 5-hydroxytryptophane (JOUVET, 1967). The concentration of serotonin in the brain varies during day and night, so that serotonin has also been called "somnotonin" (KOELLA, 1970). The hallucinogenic lysergic acid diethylamide is an antagonist to serotonin in various peripheral organs. However, it has not yet been proven that its actions are due to the inhibition of serotonin. Iproniazide, a monoamine oxidase inhibitor, results in the accumulation of serotonin in the brain, and is described as a psychoenergetic agent by the pharmacologists. It inhibits the breakdown of the catecholamines as well as of serotonin.

c) Carcinoid Syndrome

Today it is doubtful whether the carcinoid syndrome is due entirely to the over-production of serotonin. However, there is, almost without exception, increased production of serotonin in this syndrome. Over-production of serotonin is probably responsible for individual symptoms if not the cause of the syndrome. Carcinoid syndrome is dealt with here for these reasons as a hyperfunctional syndrome of the tissue hormone, serotonin.

α) Morbid Anatomy

The carcinoid syndrome has two main forms (Table 2); the pseudocarcinoid syndromes, i.e. groups of symptoms simulating carcinoid syn-

Table 2. Different forms of carcinoid syndrome

	Tumor	Clinical symptoms	Biochemistry
1. Typical carcinoid syndrome	Carcinoid	Typical	Typical
2. Atypical carcinoid syndrome	a) Carcinoid b) Noncarcinoid	Atypical Typical	Atypical Typical

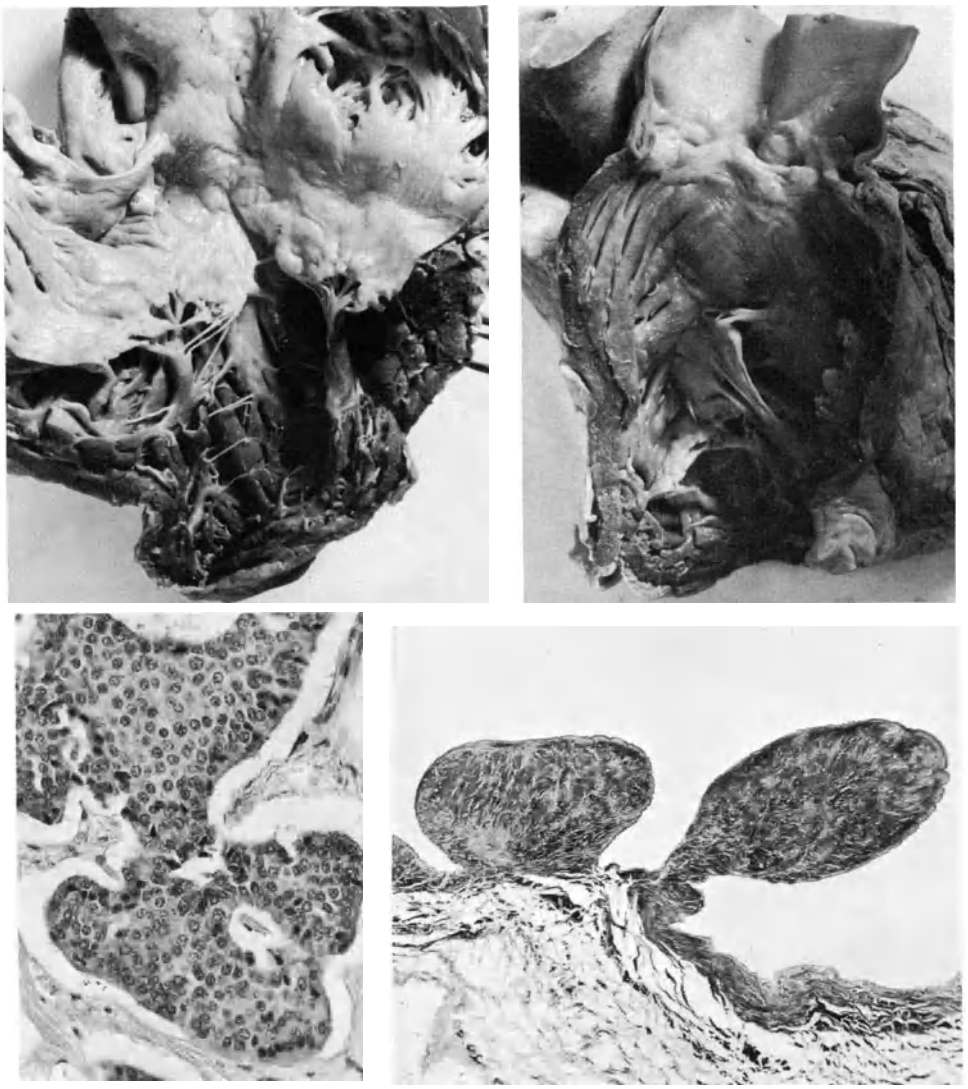

Fig. 10. Carcinoid syndrome. S 1597/53, 76-year-old male. Upper left: Fibrous thickening of the tricuspid valve and of the endocardium in the right atrium. Upper right: Chronic fibrous endocarditis of the pulmonary valves with pulmonary stenosis. Lower left: Hepatic metastasis of a carcinoid of the ileum. Lower right: S 726/56, 65-year-old male with metastasizing carcinoid. Polyp-like fibrous thickening of the endocardium in the right atrium

drome, must be differentiated from these two forms.

Carcinoids. Carcinoids are usually situated in the gastrointestinal tract, primarily in the thin bowel, in the appendix and less often in the stomach, the colon, or in Meckel's diverticulum. Carcinoids, however, also occur in the bronchial tree or in teratomas of the ovaries or testicles. Carcinoids of the gastrointestinal tract derive from argentaffin or enterochromaffin cells characterized by their affinity to silver salts which they reduce without reducing agents to metallic silver and form granular black precipitates in the cytoplasma of these cells. A part of the tumor is, however, only argyrophil, i.e., the granula are made black by silver salts only if a reducing agent is added. The argentaffinity is very labile and can disappear within two hours, so negative findings are to be cautiously considered. There is no parallel between the frequency of the carcinoids in the different parts of the gut and the number of the argentaffin cells in the corresponding parts. Primary tumors of the gastrointestinal tract are usually small, the size of a cherry, and occasionally multiple. The metastases occur especially in the mesenterial lymph nodes and in the liver. They can also occur in more distant parts. The full-blown carcinoid syndrome usually only occurs if meta-

stases in the liver have developed. Mass and extension of the metastases do not parallel the intensity of the syndrome. Carcinoids outside the portal system, e.g., carcinoids in teratomas of ovaries and testicles, can produce a full carcinoid syndrome without metastases. The carcinoids of the bronchial tree produce the syndrome only if liver metastases occur. The carcinoids of the stomach produce especially atypical syndromes (see p. 990). This type seems to produce predominantly bone metastases.

Other Tumors with Carcinoid Syndrome. Anaplastic, particularly oat-cell bronchial carcinoma, can produce the carcinoid syndrome without typical carcinoids. Also, medullary carcinoma of the thyroid, tumors of the pancreas, and especially of the islets, as well as other tumors can produce the syndrome.

Cardiac Changes. The most impressive secondary symptoms are the changes in the heart. Metastasizing thin-bowel carcinoids, changes of the tricuspid and pulmonary valves with pulmonary stenosis form a typical triad (ISLER and HEDINGER, 1953). The changes in the endocardium are due to a thickening of the tricuspid and pulmonary valves with a strange frosting-like mass which spreads over the surrounding parts of the endocardium of the right atrium, right ventricle, and the pulmonary artery (Fig. 10). The thickening consists of a tissue rather rich in cells with a basophilic and metachromatic ground substance spread over the endocardium. Occasionally, the valves of the left heart can also be attacked, especially if there is a shunt between the right and the left heart, for instance if there is an open foramen ovale.

Vascular Changes. In the regions where the flush occurs, there are enormous dilatations of the subepidermal capillaries (angioma telangiectaticum – SCHOLTE, Steiner-Voerner syndrome – PARKES-WEBER) with edema and basophilic infiltration of the surrounding collagen tissue. After removal of the tumor these changes may regress.

Other Findings. Besides the flush and its sequelae, a kind of pellegra may occur which disappears after removal of the tumor or after treatment with niacin. Occasionally, a thickening of the collagen tissue of the pelvis with a ring-like wall around the bladder and the rectum has been observed. There are no significant inflammatory infiltrates. It is possible that there is fibrosis as a sequel to accumulation of agents which act on the connective tissues and are secreted by the metastasizing carcinoid into the abdominal cavity.

β) Frequency and Incidence

Asymptomatic carcinoids are found relatively often. In 0.65% of all necropsies there are small carcinoids in the gastrointestinal tract. Carcinoids are found in about 0.2–0.5% of the surgically removed appendices. Classic carcinoid syndromes are, however, relatively rare. WALDENSTRÖM (1962) in Malmö observed 6 cases in a population of about 200000 persons within a period of 10 years. In the same period, there were three cases of pheochromocytoma and only one active insuloma.

Atypical carcinoid syndromes with simultaneous hyperinsulinism, ACTH overproduction, prostaglandin secretion, histamine release, etc. are rarities. Carcinoid syndromes due to other types of tumors or carcinoids in endocrine adenomatosis seldom occur. The relative frequency of different localizations of carcinoids is reviewed in Table 3.

Table 3. Localization and incidence of carcinoids

Localization	Incidence (%)	Argentaffinity	
		Carcinoid	Normal mucosa
Bronchial tree	1	Rarely	(+)
Stomach	3	Rarely	++++
Pancreas	Rarely	Often	(+)
Duodenum	2[a]	Mostly	+++++
Jenunum / Ileum	33[a]	Mostly	++
Meckel's diverticulum	1	Often	++
Appendix	46	Often	++
Colon	2	Not always	+
Rectum	1	Rarely	+++
Bile ducts	0.2	Rarely	+
Hamartomas	Rarely	Variable	
Teratomas	Rarely	Variable	

[a] Craniocaudal increase in incidence.

The statistics published by MOERTEL (1961) show a male preponderance of approximately 2:1. The patients are mostly between 50 and 60 years old. The syndrome has, however, also been found in juveniles and elderly people.

γ) Clinical Features

The clinical illness is dominated by the following four cardinal symptoms:

1. Skin symptoms: flush, constant cyanosis, telangiectases.
2. Gastrointestinal symptoms: colic, diarrhea, obstruction.

	Symptom	Incidence	%→
Skin	Flush	129	93.5
	Constant cyanosis	25	18.1
	Telangiectasias	35	25.2
	Pellagra-like dermatosis	9	6.5
Respiratory system	Asthma	26	18.9
Gastrointestinal tract	Diarrhea	107	77.5
	Colic-like abdominal pain	70	50.7
	Ileus or subileus	21	15.2
Heart	Endocardial fibrosis in the right ventricle (autoptically) or valvular alteration proven by heart catheterisation	55	39.9
	Endocardial fibrosis of the left ventricle (only detected by necropsy)	18	13.1
Water balance	Oliguria or edema (no signs of cardiac diseases)	26	18.9
Articulations	Joint pains, "Arthritis"	10	7.3
Tumor	Palpable tumor of the liver	86	62.4
Body weight	Weight loss	65	47.1

Fig. 11. Type and incidence of symptoms in typical carcinoid syndrome in 138 patients. (According to KÄHLER, 1967)

3. Respiratory symptoms: bronchial asthma, tachypnea, hyperpnea.

4. Cardiac symptoms: pulmonary stenosis, tricuspid insufficiency, right-sided failure.

The frequency of the main and minor symptoms is given in Fig. 11.

The symptoms start slowly and the course may be drawn out over years or even decades since the tumors grow slowly and are relatively benign in spite of metastases. On average, however, the illness lasts for 2–4 years, and the long-term prognosis is poor with very few exceptions.

1. Skin Symptoms. The most characteristic and pathognomonic symptom in the typical course of the disorder is the flush: a striking reddening of the face, consisting of large spots or patches, which may change into cyanosis and may be associated with a sensation of heat. The duration of an attack and the frequency can vary greatly. As a rule, the attacks last for a few minutes but may last for hours. At the beginning they arise monthly or weekly. Later, they can occur several times a day. The flush develops spontaneously at any time, but it is especially frequent on wakening. It can, however, be precipitated by physical exertion, excitement, intake of food, especially of alcohol, and by mechanical pressure on the tumor or on metastases. In addition to the unpleasant sensation of heat, the patients suffer from congestion in the head and sometimes from nausea and vomiting. They may experience a burning in the areas of skin involved. Itching seldom arises. The flush goes through three stages. First the precapillary arterioles become dilated. Cheeks and nose become brick red, and the reddening spreads to the neck, thorax and perhaps the extremities. The conjunctivas are injected. The skin then becomes purplish red. At the same time edematous swelling arises, especially in the lips and lids. The skin is hot. In the subsiding phases, patchy cyanosis develops – the arterioles are constricted and the capillaries dilated. The skin is then cold. The cardiac output is first reduced, then increased. Tachycardia develops, with slightly elevated diastolic and systolic pressures. Finally, hypotension arises, and collapse may ensue.

Apart from the flush during attacks, persistent reddening of the face may develop, and finally, constant cyanosis due to local hemostasis in the dilated capillaries. The telangiectases on the nose and cheeks are characteristic. They may disappear after the tumor has been removed. Finally, pellagra-like changes become noticeable in the skin as goldenbrown pigmentation in the

face and on the back. Hyperkeratosis may be associated with stomatitis, glossitis and vulvitis.

2. Gastrointestinal Symptoms. These arise early in the form of irregular watery diarrhea and colic-like attacks of pain. They may occur together or separately. Loud borborygmi are characteristic. Colic and diarrhea occur either occasionally or as often as 20 times daily. The feces may contain undigested food, and radiological examination reveals exceptionally accelerated motility of the gut. Occasionally steatorrhea may develop.

Obstruction, sub-ileus, and ileus are due to the primary tumor or the metastases.

Finally, in over 50 percent of cases, a tumor is palpable in the liver.

Diarrhea and colic may arise with the flush or independently.

3. Respiratory Symptoms. As a rule, the flush is associated with tachypnea and hyperpnea, which is usually accompanied also by bronchial spasm with typical bronchial asthma. Occasionally the asthmatic symptoms may precede the typical carcinoid symptoms. The asthma varies from breathing with mild stridor to extremely severe attacks with asphyxia.

4. Cardiac Symptoms. Endocardial fibrosis involves predominantly the right side of the heart. Changes in the left side of the heart have only been found at autopsy and almost exclusively with pulmonary carcinoid or with intracardial shunts. The cardiac changes are a late symptom, and they are irreversible. In rare cases the pericardium is slightly affected by fibrosis as well as the endocardium. Half the patients with cardiac involvement die of cardiac failure; pulmonary valvular stenosis, occasionally combined with mild pulmonary insufficiency and all the corresponding typical auscultatory findings, dominates the clinical picture. The values obtained by cardiac catheterization are also typical. The ECG shows right ventricular overload and damage. The X-ray may reveal a protruding pulmonary arch. The right ventricle does not become enlarged until cardiac failure develops. Tricuspid insufficiency usually arises only when the pulmonary stenosis leads to increased pressure. The right side of the heart soon becomes insufficient and fails. Tricuspid insufficiency can be recognized from the venous and hepatic pulsations.

5. Other Symptoms. Disturbances in water balance – oliguria, edema, and occasionally ascites and pleural effusions – are less frequent symptoms. They may also occur in the absence of cardiac failure. Their development cannot be readily explained. Serotonin is thought to increase the venous pressure and capillary permeability.

Joint pains in small and large joints, occasionally with slight inflammatory signs, do not necessarily correspond to true arthritis. Duodenal ulcers are thought to occur frequently.

Cases of bronchial carcinoid with hypoglycemia and increased immunoreactive insulin in the serum as well as in the tumor have been observed (SHAMES, 1968).

6. Psyche. Critical investigation of patients with carcinoid syndrome has not revealed any psychopathologic manifestations which can be directly related to 5-hydroxytryptamine. Acute or chronic over-administration of serotonin does not have any immediate effect (SCHNEIDER, 1957; KIND, 1957).

In addition to the full-blown presentation which is easy to diagnose, individual organic symptoms may completely dominate the picture. Thus a tumor form, an enteral form, a cardiovascular form, and a pulmonary form can be differentiated (HEDINGER, 1962).

δ) Pathogenesis

Not every carcinoid, and not even every carcinoid with liver metastases, results in carcinoid syndrome. Conversely, in rare cases, the full picture of the syndrome may be found in the absence of the morphological correlate of a carcinoid tumor.

Carcinoids are tumors of the enterochromaffin or argentaffin cells which form the tissue hormone serotonin. The tumors contain relatively large amounts of serotonin while dopadecarboxylase activity is high and amino oxidase activity low, so that the serotonin pool in the carcinoid patient can be estimated to be as much as several grams (ZIEGLER, 1967). The level of serotonin in the blood is elevated almost without exception, and increased amounts of 5-hydroxy indole acetic acid, the breakdown product of serotonin, are excreted in the urine. A hyperfunctional syndrome of serotonin was formerly thought to be recognized in the carcinoid syndrome, since serotonin acts on the gut, dilates the capillaries and produces edema and bronchial spasm. Supporting this view is the fact that pressure on the tumor or on the metastases can cause an attack. On the other hand, however, one finds that during the flush, the serotonin in the blood is not raised, and that injections of serotonin produce certain vascular reactions but are hardly capable of releasing a typical flush.

In addition, despite all efforts, cardiac changes have not been successfully produced in animal experiments by the chronic administration of serotonin which would correspond to the carcinoid syndrome. Serotonin over-production is probably responsible for the diarrhea at the most.

Tumor metastases in the liver, in contrast to healthy liver tissue, contain considerable amounts of kallikreinogen, or kallikrein, the enzyme which liberates the kinins, particularly kallidin or lysyl-bradykinin, from the kininogen in the plasma. Bradykinin releases the typical flush in both the healthy subject and the carcinoid patient. At the same time it causes bronchospasm and intestinal contractions. As a rule, however, the concentration of bradykinin in the hepatic vein is not always elevated during the flush.

The catecholamines, adrenaline and noradrenaline, can also produce a typical flush. The carcinoid tumors, especially metastases, liberate kallikrein under the influence of catecholamines, which then leads to a rise in the bradykinin in the blood. On the other hand, serotonin can also liberate catecholamines and vice versa. It is probable that all three substances are involved in the flush, the diarrhea, and the asthma to some extent. It can be concluded that the diarrhea is due predominantly to serotonin, since the serotonin antagonist, methysergide, causes only the diarrhea to cease. The flush can be counteracted successfully with glucocorticoids. It is known that glucocorticoids inhibit the activity of kallikrein (see p. 977). The pathogenesis of the cardiac symptoms has not yet been explained. It is likely that they are produced by a substance found in the vena cava and only rarely contained in the pulmonary veins. It is generally assumed that both serotonin and bradykinin are found in higher concentrations in the pulmonary artery than in the pulmonary veins. However, changes in the left side of the heart may also occur in the absence of pulmonary carcinoids, metastases, or of a right-left shunt. Bradykinin increases endothelial permeability. It has yet to be proven that bradykinin or similar substances cause endocardosis. The changes in the heart are not related in any way to the duration of the illness or to the size of the liver metastasis (ROBERTS, 1964).

The predisposition to edema and oliguria may be due to serotonin. The pathogenesis of the joint pain is not clear. The pellagra-like cutaneous manifestations and pigmentations are probably the results of a nicotinic acid deficiency. This deficiency is probably due to the removal of tryptophane by the carcinoid tumors so that the basic substance is not available in adequate amounts for nutrition.

ε) Laboratory Diagnostic Tests

Routine laboratory investigations such as ESR, blood picture and urine analysis generally yield normal results. Occasionally thrombocytosis is found. There is hypoproteinemia in about 25 percent of cases.

The diagnosis is confirmed by the demonstration of a definitely increased content of 5-hydroxy indole acetic acid in the 24-hour urine. This substance can be estimated colorimetrically after suitable extraction and purifying processes (UDENFRIEND, 1955). The qualitative and semiquantitative urinary tests are not reliable. Conditions necessary for the test are the withdrawal of all possible drugs, especially those of the phenothiazine group, and the elimination of fruit with a high serotonin content, such as bananas, walnuts, and pineapples from the diet, before collection of the 24-hour urine.

Values of 2–8 mg are considered normal. Values above 15 mg/24 h are certainly pathologic. Values of 50–300 mg/24 h are found in carcinoid syndrome. A distinctly elevated value is evidence of carcinoid syndrome. Normal values, however, do not exclude a carcinoid. Serotonin may be released intermittently, and the amount of 5-hydroxy indole acetic acid in the urine may vary from one day to the next. When there is clinical suspicion of a carcinoid and the values are normal, a provocative test with reserpine is indicated. This test proves that a carcinoid is present when the result is positive but does not exclude a carcinoid when the result is negative. 2–5 mg reserpine is given by i.m. injection, and the 5-hydroxy indole acetic acid excreted in the 24-hour urine is measured for 2–3 days. A rise of over 15 mg excretion is required for a positive result. Slight increases occur in normal individuals. If the test gives a negative result with this dose and the reserpine is well tolerated the test can be repeated with 5–10 mg reserpine (LANGEMANN, 1955; KÄHLER, 1967).

Attempted precipitation of a flush by administration of 1–10μg adrenaline intravenously is a useful clinical test.

ζ) Differential Diagnosis

The carcinoid flush must be differentiated from menopausal hot flushes which are not, however, so severe and are not associated with cyanosis and the unpleasant concomitant manifestations. The swelling of the lids and mouth may suggest Quincke's edema. The histamine-induced flush in mastocytosis, i.e., urticaria pigmentosa, is bright red, lasts longer, and results in pigmentation. Finally, the emotional rubeosis of vege-

tatively labile young people may occasionally come into the differential diagnosis.

If the diarrhea is not accompanied by a flush, all types of spasmodic diarrhea especially those due to endocrine factors, must be considered in the differential diagnosis. In contrast to bronchial asthma, bronchial spasm in the carcinoid syndrome is always associated with tachypnea and hyperpnea. The cardiac symptoms of the carcinoid syndrome arise late, and acquired pulmonary stenosis in later life, especially in combination with tricuspid insufficiency, is almost pathognomonic.

η) Therapy
(KABAKOW, 1959; MENGEL, 1965; KÄHLER, 1967)

When the carcinoid syndrome becomes manifest, metastases are almost always already present, with the sole exception of the rare gonadal carcinoid. Curative treatment by surgery is therefore only possible in a few cases. Surgical intervention is, however, vitally indicated in cases of intestinal obstruction and as a palliative measure in the progressive course of the disorder. It is worthwhile removing individual large metastases and sometimes even a hemi-hepatectomy is indicated. The operation may allow the patient to be symptom-free for years. However, carcinoid patients are especially at risk during surgery and the symptoms can also be relieved by drugs. The indications for a palliative operation must therefore be very carefully considered.

The carcinoid is not very radio-sensitive, and radiation is therefore not helpful. Cystostatics, such as cyclophosphamide, can result in subjective improvement, objective reduction in the size of the metastases, and regression in the 5-hydroxy indole-acetic acid excretion. A local perfusion of the liver with 5-fluorouracil may occasionally be considered.

The flush is best influenced by a daily dose of 20–40 mg prednisone, which inhibits the activation of kallikrein and thus the formation of bradykinin. The alphareceptor blockers dibenzyline and phentolamine (Regitin) also act symptomatically. Decarboxylase blockers such as alpha-methyl-dopa have no effect. Trasylol, the kallikrein inhibitor, suppresses the flush only during slow infusion. Reserpine cannot be used since it does not deplete the enteral store of serotonin. On the other hand, chlorpromazine can greatly improve the flush, diarrhea, abdominal pain and bronchial spasms, or even cause them to disappear. In addition to being a sedative, chlorpromazine is also an antagonist to bradykinin. Only the diarrhea responds to the serotonin antagonist, methysergide. The use of parachlorophenylalanine is of theoretical interest. It competitively inhibits the hydroxylation of tryptophane to 5-hydroxytryptophane. The administration of several grams daily improves the diarrhea but depletion of the serotonin storage in the central nervous system results in side effects such as depression and hallucinations (ENGELMANN, 1967).

ϑ) Atypical Carcinoid Syndrome

There are carcinoids which are not quite typically situated and in which the histology, clinical symptoms, and biochemistry are also atypical. On the other hand, noncarcinoid tumors may be associated with typical clinical carcinoid symptoms and biochemistry (HEDINGER, 1962; MOERTEL, 1965).

The former are associated with a light red, patchy, often very extensive flush, and besides serotonin, they produce 5-hydroxytryptophane and, especially, histamine which are demonstrable in increased amounts in the blood and urine. The stomach and bronchus are given as the most frequent sites (WALDENSTRÖM, 1963; MELMON, 1965).

The typical carcinoid syndrome may arise in association with carcinomas of the stomach, liver, biliary passages, and pancreas. In most of these cases, an increased formation of serotonin and a raised excretion of 5-hydroxy indole acetic acid can be demonstrated. On the other hand, carcinoids of the ovary can provoke reversible alterations of the heart without any flushes occurring. This suggests that the flushes may not be caused directly by serotonin (CHATTERJEE, 1968).

Finally, there are intermediary stages of the paraneoplastic syndrome in which different tumors, especially the oat-cell bronchus carcinoma, can produce a carcinoid syndrome and other endocrine hyperfunction syndromes such as CUSHING's syndrome at the same time (SIEGENTHALER, 1965). Finally, there are different combined forms of endocrine adenomatoses and Zollinger-Ellison syndrome (WILLIAMS, 1962; SCHMID, 1964).

E. The Prostaglandins

The observation that human seminal fluid contains substances which activate smooth muscle fibers (KURZROK and LIEB, 1930; GÖEDBLATT, 1933; v. EULER, 1934) led to the isolation and the constitutional examination of the prostaglandins (BERGSTRÖM, 1966). Prostaglandins are unsaturated, aromatic, long-chained fatty acids with free hydroxy and keto groups.

Three groups with different actions have been differentiated: prostaglandin E, with a keto group and an alpha-hydroxy on the five-membered ring, prostaglandin F, with two alpha-hydroxyl groups, and prostaglandin A, with a keto group and a double bond on the ring. Within these groups, additional double bonds and hydroxyl groups allow differentiation of E 1–3, F 1–2 and A 1–8, so that around 20 active compounds are now known.

Prostaglandins are found in the seminal fluid of man, monkey, sheep and goat but not in other mammals. They can be extracted from the seminal vesicles of sheep. The physiological significance for the muscular contractions of the uterus or tubes is currently being investigated. They are also found in human menstrual blood as well as in numerous other tissues such as the lungs, kidneys, brain, pancreas, thymus, and iris.

Prostaglandins are composed of essential fatty acids, especially arachidonic acid. They accumulate in the kidneys and liver and are oxidized and quickly metabolized in the lungs and liver (SAMUELSON, 1967). Their physiological importance is presently unknown. Biological actions have been demonstrated on smooth muscle, on the heart, on the vasomotor system, on the kidney, on the lungs, on the gastrointestinal tract, on the fatty tissues, on the blood, and on the central nervous system.

In addition, there is an effect on the female reproductive organs. Hypotheses and facts concerning the physiology are reviewed by HORTON (1969), for current papers see the journal "Prostaglandins", edited by ANDERSON, CALDWELL, and SPEROFF since 1972.

Prostaglandins E and F act very strongly on smooth muscle fibers outside of the vasomotor system, while Prostaglandin A has only a weak effect. As a rule, they produce contractions (diarrhea) but may also induce dilatation, depending on the dose and the state of the muscle (e.g. the uterus). E and A cause the blood pressure to fall; F causes a rise. The peripheral resistance is reduced, independently of the alpha- and beta-receptors and the action of noradrenaline. When PGA is used, no side effects on the gastrointestinal tract arise. The cardiac output increases due to tachycardia.

It is possible that prostaglandin A, which is particularly abundant in the outer layers of the renal medulla ("medullin") represents the renal hypotensive factor. When this factor is lost, renoprival high pressure develops. It inhibits the Goldblatt mechanism in the presence of an intact contralateral kidney. As a renal hormone, PGA may have a generalized vasodilatory action, or it may act locally within the kidney to increase the blood supply to the cortex and cause the loss of sodium in the urine (LEE, 1967).

The relations between prostaglandins and the natriuretic "third factor" (see Chap. VII, p. 301) are controversial. The prostaglandins seem to increase plasma renin activity (CARLSON, 1967; WERNING, 1970) while they also have an antagonistic effect towards angiotensin II (WERNING, 1970).

PGE has an anti-lipolytic action on spontaneous or hormone-induced lipolysis in the fatty tissues of rats *in vitro*. It is possible that this action is due to the cyclase. In the intact animal PGE (but not PGF) in high doses reduces the free fatty acids induced by noradrenaline. Low doses can probably increase them through a sympathetic activation. Finally the prostaglandins in group E act on the central nervous system. They are liberated spontaneously, but especially under electrical stimulation and under the influence of spasmogenic substances. They appear to modify the action of carrier substances without being such substances themselves. E_1 and E_2 have recently been found to be stimulators of bone resorption (RAISZ, 1973).

It is possible that a hyperfunctional syndrome of the prostaglandins exists in medullary carcinoma of the thyroid gland, as well as calcitonin overproduction (see p. 232).

This type of thyroid carcinoma, which is associated with multiple familial phaeochromocytomas and fibromas (see p. 232), is often associated with persistent diarrhea. In 4 of 7 such tumors, prostaglandins were shown to be the active substance (WILLIAMS, 1968).

On the other hand, many tumors of the bronchi and other organs produce prostaglandins which can provoke diarrhea besides other ectopic hormones (SANDLER, 1968). Further, an increased content of prostaglandins has been found in the diseased kidney in renovascular hypertension (STRONG, 1966).

New pharmacological properties with possible therapeutic applications are being discovered all the time.

Prostaglandins are used as hypotensive agents, in the prophylaxis of thrombosis, and in the treatment of peptic ulcer and arthritis. They are currently being tested in the induction of labor and abortion; they are harmless, though not completely free of side effects (diarrhea and vomiting). Particular interest is devoted to their possible application as a contraceptive. Abortion can be induced in the human in early as well as late pregnancy by the infusion of high doses of PGE 1, PGE 2, or PGF2α (EMBREY, 1970; KARIM, 1970). Topical application avoids the side effects. Low doses can be used to induce parturition at term.

PGE 2 stimulates progesterone synthesis *in vitro* (SPEROFF, 1970), whereas PGF 2α *in vivo* has a luteolytic action (MCCRACKEN, 1970; KIRTON, 1970). Probably the reduced blood flow through the ovary causes resorption of the corpus luteum and a fall in the level of progesterone in the blood so that implantation of the ovum in the endometrium does not take place.

All these uses of the prostaglandins are still at the testing stage.

The main physiological or pharmacological effects currently known can be summed up by stating that the prostaglandins influence 1. the smooth muscles of the female reproductive tract, 2. parts of the endocrine system, 3. the adipose tissue, 4. the central nervous system, 5. the peripheral nervous system, 6. the cardiovascular system, 7. the urinary system, 8. the blood platelets, 9. the motility and secretions of the gastrointestinal tract, and 10. the smooth muscles of the respiratory tract.

XVI. Endocrine Hyperfunctional Syndromes by Ectopic Hormone Formation (Paraneoplastic Syndromes)

A. LABHART

A. Definition

Ectopic formation of hormones means the production of most probably normal hormones by tumors of tissues which normally form no hormones or different hormones. These tumors are with few exceptions malignant.

The term "ectopic hormone formation" is preferable to the word "paraneoplasia" since the term paraneoplastic syndrome includes both hormonal and non-hormonal distant effects of malignant tumors, such as neuropathy, myopathy, angiopathy, blood disorders and dermatoses.

At present, 15 syndromes caused by overproduction of ectopically formed hormones are known. In 11 of these syndromes, protein and polypeptide hormones, which are otherwise produced by endocrine glands, are formed ectopically. Mostly they are of polypeptide nature formed in malignant tumors of tissues which are of ectodermal origin (neutral crest) or arise from entodermal tissue (WEICHERT, 1970). It is striking that so far no ectopic steroid formation which stems from tissues of neurodermal origin has been discovered (Table 1 after LIPSETT, 1964).

Relations between malignant tumors and endocrine diseases have been known since 1928, when BROWN first described what was apparently CUSHING'S syndrome associated with a bronchus carcinoma. The fact that malignant tumors produce hormones became obvious when it was observed that the endocrinopathy disappeared after the removal of the tumor and reappeared with the development of metastases. LIDDLE

Table 1. Hyperfunctional syndromes caused by ectopically formed hormones

Syndrome	Demonstration of hormone	
	in blood	in tumor
Glandular polypeptide hormones		
Cushing's syndrome	ACTH↗	ACTH, MSH
Cushing's syndrome		CRF
Hyperparathyroidism	Parathormone↗	Parathormone
Schwartz-Bartter syndrome	Vasopressin↗	Vasopressin
Hyperthyroidism	TSH↗	TSH
Acromegaloid / Osteoarthropathy	STH↗	
Precocious puberty / Gynecomastia	FSH↗, LH↗	FSH, LH
Gynecomastia	Placental lactogen↗ Chorionic gonadotropin↗	Placental lactogen Chorionic gonadotropin
Hypoglycemia	Insulin (IRI)↗	Insulin (IRI)
Galactorrhea	Prolactin↗	Prolactin
Constipation / Steatorrhea	Glucagon	Glucagon
Tissue hormones		
Polycythemia	Erythropoietin↗	Erythropoietin
Carcinoid with bronchus CA	Serotonin↗ ? Bradykinin↗	Serotonin? Bradykinin
Zollinger-Ellison syndrome	Gastrin↗	Gastrin
Medullary Ca of the thyroid gland	ACTH↗	Calcitonin Prostaglandin
Similar syndrome produced by non-endocrine humoral substances		
Hypoglycemia in large tumors		Tryptophane? Niacin?

(1961), CHRISTY (1961) and HOLUB (1961) have succeeded in demonstrating ACTH in tumors and in the plasma of patients with paraneoplastic Cushing's syndrome. It is now almost certain that the ectopically-formed ACTH is identical to pituitary ACTH, since they both have the same chemical, physical, biological and immunological properties as far as can be determined by present-day methods. Since then, vasopressin, a parathormone-like polypeptide, FSH, LH, TSH, STH, erythropoietin, serotonin, gastrin, and prostaglandin have been successfully demonstrated in the blood, in tumors, or in both. It is, however, not certain whether these latter hormones formed ectopically are chemically identical to the corresponding glandular hormones. One tumor can produce a very wide variety of hormones (O'NEAL, 1968), and different tumors may form the same hormones.

The hormone-producing tumors are almost always malignant. The oat-cell bronchus carcinoma is especially common, but other tumors can be responsible: squamous-cell bronchus carcinoma, carcinoma of the thymus, islet-cell carcinomas, adrenocortical carcinomas, hypernephromas, adenocarcinomas of the gut, hepatomas, tumors of the uterus, prostate and nervous tissue. Benign tumors have been observed to form erythropoietin.

B. Pathogenesis

The question of how the undifferentiated cancer cell with a defective genetic system, a disturbed metabolism, and uncontrolled growth can complete complicated syntheses of polypeptides with molecular weights from 176 (serotonin) to over 30000 (gonadotropin) is one of the most fascinating problems in endocrinology, oncology, and genetics.

Since hormones have been successfully extracted from the tumors, numerous earlier hypotheses such as the predisposition of endocrinopathies to tumors or of neoplasia to endocrinopathies have been discarded. The view that the tumors only represent a sort of sponge for the hormones which stores normally formed hormones and protects them from degradation can be excluded by the duration of the illness and the high production rates which can be demonstrated for certain hormones formed ectopically. The argument that it is possible that a few of the many constellations of the amino-acid compounds developed within the abnormal metabolism and abnormal growth of the cancer cell could accidentally correspond to polypeptide hormones (BOWERS, 1966), is easily refuted by application of the law of probability. There is an extremely large number of possible variations for the arrangement of the amino acids of a protein hormone such as FSH with a molecular weight of 30000.

The hypothesis put forward by LIPSETT (1965) now seems the most probable: Every cell of the body is probably provided with the same genetic code, so that presumably each possesses the information necessary to synthesize any protein. Under normal conditions, most of this information is repressed. In the neoplastic variation of the cell, malignant or benign, derepression occasionally occurs, which is not normal in postnatal life (WALDENSTRÖM, 1970). This process could also be compared to a dedifferentiation, where there is a loss of the specific control mechanisms which prevent every cell from using all the information stored in its DNA. Derepression of protein-forming templates only active in the fetus have been observed, such as the formation of fetuin in hepatomas.

The clinical pictures of the hyperfunctional syndromes of ectopic hormones are dealt with in the appropriate chapters. They may differ in several aspects from the usual endocrine disease, as in Cushing's syndrome (see Chap. VII). We refrain from discussing there the syndrome of severe and often fatal hypoglycemia associated with large, usually retroperitoneal, tumors. It was not possible to demonstrate any insulin or insulin-like activity in the plasma of the patients or in the tumors of the majority of well over 100 cases reported. The demonstration of an insulin-like activity with the diaphragm of the rat or by the epididymal fatty tissue methods can only be accepted as specific if it can be inhibited with insulin antibodies. Hyperinsulinism has been demonstrated immunologically only twice (OLEESKY, 1962; SHAMES, 1968). In the tumors themselves it has only once been possible to detect immunologically reactive insulin. However, with the fat-pad method no more insulin-like activity could be detected than in other tissues. It is improbable that these tumors, which are always very large, produce insulin. On the other hand, they appear to block glycogenolysis, gluconeogenesis and lipolysis through humoral substances (JAKOB, 1967; FROESCH, 1968) (see p. 818).

Only the cases of hypercalcemia and *hypo*phosphatemia can probably be included in the syndrome of the ectopic formation of parathormone. Increased amounts of vitamin D or similar substances cannot be demonstrated in the blood or in the tumors in cases with hypercalcemia and *hyper*phosphatemia which are often seen with bone metastases and can be normalized by cortisone application. Increased production of

gonadotropins with endocrine syndromes (pubertas praecox, gynecomastia) can only be attributed to the syndrome of ectopic hormone production if these gonadotropins are not produced by tumors of the placenta or of trophoblastic tissue. Increased amounts of FSH and LH have been demonstrated in the blood and tumors of patients with bronchus carcinomas (see p. 488). The excretion of gonadotropin and estrogen is increased (BECKER, 1968; ROSEN, 1968), and strangely, osteoarthropathy of unknown pathogenesis usually exists at the same time. Galactorrhea can result form prolactin production in malignant tumors (TURKINGTON, 1971). In one case of osteoarthropathy with a bronchus carcinoma, in the absence of gynecomastia the growth hormone concentration in the blood was found to be raised. This returned to normal with the disappearance of the joint complaints after removal of the tumor (STEINER, 1968). Growth hormone can be synthesized by cell cultures of lung carcinoma (GREENBERG, 1972).

By the strictest definition, the Zollinger-Ellison syndrome is due to the ectopic formation of gastrin. However, since the pancreas might be a potential producer of gastrin under pathological conditions (see p. 973), only the atypical forms which do not develop from an islet-cell adenoma are to be considered as the paraneoplastic syndrome. The carcinoid syndrome (see p. 984) can only be considered as paraneoplasia in its atypical forms or if combined with production of other ectopic hormones.

The therapy can only be causal and involves the surgical removal of the hormone-active tumor. Not uncommonly, the endocrine illness can cause the tumor to be detected relatively early (gynecomastia in heavy smokers). When the tumors are inoperable or have metastasized, radiation and cytostatics must be considered. Removal of the end-organ is only justified in exceptional cases such as in the Zollinger-Ellison syndrome.

XVII. Thymus

P. J. GROB and A. LABHART

Studies over the past years have established that the thymus has a central role in the immune system (MILLER, 1969; METCALF, 1966; HESS, 1968; BURNET, 1962). Evidence has been found that the thymus might exert at least part of its function by acting as an endocrine organ. Recent findings also suggest that thymic hormones might influence the neuromuscular function (GOLDSTEIN, 1971; WHITE, 1970).

1. Embryology and Structure

Embryologically the thymus arises from an epithelial outgrowth of the third and the fourth branchial pouches, which later forms a sponge-like structure. In fetal life the human thymus becomes predominantly lymphoid and this histological pattern is preserved throughout childhood. Thereafter, the lymphoid component gradually decreases. The human thymus accounts for approximately 0.8% of the body weight at birth. Its relative size then gradually decreases. Although it has not been fully established, many data suggest that the lymphoid cells within the thymus originate from stem cells of bone marrow or related organs (FORD, 1966). They divide within the thymus, and most of them die in situ while others seem to go on to populate the peripheral lymphatic organs.

The histological units of the thymus are lobules, which are joined in the center of the organ. The cortical areas of the lobules are packed with predominantly small lymphocytes, which show a high rate of mitoses and cell death. These cells are highly sensitive to X-ray irradiation. In contrast to peripheral lymph nodes, no germinal centers are usually seen. In the medullar region, on the other hand, where the epithelial mesh work is densest, relatively few lymphocytes are present which do not divide and are not sensitive to X-ray irradiation. Epithelial cells are aggregated into whorled patterns (the Hassall's corpuscles). Myoid cells are also found.

2. Thymus and Immune Function

A normally functioning thymus is necessary for the development and expression of at least part of lymphoid tissue and its immunological function (MILLER, 1969; ROITT, 1969): lymphoid stem cells appear to differentiate and acquire immunologic competence under its influence. Most of the evidence collected points to two possible modes of thymic action: a) Lymphoid stem cells migrate into the thymus where they mature and attain immune reactivity by direct contact in situ within the gland. b) Thymic hormones, such as thymosine and others, act locally and/or peripherally to endow lymphoid cells with the capacity to respond to antigenic stimuli. Evidence for the endocrine hypothesis derives from experiments in which neonatally thymectomized mice were reconstituted with cell-free thymic extracts or with thymic tissue placed in cell-impermeable Millipore chambers (OSOBA, 1963). Both mechanisms (a and b) could act cooperatively or additively.

An immunoactive thymic extract called thymosine was described by GOLDSTEIN and collaborators in 1966. Further investigations have suggested that it might be a protein influencing the rate of maturation of immunological competence in more primitive potentially competent lymphoid cells. Further evidence of immunoactive factors has been found by COMSA (1955), TRAININ (1970), BACH (1971), DUTTON (1971) and others.

While the thymus plays a major role in the ontogenesis of the immune system, its influence in adult life is less clear. It may act as a supply organ, functioning predominantly when the peripheral lymphoid system is exhausted.

The immune system is divided into cell-mediated (cellular immune response) and antibody-mediated phenomena (humoral immune response). T cells (mediators of cellular immunity) seem to derive from and be under the control of the thymus, while the B cells (mediators of the humoral immune response) seem to be less dependent on its influence. On the other hand, T cells have recently been found to amplify the B-cell function by a "helper"

mechanism (cell cooperation). Thus, the thymus may modulate the B cell-mediated reactions at least indirectly. (Its influence is necessary for primary antibody production against certain antigens.) It is also possible that there are various subpopulations of T cells (RAFF, 1971).

Our knowledge of thymic function and of the consequences of defects is based mainly on observations in animal experiments. At least some conditions point to similar situations in man: Congenital absence or dysfunction of the thymus in the human, as for example in infants with DiGeorge syndrome, is characterized by an almost total absence of cell-mediated immune responses, causing conditions such as lymphopenia and a marked susceptibility to a wide variety of infectious agents, particularly of viral or fungal nature (DIGEORGE, 1968). Transplants are not rejected, and delayed skin reactions cannot be elicited. In contrast, only inconsistent antibody deficiencies are observed. Patients with DiGeorge syndrome have been successfully treated with thymic transplants (AUGUST, 1968; CLEVELAND, 1968). There are other human diseases associated with thymic abnormalities and partial or total defects of cellular immune functions, such as reticular dysgenesis, alymphocytic agammaglobulinemia (Swiss type), ataxia telangiectatica and other combined immune deficiencies (NEZELOF, 1964; ROGERS, 1968; GABRIELSEN, 1969).

SORKIN *et al.* (SORKIN, 1970; PIERAPOLI, 1969; FABRIS, 1972) have found evidence that thymic function itself might be under the control of the adenohypophysis. These authors also emphasize the possible importance of the thymus as a biological clock and of hormones in the aging processes of lymphocytes and in aging as such. Their evidence is based mainly on work with hypopituitary dwarf mice.

3. Thymus and Neuromuscular Function

The frequent association of myasthenia gravis and thymic abnormalities is well known. Thymectomy may be of value in patients with myasthenia gravis (PAPATESTAS, 1971). Recently, GOLDSTEIN *et al.* have found experimental evidence for two different biologically active extracts of thymic origin, "thymotoxin", a basic polypeptide which induces myositis, and "thymin", which leads to a neuromuscular block similar to that seen in myasthenic patients when given by injection in rat (GOLDSTEIN, 1971).

4. Other Thymic Hormones

Other hormone-like agents have been attributed to the thymus, as well as thymosin and related substances. These include promin, which promotes growth, and retin (SZENT-GYÖRGY, 1962), which is thought to inhibit growth and fertility. The thymus extract thymocrescin (Asher) is also thought to promote growth. Another substance, infertin, has been isolated from promin and is believed to induce sterility in rats, temporarily in adult and permanently in young animals. These substances have so far neither been sufficiently characterized to qualify as hormones, nor is their nature or mode of action clearly understood.

XVIII. The Pluriglandular Syndromes

A. LABHART

A. Endocrine Adenomatoses

The rare hereditary syndromes of endocrine adenomatosis have been known to pathologists since the turn of the century (ERDHEIM, 1903). Clinicians have been able to diagnose the syndrome for the past 30 years (ROSSIER, 1939; SHELBOURNE, 1945; UNDERDAHL, 1953; WERMER, 1954), and about 100 cases have now been described (BALLARD, 1964; JOHNSON, 1967). There is a hypothesis concerning the pathogenesis of these syndromes which also takes into account the occasional occurence of ectopic peptide hormones in certain types of endocrine adenomatosis (WEICHERT, 1970). It is proposed that neuroendocrine cells migrate to the primitive gastrointestinal tract from where they form the endocrine cells of the anterior pituitary and the parathyroid glands and islet cells of the pancreas. Neuroendocrine cells, as argentaffin cells, are scattered throughout the gastrointestinal tract mucosa and also occur in other organs such as the bronchi. Related cells can be found in the adrenal medulla. These neuroendocrine cells may occasionally develop in the tumors producing peptide hormones. Thus, the syndrome of endocrine adenomatosis may be a dysplasia of neural ectoderm. Cytochemical methods make it possible to distinguish a series of cells stemming from the primitive alimentary tract and maturing into endocrine cells of the anterior pituitary, the pancreas islet α_2- and β-cells and the c-cells of the thyroid. On the other hand, they form the enterochromaffine cells of the gut and argyrophil cells of the stomach. They all have the ability to form peptide hormones and have been called cells of the APUD-series (amine-precursor-uptake and decarboxylation (PEARSE, 1968).

There are two distinct types of endocrine adenomatosis; one is characterized by benign tumors of the parathyroids and pituitary, and benign or malignant growths in the islet cells of the pancreas, and the other by medullary carcinoma of the thyroid and bilateral pheochromocytoma, the medullary carcinoma producing ectopically formed hormones in addition to calcitonin.

1. Multiple Endocrine Adenomatosis (Endocrine Polyadenomatosis, Familial Multiple Endocrine Adenoma (MEA), Wermer's Syndrome, "Job's Syndrome", Steiner's Multiple Neoplasia,Type I)

This syndrome is centralized around benign tumors of the parathyroids and adenohypophysis, and benign or malignant growths in the islet cells of the pancreas. Corresponding endocrine hyperfunctional or deficiency syndromes are also present; in addition, the majority of patients suffer from peptic ulcers. The fully developed Zollinger-Ellison syndrome may sometimes be present, or sometimes there is a tendency to recurrent and often multiple gastric and duodenal ulcers.

The tumors and hyperplasia occasionally observed in the thyroid gland, adrenal medulla and cortex and testes probably do not belong to this syndrome. The illness can become manifest at any age and the frequency is the same in both sexes. The disease begins as hyperfunction of one gland and can be followed by hyperfunction in other glands and/or pituitary failure. Every combination is possible.

The parathyroids are most frequently affected (80–90%). Functioning adenomas are usually found in several glands and there may be several in each of the parathyroids. Patho-anatomical examination reveals hyperplasia of the chief cells, chief cell adenomatosis or adenomas (see p. 908). A striking feature is the benign course of hyperparathyroidism over years and sometimes even decades with only slight hypercalcemia. Renal stones and nephrocalcinosis occur significantly less frequently than in ordinary hyperparathyroidism. Skeletal involvement is uncommon, and hypercalcemia is often an incidental finding. This and the multiplicity of the adenomas indicates reservation in surgical treatment, which is only justified if the patient complains or if complications appear likely. Total resection of the three largest glands and subtotal resection of the smallest is usually necessary in such cases, and the latter should be marked in case another operation is required (see p. 932).

Recent reviews suggest that tumors of the islet cells are found in 45–80% of cases and are nearly always multiple. Adenomas or carcinomas (multiple) of the non-B-cells are found in over half the cases. About one third of the cases are affected by multiple B-cell adenomas and occasionally by B-cell carcinomas. Solitary adenomas and different combinations are found in the remaining cases.

In a third of the cases there is hyperinsulinism with hypoglycemic attacks requiring exploratory surgery and usually subtotal resection of the pancreas because of the frequent multiplicity of the adenomas. Non-B-cell adenomas or carcinomas cause the Zollinger-Ellison syndrome (see Chap. XV), which typically occurs in one fifth of multiple endocrine adenomatoses and is familial, probably developing through the same gene. On the other hand, they also cause the syndrome of pancreatogenic diarrhea ("pancreatic cholera", WDHA-syndrome), a severe illness with massive watery diarrhea and a heavy loss of potassium (see Chap. XV, p. 974), which is found in only about one eighth of cases.

Apart from the Zollinger-Ellison syndrome, over half of the patients with endocrine adenomatosis suffer from peptic ulcers which are more often multiple than solitary. The relationship of endocrine adenomatosis to "ordinary" ulceration is, however, not yet clear. Increased numbers of parietal cells are found in the gastric mucosa (MIEHER, 1962) in subjects with endocrine adenomatosis as well as in subjects with duodenal ulcers, and it is possible that this parietal cell hyperplasia has the same genetic basis or is a result of gastrin overproduction. The recognized frequency of the peptic ulcer in hyperparathyroidism (see p. 919) cannot entirely explain the nature of the relationship since the peptic ulcer occurs much more frequently in multiple endocrine adenomatosis than in hyperparathyroidism. Finally, increased secretion of gastrin or the interaction of different factors must be considered even if there is no evidence of non-B-cell tumors.

See p. 974 for the difficulties inherent in the therapy of the Zollinger-Ellison syndrome and pancreatogenic diarrhea.

Adenomas of the anterior pituitary occur in 65–70% of patients suffering from MEA. Almost half are chromophobe adenomas and one fourth are eosinophil adenomas associated with acromegaly. Chromophobe adenomas may be an incidental finding, or they may present the typical symptoms of loss in the visual fields and pituitary failure. Acromegaly in endocrine adenomatosis does not differ in any way from ordinary acromegaly. It is improbable that a basophil hyperplasia or a basophil adenoma are symptoms of this syndrome since Cushing's syndrome, which is radiosensitive was observed only once among 100 cases. A chromophobe adenoma was once observed with hyperthyreosis due to increased TSH production, acromegalia, and parathyroid adenoma (LAMBERG, 1969). See p. 122, 115 for the therapy of chromophobe and eosinophil adenomas. Conservative treatment must be selected in these cases too, because of other manifestations of the syndrome which are usually more important.

In addition, there appears to be a general predilection for developing tumors, and multiple lipomas, fibromas, sarcomas, polypoid adenomas of the gastrointestinal tract, meningiomas, and papillomas have been reported.

Observation of 12 families over 6 generations permitted the recognition of an autosomal dominant mode of inheritance with a high penetrance, variable expressivity and pleiotropy. The peculiarity of this very variable illness was usually repeated within one family. Sometimes up to half the affected members of the family were symptom-free (JOHNSON, 1967). However, multiple endocrine adenomatosis can be fatal, especially in combination with the fully developed Zollinger-Ellison syndrome. The ulcer condition with all its complications, particularly perforations, is the most common cause of death. Less frequently patients die from a unrecognized hypoglycemia or islet-cell carcinoma.

Life is particularly hard for those patients in whom one glandular disorder after another becomes manifest giving vital indications for repeated operations, and who see the suffering of other members of their family. This has led to the suggestion of naming the syndrome "JOB's" syndrome after the biblical sufferer (MOLDAWER, 1962).

Although this syndrome is rare, it is important to recognize it, since when the first manifestation is recognized as a part of multiple endocrine adenomatosis, it may be possible to institute purposeful life-saving surgical or substitution therapy, which may avoid the repeated, disappointing, and useless surgical interventions frequently recorded in the case histories of these patients (RENWICK, 1968).

The syndrome has also been observed in the dog (RUTISHAUSER, 1943) and can be produced in the rat by radiation (BERDJIS-CHAMSI, 1960).

2. Medullary Thyroid Carcinoma – Bilateral Pheochromocytoma (Sipple's Syndrome, Steiner's Multiple Endocrine Neoplasia, Type II)

Medullary carcinoma of the thyroid derives from the C- or parafollicular cells of the thyroid (see p. 232) which are the source of calcitonin.

The calcitonin concentration is grossly increased in the blood of patients with medullary carcinoma, which may be diagnostic for this tumor. Characteristically, this thyroid carcinoma also produces amyloid, which allows histological diagnosis. SIPPLE (1961) recognized the nonfortuitous association of medullary carcinoma with pheochromocytoma. In 60 to 80% of cases, the latter is bilateral. The syndrome is also transmitted by an autosomal dominant mode of inheritance with reduced penetrance (SAROSI, 1968). (Besides the hereditary form this disease can also occur sporadically.) In addition, there are often other malformations such as neurofibromatosis, intestinal ganglion neuromatosis, and neuromas of the mucosa, which appear mainly on the tongue and on the eyelids. The patients have a peculiar constitution reminiscent of the Marfan syndrome, with coarse features, thick lips, and chloasma-like pigmentations, especially around the mouth. In spite of the gross overproduction of calcitonin, the serum calcium of these patients is usually normal or only slightly below normal. However, very often there is hyperplasia or adenoma of the parathyroids. This might be due to a compensatory effect on chronic hypocalcemia or a direct stimulatory effect of calcitonin on the parathyroid cells (FISCHER, 1971).

If medullary carcinoma is diagnosed, all members of the patient's family should have the calcitonin content of their blood tested.

Diabetes mellitus is occasionally seen in these patients and may result from the inhibition of insulin release by the hormonal secretions of a pheochromocytoma.

Besides calcitonin, a medullary carcinoma is able to produce ACTH, MSH, prostaglandins, and serotonin. Thus Cushing's syndrome with various clinical characteristics is observed in about 3% of the patients with these syndromes. Bilateral adrenalectomy or necropsy always reveals marked bilateral hyperplasia of the adrenals (DONAHOWER, 1968).

About 30% of the patients suffer from diarrhea and sometimes steatorrhea. After removal of the tumor the diarrhea ceases. Prostaglandins have been found in high concentration in some medullary tumors; some prostaglandins are known to stimulate peristalsis. Serotonin has sometimes been detected, which can activate bradykinin and may explain the flush which occasionally occurs in these patients. Serum histaminase may be increased and can be inhibited by aminoguanidine.

For treatment of the hereditary type of medullary carcinoma, total thryoidectomy with removal of the regional lymph nodes is indicated as the carcinoma may be multicentric. Because of the relatively long benign course in the sporadic cases the operation can be restricted to the elimination of the tumor and resection of one lobe. Radiotherapy is probably beneficial. Radioiodine treatment is useless because there is no uptake by the tissue. Thyroxine medication should be given prophylactically. In any thyroidectomy for medullary carcinoma enlarged parathyroid glands should be looked for, even if the blood calcium level is normal. Pheochromocytoma and diabetes should also be ruled out.

For a review of familial medullary thyroid carcinoma and the syndrome of "familial chromaffinomatosis", based probably on an inherited defect of cells originating in the neural crest ["APUD" (PEARSE, 1971)], see MELVIN (1972).

It is still not definitely known whether there is a third syndrome of papillary thyroid carcinoma and adenomas of the parathyroids (ELLENBERG, 1962).

B. Autoimmune Polyendocrinopathy (Pluriglandular Insufficiency, Multiple Endocrine Sclerosis, Schmidt's Syndrome)

1. Definition

The syndrome of endocrine autoimmune polyadenopathy includes the primary disorder of two or more endocrine glands resulting, as a rule, in their insufficiency. The so-called primary or cytotoxic, non-tuberculous atrophy of the adrenal cortex is the main feature of the syndrome. It is most often combined with Hashimoto's thyroiditis or with hypothyroidism, and less commonly with hyperthyroidism. They are frequently associated with diabetes mellitus. Hypoparathyroidism may develop in addition to this triad. More often, however, it is found with primary adrenocortical atrophy combined only with moniliasis (see p. 895, 899). Primary failure of the gonads has also been observed. The pathogenesis can be complicated by the presence of "hypophysitis", a lymphocytic infiltration of the pituitary gland with or without fibrosis. When this arises, primary failure is theoretically possible in addition to the secondary. Finally, autoimmune diseases, in particular pernicious anemia, immunologically dependent steatorrhea, sporadic myasthenia gravis, and certain kinds of liver cirrhosis commonly occur with this syndrome. Occasionally striking alopecia is seen in women. All combinations are possible and most of these have been described. Table 1 gives the various frequencies. Over 150 cases of endocrine polyadenopathy have been detected so far. It shows a familial fre-

quency and the female sex is affected more often. Morphologically similar lymphocytic inflammations can be produced experimentally with organ extracts (LE COMPTE, 1966; LEVINE, 1967).

Table 1. Frequency of the combinations of the polyendocrinopathies. (After STEINER, 1968)

	Cases
Hypothyroidism + Addison's	102
Hypothyroidism + Addison's + Diabetes mellitus	32
Hypothyroidism + Addison's + Hypoparathyroidism	5
Hypothyroidism + Addison's + primary amenorrhea (2 d. m.)	8
Hypothyroidism + Diabetes mellitus	55
Addison's + Diabetes mellitus (also a few with adrenal TB)	125
Hypophysitis	3
Hypoparathyroidism + Addison's	22
Hypoparathyroidism + Hypothyroidism	?
Hypoparathyroidism + Diabetes mellitus	10
Hypoparathyroidism + Gonadal insufficiency	2
Hypoparathyroidism + Gonadal insufficiency + Addison's	1
(Hyperthyroidism + Addison's	68)

The syndrome was first described by CLAUDE and GOUGEROT in 1908 as "insuffisance pluriglandulaire". FALTA in 1912 suggested the term "multiple endocrine sclerosis" to emphasize the multiple, independent primary disorders of the endocrine system. Despite this, the term was frequently applied to classical cases of hypopituitarism. In 1926 SCHMIDT described the morbid anatomy of two cases of primary adrenocortical atrophy and a lymphomatous goiter with characteristic lymphocytic infiltration of the adrenals and thyroid gland. This infiltration can be clearly distinguished from the lymphocytic foci found in Addison's disease. Over the past ten years thyroid antibodies have successfully been demonstrated in Hashimoto's thyroiditis and in hypothyroidism (see p. 243, 152), adrenal antibodies in primary adrenocortical atrophy (see p. 313), antibodies to the gastric mucosa and the intrinsic factor in pernicious anemia, and to muscular tissue in myasthenia gravis; finally, antibodies to the parathyroids have been demonstrated in hypoparathyroidism (see p. 899). These antibodies can be detected in the blood in most, but not all, cases of endocrine polyadenopathy. Antibodies to the thyroid gland, the parathyroids, or the parietal cells of the gastric mucosa may be found in primary adrenocortical atrophy, even in the absence of demonstrable involvement of these organs. In any case, there is no correlation between the severity of the illness and the titer of the antibodies. It is worth mentioning that women with gonadal dysgenesia, and their relatives, often have antibodies to ovarian tissue, the thyroid gland, and the gastric mucosa (VALLOTON, 1967).

2. Pathogenesis

The demonstration of organ-specific antibodies and of chronic lymphocytic inflammation leading to atrophy strongly indicates immunological processes. The higher incidence in the female sex and the familial frequency of the syndrome also suggest immunological diseases. Nonetheless, no causal relation between the organ-specific antibodies and atrophy of the endocrine glands has been proven, and the question of the pathogenesis of this syndrome is still unanswered. It is hardly probable that the circulating antibodies alone are directly responsible for the lymphocytic infiltration and atrophy of the glands. The cellular immunological systems seem to be deranged, which may explain the lack of correlation between the severity of the disease and the antibody titer. The fact that no antibodies have been found in Addison's disease due to tuberculosis or other infections, however, makes it appear unlikely that the damaged glands liberate antigens and activate the immunological system. It is probable that these patients possess a familial, inherited disposition to autoimmune reactions, depending on a disturbed immune tolerance (IRVINE, 1967), and that the antibodies rather reflect a disturbed immunological system than that they cause it. Organspecific antibodies are also frequently found in healthy members of a patient's family (EVANS, 1967). Nevertheless, an indirect action of the antibodies in the precipitation or maintenance of the disease process cannot be excluded (BLIZZARD, 1967). Whereas disorders such as pernicious anemia and myasthenia gravis, considered to be organ-specific autoimmune diseases, have been observed with the autoimmune polyendocrinopathy, it is not known whether the so-called collagen diseases with organ-nonspecific antibodies to components of the cell nucleus, e. g. lupus erythematosus, occur more frequently than just by chance (BECKER, 1965). Besides hypothyroidism and Hashimoto's thyroiditis, hyperthyroidism is the only hyperfunctional syndrome which frequently occurs concomitantly with primary adrenal atrophy. This may be due to the immunological processes involved in thyrotoxicosis and the possible transition of hyper- into hypothyroidism. Immunological processes today also occupy a prominent position in the pathogenesis of diabetes mellitus (see p. 762), and antibodies to the thyroid gland and the gastric mucosa are found more fre-

quently in diabetics than in non-diabetics (MOORE, 1964). In addition to gastritis, latent or manifest malabsorption also occurs and may have an immunological basis (SIURALA, 1968). The occurence of endocrine adenomatosis and endocrine autoimmune-polyadenopathy, which has recently been observed in one family, remains unexplained (MERSHON, 1966). The role of the giant-cell granulomas in individual endocrine glands described in the earlier literature is not yet known.

3. Clinical Features

Adrenal insufficiency dominates the clinical picture. It usually, but by no means always, becomes manifest first, causes most of the complaints and endangers the patient most. Pigmentations are present and sometimes vitiligo; the latter may have a common autoimmune pathogenesis (MCGREGOR, 1967). They are, however, not so striking as in the usual Addison's disease, especially if hypothyroidism with pallor and myxedematous skin develops. The lack of animation and the bloated expressionless features contrast to the sharply chiselled face of the Addisonian patient, and may give a clinical indication of associated hypothyroidism, If the gonads are also involved and there is absence of axillary and pubic hair and atrophic testes in the male or amenorrhea in the female, differentiation from hypopituitarism is difficult and only the pigmentation instead of the pallor suggests a primary glandular disorder. The diagnosis must be confirmed by laboratory tests when pituitary insufficiency is suspected; if the suspicion is correct an increase instead of an absence of gonadotropins will be revealed. Negative ACTH and TSH tests confirm the diagnosis. Occasionally, resorption is also impaired (SIURALA, 1968).

It is difficult to control the diabetes in spite of cortisone substitution, and the long-term prognosis is not favorable even with correct replacement therapy.

It has long been observed that hyperthyroidism and hypothyroidism (GASTINEAU, 1964, 1963) and diabetes mellitus (BEAVEN, 1959) occur frequently in Addison's disease. It is therefore worthwhile to examine thyroid function and to estimate the calcium and blood sugar in Addison's disease, especially in those cases with no history of tuberculosis. Wherever there are facilities, antibodies to the adrenals, the thyroid gland, the parathyroids and the gastric mucosa should be investigated. This enables the concomitant disorder to be detected before it becomes manifest. On the other hand, it is not worthwhile to undertake the systematic tests for concomitant endocrine disorders in hypothyroidism (BLIZZARD, 1967).

The treatment is no different from that for ADDISON's disease, hypothyroidism, and diabetes mellitus.

C. Syndrome of Diabetes Mellitus, Diabetes Insipidus, and Optic Atrophy

This rare syndrome has been observed in eight members of five families and is probably transmitted by an autosomal recessive mode of inheritance (BRETZ, 1970).

XIX. Growth and Development

A. PRADER

A. General Concepts of Growth and Development

Growth is due to an increase in the number and size of the body cells and to the development of cartilagenous and osseous substances. Anabolism exceeds catabolism in the continuous process of transformation of protoplasm and bone tissue in the growing organism. In other words, growth is an *anabolic process*. This process is characterized clinically by an increase in height and weight, and metabolically in particular by retention (positive balance) of water, nitrogen and electrolytes.

Development, i.e. the morphological differentiation and functional specialization of certain parts of the organism, progresses parallel to growth.

The final size of an adult depends both on the rate of growth and on the duration of growth. Longitudinal growth, however, is only possible as long as the epiphyses of the bones are not closed. Consideration of the *maturation of the bones* is thus of great significance for an understanding of growth. Bone maturation does not imply longitudinal growth of bones but rather the degree of ossification which is radiologically detectable (p. 1026).

Almost all endocrine disorders beginning in the first 2 years of life have a decisive influence on growth and development. The deviation of growth and development from normal often indicates not only the type of disorder but also the time of onset. Precise knowledge of normal and pathologic growth and development is therefore indispensable in pediatric endocrinology.

1. General Factors of Growth

As far is known, conditions necessary for normal growth can be summarized (Fig. 1) as follows:

1. *Building material* obtained from the nourishment must be completely adequate in quality and quantity. The more marked growth in the upper social classes and the acceleration of growth observed over the past 100–150 years are probably due to better nutrition. *Psychological factors* can also affect the intake of food and thus growth and development.

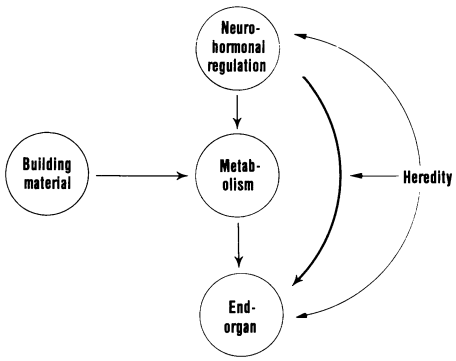

Fig. 1. General growth factors

2. *Neurohormonal regulation.* The hypothalamo-hypophyseal system is responsible for the integration of all the growth-regulating influences. The influence of hormones is discussed in detail on p. 1016. Cerebral and hormonal disorders can result in severe growth disturbances.

3. *Metabolism.* The building material available must be properly absorbed, transported and assimilated. The intestinal, cardiac, renal and other forms of dwarfism are due to impairments of these metabolic processes.

4. *The end organ* (protoplasm, bones) must posses a normal *growth potential.* Chondrodystrophy is an example of reduced growth potential of the long bones.

5. *Genetic factors* can influence growth via points 2–4.

2. Body Growth and Growth of the Endocrine Glands

Growth and development of the body show many features related more or less closely to the weight curve of the endocrine glands and the excretion of hormones in the urine. The growth curves of the whole organism, the individual organic systems and endocrine glands

are not at all similar. Broadly speaking, the following types of growth can be recognized.

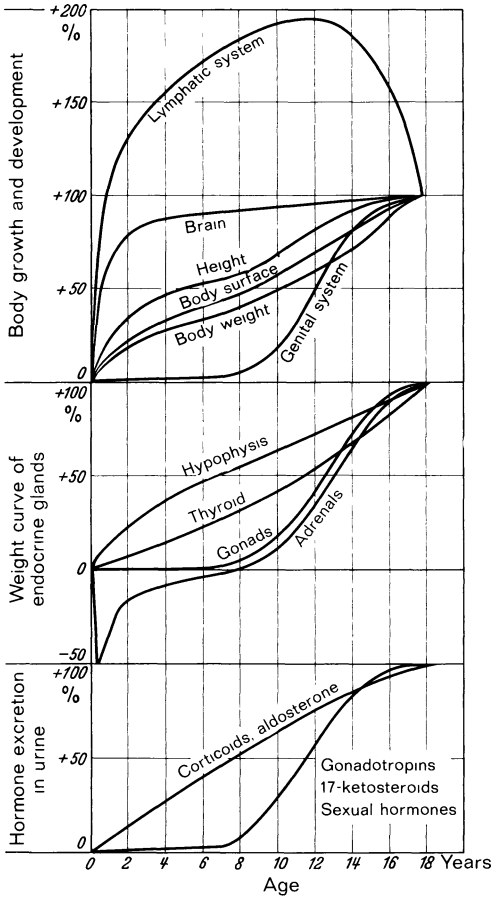

Fig. 2. Graph showing body growth, growth of the endocrine glands and increase in hormone excretion from birth to adulthood (as percentages of the postnatal increase in size) (PRADER, 1956)

a) General Growth

Increases in height and weight, in body surface, musculature, skeleton and other organs all demonstrate a similar type of growth at first glance. On closer analysis, however, four different phases can be recognized. To begin with, the body grows extremely quickly. This is followed by a slower but quite constant period of growth extending to puberty. In this phase the growth curve is roughly parallel to the weight curves of the hypophysis and the thyroid gland. Puberty is accompanied by a new spurt of growth which is obviously related to the sudden increase in weight of the gonads and adrenals and the production of sexual hormones. The pubertal spurt in growth gradually subsides and is followed by an arrest of growth.

b) Neural Growth

There are no parallels in growth of the endocrine glands and in the excretion of hormones corresponding to the disproportionately rapid increase in the circumference of the head and the weight of the brain during the first 3 years of life, followed by the insignificant growth in subsequent years. This type of growth is probably largely independent of hormonal factors.

c) Lymphatic Growth

Growth of the lymphatic system (measured from the weight of the thymus) is characteristically more intense and more prolonged. A strong involutional process begins at puberty and a temporal connection with the accelerated growth of the gonads and adrenals cannot be mistaken.

d) Genital Growth

The genital system grows very little before puberty and then completes its entire phase of growth within a few years. The weights of the gonads and adrenals and the excretion of gonadotropin and sexual hormones follow a similar course and show that genital development is dependent on the hypophysis, gonads and adrenals.

The growth curve of the adrenals is the most striking of all. Apart from minimal fetal hyperplasia and postnatal involution, which are still not understood (p. 286), before puberty the curve corresponds to the steady increase in the excretion of corticoids and aldosterone and during puberty to the sudden increase in the weight of the gonads and excretion of gonadotropins and sexual hormones. The shape of this curve reflects the uniform increases in the production of gluco- and mineralocorticoids on one hand, and the rapidly rising production of adrenocortical androgens (adrenarche, p. 1039) beginning in puberty on the other.

B. Hormonal Influence on Growth and Bone Development

Hypophyseal growth hormone (STH), thyroid hormones and probably insulin have a decisive effect on growth as a whole. In contrast to this prolonged action, gonadal hormones and probably certain adrenocortical hormones promote growth and bone development only during puberty. A growth-promoting action was attributed to the thymus earlier, but this has never been confirmed.

True *growth hormones* are only those with protein-anabolic, i.e. nitrogen-retaining actions such as STH, insulin, and testosterone. Other hormones, with no anabolic action, such as thyroxine, are also essential for normal growth but cannot be termed true growth hormones.

Table 1. Influence of hormones on growth and bone development

	Growth	Bone development
Hypophyseal growth hormone (STH)	+ + +	+
Thyroid hormones	+	+ +
Insulin	?+	?+
Glucocorticoids	−	−
Androgens*	+	+ +
Ovarian estrogens*	0	?+

+ promoting action, 0 no effect, − inhibitory action, * only during adolescence.

Table 2. Growth and bone development in over- and underproduction of hormones

	Growth	Bone development
Hyperfunction		
STH (hypophyseal gigantism)	+ + +	0−
Thyroid hormones (hyperthyroidism)	+	+
Insulin (islet-cell adenoma)	+	?
Adrenocortical glucocorticoids (Cushing's syndrome)	− −	− −
Adrenocortical androgens (adrenogenital syndrome)	+ +	+ + +
Testicular androgens (Leydig cell tumor)	+ +	+ + +
Ovarian estrogens (Granulosa cell tumor)	+	+ +
Hypofunction		
STH (hypophyseal dwarfism)	− − −	− −
Thyroid hormones (hypothyroidism)	− −	− − −
Insulin (diabetes mellitus)	−	−
Adrenocortical steroids (Addison's disease)	? 0	? 0
Testicular androgens (hypogonadism)*	0	−
Ovarian estrogens (hypogonadism)*	0	−

+ accelerated, 0 uninfluenced, − retarded, * only during adolescence.

1. Survey

Tables 1 and 2 give a schematic survey of the present-day interpretation of the action of various hormones on growth and bone development in normal and pathologic conditions.

2. Hypophyseal Growth Hormone (STH, GH)

In pituitary gigantism (p. 107), growth is greatly accelerated whereas bone development is normal or delayed. In pituitary dwarfism (p. 98), due to an isolated STH deficiency, growth is greatly retarded and bone development only slightly retarded.

Experimentally, STH has anabolic and growth-promoting actions (p. 88). In rats, hypophyseal gigantism can be induced by injection of STH, and hypophyseal dwarfism by hypophysectomy. In spite of its short half-life (p. 84) and the irregular fluctuation of its plasma concentration, the growth-promoting effect of STH is constant, exerted not directly but indirectly via the sulfation (p. 88) and thymidine factors to enhance protein synthesis. This action can easily be measured by means of nitrogen retention. Administration of exogenous STH produces much better nitrogen retention and growth in patients with endogenous STH deficiency than in patients with normal endogenous STH production (p. 101). The optimum effect, however, is only attained in the presence of thyroxine and insulin.

STH is demonstrable in the hypophysis and plasma of the human fetus from the 4th fetal month. Since STH cannot pass through the placenta, there is no exchange between maternal and fetal STH. STH concentration in the plasma of the newborn is considerably higher than in the mother. It therefore appears probable that prenatal and neonatal growth, characterized predominantly by an increase in the number of cells, is related to the increased plasma concentration of STH. In fact, promotion of cellular multiplication is the main function of STH, and it also promotes cell growth but to a lesser degree (Cheek, 1970). The fact that anencephalic babies are of more or less normal size at birth led to the interpretation in the past that STH was not essential for fetal growth. Further support for this assumption was found in the fact that prenatal growth and growth in the first months of life were normal in pituitary dwarfism. However, this interpretation does not take into account the fact that most cases of STH deficiency were due to cerebral injury at delivery and that the effects of this could only arise postnatally. It now appears more likely that in prenatal STH deficiency body

size compared to weight is slightly impaired even at birth. It can be assumed from this that prenatal and neonatal growth are at least partly dependent on STH.

Serum phosphorus and alkaline phosphatases are higher in the growing child than in the adult. The concentration of phosphorus can be considered an index of STH production, and alkaline phosphatase an index of osteoblastic activity. In overproduction of STH (pituitary gigantism, acromegaly) the serum phosphorus is elevated but is normalized by the administration of androgenic or estrogenic hormones. Serum phosphorus is diminished in STH deficiency and rises on administration of human growth hormone. In rats, treatment with STH leads to a rise of phosphorus and alkaline phosphatase in the serum whereas hypophysectomy results in a fall.

3. Thyroid Hormones

One of the chief results of infantile hypothyroidism (p. 165) and thyroidectomy in the young animal is inhibition of growth and bone development. As a rule, bone age is more retarded than growth. In contrast to this, growth and bone development are usually somewhat accelerated in infantile hyperthyroidism. These disorders can easily be imitated experimentally in animals.

Thyroid hormones are formed by the fetal thyroid gland. Because of this, bone maturation and brain development are found to be retarded even at birth in cases of congenital athyroidism. Only small amounts of thyroid hormones pass through the placenta, and maternal thyroid hormones are therefore unable to compensate fully for the absence of the fetal thyroid gland.

Thyroid hormones are responsible for normal postnatal growth and, even more, for normal bone maturation. Physiological doses produce this effect only in athyroidism and hypothyroidism. The presence of STH is essential. In the presence of STH deficiency thyroid hormones can only correct the delay in bone maturation and not the delay in growth. Higher doses accelerate bone maturation considerably and only slightly affect growth in normal subjects.

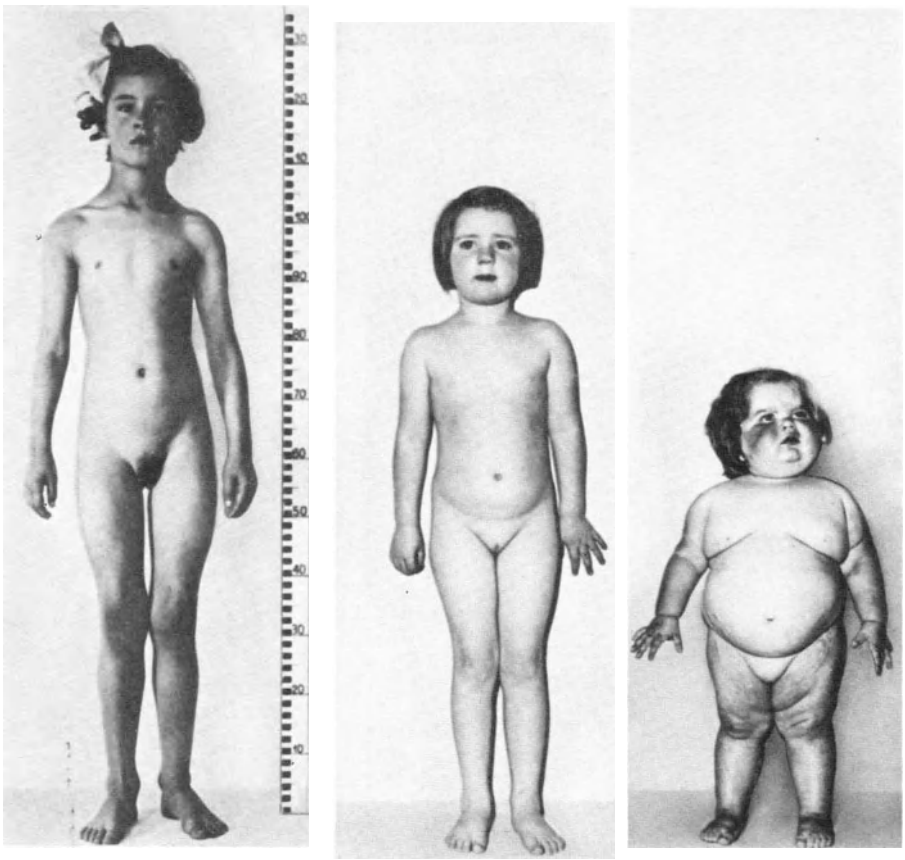

Fig. 3. Influence of adrenocortical hyperfunction on growth. The three girls are all the same age (4–4.5 years). The increased production of anabolic adrenocortical androgens in the adrenogenital syndrome (left) promotes growth. The increased production of catabolic glucocorticoids in Cushing's syndrome inhibits growth (right) (PRADER, 1956)

In hypothyroidism, growth retardation is probably not only due to deficiency of thyroid hormones but also to a secondary STH deficiency. The rise in STH is found to be inadequate after hypoglycemia induced by insulin. This defect disappears on treatment with thyroid hormone. Besides the change in the basophil cells in the hypophysis (p. 80) a decrease in the number of eosinophil cells, which presumably form STH, following thyroidectomy is consistent with this viewpoint.

4. Insulin and Glucagon

Normal protein anabolism in the organism can only occur in the presence of adequate amounts of insulin. It is therefore assumed that *insulin* is essential for the anabolic and growth-promoting action of STH. This interpretation is supported by the facts that growth is retarded in badly treated juvenile diabetics and that growth is rather accelerated in patients with islet-cell tumors. In over-weight babies of diabetic mothers and in infantile obesity, mild gigantism is a characteristic feature. Provocation methods in both instances cause a pronounced rise in insulin, whereas the rise in STH is reduced. Conversely, after the administration of large amounts of glucose to patients with STH deficiency, the insulin rise is diminished and can be normalized by treatment with human STH.

Very little is known about the action of glucagon on growth. Nevertheless, the STH concentration in the blood can be stimulated by glucagon in normal conditions.

5. Adrenocortical Hormones

Over-production of the anabolic-acting androgenic adrenocortical hormones results in the adrenogenital syndrome (p. 358). Growth and bone development are greatly accelerated in these patients (Fig. 4). Since bone development is accelerated more than growth, epiphyseal fusion and arrest of growth occur before normal adult height is attained (Fig. 29). The gigantism in childhood is thus replaced by dwarfism in adulthood.

Over-production of the catabolic-acting glucocorticoids is present in Cushing's syndrome (p. 340). In the pure Cushing's syndrome during childhood, growth and bone development are greatly inhibited (Fig. 3). Analogously, long-term cortisone treatment in children leads to definite inhibition of growth which can usually be recompensated after treatment has been terminated. The effect may be due in part to a secondary STH deficiency. In fact, the STH level in the plasma is reduced in Cushing's

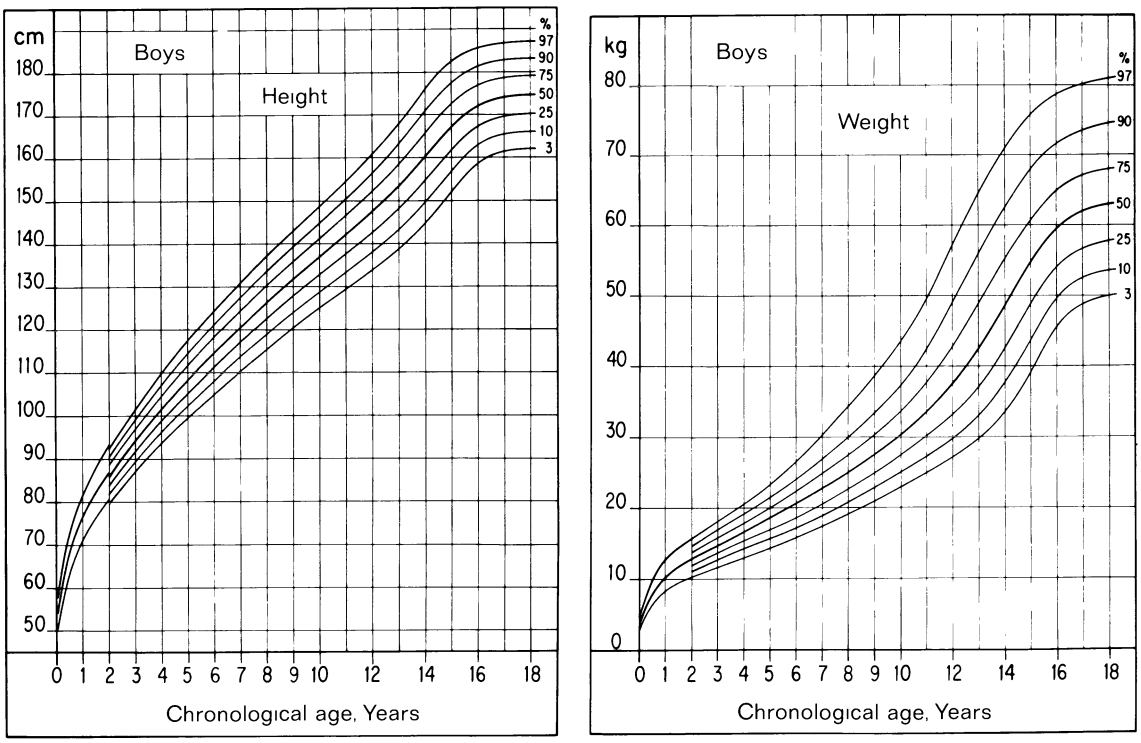

Fig. 4. Height and weight of boys (TANNER, 1966). Percentile 50 represents median values. Percentile 10 (or 90) signifies that 10% (or 90%) of all subjects of the same age are shorter or lighter and 90% (or 10%) are taller or heavier

syndrome and during treatment with high doses of cortisone, secretion and the peripheral anabolic action of STH being more severely impaired than its production. During therapeutic use of glucocorticoids it must be borne in mind that cortisone and cortisol inhibit growth to a lesser extent than prednisone and prednisolone and that equivalent doses of the other synthetic glucocorticoids have an even greater growth-inhibiting action. The latter compounds should therefore never be used during childhood. The growth-inhibiting action is even slighter if cortisone is given every other day or if ACTH is used instead.

In *chronic adrenocortical insufficiency* such as is seen in Addison's disease and in adrenalectomized rats, growth is only inhibited if inadequate amounts of salt and cortexone (desoxycorticosterone) are given. Bone development is almost normal.

In summary, growth and bone development are promoted by androgenic adrenocortical hormones and inhibited by glucocorticoids (Fig. 3). Growth and bone development remain normal in the absence of both types of hormones. The influence of adrenocortical hormones on normal growth in puberty is discussed on p. 1021.

6. Gonadal Hormones

Up to shortly before puberty, the gonads produce only very small amounts of hormones. During normal puberty as well as in premature puberty and in the absence of puberty, growth and bone development show characteristic features associated with the endocrine function of the gonads.

a) Testicular Androgens

Over-production of androgens by the testes occurs only with Leydig-cell tumors (p. 1051). The clinical picture is similar to that of precocious pseudopuberty (p. 1045). As with the overproduction of adrenocortical hormones, growth and bone development are accelerated, especially the latter. The same is applicable to true precocious puberty (p. 1045), where the testes produce androgens prematurely but in the normal manner. In this condition too, the result of the accelerated bone development is that growth is arrested even before normal adult height has been reached.

Failure of the testes to produce androgens, pre-puberal castration and eunuchoidism (p. 457) result in partial inhibition of bone development while growth is not suppressed. The spurt of growth during puberty fails to occur but delay testes in the male or amenorrhea in the female. duration of growth. The result is a height somewhat above the normal and strikingly long extremities (eunuchoid gigantism, p. 458).

Testosterone, the androgenic hormone secreted by the testes, has a very strong anabolic action (p. 453). Like the endogenous androgen production, testosterone used therapeutically during the period of growth results in acceleration of growth and bone development, the latter being the more markedly affected. In the presence of an STH deficiency, the anabolic action of testosterone promoting growth and the androgenic effect are reduced (p. 102). Conversely, testosterone enhances STH secretion: there is a greater rise is plasma STH after provocation in a child receiving testosterone, and the increase is greater in adults than in children.

b) Ovarian Estrogens

Primary *overproduction of estrogens* during childhood due to granulosa-cell tumors (p. 1050) leads to the picture of pseudosexual precocity (p. 1045). Growth and bone maturation are usually accelerated as in true precocious puberty and in the adrenogenital syndrome.

Failure of the ovaries to produce estrogens (pre-puberal castration), like male eunuchoidism, gives rise to slight inhibition of bone development without growth impairment so that the end result is a eunuchoid gigantism. In contrast, bone development in Turner's syndrome is found to be normal or slightly retarded and there is usually pronounced dwarfism which has a genetic and not a hormonal cause.

In contrast to testosterone and anabolic steroids, estrogenic hormones have not been found to have any definite anabolic action, experimentally or therapeutically. They do not promote growth, tending rather to inhibit it, and probably promote bone development to a small extent. As in pseudosexual precocity due to a granulosa cell tumor, an apparently paradoxical effect is often seen when Turner's syndrome is treated with estrogens: not only does pubic hair develop but growth as a whole is also promoted (p. 720). In pituitary dwarfism it is only possible to achieve both actions with testosterone. Treatment with estrogens probably stimulates the production of androgenic adrenocortical hormones in the presence of an intact hypophysis (p. 1040).

c) Hormonal Control of Growth during Puberty

A period of accelerated growth begins at puberty, subsiding towards the end of puberty

and coming to a standstill with the fusion of the epiphyses. As has been shown in the preceding sections, this is also applicable to true precocious puberty and to precocious pseudopuberty associated with isolated hyperfunction of the gonads or adrenal cortex. Both androgenic gonadal hormones and androgenic adrenocortical hormones interact with STH to promote growth and bone development. The puberal growth spurt is apparently due to secretion of androgenic steroids and STH. In the absence of gonadal hormones, there is no spurt of growth during puberty, but a deficiency of adrenocortical androgens may also play a great part (p. 1038), particularly in girls. Because the epiphyses fuse late, the period of growth is prolonged, but the rate of growth is so slow in the last few years that the resultant gigantism is insignificant.

The earlier normal puberty or a pathologic form of puberty arises, the shorter is the total duration of growth and the smaller is the final size attained. The average size of women is less than that of men since the more rapid bone development in girls is paralleled by earlier puberty so that growth also ceases sooner.

C. Normal Values for Body Measurements and Development of Bones and Teeth

1. Height and Weight

Height and weight are the most important measurements for assessment of physical development, but at the same time it must not be forgotten that there are wide physiological variations. Heredity, standard of living and the acceleration of growth from one generation to another all have marked effects.

Normal percentile curves for boys and girls from birth to the 18th year are given in Figs. 4 and 5. The terminal point of the growth curve can be used to estimate the height in adults. Since weight continues to increase after growth has ceased up to the 30th year, special tables (Table 2) are necessary for the assessment of adult weights.

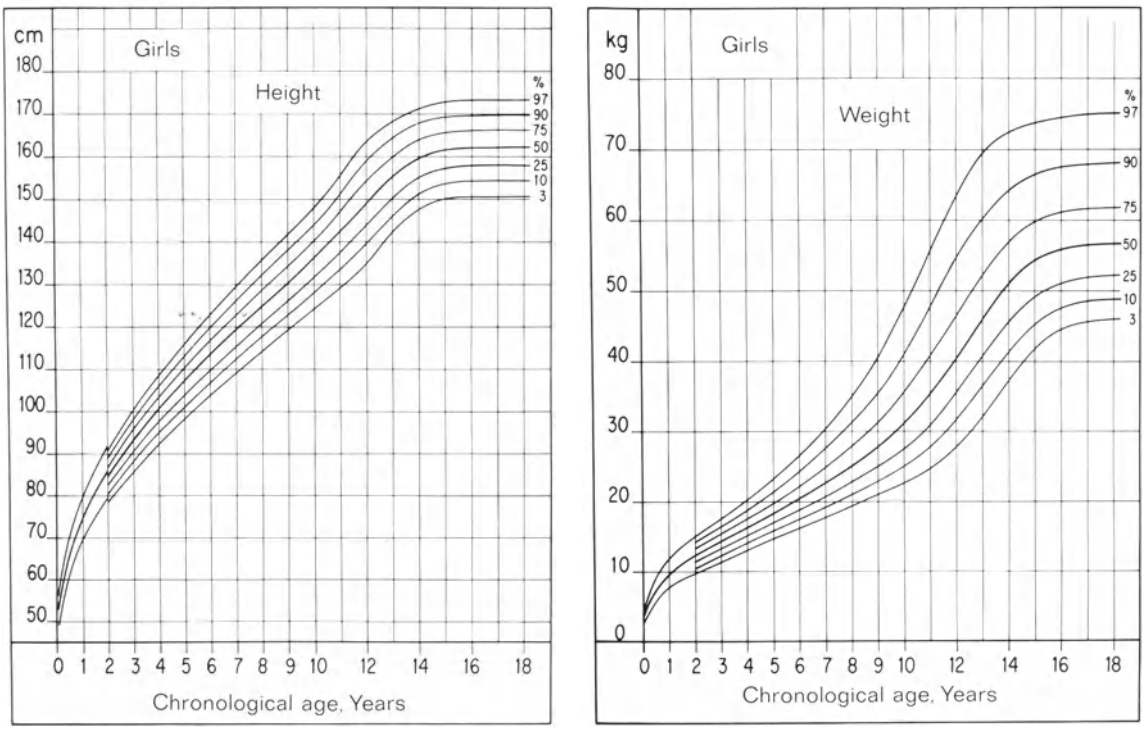

Fig. 5. Height and weight of girls. Percentile 50 represents median values. Percentile 10 (or 90) signifies that 10 % (or 90 %) of all subjects of the same age are shorter or lighter and 90 % (or 10 %) are taller or heavier

Height age and weight age signify the average age at which a certain size and weight are reached (percentile 50 in Figs. 4 and 5). A deviation of $\pm 20\,\%$ from the chronological age is completely normal and roughly corre-

sponds to the area of dispersion between percentiles 10 and 90.

If the average yearly increase in height and weight during the entire period of growth is considered (Fig. 6), the striking feature is the marked increase in height at the beginning of puberty. This spurt in growth does not occur in the absence of puberty.

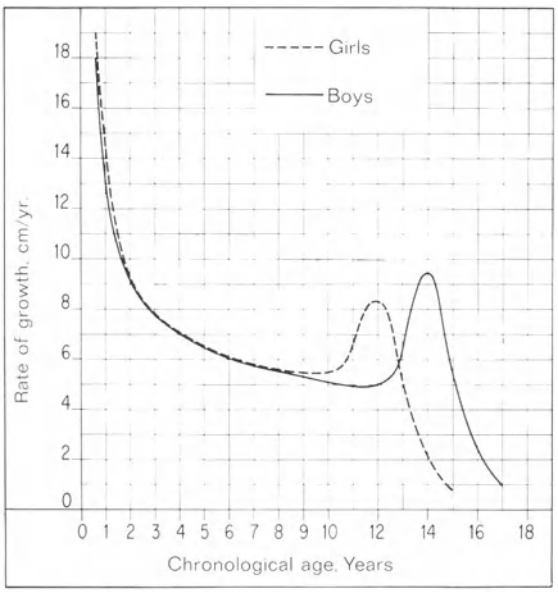

Fig. 6. Rate of growth (cm years) in a typical individual growth curve (TANNER, 1966)

2. Body Surface and Dosages for Tolerance Tests

Dosages per kg body weight used in tolerance tests given in this book are only applicable to adults. These dosages would be too low for children. During childhood, it is preferable to give the dose per m^2 body surface. The dosage according to body surface, however, can be used just as well in adults and can thus be employed more universally than the dosage according to body weight. The body surface can be assessed from body height and body weight with the aid of a nomogram. Experienced workers can estimate the body surface from the following rough scale of normal values: newborn = 3.5 kg = 0.2 m^2, 2 years = 12 kg = 0.5 m^2, 9 years = 30 kg = 1.0 m^2, adult = 65 kg = 1.7 m^2.

3. Body Proportions

As growth increases, the head becomes progressively smaller and the extremities progressively longer in proportion to the trunk. The relative lenghts of the trunk and the extremities is important in endocrinology. The simplest way of estimating these proportions is to measure the lower length or lower segment (height from floor to the upper edge of the pubic symphysis) and then calculate the upper length or upper segment (body height minus lower segment). The *sitting height* is very often measured instead of the upper segment and is only slightly different. The ratio of upper segment/lower segment is about 1.7 in the newborn and decreases with increasing age (Fig. 9). The ratio is about 1.0 in a 10-year-old. During puberty, the extremities are comparatively longer than at any other time of life so that the quotient may fall to 0.9 in boys and 0.95 in girls. It is slightly more than 1 in adult women and slightly less than 1.0 in men.

A rougher estimate of the proportion between trunk length and extremity length can be made by measuring the arm span (distance from finger tips of one outstretched arm to finger tips of the other outstretched arm) and body height. The arm span is slightly less than the body height before the 10th year of life and slightly more after the 10th year. It exceeds body height by a maximum of 4–7 cm in adults. The fact that arm span corresponds to height and the lower segment to the upper segment in the man is seen in LEONARDO DA VINCI'S famous artistic sketch of human proportions (Fig. 7).

The development of these proportions is retarded, i.e. the relative length of the extremities is too short (Fig. 8), in certain forms of dwarfism, particularly in hypothyroidism and chondrodystrophy. The ratio of upper segment/lower segment is higher than normal and the arm span shorter. The same is applicable to all forms of true and pseudosexual precocity after growth has ceased. In these patients epiphyseal fusion occurs before adult proportions are attained. Conversely, in other subjects the extremities are longer than normal, particularly in eunuchs and in arachnodactylia. This feature is less marked but still obvious in almost every case of delayed puberty. The ratio of upper segment/lower segment is then lower and the arm span longer than normal (eunuchoid stature).

4. Bone Development

Bone development is most easily assessed from an X-ray of the hand. Developmental age of the skeleton of the hand (bone age) can be determined by comparing the X-ray with Figs. 10–13. There are special atlases from which the precise bone age of the hand can be read (GREULICH-PYLE). Even more exact methods

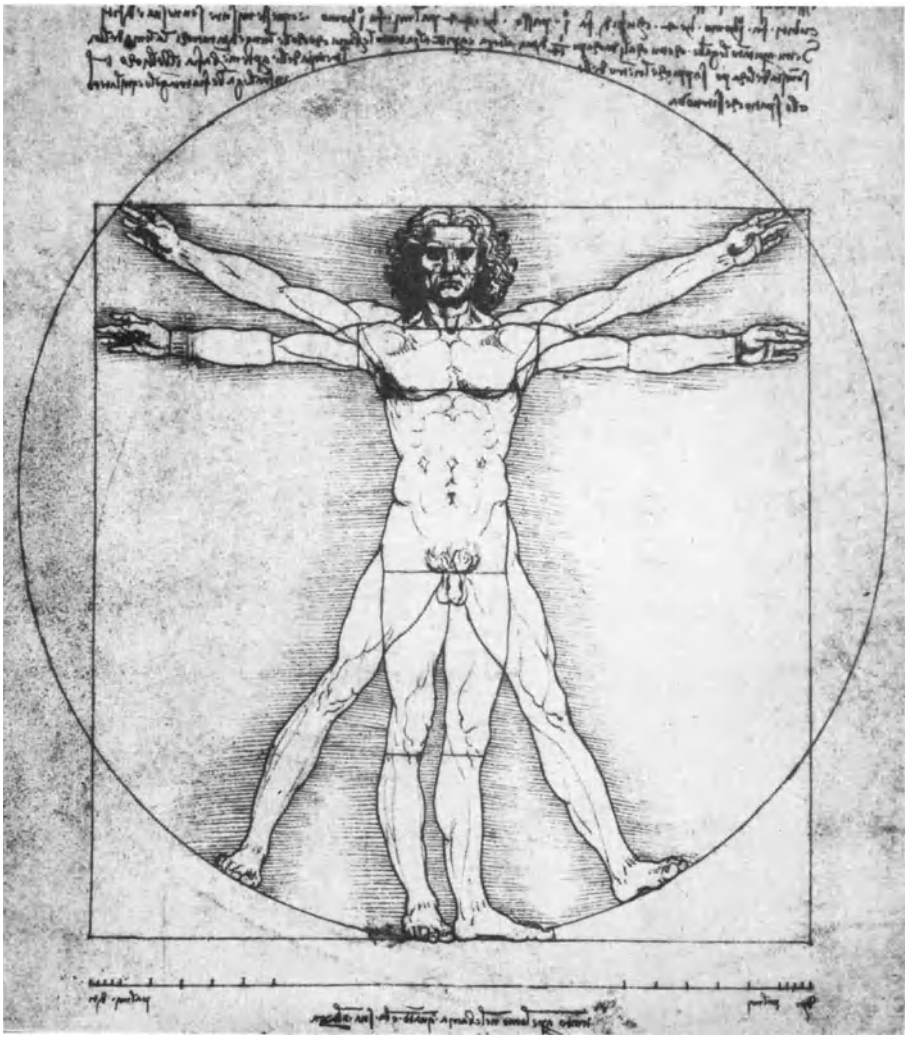

Fig. 7. LEONARDO DA VINCI'S sketch of the human proportions

are based on counting all the centers of ossification on one side of the body (SONTAG).

As in the case of height age and weight age, a deviation of about $\pm 20\%$ of bone age from chronological age is completely normal. Bone development is faster in girls than in boys, the greatest difference being found during puberty when bone development is about 2 years ahead in girls. It is not unusual to find a slight dissociation, i.e., a disturbance in the sequence in which the ossification centers arise. Marked dissociation is especially common in hypothyroidism and following severe generalized diseases.

Comparison of height age and bone age is valuable in the investigation of many growth disorders. In pituitary dwarfism (p. 98), height and bone age are retarded severely and to approximately the same extent. Bone age is more retarded than height age in untreated hypothyroidism during infancy (p. 165). Height age alone is advanced in hypophyseal gigantism (p. 107). Bone age is more advanced than height age in true and pseudosexual precocity (p. 1045).

In some endocrine disorders the X-ray of the hand is of value not only in the estimation of bone age but also in the assessment of bone structure. A marked calcified endplate of the radius and ulna with splintering of the ossification center of the ulna (epiphyseal dysgenesis) points to hypothyroidism (p. 173), whereas bone absorption in the region of the phalanges indicates hyperparathyroidism (p. 915). Generalized calcium deficiency is found in various disorders of calcium/phosphorus metabolism. Coarse ropelike structural changes are found in Turner's syndrome. Transverse lines in the vicin-

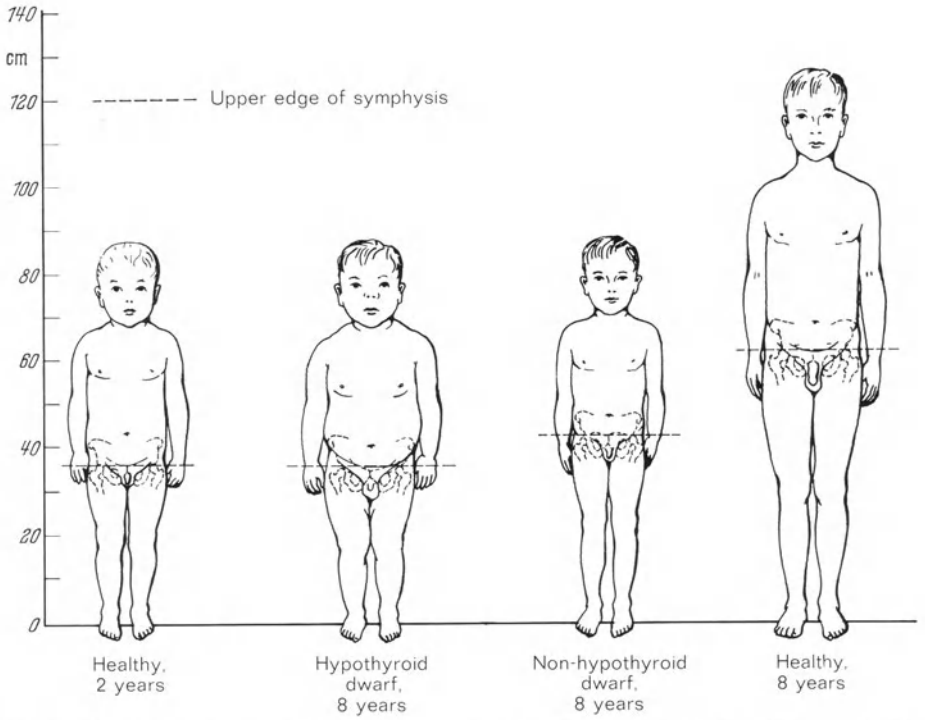

Fig. 8. Body proportions (upper segment/lower segment) in healthy subjects at ages of 2 and 8 years. In the middle, an 8-year-old hypothyroid dwarf whose proportions correspond to those of the healthy 2-year-old, and an 8-year-old non-hypothyroid dwarf with proportions appropriate to his true age. (According to WILKINS)

ity of the epiphyses in long bones and a coulisse-like structure of the ossification centers (Fig. 10, p. 173) can indicate a sudden change from slow to rapid bone growth even months to years after a temporary inhibition of growth in generalized illness or the onset of treatment with thyroid extract in hypothyroidism.

5. Prognosis of Puberty and Growth from Body Height and Bone Development

Bone age is a much more reliable indicator of the time puberty will occur than chronological age or body measurements. The appearance of the first sesamoid bone of the thumb (Fig. 11) at a bone age between 10–11.5 years in girls and between 12.5–13.5 in boys usually coincides with the onset of puberty. Menarche and the point at which mature spermatazoa are probably produced for the first time usually occur about two years later.

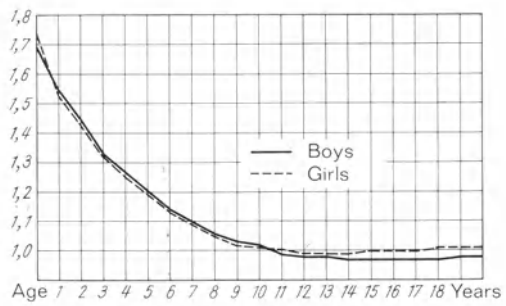

Fig. 9. Mean values for ratio of upper segment/lower segment. (After ENGELBACH, 1932)

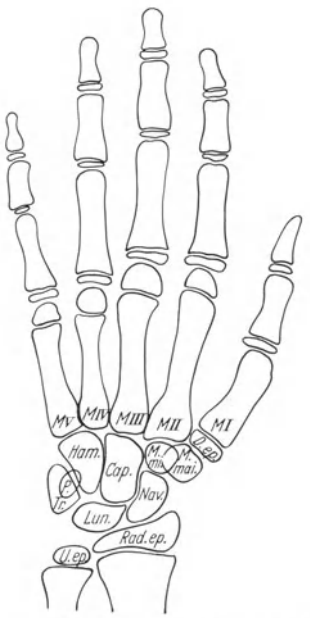

Fig. 10. Skeleton of the hand of a 12-year-old boy (KspZ)

This allows a rough prediction of the time puberty will occur after the 8th year. Thus for example, if bone age is two years in advance of chronological age in a 9-year-old boy puberty can be expected at the age of 11 instead of at 13.

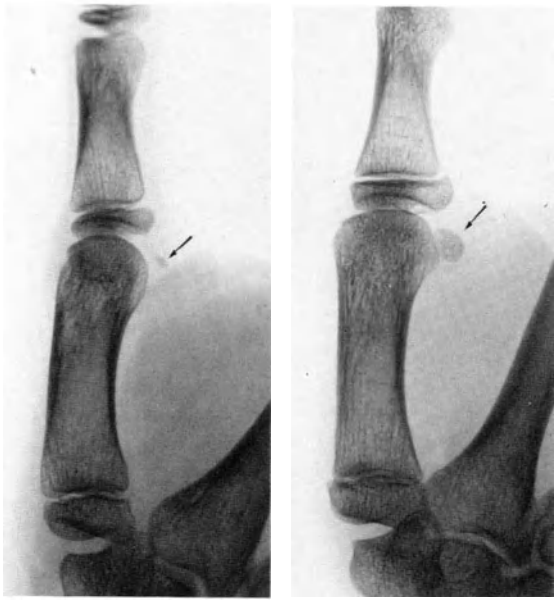

Fig. 11. First sesamoid bone of the thumb shown on the X-ray. Left, in a boy at the age of 13; right, in a boy of 15 (KspZ)

Since growth ceases in girls at a bone age of 16–17 years and in boys at a bone age of 18–19, the further course of growth can be roughly predicted from body height and bone age in children with a bone age of at least 6 years (Table 3). However, this necessitates a completely accurate assessment of bone age, which can be obtained with the aid of the *Greulich-Pyle Atlas*. This possibility is of importance since parents of children growing too slowly or rapidly despite the absence of any endocrinological abnormality are particularly likely to demand a prognosis on growth from the doctor.

6. Dental Development

Development of the teeth is best assessed from a lateral X-ray of the lower jaw. The developmental age of the teeth (dental age) can be assessed by comparing the degree of mineralization of the teeth with Fig. 14. Fig. 14 also shows hypoplasia of the enamel of the permanent incisors is caused by a disorder ot calcification during very early childhood (rickets, hypoparathyroidism).

Table 3. Table for predicting adult height from body height and skeletal age. The figures indicate the percentage of final adult height at a given skeletal age. (From BROCK after tables by BAYLEY and PINNEAU)

Skeletal age in years and months	Boys			Girls		
	Skeletal age			Skeletal age		
	advanced	normal	delayed	advanced	normal	delayed
6. 0			68.0		72.0	73.3
6. 6			70.0		73.8	75.1

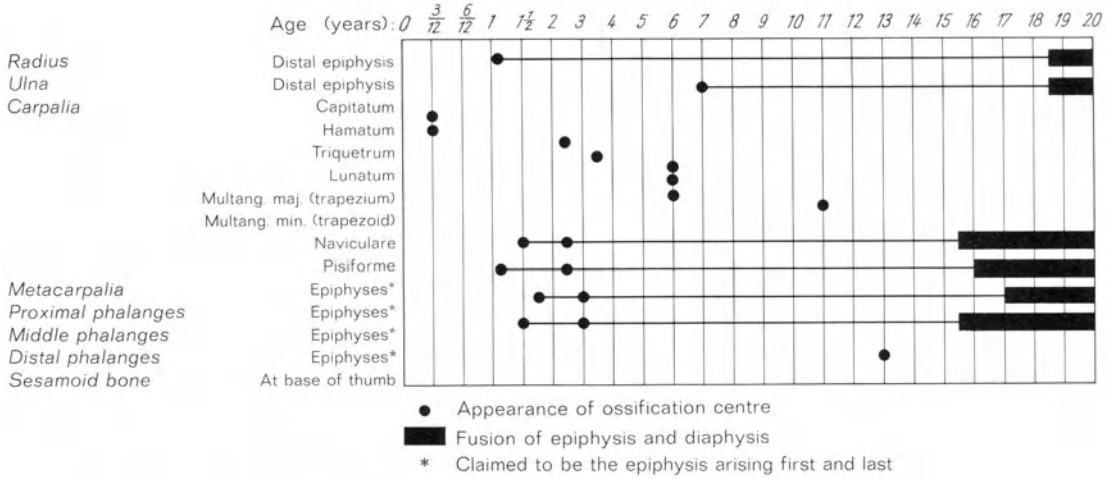

Fig. 12. Development of the skeletal structures of the hand in the male sex

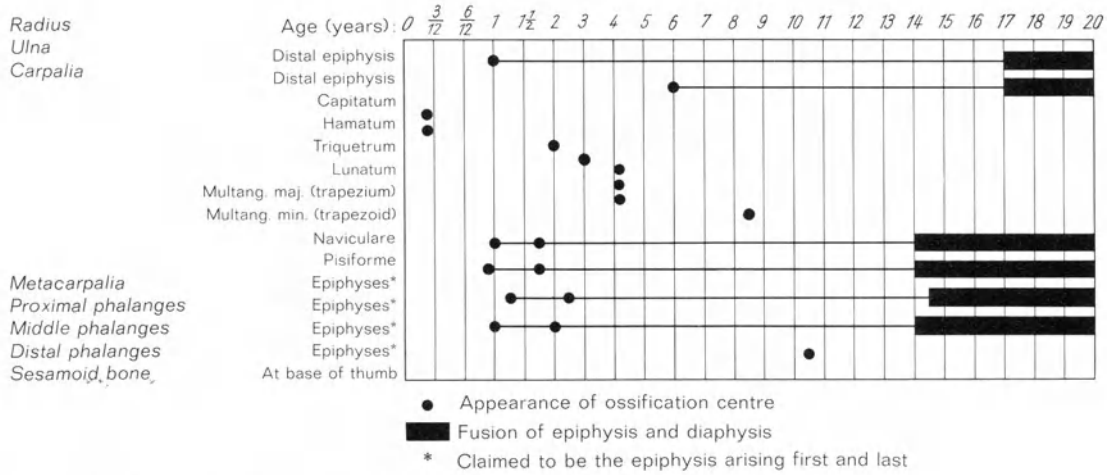

Fig. 13. Development of skeletal structures of the hand in the female sex

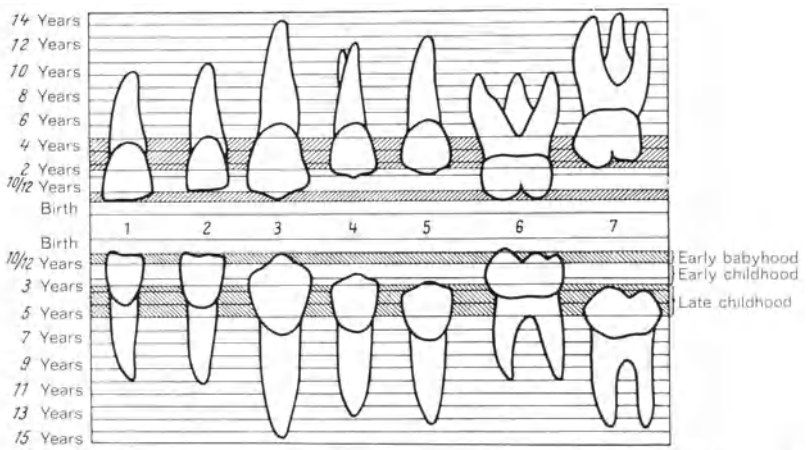

Fig. 14. Radiologically detectable mineralization of permanent teeth. (After MASSLER)

Development of the teeth usually deviates less from the normal than bone development in endocrine disorders. Thus, dental age is less retarded than bone age in infantile hypothyroidism (p. 165) and in pituitary dwarfism (p. 98). In contrast, dental age is normal or only slightly advanced in all forms of pseudo- or true precocity, although bone age is extremely advanced (Fig. 29). Development of teeth is obviously less dependent on endocrine factors than bone development. Hypoparathyroidism arising during infancy is an exception (p. 895), since development of the teeth is often considerably impaired due to deficient calcification of the roots. The X-ray is valuable in the diagnosis of hyperparathyroidism (p. 915) since it reveals the absence of the lamina dura (cortex of the dental alveoli).

7. Graphic Representation of Growth and Development

Fig. 9 on p. 172 and Fig. 29 on p. 1047 show a simple and clear graphic representation with chronological age plotted along the abscissa and developmental age along the ordinate. The curve appropriate to each developmental age (height age, weight age, bone age, mental age, etc.) is then drawn in. The different measures of development can then be determined at a glance.

D. Disorders of Growth

1. Definition of Dwarfism and Gigantism

Any definition of small and large stature and dwarfism and gigantism is subjective and therefore none can claim to be standard.

During childhood, the concepts of small and tall stature are used (Chap. XVIII) when the height age deviates by more than 20% from the norm, and those of dwarfism or gigantism when the deviation exceeds 40%. According to another definition, dwarfism or gigantism is present if the height differes more than three standard deviations from the normal mean. Both definitions incorporate almost the same limits during childhood. If the same form of measurement is applied to adults, dwarfism (or small stature) is present in a male if he is smaller than 145 cm (or 165 cm), and gigantism (or large stature) if he is taller than 200 cm (or 185 cm). Similarly, dwarfism (or small stature) is present in a woman if she is smaller than 135 cm (or 155 cm) and gigantism (or tall stature) present if she is taller than 185 cm (or 170 cm).

Table 4. Etiological classification of dwarfism

1. *Deficiency of building materials*
Hypocaloric dwarfism
Intestinal dwarfism (see under 3)
2. *Neural and hormonal disorders*
Hypothalamus and pituitary
Dyscerebral and microcephalic dwarfism, Laurence-Moon-Biedl-Bardet syndrome
Constitutional retardation of growth and puberty
True precocious puberty
Pituitary dwarfism
Thyroid
Hypothyroid dwarfism
Pancreas
Badly stabilized diabetes mellitus
Adrenals
Cushing's syndrome
Gonads
Pseudosexual precocity[a] with gonadal tumors
3. *Nonhormonal metabolic disorders*
Renal dwarfism
Renal malformations, chronic nephritis, Fanconi syndrome, renal diabetes insipidus, etc.
Intestinal dwarfism
Celiac disease, cystic fibrosis, megacolon, etc.
Hepatic dwarfism
Glycogen storage disease, cirrhosis, etc.
Anoxemic dwarfism
Congenital heart disease, bronchiectases, chronic anemia, etc.
Rachitic dwarfism
Vitamin-D deficiency and vitamin D-resistant rickets
Lipoidosis
Gaucher's disease, Niemann-Pick, Hand-Schüller-Christian, and Pfaundler-Hurler's disease
4. *Deficient growth potential of bones*
Primordial dwarfism and progeria
Congenital skeletal disorders
Achondroplasia, dysostosis (d. multiplex Pfaundler-Hurler, d. enchondralis Morquio, d. cleidocranialis, etc.)
Acquired skeletal disorders
Rickets, hyperparathyroidism
Congenital dysmorphic syndromes
Gonadal dysgenesis, pseudohypoparathyroidism, autosomal chromosomal disorders (Down's syndrome, etc.)

[a] Growth retardation only after epiphyseal fusion.

2. Etiological Classification of Dwarfism

A survey of the various forms of dwarfism is presented in Table 4. The etiological classification corresponds to the growth factors given on p. 1015. The different forms of dwarfism due to endocrine disorders are discussed in the appropriate chapters dealing with the organs and on p. 1031. This chapter deals with the nonhormonal forms of dwarfism which are frequently misinterpreted as endocrinopathies and the differential diagnosis of dwarfism.

3. Dyscerebral and Microcephalic Dwarfism

Microcephalia, brain malformations, and congenital and acquired brain damage of all types are often connected with dwarfism. A deficiency of growth hormone is only exceptionally found to be the cause in such cases. This suggests that cerebral and hypothalamic factors can also influence growth and development via nonhormonal routes.

4. Hypocaloric and Psychosocial Dwarfism

Numerous studies on growth in school children during war and postwar times have shown that deficient nutrition definitely impairs growth and that proper nourishment promotes growth in undernourished children. The best examples of hypocaloric dwarfism can be found among incorrectly and poorly fed babies, children with severe chronic generalized illnesses, and children with anorexia persisting over many years. These last patients illustrate extremely well that psychological influences can also interfere with normal growth by their effect on nutritional uptake.

In addition to children in whom undernourishment or long-standing severe psychological conflicts are apparent there are others with dwarfism, striking emaciation and slightly retarded bone development. In these children, a deficient diet is only discovered to be the cause of the dwarfism after change of environment and an optimal diet have produced an acceleration in growth.

In the U.S.A. there has recently been a special study of forms of dwarfism due to a combination of psychological and social factors. These types of dwarfism are usually reversible (PATTON, 1962; POWELL, 1967), and are referred to as "emotional deprivation" or "maternal deprivation" or as psychosocial dwarfism. Apart from the dwarfism, behavioral disturbances and neglect are also dominant features. It is not quite certain whether psychic factors can inhibit growth directly or whether the dwarfism is connected with the malnutrition. The latter appears more probable. In some cases the concentration of growth hormone in the blood was found to be low and to respond insufficiently to stimulation. A functional, i.e. reversible, growth-hormone deficiency may therefore be present. The growth hormone concentration is, however, raised in other cases of more acute undernourishment with protein deficiency (Kwashiorkor) (PIMSTONE, 1966). If the child can be successfully removed from this situation by a change of environment or improved diet, accelerated compensatory growth can be observed with complete correction of the condition. If it is left untreated, the growth curve is similar to that in patients with growth-hormone deficiency (p. 98) or to that found in constitutional delay of growth and puberty, discussed in the following section.

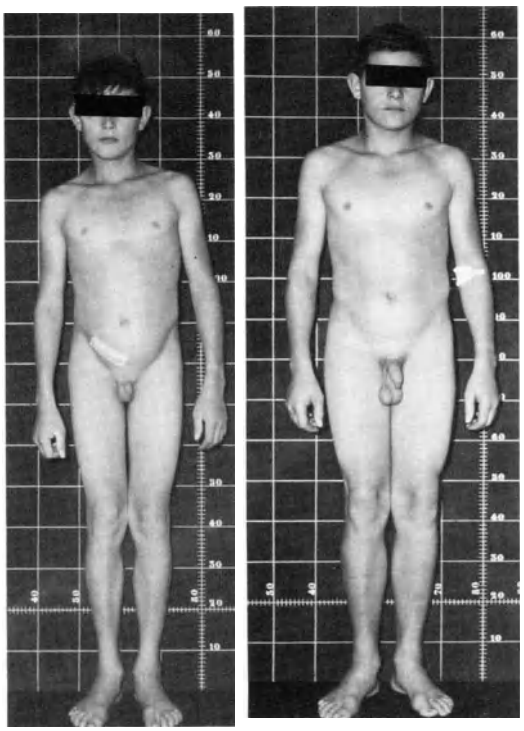

Fig. 15. Familial constitutional delay of development with spontaneous puberty at the age of 18. Left, boy of almost 18 with definite dwarfism, puberty still absent, slightly eunuchoid proportions. Bone age of almost 13 years signifies that puberty is imminent. Right, exactly one year later. As expected, puberty occurred spontaneously and there was a marked acceleration in growth (PRADER, 1955)

5. Constitutional Delay of Growth and Development

Bone development and puberty are retarded in many children with dwarfism in whom no pathologic findings and no proof of inadequate nutrition can be detected. During shool age, height, weight, and bone development are usually retarded by 2–4 years. Puberty and the puberal spurt in growth occur somewhat later than in other children, between the 14th and 18th years, but are absolutely normal. As the period of growth is prolonged to the 20th to 23rd year of life these individuals reach a normal height, even if at the lower normal limits, at a later date.

This delay in growth and puberty is the most common cause of dwarfism in childhood. It is usually familial. The case history may

reveal that the father was also one of the smallest at school and was still growing at the age of 20, or that menarche was late in the mother, occurring at the age of 15 or 16, or that puberty developed very late in older siblings and they only started to catch up on growth after this.

The clinical diagnosis is based on the following elements: the child or youth gives a healthy and robust impression, there are no signs of endocrinopathy, the growth curve lies below and almost parallel to that of the 3rd percentile, bone age is retarded to the same extent as growth, the family history may reveal similarly retarded growth and puberty in the father or mother or older siblings. In such circumstances detailed endocrinological examinations are not indicated. If, however, the growth curve deviates further from the 3rd percentile, isolated growth hormone deficiency must be considered in the differential diagnosis and appropriate tests initiated.

The ability to predict from the bone age when puberty can be expected (p. 1024) and what the future adult height will be (p. 1024) is crucially important in the selection of *treatment*. In order to leave endogenous development of puberty undisturbed, every type of hormonal therapy should theoretically be postponed until the bone age (girls about 11.5 years, boys about 13.5 years) at which the first signs of puberty should appear is reached. When these do not appear as expected the diagnosis of constitutional growth and developmental retardation must be discarded and a true hypogonadism assumed as the cause. As a general rule it is permissible to delay treatment if puberty is almost imminent. But after the 15th year or sometimes even earlier, a true psychological emergency may arise. During confidential talks with the patient it suddenly becomes apparent how inadequate he feels physically and often socially, how difficult it is for him to keep up in sports, how awkward, inferior, and abnormal he feels, how he is made fun of and terrorized by his associates and how he lives in a constant state of fear. This situation presents a pressing psychosocial indication for temporary treatment with chorionic gonadotropin or testosterone. Chorionic gonadotropin has the advantage that any expected response of the testes to stimulation can soon be recognized as secondary sexual characteristics develop quickly. A weekly injection of 2000 units for 3 months is a suitable dosage. Treatment with testosterone is correct either from the beginning or subsequent to administration of chorionic gonadotropin (10–25 mg methyl testosterone daily orally, or 250 mg of a depot testosterone preparation given by i.m. injection each month). Testosterone, however, should only be given until a bone age of 13.5 years has been reached. Body weight, height, and physical strength will increase rapidly during treatment. Secondary sexual characteristics appear at the same time but the testes remain small in size since endogenous gonadotropin production is inhibited by the treatment. Appetite, efficiency, and self-confidence also increase. Puberty continues spontaneously under the control of endogenous gonadotropins after treatment is discontinued, and the testes rapidly increase in size providing the bone age has passed the stage of 13–13.5 years.

6. Primordial Dwarfism

In primordial dwarfism, body proportions, bone development, development of puberty and the age at which growth stops correspond roughly to the chronological age. In other words, with the exception of growth in height and weight, these children develop absolutely normally and are capable of reproduction. The incidence of this form of dwarfism is both sporadic and familial. Growth is usually retarded at the time of birth in spite of a pregnancy of normal duration (Fig. 17). It is not unusual for subjects in whom the condition is sporadic to have children of normal size. In other cases, the family tree shows a true selection for dwarfism, since small people prefer to choose small marriage partners and they in turn have small children.

7. Progeria

Progeria (Hutchinson-Gilford syndrome) is a very rare, non-familial, congenital growth disorder with premature aging. The patients are of normal intelligence and all have exactly the same unmistakable appearance. As well as dwarfism and deficient panniculus, the condition is characterized by an old-looking bird-like face (Fig. 16).

Typical symptoms usually arise as early as the first year of life. Growth is greatly retarded but ceases at the normal time. Average height is only 117 cm and the mean weight only 16.5 kg at the age of 18 (Thomson, 1950). The face is strikingly small compared to the skull, which has a slightly hydrocephalic appearance. The eyes are prominent and the nose is beak-like and pronounced. The lower jaw is hypoplastic. Hair on the head, eyebrows, and eyelashes is usually sparse or completely absent. Veins on the forehead are greatly dilated and protruding. X-rays show a mild calcium deficiency in the bones, coxa valga,

and hypoplasia of the distal ends of the clavicular. Extremities are always held in a position of slight flexion. Arteriosclerotic and arthrotic changes always arise at a very early age. Death usually occurs during the 2nd decade and is most often due to coronary insufficiency. The oldest known case reached the age of 26 years.

Fig. 16. Classic progeria in a $3\frac{1}{2}$-year-old boy. Body height is 85 cm instead of 95 (Rossi, 1951)

The cause of progeria is unknown. Some time ago hypophyseal insufficiency was thought to be the cause, but this has never been proved. More recently, hereditary mesenchymal dysplasia with resistance to growth hormone and insulin has been postulated (Villee, 1969).

8. Dysmorphic Syndrome with Dwarfism

The numerous syndromes of dwarfism with multiple dysmorphic features or multiple malformations are extremely difficult to diagnose and even more difficult to treat. The regions predominantly affected by the multiple malformations are those of the head, face, hands, feet, heart, and external genital organs. Dwarfism is commonly already present at birth. Bone development corresponds to the chronological age or is retarded. Intelligence is normal or below normal depending on the type of syndrome. Turner's syndrome (gonadal dysgenesis, p. 713), pseudo-Turner's syndrome (p. 719), pseudohypoparathyroidism (p. 899), autosomal chromosomal disorders of which mongolism (Down's syndrome) is the most frequent, and numerous other syndromes belong to this group. The diagnosis is important for prognostic reasons and for genetic counselling, but it requires special knowledge in this field (Smith, 1970) and cannot be discussed any further at this point.

9. Clinical Investigation of Dwarfism

The survey of the various forms of dwarfism (Table 4 on p. 1027), the types of growth in Fig. 17, and the summary of the differential diagnosis in Table 5 should be kept in mind during the following account.

Clinical investigation of dwarfism is often laborious and time-consuming. The cause can only seldom be detected at first glance (hypothyroidism, chondrodystrophy, mongoloid idiocy, etc.). An exact family history (height of parents and siblings, age at onset of puberty, and at cessation of growth) and a careful personal history giving information about the course of growth until the present time, nutrition, appetite and previous illnesses are absolutely essential. Thorough general physical examination with urinalysis is also of the utmost importance. It is very important to record height, weight, bone age, body proportions and the state of puberal development to provide a standard of comparison in assessing the subsequent course of growth and development at later examinations. The X-ray of the hand is used to assess bone age and also reveals any metabolic and endocrine skeletal disorder.

Only tests aimed at confirming a suspected diagnosis should actually be performed; even consideration for the patient alone forbids indiscriminate testing for all conditions which can cause dwarfism.

A thorough case history and clinical examination nearly always lead to the diagnosis in adults. The diagnosis is more difficult in children but far more important for prognostic and therapeutic reasons. Often, however, even the most careful investigations do not definitely reveal the cause of the dwarfism in the child. Periodic observation is very valuable since the course of growth is quite characteristic for most forms of dwarfism.

If investigations do not reveal an easily detectable endocrinopathy (hypothyroidism, Cushing's syndrome), or metabolic disorder, cerebral disturbance or skeletal disorder, and the child gives a generally healthy impression and appears to be of normal intelligence, the condition is frequently due to constitutional

retardation of growth and puberty (p. 1028). Less commonly, it may be primordial dwarfism (p. 1029), pituitary dwarfism (p. 98) or Turner's syndrome (p. 713) without striking dysmorphic features. Pituitary dwarfism can be detected by means of thorough examination of pituitary function with estimations of growth hormone. Turner's syndrome must be condidered in every girl of small stature, and pterygium etc. must be looked for carefully. A negative sex

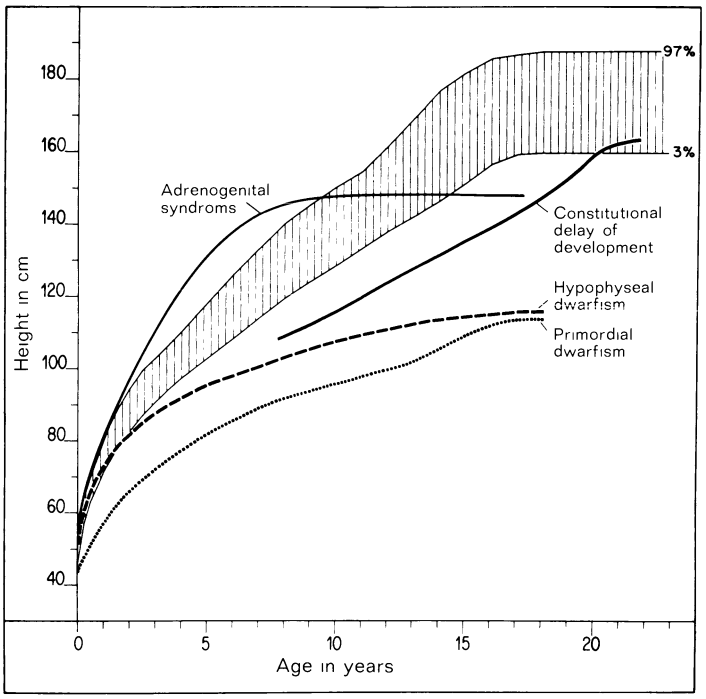

Fig. 17. Typical growth curves in various forms of dwarfism (PRADER, 1971)

Table 5. Differential diagnosis of endocrine dwarfism in childhood

Diagnosis	Growth	Bone maturation (and puberty)	Intelligence	Special features
Dyscranial dwarfism	Delayed	Delayed	Reduced	Microcephalia Neurological findings possible
Hypocaloric dwarfism Psychosocial dwarfism	Delayed	Delayed	Normal	History Emaciation
Constitutional delay of growth and puberty	Both similarly delayed		Normal	Parental history Healthy
Primordial dwarfism	Delayed	Normal or slightly delayed	Normal	Parents often very small Healthy
Pituitary dwarfism				
a) isolated deficiency of growth hormone	Very delayed	Less delayed than growth	Normal	Doll-like appearance Normal body proportions
b) deficiency of several pituitary hormones	Both similarly delayed		Normal	As in a) associated with other hormonal failures
Hypothyroidism	Delayed	More delayed than growth	Reduced	Characteristic appearance Infantile body proportions
Cushing's syndrome	Delayed	Delayed	Normal	Obesity with other Cushing symptoms
Turner's syndrome (gonadal dysgenesis)	Very delayed	Less delayed than growth	Normal or slightly reduced	Typical dysmorphic characteristics
True and pseudo-precocious puberty	Accelerated up to 12th year, then standstill with dwarfism	Greatly accelerated	Normal	Accelerated somatic development premature secondary sexual characteristics

chromatin confirms the diagnosis whereas a positive sex chromatin does not help and demands analysis of the chromosomes when Turner's syndrome is clinically suspected.

10. Prognosis and Treatment of Dwarfism

The *prognosis for growth* is of greatest practical importance in children. If an endocrine hypofunction is present the prognosis will depend on regular substitution therapy. The time at which puberty will occur and the future adult height can be predicted quite accurately in all other forms from body height and bone age (p. 1024). Obviously no further growth is possible after fusion of the epiphyses.

Causal treatment is possible in only a few cases of dwarfism. It includes optimal nutritional intake if the condition is due to malnutrition, administration of human growth hormone in pituitary dwarfism, or of thyroxine in hypothyroidism, insulin treatment in diabetes mellitus, surgical removal of endocrine-active tumors, treatment with cortisone in cases with the adrenogenital syndrome and inhibition of gonadotropins in cases of sexual precocity.

Some of the growth-promoting drugs recommended for *symptomatic treatment* are:

1. Pituitary Growth Hormone. Extracts from animals are useless. The amounts of growth hormone extracted from human pituitary glands at our disposal are barely adequate for the treatment of pituitary dwarfism, so that we have very little experience of its action in other forms of dwarfism. The usual doses currently used for symptomatic treatment (2–6 IU 2–3 times weekly) appear to have little or no effect.

2. Thyroid Hormones. The growth-promoting effects of these hormones are very slight except in hypothyroidism. This form of treatment must be used with caution since it involves the risk of accelerated development of the bone age.

3. Testosterone. Testosterone promotes growth considerable. Its androgenic action is a disadvantage and only very low doses can be used before puberty. Another drawback is its stimulating action on bone maturation. Since bone maturation is promoted more than growth (p. 1020), there is a risk of premature epiphyseal fusion with premature arrest of growth as with an overproduction of endogenous androgens (p. 713). In other words, the acceleration of growth is obtained at the expense of a reduction in future adult height. Testosterone should therefore only be given after the 12th year of age and only to boys with a good growth prognosis. Symptomatic use of testosterone has been discussed in connection with the treatment of constitutional retardation of growth and puberty (p. 1029).

4. Anabolic Steroids. It has been claimed that the growth-promoting anabolic action of various synthetic testosterone derivatives is much greater than their androgenic effect. In practice, however, it has been found that, like testosterone, they usually have stimulating and androgenic effects on bone maturation in doses promoting growth. The misgivings applicable to testosterone are thus also applicable to these drugs. Exceptional caution is required, particularly in treating girls, because of the androgenic action.

5. Insulin. Findings from animal experiments (p. 1019) and theoretical consideration suggest that symptomatic promotion of growth may be possible with insulin. Its use, however, is problematic because of the danger of hypoglycemia and there is no practical experience as yet.

6. Nutrition. An optimal intake of calories and proteins is advisable in every form of dwarfism. Definite success can only be expected if the inhibition of growth is due to deficient nutrition. Trying to force anorexic children to eat is usually useless and only leads to psychoreactive disturbances.

7. Vitamins, Liver Preparations, Antibiotics and Antiallergics. It has been claimed that vitamin B_{12}, liver extracts, certain antibiotics and, more recently, certain antiallergic drugs can promote growth directly or by stimulation of the appetite. There is no definite evidence of an action of this kind in man. Even if a clinician is sceptical about their validity, trials with these drugs are occasionally indicated for psychological reasons. Vitamins and liver preparations are then preferable, and the use of actual pharmaceutical preparations is only justifiable if regular check-ups are carried out.

11. Tall Stature and Gigantism

The various forms of gigantism are presented in Table 6, in which the same etiological classification has been used as for dwarfism (Table 4). The different forms of gigantism due to endocrine factors are dealt with in the corresponding chapters. A few nonhormonal forms of gigantism which are still frequently misinterpreted as endocrinopathies are discussed below with the differential diagnosis.

Table 6. Etiological classification of gigantism

1. *Excessive building materials*
Prepubertal and pubertal obesity (subsequent to pituitary hyperfunction)
2. *Neural and hormonal disorders*
Hypothalamus
Dyscerebral gigantism with hydrocephalus, etc.
True precocious puberty
Hypophysis
Hypophyseal gigantism
Thyroid
Hyperthyroid gigantism
Adrenals
Adrenogenital syndrome
Gonads
Pseudo-precocious puberty with gonadal tumors
3. *Nonhormonal metabolic disorders*
Arachnodactylia (Marfan syndrome)
Homocystinuria
4. *Excessive growth potential of bones*
Primordial gigantism
XYY syndrome
Wiedemann-Beckwith syndrome with omphalocele and macroglossia

In *cerebral gigantism*, gigantism is present from birth or babyhood. The striking features are: the large dolichocephalic head with the high forehead and large orbits, large plump hands and feet, often mild mental deficiency and generalized motor clumsiness. Bone age and puberty are usually somewhat advanced. The EEG is frequently found to be pathologic and there is often slight hydrocephalus. The syndrome occasionally arises among siblings. Hormonal findings correspond to the developmental age. Contrary to expectation, growth hormone levels are not raised. The pathogenesis is just as obscure as is that of microcephalic dwarfism.

There is also a *primordial form of gigantism*. Apart from the conspicuous height, these individuals are healthy and normal in every respect. Bone maturation and development of puberty are within normal limits. This form of gigantism is frequently familial. For understandable psychological reasons, very tall individuals often marry each other, so that as in dwarfism, there is true selection of gigantism.

The *differential diagnosis* is seldom difficult. The general examination and family history usually allow a definite diagnosis to be made. In the presence of impaired vision, and disorders of the nerves supplying the ocular muscles, the rare diagnosis of a pituitary tumor would have to be considered. The common XYY syndrome (p. 468) must be considered in cases where youths are extremely tall compared with their parents. The diagnosis is confirmed by means of Y-fluorescence staining of the buccal smear or by direct chromosomal investigation.

The *prognosis* about when puberty will occur and the future adult height can easily be determined from the age, height and bone age.

Causal treatment is only possible in the rare hormonal disturbances. There is no causal therapy available for the other types or for constitutional gigantism, which is very common. During school age and adolescence, extreme body height often leads to serious psychological problems and to organic kyphosis (Scheuermann's disease) or to psychogenic posture kyphosis. If the expected adult height is extreme, symptomatic treatment to reduce the future height is desirable. An urgent psychosocial indication for this type of treatment may present particularly in girls. As in precocious puberty, high doses of sexual hormones can reduce the phase of growth and thus the expected adult height (in girls, estrogen medication with gestagens every 4th week, testosterone in boys). Therapy of this kind inhibits gonadotropin secretion and thus suppresses gonadal development, at least temporarily, but current knowledge of the optimal dose and the complications associated with the treatment is not sufficiently advanced for it to be recommended for general use.

E. Puberty

1. Survey

Puberty is the phase of development at which secondary sexual characteristics arise and the gonads attain incretory and secretory maturation. It begins with the development of the first secondary sexual characteristics, generally lasts for about 5 years and ends when fertility has been attained shortly before cessation of body growth. Occasionally, puberty is defined as the first phase of development up to menarche (roughly the same period of time in boys), and the term adolescence is applied to the subsequent phase of development up to termination of growth. No distinction is usually made now, however, between puberty and adolescence. On average, puberty arises almost two years earlier in the female than in the male sex. Time relations vary according to race and other hereditary factors and are also influenced, like growth, by exogenous factors, way of life and nourishment. In addition, an earlier maturation (pubertal acceleration) has become obvious over several generations, which is presumably also related to exogenous factors.

The onset of puberty is now between the ages of 8 and 14 years in girls, and between 10 and 16 years in boys. Girls are sexually mature and adult between the ages of 14 and 16 years, and boys between 16 and 20.

The reader is referred to the chapters on the ovary and testis for the histology of gonadal maturation. Only external characteristics of puberty and the underlying hormonal relations are discussed in this section.

2. External Characteristics and Course

Tables 9 and 10 show the average course of puberty in girls and boys. Tables 7 and 8 show the usual stages used today for the development of pubic hair and breasts. Fig. 21 gives the normal values for testicular volume. The development as a whole shows a wide chronological variation between individuals (Figs. 18 and 19), whereas the order in which the individual characteristics arise and the time intervals between them vary much less.

As described in the discussion of growth (p. 1015), the *spurt of growth during puberty*, the *bone maturation* leading to fusion of the epiphyses and *standstill of growth* are the main characteristics of puberty. Bone development is related much more closely to puberty than chronological age or body size. This makes it possible to predict the onset of puberty from the chronological age and bone age. The relations between puberty and bone development and between bone development and arrest of growth also explain why growth comes to a halt sooner with early puberty. This rule, however, only applies to individual development and not to the generalized acceleration of growth and puberty observed in modern children. Puberty occurs at an earlier age now than in earlier generations and children, therefore, now reach adulthood earlier, but even so they are also taller than children of past generations. This increase of body height in spite of earlier puberty can be explained by the fact that the more intense prepubertal growth more than compensates for the shorter duration of growth.

Table 7. Stages of breast development. (After TANNER, 1962)

B 1	No palpable glands
B 2	Breast bud: areola enlarged, protusion of glands in region of areola
B 3	Gland larger than areola
B 4	Budding breast: glands in region of areola become elevated separately from the other glands
B 5	Mature breast: retraction of the areolar protusion into the general contour of the breast

Table 8. Stages of pubic hair. (After TANNER, 1962)

P 1	No hair
P 2	A little pubic hair around root of penis or on labia majora, unrecognizable on photo of whole body
P 3	Dense hair in circumscribed limits, visible on photo
P 4	Dense hair as in adult but less extensive
P 5	Extensive dense hair with horizontal upper margin and extending laterally onto thighs
P 6	Triangular extension towards umbilicus

Table 9. Chronological table of the development of puberty in girls

Age (years)	Physical characteristics
Before 8	Infantile state
10–11	Breast buds = thelarche (B 2) Acceleration of growth Maturation of vaginal mucosa
11	First pubic hair = pubarche First sesamoid bone of thumb
11–12	Marked growth of external and internal genitalia
12–13	Pubic hair and breast development in Stage 3 Peak height velocity
13	Menarche, irregular anovulatory menstruation Axillary hair Pubic hair and breast development in Stage 4
14–15	Regular ovulatory menstruation Pregnancy possible Pubic hair and breast development in Stage 5
16–17	Epiphyseal fusion and standstill of growth

Table 10. Chronological table of the development of puberty in boys

Age (years)	Physical characteristics
Before 10	Infantile state
11–12	Testes begin to grow
12–13	Appearance of pubic hair = pubarche Enlargement of penis starting Acceleration of growth
13–14	Marked growth of testes and penis Pubic hair in Stage 3 Mild swelling of breasts First sesamoid bone of thumb
14	Peak height velocity
14–15	Moustache appearing on upper lip Pubic hair in Stage 4 Axillary hair Marked breast swelling
15–16	Breaking of voice Pubic hair in Stage 5 Testes and penis fully grown, mature spermatozoa Regression of swelling of breasts
17–19	Increase in facial and body hair Pubic hair in Stage 6 Masculine hair border on forehead Epiphyseal fusion and growth standstill

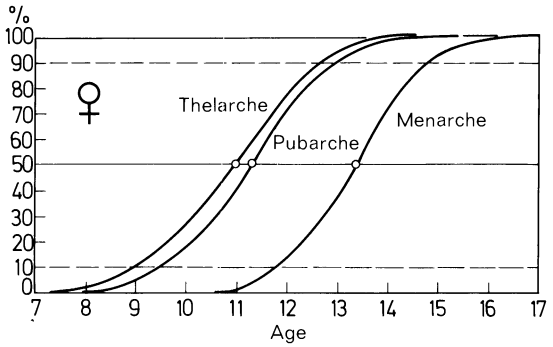

Fig. 18. Chronological scattering of the development of puberty in girls (VAN WIERINGEN, 1968)

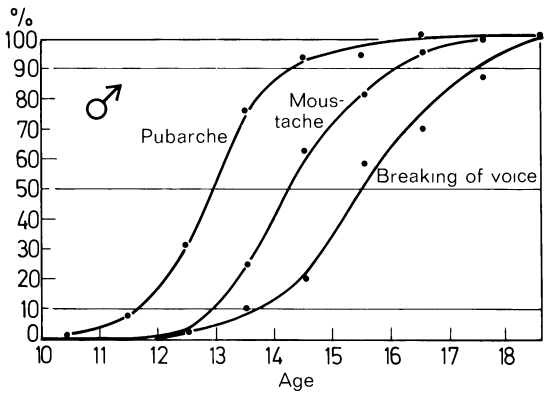

Fig. 19. Chronological scattering of the development of puberty in boys

The *striking length of the limbs* and the marked growth of the hands and feet (pubertal acromegaloid) are further features of growth during puberty. The comparative length of the extremities is greater, i.e., the ratio of upper to lower segment (p. 1024) is lower in the first phase of puberty than at any other time of life. This is explained by the fact that the extremities grow more than the trunk before and at the onset of puberty and that they also stop growing at an earlier stage. These almost eunuchoid proportions are more obvious the later puberty arises.

Sex-specific skeletal characteristics develop parallel to generalized bone maturation during puberty. These features (wide hips in the woman, broad shoulders in the man, etc.) together with the development of the musculature and adipose tissue determine the characteristic stature of the man and woman.

Development of the mammary glands or *thelarche* is the first of the *secondary sexual characteristics* to arise in the girl. The development is often unilateral to begin with, occurs more frequently on the left side, and there is often a difference between the two sides even later on. At first, the swelling of the glandular tissue can only be palpated, then the areola protudes. All stages of breast development occur during 3–4 years. At the same time, the labia minora become enlarged.

Parallel to this, gradual maturation of the vaginal mucosa can be followed in the vaginal smears and the steady increase in size of the uterus can be determined by means of rectal examination. The first pubic hair, or pubarche, appears shortly after the onset of breast development or more uncommonly before. The first sesamoid bone of the thumb becomes visible on the X-ray at about this time. This occurs at a bone age of about 11 years. The peak of the pubertal spurt of growth occurs about a year later and axillary hair develops after another year, at about the time when *menarche* arises. The first menstrual periods are usually painless, still irregular and not accompanied by the typical biphasic temperature curve (anovulatory cycle, p. 576). Fertility is not reached until 1–2 years later, with the development of regular and often painful menstruation (ovulatory cycle, p. 564).

Increase in the volume of the testes is the first *secondary sexual characteristic* in boys. Shortly after this the first pubic hair arises (pubarche) and the penis begins to grow at the same time. As in girls, the first sesamoid bone of the thumb appears on the X-ray roughly at the same time, corresponding to a bone age of 13 years. The peak of the spurt of growth during puberty is reached shortly after. Axillary hair appears later, and the beard begins to grow and the voice to break. The various characteristics become more pronounced in subsequent years. The rapid growth of the penis and testes is particularly striking, and development of these organs is complete by the age of 16. The *typical characteristics of body hair in the male* are the tapering upper border of pubic hair extending towards the umbilicus and dense generalized body hair. Beard and the temporal retrogression of the hair margin on the forehead develop later. *Swelling of the breasts* (pubertal macromastia or physiological pubertal gynecomastia) is less striking, arises in most boys at the onset of puberty, usually disappears after 2–3 years and hardly ever exceeds the diameter of the areola. It is difficult to state definitely the point at which fertility is reached, i.e. when mature spermatazoa are produced. Although pollution and ejaculation occur very early on in puberty, mature sperms are not usually formed until a few years after the onset of puberty.

Changes in the skin also belong to the secondary sexual characteristics in both sexes but particularly so in boys. Sweat excretion

increases, particularly in the axillae, and the sweat acquires a penetrating odor. Function of the sebaceous glands is greatly increased particularly in the facial region and *acne* of varying severity may be the presenting feature. The acne usually only involves the face and upper trunk and usually disappears spontaneously after a few years. *Striae distensae of the gluteal region* and occasionally also of the upper parts of the thighs is another cutaneous symptom appearing in both sexes. Little attention is paid to this symptom but it is not uncommon and does not occur only in obese children but not infrequently also in thin subjects.

Objective assessment of the size of the testes and occasionally also of the penis is very useful in the assessment of puberal disorders or hypogonadism. *Testicular volume* depends mainly on the development of the seminiferous tubules and only to a slight degree on the Leydig cells. Testes which are too small suggest inadequate spermatogenesis due to primary testicular insufficiency or gonadotropin deficiency. A conspicuously enlarged testis is often found in the absence of the contralateral testis and occasionally in the adrenogenital syndrome due to hyperplastic intratesticular adrenocortical tissue (p. 366). The simplest method for estimating the volume is comparative palpation of the testis and testicular models of known volumes (Fig. 20). The volume before puberty is about 0.75 ml to 2 ml at the most. The volume increases to 3–12 ml before the appearance of pubic hair and the final volume is reached by the 16th to 17th year (Fig. 21).

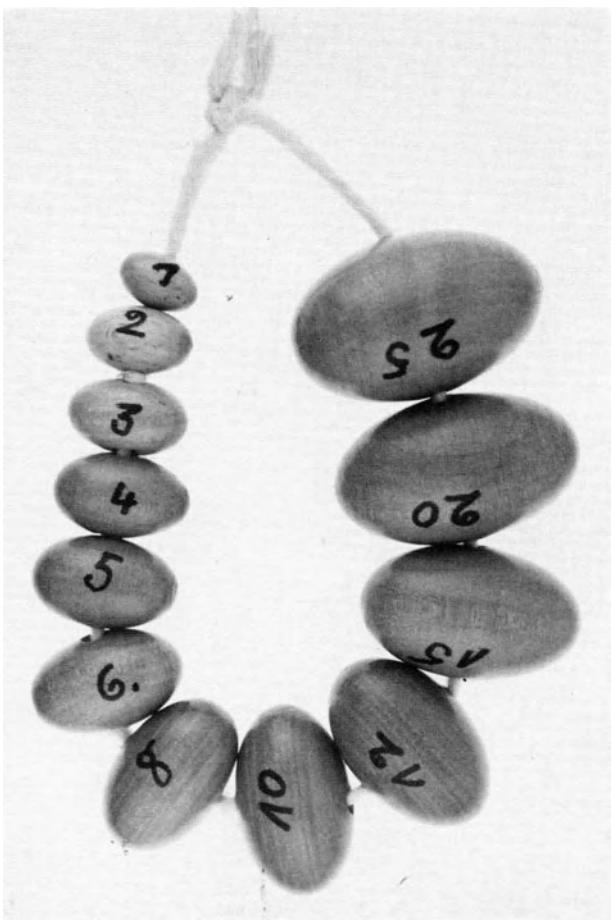

Fig. 20. Orchidometer. Models of known volumes for estimating testicular volume by comparative palpation

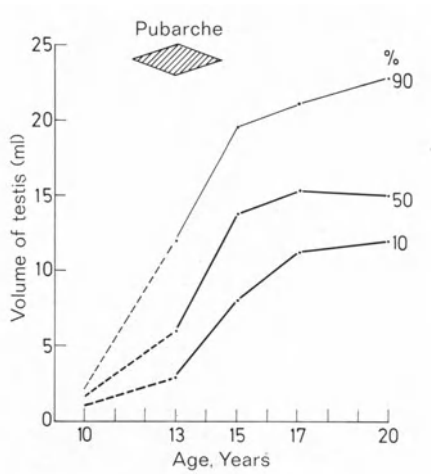

Fig. 21. Average testicular volume. Percentile 50 represents the median values. Percentile 10 (or 90) means that 10% (or 90%) of all healthy boys of the same age have smaller testes and that 90% of them (or 10%) have larger testes

The *size of the penis* is assessed by measuring the dorsal length of the stretched penis, which corresponds roughly to the length of the erect penis. The circumference of the penis may also be measured. The length of the stretched penis before puberty is about 4–8 cm and after the age of 16 it is 10–17 cm. The circumference of the flaccid penis is 3–6 cm before puberty and between 6–11 cm after the age of 16.

3. Hormonal Findings

The concentrations of gonadotropins and sexual steroids in the plasma and urine are very low before puberty, although the hypothalamo-hypophyseal-gonadal axis is definitely already in action. Shortly before secondary sexual characteristics arise or during their development the concentration of these hormones rise steadily

and reach normal adult values during or at the end of puberty.

The newly introduced radioimmunological methods for the estimation of *gonadotropins* have yielded the following picture (BAGHDASSARIAN, 1970): before puberty in both sexes LH and FSH values in the serum are between 2–6 ImU/ml (international milliunits, 2nd IRP-HMG, p. 558). These values begin to rise shortly before puberty or sometimes with the appearance of the first characteristics of puberty FSH reaching adult levels of about 5–15 ImU/ml about mid-puberty and LH at the end of puberty. Urinary values of FSH correspond to those in the plasma, rising from about 0–4 IU/24 h to 5–15 IU/24 h. LH values increase much more and reach a concentration of 20–40 IU/24 h at the end of puberty.

Urinary 17-ketosteroid levels rise slowly before puberty and very steeply during puberty (Fig. 22). At first, there is not sex difference and levels reach adult values towards the end of puberty, mean values being slightly higher in men than in women (p. 384). The rise during puberty is mainly due to the rapid increase in adrenal androgens (adrenarche) and their metabolites. This is seen in both sexes from the increase of dehydroepiandrosterone sulfate, dehydroepiandrosterone and androsterone in the plasma (MIGEON, 1957; ROSENFIELD, 1969) and of dehydroepiandrosterone, androsterone and etiocholanolone sulfates and glucuronides in the urine.

Testosterone and androstenedione are demonstrable in the plasma of children. According to FRASIER and HORTON (1966) the mean concentration of testosterone is 42 ng/100 ml in boys and 19 ng/100 ml in girls whereas the mean concentration of androstenedione is 86 ng/100 ml in boys and 30 ng/100 ml in girls. FOREST and MIGEON (1970) found a mean testosterone concentration of 25 ng/100 ml in boys and 9 ng/100 ml in girls, and a mean androstenedione concentration of 25 ng/100 ml in boys and 65 ng/100 ml in girls. They also found that the protein-bound fraction was higher than in adults. The same teams found 800 and 625 ng/100 ml testosterone and 60 and 109 ng/100 ml androstenedione in men and 42 and 49 ng/100 ml testosterone and 140 and 181 ng/100 ml androstenedione in women. It is worth mentioning that in contrast to the relative concentrations in men, androstenedione values are much higher than testosterone values in women and children and that the androstenedione concentration is lower in men than in women. From the results cited, it is even possible that the androstenedione concentration is lower in boys than in girls. This would indicate that the activity of 17-reductase (17-hydroxysteroid dehydrogenase) which is responsible for the conversion of androstenedione to testosterone, is physiologically limited in women and children. 5α-Dihydrotestosterone is found in the plasma of adults but not of children (ITO, 1970).

Testosterone is also demonstrated in urine even during childhood. Values lie below 4 μg/24 h (KNORR, 1967) and rise to normal adult levels during puberty (p. 449). In boys, testosterone production can be stimulated by means of chorionic gonadotropin even before puberty (SAEZ, 1968; RIVAROLA, 1970), the basal value

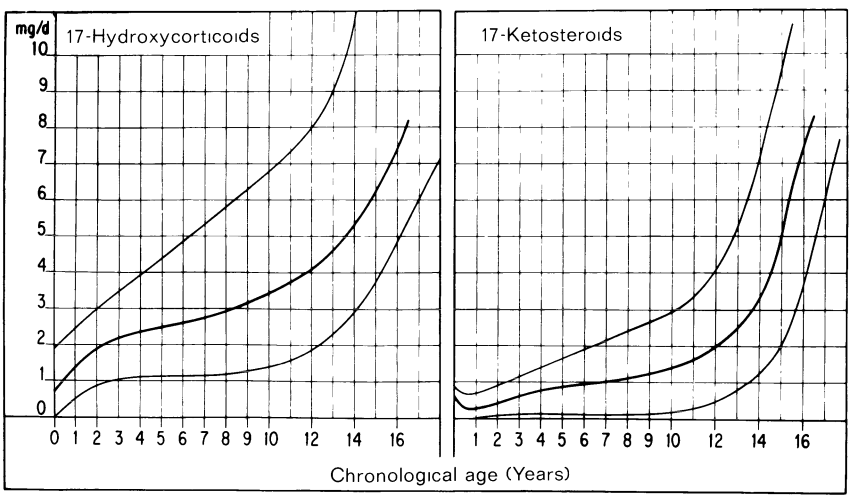

Fig. 22. Normal range of 24-hour urinary excretion of 17-hydroxycorticoids and 17-ketosteroids in boys and girls. (After KNORR, 1965).

and rise being dependent on the developmental age (ZACHMANN, 1972). It has been found that adult values can be attained after stimulation over several days.

There have been few investigations so far on *estrogens* in the plasma of children, due to technical difficulties. In urine, values between 1–3 μg/24 h have been found for estrone, between 0–2 μg/24 h for estradiol and 3–6 μg/24 h for estriol (PENNINGTON, 1969). KNORR and his team (1970) found as little as 50 ng/24 h for estrone and less than 20 ng/24 h for estradiol when they used a modern gas chromatographic method. Values rise to normal adult levels during puberty (p. 527). The same group has recently reported plasma estrogen values in children, determined by a sensitive radioimmunoassay. In males, estrone ranges from 10.6 pg/ml (pubic hair stage 1) to 31.5 pg/ml (stage 5), estradiol from 7.5 pg/ml (stage 1) to 20.7 pg/ml (stage 5). In girls, estrone values of 13.5 pg/ml (stage 1) to 74.6 pg/ml (adult women) and estradiol values from 8.2 pg/ml (stage 1) to 121 pg/ml (adult women) were found. Pregnanediol excretion is minimal before puberty. The high levels typical for the second half of the cycle are only reached 1–2 years after menarche, with the transition from anovulatory to ovulatory cycles.

In contrast to the steep rise in the production of adrenal androgens during puberty, the *production of cortisol and aldosterone* show quite a gradual increase parallel to the increase in body surface. This can be seen from the plasma concentration of cortisol, which remains constant, and from the slow rise of 17-hydroxycorticoids (Fig. 22) and aldosterone in the urine.

Basal values for growth hormone concentrations in the blood in puberty are similar to those in childhood, but after provocation with insulin and arginine, values increase above those found prior to puberty (SPERLING, 1970; FRASIER, 1970).

4. Hormonal Dependence of Secondary Sexual Characteristics

There is no doubt that the entire development of puberty is induced through the increase in androgenic and estrogenic steroids. These steroids are therefore also called sexual hormones. Whether an increased response of the target or end organs also plays a part in the appearance of pubertal characteristics has not yet been adequately investigated.

Estrogens control breast development, growth and maturation of the uterus, vagina, and labia minora, and finally menstruation. In addition, *progesterone* is also responsible for the true ovulatory cycle. *Androgens* promote growth of the penis, prostate and scrotum in boys and of the clitoris and labia majora in girls. They are also responsible for the breaking of the voice in boys and the sexual hair in both sexes.

The cause of the spurt of growth during puberty has still not been adequately explained. Both testosterone and growth hormone have anabolic growth-promoting effects. The growth hormone concentration in the blood can be raised experimentally with testosterone and estrogens after the induction of hypoglycemia with insulin. In fact, higher values are found for growth hormone in both sexes during puberty after provocation than before puberty. It therefore appears probable that androgens and estrogens work together with growth hormone to induce the pubertal spurt of growth. The more marked spurt of growth in boys can presumably be explained by the higher testosterone production.

Fusion of the epiphyses and thereby termination of growth is probably due to the action of testosterone and estrogens. Isolated growth hormone deficiency does not prevent epiphyseal fusion whereas epiphyseal fusion never occurs in the presence of a deficiency of sexual hormones.

The development of acne is connected with the increased production of androgens in both sexes. No clear reason has yet been found to explain why the acne is only temporary in spite of the continuous production of androgens. Just as little is known about the cause of the swelling of the mammary glands in boys (see also pubertal gynecomastia on p. 1041).

5. Hypothalamus, Gonadarche, Adrenarche and Puberty

It is known from experiments with animals that testosterone secreted by the fetal or neonatal testes exerts an irreversible imprinting effect on the brain (p. 707). This imprinting determines the subsequent continuous production of gonadotropins typical of the male animal. If this effect is absent due to the absence of testes and the presence of ovaries, the cyclic production of gonadotropins typical for the female later develops. It is not known whether this imprinting also occurs in the human. It appears rather doubtful, however, since female patients with the congenital adrenogenital syndrome (p. 374), who are subjected to abnormally strong androgenic influences during the prenatal

and neonatal periods, usually develop normal cycles later with adequate cortisone treatment. The question has not been definitely settled, however, since it is possible that the androgenic imprinting occurs at an earlier point and necessitates larger amounts of androgens.

The tuber cinereum is considered the hypothalamic sexual center in the human (p. 28). This center secretes gonadotropin-releasing hormones (p. 32) which stimulate gonadotropin production and hypophyseal secretion. It controls the negative feedback mechanism of the sexual hormones, either directly or indirectly via the epithalamic pineal region, i.e. it is inhibited by sexual hormones. It is probably also influenced by other central nervous factors and possibly by humoral factors as well.

The hypothalamo-pituitary-gonadal axis is already active during childhood in spite of the low concentrations of gonadotropins and sexual steroids in the blood, as has been shown in numerous animal experiments. Clinical experience is also in keeping with this, since radioimmunological methods often reveal elevated gonadotropin levels in association with Turner's syndrome even in childhood, and diminished gonadotropin values with pituitary dwarfism. In the healthy child, only very low concentrations of gonadotropins and sexual steroids acting on the negative feedback mechanism are present. This means that the hypothalamus can react even to very small amounts of sexual steroids, i.e., it is extremely sensitive (DONOVAN, 1965). This sensitivity disappears during puberty. Because of this, more gonadotropins are secreted and this in turn causes an increased production of sexual steroids in the gonads. The activity of the hypothalamo-pituitary-gonadal axis is thus intensified to give a higher concentration of gonadotropins and sexual steroids.

Clomiphene (p. 599) administered to adults in a dosage of 25–200 mg causes gonadotropin secretion to be increased (positive feedback mechanism) whereas in a dosage of 500 mg it inhibits gonadotropin secretion (negative feedback mechanism). A dose of 1–100 mg/m^2 before puberty has an inhibitory effect on plasma gonadotropins whereas a smaller dose has no effect (KULIN, 1969, 1970). The known competitive action of estrogens and clomiphene on the hypothalamus causes the positive feedback mechanism in adults, whereas the mild estrogen-like action of clomiphene explains the negative feedback mechanism. The negative feedback mechanism, which can be induced by much smaller doses before puberty, is indirect proof of the increased sensitivity of the hypothalamus to sexual steroids during this phase of development. This does not adequately explain the absence of a positive feedback mechanism before puberty, however.

The factors inducing puberty, i.e. the factors causing the decrease in sensitivity of the hypothalamus to sexual steroids, are not known. It is possible that inhibitory central nervous influences from the pineal region or other centers disappear or that gonadotropic-inhibiting humoral factors (SOFFER, 1965) characteristic of childhood also vanish. But, even with these assumptions another cause must be searched for, since they do not explain why the development of puberty is associated less with a certain age or a certain body height and much more with a certain body maturation, which is best assessed from bone age. More recently, body weight has also been looked upon as a possible standard factor for the onset of puberty (FRISCH, 1970).

Gonadal maturation induced by the increased gonadotropin concentration and the associated increase in the production of sexual hormones is also known as *gonadarche*. The adrenals show a similar maturation process during puberty, which is called the *adrenarche*, although only androgenic production is affected and production of cortisol and aldosterone is not. This is illustrated clinically by the fact that adrenal failure leads to loss of pubic hair in women whereas gondal failure has no such effect. Adrenal androgens appear to be responsible for the development of pubic and axillary hair. Adrenarche is also manifest in the hormonal findings in the blood, the concentration of dehydroepiandrosterone sulfate in the blood rises rapidly during puberty (ROSENFIELD, 1969).

It has been shown that gonadarche is controlled by the gonadotropins whereas the regulation of adrenarche remains unsolved. ACTH need hardly be considered since it would also cause a steep rise in cortisol production during puberty, which does not in fact occur. The possibility of a stimulant action of LH on the androgen production of the adrenals is disputed and largely rejected. It is possible that adrenarche is induced and controlled by some pituitary hormone which is still unknown. Certain observations suggest that adrenarche is stimulated directly or via this hypothetical pituitary hormone by the sexual hormones produced by the gonads. Thus, the very poorly developed pubic hair in an untreated Turner's syndrome usually improves with estrogen treatment whereas the same treatment in cases of anterior pituitary deficiency does not promote growth of pubic hair. Furthermore clomiphene, which has a slight estrogenic action (p. 599), has been found to induce higher plasma levels of andro-

stenedione and dehydroepiandrosterone sulfate when given before puberty (CATHRO, 1969).

The physical development during puberty can be said in summary to be due to the combined action of gonadarche and adrenarche. In contrast to this, cases of isolated premature pubarche are probably due to premature adrenarche in the absence of gonadarche while cases of precocious puberty are probably caused by isolated premature gonadarche without adrenarche.

F. Special Variations of Normal Pubertal Development

1. Survey

As mentioned above, the time of onset of puberty and the order in which the pubertal characteristics develop and the degree of development of the individual features are very variable. Wide deviations from the mean should not be considered pathologic providing the object of pubertal development is reached – i.e. maturation to healthy adulthood and the capacity for procreation. Conspicuous deviations usually have to be recorded as constitutional or idiopathic variations of normal pubertal development as the ultimate reasons for them are unknown. The conditions listed below belong to this group.

1. Puberty arising unusually early or late but otherwise normal: *idiopathic precocious puberty* (p. 1045) and *idiopathic delayed puberty* (p. 1054).

2. Isolated premature appearance of individual secondary sexual characteristics: *premature pubarche* (p. 1040) and *premature thelarche* (p. 1041), which are both quite common, and *premature menarche* which is very rare.

3. Severe and persistent *pubertal gynecomastia* (p. 1041).

4. Generalized somatic, psychic and psychosexual *variations of "masculinity" and "feminity"* (p. 1042) which are completely unrelated to true intersexuality.

5. Obesity and emaciation arising before or during puberty: prepubertal and pubertal obesity (p. 1043) and pubertal emaciation (p. 1045).

Idiopathic forms of precocious puberty and delayed puberty are discussed with pathological forms in a different section (p. 1045) and the other observations and syndromes are dealt with below.

2. Isolated Premature Pubarche

Isolated premature pubarche, i.e. premature appearance of sexual hair without other secondary sexual characteristics, is seen more often in girls than in boys, and particularly frequently in children with cerebral damage (cerebral palsy, idiocy, epilepsy). Hair develops during babyhood or infancy, is limited at first to the labia majora (Fig. 23) or root of the penis and then extends very slowly into the pubic region. Axillary hair appears after a longer interval than in normal puberty. This condition differs from precocious puberty in that all the other secondary sexual characteristics are absent, and from the adrenogenital syndrome in the absence of any signs of virilization. Careful examination reveals only a slight advance in growth and bone maturation. The course is completely benign and true puberty develops at the normal time with the appearance of the remaining secondary sexual characteristics.

Fig. 23. Premature pubarche in a girl of 4 years (KspZ)

The excretion of 17-ketosteroids is slightly elevated. This is due mainly to a significant rise in the levels of dehydroepiandrosterone, androsterone and etiocholanolone, which are derived predominantly from adrenal androgens (VISSER, 1966). In contrast to the adrenogenital syndrome, testosterone is normal or only slightly elevated. The same steroids have been found to be raised and to sink to normal levels with dexamethasone in isolated cases (CONLY, 1967). Serum levels of LH and FSH are normal (PENNY, 1970) or even slightly diminished (KENNY, 1969). This may be attributable to the inhibition of gonadotropins by the adrenal androgens, working via the hypothalamus, which is very sensitive before puberty (p. 1039).

This condition is obviously due to a premature rise in the androgen production (premature adrenarche). In contrast to normal puberty and to true precocious puberty, there is no simultaneous gonadal activation. Associated brain damage is frequently found, which indicates a hypothalamic cause, but it is still not clear what mechanisms are responsible for the premature induction of adrenarche.

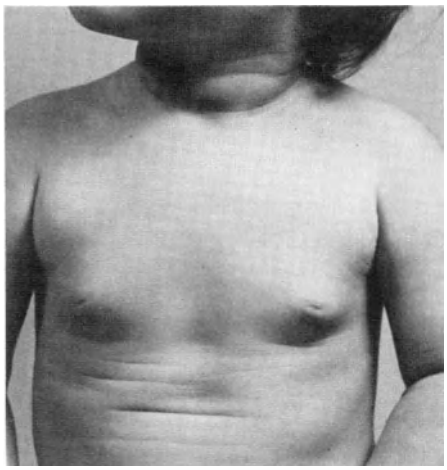

Fig. 24. Premature thelarche in a 2-year-old girl (KspZ)

3. Isolated Premature Thelarche

It is not particularly uncommon to find swelling of the mammary glands in otherwise normal girls during babyhood and infancy. The size of the swelling usually varies between that of a hazel nut and that of a plum, but there is no enlargement or pigmentation of the nipples or areolae and there are no other signs of sexual precocity, i.e., no pubic hair and no enlargement of the labia minora and uterus (Fig. 24). Vaginal smears and the cellular sediment of the urine often demonstrate a mild estrogenic action. Growth, bone age and excretion of 17-ketosteroids are appropriate to chronological age. The swelling may last for a few months or even years, after which it regresses spontaneously or gradually gives way to normal puberal development. The cause is probably a trivial premature production of estrogens by the ovaries (premature gonadarche). Serum levels of LH and FSH are normal (PENNY, 1970) or slightly raised (KENNY, 1969).

4. Puberal Gynecomastia

In a few boys the physiological mammary swelling or macromastia during puberty reaches such proportions that it can hardly be distinguished from normal female mammary development. This form of gynecomastia is usually bilateral and more rarely unilateral, more often on the left side. Occasionally it appears to be hereditary. In a few isolated cases, the breasts may become as large as those of a young woman. Whereas physiological swelling of the breasts during puberty disappears after a few months or years, this form usually persists unchanged into adulthood. Milk secretion does not occur.

The mammary tissue does not differ histologically from that in other forms of gynecomastia (p. 487).

Apart from the gynecomastia, there are no pathologic findings in the somatic development. The testes are of normal size, secondary sexual characteristics are normally developed and psychosexual development is normal. Shame and fear of being made fun of by their associates, and the endogenous uneasiness about the de-

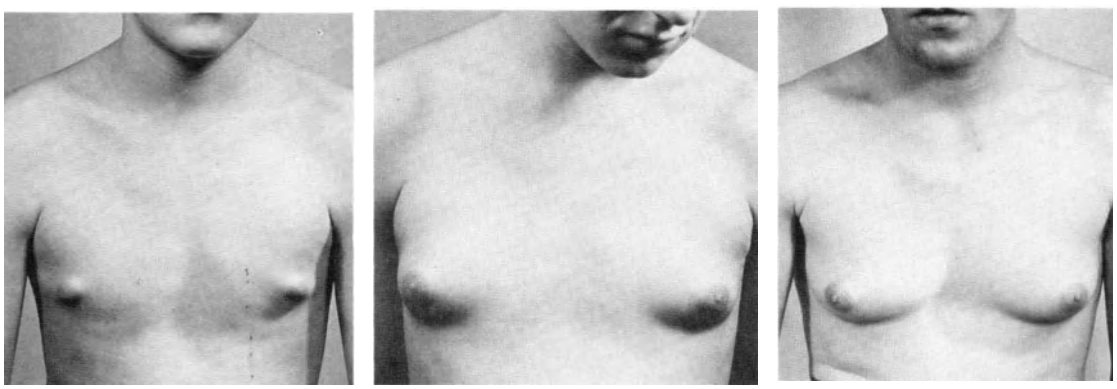

Fig. 25. Puberal gynecomastia of varying degrees in 3 boys with otherwise absolutely normal puberal development, testes of normal size and normal gonadotropin and 17-ketosteroid excretion (PRADER, 1955)

velopment of the breasts, cause these boys to hide their "trouble" and make a secret of it, avoiding gymnastics and swimming and withdrawing more and more from their surroundings.

The cause of this syndrome is unknown. Excretion of 17-ketosteroids, estrogens and gonadotropins does not appear to deviate significantly from normal, although a mild estrogenic action is found in the cellular urinary sediment. Increased estrogenic production by the testes and an age-specific metabolism of testosterone (liver) may be involved.

The diagnosis is usually easy but other causes of gynecomastia (p. 488) must always be considered as well. Apart from this, gynecomastia can also be simulated by severe panniculus (pseudogynecomastia). Differentiation from the gynecomastia in *Klinefelter's syndrome* is extremely important. Secondary sexual characteristics are more or less normally developed in both syndromes. Testicular size is the only clinical difference. In *Klinefelter's syndrome* the testes are small whereas they are of normal size in puberal gynecomastia. In doubtful cases, assessment of the sex chromatin, measurement of the gonadotropins in the plasma and urine, investigation of the sperms, and testicular biopsies will allow differentiation. These investigations all yield normal results in puberal gynecomastia, in contrast to *Klinefelter's syndrome*. Differentiation between the two syndromes is important since puberal gynecomastia is only a constitutional variation with normal reproductive function whereas *Klinefelter's syndrome* is a true endocrinopathy associated with sterility. Idiopathic gynecomastia in boys of prepuberal age is very rare but must also be differentiated from puberal gynecomastia.

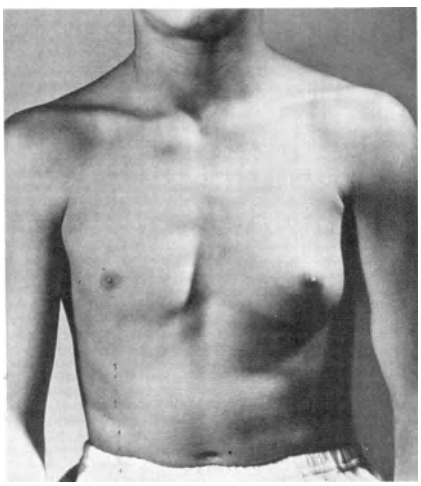

Fig. 26. Very marked unilateral puberal gynecomastia in a 15-year-old boy (KspZ)

There is no hormonal *treatment* for puberal gynecomastia. Administration of chorionic gonadotropin or testosterone is useless and illogical since these drugs themselves occasionally induce gynecomastia. In addition, such treatment can only inhibit endogenous pituitary and testicular function. The doctor must explain the harmlessness of the disorder to the patient and his relatives and warn them against hormonal treatment. If the breasts show no tendency to regress spontaneously surgical removal is the only possibility left. This decision is reached earlier when the gynecomastia produces severe psychological reactions. The incision is made along the edge of the areola and extended outward to the side. The cosmetic results of this incision are excellent.

5. Generalized Somatic, Psychic and Psychosexual Variations of "Masculinity" and "Femininity"

Only a very small proportion of the numerous physical and psychological differences between healthy individuals can be explained by hormonal variations. Most of these differences are due to constitutional and exogenous factors independent of the hormonal interaction. This must be borne in mind particularly during puberty. "*Feminine*" *features* become obvious *in individual boys* shortly before and at the onset of puberty. The body is rounded, the pelvis broad, the shoulders narrow, the voice soft and clear, and body movements girlish and affected. Conversely *girls* with "*sporty masculine*" *features* are also seen, with broad shoulders, narrow hips, dense body hair (hirsutism, p. 359), well-developed musculature, harsh voice, and energetic movements. Psychological features reminiscent of the other sex are often found in the same individuals. The boys are sensitive, shy, blush easily, like to stay at home, read a lot and avoid sports and company. Conversely, some girls are loud and noisy, energetic and robust. They are not interested in clothes and books but in sports and outdoor games.

This *combination of masculine and feminine features in stature and psyche* often causes relatives to suspect a "glandular disturbance" and to fear sexual abnormality or sterility, especially in cases where boys are obese and puberty is delayed. Thorough physical examination, however, hardly ever reveals any actual proof of an endocrine disorder. One of the doctor's main duties is to speak to the parents of these children and to talk them out of their ideas of "glandular disorders" and "abnormal

sexual tendencies". It is never admissible to deduce somatic intersexuality or homosexuality from the symptoms mentioned. Some or most of these features disappear during puberty and these children often develop into perfectly ordinary adults.

Relatives occasionally find another source of worry in the undirected sexuality evolving during puberty, which is particularly strongly developed in boys and leads to renewed suspicions of "glandular disorders" or "abnormal sexual inclinations". Reasons precipitating these fears are close friendship with members of the same sex, masturbation, and isolated homosexual acts. All these features belong to the *physiological, psychological and sexual unrest and urgency of adolescence* and spontaneously give way to unobtrusive mature heterosexual sexuality. The best counter to it all is a truthful explanation of the facts of life at an early stage and a healthy, honest relationship between parents and child, with the opportunity of discussing sexual problems openly. Again, the doctor must correct parental fears; he should remind the parents of their own youth and plead for understanding in these puberal crises. A talk with the youth, making him able to feel that the doctor is well disposed towards him and understands his difficulties, is the best form of psychotherapy and usually permits the doctor to recognize the isolated cases needing psychiatric treatment.

6. Prepuberal and Puberal Obesity

Although obesity at any age presents a difficult medical problem, an underlying endocrine disorder is never so frequently suspected as with prepuberal and puberal obesity. In many cases these children were abnormally fat during infancy, but the obesity often starts after the 8th to 10th year and reaches its peak shortly before puberty or at the onset of puberty. In addition, the panniculus undergoes most of its physiological increase during these years, and children of this age tend to put on weight particularly easily.

The panniculus is usually uniformly distributed. The skin is usually normal but may often be strikingly red. In severe cases there may be pale or red striae distensae on the hips, thighs, and buttocks, and laterally on the breasts. In the majority of cases, growth is slightly in advance of the average for the age and the skeleton is broad and powerfully built. Hands and feet are often strikingly small in comparison (aeromicria) but acromegaloid features of puberty are also often dominant. Knock knees and foot deformities are frequently present and can be explained as static damage due to the obesity. Blood pressure is normal or slightly elevated. These patients are usually languid, good natured, and passive. A good case history usually reveals that nutrition is very ample or excessive.

Puberty usually arises prematurely in *girls* (Fig. 27), in keeping with the accelerated bone maturation. Growth also ceases earlier and occasionally even before normal adult height is reached. The obesity, very wide hips and the often massively developed breasts, consisting of glandular tissue and panniculus, often give these girls a matronly appearance when they are still quite young. In *boys* (Fig. 28), the onset of puberty tends to be later than average but still within the normal age range. The mild gigantism, the slight delay in puberty, the resultant mildly eunuchoid proportions (p. 1022) and the fact that the genitalia are almost completely obscured by panniculus suggest hypogonadism to the inexperienced. This impression is often supported by the isolated feminine features such as soft rounded body curves, simulated breast enlargement, soft, shy voice and girlish movements. Parents are struck by all these symptoms, suspect a glandular disorder, and consult the doctor, whose main problem is then to decide whether the boy has *Fröhlich's syndrome* (dystrophia adiposogenitalis).

The case described by Fröhlich was that of a boy in whom a hypothalamic tumor led to mild obesity, permanent hypogonadism and inhibition of growth. Although the syndrome described, later also termed dystrophia adiposogenitalis, was exactly defined and included the hypothalamic disorder, some authors subsequently applied this term to all boys with obesity and infantile genitalia, i.e., all fat boys not yet in puberty.

When prepuberal and puberal obesity are termed dystrophia adiposogenitalis, these boys are branded with the suspicion of hypogonadism and subjected to incorrect and unnecessary hormone treatment when no hypogonadism or endocrinopathy is in fact present. Thorough examination always shows that the genitalia only appear to be infantile because of the padding of pubic fat and that the scrotum, penis, and testes are in fact normally developed for the age.

Metabolic investigations often show that there is a marked rise in insulin levels during the glucose tolerance test and that glucose tolerance is occasionally reduced at the same time. It is also found that the sensitivity to insulin is reduced and there is no rise in the growth hormone concentration in the blood

after stimulation with insulin or arginine. The basal metabolic rate, related to body surface or size of the patient, is usually within normal limits. Steroid excretion is normal; corticoid excretion may be slightly raised but not high enough for the diagnosis of Cushing's syndrome.

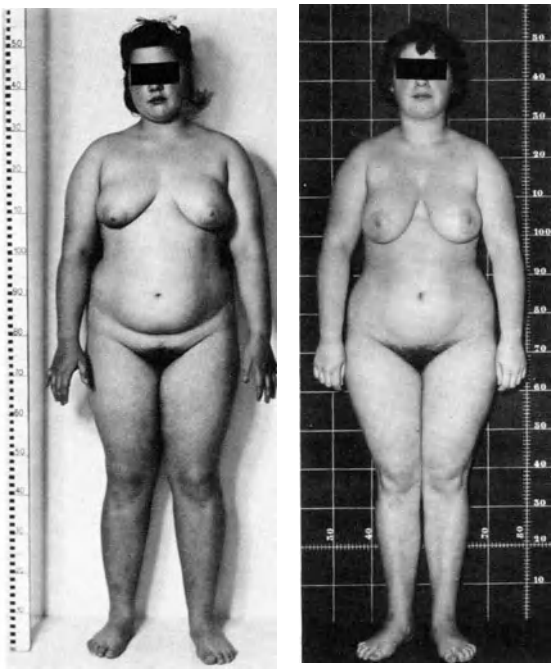

Fig. 27. Two 13-year-old girls with puberal obesity. Note the marked breast development and matronly stature which make these girls look older (KspZ)

There is no doubt that the main *cause* is *the high nutritional intake*, supported to some extent by the *eating habits* of the family. Too little physical exercise and often an unfavorable mother-child relationship also play a part; the mother often fusses over the child and protects him in an exaggerated manner (overprotective mother), gives him too much care and too much food, pampers and watches over him during school age as if he were still an infant, prevents normal relationships with other children and thus makes healthy psychological development impossible. This domineering attitude of the mother is interpreted as compensation for the neglect she herself experienced as a child or as a subconscious rejection of the child. As a result, these children become emotionally embittered, are dissatisfied, sullen and bored and find satisfaction only in eating. In addition the family seems to be predisposed to obesity, but it is difficult to distinguish between true heredity and acquired eating habits. The involvement of hormonal factors in the *pathogenesis* is still a controversial subject. In any case there is no definite proof of this.

No definite *prognosis* can be made. A few patients lose weight towards the end of puberty (Fig. 28) but this is probably due to the reduction of food intake resulting from a changed psychological situation. In the majority of patients, however, the obesity persists unchanged into adulthood.

In the *differential diagnosis*, the more uncommon forms of obesity associated with hypothalamic disorders, Cushing's syndrome (p. 340), and hypothyroidism (p. 165) must be considered. In addition to the postencephalitic and posttraumatic forms of the true Fröhlich's syndrome, pituitary dwarfism and the Prader-Labhart-Willi syndrome (p. 810) belong to the group of organic hypothalamic disorders. The Laurence-Moon-Bardet-Biedl syndrome is transmitted on an autosomal recessive gene and is characterized by debility, retinitis pigmentosa, polydactyly and moderate obesity. Dwarfism and hypogonadism are occasionally also present.

All these organic forms of obesity occur much less frequently and can be differentiated from most cases of prepuberal and puberal

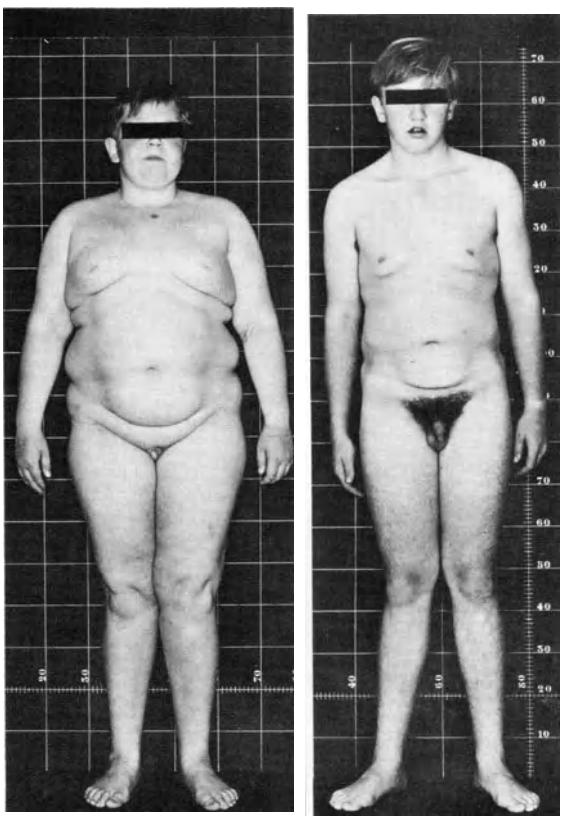

Fig. 28. Endocrinologically healthy boy with psychogenic prepuberal obesity at the age of 13 years (left), and after slimming at the age of 15 (right) with absolutely normal puberal development

obesity as dwarfism is almost always present in organic forms. The following general rule can be applied to children up to the age of puberty: there is usually no endocrinopathy and no organic cause whatsoever for obesity combined with above-average height, whereas careful seting for the endocrinopathies listed above and hypothalamic disorders is indicated in cases of obesity with dwarfism.

As in other benign deviations from normal puberal development, *therapeutic* measures consist in convincing the parents and patients that there is no "glandular disorder" by pointing out any puberal factors already apparent or by indicating the favorable prognosis of the onset of puberty, which can be precisely predicted chronologically from bone age. The obesity must be treated by diet and increased physical exercise. Amphetamines should not be used to inhibit the appetite in this age group or only with extreme caution. Special psychotherapeutic attention is advisable in isolated cases. Treatment with pituitary or thyroid extracts or with sexual hromones has no scientific basis and must be rejected as a pointless intervention in the endogenous hormonal equilibrium.

7. Puberal Emaciation

Puberty is the commonest time for the onset of psychogenic anorexia mentalis or anorexia nervosa in the female sex. The extreme emaciation was previously looked upon as a result of a pituitary insufficiency, but since the picture of pituitary insufficiency in women has become familiar (p. 93), puberal emaciation is hardly ever still mistaken for endocrine disorders. As in other severe generalized illnesses, there is often a secondary reversible failure of gonadotropins and sexual steroids, and growth often ceases while basal growth hormone values are normal or increased but in many cases cannot be stimulated by insulin or arginine. The other endocrine functions are completely or almost intact (p. 1028).

G. Precocious Puberty

There is no clear biologically based definition of premature puberty or precocious puberty. In general precocious puberty is the term used when puberal characteristics arise before the age of 6 in girls and before the age of 8 in boys. "Premature puberty" is used when signs of puberty arise between the 6th and 8th years in girls and between the 8th and 10th years in boys.

1. Survey

a) Etiological Classification of True Precocious Puberty and Precocious Pseudopuberty

True hypothalamic precocious puberty with the premature development of puberty is due to a premature secretion of hypothalamic gonadotropin-releasing factors. These stimulate the production of gonadotropins by the pituitary, which is followed in turn by gonadal maturation. Gonadal function is no different from that reached during normal puberty. The ability to reproduce is also reached during premature puberty just as during normal puberty.

Premature puberty frequently occurs with tumors and other disorders affecting the hypothalamus, but there is no known pituitary tumor associated with precocious puberty. In contrast to hypothalamic precocious puberty, there is no primary pituitary precocious puberty.

If the symptoms of premature puberty are not induced by premature hypothalamic activity, the term *pseudosexual precocity* is used. The hormones responsible for the signs of puberty are derived from tumors or diseased glands or obtained from an exogenous source. Neither hormone production nor gonadal function is as in normal puberty. Patients are therefore also infertile. This classification into pseudo- and true precocity does pose some problems, since fertility is theoretically possible in cases with gonadotropin-producing tumors and interpretation as either pseudo- or true sexual precocity would be possible in such cases.

The different forms of precocious puberty in boys and girls are summarized in Tables 11 and 12. True idiopathic precocious puberty in girls is by far the most common form, followed by pseudosexual precocity affecting both sexes equally and associated with the adrenogenital syndrome.

b) Features Common to all Forms of Precocious Puberty

The *secondary sexual characteristics* are the most striking features in all forms, can arise at any age, and may even be present at birth. The order in which the individual secondary sexual characteristics arise and the time interval between them vary very much more widely than in normal puberty. The rapid appearance of all the secondary sexual characteristics suggests a brain or gonadal tumor or a gonadotropin-producing tumor. In addition, growth and bone development are found to be accelerated, i.e. *general somatic development is advanced.* The extent of this advance is usually proportional to the length of history of the sexual

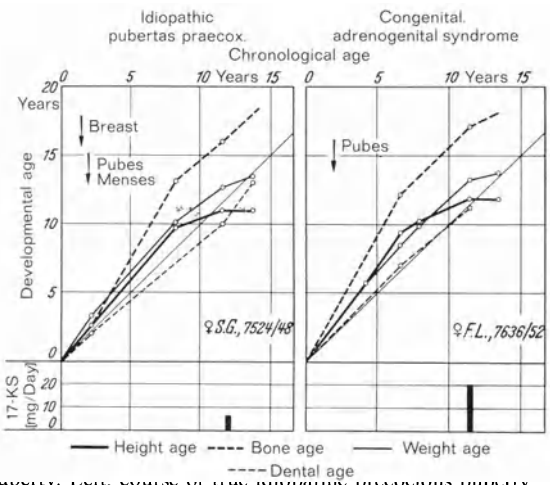
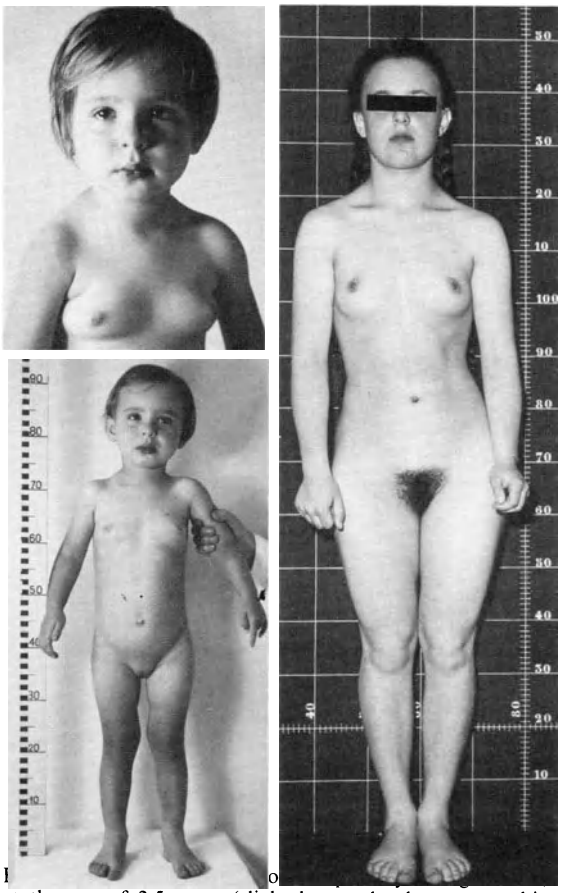
precocity, and occasionally it is absent when the history is very short. In contrast to normal puberty, bone age at the beginning of precocious puberty has not reached the stage usual at puberty in spite of acceleration of bone development. Cases with harmonic development of puberty and bone age must be considered as early normal puberal development and not as a pathologic form of puberty. Accelerated bone development results in premature epiphyseal fusion and cessation of growth before normal adult height is reached. In other words, the patient is taller than normal as a child and shorter than normal as an adult. Nevertheless, many of these patients reach an adult height within the lower normal limits. This entire process is illustrated by two examples in Fig. 29.

In contrast to the general advance in somatic development, psychological, psychosexual and intellectual development usually correspond to chronological age. Exceptions with advanced psychological and intellectual development and cases of debility (brain disorders) are, however, not very uncommon. The discrepancy between

somatic and psychological development is usually so marked that difficulties arise at home and at school. The advanced somatic development arouses the penetrating curiosity of other children and also, unfortunately, of adults and causes too high psychological and intellectual demands to be made. Patients suffer less from the premature puberty than from the psychoreactive disturbances caused by the striking external changes and from the unskilled psychological attitude of other people. The children are therefore often confused, shy, and withdrawn, but often become coarse and aggressive as soon as they become aware of their superior strength. Early sexual interest and aggression are much less common than would be expected from the anecdotes in ancient literature. The disprepancy between the childish psyche and the somatic sexual maturity becomes particularly grossly apparent when girls with precocious puberty become pregnant and give birth to children. According to most observers, these young mothers have no understanding of the significance of pregnancy and birth It is the doctor's duty to help the parents to understand these children and to assist with the difficult problem of education.



F
puberty. Left, course of true idiopathic precocious puberty in a girl (same patient as in Fig. 30). Right course of pseudosexual precocity due to a congenital adrenogenital syndrome in a girl. Note the acceleration of growth and bone development, premature standstill of growth, and normal dental development. This course is typical for all forms of premature puberal development (KspZ)



I
at the age of 2.5 years (slight breast development, pubic hair not marked, menarche). Right, at the age of 13 years 2 months, growth already terminated (epiphyseal fusion). The growth curve and remaining developmental data of this girl are presented in Fig. 29 (left) (KspZ)

2. Idiopathic Precocious Puberty

Idiopathic, constitutional or genuine precocious puberty is by far the most common form of premature puberty (Fig. 30). Girls are affected 4 to 7 times more frequently than boys. Most cases in girls are sporadic. Familial cases have been described, especially in boys, whereby the condition can be inherited via healthy mothers as well as via affected (occasionally also healthy) fathers. The mode of inheritance is presumably autosomal sex-lined dominant. Families with autosomal recessive inheritance in which sexual precocity arises not only in boys but also in girls are much less common.

Most affected children have a normal, and often shortened, puberty, but puberty is sometimes very prolonged, and spontaneous regressions occasionally occur (transitory precocious puberty). The children are extremely healthy; emotional and intellectual development correspond to age, and life expectancy is normal. Reproductive function is normal. Pregnancy in little girls with idiopathic precocious puberty has frequently been reported. The youngest reported case, who gave birth to a child by Cesarean section, was 5.5 years old (ESCOMED, 1939).

The expected gonadotropin excretion was often not detected in investigations in the past. With more modern methods and repeated investigations, however, it has been found that values of LH and FSH in serum and urine are usually just as high as in puberty arising at the normal time. The 17-ketosteroid excretion is only slightly higher than normal values, and is lower than during normal puberty. In contrast to this, the excretion of estrogens in girls and of testosterone in boys is significantly elevated and often as high as normal adult values. The combination of low levels of 17-ketosteroids and high levels of sexual steroids in the urine indicates that in contrast to the situation during puberty arising at the normal time, only gonadal steroid production (gonadarche), and not adrenal androgen production (adrenarche), has started to function prematurely. In other cases, however, 17-ketosteroid levels are found to be as high as those in normal puberty. The diagnosis of idiopathic precocious puberty should only be made after all other forms of sexual precocity have been excluded as far as possible. Periodic neurologic examination is essential because of the possibility of a clinically silent brain tumor. Treatment is discussed on p. 1053.

3. Precocious Puberty with Organic Brain Disorders

Precocious puberty due to organic brain disorders (*cerebral or neurogenic precocious puberty*) is quite uncommon. It is seen with hyperplastic malformations of the tuber cinereum (hamartoma) and also with various cerebral disorders such as malformations of the brain, hydrocephalus (Fig. 31), postencephalitic states, brain tumors, von Recklinghausen's neurofibromatosis, tuberous brain sclerosis and occasionally also with mongolism.

The hamartoma of the tuber cinereum is a hyperplastic malformation of the sexual center. It presumably produces gonadotropin releasing factors autonomously, thus leading to the premature development of puberty. Since it is a very small structure, there are often no general symptoms of a brain tumor.

The other cerebral lesions giving rise to precocious puberty are usually accompanied by *hydrocephalus of the third ventricle* and by nonspecific changes of the tuber cinereum, so that these forms of precocious puberty are probably also induced via the sexual center in the tuber cinereum. Definite neurologic disturbances are usually found during the general examination.

Tumors of the pineal body are a special form of localized tumors which arise almost exclusively in boys and often give rise to precocious puberty (pineal precocious puberty). Calcification of these tumors is frequently visible radiologically. The pathogenesis of precocious puberty with tumors of the pineal body is just as controversial as the endocrine function of the pineal body. If the pineal body normally inhibits puberal development (p. 1039), the precocious puberty is due to a loss of his inhibition. If the pineal body normally has no endocrine function, it is more likely that these tumors induce premature puberty via a direct or indirect pressure effect on the sexual center in the tuber cinereum. Unfortunately, pathological investigations have failed to solve this problem.

Fig. 31. True precocious puberty due to hydrocephalus (brain tumor?) in a boy aged 1 years 10 months (KspZ)

Apart from the fact that pregnancies have never been observed in neurogenic precocious puberty, the hormonal situation in neurogenic precocious puberty is no different from that in idiopathic precocious puberty.

The decisive diagnostic findings are neurologic in nature. Often, gross neurologic disturbances are present, such as epilepsy, manifest hydrocephalus, cerebral palsy, or severe idiocy, and these indicate a cerebral cause of the precocious puberty at once. Special attention must be paid to signs of increased intracranial pressure (headaches, vomiting, papilledema), calcifications in the region of the pineal body (tumors of the pineal body), general diencephalic metabolic symptoms (polyuria, polyphagia, nycturia,

obesity), and ocular disturbances (visual disturbances, limitation of visual fields, paralysis of ocular muscles). Conjugate paralysis on looking upwards is a very important symptom in certain tumors of the mid-brain (Parinaud syndrome).

4. Precocious Puberty with Fibrous Dysplasia of the Bones

This form of precocious puberty, which is also known as Albright's syndrome or the McCune-Albright syndrome (McCune, 1937; Albright, 1937), occurs almost exclusively in the female sex and is characterized by the following triad of symptoms: 1. true precocious puberty, 2. polyostotic fibrous dysplasia (osteodystrophia fibrosa disseminata) and 3. map-like, milk-coffee colored skin pigmentations. A goiter is often present and hyperthyroidism has occasionally also been observed.

Bone changes are clinically silent or become apparent mainly because of asymmetric bone deformities (shepherd's staff shape of the femora in particular), spontaneous fractures or distension of the facial bones. X-rays show cystic translucent areas in the long bones, arranged unevenly and often involving only one half of the body, osteosclerosis and hyperosteosis in the region of the base of the skull, orbits, and facial bones. The bone changes are painless. Calcium and phosphorus metabolism appears to be undisturbed. Serum levels of alkaline phosphatase are only slightly elevated at the most. The histological picture consists of tough, connective tissue containing few cells, which replaces normal bone tissue. The same disorder occurs in both sexes, often in the absence of endocrine symptoms and with or without skin pigmentation (osteodystrophia fibrosa disseminata, Jaffé-Lichtenstein).

The patches of *pigmentation* vary very widely in size and localization. They are not raised, are the color of milk coffee, and have indistinct borders. They show a predilection for the skin segments corresponding to the bone lesions and are often localized to the same half of the body as the bone lesions.

The *etiology* of this strange syndrome is not known, but the condition is probably due to a combination of disorders. Most authors seem to think that this form of precocious puberty, like idiopathic precocious puberty, is due to a hypothalamic disorder or to a pressure effect of the thickened base of the skull on the hypothalamus. Elevated LH levels corresponding to those found during puberal development have been demonstrated in isolated cases. It is not known why this syndrome occurs almost entirely in girls and extremely rarely in boys.

The *prognosis* is good. Bone changes do not progress very much during childhood and come to a standstill during early adulthood. Spontaneous fractures usually heal well except for fractures of the upper region of the femur. As in all forms of true precocious puberty, reproductive function is normal and body height is above average during childhood and below average in adulthood.

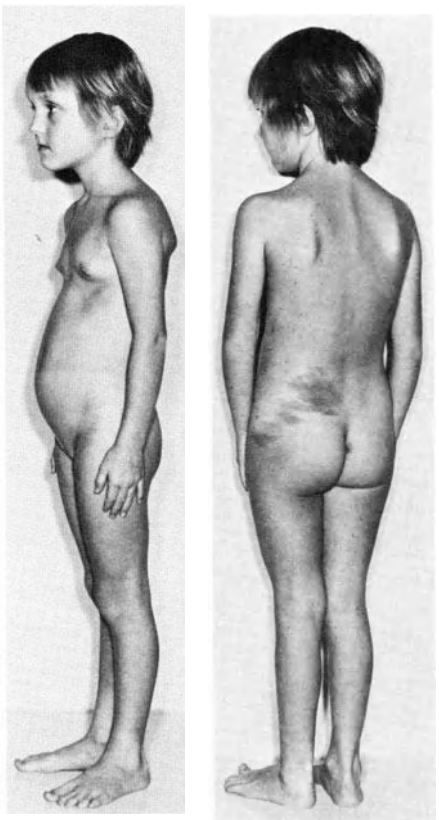


Fig. 32. Girl aged 5.5 years with the *McCune-Albright syndrome*; precocious puberty, osteodystrophia fibrosa disseminata and typical skin pigmentation (KspZ)

The *differential diagnosis* includes hyperparathyroidism (osteodystrophia fibrosa generalisata v. Recklinghausen (p. 911), xanthomatosis (Hand-Schüller-Christian), and von Recklinghausen's neurofibromatosis. A rather similar triad of symptoms also arises sometimes in neurofibromatosis, where the precocious puberty is caused by an intracranial neurinoma. Bone lesions are usually less severe, pigmentation patches are well demarcated and the appearance of cutaneous fibromas and neurofibromas confirms the differentiation.

5. Precocious Puberty due to "Hormonal Overlapping"

During the past few years, about 20 children with primary hypothyroidism (predominantly girls), some with Down's syndrome (mongoloid idiocy), and one boy with primary adrenal insufficiency and sexual precocity in addition have been reported. Puberal signs regressed in all cases with hormonal substitution therapy of the primary disorder. It is assumed that the TSH production always present secondary to primary hypothyroidism (similar to ACTH overproduction in primary adrenal insufficiency) does not remain absolutely isolated but also involves gonadotropin overproduction with corresponding sexual precocity. This phenomenon is termed "hormonal overlapping" of the hypothalamopituitary feedback mechanism (VAN WYK, 1960). It is, however, strange and puzzling that overlapping of this kind is so unusual and does not always occur with hypothyroidism and adrenal insufficiency.

The clinical picture is a combination of the classic symptoms of hypothyroidism and precocious puberty. Growth and bone maturation are delayed and thus contrast with the acceleration of body development usually seen with sexual precocity. The sella turcica is frequently enlarged, as in primary hypothyroidism. Estrogenic features, breast development, and menstruation are very pronounced. Androgenic features, and pubic and axillary hair are often absent. Galactorrhea has been observed in several cases (increased prolactin production). Urinary gonadotropins were only demonstrated in isolated cases. Excretion of 17-ketosteroids was hardly increased.

6. Precocious Puberty with Gonadotropin-Producing Tumors

Gonadotropin-producing tumors are uncommon and practically always highly malignant. Chorionepitheliomas, teratomas and malignant hepatomas secrete gonadotropins. Gonadotropin excretion, particularly LH excretion, is usually elevated and varies between normal adult values and values found in pregnancy (pregnancy test positive). The excretion of 17-ketosteroids is low or only slightly elevated.

Teratomas and chorionepitheliomas occur in both sexes and are found in the ovary or extragenitally, e.g. in the mediastinum or even in the brain.

Malignant hepatomas with sexual precocity have so far been observed only in boys. The enlarged and firm, smooth, or nodular liver leads to the diagnosis. The testes are not enlarged or only slightly, and contain Leydig cells. Tubular maturation may be absent or incomplete. Removal of the tumor containing gonadotropin results in the regression of gonadotropin excretion and of secondary sexual characteristics, but death usually follows within a few months due to lung metastases.

7. Pseudosexual Precocity with Disorders of the Adrenal Cortex

This condition is usually due to the adrenogenital syndrome which leads to isosexual pseudosexual precocity, in girls and to heterosexual pseudoprecocity in boys. It has been discussed fully elsewhere (p. 358). Pseudosexual precocity due to adrenogenital tumors is extremely rare in boys and girls (p. 375).

8. Pseudosexual Precocity with Ovarian Tumors and Cysts

Granulosa cell tumors (p. 634) are the most common ovarian tumors inducing pseudosexual precocity. They are usually unilateral and not very malignant at this age, and vary between the size of a pea and that of a child's head. The histology shows all transitional forms of luteinized (pure?) granulosa and theca cell tumors. When luteinization is very marked, the term luteoma is used.

These girls appear to be clinically healthy. All the secondary sexual characteristics arise in quick succession. Although these tumors theoretically produce predominantly estrogen (and some progesterone), pubic hair also appears prematurely. This feature may be due to the small amounts of androgens secreted by the tumor itself or to adrenarche (p. 1038) induced by the estrogens. Menstruation is often irregular but is sometimes so regular that a true menstrual cycle can be simulated. Apart from rare cases where the tumor can be palpated in the abdomen, the clinical diagnosis is based on rectal examination, but this is not very reliable if tumors are very small. The diagnosis may occasionally be suspected from the development of ascites before the tumor can be palpated rectally.

Estrogen excretion in the urine is sometimes extremely high (as in pregnancy) but is sometimes in the normal puberal range. 17-ketosteroids are usually slightly elevated. Demonstration of pregnanediol indicates a luteinized tumor.

Laparotomy is indicated where there is the slightest suspicion of this type of tumor. Bleeding occurs a few days after removal of the tumor as a reaction to the sudden withdrawal of estrogens. Menstruation subsequently

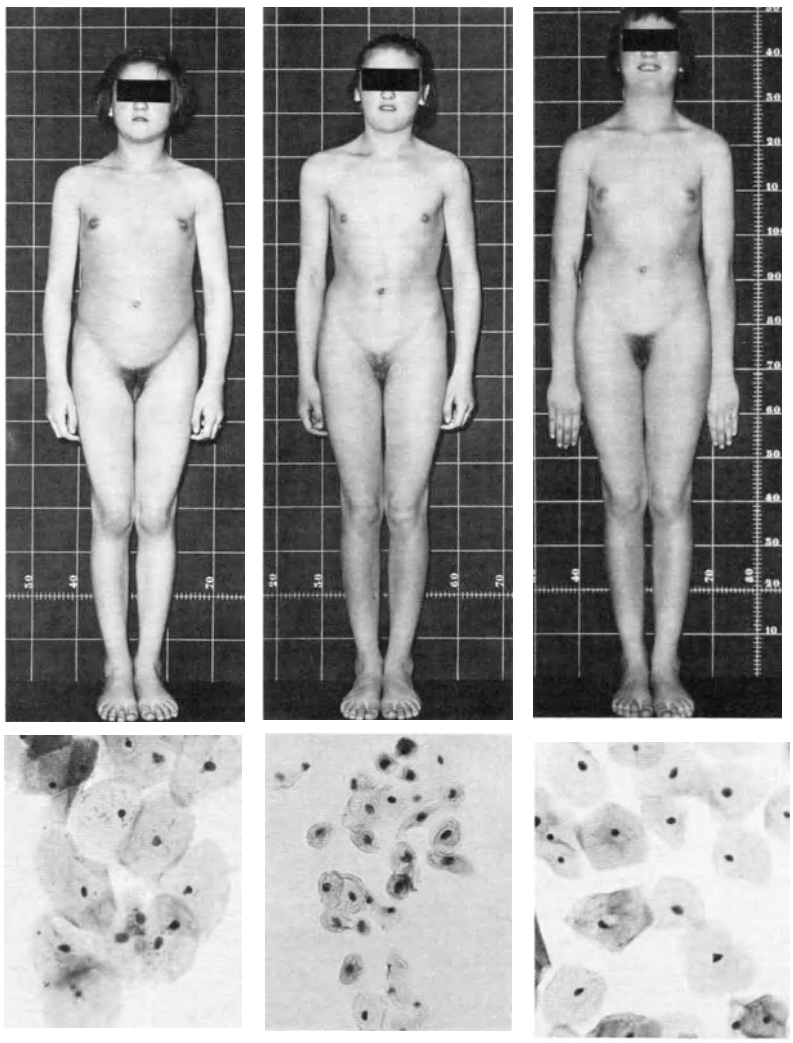

Fig. 33. Pseudosexual precocity due to a granulosa cell tumor. (The lower part of the Fig. shows the vaginal smear.) Left, at the age of 9, immediately before the operation. All the signs of puberty are recognizable. Center, one year after, partial regression of mammillae and pubic hair, and findings in vaginal smear. Another year later later (right) at the age of 11, development of normal puberty (KspZ)

ceases. Secondary sexual characteristics regress slowly, but usually not entirely. The prognosis is good in most cases.

Other ovarian tumors are occasionally also found to cause an isosexual precocious puberty. Teratomas, chorionepitheliomas (p. 688) and dysgerminomas are in this group. Androgen-secreting tumors of the ovary associated with heterosexual precocity (p. 638) have also been described several times.

Some authors also consider *follicular cysts* a cause of precocious puberty, but this association has not as yet been confirmed. Removal of the affected ovary results in regression of secondary sexual characteristics only in some cases. The other cases seem to be more similar to true idiopathic sexual precocity. Exactly the same type of follicular cyst is also found in normal ovaries.

9. Pseudosexual Precocity with Testicular Tumors

Pseudosexual precocity due to a *Leydig cell adenoma* is not very uncommon. The unilateral irregular testicular enlargement is characteristic. Excretion of 17-ketosteroids is sometimes only slightly elevated and sometimes excessively high (3–520 mg/24 h). This suggests that the metabolism of these tumors is not uniform. In the presence of high values, the adrenogenital syndrome due to adrenal hyperplasia with hyperplastic ectopic adrenocortical nodules in the testicular region must be suspected (p. 366). Excretion of 17-ketosteroids can be elevated in both conditions, unilateral irregular testicular enlargement can be present in both, and histological differentiation of Leydig cells from

adrenocortical cells is difficult. If cortisone therapy produces a reduction in the size of the testis containing the tumor and a regression of urinary 17-ketosteroids and if pregnanetriol excretion is high, the condition is more likely to be an adrenogenital syndrome.

Surprisingly, removal of the tumor does not result in regression of the clinical symptoms and reduction of 17-ketosteroids to prepuberal values in all cases. There are two possible explanations for non-correction of the symptoms. Either bone age is so far advanced that true puberty with normal testicular maturation and corresponding testicular enlargement has occurred or an adrenogenital syndrome has been missed.

10. Pseudosexual Precocity of Exogenous Etiology

It is obvious from our knowledge of the actions of gonadotropic hormones and sexual hormones that secondary sexual characteristics can arise prematurely during treatment with these hormones during childhood. Male-type puberal characteristics arise particularly when too high doses of anabolic steroids (for dwarfism) and chorionic gonadotropin (for cryptorchidism) are used. Female features are seen often with the use of skin creams containing estrogens or hair spirits with estrogens, and also when a mother uses a cream containing estrogens for her breasts and it is unintentionally acquired by the baby during breast-feeding. In rare cases secondary sexual characteristics also result from handling stilbene compounds used for castrating birds and from the intake of vitamins and drugs which have been accidentally contaminated with estrogens during manufacture. Not only the appearance of female secondary sexual characteristics is observed with the accidental intake of estrogens, but pigmentation of the mammillae and linea alba is accentuated and pubic hair arises. Any explanation of the last feature must assume that adrenarche is induced by estrogens.

11. Differential Diagnosis

Precocious puberty can usually be recognized without any difficulty. In *premature pubarche* (p. 1040) and *premature thelarche* (p. 1041), in contrast to precocious puberty, only one secondary sexual characteristic is found and hormonal findings in the urine are normal. *Vaginal bleeding in infancy* in the absence of other symptoms is only rarely endocrine in nature. Much more commonly the bleeding is due to a foreign body in the vagina, local damage, small benign tumors, or a hemorrhagic diathesis, or there has been a mistake and the bleeding is actually from the urethra or rectum. Thorough inspection of the vagina under a general anesthetic and a vaginal smear to see whether any estrogenic effects are present are often sufficient for a diagnosis.

Greater difficulties are encountered in the differential diagnosis of the etiology of precocious puberty.

The *case history* alone occasionally gives some indication of the etiology. Where there is a familial incidence, true idiopathic precocious puberty and the congenital adrenogenital syndrome must be considered. Heterosexual development of the sisters of a male patient can only occur in the adrenogenital syndrome. A family history of neurofibromatosis suggests that an intracranial neurinoma is the cause of the precocious puberty. Leading questions about cerebral symptoms (headache, vomiting, visual disorders) must be asked when the personal history is taken because of the possibility of a brain tumor. The doctor should also make a point of asking about any therapeutic or accidental contact with exogenous hormones. Slowly developing puberty is suggestive of idiopathic precocious puberty, whereas a very rapid development always suggests a tumor as the cause.

The *general examination* immediately singles out heterosexual precocity, which is always associated with an adrenocortical disorder (Fig. 34). Most cases of precocious puberty due to cerebral disorders are recognized from the neurologic examination (p. 1048). Observation of the skin pigmentation is also of importance. Smooth, well-defined pigmentation areas with subcutaneous nodules suggest sexual precocity due to neurofibromatosis, whereas patches of pigmentation with irregular borders associated with facial asymmetries or bone deformities suggest precocious puberty with fibrous bone dysplasias (Albright's syndrome).

No real conclusions about the etiology of precocious puberty can be made from the age at which the first symptoms appear and the degree of the advance in somatic development. In investigating the etiology it is essential to assess *gonadal function* as precisely as possible. This also applies to cases in which the cause of the precocious puberty seems apparent from the case history and the general examination alone. Gonadal function is assessed by the 17-ketosteroid excretion, the levels of gonadotropins, and whenever possible, also testosterone or estrogen levels in serum and urine. A positive Ascheim-Zondek test suggests a tumor-producing chorionic gonadotropin, and

in girls with true sexual precocity, the possibility of a pregnancy must be considered.

In boys, testicular size (Table 10) is easy to assess (Chap. XVIII). A unilateral, irregular enlargement is of particular significance since it suggests the presence of a tumor. Excretion of 17-ketosteroids is only slightly elevated in true sexual precocity, whereas it is very high in adrenocortical and gonadal pseudosexual precocity. If differential diagnosis is not possible with the methods so far described the action of cortisone on the excretion of 17-ketosteroids (Chap. XVIII) and the testicular biopsy (Table 10) may be helpful. The possibility of incipient brain tumor causing few symptoms must never be forgotten.

In girls (Table 9) careful rectal examination under a general anesthetic is necessary and when possible should be combined with laparoscopy for assessment of the size of the uterus and exclusion of the possibility of an ovarian tumor. The vaginal smear for assessment of the estrogenic action and estimation of the 17-ketosteroids must never be omitted. These investigations very often give no definite indication of the classification of the sexual precocity, in which case true idiopathic precocious puberty must be considered present by a process of elimination. It must always be borne in mind, however, that cases of clinically silent brain tumors and of nonpalpable ovarian tumors can be concealed under this diagnosis. A decision can often only be reached after regular follow-up examinations.

12. Treatment

From a superficial point of view, any treatment appears superfluous in *hypothalamic precocious puberty* of the idiopathic type or associated with fibrous bone dysplasia, since the advanced development produces no unfavorable effects except premature arrest of growth. The psychological problems are usually so pressing, however, that an effective form of therapy would be much appreciated. The ideal preparation would be capable of arresting premature activation of the hypothalamic-pituitary-gonadal axis, thus preventing all features of precocious puberty, without exerting any peripheral androgenic or estrogenic actions at the same time.

Trials with gestagenic drugs inhibiting gonadotropins have so far been only partly successful and it is debatable whether long-term use of these compounds in the high doses necessary is harmless and justifiable. The drugs most commonly in use are medroxyprogesterone acetate (p. 553) (Depot Provera, 100 to 200 mg/week, i.m.) and chlormadinone acetate (Gestafortin, 5 to 15 mg/day p.o.). These doses suppress secondary estrogenic sexual characteristics (menstruation, mamma development) quite efficiently in idiopathic precocious puberty and even in cases of hamartomas. Androgenic features are only partially suppressed (sexual hair, acne, masturbation). In most cases, however, these drugs do not unequivocally arrest acceleration of growth and bone maturation. There have been several reports that medroxyprogesterone acetate reduces previously elevated values of LH, FSH and testosterone in the plasma. Unfortunately it also has a mild cortisone action and thus suppresses ACTH.

Trials with the new anti-androgenic drug, cyproterone acetate (50–100 mg/day p.o.) have yielded similar results (p. 472), but it is still too early to draw any conclusions about this therapy. Cyproterone acetate reduces the con-

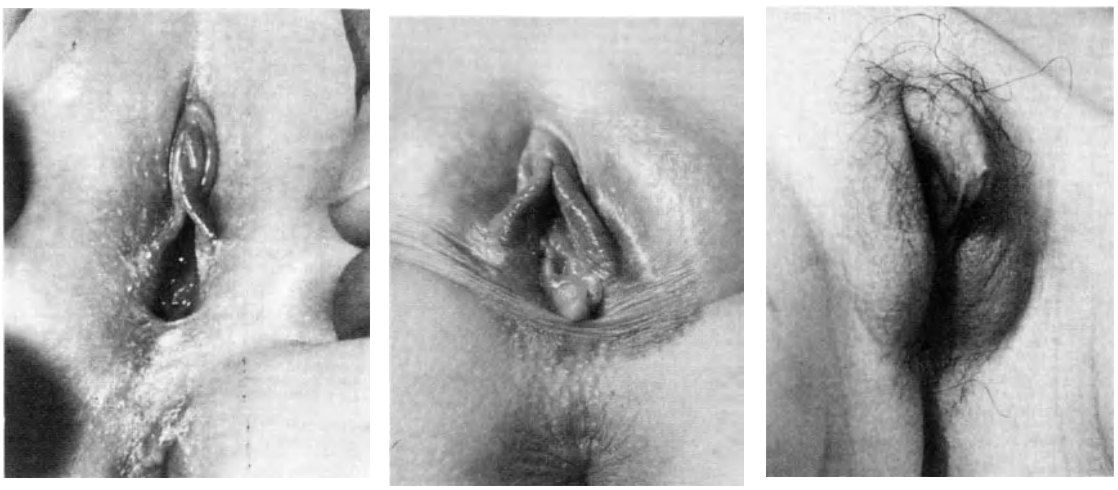

Fig. 34. Genitalia in girls during infancy. Left, normal. Center, labia minora enlarged due to true isosexual precocious puberty. Right, clitoris enlarged due to heterosexual pseudosexual precocity with an adrenogenital syndrome (KspZ)

centrations of gonadotropin and testosterone in the plasma and urine, whereas cyproterone has only peripheral anti-androgenic actions and is thus less suitable for treating precocious puberty.

In *cerebral precocious puberty*, neurosurgical intervention (excision of the tumor) is occasionally successful. Usually, however, the cerebral lesions are inoperable tumors or malformations, and only a palliative neurosurgical operation followed by radiation is possible.

For *gonadotropin-producing tumors*, the only possible treatment is immediate surgical removal of the tumor followed by radiation. The prognosis remains poor, however, due to the malignancy of the tumors.

Treatment of adrenocortical pseudosexual puberty is very rewarding, whether it involves removal of an adrenal tumor or treatment of adrenal hyperplasia with cortisone (p. 373).

Removal of the tumor (hemicastration) is the treatment of choice for *gonadal precocious pseudopuberty*. The prognosis is usually quite good since these tumors are often benign.

Precocious puberty due to *hormone overlapping* usually disappears spontaneously if the underlying endocrine disorder is correctly treated.

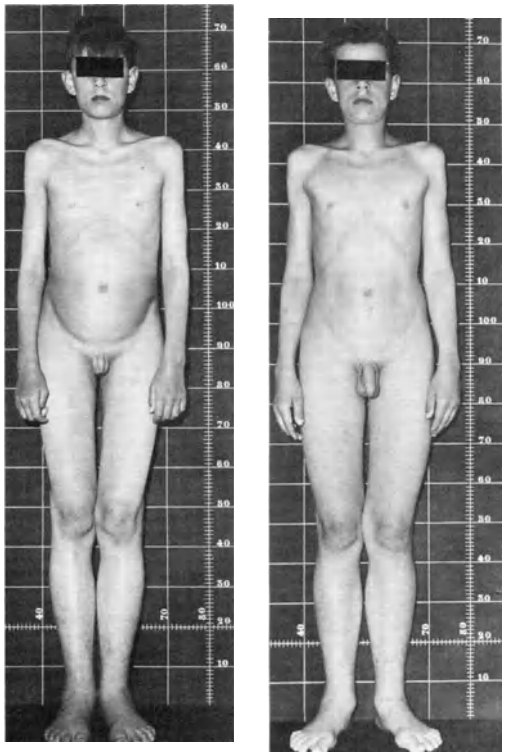

Fig. 35. Delayed puberty without generalized developmental retardation in a boy with hyperthyroidism. Left, at the age of 16.5 years, normal height but puberty absent and proportions definitely eunuchoid. The bone age of 12.5 years indicates that puberty is imminent. Right, at the age of 17 years 10 months. Spontaneous development of puberty after treatment with methimazole (Tapazole) (PRADER, 1955)

H. Delayed Puberty

The term "delayed puberty" is applied when the first secondary sexual characteristics appear after the age of 14 in girls and after the age of 16 in boys.

If no signs of puberty are present at this point, the cause of the delay must be thoroughly investigated. No endocrinopathy can be demonstrated in most cases, however, so that a chronologically displaced but otherwise normal puberty can be expected. Detailed investigation of the state of development, particularly of the height and bone age and of the often eunuchoid proportions (Fig. 35) is of the utmost diagnostic and prognostic importance. Bone age is significant since puberty normally arises at a bone age between 10.5–11.5 years in girls and between 12.5–13.5 in boys (p. 1023). If this stage of bone development has not yet been reached, puberty cannot yet be expected, but in delayed puberty where no endocrinopathy has been found, the point at which puberty can be expected can be predicted quite accurately from the bone age.

In pituitary dwarfism with gonadotropin deficiency, puberal characteristics never occur and bone age just reaches the puberal phase. In pituitary dwarfism without gonadotropin deficiency, puberty is delayed in keeping with the retarded bone maturation but is otherwise normal. In other endocrinopathies (Turner's syndrome, gonadal dysgenesis (p. 721), idiopathic eunuchoidism (p. 469), and anorchia (p. 461)) characterized by the absence of puberty, sparse pubic hair arises but the other secondary sexual characteristics fail to develop. The pubic hair is caused by adrenocortical androgens (see adrenarche, p. 1038). Bone development is retarded but gradually reaches the normal or almost normal adult state. The difference is explained by the fact that in panhypopituitarism, not only gonadotropins are absent but also growth hormone, TSH and ACTH, all of which contribute directly or indirectly to skeletal maturation (p. 1017).

The various forms of delayed puberty have been discussed in the sections of dwarfism (p. 1027), Turner's syndrome (p. 713), and pure gonadal dysgenesis, as well as in the chapters dealing with the pituitary, testis and ovary. This section gives only a survey indicating the differential diagnosis (Table 13). It must be remembered, however, that true endocrino-

pathies in which puberty fails to develop (sexual infantilism, 2a, f, 3b, c and d in Table 10) are much more uncommon than benign variations of development where puberty is merely delayed but otherwise normal (1a, 2a, b, c, 3a, e in Table 13).

Table 13. The most important aspects of the differential diagnosis of late-onset puberty

1. *Obesity*
   a) *Prepuberal obesity in boys* in whom growth is normal or accelerated (p. 1043)
2. *Dwarfism*
   a) Hypocaloric dwarfism (p. 1028)
   b) Constitutional delay of development (p. 1028)
   c) Delay of development due to chronic disease
   d) *Hypothalamo-pituitary dwarfism without gonadotropin deficiency* (p. 98)
   e) *Hypothalamo-pituitary dwarfism with gonadotropin deficiency* (p. 101)
   f) *Turner's syndrome* in patients with purely female external appearance (p. 713)
3. *Normal growth or gigantism*
   a) *Delayed puberty* (idiopathic, p. 1054)
   b) *Idiopathic eunuchoidism* and other forms of isolated gonadotropin deficiency (p. 456)
   c) *Anorchia* and other forms of Leydig-cell insufficiency (p. 461)
   d) Pure gonadal dysgenesis (p. 721)
   e) Prepuberal obesity in boys (see 1a)

In *dwarfism with delayed puberty* it is difficult to differentiate between generalized developmental delay with a poor prognosis and associated with organic hypothalamo-pituitary damage (2e) or Turner's syndrome (2f) or growth hormone deficiency without gonadotropin deficiency (2d) (where the prognosis for puberty is good) and generalized developmental retardation with no primary pituitary or gonadal disorders (2a, b, c). In the presence of *normal growth*, idiopathic delayed puberty with a good prognosis must be differentiated from idiopathic eunuchoidism (3b), which has a poor prognosis.

The reader is referred to the section on dwarfism (p. 1027) for the *differential diagnosis of generalized developmental retardation*. When growth, bone development and puberty are all retarded to the same extent, a benign constitutional delay of growth and development is the most probable cause. Pituitary dwarfism and generalized developmental retardation due to malnutrition or chronic illness are much rarer.

In cases where puberty does not arise at the normal time in spite of otherwise normal growth *idiopathic delayed puberty* is usually present. This condition is basically similar to benign constitutional delay of growth and development except that hereditary gigantism is also present. The normal body height associated with retarded bone age indicates the future gigantism. More rarely, delayed puberty is due to true idiopathic eunuchoidism (p. 456) where puberty is not really delayed but permanent hypogonadotropic hypogonadism is present due to isolated failure of the gonadotropin secretion. The two forms cannot be definitely differentiated from each other by means of conventional diagnostic methods while bone age is below 13.5 years, but it may become possible in the future by means of radioimmunological estimations of LH and FSH in serum and urine. To be on the safe side, however, any form of hormonal therapy should be postponed. If this is impossible for psychological reasons, temporary substitution treatment with chorionic gonadotropin (p. 476) or testosterone (p. 475) must be instituted and continued until a bone age of about 14 years is reached. If puberty continues spontaneously after discontination of treatment, it was merely delayed, but if signs of puberty regress after discontinuation of the drugs, a permanent gonadotropin deficiency is present. At this stage, the clinical diagnosis can also be confirmed by measuring urinary gonadotropins by conventional methods.

XX. Fundamentals of the Hormone Treatment of Nonendocrine Disorders

A. LABHART and G. MARTZ

A. Endocrine Therapy of Carcinomas of the Breast, Prostate, and Corpus Uteri and of Prostatic Hypertrophy

1. Introduction

Whereas the proportion of patients with malignant growths within the total hospital population has increased considerably over the past 25 years, effective, albeit still only palliative, methods of treatment have now become available. Malignant tumors of endocrine-regulated organs (breast and prostate) are very common. When the surgical and radiotherapeutic possibilities have been exhausted, treatment with hormones is available for these cases, which are of interest to the endocrinologist as well as to the oncologist.

In keeping with the interest of the endocrinologist in this, perhaps the widest, use of hormones, the principles of endocrine therapy of these three neoplasias will be discussed in this chapter. The chapter is based on the monograph by one of us (MARTZ), from which the synoptic tables are also derived.

BEATSON started the era of the endocrine treatment of tumors in 1896 by performing a successful surgical castration for metastasizing breast carcinoma. His theoretical reasons have since been disproved. It was HUGGINS, in 1941, who made castration known to physicians as the most important palliative treatment for inoperable carcinoma of the prostate. He based his reasoning on critical experimental trials in animals. He recognized that two different properties of the malignant growths – the hormone dependence and the hormone sensitivity of organs under endocrine control, such as the prostate – could be exploited therapeutically. This shattered the dogma of the autonomous growth of all malignant tumors. The extremely variable results and the initially deficient theoretical bases, some of which did not at first admit of experimental documentation, have led to general uncertainty over the last 25 years. This has resulted partly in uncontrollable endocrine polypragmasia and partly in therapeutic nihilism. A reliable, although empirical, foundation for this therapy has only emerged since the advent of controlled studies on a cooperative basis. Such terms as "tumor regression," "therapeutic success," and "period of survival" have been internationally defined according to strict criteria. The basic information given here is derived from 12 years' experience of such cooperative studies, in many of which the Division of Oncology at the Kantonsspital Zurich participated.

2. General Features

Every malignant tumor of the breast, prostate or the body of the uterus must first be placed in the hands of the surgeons and radiologists, providing it is still localized. The disseminated tumor belongs in the domain of medical therapy which almost without exception still has only a palliative effect. Whereas cytostatic drugs attack the tumor directly, the endocrine measures act on the host, and thus only indirectly on the tumor. The mode of action at the cellular level is still unknown, as is the mode of most hormonal actions.

One quarter of all deaths due to malignant tumors are due to the potentially hormone-dependent carcinomas of the breast, prostate and body of the uterus. However, only a number of these malignant tumors respond to hormonal therapy and then only for a limited time. (See MARTZ, 1968, for other rare tumor types which can be influenced by hormones.)

3. Endocrine Therapy of Carcinoma of the Breast

With a morbidity of 3 %, carcinoma of the breast is the most common form of cancer leading to death. Curative treatment is impossible in about one third of patients at the time of diagnosis, and there are recurrences within 10 years in about two-thirds of those subjected to surgery. The very variable spontaneous course of carcinoma of the breast must always

be kept in mind. In addition to the types of carcinoma which can lead to death within months, there are "benign" forms with a course lasting over 20 years, so that the term "five-year survival" is obsolete. This means careful follow-up and the prospective studies mentioned above are essential for rational therapy.

Growth and function of the breast are subject to manifold hormonal influences (p. 694). Some carcinomas of the breast are hormone-dependent and others are not. The ones that are, however, always become independent after some time. There is no histological difference between the two types. Basically, *ablative* therapy is possible by the withdrawal of hormones, and *additive* therapy by the administration of hormones. Ablative therapy is generally more effective. The sequence of treatment is summarized in Table 1.

Table 1. Sequence of treatment (MARTZ, 1968)

Patient before or shortly after onset of menopause	
Initial treatment	Ovariectomy
Second measure	
a) After remission following ovariectomy	Hypophysectomy or adrenalectomy
(If surgery is not possible or is refused by the patient:	Androgens)
b) If ovariectomy has had no effect:	Chemotherapy
Third measure	Chemotherapy, corticosteroids

Patient more than 5 years after onset of menopause	
Initial treatment	Estrogens
Second measure	
a) After remission by estrogens:	Androgens or estrogens + progesterone
b) If estrogens have no effect:	Chemotherapy
Third measure	
a) If previous hormone therapy was effective:	Hypophysectomy or adrenalectomy
b) In all patients	Corticosteroids, chemotherapy

a) Treatment by Withdrawal of Hormones

The purpose of this treatment is the most extensive elimination possible of all hormones which promote the growth and spread of carcinoma of the breast.

α) Elimination of Ovarian Function

One quarter to one third of patients in the premenopause respond to ovariectomy with an objective remission lasting about 10 months on average. The effects are greatest on metastases of the soft tissues (skin, lymph nodes, breast) and of the skeleton, and perhaps also on the primary tumor itself. Metastases of the liver and central nervous system are least affected. The results are often dramatic. Metastases disappear completely, the general condition, appetite and body weight improve and, above all, bone pain disappears rapidly, often within hours after the operation. The analgesic effect is not always associated with objective remission of the metastases. There is no certain criterion allowing accurate prediction of the result of the operation. Patients shortly before or after menopause react best, whereas the chances of success are slighter in women under 30. After the menopause, the vaginal cytology and the estimation of the urinary gonadotropins can indicate how active the ovaries still are. A further criterion is the free interval between the development of the primary tumor and the appearance of metastases; the longer this free interval is, the more likely the ovariectomy is to be successful.

Indications and statistical chances of success of castration can be summarized as follows: ovarian elimination is indicated as the first endocrine measure in all patients with metastasizing carcinoma of the breast in the premenopause and up to 5 years after the menopause.

Surgical ovariectomy is preferable whenever it is possible. It has the advantage of a rapid onset of action and its success can often be assessed immediately after the operation. The elimination of ovarian function by radiation has the advantage of slighter stress to the patient, but there is a risk of mucosal lesions of the intestine. Above all, the onset of action is delayed, and the result cannot usually be assessed until 3–6 months afterwards. As a rule, a patient should only be radiated when her condition does not permit surgery. Prophylactic menolysis radiation is an exception (p. 1063). Additional endocrine treatments should definitely be avoided after ovariectomy until the succes or failure of the operation has been determined. Hot flushes due to castration should be treated with sedatives and not with hormones.

In spite of contradictory statistics, *prophylactic* ovariectomy in carcinoma of the breast, i.e. ovariectomy in the absence of demonstrable metastases, is not justified. Several rigorous prospective trials have proved the ineffectiveness of this procedure. The main argument against prophylactic castration is the fact that 30 to 50% of the patients are definitely cured by the primary surgical treatment so that this operation,

which is associated with severe psychic stress, would be needless. If axillary metastases are present prophylactic ovariectomy must be seriously considered. The decision should be made in the light of the patient's attitude and of whether she has or wishes to have children. Strictly speaking, ovariectomy is no longer a prophylactic measure in a case with metastases. However, radiation of the ovaries seems to have a beneficial effect in postmenopausal patients.

β) Elimination of the Pituitary and the Adrenal Cortex

After gonadal ablation the production of sexual hormones in the adrenals sometimes increases (p. 459). Ablation of the pituitary or adrenals should be considered as the second or third step in the endocrine therapy of metastasizing carcinoma of the breast. It leads to the complete elimination of the sexual hormones and related steroids. The best results are obtained in cases where previous castration has been effective. The analgesic effect is often immediate. Objective improvement is to be expected in 30 to 40% of cases and subjective effects in 60 to 80%.

The indications for elimination of the pituitary or adrenals are based on the following conditions:

previous response to other endocrine treatments;
painful skeletal metastases;
absence or small size of visceral metastases.

The surgical technique for adrenalectomy and the substitution therapy are discussed on p. 330, 356, and the possible methods of eliminating the pituitary by surgical, radiological, or stereotactic measures and of pituitary substitution on p. 105, 115.

After α-particle radiation, which is a complicated and expensive procedure, stereotactic isotope implantation or bipolar electrocoagulation presents the least stress for the patient. According to experience so far, the results of adrenalectomy and hypophysectomy are comparable. Prospective comparative series are in progress but cannot yet be evaluated. However, a trend in favor of hypophysectomy is beginning to appear. In contrast to stereotactic elimination of the pituitary, bilateral total adrenalectomy is a major operation.

b) Treatment by Hormone Administration

α) Androgens

About 20% of patients with metastasizing carcinoma of the breast respond to treatment with high doses of the male sexual hormones. Very high doses are necessary (100 mg testosterone propionate i.m. 3 times weekly, or 20–30 mg fluoxymesterone daily; see Table 2). They lead without exception to severe and often irreversible manifestations of virilization, which is an extremely severe psychological trauma for the patient (Table 3; p. 1064). Women of all ages respond to this therapy.

Table 2. Dosage scheme

Preparations	Dosage
1. *Estrogens*	
Diethylstilbestrol, p.o.	5 mg 3 times daily
Ethinylestradiol, p.o.	1 mg 3 times daily
Estradioldipropionate(-benzoate), i.m.	5 mg 2–3 times weekly
2. *Androgens*	
Testosterone propionate, i.m.	100 mg 3 times weekly
Testosterone ester depot i.m.	250 mg once weekly
Fluoxy mesterone, p.o.	10 mg 3 times daily
3. *Progesterone* (in combination with estrogens)	
Hydroxyprogesterone capronate, i.m.	1000 mg weekly
4. *Adrenal steroids*	
Prednisone, p.o.	10–20 mg 3 times daily
Triamcinolone, dexamethasone or similar preparations	According to the effective equivalent for prednisone (see p. 309)

The antineoplastic action is apparently coupled with the androgenic properties, and anabolic steroids only have a comparable effect when given in doses which have a virilizing effect. On the other hand, a careful study carried out on a cooperative basis with Δ-1-testololactone, an artificial steroid which has no hormonal activity, has given results as good as are obtained with testosterone. The preparation must be given in the same high doses – 100 mg i.m. 3 times weekly.

Water retention is another side effect of testosterone therapy and can be better controlled. It can be prevented by limiting the intake of salt or by giving diuretics. Other, rarer side effects are mild hypertension and erythrocythemia and exacerbation of skeletal pain in 10–20%, perhaps associated with a rise of the serum calcium. This initial stimulation of the tumor usually declines after a few days or at the most weeks of uninterrupted administra-

Table 3. Side effects of hormonal therapy (MARTZ, 1968)

Mode of action	Side effects	Therapy of side effects
Castration	Menopausal symptoms (hot flushes, etc.)	Sedatives *no hormones*
Adrenalectomy	Symptoms of endocrine insufficiency	Substitution
Hypophysectomy	Symptoms of endocrine insufficiency	Substitution
	Liquorrhea	Repeated spinal taps; surgery
	Lesion of the optic nerve	–
Estrogens	Lack of appetite, nausea	Change of preparation
	Withdrawal bleeding	Ceases spontaneously during continued medication with estrogens. If not: injection of 100 mg progesterone
	Pigmentation of the nipples	–
	Water retention	Diuretics, cardiac therapy
	Hypercalcemia	Discontinuation of therapy, low-calcium diet, intensive supply of liquids, therapy with phosphates, 100 mg prednisone/24 h
Androgens	Virilization (deep voice, growth of beard, baldness)	–
	Increase in libido	–
	Rise in blood pressure	Blood pressure-lowering preparations,
	Water retention	diuretics, cardiac therapy
Corticosteroids	Cushingoid habitus	–
	Ulcer of stomach and intestine	Antacids
	Diabetes	Diabetes therapy
	Infections	Antibiotics
	Osteoporosis	Calcium and/or fluor preparations

tion of the androgens. It is not an absolute indication for discontinuation of the therapy if the patients are in hospital under careful observation. These cases must be distinguished from those with progressively spreading metastases in hormone-insensitive carcinomas. Objective remission is noticeable after about 2 months at the earliest. Skeletal pains disappear, and skeletal and soft tissue metastases regress. The effect lasts an average of 7–10 months.

β) Estrogens

Postmenopausal women respond to estrogens more frequently and for longer periods than to androgens, i.e. in 35 % of cases as against 20 %. There is very little chance of success in younger women. Low doses are advocated at the beginning of treatment because of possible gastrointestinal intolerance. The optimal daily maintenance dose of 15 mg stilbestrol or 3 mg ethinyl estradiol should be attained within a week. All metastases can be influenced, especially those in the soft tissues. Objective remissions are determined about 2 months after the beginning of the treatment. The effects usually last longer than those obtained with androgens on average 13 months. In rare cases estrogens lead to an exacerbation of the tumor growth, which can be recognized in the presence of bone metastases from the appearance of pain.

Uterine withdrawal bleeding is the main side effect. It usually ceases spontaneously with the continuation of the treatment, or it can be arrested with high doses of progesterone. Water retention can be prevented by limitation of salt intake and administration of diuretics. Urinary incontinence and vaginal discharge occur in some cases. Hypercalcemia arises in about 10 % of cases; it is a serious complication which necessitates immediate energetic measures (p. 933, 968).

γ) Cortisol and its Derivatives (p. 303)

δ) Gestagens

The relatively slight experience so far available seems to indicate that the results with high doses of gestagens in metastasizing carcinoma of the breast are not as good as those obtained with androgens or estrogens. Some advantage may be gained by combining gestagens with estrogens. The first observations in patients receiving ovulation inhibitors indicate therapeutic and prophylactic effects for this combination. The combination of androgens and estrogens, however, does not produce any better results than are obtained with either of these hormones alone.

The combination of hormone therapy with cystostatics may prove more effective than either method alone. It cannot be assessed at present.

c) Indications and Strategy

With the possible exception of prophylactic castration in women in the menopause, endocrine therapy is only justified when metastases of the tumor can be demonstrated. Histological proof of the primary tumor is essential, and proof of easily accessible metastases is desirable. Localized metastases should be treated locally whenever possible, i.e. by surgery and/or radiation.

A trial with hormones should be avoided in patients with no symptoms and no local or generalized signs of tumor progression. Endocrine treatment should be instituted when symptoms arise or when spread of the metastases has been demonstrated. Careful supervision of each patient is an important requirement.

The most objective assessment of the metastases possible, i.e. frequent measurements of their size, is essential for successful endocrine therapy. A so-called metastatic series of 7 X-rays should always be taken (lateral skull, thorax and pelvis a.p., thoracic and lumbar vertebrae a.p. and lateral). Experience has shown that these reveal more than 90% of all skeletal metastases occurring in this condition.

In summary, the following rules should be adhered to: Therapeutic trial only after there is evidence of progression of the metastases or of symptoms due to the tumor. Measurement and recording of all direct and indirect manifestations of the tumor present before and during the treatment. Never more than *one* hormonal measure at the same time. Continuation of the measure introduced until renewed growth of the tumor can be objectively confirmed. Hormone therapy with estrogens or androgens, once started, should be continued in the same doses until a recurrence can be demonstrated under continuing treatment. At this point, the hormone must be completely withdrawn and no further treatment started. An observation period must then follow. In some cases, the abrupt withdrawal of high doses of estrogens or androgens can bring about an inhibitory effect on the tumor once more, so that a remission arises as a result of the withdrawal alone. This withdrawal effect, which is not, however, common, should be watched for before subsequent introduction of a different treatment (Table 1).

Prognosis. With the exception of the length of the free interval (p. 1062), there is at present no means of predicting the chances of success of an endocrine therapy. The histology of the tumor or the metastases gives no indication. The laboratory tests have so far failed entirely, even the calciuria test after estrogens and the sex chromatin in the tumor tissue. Refer to MARTZ (1968) for further tests (P_{32} uptake by HALE, discriminants of BULBROOK [relative amounts of the excreted steroids]). See Tables 1, 2 and 3 for the plan of treatment, dosages, side effects and countermeasures.

4. Endocrine Therapy of Metastasizing Carcinoma of the Breast in the Male

The incidence of carcinoma of the breast in men is 1% of that in women. There is no connection with gynecomastia. Orchidectomy, as the most effective therapeutic measure, is the treatment of choice; it probably achieves a higher percentage of remissions (which are also of longer duration) than is obtained in women receiving endocrine therapy. Adrenalectomy and hypophysectomy have to be considered when there are recurrences. Estrogens are only effective in isolated cases. Treatment with cortisol can be tried as a last resort in this condition.

5. Endocrine Therapy of Carcinoma of the Prostate

Carcinoma of the prostate is the most common type of malignant neoplasia in men over 50 in the Western Hemisphere except for skin carcinoma. Only an average of 10% can be treated by radical surgery at the time the diagnosis is made. Palliative treatment is therefore of great importance. Aims of the treatment are correction of symptoms associated with micturition, removal of pain, improvement of the general condition and prolongation of life. An objective assessment of the status before and during treatment is esssential for the administration of an optimal therapy in this condition also. Estimation of the acid phosphatase in the serum often gives an indication of the extent of the metastases.

It must be observed at this point, however, that for some unknown reason 50% of cases of metastasizing carcinoma of the prostate are not associated with a rise of the acid phosphatase.

a) Therapy by Withdrawal of Hormones

Orchidectomy, i.e. the withdrawal of androgen production, leads to atrophy of the healthy as well as of the neoplastically transformed prostate. It subjects the patient to little stress, even in the advanced age group. But castration can cause severe psychological trauma. Impotence and loss of libido can (but need not) arise.

When the effects of orchidectomy wear off, the tumor increases in size and the symptoms worsen. In general nothing more can be expected of treatment with estrogens after this. The possible alternatives are adrenalectomy and hypophysectomy to eliminate the increased androgen production by the adrenals which follows castration. In elderly patients stereotactic elimination of the pituitary, which involves only slight stress to the patient, is the procedure usually considered. It promises at least an analgesic action.

b) Estrogen Therapy

The optimal dose of estrogens for this condition is not known. It is probably less than that for carcinoma of the breast, and the lowest effective dose should be used. Two methods can be recommended. An intramuscular injection of a depot estrogen preparation such as polyestradiol phosphate in a dose of 40–80 mg every 2 to 4 weeks, or oral administration of 1–3 mg ethinyl estradiol or 5–15 mg diethylstilbestrol daily. The actions of diethylstilbestrol diphosphate correspond to those of the other estrogen preparations. Estrogen therapy brings about the disappearance of bone pain and an improvement in general condition in 70–80% of patients. There is an increase in body weight and hemoglobin, and the primary tumor decreases in size, so that the patient can often be relieved of the indwelling catheter. The prolongation of survival is not known. Regression of the skeletal metastases is only occasionally seen on X-rays.

Metastases in the soft tissues can disappear. Undesirable side effects are loss of libido, impotence, feminization, and hot flushes, and also the syndrome of the male climacteric. The painful gynecomastia which accompanies estrogen treatment can be prevented by previous radiation of the breasts. Retention of NaCl and water, which can be dangerous in the presence of circulatory failure, can be prevented by limiting the salt intake and giving diuretics or digitalis.

Estrogen therapy should only be employed in inoperable carcinoma of the prostate which causes symptoms. The primary tumor can regress and become operable under treatment with estrogens. Estrogen therapy is indicated when metastases are demonstrated, whenever possible histologically or by elevated acid phosphatase, and when metastases cause symptoms.

c) Treatment with Cyproteron

The synthetic anti-androgenic steroid cyproteron or cyproteron acetate (p. 472) can block the peripheral action of androgens completely when given in adequate doses (p. 472). Therapeutic trials in prostatic carcinoma have been favorable so far. A broad prospective study is in progress. Cyproteron has one advantage over the estrogens in that it has no feminizing action, but there is usually a loss of libido and potency.

d) Cortisol and Derivatives

The glucocorticoids are thought to be as effective as hypophysectomy and adrenalectomy in carcinomas of the prostate which no longer react to estrogens or orchidectomy. This procedure is therefore preferable when the advanced age of the patient must be taken into account (p. 1069).

e) Gestagens

Gestagens are also thought to act on prostatic carcinoma, but this therapy is still in the trial stages.

f) Therapeutic Strategy

Histological proof of carcinoma is an essential condition for any specific therapy. The extent of the disease should then be estimated by means of palpation, radiology and chemical analysis of the blood. Age, general condition, the most optimistic life expectancy, and the psychological factors must be carefully weighed against the symptoms caused by the prostate carcinomal and against the side effects expected to result from endocrine treatment. Younger patients are advised to undergo orchidectomy providing it can be tolerated psychologically. Estrogens, cortisol and its derivatives and possibly cyproteron should be considered for older patients. It is sometimes best to delay endocrine treatment in elderly patients with no symptoms, even if there are extensive metastases.

Local urological measures and the radiation of painful metastases must not be neglected.

Once an endocrine therapy has been chosen, it must be continued until definite signs of renewed tumor growth are recognized.

When the estrogen therapy which was successful at first fails, another remission can often be obtained with orchidectomy. As has been mentioned above, estrogen therapy has no chance of success after primary castration. A further response can also be achieved by increasing the dose of the estrogen preparation by 10 times or more or by changing the type of estrogen preparation. Cortisone derivatives and progesterone can also be considered, and a favorable effect is paradoxically produced

with androgens in isolated cases. Finally, there are cytostatics such as cytoxan or fluorouracil and P_{32}.

6. Endocrine Therapy of Carcinoma of the Body of the Uterus

The frequency of carcinoma of the body of the uterus appears to be increasing, although the tumor is less common than carcinomas of the breast and the prostate. Surgery and radiotherapy are successful in 60–70% of cases. The inoperable or metastasizing cases, however, usually have a rapid progressive course. Endocrine disorders appear to be common in patients with carcinoma of the body of the uterus, and there is an obvious tendency for cystic and adenomatous hyperplasia of the mucosa of the body to become malignant in 10% of cases due to untimely or increased estrogen stimulation.

NATHANSON in 1960 was the first to achieve objective tumor regression, in some cases lasting several years, in one third of 22 patients with high doses of progesterone. It has since been confirmed that about 30% of all cases respond to high doses of progesterone. The mode of action is unknown.

As in carcinoma of the breast, a long free interval between surgical removal of the primary tumor and the development of metastases is the only indication of a probable favorable response to endocrine therapy. This treatment seems to act most favorably on metastases of the lungs and bones. Local tumor recurrences respond less well. Hormone therapy cannot be used for undifferentiated carcinomas or for sarcomas.

The optimal dose is still not known. It is assumed that a dose of 500 mg 17-alpha-hydroxyprogesterone capronate given by i.m. injection twice weekly is adequate for lung metastases. Doses of 2–5 g per week are necessary for skeletal, abdominal, and pelvic metastases. Medroxyprogesterone acetate is a depot preparation and should be given in a dose of 1–3 g i.m. every week or of 200–300 mg p.o. daily. The initial doses must be high and should then be gradually reduced. The therapeutic effect can only be assessed after about 2 months. The treatment must be continued without interruption until it fails. An increase in the dose or a change of the drug may then bring about a further remission. In some patients progesterone therapy can cause an inoperable tumor to become operable.

In contrast to other endocrine therapies, progesterone causes practically no side effects. Mild loss of appetite and nausea occur rarely and are of short duration. Progesterone preparations should therefore be considered for the prophylaxis of metastases, but no controlled studies relating to this application have yet been published.

7. Endocrine Treatment of Prostatic Hypertrophy

Prostatic hypertrophy or the benign adenoma of the prostatic gland can also be influenced and treated palliatively by hormones, but hormonal treatment is no substitute for prostatectomy and should only be considered if surgery is contraindicated.

The subjective improvements which can be induced by androgen treatment are probably nonspecific and are based on increased tonus of the muscles of the bladder. If carcinoma of the prostatic gland can be excluded, it is permissible to give men under 55 25 mg of testosterone propionate twice weekly for 6 weeks. This medication can be repeated not more than twice a year. Estrogens inhibit secretion and the swelling of the epithelial parts of the adenoma. Micturition can be improved by 5 mg diethylstilbestrol p.o. daily, but the side effects of this treatment are loss of potency and gynecomastia.

The anti-androgen cyproteron acetate blocks the effect of testosterone (p. 472) without feminization. The usefulness of this preparation is still in the trial stage.

There have recently been reports of improvements brought about by gestagens (GELLER, 1965; VERNET, 1970).

B. Pharmacological Use of Hormones

1. Cortisol and its Derivatives

Since HENCH'S observation of a definite effect of cortisone on rheumatoid arthritis in 1949, cortisol derivatives have also been used extensively outside the field of endocrinology because of the following effects:

1. Anti-inflammatory effect;
2. Immunosuppression (anti-allergic effect);
3. Palliative antineoplastic effect;
4. Antihypercalcemic effect;
5. Various other, mostly unexplained effects.

a) Anti-Inflammatory Action

Cortisol and its derivatives in doses four to twelve times greater than required for substitution therapy usually have a definite inhibitory action on inflammation. An effect can also be achieved in certain cases with small

doses which, when divided equally over 24 hours, may even be below the substitution dosage. A constant cortisol level is thus obtained in place of the normal nyctohemeral rhythm (p. 300). Although more than two dozen actions of cortisol have been experimentally investigated on the whole organism, on organs, on cells, and on cell constituents (WEISSMANN, 1971), only the morphology of the anti-inflammatory process can be described; the mechanism of the anti-inflammatory action of glucocorticoids remains largely unexplained. Yet some insight into this mechanism is dawning, on the basis of molecular biology: there is evidence that cortisol has a stabilizing effect on the cellular membrane and on the cell organelles. It also protects the lysosomes in particular from being destroyed (WEISSMANN, 1964). Cortisone prevents the fusion of lysosomes, which is important for this system in intact cells and inhibits the release of lysosomal material into the damaged tissue (WEISSMANN, 1971). It can be morphologically demonstrated that exudative and proliferative inflammatory processes regress due to a decrease in the capillary permeability and a limitation of the fibroblastic proliferation (p. 305). The inflammatory hyperemia decreases. The action is probably achieved partly via inhibition of the release of kinins (p. 977). There is, however, no action on old granulation tissue. These actions are pharmacological ones, although in some situations the body can produce glucocorticoids in amounts with antiphlogistic effects. It is improbable that physiologically the mineralocorticoids favor the process of inflammation (p. 311).

The anti-inflammatory action of the steroids is connected with and parallels their gluconeogenetic activity and their inhibitory effect on the hypothalamus and the pituitary.

The effects obtained with cortisol can also be achieved with ACTH infusions or intramuscular injections of depot-ACTH. Apart from the inconvenience of administration, ACTH also has the disadvantage of causing the release of increased amounts of androgens by the adrenals, and in contrast to most of the cortisone derivatives it leads to sodium and water retention. In our opinion, ACTH has no therapeutic indications and its use is limited to diagnostic tests.

Inflammation can be useful to the organism, by inhibiting the spread of noxious agents and invalidating them. Often, however, the damage caused by the inflammation itself is considerably more detrimental to the organism than the original harm due to the noxious agents. Anti-inflammatory therapy is justified in such cases. The dramatic effect of cortisol and its derivatives is usually limited to the duration of administration. The glucocorticoids suppress the inflammatory processes but do not eliminate them. The inflammatory manifestations usually return unchanged when the drug is withdrawn. This is an important point in the indications for cortisone treatment. The main indication for cortisol and its derivatives is self-limiting inflammatory disease or inflammatory disease with an episodic character where severe permanent damage can be caused during the inflammatory phase. Acute rheumatic carditis is an example. Anti-inflammatory therapy with hormones is only of limited use in chronic inflammatory diseases, since the side effects can sometimes exceed the symptoms of the original disease. Even the most serious side effects must be accepted where there is a vital indication in potentially fatal diseases (panarteritis nodosa, pemphigus, exfoliative dermatitis, erythroderma, dermatomyositis). High doses should be given at the beginning of treatment and gradually reduced to the lowest dose which is still effective. In chronic diseases which result in invalidity but are not potentially fatal, it is advisable to give doses in an attempt to produce a palliative action sufficient to permit the patients to work again. The lowest possible dose is given at first and this is gradually increased until the symptoms are tolerable. Inflammatory diseases in which the action of the noxious agent regresses and the reaction of the host organism is the dominant feature are especially well suited for anti-inflammatory cortisone therapy (allergy, rheumatic diseases, collagen diseases). Not only does cortisol have a decisive effect in exudative inflammations, but certain granulomatous processes such as sarcoidosis or histiocytosis may also be considerably improved by its use.

Infections were previously considered an absolute contraindication for treatment with cortisone since the spread of the pathogens could be favored by the suppression of the inflammatory reaction. Cortisone therapy in combination with chemotherapy and antibiotics can now be useful or even the deciding factor in some infections with hyperergic inflammatory reactions, e.g. certain forms of tuberculosis (meningitis). Experience and the utmost care are essential when cortisone is used in the treatment of these infectious diseases.

b) Immunosuppression

Contrary to original views, the formation of antibodies is not suppressed by cortisol and its derivatives. Nevertheless, cortisol in high doses inhibits the immunological processes by

blocking the binding of the antibody with the antigen and in particular with intracellular antigens, i.e. invasion of the antigen-containing tissue by sensitized cells is prevented. Cortisol also influences the lymphocytes and plasma cells. It causes a delay in their formation and maturation, inhibits their release into the blood, and promotes lymphocytolysis. The inhibition of the activation of kinins during the antigen-antibody reaction can also influence immunological processes. It is often difficult to separate immunosuppression and inflammatory inhibition from each other, especially when both properties of cortisol come into effect in the autoimmune diseases. Thus, immunohematological disorders, especially the immunohematolytic syndromes and less commonly autoimmune leukopenia and autoimmune thrombocytopenia, are indications for treatment with cortisol. Autoimmune diseases such as visceral lupus erythematosus and panarteritis nodosa are important indications for cortisol and its derivatives, and combination with azathioprine might be indicated. It is not known to what extent the beneficial effect on nephrosis is due to immunosuppression. Immunosuppression with cortisol derivatives combined with azothioprime is now a routine procedure for organ transplantations.

Anti-inflammatory action and immunosuppression explain the anti-allergic properties of cortisol. Acute potentially fatal allergic reactions, such as anaphylactic shock and similar reactions, are an absolute indication for treatment with cortisol. The greatest caution is indicated in chronic allergic diseases because of the side effects. Local application of cortisol derivatives is justifiable in these conditions. The anti-inflammatory action of cortisol alone is probably responsible for the improvement in chronic inflammatory autoimmune and allergic disorders such as rheumatoid arthritis and chronic asthmoid bronchitis. The indications are relative in these disorders, because of the side effects with long-term treatment.

c) Oncological Indications

Oncological indications are advanced stages of metastasizing carcinomas of the breast and prostate. An improvement of the general state can be expected in particular. The action is not due to inhibition of the adrenals or "pharmacological adrenalectomy" as was previously supposed. It is probably due to the anti-inflammatory properties of cortisol and its derivatives. It is possible that cortisone interferes with the metabolism of ribonucleic acid (KUMMER, 1968). The glucocorticoids are indicated especially in the following complications: 1. Metastases in the central nervous system and in the liver. Doses of 50–100 mg prednisone daily are necessary. 2. Pleural and pericardial effusions due to the tumor. These are often resistent to other hormonal therapy, but regression can be achieved in more than 50% with an initial treatment with 50–100 mg daily. Prednisone should later be given sporadically with therapy-free intervals.

Treatment with cortisol is also indicated in acute leukosis when it should be used in combination with cytostatics. In this condition high doses of prednisone, up to 400 mg daily, must be given. The success obtained with this treatment is very impressive but lasts for a limited time. The younger the patient, the more lasting and better the result. In chronic lymphadenosis cortisol is indicated only in the presence of disturbing infiltrations, complicating anemia, or thrombocytopenia. Cortisol has also proved to be effective in combination with cytostatics and radiation for malignant lymphomas.

d) Hypocalcemic Effect

In *hypercalcemia* of various etiologies, particularly when it is associated with malignant tumors but not with hyperparathyroidism, the serum calcium falls or returns to normal under the influence of cortisol. This action can save a patient's life. The mode of action is not explained although cortisol inhibits calcium absorption from the intestine as well as reabsorption in the renal tubules. Cortisol also has a hypocalcemic effect in patients fed parenterally, however.

e) Other Indications

Paget's disease with arteriovenous shunts disturbing hemodynamics and alopecia areata are indications for treatment with cortisol, although there is still no explanation for the mode of action.

f) Untoward Side Effects of Pharmacological Treatment with Cortisone

The so-called side effects are inseparably bound up with the anti-inflammatory action of cortisone and its derivatives, with the one exception of sodium retention. The untoward side effects of treatment with cortisol are best recognized in the symptoms of Cushing's syndrome; as a rule treatment with over 50 mg cortisol or the corresponding equivalent doses of the derivatives for over 2 weeks results in an iatro-

genic Cushing's syndrome. The degree of the changes and the speed at which they develop are subject to wide individual variations.

Osteoporosis is the most severe side effect in long-term treatment. There is a correlation between the dose of cortisol and the duration of the treatment, but again there is such wide individual variation that some patients treated with average doses for over 10 years do not have clinically detectable osteoporosis, while other patients develop pathologic fractures after 2.5 years even with lower doses. The pathogenesis is only partly explained. It is related to the switchover of the metabolism from protein synthesis to carbohydrate production. It is also related to the actions of cortisol on calcium metabolism. Qualitatively and quantitatively inadequate matrix probably has some effect in this type of osteoporosis. Prophylaxis of cortisol-induced osteoporosis is as uncertain as its pathogenesis. Movement, pressure, and traction exerted by the muscular tone on the bones are the greatest stimuli for building bone and the best means of preventing osteoporosis. Very high doses of androgens and anabolic steroids, usually in the virilizing range, can convert a negative nitrogen balance into a positive one. The metabolic changes due to cortisone are not, however, abolished. It can be shown histologically that the effects of cortisone can be reduced but not abolished by testosterone. It is difficult to assess to what extent cortisone osteoporosis can be clinically diminished or delayed by anabolic drugs. It is generally accepted that anabolic medication is not certain to prevent cortisone osteoporosis. An optimal nutritional state is reached with additional calcium medication, but the organism absorbs less calcium when the endogenous supply of calcium rises, and it is questionable just how much can be achieved with increased intake. Apart from the cortisone osteoporosis, aseptic necroses have frequently been observed in the parts of the skeleton most exposed to pressure, such as the head of femur and humerus. Charcot's joints, with the disappearance of cartilage, have also been observed after local cortisol treatment. The anti-anabolic action of cortisol leads to a standstill in growth and maturation in children. This is reversible, however, after withdrawal of the cortisol.

The increase in gluconeogenesis caused by cortisone in the usual anti-inflammatory dosage results in an increase of 10–20 mg% in the blood sugar in healthy subjects. The increased amounts of glucose produced are deposited as glycogen and fat under the influence of increased insulin secretion. Cortisol causes potential diabetes to become subclinical or manifest only when the insulin reserve of the pancreas is inadequate (so-called "steroid diabetes"). One should not refrain from giving cortisol to the diabetic if there is a definite indication, but the increased need for insulin must be met. The effects on the psyche again vary widely individually and are dependent on the premorbid personality. They vary from mild euphoria or depression to all degrees of schizophrenia like symptoms and the "acute exogenous reaction type". Finally, the disfiguring changes in the face, in the body stature, and in the skin, with rubeosis, acne, and hirsutism can be a severe psychological burden, particularly to female patients. Peptic ulcer is a side effect of cortisol which curiously does not occur in Cushing's syndrome. Cortisol does not promote the secretion of hydrochloric acid or of pesin but the incidence of both gastric and duodenal peptic ulcers is increased during cortisone therapy. This is probably attributable to influence on the production of the protective mucin by the gastric mucosa.

Other untoward side effects are the increased risk of infection, acute pancreatitis and pancreatic necrosis, influence on the nervous system, intracranial pressure leading to the so-called "pseudotumor cerebri", changes in dentine and dental enamel, changes in the eye, cataract of the subcapsular region of the lens, increased intraocular pressure leading to glaucoma, and after local application trophic corneal disorders (for literature see KAISER, 1973).

Secondary adrenocortical insufficiency is an unavoidable result of effective long-term cortisol therapy. An adrenal insufficiency lasting for several days is always seen after treatment with over 60–75 mg of cortisol for more than one week, or after 15 mg prednisone daily in 3–4 doses. First the adrenals secrete only the basal amounts of cortisol and later they become less responsive to ACTH, i.e. there is first an inhibition of the hypothalamus, followed by changes in the adrenal cortex itself. The response usually returns in 1–2 days. The adrenocortical secretion does not exceed the basal values, however, since the pituitary has no ACTH reserve. A maximal adrenal atrophy is reached in 15–20 weeks with a dose of 60 mg or more of cortisol. This state often lasts up to 6 months. Stress is dangerous for the patients during this period. There is secondary adrenal insufficiency, and there have been fatalities. The degree and duration of the secondary adrenal insufficiency is dependent to some extent on the duration and dosage of the steroid medication and possibly also on the particular compound when amounts high enough to exert an anti-inflammatory effect are given, but individual factors play a very large part. The

localization of the disturbance does not seem to be the same in all patients. In many patients, there is a temporary phase of hyporeactivity of the adrenal cortex (GRABER, 1965), and the rise in the ACTH concentration in the plasma sometimes precedes that of the plasma corticoids by a few months. In other cases, a disturbance in ACTH secretion is dominant (CARREON, 1960). Cases are also known in which no change in adrenal function can be detected after years of treatment with high doses of steroids (JASANI, 1967). An intravenous injection of cortisol hemisuccinate should always be kept ready during any operation on a patient who has received corticosteroids up to 6 months previously. A "preventive steroid protection" is not advisable in general, since only 5–10% of patients treated with cortisone react inadequately to surgical stress. The secondary adrenal insufficiency can present as tiredness, anorexia, malaise and tendency to collapse. Adrenal atrophy does not occur after ACTH therapy, but the ACTH reserve in the pituitary is diminished. Incidents, however, seem to occur rather less frequently. To prevent secondary adrenal insufficiency it is advisable to reduce the cortisol or its derivatives step by step, by withdrawing first the nightly dose and then the evening dose, finally giving a dose in the morning only. This procedure re-establishes the daily rhythm of cortisol secretion. Depot-ACTH given intramuscularly for 3–5 days after the withdrawal of cortisone restores the capacity of the adrenals to respond, but little is actually gained since ACTH secretion by the pituitary is inhibited.

It has recently been recommended that high pharmacological doses of cortisone be given only once daily in the morning, or a synthetic glucocorticoid with a long half-life intermittently every other day in a single dose in the morning (DUBOIS, 1963; HARTER, 1963; GRANT, 1965; MACGREGOR, 1969; MARTIN, 1969), or that steroids be administered on three consecutive days of one week. The ACTH secretion should start again after 12 or 36 hours and adrenal atrophy is thought to be prevented by these methods of administration. The pharmacological action is thought to be adequate during this time when high doses are used. The experience obtained so far with this intermittent steroid therapy varies, however, and no definite conclusion can yet be drawn as to whether the risk of a secondary adrenal insufficiency can in fact be considerably reduced without diminishing the therapeutic action of the steroid compound at the same time. Monitoring by means of the insulin plasma cortisol test and the methyrapone test has also revealed disorders in the hypothalamo-pituitary-adrenal system after *intermittent* steroid treatment (MARTIN, 1968; MALONE, 1970).

Secondary adrenal insufficiency after long-term cortisone therapy is best avoided or reduced by gradual reduction of the dose of cortisone by 25–10 mg weekly or of the cortisone derivatives by the corresponding amounts.

A second withdrawal syndrome worth mentioning is the flare-up of the inflammatory manifestations. This occurs particularly frequently in rheumatoid arthritis. Mild exacerbations disappear after a few days. In more severe instances, the cortisone dosage must be increased again, and an attempt made to reduce it even more slowly, possibly assisted by other antirheumatic agents.

A large number of cortisol derivatives have been examined for advantages over the genuine hormone cortisol in pharmacological use. The first major breakthrough was achieved with the artificial steroids prednisone and prednisolone, which have a greatly reduced sodium-retaining effect as compared to cortisol, due to a double bond 1–2 at the A ring. Further modifications such as methylation and fluoridation at atoms 9, 6 and 16 have produced more potent preparations per unit of weight but not improved the ratio of desired to undesired effects. Thus, prednisone is currently the most economical derivative of cortisol and therefore the standard drug for anti-inflammatory treatment. The anti-inflammatory action has never successfully been separated from the gluconeogenetic and catabolic actions although the hypothalamic side effects and the peripheral metabolic effects have been successfully dissociated. The preparation 6-dehydro-16 methyl cortisol appears to have an inhibitory effect on the hypothalamus without having any essential peripheral metabolic actions. It is of therapeutic interest as a therapeutic agent or at least as a palliative drug in Cushing's syndrome.

The preparations triamcinolone, prednisolone, dexamethasone, betamethasone and paramethasone have basically the same qualitative actions as prednisone except for the mineralocorticoid effect. Their half-lives are longer and may very well be related to the varying binding to the carrier proteins in the plasma.

An exception within the group of cortisol derivatives, is the preparation 9-alpha-fluorocortisol, which has a very pronounced mineralocorticoid action in addition to its marked glucocorticoid effect. It is well absorbed orally and replaces aldosterone for substitution in primary adrenal insufficiency. In a dosage of 0.1–0.3 mg daily it can be useful in the treatment

of various hypotensive states and especially of orthostatic hypotension (HICKLER, 1959; LEGELER, 1971).

g) Forms of Administration

Oral administration of cortisol derivatives in tablet form is the route of choice. A continuous intravenous infusion of cortisol or of prednisolone hemisuccinate or phthalate is given during operations. In emergency these preparations can also be administered intramuscularly, but the onset of action is slower. Local external application on the skin and mucosa is also possible and advantageous (equivalent dosage schedule is given on p. 1073).

h) Indications for Treatment with Cortisone

Cortisone is a potent pharmacological agent, but the drawbacks must never be overlooked. Prophylaxis of the damage caused by cortisone is hardly possible and the risk of untoward side effects can never be eliminated completely. Thus the doctor must be aware of his responsibility and weigh the danger of the condition to be treated carefully against that of the therapy. In vital indications or in disabling diseases, e.g., pemphigus, lupus erythematosus and panarteritis nodosa, the risk of osteoporosis has to be accepted. Even if osteoporosis becomes manifest, it is sometimes correct to continue cortisone therapy. On the other hand, the decision to start cortisone treatment for a skin condition which is troublesome but not potentially fatal entails severe consequences as the treatment may be long-term. The following can be taken as a guiding rule: treatment in short bouts of a few days or at the most weeks is permissible in diseases where only the subjective symptoms are severe, but long-term treatment or sporadic treatment which might extend into a long-term therapy is only warranted if there is a vital indication. Doctor and patient must both be aware of the risks and be prepared to accept them. The decision as to where to draw the line must be made individually for each case.

2. Anabolic Therapy

a) Mode of Action

In addition to its effects on the secondary sexual characteristics of the male and a virilizing action on the women, the male sex hormone, testosterone, promotes protein synthesis in the liver and periphery in both males and females. It promotes growth, but as it stimulates skeletal maturation at the same time, growth comes to a premature standstill after a temporary acceleration (Chap. XIX, p. 1032).

Steroid compounds, mainly derivatives of testosterone, which promote protein synthesis without the virilizing properties of testosterone, or with less of these properties, have been under investigation for the past 20 years. A whole series of derivatives of testosterone or progesterone with an improved ratio of protein synthesis-promoting action, the so-called anabolic effect, to androgenic action have been successfully produced. Many anabolic agents are now commercially available (KRÜSKEMPER,

Table 4. The most important indications for cortisone and its derivatives (in parenthesis: "only in special conditions")

Allergic diseases
Anaphylactic shock
Serum sickness
Status asthmaticus (asthma bronchiale)
Dangerous insect bites
Urticaria
Angioneurotic edema
Rheumatic and other inflammatory tissue diseases
Acute rheumatic fever with carditis
(Rheumatoid arthritis)
Lupus erythematosus disseminatus
Periarteriitis nodosa
Skin diseases
Pemphigus
Exfoliative erythroderma
Dermatomyositis
(Certain allergic dermatitides)
Blood diseases
Acquired hemolytic anemia
Idiopathic thrombopenia
(Leukemia)
(Lymphogranuloma)
Gastrointestinal diseases
Colitis ulcerosa
Enteritis regionalis
Sprue
(Hepatitis)
Kidney diseases
(Nephrosis)
Infectious diseases in combination with antibiotics
Meningitis tuberculosa
Lung diseases
Sarcoidosis and other granulomatoses
(Tuberculosis)
Eye diseases
Certain allergic and inflammatory eye diseases
Organ transplantations
For immunosuppressive therapy in combination with azothiaprine
Malignancy
For symptomatic palliative treatment, especially hypercalcemic syndrome

Table 5. Generic names and equivalent dosages of the most-used anti-inflammatory steroids

Cortisone	25 mg
Cortisol (Hydrocortisone)	20 mg
Prednisone	5 mg
Prednisolone	5 mg
16-Methylen-prednisolone	10 mg
6α-Methyl-prednisolone	4 mg
Triamcinolone	4 mg
Paramethasone	2 mg
Dexamethasone	0.75 mg
Betamethasone	0.75 mg
Water-soluble preparations:	
Cortisol hemisuccinate	
Paramethasone-disodium phosphate	
Dexamethasone phosphate	
Prednisolone hemisuccinate	
Prednisolone-Na tetrahydrophthalate	
Methyl-prednisolone hemisuccinate	

1965). Complete elimination of the androgenic action has never been achieved. Great caution is necessary in extrapolating conclusions drawn from their actions in animals to man since it is not possible to predict how a compound which has acted favorably in animals will affect the human. In addition, the sensitivity to the virilizing properties in the anabolics varies widely from one woman to another, so that it is only possible to give tentative estimates of borderline doses with which there is generally no risk of virilization. Children, premature babies, and the fetus are especially sensitive to anabolic drugs, which are therefore contraindicated in pregnancy.

Anabolic agents are recommended in chronic tiredness, to improve the general condition and to increase the appetite and weight, particularly in chronic illness and in advanced age. They have been credited with shortening convalescence after operations and after fractures and also with shortening the duration of acute and chronic infections. It has also been claimed that they improve the condition in cachectic disease, improve osteoporosis, reduce the catabolic action during long-term cortisone therapy, and improve delayed growth and retarded weight gain in children.

The indications, however, are generally much too liberal. Anabolic agents cannot increase the protein synthesis beyond given limits when protein intake is inadequate or proteins are lost, i.e. in amino-acid deficiency. It has been demonstrated that a negative nitrogen balance can become positive under the influence of anabolic drugs only when there is a constant low protein intake. Unlimited protein intake can achieve the same results. Protein synthesis is regulated by physical activity, nutrition, and different hormones (growth hormone, insulin). Adequate nutrition is, however, a primary requirement. Anabolics should therefore only be employed when simpler and less dangerous measures have failed.

Until recently the only indication based on confirmed facts was thought to be postmenopausal and senile osteoporosis. However, there is currently some controversy about the pathogenesis of osteoporosis again, and the value of anabolic agents is being questioned for reasons based on histometric measurements in vitally stained series of bone biopsies. The hypothesis of increased skeletal breakdown rather than inadequate osteoblastic activity is currently prevalent. Nevertheless, subjective improvement is achieved with anabolic agents in osteoporosis, possibly by an effect on the muscles, and anabolics are still indicated along with other measures in crippling osteoporosis, despite the uncertain theoretical bases.

The use of anabolic agents to promote growth in dwarfism or in delayed growth, and the great caution necessary with this treatment, which should only be undertaken by the very experienced doctor, are discussed in Chap. XIX.

A nitrogen deficit and calcium loss after multiple or severe fractures with prolonged immobilization is usually best treated with an adequate intake of proteins, calories, and calcium, and exercises even for patients confined to bed. Mobilization as quickly as possible with auxiliary measures is the most effective method. Nevertheless, the use of anabolic agents in addition is occasionally justified. There is no evidence that anabolics, including testosterone, can shorten the surgical or medical convalescent period, but there are no controlled prospective studies. It is stated that most anabolic drugs effectively improve anorexia, tiredness, and other subjective symptoms. Only a few controlled comparative studies are available (WATSON, 1959). The appetite does appear to be improved in some patients, and there has been a short trial of anabolic agents as appetite stimulants in adults in whom other drugs have failed.

It must be borne in mind when anabolic drugs are given to geriatric patients that androgens raise cholesterol and beta-globulins, which promote coronary sclerosis.

Convalescence is not a general indication for anabolics. True convalescence has a rapid course and cannot be accelerated. Delayed convalescence is usually due to a second unknown disease, and loss of appetite due to psychological factors, such as anorexia nervosa, is not affected by anabolics.

Preparations mixed with vitamins are especially questionable since they are offered as roborants and the character of the anabolic substance is hidden. "General exhaustion", "school tiredness", and "spring tiredness" should be examined for underlying causes and are not indications for hormone therapy. There are less harmful drugs which will have an equally good placebo effect.

The use of anabolic drugs in renal failure to reduce the urea by protein synthesis has no clinical (SCHWARTZ, 1968) or experimental (GERBER, 1961) basis. On the contrary, they should be used with the utmost caution in renal diseases because of the sodium retention and the formation of edema.

Whether there is a causal relationship between long-term anabolic steroid therapy and development of hepatocellular carcinoma has still to be proved true or false (JOHNSON, 1972).

b) Indications and Contraindications

All anabolic androgens methylated at the atom 17 have a more or less cholestatic action on the liver. With the less harmful of these compounds only a temporary increase in the retention of bromsulphthalein is demonstrable. These effects on the liver are generally reversible. However, fatalities due to hepatic failure during the use of some anabolic steroids have been described.

Virilization is the most frequent side effect; it is not dangerous but is a burden to women. It is usually irreversible even after the anabolic treatment has been discontinued. The maximum nonvirilizing doses for long-term treatment are: for metandrostenolone (Dianabol) 5 mg daily, for nandrolone decanoate (Decadurabolin) 50 mg i.m. every three weeks, for methenolone nantate (Primobolan depot) 50–100 mg i.m. every 2–3 weeks depending on the body weight. For oral methenolone acetate (Primobolan) the maximum dose is 10–20 mg daily. Damage can be avoided with these doses even in hypersensitive women, but mild side effects are nevertheless still possible. Changes in the voice arise particularly frequently even with correct doses in sensitive women. The voice can change within days. Laryngeal growth is not necessary for this. Tissue changes in the vocal cords develop under the influence of androgens, resulting in an altered vibration. The voice becomes hoarse, breaks, and finally becomes a chest voice. The changes in the voice are irreversible.

The increase in the libido due to the action of androgens varies considerably. In some cases it is only stimulation while in others it can be very distressing. Hirsutism, acne, amenorrhea, and growth of the clitoris are also possible with doses within these limits in sensitive women, even though they do not generally arise with the recommended dosages.

The damage caused by extensively used anabolic agents is probably greater than the benefit gained. Aplastic anemias, myelofibrosis, and myelid metaplasia are further indications for testosterone or anabolic agents, as they promote erythropoiesis. The side effects, in particular the virilization, must be accepted in these serious diseases, and testosterone in high or in very high doses is indicated for both men and women.

3. Progesterone in Respiratory Dysfunction

Progesterone increases alveolar ventilation in pregnancy and in the luteal phase of the cycle, and also in men when given in pharmacological doses. It has been used in high doses in obstructive pulmonary emphysema (TYLER, 1960) and also in hypoventilation of severe obesity (Pickwick syndrome). Ventilation can be improved with 100 mg progesterone daily i.m.; the hypercapnia is normalized and the respiratory acidosis disappears (LYONS, 1968).

It is still undecided whether treatment with progesterone has a favorable effect on scleroderma (KORTING, 1967).

4. Glucagon

a) In Heart Failure and Arrhythmias

In high pharmacological doses glucagon has an effect on the circulatory system. There is a slight positive chronotropic effect on the sinus rhythm and a positive inotropic effect on the myocardium, and the cardiac output is increased. It accelerates auriculoventricular conduction in the heart and slightly decreases the peripheral resistance.

These effects on the heart are not dependent on catecholamines and are not influenced by beta-blocking agents. The positive inotropic effect is independent of and additive to that of digitalis. It activates adenylcyclase, so supplying ATP, and has a glycogenolytic effect on the liver via cyclic AMP.

The dosage is 5 mg i.v. followed by an i.v. infusion of 2 mg/h in 5% glucose solution over some hours or days for the following complications: heart failure in acute arrhythmias or metabolic disorders where catecholamines or digitalis are contraindicated. Intoxication by digitalis or beta-blocking agents is said to be an absolute indication. Side effects are nausea and vomiting, while glycemia and electrolytes are not significantly changed. So far, little or

no influence of glucagon on chronic heart failure has been proved.

This kind of cardiac treatment is still in the experimental phase; it involves high costs and the results so far are encouraging but not conclusive. There are some misgivings associated with the fact that *in vitro* the positive inotropic effect can only be demonstrated in the healthy and not in the damaged papillary muscle (EPSTEIN, 1970).

Table 6. Indications for glucagon in circulatory disorders. (After ROBERT and HUMAIR, 1970)

Generally, it has to be regarded as an adjunct to standard therapeutic measures or for use when these are contra-indicated

Acute heart failure, cardiogenic shock or congestive heart failure complicated by
1. *Dysrhythmias*
Bradycardia, e.g. auricular fibrillation
Atrioventricular block
Ventricular extrasystoles, increased ventricular automatism
2. *Metabolic disorders*
Hypokalemia
Hypoxia
Renal failure
3. *Drug intoxications*
Beta-blocking agents
Antiarrhythmic agents
Digitalis

b) In Paget's Disease

Glucagon given in i.v. infusions (0.2–0.8 mg/h) seems to have a beneficial effect on bone pains as well as on the metabolic parameters of the disease. There is a fall in plasma alkaline phosphatase and in urinary calcium and hydroxyproline excretion. The mechanism of this action is not yet known. Release of calcitonin or pyrophosphatases might be involved (CORDON, 1971).

Monographs on Endocrinology

Editors: F. Gross, A. Labhart, M. B. Lipsett, T. Mann, L. T. Samuels, J. Zander

Volume 1
S. Ohno: Sex Chromosomes and Sex-linked Genes
33 figs. X, 192 pp. 1967
Cloth DM 38,—; US $14.70
ISBN 3-540-03934-1

Volume 2
K. B. Eik-Nes, E. C. Horning: Gas Phase Chromatography of Steroids
85 figs. XV, 382 pp. 1968
Cloth DM 38,—; US $14.70
ISBN 3-540-04277-6

Volume 3
F. G. Sulman: Hypothalamic Control of Lactation
In collaboration with M. Ben-David, A. Danon, S. Dikstein, Y. Givant, K. Khazen, J. Mishkinsky-Shani, I. Nir, C. P. Weller
58 figs. XII, 235 pp. 1970
Cloth DM 52,—; US $20.10
ISBN 3-540-04973-8

Volume 4
U. Westphal: Steroid-Protein Interactions
144 figs. XIII, 567 pp. 1971
Cloth DM 86,—; US $33.20
ISBN 3-540-05312-3

Volume 5
J. Müller: Regulation of Aldosterone Biosynthesis
19 figs. VII, 137 pp. 1971
Cloth DM 36,—; US $13.90
ISBN 3-540-05213-5

Volume 6
K. Federlin: Immunopathology of Insulin
Clinical and Experimental Studies
53 figs. XIII, 185 pp. 1971
Cloth DM 49,60; US $19.10
ISBN 3-540-05408-1

Volume 7
E. W. Horton: Prostaglandins
97 figs. XI, 197 pp. 1972
Cloth DM 58,—; US $22.40
ISBN 3-540-05571-1

Aspects of Neuro-endocrinology

V. International Symposium on Neurosecretion, 20.-23. August 1969, Kiel
Editors: W. Bargmann, B. Scharrer
145 figs., 1 portrait. XI, 380 pp. (41 pages in French, 46 pages in German). 1970
Cloth DM 98,—; US $37.80
ISBN 3-540-04772-7

Handbuch der experimentellen Pharmakologie/ Handbook of Experimental Pharmacology

Heffter-Heubner. New Series

Herausgeber/Editors:
O. Eichler, A. Farah, H. Herken, A. D. Welch

Volume 14
The Adrenocortical Hormones
Their Origin, Chemistry, Physiology, and Pharmacology
Part 1: Editor: H. W. Deane
224 figs. XXIV, 738 pp. 1962
Cloth DM 260,—; US $100.10
ISBN 3-540-02830-7
Part 2: Editors: H. W. Deane, B. L. Rubin
XII, 214 pp. 1964
Cloth DM 75,—; US $28.90
ISBN 3-540-03146-4
Part 3: Editors: H. W. Deane, B. L. Rubin
36 figs. XII, 452 pp. 1968
Cloth DM 152,—; US $58.60
ISBN 3-540-04147-8

Volume 23
Neurohypophysial Hormones and Similar Polypeptides
Editor: B. Berde. 150 figs.
XX, 967 pp. 1968
Cloth DM 192,—; US $74.00
ISBN 3-540-04149-4

Volume 25
Bradykinin, Kallidin and Kallikrein
Editor: E. G. Erdös
Technical Editor: A. F. Wilde
117 figs. XIX, 768 pp. 1970
Cloth DM 248,—; US $95.50
ISBN 3-540-04847-2
