***Clinical Presentation.*** Oral malignancies typically present as visible lesions ranging from deep ulceration to fungating exophytic growth. They may be white or red compared to normal mucosa (Fig. 16-8). Cancers tend to be firm and thick compared to normal surrounding tissue when palpated. Malignant lesions may be painless, but more commonly are the source of deep persistent pain which may be referred to the ipsilateral ear. Bleeding is a common feature, attributed to neovascularity of malignant angiogenesis and fragility of feeding vessels. Loosened teeth or poorly fitting dentures may draw attention to alveolar ridge lesions. In some cases, a firm submandibular or upper jugular lymph node may be the presenting sign of OSCC.

## Diagnostic Evaluation and Clinical Staging

A thorough history must be obtained to initiate the workup of an oral cancer, ascertaining the time course of appearance and progression of the lesion, exposure to known risk factors and pertinent medical history. A complete head and neck exam follows with attention to the physical features of the lesion (precise location, dimension, thickness, friability) as well as screening for possible second lesions. Visualization requires good illumination, gauze, and instruments to move the lips and the tongue in order to see all surfaces thoroughly. Palpation is of great importance to detect submucosal extension and tumor thickness. Careful attention to pertinent lymph node basins in the neck follows. Bimanual palpation of the submental and submandibular regions is quite helpful to discern the presence of small but firm nodes in this region. Posteriorly positioned lesions of RMT, posterolateral tongue, or posterior FOM, because of their less accessible location in the oral cavity, are sometimes difficult to assess (Fig. 16-9). Sensory nerve distribution here is less precise making it difficult for some patients to accurately identify the source of cancer pain. Gag reflex and tongue resistance to manipulation further hinders efforts by the clinician to locate visible posterior tumor or precursor lesions on oral screening evaluations. These tumors will often remain unnoticed until the patient presents with progressive persistent pain, dysphagia and weight loss, referred otalgia, or trismus.

Assessing mandibular invasion by physical exam alone can be challenging. Involvement of the maxilla may also occur, and masticator space involvement is a particularly poor prognostic factor.[60] Physical mobility of the tumor mass relative to the mandible can be judged by bimanual manipulation which may be facilitated by general anesthesia in some cases. Imaging by CT may help to clarify the status of bony involvement. However, the sensitivity of CT for determining bony involvement is only 50%. Lane and others, in a review of patients treated for cancer of the RMT over a 14-year period, found that bony invasion was not

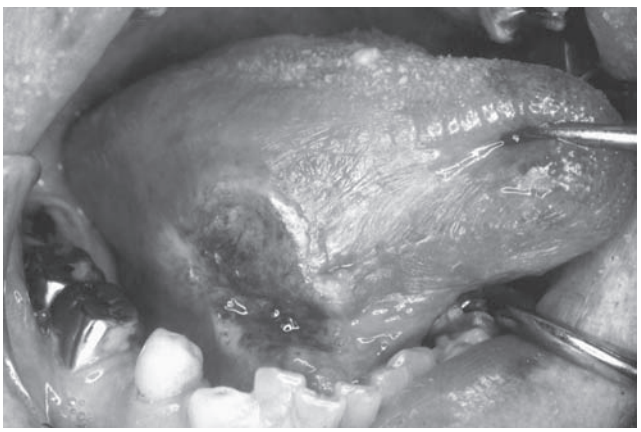

**FIGURE 16-8.** Ulcerated, flat, mostly endophytic carcinoma of the lateral border of the tongue.

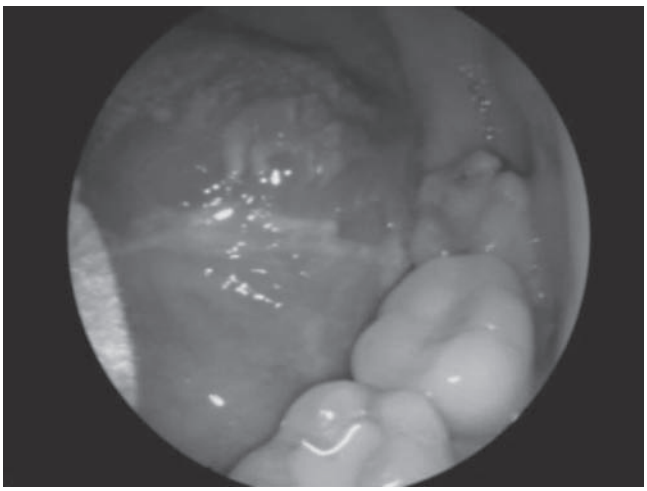

**FIGURE 16-9.** Erythroleukoplakia on the posterolateral oral tongue.

(c) 2014 Wolters Kluwer. All Rights Reserved.

identified correctly by radiograph in 27% of patients with preoperative CT scans.[61] The reported accuracy of MRI in detecting mandibular invasion in the literature has also been mixed.[62–64] PET scanning may help with detection of invasion in the setting of intact dentition, whereas MRI appears to be superior for detection of marrow involvement (Fig. 16-10).[51]

***Radiologic Evaluation.*** The timing and type of radiographic imaging selected for workup of oral cancer depends on several issues. Small surface lesions may not require any imaging since they will not be visible and the risk of nodal spread is small. CT, MRI, and PET scanning can help delineate the extent of larger lesions, particularly pertaining to deep tongue and mandibular invasion as well as nodal metastasis. The timing of PET scanning is particularly worthy of comment since recent biopsy may result in inflammatory metabolic activity in regional nodes rendering a false-positive uptake that could be interpreted as indicative of metastatic tumor. CT with intravenous contrast is often the first choice in this setting, as it provides excellent visualization of bone/soft tissue borders, particularly important in oral cavity lesions. Contrast enhancement is present in many tumors due to increased blood supply. MRI is the imaging modality of choice when evaluating soft tissue lesions and may be more useful for demonstrating the extent of the primary lesion. In particular, MRI provides superior imaging of lesions of the oral tongue and the tongue base. For lesions where there is a question of base of skull involvement, MRI likewise provides superior imaging.

PET with fluorodeoxyglucose (FDG) is now a standard component of the staging of head and neck cancers and in screening for second primary cancers and regional and distant metastatic disease. However, the contribution of PET imaging to the preoperative workup for staging the clinically N0 neck remains uncertain and may not be a replacement for staging neck dissection.[65,66] Schwartz and others, in a prospective series comparing pretreatment CT alone with fusion PET-CT in patients with head and neck cancer, found that PET-CT was superior in identifying regional lymph node metastasis. Although the majority of these patients had advanced-stage disease (stage III or IV), their findings provide evidence to support including functional PET imaging in the preoperative workup.[67] PET/CT scanning promises increased sensitivity for detection of distant metastatic disease over that provided by conventional CT scanning.[68] As the rate of synchronous primary cancers may range from 2.6% to 15%, a systemic workup is of importance preoperatively, particularly for patients who have been smokers. Again, the relative value of PET/CT compared to panendoscopy for detection of second primary cancers of the upper aerodigestive tract is yet to be determined.[69,70]

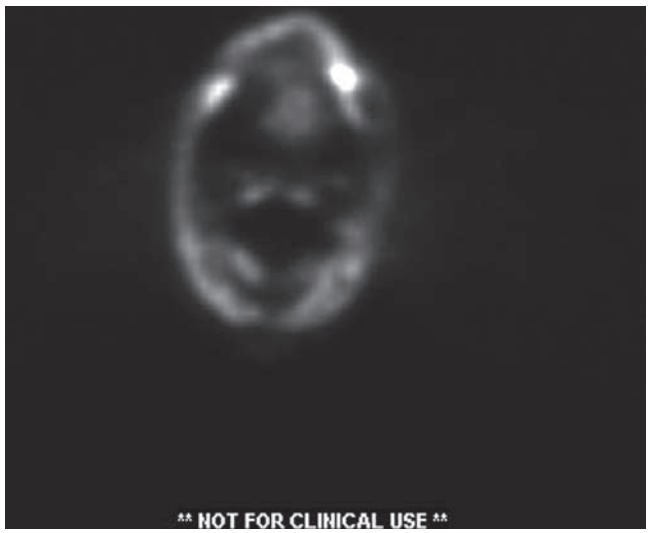

**FIGURE 16-10.** FDG-PET scan showing high metabolic uptake in the marrow space of the left hemimandible.

***Biopsy.*** An incisional biopsy to confirm the diagnosis of a suspicious lesion is mandatory. It may be necessary to sample several areas if there are regions with varying appearance. Because of the highly specialized histologic criteria for classification of the stages of oral mucosal premalignancy and the spectrum of minor salivary gland tumors, the experience of the pathologist reading the biopsy material is a key factor in proper workup. Biopsy of most sites within the oral cavity is feasible in the office under local anesthesia when the patient has even modest ability to cooperate.

***Tumor Staging.*** The stage of oral cavity cancers is based on the greatest dimension of the surface extent. A tumor may be staged T4 due to deep tongue, soft tissue, or bone invasion regardless of surface dimension (Table 16.2). Staging for nodal metastasis is identical to that of other head and neck sites. T and N stage are both excellent prognostic factors in most clinical series with good delineation between stage categories.[3,71] However, the UICC sixth edition staging categories of IVa versus IVb and T4a versus T4b did not differentiate between statistically different subpopulations in a recent report of 300 OSCC patients indicating a weakness in distinguishing between low- and high-risk advanced tumors using this schema.

# MANAGEMENT STRATEGIES

## Pretreatment Considerations

Several factors must be taken into consideration when choosing a management strategy for the patient with oral cancer. General physical health and functional status are important in determining the suitability of the patient for both surgical and nonsurgical approaches. This includes evaluating and optimizing comorbidities and the nutritional status of the patient. The patient's ability

**TABLE 16.2 T Staging of Oral Cavity Cancer**

| | |
|---|---|
| Tx | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| Tis | Carcinoma *in situ* |
| T1 | Tumor ≤2 cm in greatest dimension |
| T2 | Tumor >2 cm but not >4 cm in greatest dimension |
| T3 | Tumor >4 cm in greatest dimension |
| T4 (lip) | Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, skin of face (chin, nose) |
| T4a (oral cavity) | Tumor invades adjacent structures (cortical bone, deep [extrinsic] muscle of tongue, maxillary sinus, skin of face) |
| T4b | Tumor invades masticator space, pterygoid plates, or skull base, or encases internal carotid artery |

to undergo extensive surgery, cooperate with rehabilitation, and withstand changes in safe and efficient swallowing must be considered. The expectations of the patient for postoperative quality of life (QOL) must also be considered, particularly pertaining to cosmesis, articulation, and the ability to eat a normal diet in social situations. When tumor factors prevent adequate oral intake prior to treatment resulting in weight loss and debility, placement of a gastrostomy tube may be indicated. Several weeks of hyperalimentation are required to reverse starvation and promote anabolic enzymes needed for wound healing. An evaluation of cardiovascular health is also required for any patient undergoing surgery, particularly in cases requiring a more complex reconstruction, such as free tissue transfer. In fact, severe peripheral vascular disease may preclude microvascular reconstruction because of a lack of suitable recipient vessels in the neck.

Age alone is not considered a contraindication to surgery; however, medical comorbidities are important predictive factors for postoperative complications and overall survival, at any age.[72] In addition, longer operative times and large fluid shifts have been shown to correlate with an increased incidence of postoperative complications in head and neck cancer patients.[73] Assessing the cardiovascular fitness of patients preoperatively is essential. A thorough preoperative dental evaluation is recommended for patients undergoing treatment for oral carcinoma. For the surgical patient, this may include consultation with a prosthodontist in preparation for management of a postsurgical defect. For those patients who may require radiation therapy, an assessment of dental status with needed extractions or restorations is highly recommended prior to the initiation of radiation in order to reduce the risk of osteoradionecrosis (ORN). Furthermore, pretreatment consultation with other members of the multidisciplinary team, including speech language pathologists, medical and radiation oncologists, and social workers help prepare the patient and the caregivers for the chosen management strategy.

Finally, an understanding of the patient's social history is relevant when choosing among treatment modalities, particularly in those advanced cases where multidisciplinary support is necessary. These patients benefit from extended support from family and friends, home health care assistance, transportation resources, and help with smoking and alcohol cessation. In an analysis of 213 patients diagnosed with head and neck cancer, Chan and others demonstrated that nearly half continued to smoke after diagnosis or during treatment.[74] As patients who continue to smoke are at increased risk for second primary tumors, following through with a smoking cessation program is of paramount importance.

## Management Strategies: Selection of Treatment of the Primary Lesion

Surgery is most often the treatment modality of choice for oral cancer. This is due to a number of factors. First, most oral cancers can be reached easily for excision using a transoral approach. Second, many oral excisions can be accomplished with satisfactory retention of function including speech and deglutition. Third, maxillodental bony structures interfere with transmission of ionizing radiation complicating the delivery of primary external beam radiation. Air–tissue interfaces within the mouth and involuntary mobility of the tongue and the soft palate further challenge the delivery of therapeutic radiation. Alternative radiotherapy techniques such as the incorporation of interstitial brachytherapy have been extensively evaluated in the oral cavity and recently summarized by the European Brachytherapy Group.[75] In the absence of any randomized evidence, population-based analyses such as the Patterns of Care Study can help to direct treatment. This study reported results of 434 patients with oral tongue and FOM carcinoma clinical stages III and IV after a minimum of 2-year follow-up. Wallner et al. demonstrated that of a 120 patients treated with radiotherapy, 86% experienced an in-field relapse.[76] In contrast, 58 similar-staged patients treated with surgery and radiotherapy demonstrated an in-field relapse rate of only 27%.[76] Minor salivary gland cancers and sarcomas similarly have limited response to nonsurgical treatment. Patients with significant comorbidity unable to withstand the surgical experience may be best treated with primary radiation with the addition of chemotherapy depending on tumor and patient factors.

We will discuss the management for each subsite separately.

***Lip.*** In lesions that involve less than one-third of the lip, simple excision with primary closure offers acceptable oncologic and reconstructive results. Full-thickness excisions with margins of 8 to 10 mm are necessary. Proper alignment of the vermilion border is critical ensuring cosmesis and function. For lesions larger than one-third, but less than two-thirds the length of the lip, reconstructive options including an Abbe-Estlander "lip-switch" flap or a Karapandzic flap may be utilized. More extensive local advancement flaps including Gillies fan flaps or Bernard-Burow flaps may be employed for lesions greater than two-thirds the length of the lip. However, due to increased risk of an unacceptable cosmetic result, microstomia, and oral incompetence when advancement flaps are used for large lesions, free tissue transfer is now often chosen for reconstructing large defects (Figs. 16-11 and 16-12). To ensure oral competence after the use of an adynamic soft tissue free flap to reconstruct the lower lip, adjunctive procedures such as a fascial sling, palmaris longus sling, or temporalis muscle sling may be necessary.[77,78]

Brachytherapy can also be used effectively for lip squamous and basal cell carcinomas with local control rates >90% reported for T1–2 lower lip using both low-dose rate (LDR) implants (typically 60–68 Gy)[79–82] and high-dose rate (HDR) implants (40.5–45 Gy in 8–10 twice-daily fractions).[83] One comparative analysis based on a change in institutional practices demonstrated no significant difference in local control rates or complications between LDR-treated (median 60 Gy at 0.7 Gy/hour) and HDR-treated (median 36 Gy in 4 Gy twice daily over 5 days) patients with lip SCC.[84] Similar high local control rates (>90%) for T1–2 lesions have been reported with external beam orthovoltage radiation (median 45 Gy in 10 daily fractions).[85] Thus,

**FIGURE 16-11.** Squamous cell carcinoma recurring in reconstructed left upper lip and oral commissure after Abbe Estrandler lip switch reconstruction was performed at the time of initial tumor resection.

**FIGURE 16-12.** Reconstruction near total left upper lip resection involving the oral commissure and buccal mucosa using radial forearm free tissue transfer and microvascular anastomosis.

alternative techniques such as external orthovoltage and HDR brachytherapy techniques offer alternative treatment options for the medically unresectable patient or for lesions where functional preservation would be sacrificed by resection. Good to excellent cosmesis and function preservation has typically been reported after radiation with severe late complications (soft tissue and bone necrosis) found in <5% of patients. These risks are reduced with the fabrication of dental lead-lined appliances.[80]

The management of the neck in patients with lip cancer can often be expectant, as regional lymph node metastases occur in only 10% of patients. Elective neck dissection is warranted for higher grade, larger (T2 or greater and for thicker lesions >1 cm) and locally recurrent lesions.[80,85,86] Regional lymph node metastases adversely affect outcome and may decrease survival by 50%. The submental and submandibular nodal basins are the primary echelon drainage pathways. However, drainage may go to the intraparotid or jugular chain lymph nodes. In addition, whereas the upper lip has ipsilateral drainage to levels I to III, the lower lip has both ipsilateral and contralateral drainage to levels I to III.

***Buccal Mucosa.*** Surgical approaches for addressing buccal carcinoma vary with the size and location of the primary lesion. Small lesions may be excised with wide margins via a transoral approach. For less accessible, more extensive lesions, an open cheek-flap approach may be necessary. Later stage lesions may involve the mandible or maxilla, necessitating marginal/segmental mandibulectomy or partial maxillectomy. Reconstructive requirements depend on the extent of resection. For small lesions, primary closure or healing by second intention may be permissible. Rotation flaps of adjacent buccal mucosa may be used to help prevent trismus due to loss of flexibility of mucosal lining. Buccal fat can also be employed to fill in a mucosal defect while serving as a scaffold for reepitheliazation.[87] Larger, deeper defects may be addressed with regional flaps such as a temporalis muscle or temporoparietal fascial flap for bulk, with a mucosal skin graft. A pectoralis myocutaneous flap may be utilized in a similar fashion. Alternatively, a folded regional fasciocutaneous flap, such as a temporalis island flap may be used for both mucosal coverage and bulk.[88] Radial forearm free tissue transfer provides reliable, thin, pliable tissue for reconstruction of major buccal defects, especially those involving through-and-through tissue loss. For defects requiring composite resection with segmental mandibulectomy, free tissue transfer with an osteocutaneous flap is necessary. In situations where branches of the facial nerve are sacrificed with the resection, facial reanimation techniques may be employed.

Nonsurgical management options may also include interstitial LDR brachytherapy especially for lesions <5 cm and <1.5 cm for which excellent local control rates have been reported.[89,90] Tumors approaching or involving mucosa of the RMT or other surfaces adjacent to bone are contraindications for consideration of a brachytherapy implant. Lapeyre et al. described significant local control advantages of a looping LDR brachytherapy technique when compared to the use of parallel wire technique (5-year local control rate of 91% vs. 58%) The preferred technique loops one of the implanted ribbon of seeds posteriorly ensuring sufficient dose delivery to the posterior extent of the tumor.[90] The striking differences in local control rates speak to the insidious risk of tumor extension posteriorly in the buccal mucosa and extension into the masticator space.

The management of the neck in these patients is predicated on the dismal prognosis for patients with regional lymph node metastasis. In the MD Anderson experience published by Diaz and others, 5-year survival declined from 70% for N0 patients to 49% for N-positive necks.[91] Elective supraomohyoid neck dissection in N0 necks may be considered in these patients with plan to extend the area of dissection if clinical nodal disease is encountered during surgery. Finally, while primary radiotherapy may be considered for select patients who are not candidates for surgical resection, treatment is often unsuccessful with recurrence rates approaching 50%.[92]

***Floor of Mouth.*** Carcinomas of the FOM are centered anteriorly or laterally under the oral tongue. Early lesions involve the mucosa and may extend to underlying submucosal structures including sublingual salivary glands. These are amenable to simple excision to clear margins. Lesions may grow deep into the musculature of the FOM, including the genioglossus, the hyoglossus, and the mylohyoid and may involve the periostium alone or the substance of the mandible. More extensive lesions require a composite resection removing involved portions of the FOM musculature, the mandible, and the oral tongue. FOM tumors have a propensity to spawn early regional lymph node metastasis. In addition, perineural invasion through the inferior alveolar nerve may facilitate the spread of tumor to the skull base.

Surgical approaches to the FOM include transoral excisions for T1–2 lesions, with primary or split-thickness skin graft closure. The transoral approach can also encompass a superior marginal mandibulectomy (Fig. 16-13). Some surgeons advocate for

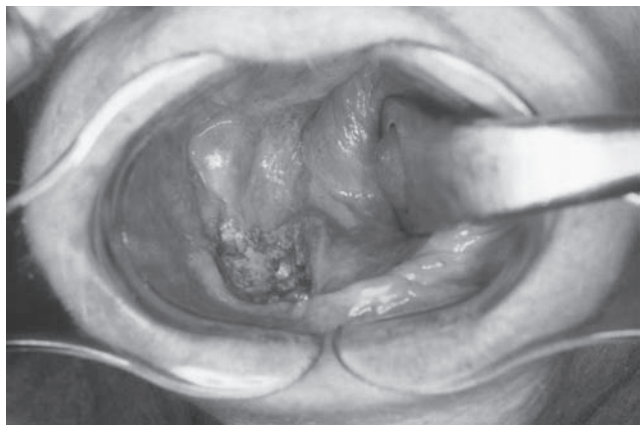

**FIGURE 16-13.** Ulcerated carcinoma of the floor of the mouth involving lower gum.

(c) 2014 Wolters Kluwer. All Rights Reserved.

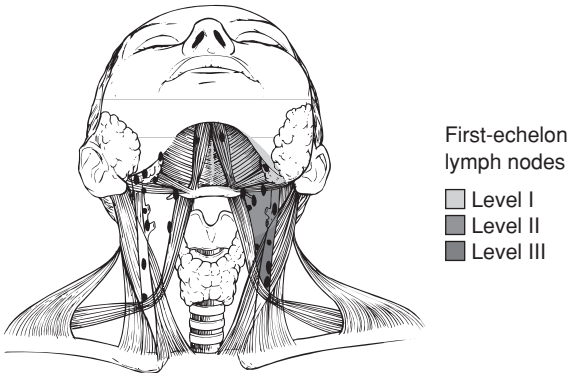

**FIGURE 16-14.** Mandibulotomy.

avoidance of the lip split, citing the ability to remove tumor and reconstruct even large defects through a transoral approach (in the absence of trismus).[93] However, in order to assure rigorous tumor resection to clear margins and facilitate accurate inset of reconstructive tissue, midline or paramedian mandibulotomy with mandibular swing provides excellent access to the FOM for more extensive lesions. We prefer to split the lip in midline and traverse around the chin pad using natural contours (Fig. 16-14). A recent study confirms a low rate of perception of disfigurement on the part of patients and associated problems with oral competency and lip sensation with the lip split approach.[94] Mandibulotomy may be fashioned to avoid injury to the mental nerve and its attachments to the lip. A step or V-shape cut provides enhanced stability for the repair with plates (Fig. 16-15). Invasive lesions require marginal mandibulectomy if there is only periosteal or superficial cortical bone involvement, or segmental mandibulectomy if there is bony invasion (Fig. 16-16).[95,96] Marginal mandibulectomy may be sagittal (inner table only), horizontal (upper portion only), or some combination. If the remaining bony bridge is thin, the placement of a reconstruction plate to reinforce it may prevent subsequent fracture. If mandibulectomy is anticipated, the mesial extent of planned resection should be

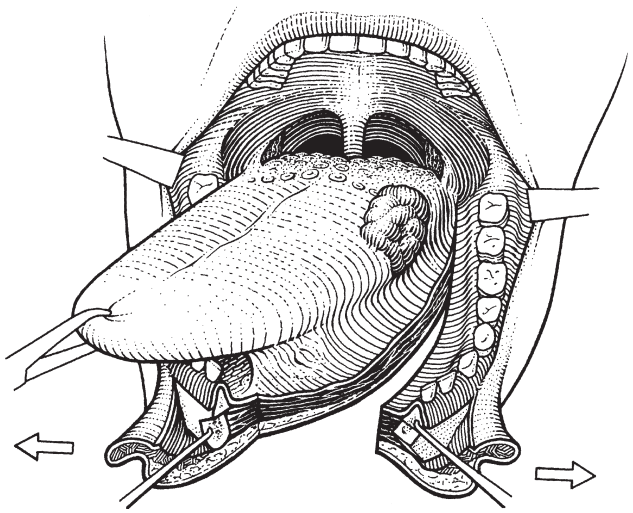

**FIGURE 16-15.** Mandibulotomy.

the location of the entry osteotomy so as to preserve as much healthy native bone as oncologically possible. The reconstructive options for FOM defects range from split-thickness skin graft with a bolster for small lesions, to regional pedicled flaps and free tissue transfer for larger defects with soft tissue or bony defects. Regardless of the reconstructive option, obtaining a watertight seal is critical in preventing a postoperative fistula, which can lead to wound break down, as well as hardware and great vessel exposure. Recent advances in free tissue transfer include the use of two flaps simultaneously (fibula and radial forearm) for large through-and-through defects[97] and anterolateral thigh flaps particularly when more bulk is desired.[98]

For the medically unresectable FOM carcinoma, nonsurgical management with radiotherapy is an option. Institutional series have demonstrated high local control rates with the historic use of an intraoral cone technique[99] as well as interstitial brachytherapy implants for early T1–2 lesions. Implants are typically combined with external beam radiotherapy (EBRT) with long-term local control rates >80% reported.[100–103] However, an interstitial implant alone may also be used for the management of early T1–2 N0 FOM carcinomas managing the neck either with observation or neck dissection.

Reported experience suggests that when an implant is combined with EBRT, higher local control rates are observed when a significant proportion of the dose is delivered through the implant. In the Patterns of Care Study reported by Wallner et al., 41% of 73 clinical stages I and II patients treated with EBRT alone experienced an in-field relapse.[76] In contrast, 102 similar-staged patients treated with EBRT and an implant had only a 26% in-field relapse.[76] The superior local control rates when a greater proportion of dose is delivered through a brachytherapy implant has been attributed to reducing the overall treatment time possibly due to the unfavorable impact of tumor repopulation that may occur to a greater extent with fractionated EBRT.[101] For the intraoral cone technique, treatment time was also reduced using a hypofractionated schedule (typically 21–24 Gy in 3 Gy fractions). This schedule was found to be safe due to direct

(c) 2014 Wolters Kluwer. All Rights Reserved.

delivery of radiation to the tumor mass and the use of electrons thereby limiting the volume exposed to the larger fraction size. The use of a brachytherapy implants for the FOM (as compared to the oral tongue) appears to increase the risk of tissue necrosis, especially ORN due to the proximity of the tumor to the mandible.[103]

Management of the neck in patients with FOM cancer is critically important because of the frequency of regional lymph node metastasis at diagnosis. McGuirt and others documented a 23% rate of occult disease of 129 patients with FOM cancer over a 20-year period.[13]

***Retromolar Trigone.*** In a report from the 1980s, radiation and surgery were reported to be equivalent in the locoregional control and disease-free survival of RMT lesions.[104] A more recent retrospective report suggests the optimal management of cancer of the RMT is surgery with neoadjuvant or adjuvant radiotherapy rather than radiation alone.[105] As with other early lesions of the oral cavity, small lesions of the RMT may be addressed surgically via a transoral approach. More extensive lesions may require lateral, paramedian, or median mandibulotomy with or without marginal mandibulectomy or segmental mandibulectomy. Although marginal mandibulectomy is sufficient in selected patients with only periosteal involvement, it is generally contraindicated in patients who have been previously radiated in part because of the observation that in radiated bone, bony involvement occurs in a multifocal pattern along the cortex of the mandible, whereas in nonradiated bone, bony involvement occurs through the occlusal surface in a more focal, direct pattern.[106]

Reconstruction options for addressing RMT primary defects are numerous, including split-thickness skin grafts, local and regional flaps, as well as free tissue transfer with or without vascularized bone. Decisions regarding the particular method of reconstruction are based on the size of the defect, deficit of mandible and/or maxilla, the desirability of dental rehabilitation, and surgeon preference. The inner surface of the mandible presents a reconstructive challenge because of the thin native mucosa immediately overlying cortical bone with any remaining teeth further complicating work in the region. Bone exposure particularly in the setting of previous or future radiation puts the patient at risk for subsequent ORN.

***Oral Tongue.*** The generally accepted primary management of oral tongue carcinomas is upfront surgery. Surgical management of oral tongue carcinoma can range from local excision with margin control for T1 to a partial glossectomy for T2 lesions to a subtotal or total glossectomy for more advanced disease. Early-stage lesions are often successfully resected transorally. Median or paramedian mandibulotomy may be necessary to adequately remove later stage lesions, particularly if the FOM is involved. Large lesions limited to the tongue may be approached transcervically by detaching the tongue from the FOM and pulling it into the cervical wound, leaving the mandible intact. This approach has the advantage of reducing torque injury to the temporomandibular joint, but makes exposure for resection and closure more cumbersome. Placement of a suture for retraction of the tongue may be helpful during resection, but care must be taken not to distort the tissues to obscure palpation of deep extension during the resection. Anticipation of the location of the lingual artery with proactive management during transection of surrounding muscle may limit hemorrhage.

As with tumors in other subsites of the oral cavity, a preoperative assessment of bony involvement is critical. Criteria for performing marginal mandibulectomy or segmental mandibulectomy are the same as for other subsites of the oral cavity. Primary closure, healing by secondary intention, or closure with split-thickness skin grafts are adequate for early-stage tumors, whereas hemi- or total glossectomy defects may be best managed with free tissue transfer or regional pedicled flaps.

Early tongue carcinomas have also been treated with radiotherapy (especially with LDR brachytherapy) alone in hopes of preserving function through tissue preservation (Fig. 16-17).[76,102,103,107–112] Typically, local control rates of 85% or greater may be expected. Local control rates with brachytherapy decreased with larger T-stage disease[113] or tumor size. Suboptimal local control rates with EBRT stood in contrast to the high local control rates observed with brachytherapy implants that appeared comparable to those achieved surgically. A dose of 65 to 70 Gy at a rate of 0.3 to 0.5 Gy/hour has been recommended.[103] Alternative HDR brachytherapy schedules have been evaluated and compared to LDR schedules with (59 Gy in 6 Gy twice daily vs. 61 Gy over 5–6 days). Inferior local-control rates were observed favoring LDR schedules (T1: 85% vs. 64%; T2: 71% vs. 38%).[114] At this time, the HDR schedule for oral tongue carcinomas cannot be recommended.

As reconstructive techniques advanced, many advocated for upfront surgical resection especially for larger T-stage disease where the local control and complication rates for brachytherapy were less than ideal.[115] Nevertheless, this body of experience is important as a brachytherapy implant remains a viable consideration for the medically unresectable T1–2 tongue carcinoma patient.

Management of the neck for patients with squamous cell carcinoma of the oral tongue has generated much discussion. The neck in patients with early-stage lesions with a thickness of <2 mm can be managed expectantly. There is evidence to suggest that a supraomohyoid neck dissection of levels I to III may be insufficient in treating the N0 neck for larger tongue primaries. Byers and others demonstrated that patients may develop "skip metastases," whereby level IV may be the only involved level, or level III may be involved with no disease present in level I or II.[116] Considering these data, a selective dissection of levels I to IV may be appropriate in these patients. Finally, as primary oral tongue carcinomas close to or involving the midline have an increased risk of bilateral regional lymph node metastasis, staging neck dissections in these circumstances should address the bilateral nodal basins.

***Carcinoma of the Palate.*** Primary surgery is typically selected for most carcinomas of the hard palate. For early-stage lesions, wide local excision with 1 to 2 cm margins is sufficient, whereas larger

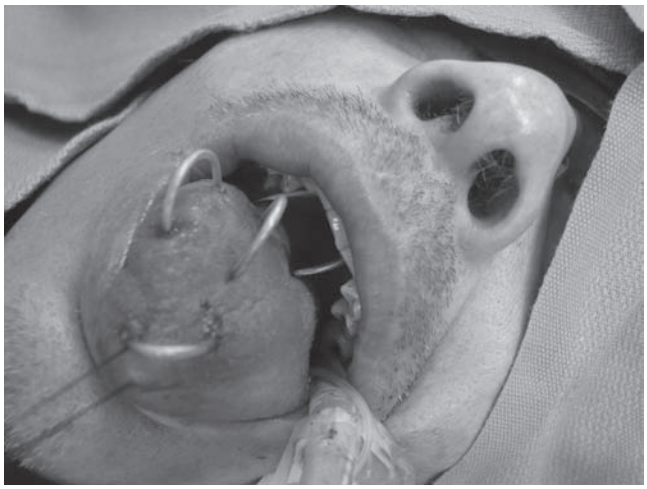

**FIGURE 16-17.** Brachytherapy catheters placed in oral tongue tumor.

(c) 2014 Wolters Kluwer. All Rights Reserved.

lesions often require partial or total maxillectomy with resulting through-and-through defect into the nasomaxillary cavities.

The dental prosthodontist and speech and language pathologist are essential members of the pre- and postoperative multidisciplinary team. Preoperative obturator construction can help to ensure early speech and swallowing rehabilitation. The creation of a more definitive prosthesis may be delayed until the completion of therapy, which may include adjuvant radiotherapy. Free tissue transfer has an expanding role in the reconstruction of hard-palate defects, particularly for large defects after a total maxillectomy with or without orbital exenteration for more advanced disease. Management of the N0 neck is typically expectant because of the low rate (~10%) of occult regional lymph node metastasis.

***Carcinoma of the Alveolus.*** Carcinoma of the mandibular alveolus is treated similarly to carcinoma of the RMT and FOM. These lesions often present with early mandibular involvement necessitating marginal or segmental mandibulectomy. Likewise, carcinoma of the maxillary alveolus is treated similarly to carcinoma of the hard palate. Advanced lesions may invade adjacent structures, including the nasal cavity, the paranasal sinuses, the orbit, and the skull base. Ablative surgery often results in large maxillofacial defects, necessitating complex reconstructive techniques.

Patients with alveolar lesions have a significant risk of cervical regional metastatic disease. Simentel and others, in a review of 26 patients with squamous cell carcinoma of the maxillary alveolus and hard palate over a 25-year period, found an overall incidence of cervical metastasis of 35%, with 5-year disease specific survival of 59%.[117] Lesions of the mandibular alveolus also have a significant risk for regional neck metastasis. In their review of 155 patients with carcinoma of the mandibular alveolus over a 20-year period, Eicher and others found that those patients with primary tumors that overlie the mandibular symphis, those with moderately or poorly differentiated tumors and those with those tumors having radiographic or histologic evidence of mandibular invasion are at significant risk of harboring regional metastases.[118] Treatment of the cervical lymphatics should be considered in these cases. As lesions of the maxillary alveolus drain preferentially to the jugulodigastric nodal basin, and lesions of the mandibular alveolus drain preferentially to the submandibular nodal basin, adjusted selective neck dissection may be appropriate in the elective treatment of the neck.

***Postoperative (Adjuvant) Management of Oral Carcinoma.*** Postoperative management of high-risk oral carcinoma may involve external beam radiation, interstitial brachytherapy implants, and chemoradiotherapy.[119–121] The rationale of brachytherapy implants is to irradiate the primary surgical bed only, thus reducing acute and late normal tissue toxicities. The most common indication is the presence of a close or positive surgical margin in the absence of perineural or lymphovascular invasion (LVI) in the primary site and where the neck has been found to be pathologically N0. Lapeyre et al. demonstrated that with a minimum follow-up of 36 months (mean 80 months), the 2-year actuarial local control rate using this combined strategy was 88.5%.[122] When combined with postoperative EBRT, local control rates do not appear to be compromised when the proportion of dose delivered by the implant is limited (mean EBRT 48 + 24 Gy by implant).[123]

Significant progress has been made in the development of risk-based adjuvant external postoperative radiotherapy (PORT) for oral cavity carcinomas with several randomized trials completed in the past 30 years.[124–128] The majority of patients enrolled in these randomized trials were patients with oral cavity carcinomas.[124,125] Aspects of postoperative dose,[125,128] the influence of the overall treatment time and tumor repopulation,[124] and the role of concurrent chemotherapy[126,127] have been evaluated.

The definition of a pathologic high-risk group remains a subject of much debate. There is little question that patients with (gross) extracapsular extension (ECE) and positive surgical margins constitute a high-risk population.[129] The series of randomized trials at the MD Anderson Cancer Center (MDACC) incorporated a risk definition for the endpoint of local-regional control that investigated the presence of multiple pathologic risk factors in the primary site or in the neck including perineural invasion, LVI, and the location and presence of multiple nodes in the absence of ECE. Peters et al. demonstrated that the presence of increasing number of risk factors was associated with an increasing risk of local-regional relapse. In fact, patients with four or more pathologic risk features without ECE were at a comparable risk of local-regional relapse as patients with ECE. While this empiric scoring system was demonstrated to be clinically valid, it is unable to guide a determination of whether the relapse risk is at the primary site or in the neck. For example, for a patient with N2 disease in levels II and III with perineural invasion, it is unclear if the primary site or the nodal levels are individually at a high risk for relapse. Whether they should be individually be boosted to 63 Gy (high-risk dose recommendation) as was done by Peters et al.[125] or if these anatomic sites can be treated to a minimum dose of 57.6 Gy is uncertain. This becomes a relevant consideration in the modern era of conformal radiotherapy techniques where the volume of tissues in the neck can be independently dosed.

A prospective trial reported by Ang et al. demonstrated a 5-year actuarial local-regional control rate of 90% without adjuvant therapy in the absence of pathologic risk factors (clear margins, no perineural invasion, no extranodal extension).[124] An intermediate risk group (defined by the presence of one adverse pathologic risk factor other than ECE) received PORT and had a comparable local-regional control rate to the low-risk group indirectly supporting the efficacy of adjuvant PORT.

When adverse pathologic factors predict for an increased risk of relapse, the surgical bed requires treatment with a minimum of 57.6 Gy with areas at higher risk requiring dose escalation to at least 63 Gy. Delivering doses <54 Gy to the surgical bed is associated with an increased risk of local relapse.[125] Doses >63 Gy did not further improve local-regional control rates possibly due to the adverse effects of tumor repopulation. This appears to be a particularly relevant issue in patients found to have pathologic high-risk factors for recurrence.[124] Peters et al. demonstrated an increased risk of neck relapse for patients with ECE when treated with only 57.6 versus 63 Gy (2-year actuarial neck control rates: 52% vs. 74%, respectively, $p < 0.03$).[125] Several retrospective reviews have demonstrated a reduced local relapse rate for higher total doses delivered to the site of close or positive margin disease.[130–132] In these institutional reviews, a minimum dose of 65 Gy was recommended. Thus, both the optimal radiotherapy dose to areas at higher risk for relapse and how a positive surgical margin[133] should be defined remain subjects of debate.

In the PORT study reported by Peters et al. multivariate analysis demonstrated that there was a trend for an increased risk of local-regional relapse with N2b nodal disease ($p = 0.08$).[125] Patients with N2b disease may have received a range of dose from 57.6 to 68.4 Gy raising the question of the optimal dose in this circumstance. At a minimum, 57.6 Gy in 1.8 Gy/fraction is currently recommended. However, N2b disease represents a heterogeneous cohort of patients with variable relapse risk. Within this cohort, several potential high-risk N2b disease subgroups may exist that may benefit from a higher total dose (yet to be established). For example, the presence of large number of positive nodes or the presence of nodal disease in the level IV or V region of the cervical neck may represent potential high-risk N2b disease.[127]

In the trials reported by Peters et al. and Ang et al. the prognostic influence of LVI and its implications on the radiotherapy

(c) 2014 Wolters Kluwer. All Rights Reserved.

dose was not evaluated. Although LVI has been correlated with local-regional relapse for oral tongue carcinoma,[134–135] its prognostic influence has not been consistently supported. In part, this may be related to the methodology used to assess LVI.[136,137] Its prognostic influence may also lose significance in multivariate models incorporating the nodal status. This has been observed in uterine cervical squamous carcinomas.[138] In a large retrospective report where all patients received a minimum of 60 Gy, LVI did not have significance on multivariate analysis.[131] Further complicating the discussion are questions of how the radiotherapy target volume should be modified by the presence of LVI if one postulates that it does have an independent effect on the risk of local relapse. Some have argued that the presence of LVI necessitates irradiation of the entire operative bed due to the potential for carcinoma cells in the intervening lymphatics between the operative bed and the adjacent nodal regions.

The recommended postoperative radiation dose range impacts not only cancer control but also side effects. Ang et al. demonstrated that with a median follow-up of 59 months, the risk of grade 3 to 4 dysphagia increased in patients receiving 63 Gy (13%–16%) compared to those receiving 57.6 Gy (4%).[124] As all patients were treated with nonconformal radiotherapy to both sides of the neck, these dose-risk levels may be ascribed to the irradiation of a large volume of the pharyngeal musculature and are consistent with other reports suggesting a possible dose threshold of 50 to 60 Gy for injury to the pharyngeal constrictor muscles and supraglottic larynx.[139]

*Post-operative Chemoradiation.* In recent years, the postoperative management of the oral carcinoma patient has been significantly influenced by the results of two large phase III randomized trials that compared PORT alone versus PORT with concurrent cisplatin.[126,127] Although oral cavity cases comprised only 24% to 30% of the patients enrolled in these two studies, the results have had a significant impact on routine practice due to the absence of any phase III studies addressing this issue specific to oral cavity carcinomas. Cooper et al. enrolled 459 patients with high-risk features including histological evidence of invasion of two or more regional lymph nodes, ECE, and microscopically involved mucosal surgical margins. The patients treated with concurrent cisplatin and radiation had improved local-regional control rates (HR = 0.61; 95% CI, 0.41–0.91; $p$ = 0.01) and disease-free survival rates (HR = 0.78; 95% CI, 0.61–0.99; $p$ = 0.04) compared to the radiation-alone arm. However, there was no difference in overall survival (HR = 0.84; 95% CI, 0.65–1.09; $p$ = 0.19).

The study by Bernier et al. enrolled 334 patients with the high-risk features defined as pT3 or pT4 (except pT3 N0 of the larynx), pT1/2 with N2/3 disease, ECE, positive resection margins, perineural involvement, or vascular tumor embolism.[127] In addition, involvement of level IV or V lymph nodes in oral cavity or oropharynx tumors were also defined as a high-risk factors. High-risk patients received either radiation alone or radiation with cisplatin. The results demonstrated that both progression-free survival (HR = 0.75; 95% CI, 0.56–0.99; $p$ = 0.04) and overall survival rates (HR = 0.70; 95% CI, 0.52–0.95; $p$ = 0.02) were higher in the cisplatin and radiation arm compared to the radiation-alone arm.

When these two studies were combined in a summary analysis, only patients with ECE and positive margins had clear benefit from the addition of cisplatin.[140] Based on these data, patients with oral cavity cancers are currently treated with postoperative cisplatin and radiation when these pathological features are present. Whether or not patients with close surgical margins, however defined, should receive concurrent cisplatin remains a subject of controversy. Further straining the general application of the study findings is the question of the effect of microscopic ECE.[141] Recently, Ghadjar et al. reported the results of a retrospective analysis of 74 head and neck carcinomas (27% of the oral cavity site) evaluating the adverse prognostic influence of microscopic ECE controlling for nodal size.[142] For several endpoints including regional relapse-free survival, distant metastases-free survival and overall survival, the presence of at least one node <7 mm in diameter with microscopic ECE was significantly associated with an adverse outcome. Moreover, when prognostic significance of the number of nodes with microscopic ECE <7 mm in size was considered, increasing number of lymph nodes (i.e., 2 or more compared to one compared to no lymph nodes) was also associated with adverse outcomes for all of the endpoints noted above. Thus, these findings would suggest that at least for the small lymph node showing microscopic ECE, tumor biology rather than physical size of the lymph node may be most relevant and should still warrant consideration of high-risk designation and the administration of concurrent cisplatin. It has also been suggested that the relationship between the extent of ECE and the lymph node size that has been well described in head and neck carcinomas in general may not be valid for oral cavity carcinomas.[143,144] Radiotherapy target volumes need to be as generous as possible in regions of oral cavity carcinomas with nodal ECE for appropriate target coverage. The treatment algorithm (Fig. 16-18) summarizes the options for overall management of oral cancer.

## Alternative Treatment Modalities for Oral Cancer

***Photodynamic Therapy.*** Photodynamic therapy (PDT) involves the administration of photosensitizers (PS) that may be preferentially concentrated in both tumor cells and in the extratumoral compartment especially the tumor vasculature. Photoactivation occurs with exposure to wavelength-specific light typically administered with laser light generating localized oxidative stress (typically singlet oxygen). For many of the PS that have been evaluated clinically, this process is oxygen dependent. The depth of clinical activity for the PS activation is typically limited to several millimeters although the application of brachytherapy techniques to administer an interstitial PDT implants offer treatment of larger tumor volumes.

In the oral cavity, PDT for both premalignant dysplasia and for invasive carcinomas has been evaluated. The main attraction with PDT as a therapeutic modality is the ability to offer wide-field superficial mucosal ablative therapy given the challenges that often exist in defining the peripheral extent of lesions in the oral cavity. Although effectiveness for dysplasia has been reported based on complete response rates >80% for various PSs, long-term control rates are a significant limitation.[145] Similarly, the ability for PDT and many other therapeutic modalities to influence the risk of malignant transformation remains to be established.

PDT has also been used for oral cancer. A series of 38 patients with oral lesions of the tongue, the FOM, and the buccal regions, stage T1/T2 N0 was treated. PDT was repeated after a 6- to 7-month period after initial treatment if necessary. The majority of subjects (26/38) had a complete response with a 5-year survival of 84.2%. The authors contend that the morbidity of PDT treatment is less than that of surgery, radiation, and chemoradiotherapy.[146] In another European report, 170 patients treated with PDT were reported to show an overall response rate of 90.7% with a complete response rate of 70.8%.[147]

Chemoradiation as primary therapy for oral cancer. In the past 30 years, nonsurgical management of head and neck cancer has been developed seeking functional preservation, particularly in the oropharynx and larynx. Randomized chemoradiation trials were spawned by the suboptimal results observed with EBRT alone including in the management of oral tongue carcinomas. Although surgical management has been successful for local control, surgical resection for more advanced T-stage disease begins to raise issues of loss of function in the patient.

The question of whether concurrent chemoradiation or induction chemotherapy may have a role in the management of resectable oral cavity carcinomas remains largely unexplored. Several institutions have published their experience investigating concurrent chemoradiation demonstrating that this approach may have efficacy.

Investigators at the University of Chicago have recently reported their experience in treating advanced oral cavity tumors with nonsurgical primary strategies involving chemotherapy and radiation in a manner analogous to organ preservation practiced commonly for oropharyngeal and laryngeal lesions. They report results of 21 patients with tumors of the tongue, the FOM, the RMT, and the palate, stages III and IV. Treatment involved various regimens, most commonly combination chemotherapy involving 5-fluorouracil (5FU), hydroxyurea, and twice-daily radiation using intensity-modulated methodology. Two-year disease-free survival was 90%, and 5-year disease free survival was 71% with three cases of ORN. The authors conclude that this chemoradiotherapy approach is promising with acceptable toxicity.[148] The same group led a four institution phase II study involving 39 patients with T4 oral cavity tumors treated with primary chemoradiotherapy. The 5-year progression-free survival was 51% with 69% of those with bone involvement demonstrating no relapse, although there were seven cases of ORN.[149] A report of experience with intra-arterial platinum-based chemoradiotherapy in Japan showed a 51% 3-year local control rate of 68.6% for early lesions and 53.9% for more advanced lesions.[150]

For patients with locally advanced unresectable oral cavity cancer, sequential induction chemotherapy followed by concurrent chemoradiation may have a role. Again, current induction chemotherapy data are not specific to oral cavity cancer comprising only ~15% to 20% of the study populations; however, it is a valid option for selected patients with good performance status. Currently, the most utilized regimen is a three-drug combination of cisplatin, docetaxel, and 5FU (TPF) followed by concurrent carboplatin and radiation.[151] Determination of the most appropriate patient population and identification of the optimal regimen for the induction chemotherapy are still under debate.

# OUTCOMES AND RESULTS

## Quality of Life

QOL considerations for oral cancer survivors are important in deciding among treatment modalities. In recent years, QOL research has matured with the development of assessment tools that have been validated in research studies. The University of Washington Quality of Life Scale (UW-QOL) remains the most commonly used QOL assessment.[152] This tool is a questionnaire, covering topics such as pain, appearance, activity, recreation, swallowing, chewing, speech, shoulder problems, taste, saliva, mood, anxiety, and "global" QOL. Other validated questionnaires, including the EORTC QLQ-H&N 35 and FACT-HNS, use similar methods.[153,154]

Chandu and others reviewed the literature regarding factors affecting QOL in oral cancer patients, including age, gender, site of tumor in the oral cavity, tumor size and stage, marital status, and income.[155] They found that older patients consistently reported better QOL scores than did younger patients. Whereas male patients were found to have more problems with mental illness, alcoholism, and malnutrition,[156] female patients have worse pretreatment QOL scores and greater functional posttreatment impairments.[157] With regard to oral cavity subsites and tumor characteristics, patients with more posterior tumors have worse QOL scores, whereas increasing size and stage are found to correlate with worse QOL scores. Finally, the social history of the patient is particularly relevant in QOL assessments. de Graeff and others found marital status to be independently associated with locoregional control and disease-free survival in patients with head and neck cancer, with unmarried patients at significantly increased risk. They also found family income to have no association with the outcome.[158]

Outcomes analyses of treatment modalities provide useful information in pretreatment planning as well. More extensive surgical resections and reconstructions are typically associated with poorer QOL scores. Long-term percutaneous endoscopic gastrostomy (PEG) tube dependence is associated with poorer QOL scores, adversely affecting family life, intimate relationships, social activities, and hobbies.[159] Finally, adjuvant radiotherapy has been found to adversely affect QOL scores in those patients who receive upfront surgery.[160]

## Results of Treatment

Locoregional disease control and survival for oral cancer varies with tumor site and stage, as well as patient comorbidity. In general, patients with stage I disease have approximately an 80% likelihood of successful treatment whereas those with stage IV tumors have less than a 40% 5-year disease-free survival.[161,3]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Specific information regarding outcome for various tumor sites and stages are the substance of many published reports and are beyond the scope of this chapter. A few examples follow.

In the largest published series of previously untreated patients with SCC of the buccal mucosa in North America or Europe, Diaz and others found patients with T1, T2, T3, and T4 disease to have a 5-year survival of 78%, 66%, 62%, and 50%, respectively.[91] Other series demonstrate similar survival for patients with advanced-stage disease managed with surgery and adjuvant radiation. In their series of 57 patients treated with surgery and adjuvant radiation, Fang and others demonstrated a 3-year overall survival of 64%.[162] In these patients managed with combined therapy, however, surgical salvage for patients with locoregional recurrence is less successful than is primary treatment. The Oregon Health and Science University has reported that salvage surgery does increase survival after oral cancer recurrence, whereas radiation and chemotherapy did not show a benefit for recurrent disease treatment.[163]

Obtaining local control in patients with FOM cancer is often challenging. In a review of 280 patients with FOM cancer over a 24-year period, Sessions and others demonstrated that recurrence at the primary site (41%) was the most common cause of treatment failure. Their series included patients treated with a variety of modalities, including local resection alone, composite resection with neck dissection, radiation therapy alone, local resection with radiation, and composite resection with radiation. For all patients, the overall disease-free survival was 56%, with death due to tumor in 44%. The most important prognostic factors in their series included clear margins on resection, early tumor stage, and a lack of regional lymph node metastasis. The rate of second primary lesions in this series was 20%, emphasizing the importance of staging endoscopy and/or PET-CT in the management of patients with FOM cancer.[164] Furthermore, microscopic cut-through of tumor on the first resection attempt (positive first frozen section) has been shown to portend poorer outcome even if subsequent resection clears the margin.[165] This finding suggests that a more insidious growth pattern that cannot be accurately discerned by physical findings (visual and palpable) at the time of resection is indicative of a generally aggressive tumor phenotype.

# COMPLICATIONS

## Surgical Complications

Immediate surgical complications of oral cancer resection include infection, hemorrhage, aspiration, and cardiovascular events. Later, wound breakdown, flap loss, and fistula may occur. The oral phase of deglutition is often adversely affected by surgery of the oral tongue and/or the FOM. Scarring of the residual tongue to the FOM or the mandibular alveolus limits its excursion, making formation and transfer of the food bolus difficult. Particulate foods such as rice are most troublesome. Lack of tongue sensation due to lingual nerve damage further compromises the ability of patients to accurately find food particles within the oral sulcus. Weakness of tongue motion may also occur with damage or loss of one or both hypoglossal nerves. Loss of teeth and lip function can contribute to oral motor problems by reducing oral competence with accompanying drooling. Split-thickness skin graft or free tissue transfer of thin, pliable skin (radial forearm) are designed to help prevent ankylosis of the residual tongue.

## Complications of Radiation

Immediate complications of radiation with or without chemotherapy include mucositis and subsequent fungal superinfection with dysphagia and odynophagia. Acute or early complications of radiation therapy include those which occur within the first few weeks of a standard course of therapy and persist for some weeks or months after the completion of treatment. As the effects of external beam radiation therapy are cumulative, many patients may not begin to experience any significant side effects of therapy until threshold doses for normal tissue damage are reached during the treatment course. These side effects include changes to skin and soft tissue; mucosal changes; alteration in quality, quantity, and consistency of saliva; and changes in taste. Late complications of radiation therapy are those that occur months to years after the completion of therapy and tend to be chronic in nature. Some late effects of radiation therapy are the result of persistence or progression of some of the acute complications of treatment. These complications include permanent xerostomia, dental caries and deterioration, skin and soft tissue fibrosis, damage to bone, tongue mobility, and oral excursion adversely affecting eating, swallowing, oral hygiene, and articulation.

Xerostomia, or dry mouth, underlies many of these conditions. Damage to minor and major salivary glands by therapeutic doses of radiation is the primary cause of xerostomia. Surgical ligation of ducts or removal of major salivary glands may also contribute to the condition. The advent of highly conformal radiation delivery utilizing intensity-modulated radiation therapy (IMRT) can spare salivary function in major glands that can be excluded from the field.[166] Brachytherapy can deliver high-dose radiation to local tissues with minimal impact on surrounding salivary glands. Use of brachytherapy in combination with external beam radiation therapy to complete the dose to the primary site may help reduce xerostomia.

The effects of xerostomia are several. Dry mouth is uncomfortable, one of the major complaints of oral cancer patients, adversely affecting QOL. Patients complain of disrupted sleep, often awakening to drink water to reduce the discomfort. Lack of saliva also has a negative impact on eating, as saliva is required for the first phases of digestion and the production of a soft, lubricated, and cohesive bolus for transport through the mouth and pharynx. Furthermore, saliva is important for dental health, and its absence contributes to the likelihood of enamel loss and eventual dental deterioration. Treatment of xerostomia is often inadequate to reverse all of these problems. There are a variety of proprietary products available without prescription intended to provide relief of dry mouth. In the authors' experience, none of these is widely endorsed by affected patients. Two alpha-adrenergic agonists are available as prescription drugs (Salagen and Evoxac). These medications stimulate residual salivary glands to produce saliva. The side effects of both are unacceptable to some patients, chief among these is diffuse sweating. Some patients find the sweating to be transient and the benefit of increased saliva helpful enough to endure this inconvenience. The alpha adrenergics cannot be used in patients with rapid heart arrhythmias or glaucoma. Amifostine, tested for use during radiation to spare salivary function, has not gained widespread use due to being limited by substantial side effects.[167]

Associated with lack of saliva is loss of taste (hypogeusia) resulting from radiation therapy. This condition is most difficult during radiation and in the first months that follow. Some patients then regain all taste, but most continue to find that many foods no longer have the same appeal as before treatment. Lack of taste, together with mucositis which accompanies radiation and chemotherapy, accounts for substantial weight loss in many patients undergoing treatment for advanced oral cancer.

Skin changes as a result of radiation therapy usually begin to manifest as early as the second or third week of the treatment course and include a stepwise progression from mild erythema to moist desquamation. Radiation induced dermatitis has been somewhat minimized in the contemporary era with the broad implementation of megavoltage (mV) linear accelerators over

(c) 2014 Wolters Kluwer. All Rights Reserved.

older lower energy treatment units. Megavoltage radiation offers the advantage of skin sparing by depositing dose below the skin surface. In contrast, lower energy radiation sources deposit significantly higher dose at the skin surface in order to achieve the desired dose to the target lesion. The advent of intensity-modulated radiation therapy–based treatment delivery, however, may undermine the skin-sparing effect of mV radiation sources because intensity-modulated radiation therapy employs dose delivery by hundreds of tangential beamlets which serve to increase the overall dose deposition to skin.[168] Early dermatitis can be managed with various water-based topical preparations which serve to hydrate the skin. Hydrogel dressings in combination with water-based emoillents and topical antibiotics are used in the management of higher grades of dermatitis.

Trismus, or inability to open the mouth, occurs in many oral cancer patients. The pterygoid muscles located lateral to the soft palate and the tonsil folds are the jaw-opening muscles. Surgical or radiation-induced scarring causes irreversible stiffness. Another cause of trismus is soft tissue scarring of the oral commissures and buccal mucosa. Physical therapy is of some variable help to reverse or prevent trismus. Commercial devices such as Therabite and Dynasplint are available as adjunctive tools for physical therapy (PT) treatment of trismus. Inability to open the mouth limits the types of food that can be ingested, as well as access to the mouth for dental hygiene and care and surveillance for recurrent cancer.

Dental complications of oral cancer treatment have already been mentioned as a result of lack of saliva. Loss of tongue function can also adversely affect dental function in that the tongue pressure on teeth helps maintain their position. After total glossectomy, an inward displacement of mandibular teeth is commonly seen. Direct impact by radiation to dental tissue and supportive bone further compromises dental health. Small vessel damage caused by radiation results in a loss of resistance of these tissues to infection and other stress.

Small vessel damage in bone is also the prevailing explanation for the phenomenon of ORN, which can complicate oral cancer treatment. Damage to the blood supply of the mandible and supportive mucosa by surgery and radiation results in risk of bone exposure, infection, necrosis, and eventual pathologic fracture. The best treatment of ORN is prevention. Maintenance of some saliva production is helpful. Meticulous attention to dental care and hygiene before and during radiation is key. Teeth that are tenuous before beginning radiation should be removed. Enhanced fluoride treatment is also useful. Minor ORN may be managed by debridement with removal of devitalized bone, together with good oral hygiene. More substantial ORN is often treated with hyperbaric oxygen (HBO) although the ability of hyperbaric oxygen to reverse full-fledged ORN is doubtful.[169] Hyperbaric oxygen is often used in combination with more aggressive surgical debridement. Full-fledged ORN with pathologic fracture may require resection of mandible with extensive reconstruction with vascularized bone such as with a fibular microvascular free flap.[170]

In addition to the risk of ORN, there are other problems with the mandible that can occur after oral cancer surgery, particularly when mandibulotomy is required for access to the oral cavity. Repair of the osteotomy site with internal fixation plates is typically required, and there can be problems with screw loosening either because of cortical bone resorption over time or improperly placed hardware. Infection and exposure of the plate follow. Modern design of low-profile plates with locking-head screws reduces the risk of plate-related complications in the authors' experience. A stair-step osteotomy helps with mandibular stability and may also help prevent complications.[171]

As in late damage to bone, changes in microvasculature from surgery and radiation therapy also contribute to skin and soft tissue fibrosis. Such changes may be more pronounced in patients with underlying vasculopathy.[172] Edema, secondary to lymph node dissection, also plays a role in mediating the development of fibrosis in the postoperative neck. Limited data on the use of adjuvant pentoxifylline and tocopherol have shown promise in the treatment of radiation-induced fibrosis.[173,174] The major complication risks associated with brachytherapy implants is an increased risk of soft tissue necrosis (STN) especially with the implantation of larger T stages and the risk of ORN (grade 3: ~5%)[109,175] especially for tongue implants placed juxtaposed to the mandible without the fabrication of a dental spacer.[176] Other brachytherapy-related risk factors for soft tissue necrosis or ORN identified on multivariate analysis include the total dose prescribed (>80 Gy) and the dose rate (>0.7 Gy/hour).[177]

All of the conditions that affect oral feeding also impact articulation. Although even hemiglossectomy patients can speak with sufficient clarity for most daily needs, most patients undergoing treatment of cancer of the oral cavity notice at least some articulatory sequelae. The assistance of a speech-language pathologist can ameliorate these problems. Patients are encouraged to slow the rate of speaking, overemphasize the production of some sounds, and substitute others with compensatory movements. Oral prosthedontists can assist some individuals through the fabrication of partial or full dentures with regions built up to fill in regions of soft tissue loss.

Maxillectomy with resulting communication between oral cavity and sinonasal chambers presents its own problems with speech and swallowing. Loss of food and liquid into the nasal cavity is irritative and inefficient. Speech is also affected by the loss of palatal tissue resulting in hypernasality and difficulty in producing consonants such as "d" and "t." In most cases, these problems are adequately addressed by a well-formed, well-fitted maxillary obturator. Retention of the obturator may be problematic, particularly in cases requiring resection of more than half of the hard palate and alveolus. Indwelling implants in remaining bone may be required for satisfactory fixation of the prosthesis.

## Management of Recurrence

Oral cancer survivors should be followed sequentially in surveillance clinic. PET and CT scanning together with serial oral examination by a head and neck oncologist are the mainstays of early detection of recurrence, which in turn is key to optimizing the chance for meaningful intervention. Oral screening should be performed frequently in the first 2 years after treatment (q 1–3 months) when the likelihood of recurrence is highest. When oral cancer recurs after initial treatment, the options available depend on the location and extent of the disease and details pertaining to the prior treatment. Sequelae of previous treatment may make early detection of recurrence challenging, with tumor often growing unnoticed deep into the tongue or the FOM tissues. Generally, radiation therapy is provided to the maximum lifetime tolerance of normal tissues when initially given, so that re-irradiation is hazardous and remains controversial. Brachytherapy boost to local recurrence may be tolerated, but full external beam re-irradiation risks bone exposure and loss, skin breakdown and subsequent wound-management problems, as well as further deterioration of speech and swallowing function. Repeat resection of oral tissues presents advanced challenges for reconstruction and restoration of function. In general, revision surgery of tongue recurrences necessitates wide removal of residual tongue tissue even to the extent of total glossectomy. After radiation and chemotherapy, persistent cancer may extend in lymphatics beneath the mucosa in a pattern that is not detectable until frozen section margins are taken. Salvage surgery necessitates back-up plans for intraoperative management due

(c) 2014 Wolters Kluwer. All Rights Reserved.

to uncertainty of extent of disease. Recurrence along the alveolar surface after prior marginal mandibulectomy typically necessitates a full-segmental mandibulectomy as tumor has free access to the marrow space.

Regional recurrence is generally managed with neck dissection if this has not been done previously. However, after prior neck treatment, neck surgery is difficult, and tumor may invade vital structures such as the carotid artery and cranial nerves. Prior surgical or radiation treatment of the neck also may alter lymphatic flow and the pattern of nodal metastasis putting at risk more distal nodal basins.

Distant metastasis (lung, liver, bone) is managed only symptomatically or with palliative chemotherapy. Generally, if chemotherapy has already been used in an earlier phase of treatment, it is assumed that the surviving tumor is now resistant to those agents. Therefore, alternative drugs are used for recurrence. Given the limited scope of effective agents for OSCC (platinum, taxanes, epidermal growth factor receptor [EGFR] inhibitors, antimetabolites), the options for treating distant disease recurrence are often quite limited.

## FUTURE DIRECTIONS

Early detection of oral cancer is a fundamental goal for successful management. Intense attention is being given to oral screening within the dental community. Laboratory advances may also provide important tools for oral cancer detection. Genetic alterations can serve as markers for tumor detection and surveillance. Easy access to the oral cavity through rinses and swabs makes oral cancer an ideal target for molecular detection. Numerous epigenetic, genetic, and protein markers have been demonstrated in saliva and oral rinse specimens.[178,179] Preliminary data indicate the utility of this approach in early detection of oral cancer, but the application of these pilot studies in clinical practice will require rigorous demonstration of adequate positive and negative predictive value. De novo detection of cancer in an at-risk population is particularly daunting as the number of potential markers is high, but the identification of highly specific markers is elusive.

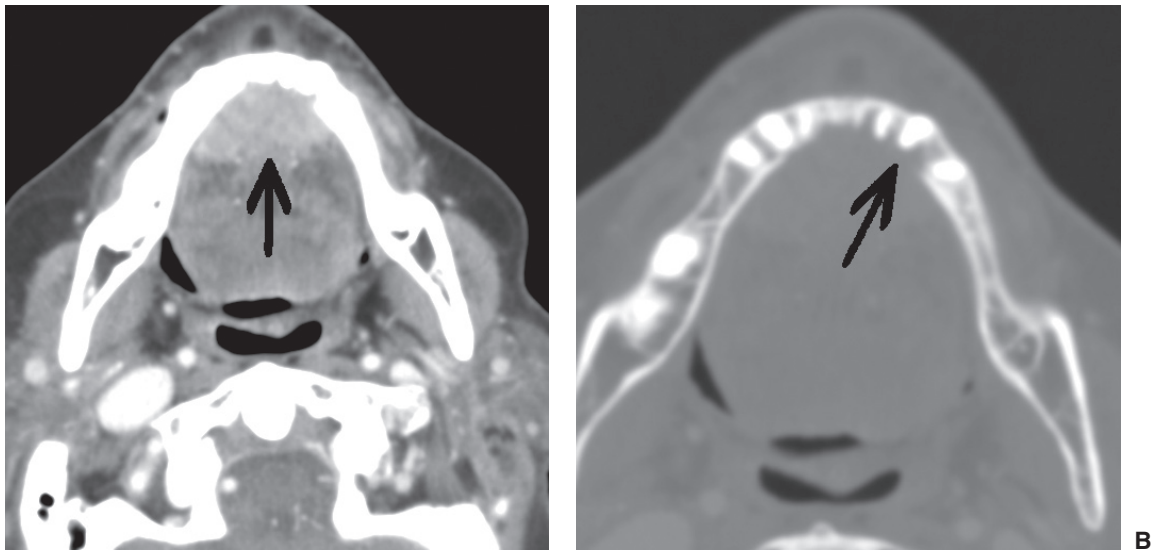
# PART B:
# Radiologic Imaging Concerns



Jeffrey A. Bennett

The greatest difficulty encountered with imaging of the oral cavity is artifact created by dental hardware and fillings (Fig. 16-19). CT is particularly susceptible to this beam hardening artifact which is why two separate CT acquisitions are typically obtained at different angles in an attempt to maximize soft tissue visualization. Dental artifact is less of a problem with MRI, which can generate exquisite soft tissue detail in multiple planes. The coronal is particularly useful for visualization of pathology in the oral cavity. Very thin-section CT with bone algorithm and multiplanar reformats are excellent for the detection of subtle cortical erosions caused by tumors[1] (Fig. 16-20). MRI may have a slight advantage for visualization of bone marrow infiltration

A B

**FIGURE 16-19.** Axial CT scan through the oral cavity **(A)** is severely limited by beam hardening artifact caused by dental fillings *(black arrow)*. The soft tissue of the oral tongue cannot be evaluated. Axial T1-weighted post gadolinium MRI **(B)** in the same patient shows an oral tongue enhancing squamous cell carcinoma *(white arrow)* and does not suffer from the same limitations as CT.

A B

**FIGURE 16-20.** Axial contrast-enhanced CT scan with soft tissue windowing **(A)** shows an enhancing squamous cell cancer filling the anterior floor of the mouth *(arrow)*. The same image with bone algorithm **(B)** shows erosion of the lingual place of the mandible *(arrow)* from tumor invasion into the bone.

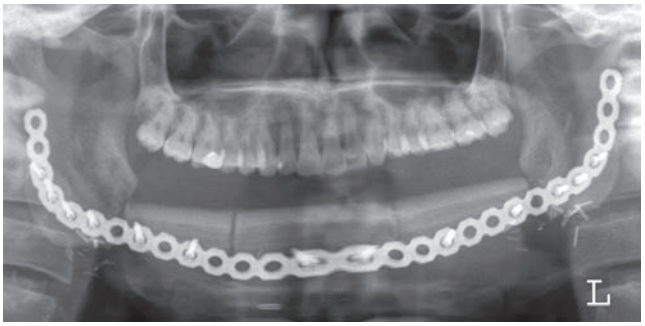

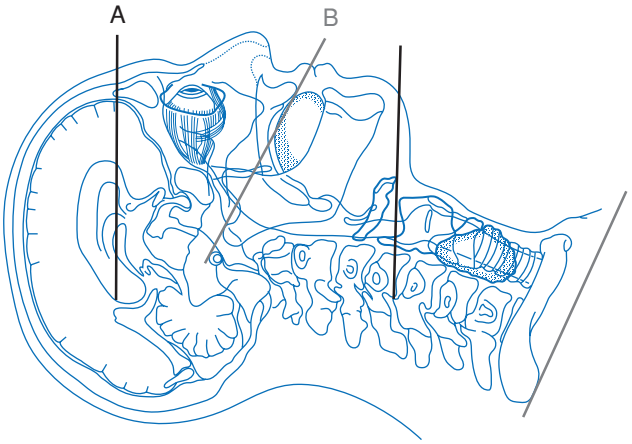

**FIGURE 16-21.** Panoramic radiograph is useful to assess the integrity of mandibular construct.

by tumor, but PET/CT can also detect this finding.[2] Panoramic radiographs and spot-occlusal radiographs are used particularly by dentists for the evaluation of the alveolus, teeth, and fixation plates (Fig. 16-21). Additional FDG-PET parameters are being investigated as potential markers for prognostic information and survival. These include the metabolic tumor volume and total glycolytic activity.[3] The most appropriate threshold values for these variables still need to be validated. Suggested CT and MRI imaging protocols are given in Figures 16-22 and 16-23.

## ORAL TONGUE

An important observation to make on images of oral tongue lesions is whether the lesion crosses the midline lingual septum (Fig. 16-24). This affects the type of glossectomy that can be

performed. Extension into the floor of the mouth can be documented clearly with coronal CT reformatted images or coronal MRI (Fig. 16-25). Posttreatment imaging can be very helpful to evaluate lesions that cannot be directly visualized underneath the surface of flaps or underneath fibrosed scar tissue. FDG-PET can be particularly useful in these cases (Fig. 16-26).

## GINGIVA

Evaluation of the alveolus for carcinoma of the gingiva is rarely performed for early disease, but is routinely performed for more advanced disease, especially for the maxillary alveolus (Fig. 16-27) and for the retromolar trigone (Fig. 16-28). The appearance of the alveolar ridge can often look irregular, especially

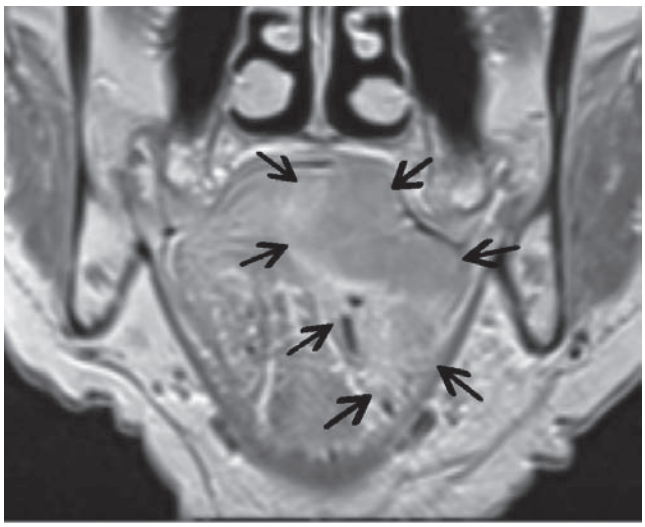

**FIGURE 16-25.** Coronal T1-weighted contrast-enhanced MRI demonstrates an infiltrating heterogeneously enhancing oral tongue mass outlined by arrows which extends into the floor of the mouth.

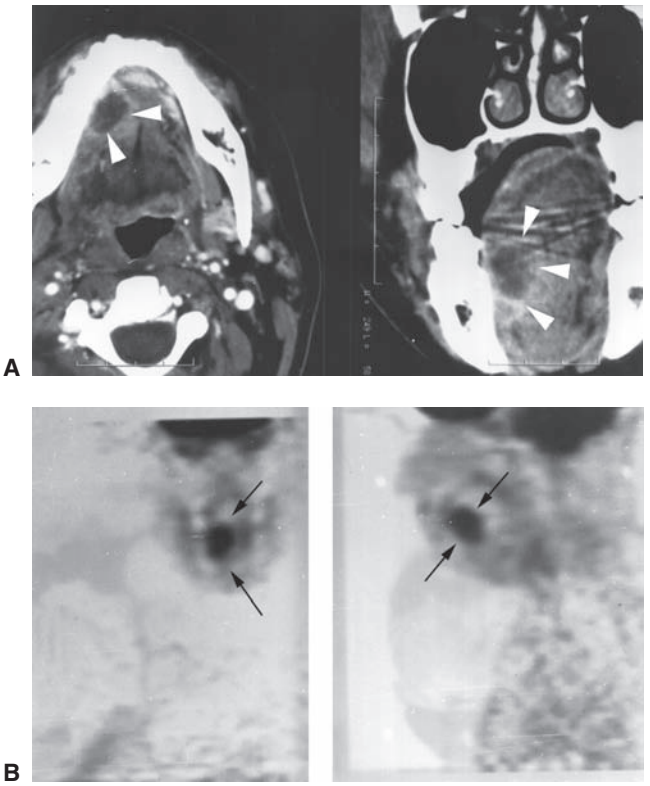

**FIGURE 16-26.** Correlation between modalities. **A:** Contrast-enhanced computed tomography in axial **(left)** and coronal **(right)** planes show necrotic process *(arrowheads)* thought clinically to be treatment-related induration. **B:** A fluorodeoxyglucose positron emission tomography scan in coronal **(left)** and sagittal **(right)** plane excludes necrosis and confirms tumor recurrence *(arrows)*.

in patients with recent tooth extractions or in edentulous patients, and this can be a limitation when trying to determine the extent of bony involvement of cancer. MRI has been shown to be relatively insensitive to bony invasion related to gingival lesions.[4] Both cone beam CT and standard CT are quite helpful to determine the proximity of a mass to the alveolar canal. In the maxilla, the extent of involvement of the maxillary sinus antrum can be seen best on coronal views (Fig. 16-27). Extension to the floor of the mouth, gingivobuccal sulcus, and posterior extension to the pterygoid processes can all be demonstrated on both MRI and CT.

## FLOOR OF MOUTH

When evaluating lesions of the floor of the mouth, posterior extension to the lingual neurovascular bundle should be commented on.[5] Invasion through the mylohyoid muscle into the submandibular space can be seen (Fig. 16-29). Submandibular gland invasion should also be differentiated from obstruction of Wharton duct.

## PALATE

The palate is best imaged in the coronal plane, where tumor invasion of bone and extension into the nasal cavity can be documented. Accurate pretreatment estimation of the extent of

(c) 2014 Wolters Kluwer. All Rights Reserved.

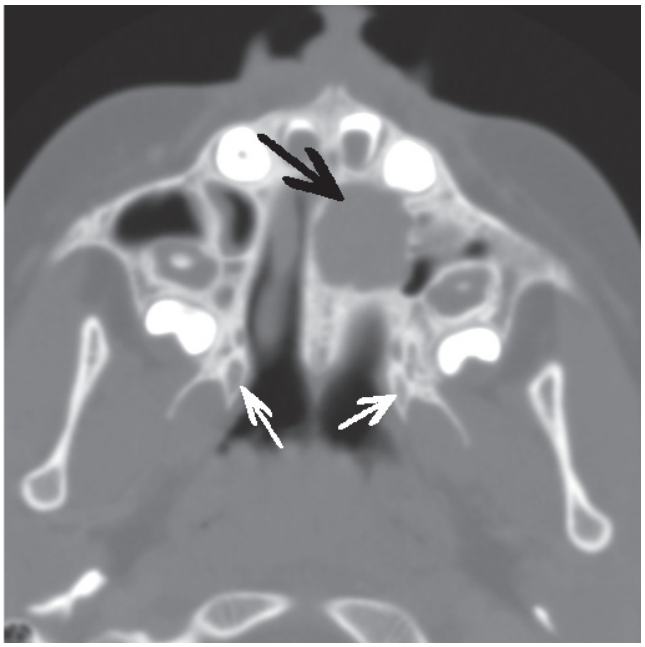

**FIGURE 16-30.** Axial CT scan at the level of the hard palate shows a lytic bone lesion in a 6-year-old *(black arrow)*. Notice the position of the greater palatine foramina *(white arrows)* at the base of the pterygoid plates. These serve as pathways of perineural spread of disease along V2 to the pterygopalatine fossa.

disease allows for early prosthesis planning and rehabilitation efforts. Careful evaluation of the palatine foramina (Fig. 16-30) and pterygopalatine fossa (Fig. 16-31) should be performed to evaluate for perineural spread of disease.

## BUCCAL MUCOSA

Imaging of the buccal mucosa is difficult as it is collapsed against the teeth. Imaging with the cheeks distended, either with gauze or air (puffed cheek imaging) may be helpful. Fortunately, imaging is rarely needed for small lesions arising on the buccal mucosa.

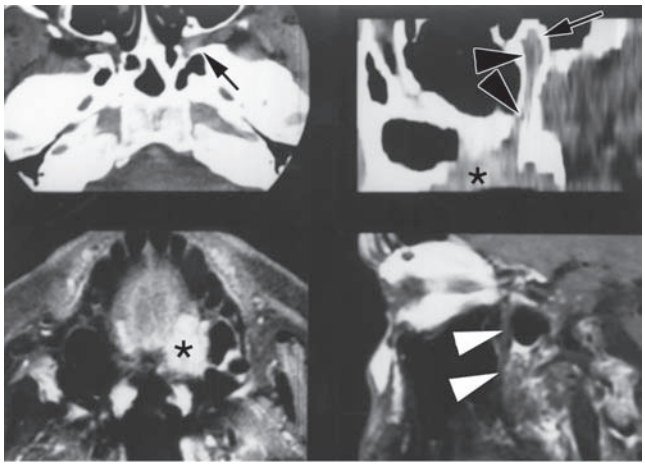

**FIGURE 16-31.** Neurotropic palate cancer. **(Clockwise from top left)** Enhanced axial computed tomogram (CT) of pterygopalatine fossa, parasagittal reformatted CT, and corresponding sagittal and axial magnetic resonance imaging (MRI) show the unanticipated extension to pterygopalatine fossa *(arrow)* along palatine canal *(arrowheads)* from the small posterior hard palate primary tumor *(asterisk)*, which is better seen on MRI than on CT.

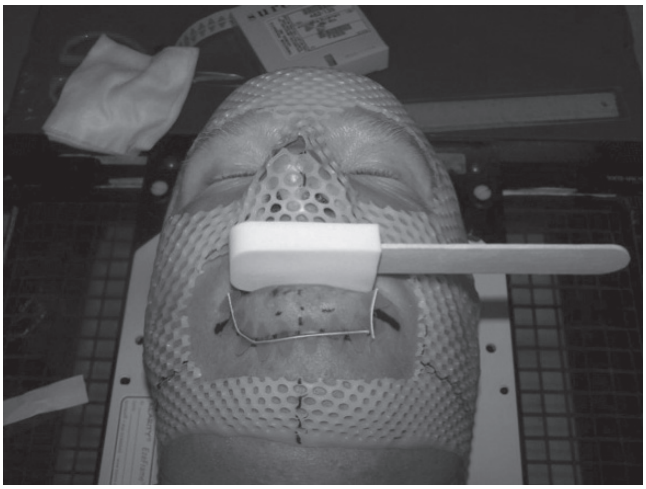
# PART C:
# Radiation Therapy Technique

Louis B. Harrison, Rudolph Woode, James Dolan, and Kenneth Hu

The most common sites treated with radiation therapy include the lip, the floor of the mouth, and the oral tongue. Lesions of the buccal mucosa, retromolar trigone are treated with techniques similar to those used for the tonsil, which are discussed in Chapter 17C. For oral cavity tumors, primary surgery is the most common approach. Radiation therapy is generally used as an adjuvant treatment in the postoperative setting. Primary RT can be used in certain situations, and brachytherapy is an important component.

Lesions of the upper lip are uncommon; the treatment techniques described hereafter apply primarily to the lower lip, but can be modified to treat the upper lip. Patients with superficial, well-differentiated squamous cell carcinoma of the lip have a low risk of cancer in the neck nodes and may be irradiated with brachytherapy alone or external beam irradiation alone. A short course of external beam irradiation precedes the interstitial implant, if the lesion is too thick to be adequately encompassed in a single-plane implant ( > 1 cm). External beam

(c) 2014 Wolters Kluwer. All Rights Reserved.



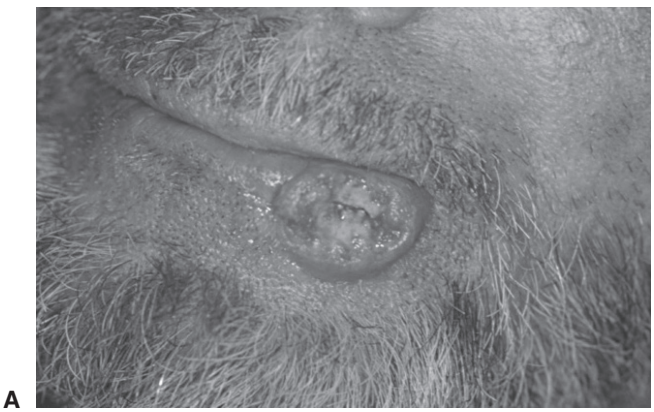


**FIGURE 16-32.** Patient has a multifocal squamous cell cancer of the lower lip. The treatment is electron beam RT to a total of 6,000 cGy in 6 weeks. 6 MeV electrons were used. Wire is seen to demarcate the field size, giving about 1.5 cm margin around the lesion. A bite block separates the lower lip from the upper lip, thus protecting the upper lip and adding to the consistency of the daily setup.

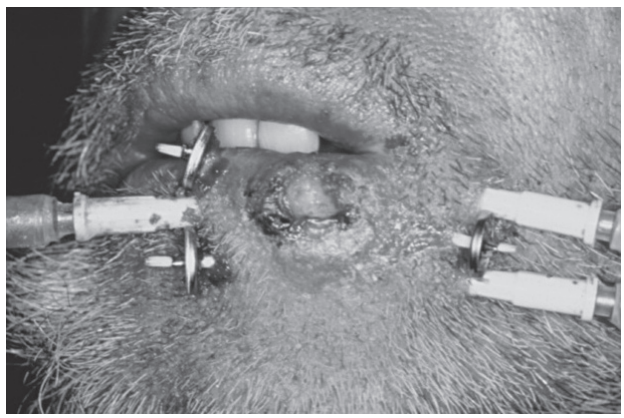

irradiation is usually done with local electron field, although photons can sometimes be used. Figure 16-32 shows a patient with squamous cell cancer of the lower lip, and the field setup for electrons.

Interstitial irradiation may be accomplished with iridium-192 ($^{192}$Ir) using the plastic tube technique. These procedures can usually be done under local anesthesia. Figure 16-33 shows a patient who had an $^{192}$Ir implant for a squamous cell cancer of the lower lip.

Small cancers of the floor of the mouth or the oral tongue can be treated with an interstitial implant alone. This is usually accomplished with an $^{192}$Ir implant afterloaded into plastic tubes. This is done under general anesthesia, in the operating room. Sometimes, a tracheostomy is performed, as a temporary protection of the airway, especially if the posterior portion of the oral tongue is involved. The tracheostomy protects the airway in the advent of the tongue swelling or bleeding. The afterloading catheters are implanted using a looping technique. The catheters enter and exit via the submental approach. Figure 16-34 shows an intraoperative photograph of an oral tongue implant and highlights the looping technique. Figure 16-35 shows AP and lateral images of an oral tongue implant, with isodose curves.

B

C

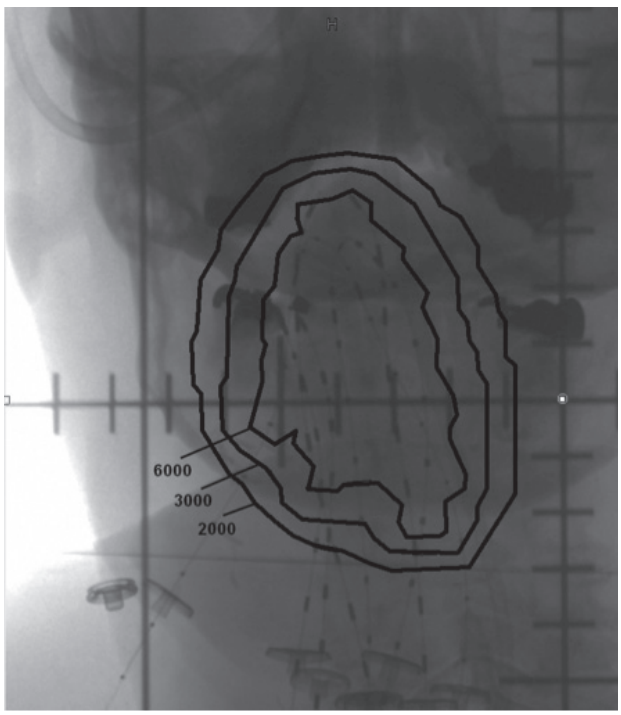

**FIGURE 16-33.** Patient had a 2.5-cm squamous cell cancer of the left side of the lower lip, near the lip commissure. Radiation was selected as the primary treatment due to the enhanced functional and cosmetic result in this particular case, given location near commissure. **A:** The lesion is seen. **B:** Patient had implantation of $^{192}$Ir via afterloading angiocatheters. A single plane implant was used and the catheters were 1 cm apart. A total of 6,000 cGy in 6 days was delivered. This photograph was taken on Day 6, just after source removal. The lesion has already regressed. **C:** Six months after implant. Patient has no evidence of disease. (See color insert.)

(c) 2014 Wolters Kluwer. All Rights Reserved.

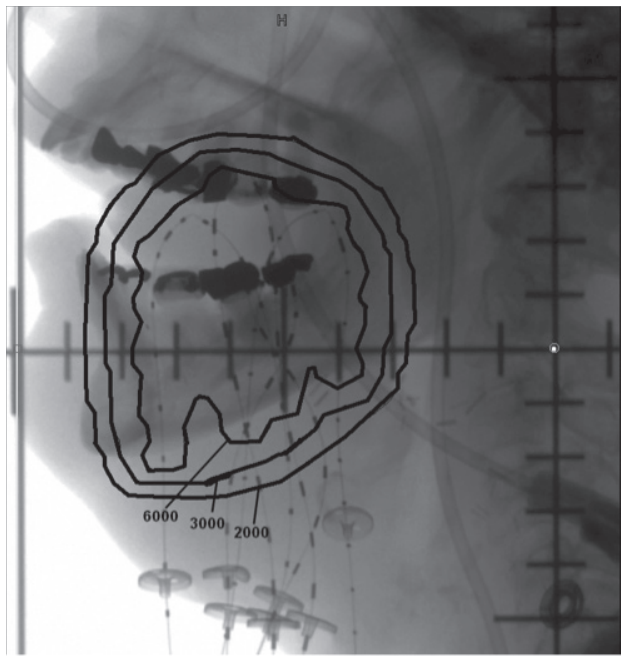

**FIGURE 16-34.** This patient had a squamous cell cancer involving the left side of the oral tongue, T2N0M0. There is irregularity and mass effect shown along the lateral aspect of the tongue and a small mucosal ulceration along the midtongue. A series of looping catheters were implanted, and the area received 6,500 cGy over 6.5 days. The patient is an attorney, so speech articulation was a key ingredient to his choice of radiation therapy. He remains free of disease for >15 years from treatment.

External beam RT techniques are similar for oral cavity sites as for other head and neck sites. Since most patients receive primary surgical treatment, especially for more advanced lesions, the main role of RT is the postoperative setting. The main reason to employ IMRT would be to provide relative sparing of key normal organs such as the parotid glands, the pharyngeal constrictor muscles, and the spinal cord. Figure 16-36 shows a clinical example of a patient with an oral tongue cancer metastatic to the neck. The contours as well as the isodose distribution are shown. Figure 16-37 shows the dose–volume histogram. This technique is similar for oral tongue, floor of the mouth, or even gingival cancer.

A

B

**FIGURE 16-35.** This patient had a T2N0 squamous cell cancer of the right side of the oral tongue. She underwent an $^{192}$Ir implant similar to Figure 16-34. She received 6,000 cGy in 6.5 days. The dummy seeds are visualized. **A:** AP radiograph showing the looping catheters with the 6,000 cGy isodose line encompassing the tumor, plus 2 cm margin, on clinical assessment. The 3,000 and 2,000 lines are also shown. **B:** Lateral radiograph showing the looping catheters as well as the 6,000, 3,000, and 2,000 isodose lines.

(c) 2014 Wolters Kluwer. All Rights Reserved.

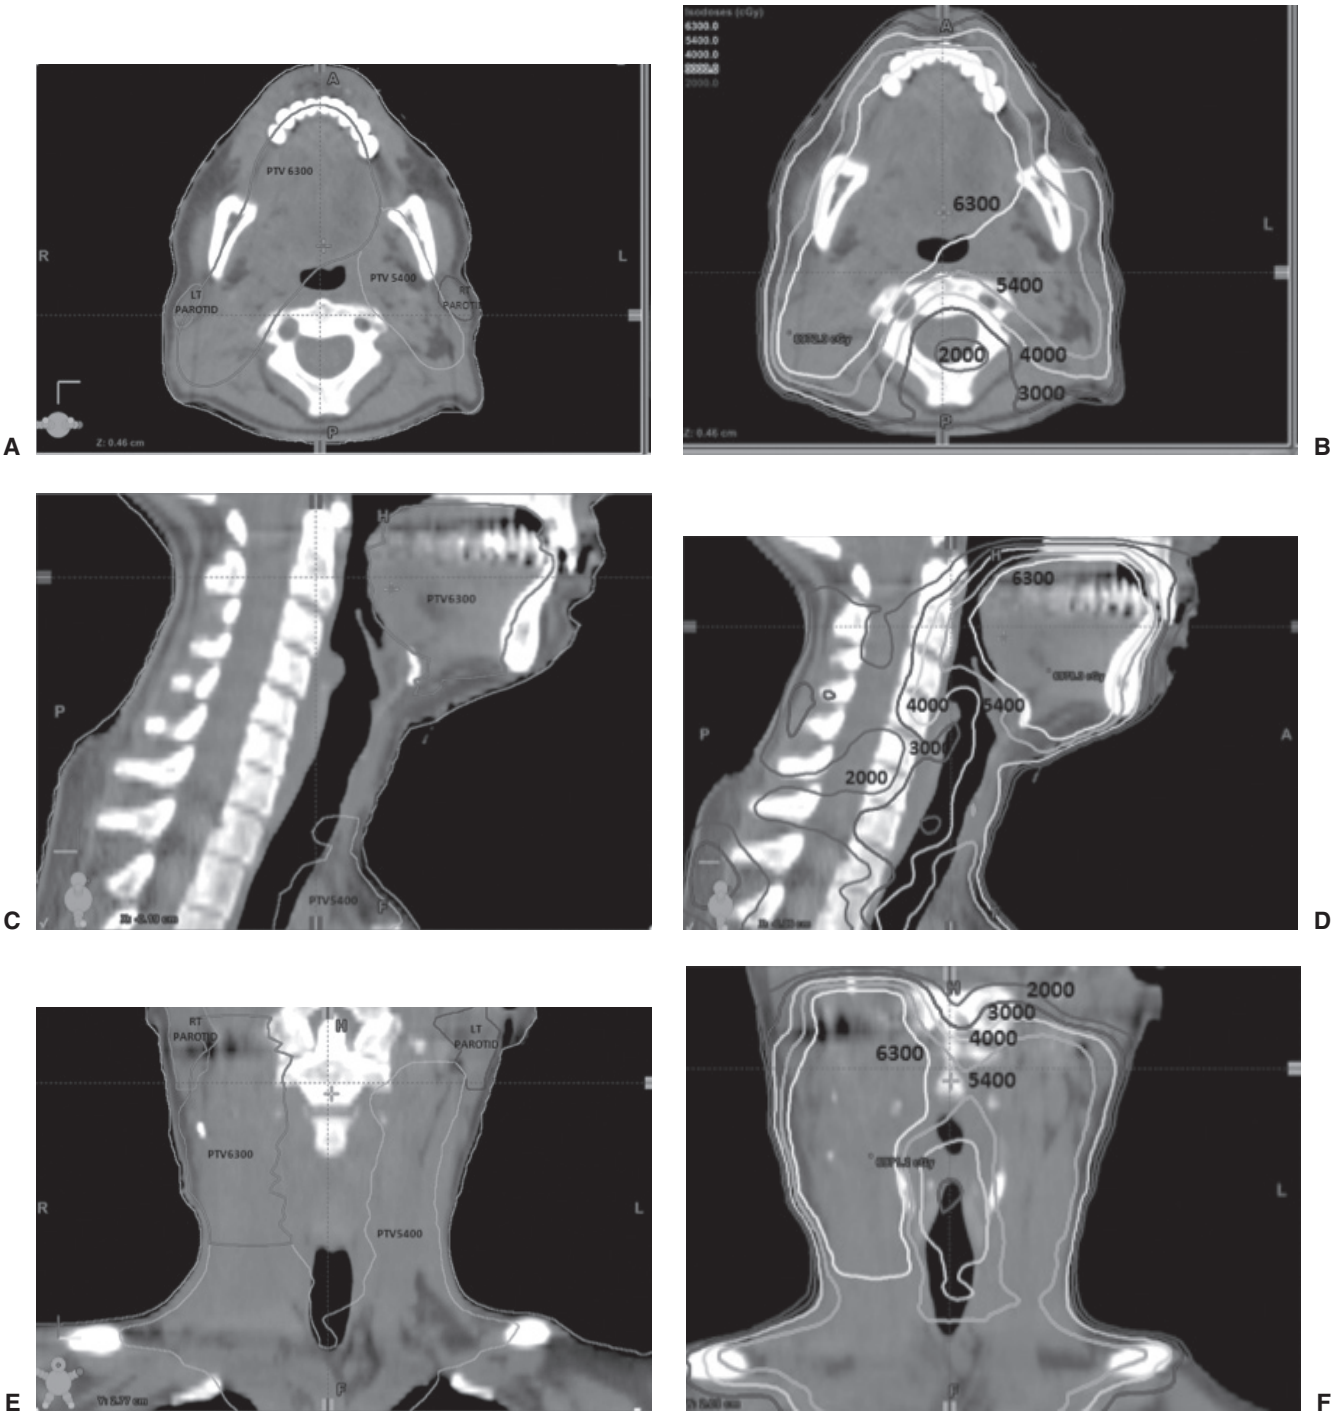

**FIGURE 16-36.** This patient had a T3N2BM0 squamous cell cancer of the right side of the oral tongue. She underwent a major glossectomy, radial forearm free-flap reconstruction, and a right neck dissection. The pathology revealed squamous cell carcinoma, moderate differentiated, with close margins and perineural invasion. The right neck revealed 4 of 26 positive nodes, all at level 2, with extracapsular spread. With these findings, the patient was treated with postoperative concomitant chemotherapy and radiation therapy, using IMRT. **A:** Axial CT for treatment planning showing the PTV63 covering the primary site bed and the right neck. PTV 63 receives 6,300 cGy in 7 weeks. The PTV54 shows the left neck which is clinically negative, but which receives elective IMRT consisting of 5,400 cGy in 6 weeks. Efforts are made to protect the left parotid gland. The right parotid gland is impossible to protect, given the extent of nodal involvement of the right level 2. **B:** Same axial CT slice as **(A)**. For ease in visual display, the contours have been removed, but the isodose curves for 6,300, 5,400, 4,000, 3,000, and 2,000 cGy are shown. **C:** Midsagittal display showing PTV63 encompassing the entire tongue bed. **D:** Same midsagittal CT slice as **C.** For ease in visual display, the contours have been removed, but the isodose curves for 6,300, 5,400, 4,000, 3,000, and 2,000 cGy are shown. Note the relative protection of the posterior pharyngeal wall. **E:** Coronal CT display showing PTV 63 and PTV 54. PTV 63 encompasses the right upper neck levels 2 and 3 in this display. The PTV 54 encompasses the right lower neck as well as the entire left neck. Note the sparing of the left (contralateral parotid gland). **F:** Same coronal CT display as **E**. As in prior figures, the contours are removed and the isodose lines are shown. (See color insert for Parts **D–F**.)

(c) 2014 Wolters Kluwer. All Rights Reserved.

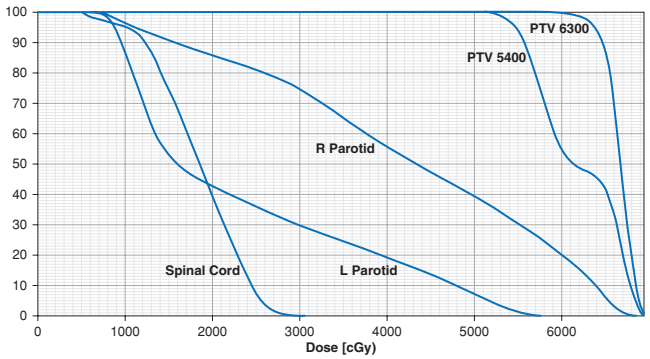

**FIGURE 16-37.** This is the dose-volume histogram for the same patient in Figure 16-36. This patient was treated with a nine-field IMRT plan.

# PART D: Surgical Technique

Charles S. Coffey and Terry A. Day

The location and behavior of oral cavity (OC) cancers make surgery the treatment of choice in the majority of cases. Many lesions can be accessed transorally without major perturbation of the surrounding uninvolved structures, resulting in improved cosmesis and satisfactory preservation of functions such as speech, chewing, and deglutition. Radiation therapy, although effective in the treatment of other head and neck sites, is hindered by the bony structures of the OC, air–tissue interfaces, and involuntary mobility of the tongue and the floor of mouth (FOM). Additionally, oral squamous cell carcinoma (SCC), minor salivary gland tumors, and sarcomas are associated with a more limited response to nonsurgical treatment. The methods of surgical approach to the OC are discussed below.

## TRANSORAL/PERORAL APPROACH

Many tumors of the OC are readily accessible for excision via a transoral approach, without the need for external incisions, or extensive dissection to achieve adequate exposure. This is particularly true for many early-stage (T1 or T2) lesions of the lip, the buccal mucosa, the anterior tongue, the FOM, or the alveolus. Transoral exposure may be maximized by use of a variety of devices, including circumferential cheek retractors, dental bite blocks, self-retaining mouth gags, or various handheld retractors for the tongue and the buccal mucosa. Exposure, access, and safety are improved when nasotracheal intubation is employed, permitting access without hindrance by the endotracheal tube in the OC. When monopolar electrocautery is employed, guarded cautery tips and coated or nonferrous retractors should be used to minimize the risk of injury to the lips and the oral commissure. Heavy suture, tongue retractors, or a penetrating clamp may be used to retract the tongue and provide additional exposure to the posterolateral tongue and the FOM. When limited transoral resection is combined with surgical management of the neck, care should be taken to avoid communication of the oral and the neck wounds when possible to minimize the risk of fistula formation. However, such concerns must always be secondary to oncologic considerations and achieving the exposure necessary for appropriate tumor extirpation. When tumors of the OC extend into the oropharynx, additional technology can afford improved visualization with transoral robotic surgery using three-dimensional visualization and robotic instruments. Transoral laser surgery has also been recommended for tumors of the OC and the oropharynx. When the transoral approach is employed, a separate neck incision and neck dissection is performed, avoiding entry into the OC whenever possible.

## COMBINED TRANSORAL/TRANSCERVICAL APPROACHES TO THE ORAL CAVITY

Achieving adequate exposure of large (T3 or T4) or deeply invasive lesions of the anterior OC may not be possible via a strictly transoral approach. In combination with surgical management of the neck, variations of either the mandibular lingual release or the "visor" approach allow excellent access to the OC through exposure via the neck.[1,2] In most cases, an upper neck dissection is performed prior to the combined approach to allow exposure of the external carotid branches, the lingual and the hypoglossal nerves, and the suprahyoid muscles.

A broad horizontal incision in a cervical skin crease is initially performed. An apron flap that is elevated to the inferior border of the mandible can be utilized in a unilateral fashion for the mandible/OC or bilaterally when large defects, anterior FOM/mandible, and bilateral tumors are treated. The unilateral approach is usually intended for lateral mandibular body, retromolar trigone, lateral FOM, or lateral tongue defects. An important consideration when elevating the subplatysmal flaps superiorly to and beyond the inferior border of the mandible is elevation and mobilization, with preservation of the marginal mandibular nerve. Ipsilateral or bilateral nodal contents are removed at this time, if indicated.

### Lingual Release

Lingual release refers to the separation of the lingual aspect of the mucosal surfaces from the inner aspect of the mandible 270° from the glossotonsillar sulcus on one side, anteriorly around the mandible to the contralateral glossotonsillar sulcus.[1] Although commonly bilateral, unilateral release is appropriate and feasible in certain small tongue or FOM cancers. In most cases, an upper neck dissection is performed prior to the combined approach to allow exposure of the external carotid branches, the lingual and the hypoglossal nerves, and the suprahyoid muscles.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Once the soft tissue and muscular attachments to the mandible are released, the entire tongue and the FOM is "released" and can readily fall into the neck and be visualized and dissected via the neck incisions, rather than transorally. If mandibular resection is not planned, mandibular lingual release may be performed without dissection of the soft tissue envelope overlying the mandible (Fig. 16-38A,B). The digastric, the mylohyoid, the geniohyoid, and the genioglossus muscles are released at their anterior attachments, and subperiosteal dissection is performed along the inner cortex of the mandible. The intraoral mucosa is released at the dental mucosal junction with preservation of the interdental papillae in the dentate patient, or along the superior alveolar crest in the edentulous patient. Following mucosal release, the tongue and the FOM are delivered into the neck. If additional posterior exposure of the base of the tongue or the lateral pharynx is required, the dissection may be extended into a pharyngotomy incision.

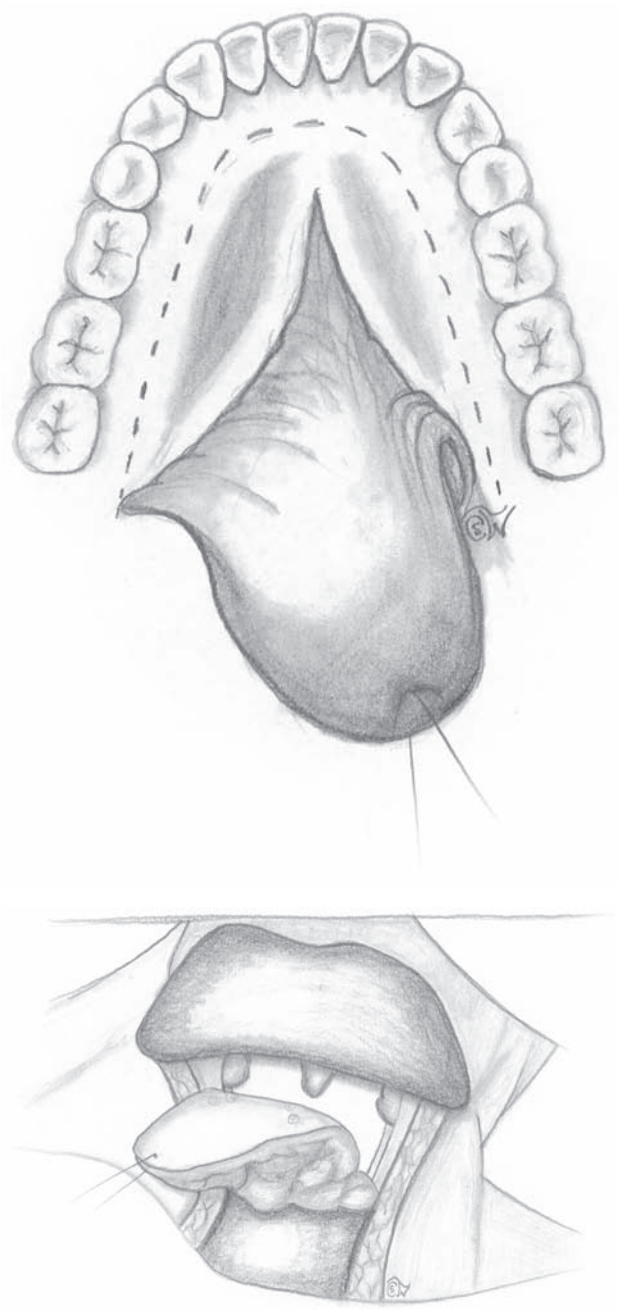

**FIGURE 16-38.** **A:** Intraoral view, lingual release. **B:** Cervical view, lingual release.

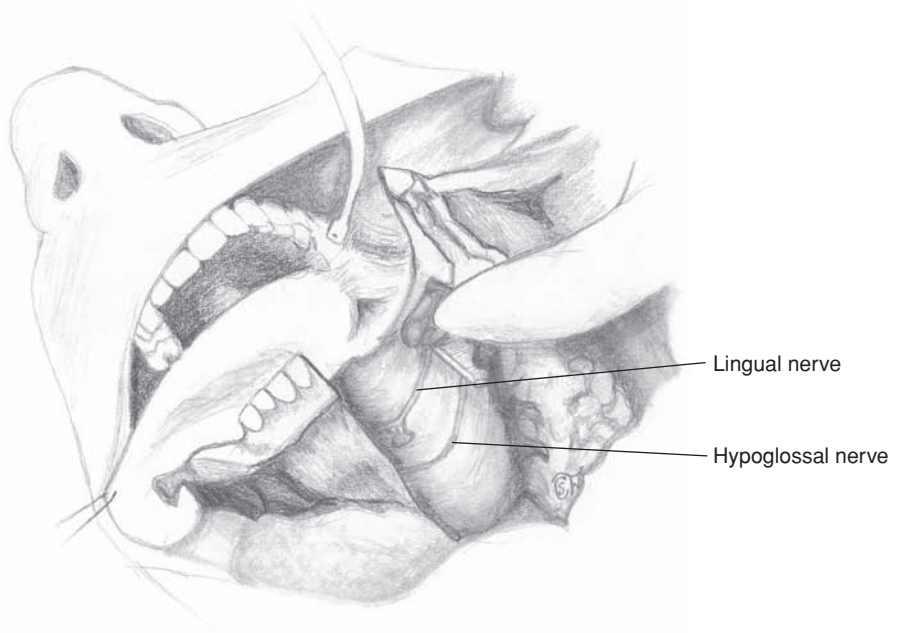
## Visor Flap for Mandibulectomy and Plating

The term "visor" is used to differentiate it from an "apron" flap, whereby visor is a bilateral neck and cheek flap elevated cephalad beyond the mandible to expose the body of the mandible bilaterally. Thus, the flap of skin can be considered a visor that nears the upper cheek and eyes. The apron flap, however, is limited in its superior extent, and thus does not reach the level of the cheek but forms an apron over the neck region. In most cases, an upper neck dissection is performed prior to the combined approach to allow exposure of the external carotid branches, the lingual and the hypoglossal nerves, and the suprahyoid muscles.



If mandibular resection is planned, a visor flap is created by subplatysmal dissection extended superiorly over the lateral surface of the mandible. This may, although not frequently, require division of bilateral mental nerves, and patients must be counseled preoperatively regarding the resulting sensory deficit. If the mandible does not require resection on one side, the mental nerve is preserved. As opposed to the "lingual" release where the incision is in the gingival or lingual aspect of the mandible, the "mandibular" release requires a releasing incision along the gingivolabial and gingivobuccal sulcus. When there is no periosteal involvement or tumor growth through the outer cortex of the mandible, the transosseous plate can be placed prior to osteotomy and removed. This may preserve occlusion and cosmesis of the mandibular contour and height. Otherwise, intermaxillary fixation may be necessary to maintain mandibular position for reconstruction. Once appropriate releasing incisions are completed, the mandible, the tongue, and the FOM are delivered into the neck. Tumor is resected with osteotomies in the bone where indicated, and margins are taken peripherally, deep, and in the neurovascular bundle and marrow of the mandible. Particular attention is paid to preservation of the lingual and the hypoglossal nerves when allowable. For large tumors of the tongue, exposure, mobilization, and ligation of the ipsilateral lingual artery in the neck prior to resection may aid hemostasis, and mobilization of the hypoglossal nerve can allow preservation of some branches when oncologically safe. Following resection, the surgical defect is appropriately reconstructed, with particular attention paid to restoring a soft tissue barrier between the OC and the neck. Native FOM musculature or myofascial tissue from the reconstruction flap should be firmly affixed to the mandible, via holes drilled into the bone, if necessary. Additional considerations would include laryngeal and/or hyoid suspension to improve postoperative swallowing function.

## Mandibular Swing Approach

The mandibular swing approach refers to a parasymphyseal or midline osteotomy and lip split, which allows the mandible and lip/cheek complex to "swing" laterally, leaving a wide open access to the OC, the retromolar trigone, the deep tongue, the oropharynx, and the parapharyngeal space without limitation by position of the lips, the cheek, or the mandible (Fig. 16-39). Such an approach may also provide access to the upper oropharynx for oral tumors extending into the soft palate, the tonsillar fossa, the glossopharyngeal sulcus, or the base of tongue. A variety of incisions for dividing the lower lip and the chin have been described, including straight line, zigzag, and chin button among others.[3,4] A visible facial scar is unavoidable, but patients who

(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 16-39.** Mandibular swing.

have been appropriately counseled are generally not dissatisfied with the postoperative appearance.[5] The most aesthetically and functionally acceptable incisions permit precise reapproximation of the vermilion and the orbicularis muscle layer and include techniques to disrupt the linear scar and minimize contracture[6] (Fig. 16-40). The lip incision is extended along the mental crease into the neck, where it is joined to the cervical incision to allow broad surgical access. Neck dissection is generally performed at this time, not only for oncologic purposes (if indicated), but also to maximize exposure of the FOM and the posterior OC. In most cases, an upper neck dissection is performed prior to the combined approach to allow exposure of the external carotid branches, the lingual and the hypoglossal nerves, and the suprahyoid muscles. If oropharyngeal exposure is required, this may also be optimized by dissection of the lateral neck.

Subperiosteal dissection is performed around the inner and outer cortices at the planned mandibulotomy site and along the inferior and anterior surfaces where fixation hardware will be placed. Disruption of vascular supply to the mandible during these cases may be significant, and as such, the periosteum should be left in place over bone whenever possible, to preserve periosteal vascularization of the mandible. The mental nerve should be identified and preserved; this is in contrast to the mandibular swing with the visor approach, which requires division of the mental nerve at least on the ipsilateral side, as well as significant retraction on the marginal mandibular nerve. Elevation or dissection along the inner surface of the symphysis should be avoided when possible in order to minimize disruption of dense muscular attachments at the genial tubercle. Because the muscular floor comprising the oral diaphragm is preserved, this approach may offer better speech and swallowing outcomes than lingual release techniques. Multiple anterior mandibulotomy techniques have been described, including straight-line symphyseal or parasymphyseal cuts and angled cuts.[7,8] Incorporation of a step-off or angle into the mandibulotomy may improve precise reapproximation of bone if only wire fixation is planned, but it is unclear whether such techniques are as useful in the era of titanium reconstruction hardware. The authors prefer a straight vertical cut in the parasymphyseal region. This minimizes risk of injury to intact dental roots and avoids detachment of the ipsilateral genioglossus and the geniohyoid muscles from the genial tubercle, thus minimizing disruption of the oral diaphragm. Of note, neither type of cut, fixation type, or irradiation (pre- or postoperative) has been shown to significantly affect rates of nonunion.[9,10] In the dentate patient, mandibular reconstruction plates are contoured and predrilled prior to mandibulotomy to optimize restoration of dental occlusion. No such preparation is required in the edentulous patient. A powered side cutter, sagittal, or reciprocating saw may be used. Following mandibulotomy, the FOM mucosa is released at the dental mucosal junction, and the mandible is laterally retracted. A mucosal incision is extended from the alveolus to the margin of planned tumor resection, and the resection is performed. If the lingual and hypoglossal nerves have been exposed in the neck, they may be further dissected into the FOM and free of the tumor, if possible. As with the release approaches, attachments of the remaining FOM to the mandible should be restored during the course of reconstruction. The risk of postoperative fistula and oral incompetence may be higher with a mandibulotomy approach compared with a delivery approach, and this approach should be avoided for patients with an atrophic mandible due to the increased risk of nonunion or fracture.[6] During closure, it is wise to "overlap" any osteotomies with gingival mucosa or flap reconstruction to avoid the suture line being directly in line with the osteotomy.

## Mandibulectomy

Careful preoperative clinical and radiographic assessment of the mandible is critical in the evaluation of OC cancer. Lesions in direct proximity to the mandible, or those exhibiting only superficial cortical invasion may be managed with marginal mandibulectomy in select cases. Edentulous patients with significant loss of vertical mandibular height are poor candidates for marginal mandibulectomy due to the high risk for pathologic fracture, particularly in the postirradiation setting. Such patients should receive segmental resection. When moderate mandibular atrophy is present, but marginal resection is deemed feasible, placement of rigid internal fixation may reinforce the mandible and limit the risk of postoperative fracture. Segmental mandibulectomy is indicated in the setting of extensive cortical or cancellous invasion,

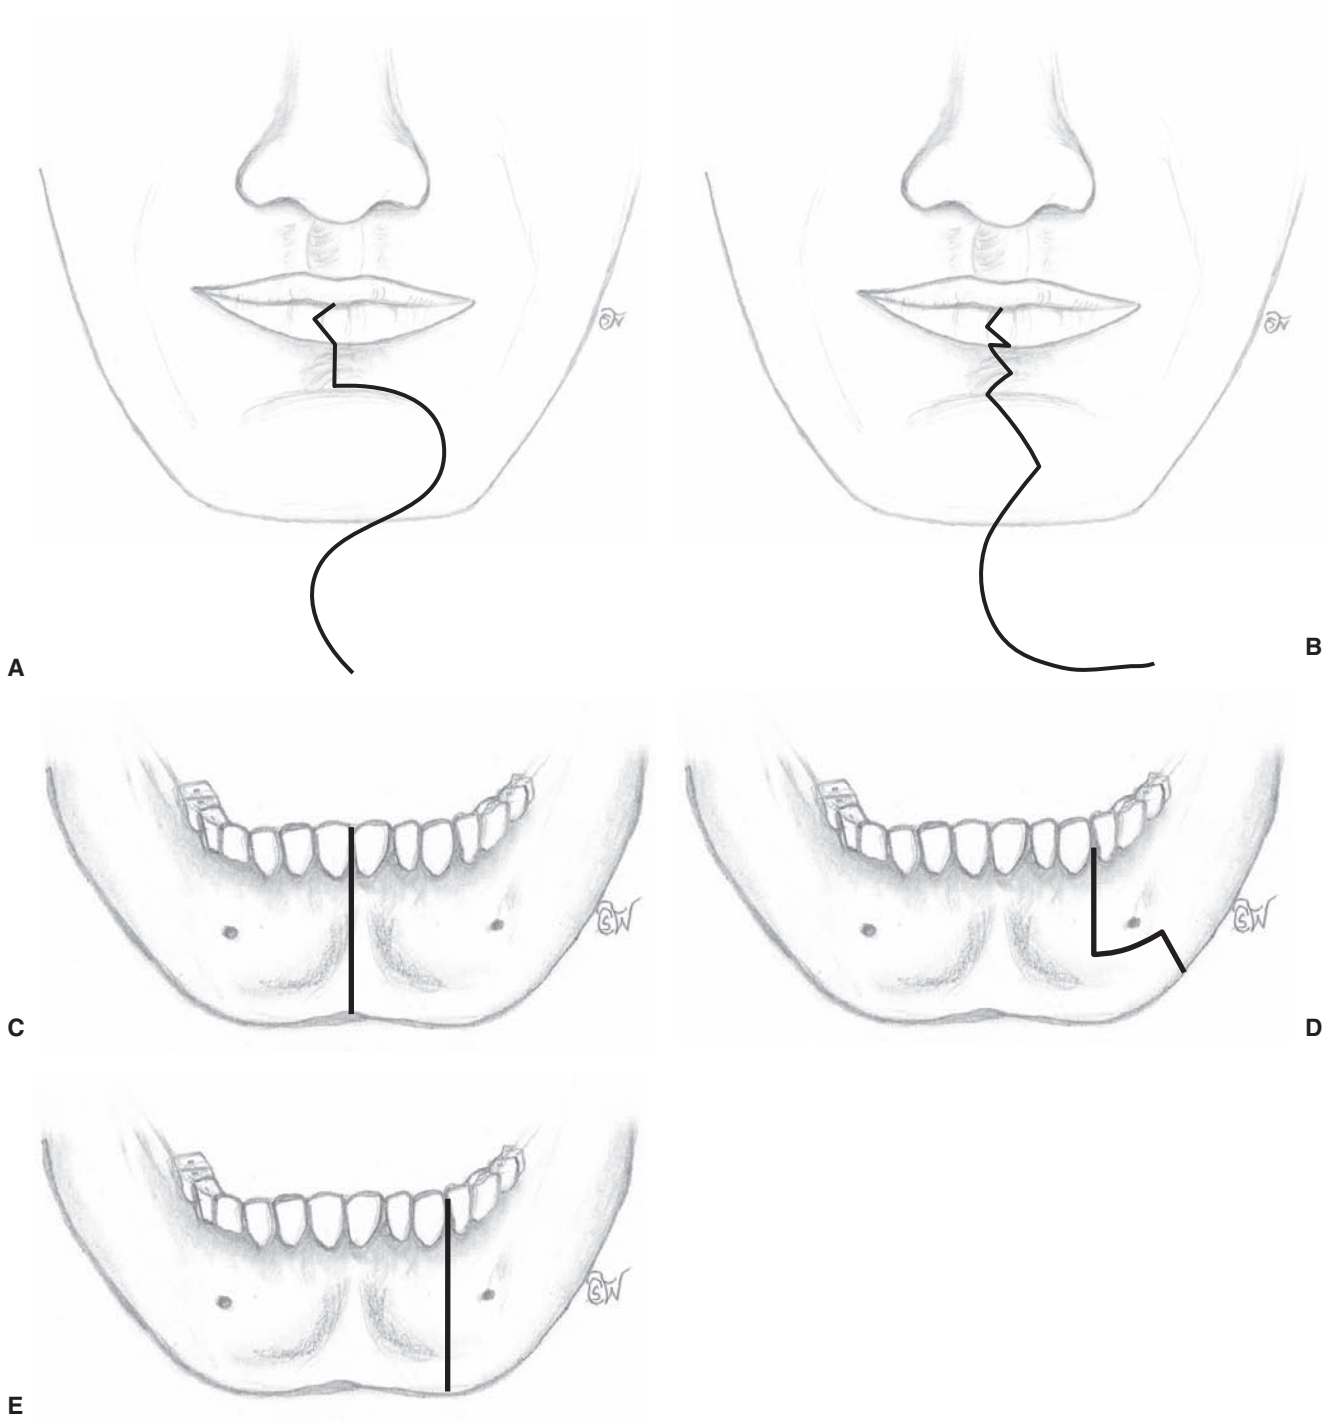

**FIGURE 16-40.** Designing lip-split incision and mandibulotomy. **A:** Broken line at vermilion and chin skin—improves precise approximation and hides scar; follows mental crease. **B:** Mucosal flap along vermilion—breaks up any straight lines into chin and maximizes precise approximation. **C:** Midline bone cut—minimizes risk of injury to dental roots, requires precise reduction and fixation with plating hardware. **D:** Parasymphseal mandibulotomy—may improve reduction and minimize risk of nonunion but confers increased risk to dental roots. **E:** Parasymphyseal straight cut, improved ease of plating because the genial tubercle is avoided; lateral position allows preservation of all attachments of geniohyoid and genioglossus while minimizing any disturbance of the oral diaphragm. This may decrease risk of fistula.

primary or metastatic bone tumor, or invasion of the marrow space, inferior alveolar nerve, or canal (Fig. 16-41).

Adequate exposure is critical, regardless of whether marginal or segmental resection is planned. An exclusively transoral approach with marginal mandibulectomy may be successful for the occasional early-stage lesion, which abuts the periosteum, but does not grossly invade the cortex. In most cases requiring mandibular resection, however, more extensive access must be achieved either via a lip-splitting incision or transcervical approach as described above. Very select low-grade lesions limited to the mandible may be amenable to marginal resection via a relatively small transoral or cervical incision. Larger lesions that are limited to the mandible may permit segmental resection via a similarly small incision. Caution is urged, however, as the degree and duration of superior retraction of the soft tissue envelope, which is required by such an approach, puts the marginal mandibular nerve at high risk of retraction injury. A lip-split or visor flap minimizes such risk. Once adequate exposure is achieved, proximal and distal mandibulectomy sites are scored with a saw blade and any necessary dental extractions are performed. In the dentate patient, an appropriate reconstruction plate is selected and precontoured to span the anticipated defect, with at least three holes predrilled on each side of the defect. In instances where tumor significantly deforms the outer contour of the mandible and precludes accurate molding of hardware, it may be necessary to estimate the desired contour when shaping the plate. Alternately, there are commercially available three-dimensional models based upon preoperative imaging, which may be customized and altered to assist with reconstruction planning. For lesions posterior to the mental foramen requiring resection of the posterior mandibular body or retromolar trigone, it may be necessary to extend a vertical cut from the mandibular angle to the sigmoid notch. This allows removal of the anterior ramus and coronoid process, while preserving the condyle and a length of posterior ramus sufficient to affix reconstruction hardware. It should be noted that aggressive attempts to preserve the condyle in such cases may be associated with an increased risk of local recurrence, and resection of the condyle and ramus without mandibular reconstruction must be favored if there is concern about achieving adequate margin status otherwise.[11] Although it is useful to delineate the intraoral mucosal margins prior to segmental mandibulectomy, performing bone cuts early in the resection will greatly improve exposure and facilitate the remainder of the soft tissue dissection. Dissection over the lateral surface of the mandible in a subperiosteal plane is usually sufficient for lesions that are limited to the medial or superior aspect of the bone. However, if tumor extends onto the buccal surface of the mandible or into the gingivobuccal surface, the margin of resection must include a cuff of overlying unaffected soft tissue.

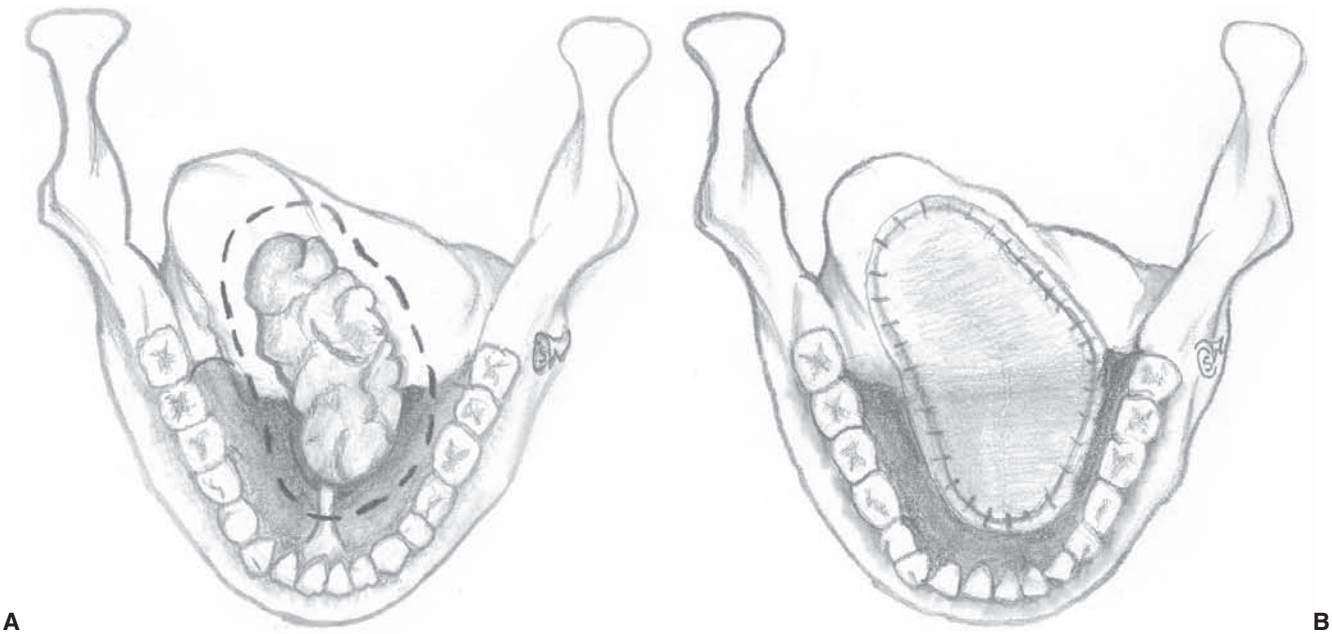
## Reconstruction

Although beyond the scope of this chapter, suffice it to say that optimal outcomes in function and cosmesis mandate appropriate reconstruction. Additionally, free tissue transfer has permitted larger surgical resections and margins around tumors with improved cosmetic and functional results, thus obviating the need to be conservative around certain areas and risk close or positive margins. In general, the authors advocate fibula osteocutaneous free flaps when feasible for mandible defects with single soft tissue layer reconstruction (mucosa or skin), while utilizing scapula/parascapular osteocutaneous flaps for mandible *and* two-layer soft tissue defects (i.e., mucosa *and* skin). For soft tissue reconstruction, primary closure, secondary intention healing, and allograft are employed commonly for early T1 and T2 cancers. However, the area and volume of the defect is important, although previously operated or radiated patients may require vascularized free tissue transfer including the radial forearm, the anterolateral thigh, and others.

(c) 2014 Wolters Kluwer. All Rights Reserved.

## Site-specific Considerations

***Lip.*** In lesions that involve less than one-third of the lip, simple excision with primary closure offers acceptable oncologic and reconstructive results. Full-thickness excisions with margins of 8 to 10 mm are necessary.[12] Proper alignment of the vermilion border and the orbicularis muscle layer reconstruction is critical in ensuring long-term cosmesis and function; precise marking with prolene sutures prior to incision may aid in reapproximation. For lesions larger than one-third, but less than two-thirds of the length of the lip, reconstructive options including an Abbe-Estlander "lip-switch" flap, or a Karapandzic flap may be utilized. As the risk of an unacceptable cosmetic result, microstomia, and oral incompetence increases when advancement flaps are used for large lesions, free tissue transfer is often used for reconstructing large defects. To ensure oral competence after the use of an adynamic soft tissue free flap to reconstruct the lower lip, adjunctive procedures such as a fascial sling, palmaris longus sling, or temporalis tendon transfer may be necessary.

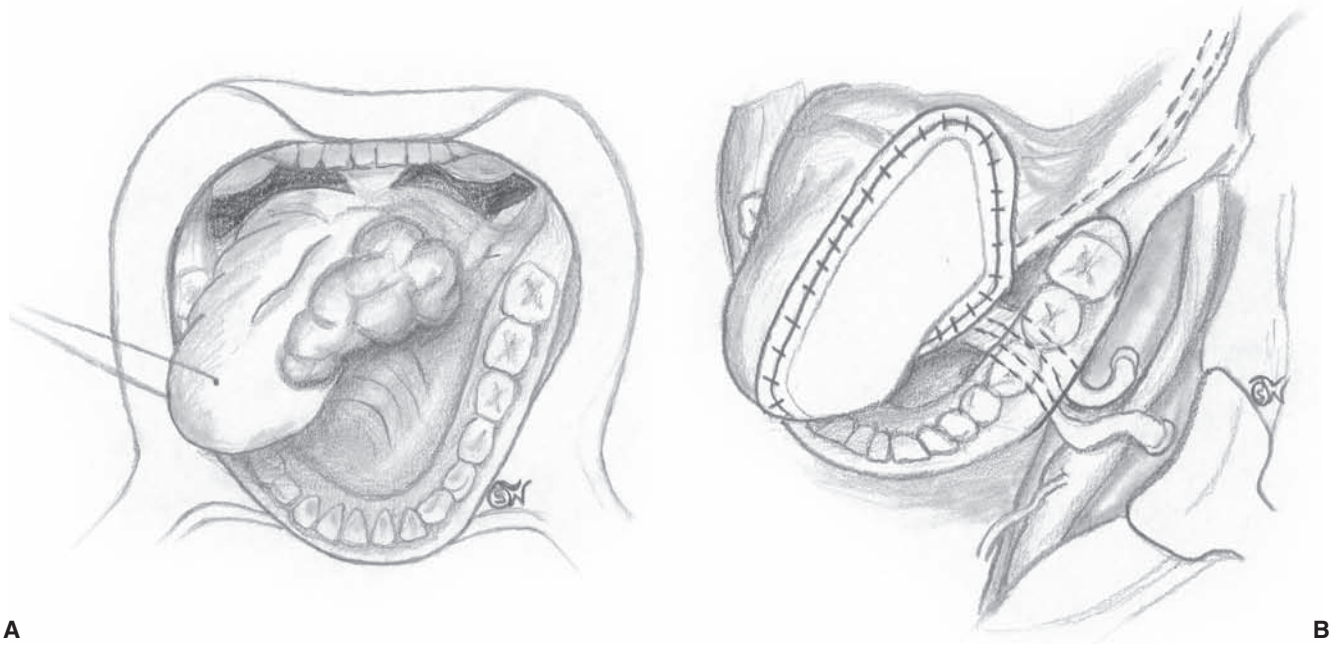


***Buccal Mucosa.*** Surgical approaches for addressing buccal carcinoma vary by the size and location of the primary lesion. These are commonly superficial, though involvement of the buccinator muscle or extension into Stenson duct may require the surgeon to consider a cheek skin or preauricular incision to assure margin clearance superficially and into the parotid. From a reconstructive perspective, a mucosal cheek flap is often used for small lesions. Contracture should be anticipated for larger lesions, and a skin graft, acellular dermal graft, or mucosal flap should be used to help prevent this. For larger defects, a radial forearm free flap may be particularly well suited for reconstruction in this region as it provides reliable, thin, and pliable tissue.

***Floor of Mouth.*** Early-stage lesions in this area may be amenable to transoral excision with primary closure or a split-thickness skin graft (Fig. 16-42), while more extensive lesions often require a composite resection involving the FOM musculature, the mandible, and the oral tongue. It is important to realize the possibility of extension into the Wharton duct, the lingual nerve, and the sublingual gland in these tumors. Reconstruction should be aimed at preserving tongue mobility and reducing mandibular/dental exposure or fistula.

***Retromolar Trigone.*** For larger RMT lesions, access to the area can be achieved through a submandibular incision as opposed to a lip-splitting incision. If the mandible is found to be involved with tumor, a marginal mandibulectomy is considered acceptable, unless the mandible has previously been irradiated or there is obvious cortical erosion. In the previously irradiated mandible, more widespread involvement is typically present, making a marginal mandibulectomy a poor choice for successful management of disease. Inner table mandibulectomies are not feasible in the RMT under any circumstances due to the thinness of the mandible in the area. If there is gross invasion of the mandible, a unilateral apron flap is considered appropriate in order to expose the medial pterygoid and masseter, which also may be involved. Appropriate mandibular release and plating can then be performed via a combined transoral/transcervical exposure. Reconstruction of lateral defects often requires vascularized tissue with scapula, fibular, or forearm osteocutaneous flaps.

***Oral Tongue.*** Depending upon the extent of the primary oral tongue lesion, surgical management can range from a partial or hemiglossectomy in T1/T2 lesions (Fig. 16-43) to a near total or total glossectomy with mandibulectomy in some T3/T4 lesions.[13] Defect closure must provide adequate mobility of the tongue to limit tethering to the FOM or gingiva. For small defects, allograft, secondary intention healing, or primary closure is reasonable if tongue mobility is not compromised. A radial forearm or anterolateral thigh free tissue transfer is often chosen for use in subtotal glossectomy defects for this reason.



***Palate.*** For early-stage lesions of the hard palate, wide local excision with 1- to 2-cm margins is sufficient, whereas larger lesions often require a total or partial maxillectomy. The removal of early lesions often can be performed transorally, while moderate size tumors and those extending to the infraorbital foramen or pterygoid region may require a sublabial approach. Early-stage

A B

**FIGURE 16-43.** Hemiglossectomy with microvascular anastomosis.

malignancies of this area include low-grade polymorphous adenocarcinoma, which may or may not require bony palate resection, and thus oronasal or oromaxillary communication. Inferior maxillectomy is appropriate for small lesions limited to the alveolar ridge and hard palate. More extensive disease requires total maxillectomy, for which a lateral rhinotomy and upper lip-splitting incision generally provide adequate exposure. For smaller defects, placement of an obturator with or without osseointegrated implants is an effective means to restore oral–nasal separation and allow for fitting of dentures. However, large defects may realize improved speech, oral competence, and cosmesis with free fibula, scapula, or forearm osteocutaneous flaps.

***Alveolus.*** Carcinoma of the mandibular alveolus is treated similarly to carcinoma of the RMT and the FOM. These lesions often present with early mandibular involvement necessitating marginal or segmental mandibulectomy. Likewise, carcinoma of the maxillary alveolus is treated similarly to carcinoma of the hard palate. Advanced lesions may invade adjacent structures, including the nasal cavity, the paranasal sinuses, the orbit, and the skull base. Ablative surgery often results in large maxillofacial defects, necessitating complex reconstructive techniques.

## SUMMARY

Technical considerations and practical aspects of the surgical approach to OC cancer encompass functional, cosmetic, and oncologic principles. Oncologically, addressing the neck and the primary separately or in continuity should afford adequate exposure for margin clearance, appropriate preservation of vital noninvolved structures, and indicated lymphadenectomy. Cosmetically, mandibular contour, neuromuscular function, and limitation of unnecessary incisions are of primary concern. Functionally, preservation of soft palate and tongue function and mobility, dental occlusion, mandibular continuity, avoiding orocutaneous fistula formation, and laryngeal suspension will address the majority of functional deficits from oral cancer surgery. Surgeons should be prepared to utilize the various weapons in their head and neck oncologic armamentarium to improve locoregional control, survival, and function.

CHAPTER 17

# Cancer of the Oropharynx

## PART A:
## General Principles and Management

Waleed F. Mourad, Kenneth S. Hu, Walter H. Choi, Bruce Culliney, Zujun Li, Adam S. Jacobson, and Louis B. Harrison

### INTRODUCTION

Oropharynx cancer (OPC) is a common manifestation for squamous cell carcinoma of the head and neck (SCCHN), and most OPC is caused by the human papillomavirus (HPV).[1] The estimated incidence of pharyngeal cancers in the United States for 2011 was 13,580 new cases and 2,430 deaths.[2] There is increasing incidence of OPC despite the decline in the overall incidence of SCCHN.[1] Current estimates suggest that by the year 2020, the annual number of HPV-positive OPC will exceed the annual number of HPV-positive uterine cervix carcinomas and there will be >15,000 cases of HPV-positive OPC per year by 2030.[1]

OPC typically involves patients in their fifth through seventh decades of life. Due to the increasing association with HPV, younger patients are being diagnosed. Men are afflicted 3 to 5 times more often than women.[2] Investigators have reported that the increase in OPC is exclusively in the base of tongue (BOT) and tonsil and that HPV/p16 accounts for approximately 70% to 90% of OPC-SCCHN.[1,3–5] Furthermore, HPV-positive OPC patients are often middle-aged (40–59 years) white men, of higher socioeconomic status, nonsmokers, and nondrinkers, but with a higher number of oral sexual partners.[1,6–15]

A history of tobacco or alcohol use can also be associated with other metachronous or synchronous tumors of the upper aerodigestive tract. Thus, tobacco and alcohol abuse still represent significant risk factors for the development of OPC and other cancers of the head and neck.[16,17] Other risk factors for OPC may include[18]

1. a diet poor in fruits and vegetables[19]
2. the consumption of maté, a stimulant beverage commonly consumed in South America[20]
3. the chewing of betel quid, a stimulant preparation commonly used in parts of Asia.[21]

Historically, the prognosis for OPC depends upon the location of the primary tumor and the stage at presentation. Studies have shown that HPV-positive OPC have more favorable prognosis, with approximately two times better 5- and 10-year overall survival (OS) compared with HPV-negative patients.[1] Likewise, recent oncologic and functional outcome data have shown superior results in HPV/p16-positive OPC patients. Of note, the significant improvement in the OS was mainly seen in patients with tonsil and BOT cancer, without obvious survival improvement in other SCCHN sites.[22] Interestingly, the survival for African Americans patients with OPC has not shown such improvement. This is attributed to the difference in OPC origin (smoking induced among African Americans vs. HPV induced among Caucasians).[10,23]

The leading cause of death in OPC and SCCHN patients is loco-regional recurrence (LRR). However, advances in radiation therapy (RT) as well as concomitant chemotherapy and RT (chemo-RT) have improved loco-regional control (LRC) rates, even for advanced-stage disease. There has also been a growing interest in the role of minimally invasive surgery (MIS) including transoral lateral oropharyngectomy (TLO), transoral laser microsurgery (TLM), and transoral robotic surgery (TORS) in the otolaryngology community.[24–29] Their application to OPC management is being actively explored. Thus, the treatment strategies for these patients are numerous, and advances in organ preservation with attention to quality of life (QOL) remain the major focus of clinical research investigations.

### ANATOMY OF THE OROPHARYNX

The pharynx is divided into the nasopharynx, the oropharynx, and the hypopharynx (Fig. 17-1). The oropharynx is located between the soft palate superiorly and the hyoid bone

(c) 2014 Wolters Kluwer. All Rights Reserved.

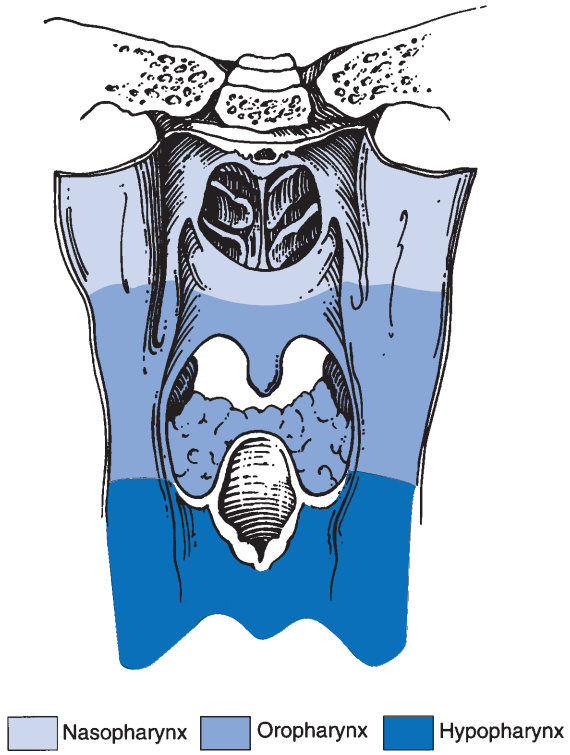

**FIGURE 17-1.** Regions of the pharynx.

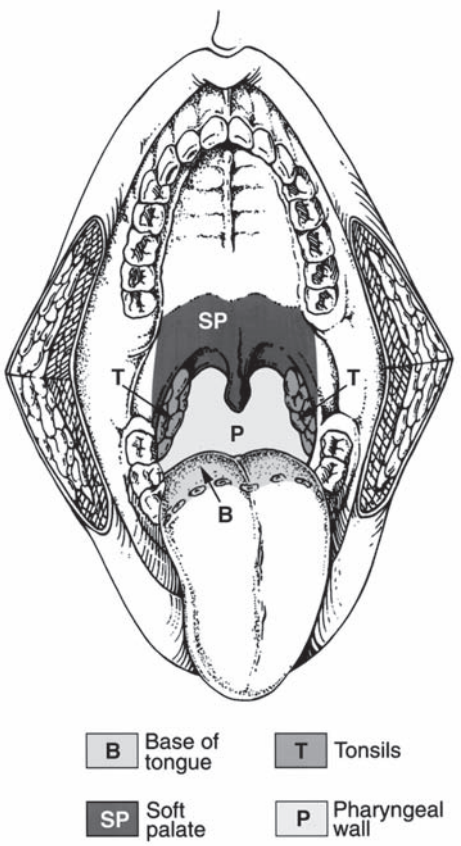

**FIGURE 17-2.** Topographic surface anatomy of the oropharynx; view from oral cavity.

inferiorly. It is continuous with the oral cavity anteriorly and communicates with the nasopharynx above and the supraglottic larynx and the hypopharynx below. Within the oropharynx are four different sites: soft palate, tonsillar region (fossa and pillars), BOT, and posterior and lateral oropharyngeal wall between the nasopharynx and the pharyngoepiglottic fold (Fig. 17-2).

## Soft Palate

The soft palate includes the uvula and incompletely separates the oral cavity and oropharynx from the nasopharynx. It is continuous laterally with the tonsillar pillars and attaches anteriorly to the hard palate. It forms both the roof of the oropharynx and the floor of the nasopharynx. The soft palate demarcates the oral cavity from the oropharynx as well as the oropharynx from the nasopharynx. Tumors arising from the oropharyngeal surface are far more common than are those arising from the nasopharyngeal surface. The authors have never actually seen a tumor arising from the nasopharyngeal surface.

## Tonsillar Region

The palatine (or faucial) tonsils, located posteriorly on the lateral wall of the oropharynx, are almond-shaped structures of largely lymphoid tissue embedded in a fibrous capsule. The tonsillar fossa, which encases the palatine tonsil, is bounded by an anterior and posterior portion, commonly called the pillars. These contain the palatoglossus and the palatopharyngeus muscles, respectively, and converge superiorly to join with the soft palate. The medial portion of the fossa becomes the glossotonsillar sulcus.

## Base of Tongue

The BOT is the tissue that extends inferiorly from the circumvallate papillae to the vallecula (base of the epiglottis) and encompasses the pharyngoepiglottic and the glossoepiglottic folds. Laterally, it extends to the glossotonsillar sulcus. The tongue musculature is composed of the genioglossus, the styloglossus, the palatoglossus, and the hyoglossus muscles. The blood supply is identical to that of the oral tongue. Motor innervation of the muscles of the tongue is through the hypoglossal nerve (XII), except for the palatoglossal muscle, which is innervated by the pharyngeal branch of the vagus nerve (X). In the BOT, both taste and general sensations are innervated by the glossopharyngeal nerve (IX).

## Pharyngeal Wall

The posterior pharyngeal wall starts at the inferior aspect of the nasopharynx, in the region of the soft palate, and extends to the level of the epiglottis inferiorly. It comprises the posterolateral surfaces of the oropharynx. The pharyngeal constrictor muscles constitute the framework of the pharyngeal wall. The wall is related to the second and third cervical vertebrae and contains the mucosa, the submucosa, the pharyngobasilar fascia, the underlying superior constrictor muscle, and the buccopharyngeal fascia. The lateral aspect of the pharyngeal wall is continuous with the pharyngoepiglottic fold and continues into the lateral aspect of the pyriform sinus. Nerve supply is from cranial nerves IX and X. The pharyngeal wall is rich in lymphatics, the primary drainage being directed to the retropharyngeal (RP) nodes and levels II and III.

(c) 2014 Wolters Kluwer. All Rights Reserved.

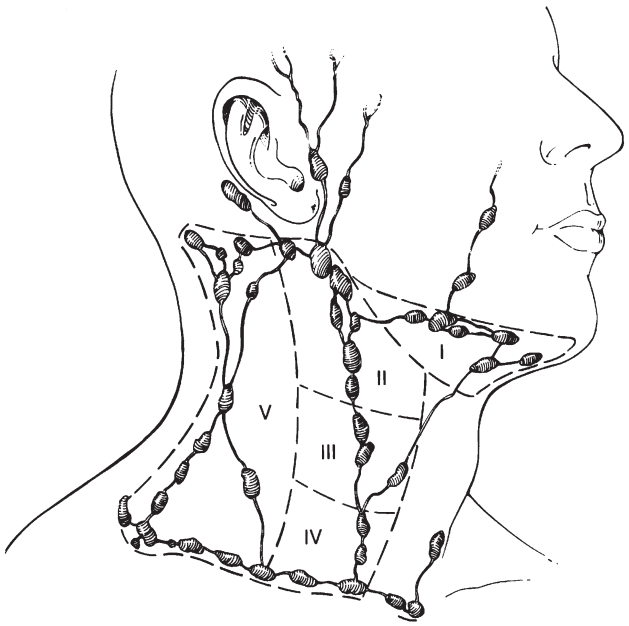

**FIGURE 17-3.** Anatomic lymph node levels of the neck.

## Lymphatics of the Oropharynx

The lymphatic drainage of the neck was described by Rouviere in 1938 and has been refined by others.[30–32] The lymph node groups are described by clinical levels I to V as depicted in Fig. 17-3.

The primary drainage of the oropharynx is to the jugulodigastric (level II) node(s) located in the upper deep jugular chain. The tonsillar region, pharyngeal portion of the soft palate, the lateral and posterior oropharyngeal walls, and the BOT are also drained by the RP and parapharyngeal nodes. These nodes are located in the RP and parapharyngeal space that is closely related to cranial nerves IX through XII, the internal jugular vein, and the internal carotid artery at the base of skull. The RP lymph nodes are subdivided into lateral (Rouviere) and medial nodal chains.[33–35] The lateral nodes lie posterolateral to the nasopharynx and the oropharynx, just medial to the internal carotid artery. The parapharyngeal lymph nodes are also known as the junctional nodes, owing to the junction of the spinal accessory (level V) and the upper internal jugular lymphatic chains.

The probability of lymphatic metastasis is related to size and location of the primary tumor within the oropharynx. The order of progression of lymph node metastases usually proceeds superiorly, from the high cervical first-echelon nodes (level II) inferiorly to the midcervical and lower cervical nodes (levels III and IV). Skip metastasis can occur in which a particular lymph node level is bypassed, but this is very unusual. Candela et al. evaluated 333 previously untreated patients with SCC of the oropharynx or the hypopharynx to ascertain the prevalence of neck node metastases by neck level. The patients underwent classic radical neck dissections. Isolated skip metastases outside of level II, III, or IV occurred in only one patient (0.3%). Otherwise, level I or V involvement was always associated with nodal metastases at other levels.[36] Metastases to the RP nodes are most commonly associated with cancers of the nasopharynx and the pharyngeal wall,[37–40] but can also occur from other subsites, particularly with advanced disease.[40–42] Notably, these metastases occur primarily along the lateral RP nodal chains. Involvement of the medial chain is extremely rare.[30,38,40]

In 1994, Hasegawa and Matsuura reported on a series of 24 patients with advanced carcinoma of the oropharynx and the hypopharynx treated with surgery and RP node dissection up to the base of the skull. This was followed by postoperative RT (PORT) of 50 Gy to RP space if nodes were pathologically involved. A total of 50% (12 of 24) of the patients had positive RP nodes: 1 of 5 (20%) with pathologic N0 neck and 12 of 19 (63%) with pathologic N-positive neck. More specifically, RP node positivity was established histopathologically in 36% (4 of 11 patients) and 61.5% (8 of 13 patients), respectively.[43] In a retrospective study of 774 patients with SCC of the nasopharynx, the oropharynx, the hypopharynx, and the supraglottis, using CT scans for RP nodes evaluation, McLaughlin et al. found an overall incidence of radiologically positive RP nodes in 9% of the patients. The highest incidence was seen in patients with cancer of the nasopharynx (74%) and the pharyngeal walls (19%). They also noted that in patients with advanced cancer of the oropharyngeal walls and the hypopharynx, the incidence of radiologically positive RP nodes was higher in patients with positive cervical nodes than in those with an N0 neck (pharyngeal wall: N+ 21%, N0 16%; hypopharynx: N+ 9%, N0 0%).[38]

Shimizu et al. reported a rate of 13% of RP node metastases for OPC. They found that the risk was higher for patients with posterior and lateral pharyngeal wall cancers (29% for lateral and posterior wall vs. 0% for others sites).[44]

Dirix et al. reported a rate of RP nodal metastases of 16% in a series of 208 patients with OPC after evaluation of pretreatment CT scans. Patients with RP nodal metastases had significantly more regional recurrences (45% vs. 10%). RP nodal involvement independently predicted the likelihood of regional recurrence in multivariate analysis ($p = 0.01$). Furthermore, disease-specific survival (DSS) was significantly lower in the RP node-positive group (38% vs. 58%).[45]

Bussels et al. analyzed the same population of 208 patients with OPC. They reported RP node involvement in 23% of those patients with nodal disease in other neck levels. More frequently, the RP nodes were involved in the case of posterior pharyngeal wall (5 of 13 = 38%) and soft palate primaries (5 of 9 = 56%). Ipsilateral involvement of level II and contralateral involvement of level III predicted for involvement of the ipsilateral RP nodes on multivariate analysis ($p < 0.05$). A solitary ipsilateral RP node was present in 3 (9%) of 34 patients with RP nodes. Two of these three patients had a primary posterior pharyngeal wall tumor. No patients presented with a solitary contralateral RP node.[46]

Yoshimoto et al. reported their series of 84 patients with BOT cancer. Two patients had RP node metastases at the time of diagnosis and two more developed recurrent cancer in the RP node. Three of these four patients had a tumor extending to the lateral pharyngeal wall. They found that the incidence of contralateral or RP node metastasis was low if the tumor neither crossed the midline nor infiltrated the lateral wall.[47]

Chan et al. retrospectively reviewed the 18F-FDG PET-CT studies of 244 patients with SCC of the oro- and the hypopharynx. RP node involvement was identified in 17%.[48]

It is clear from the data that inclusion of the lateral RP nodes is an important part of the treatment. This is especially true for patients with cervical node metastases, but it is also potentially important for patients with N0 necks.

Tumors located in the midline (the BOT, the soft palate, and the posterior pharyngeal wall) exhibit a higher propensity for bilateral nodal metastases. The probability of cervical node metastases, as demonstrated by clinical and radiological examinations of the soft palate, the tonsillar fossa, the BOT, and the oropharyngeal wall, is shown in Tables 17.1 through 17.3.[41,49,50]

## PATHOLOGY

More than 90% of tumors of the oropharynx are SCC, the remainder being malignant melanomas, minor salivary gland tumors, sarcomas, plasmacytomas, lymphomas, and other rare tumors.[51] Benign and malignant tumors that can be found in the oropharynx are listed in Table 17.4.

### Clinical Presentation, Pathogenesis, and Patterns of Spread

Patients with OPC are frequently asymptomatic until their primary tumors reach a significant size or metastasize to a lymph node in the neck. The usual complaints consist of vague discomfort or irritation, or a mass in the neck. The manifestation of symptoms depends upon the location of the primary tumor. Some tumors are visualized easily, but others can be insidious and are only found by careful examination of all the mucosal surfaces of the oropharynx. Pain can be a presenting complaint, which can be attributed either to deep infiltration of tumor or to referred pain. The following sections list some of the possible clinical scenarios based on the site of the primary tumor.

**TABLE 17.4 Differential Diagnosis of an Oropharyngeal Mass**

| Malignant | Benign |
|---|---|
| Squamous cell carcinoma | Papilloma |
| Minor salivary gland tumor | Retention cyst |
| Lymphoma | Fibroma |
| Sarcoma | Lipoma |
| Melanoma | Hemangioma |
| Plasmacytoma | Lymphangioma |
| Other | Neuroma |

***Soft Palate.*** Tumors of the soft palate are almost exclusively found on the oropharyngeal as opposed to the nasopharyngeal surface (Fig. 17-4). Tumors can extend to involve the tonsillar pillars and the BOT. Occasionally, these lesions may extend laterally and superiorly as far as the nasopharynx. Involvement of the palatine nerve can result in tumor tracking along this pathway, with extension to the skull base. Lymphatic involvement is primarily to level II. Lesions of the midline and the uvula can result in bilateral nodal metastases more frequently than do lateralized lesions. The RP nodes are also at risk.[52]

***Tonsil.*** The tonsil is the most common location for a primary tumor of the oropharynx. Common presenting symptoms are ipsilateral referred otalgia, odynophagia, or sensation of a lump or foreign body in the throat. Lesions involving the anterior tonsillar pillar can appear as areas of dysplasia, inflammation, or a superficial spreading or exophytic lesion. Frequently, these lesions become endophytic, ulcerate, and can spread laterally to the buccal mucosa and directly to the retromolar trigone (Fig. 17-5). Inferior extension to the BOT can occur. Perez et al. reported that 60% of tonsil cancers involved the soft palate and 55% extended into the BOT.[53] Superior extension can even involve the hard palate. Medial extension can involve the oral tongue. The close proximity of the anterior tonsillar pillar to the mandible places the periosteum and the bone at risk for tumor involvement in advanced cases. Posterior and superior extension with destruction of the tonsillar pillars can lead to involvement of the pterygoid muscles, with subsequent trismus and pain. The lymphatic drainage is primarily to level II but can also involve RP nodes, as previously discussed. Patients with neck node involvement are at higher risk for RP node metastases.[38]

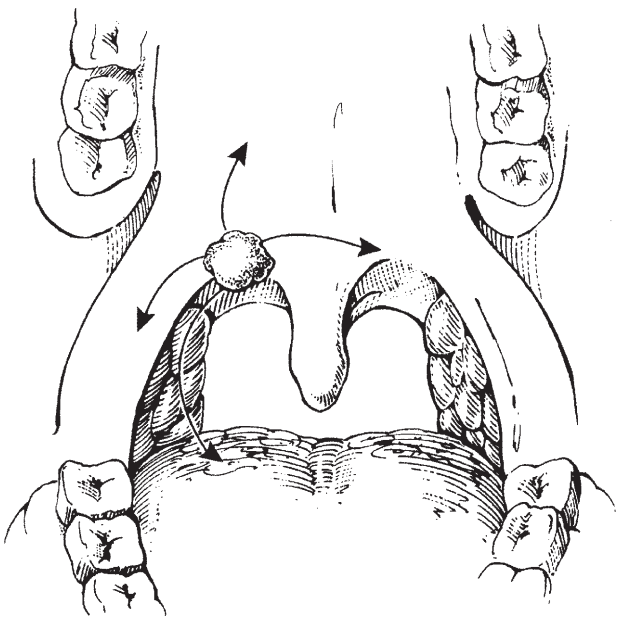

**FIGURE 17-4.** Patterns of tumor spread in soft palate.

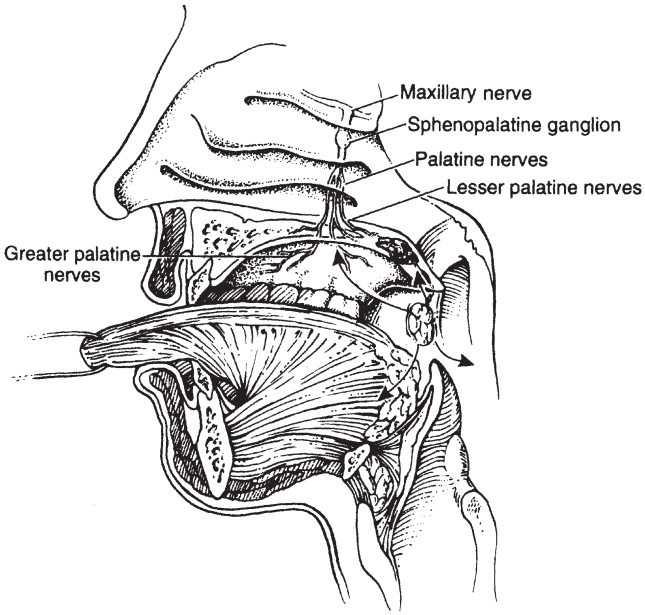

**FIGURE 17-5.** Patterns of spread of tonsillar carcinoma.

Tumors of the tonsillar fossa (in contrast to those of the tonsillar pillar) are either exophytic or ulcerative and present in more advanced stages than do tumors of the pillars or soft palate. Approximately 75% of patients will present with stage III or IV disease, for which the patterns of extension are similar to those of the tonsillar pillar. In addition, lateral extension can involve the parapharyngeal space toward the base of skull, causing neurologic signs and symptoms. Tumors of the posterior tonsillar pillar can extend inferiorly and involve the pharyngoepiglottic fold and the posterior aspect of the thyroid cartilage.

The probability of clinical lymph node involvement is greater with tumors of the tonsillar fossa in contrast to that of the tonsillar pillar. The lymphatic drainage depends upon the location of the primary tumor. Lindberg describes nodal metastases in 76% of patients with tonsillar fossa tumors.[41] The most common nodal group was level II. Contralateral lymph nodes were detected in 11% of patients. In contrast, tumors of the anterior tonsillar pillar or retromolar trigone region have an incidence of ipsilateral lymph node metastases of 45%, level II being the most common node-bearing region. Contralateral adenopathy was present in only 5% of patients. The issue of ipsilateral versus bilateral neck metastasis is discussed later in this chapter.

***Base of Tongue.*** Squamous cell carcinoma of the BOT is highly insidious. The BOT is almost devoid of pain fibers. Frequently, these tumors are asymptomatic until they have progressed significantly. Patients with cancers of the BOT often present with neck node metastases, only to be found to have a BOT lesion upon full evaluation. Visualization of this area on physical examination can be difficult, and a lesion can be often missed.[54]

(c) 2014 Wolters Kluwer. All Rights Reserved.

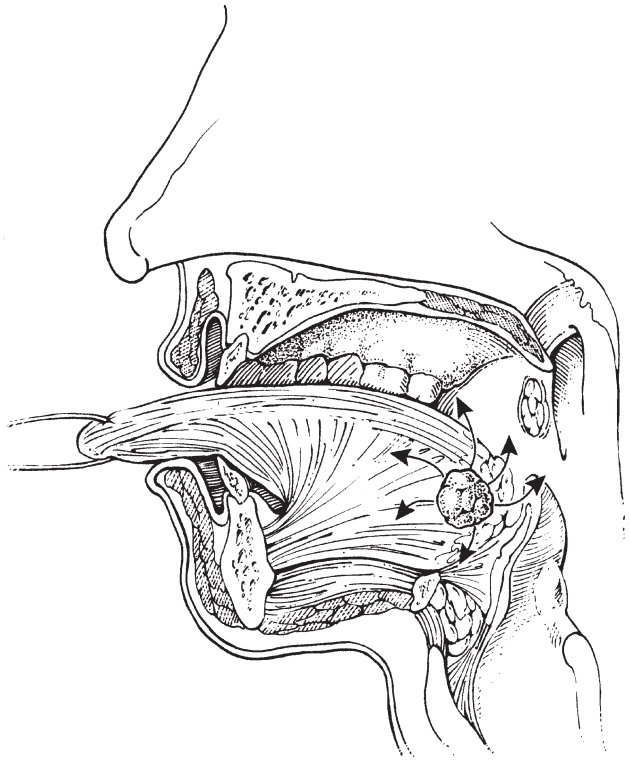

**FIGURE 17-6.** Patterns of spread of base of tongue cancer.

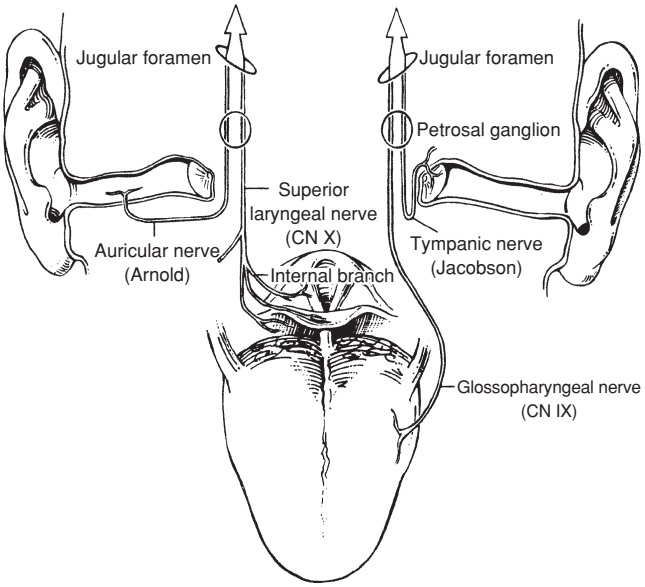

**FIGURE 17-7.** Neural pathways of referred otalgia. For pain sensed in the front of the helix and tragus, the skin of the anterior wall of the external auditory canal, the tympanic membrane, and the temple, pain is referred through the auriculotemporal nerve, which joins the lingual nerve, where the two become the mandibular nerve and enter the foramen ovale. The sensation of deep ear pain is through the tympanic nerve (Jacobson), which joins the glossopharyngeal nerve (cranial nerve IX) as the two traverse the jugular foramen. These general somatic afferent fibers innervate the base of tongue, the inner surface of the tympanic membrane, and the upper pharynx. For pain sensed in the back of the pinna, the posterior wall of the external auditory canal, and the external surface of the tympanic membrane, pain is referred through the auricular nerve (Arnold), which joins the superior laryngeal nerve (cranial nerve X), which in turn innervates the larynx, the pharynx, and the epiglottis as it traverses the jugular foramen.

Patients may experience the sensation of a mass or discomfort in the throat, with bleeding and pain at later stages. Patients might also experience difficulty with speech and swallowing. Occasionally, referred otalgia is the first symptom.

Extension anteriorly can involve the oral tongue, superior and lateral extension can involve the tonsil, and inferior extension can involve the vallecula, the epiglottis, and the preepiglottic space (Fig. 17-6). Locally advanced BOT tumors can infiltrate the deep muscle and cause fixation. Larynx and hypopharynx involvement can occur with advanced, inferior extension.

Lymph node metastasis is common, owing to the rich lymphatic drainage of the BOT. The most common first-echelon nodal region is level II, though involvement of levels III and IV is also seen. Approximately 70% of patients or more will present with ipsilateral metastases, and 10% to 20% will present with bilateral nodal metastases.[41]

***Pharyngeal Wall.*** Tumors of the pharyngeal wall are generally diagnosed in an advanced stage due to the silent location in which they develop. Symptoms can include pain and bleeding and a mass in the neck. Disease involvement can extend to the nasopharynx superiorly, the prevertebral fascia posteriorly, and the pyriform sinuses and the hypopharyngeal wall inferiorly. Clinically palpable cervical lymph node metastases are present in 25% of patients with T1 lesions, 30% of those with T2 lesions, 66% of patients with T3 lesions, and >75% of patients with T4 disease. Because most pharyngeal wall tumors extend past the midline, bilateral cervical metastases are common. RP nodes are also at great risk.[38]

***Referred Otalgia.*** Referred otalgia can be one of the first symptoms that a patient experiences with a mass in the oropharynx. The pathway for this referred pain is mediated by cranial nerves IX and X. The pathophysiology for otalgia is demonstrated in Figure 17-7.

## Diagnostic Evaluation

***History.*** The history should be part of a comprehensive evaluation of any patient with head and neck cancer. Patients can present with sore throat, odynophagia, otalgia, foreign body sensation in the throat, or a neck mass. If the history strongly reveals tobacco and alcohol use, efforts should be made to determine whether the patient is an alcoholic and continues to smoke. Alcoholic smokers are at risk for other chronic diseases of the heart, lungs, peripheral vascular system, liver, kidneys, and may present with signs of malnutrition. Before the institution of any therapeutic modality, the pathology material should be evaluated for HPV/p16 tumor status. All patients should cease alcohol and tobacco use. It may be necessary to guide the patient toward cessation programs. Clearly, those who discontinue smoking will better tolerate treatment and obtain a better result.[55]

***Physical Examination.*** The details of the physical examination are discussed in Chapter 1. Specific aspects of the physical examination should include evaluation of the lesion (exophytic or infiltrative), tongue mobility, and palatal motion. Fixation of the tongue will result in incomplete protrusion or deviation of the tongue to the side of tumor involvement. For tumors of

(c) 2014 Wolters Kluwer. All Rights Reserved.

the tonsil or the lateral pharyngeal wall, the examiner should test for anesthesia in the distribution of the ipsilateral mandibular nerve (V3). Any abnormality might suggest involvement of the inferior alveolar nerve in its pathway as it courses through the mandible or the base of skull and may direct the appropriate imaging study.[56] Because the tonsil is adjacent to the ascending ramus of the mandible, the BOT, and the parapharyngeal space, tumors may extend into these areas. This can often be detected by palpation. Indirect mirror examination and flexible endoscopy are important parts of the physical examination. It is useful to take a photograph or extensively diagram the physical findings in every patient. This can include a videotape. Such records are an excellent means of documenting the physical findings and of comparing future examination results to the initial presentation. In selected cases, an examination under anesthesia is recommended as a mean of obtaining information that is not completely accessible during office examination.

***Initial Workup and Radiographic Evaluation.*** In addition to a history and physical examination, a complete blood cell count and metabolic profile are recommended. Biopsy of a suspicious lesion is necessary to confirm the diagnosis.[57] The overwhelming majority of patients will also undergo PET-CT imaging as a key part of the staging evaluation. PET-CT may remove the need for a chest x-ray in many patients. See Chapter 4 for further discussion of general principles of head and neck imaging.

***Staging.*** The current staging criteria for tumors of the oropharynx, as defined by the American Joint Committee on Cancer (AJCC),[58] are listed in Table 17.5. This is a clinical staging system and not a pathologic staging system. If radiographic information reveals a discrepancy from clinical staging, this should be noted. Current staging allows the radiographic findings to factor into the clinical staging designation.

***Dental Evaluation and Prophylaxis.*** Treatment of OPC can result in a number of temporary and permanent effects on dental hygiene. Radiation-related xerostomia places dentulous patients at increased risk for dental caries, owing to the reduction in salivary flow, pH alteration, and proliferation of bacteria. A complete dental evaluation should be performed before any therapy is undertaken. See Chapter 9 for further discussion of dental oncology and maxillofacial prosthetics.

## Prognostic Factors

Traditionally, OPC prognostic factors for LRC, disease-free survival (DFS), or OS included TNM classification, location of the tumor, gender, age, and performance status.[59,60] As previously mentioned, in the current era, the impact of smoking and HPV/p16 tumoral positivity on OPC oncologic and functional outcomes has evolved remarkably.[61] A recent SEER analysis showed that the overall 5- and 10-year OS were approximately two times

**TABLE 17.5 American Joint Committee on Cancer (AJCC) Classification of Oropharyngeal Cancer**

| Primary tumor (T) | Stage | | | |
|---|---|---|---|---|
| T1: Tumor ≤2 cm in greatest dimension | **Stage 0** | Tis | N0 | M0 |
| T2: Tumor >2 cm by not >4 cm in greatest dimension | **Stage I** | T1 | N0 | M0 |
| T3: Tumor >4 cm in greatest dimension or extension to lingual surface of epiglottis | **Stage II** | T1 | N0 | M0 |

better for those patients with HPV-positive disease regardless of the treatment modality.[1] Although HPV/p16-positive patients have better outcomes than HPV/p16-negative patients, this advantage disappears in the HIV-positive population and heavy smokers. Mourad et al. reported on 73 HIV-positive patients with SCCHN, of whom 24 patients had OPC (12 of whom were HPV/p16 positive).[62] The outcomes revealed no difference between HPV/p16-positive versus HPV/p16-negative in the setting of HIV-positive patients and no advantage to chemo-RT over RT alone. These data are limited by their retrospective nature, but suggest that HIV status is an important prognostic factor.[63] Gillison et al. reported that the risk of OPC progression and death increases directly as a function of tobacco exposure at diagnosis and during therapy and is independent of tumor p16 status and treatment.[8] Smoking-induced OPC has been associated with mutated *p53*, epidermal growth factor receptor (EGFR) overexpression, and lower HPV/p16 expression.[64] Thus, given its unique prognostic significance, HPV is reviewed in detail in Chapter 12. In addition, Chapter 3 reviews all other important prognostic factors.

Chan and McBride et al. reported that active smoking during and after RT is predictive for decreased DSS, OS, progression-free survival (PFS), and distant metastasis–free survival (DMFS) rates.[65,66] In addition to smoking, anemia around the time of RT is associated with higher rates of persistent/recurrent disease,[60,67,68] and its correction may improve outcome.[69]

Multiple studies have investigated various molecular markers as potential predictive factors in patients treated definitely for OPC. Single-institution studies have reported that a high intratumoral microvessel density predicts for poorer LC and worse OS after definitive RT.[70] High Ki-67 labeling index is associated with local relapse[71] and shorter time to relapse[72] after definitive treatment. Shoushtari et al. reported that tissue microarray analysis using p16, EGFR, and HIF-1α for OPC could provide prognostic information.[73] These markers need validation in larger, multi-institutional trials.

Age is an important factor in the OPC management paradigm. Meta-analysis has shown that the effectiveness of chemo-RT and altered RT fractionation decreases with increasing age. For patients older than 70 years, there was no difference in survival for either chemo-RT or altered fractionation RT over conventional RT alone.[74–77] A similar observation regarding older patients (≥65 years) was also reported by Garden et al.[78] Likewise, Bonner et al. reported that the effectiveness of RT plus cetuximab versus RT alone decreases with the increase in age.[79,80] Recently, Michal et al. challenged the dogma that elderly patients (≥70) may not benefit from concomitant chemotherapy. They explored two cycles of concomitant cisplatin with RT. Older patients did experience greater myelosuppression and required more supportive care. However, their outcomes were the same as younger patients. Moreover, they recommended that age alone is not a contraindication to primary chemo-RT for locally advanced SCCHN.[81]

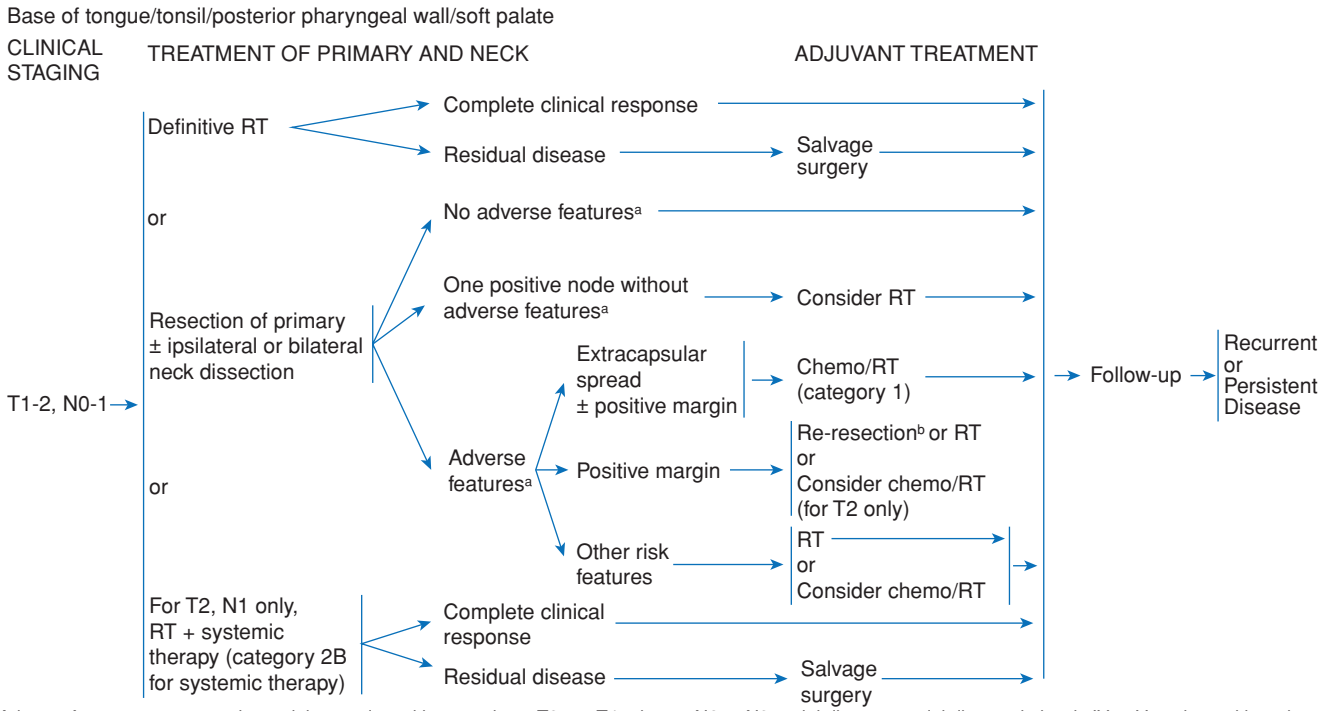
# MANAGEMENT STRATEGIES, RESULTS, AND OUTCOMES

## General Principles

Treatment decisions are always a balance between tumor control, cost-effectiveness, and QOL. The best decisions are usually made in a multidisciplinary context. It is very important to understand the goals and preferences of the patient before finalizing any recommendation. In general, early-stage disease can be treated by either RT or surgery, whereas more advanced disease introduces the potential use of chemotherapy and multimodality therapies into the discussion. RT has the advantage in many cases because it can be used as a single modality, it comprehensively treats the primary site and the neck, and it provides excellent functional outcomes. The advent of MIS, such as TORS and TLM, has augmented the role of surgery in early-stage diseases and will be discussed. For some patients, the use of TORS or TLM can reduce the need for RT, providing a trade-off, which can be attractive. Chemotherapy is generally reserved for patients with advanced disease. In the following sections, the management guidelines, outcomes, and results of OPC will be reported.

# SELECTION OF THERAPEUTIC MODALITY

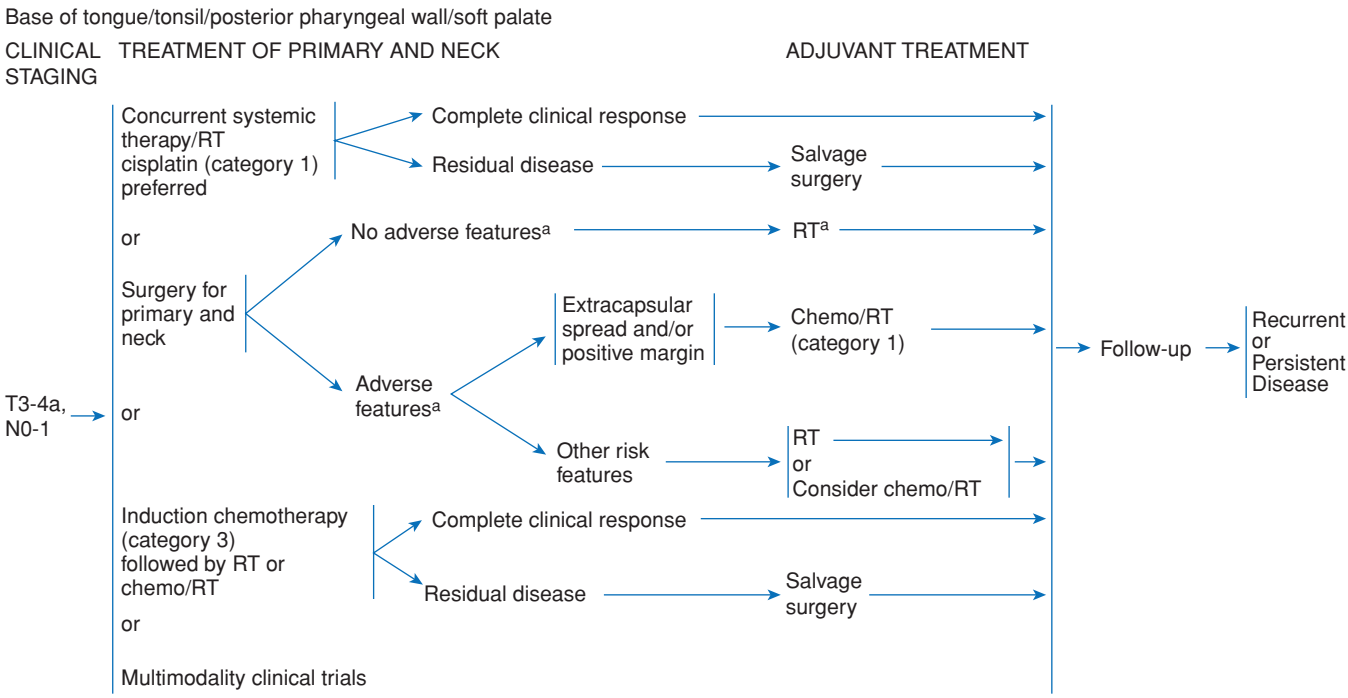
## General Principles



***Early-stage Disease.*** Early-stage OPCs can be treated with primary RT or primary surgery. RT is often used because it comprehensively includes the primary site, neck nodes, RP nodes, lymphatic channels in transit, and produces excellent long-term results. The increasing adoption of intensity-modulated radiotherapy (IMRT) with the addition of image-guided radiotherapy (IGRT) has led to high rates of LRC with low incidence of long-term functional morbidity.

Surgery involves the use of TLM or TORS for the primary site. This needs to be combined with a separate procedure to remove the neck nodes. Surgery may not be the only treatment needed, as patient may require additional treatment with RT, or chemo-RT, depending upon the pathologic findings in the primary tumor and the neck. Moreover, surgery generally does not address the RP nodes, which is an area at risk. Complete and multidisciplinary discussion is essential for every patient so that the best management decisions can be made. A fundamental management principle for early-stage disease is to maximize the likelihood of treatment with single-modality therapy by either RT or surgery alone. The best outcome for the patient is when one treatment modality is used. Multimodality therapy invariably increases morbidity and cost and should be unnecessary in most cases. Figure 17-8 shows the National Comprehensive Cancer Network (NCCN) 2012 guidelines for early-stage OPC treatment.

***Advanced-stage Disease.*** For patients with more advanced disease, combined therapy options are generally preferred. However, treatment needs to be individualized. See Figures 17-9 and 17-10 for the algorithm of care for advanced-stage OPC. In general, concomitant chemo-RT is the preferred management for most patients with stages III and IVA/B disease.[82,83] RT alone is often considered for certain patients, especially those with low bulk stage III lesions (i.e., T1–2N1M0).[63] Similarly, primary surgery may be used for selected patients with low bulk stage III disease (Hurtuk et al., 2012).[83a] If there are negative margins on the primary site resection, and the neck specimen is negative, surgery alone may be adequate. For other stage III patients, pathologic analysis may reveal positive nodes, inadequate margins, or other adverse features such as perineural invasion or lymphovascular invasion. This would trigger the use of PORT, or even postoperative chemo-RT, especially if the margins are positive or there is extranodal spread.[84,85]



In selecting stage III patients for surgery, it is important to try to choose patients who are unlikely to have indications for chemotherapy (positive margins or extracapsular spread), to minimize treatment morbidity. If a patient turns out to need postoperative chemo-RT, then it is probably true that the patient could have been treated definitively with primary chemo-RT and the surgery has not added value to the outcome. Indeed, it may have only added cost and toxicity. On the other hand, if the pathologic findings only call for PORT alone, or no adjuvant therapy, then the surgical procedure may have saved the patient from chemotherapy or RT, thus providing a trade-off, which may

be attractive to certain patients. These complex issues require the patient to have a thorough understanding of all the options and management algorithms, so that a personalized choice can be made. Multidisciplinary evaluation and discussion is mandatory.

For stage IVA/B disease, concomitant chemo-RT is the mainstay of treatment. In general, this involves concomitant cisplatin chemotherapy with IMRT. Full-dose RT is delivered to the primary site and neck. The current paradigm calls for a PET-CT scan to be done as part of the baseline evaluation. Three months after the completion of chemo-RT, a repeat PET-CT scan is done for evaluation of response and disease status. If the scan is negative, no further treatment is needed.[86] If the scan shows residual disease in the neck, then a neck dissection (ND) is performed. If the scan is equivocal in the neck, management needs to be individualized. Some patients will get ND.[87] Others will have close follow-up to assess the evolution of the findings. Sometimes, a fine-needle aspiration can help determine whether there is residual disease warranting surgery, or whether the findings are likely benign, warranting close follow-up alone, with ND reserved for salvage. Refer to Chapters 4 and 14 for comprehensive discussion on follow-up PET-CT scan and neck management, respectively.

For patients treated with primary surgery, adjuvant RT or chemo-RT will be indicated in the overwhelming majority of cases. Therefore, it is essential to balance any potential benefit of surgery with the morbidity, given the reality that chemo-RT will be needed anyway. In selected circumstances, patients with very advanced disease at either the primary site (e.g., T4) and/or neck (e.g., N3 or low neck disease) have been treated with an induction chemotherapy approach.[68,88–93] The rationale for this sequence is related to both the aggressive nature of the systemic therapy, as well as the greater risk of distant metastases in this cohort of patients. However, results from recent clinical trials have not shown any clear benefit from induction over concomitant chemo-RT,[94,95] thereby questioning the appropriateness of induction chemotherapy outside of a clinical trial.

For stage IVC, management decisions must be individualized and will be determined by the extent of the loco-regional disease, resectability, presence and extent of distant metastases, and the performance status of the patient. Thus, careful balance of morbidity, cost, and oncologic outcome must be considered. As mentioned earlier, these complex issues require the patient to have a thorough understanding of all the options and management algorithms, so a personalized choice can be made. Multidisciplinary evaluation and discussion is mandatory.

## SITE-SPECIFIC MANAGEMENT STRATEGIES, RESULTS, AND OUTCOMES

### Soft Palate

***Early-stage Disease.*** Treatment of soft palate cancer must address the primary site as well as both sides of the neck including bilateral RP nodes.[50,96–98]

Chera et al. reported on 59 patients with SCC of the soft palate, who presented with early-stage disease. All patients underwent

(c) 2014 Wolters Kluwer. All Rights Reserved.

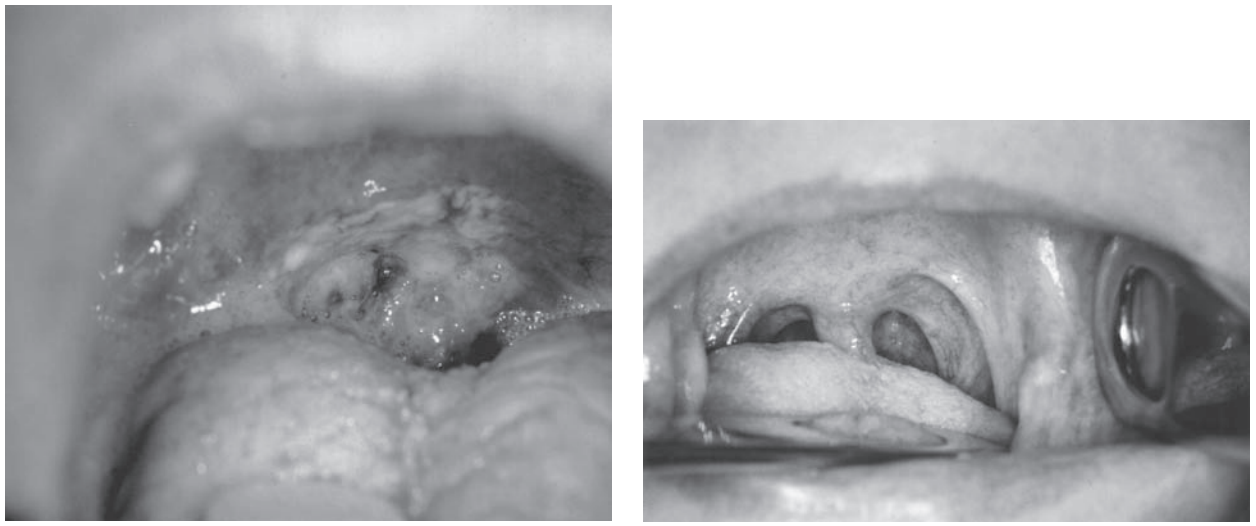

**FIGURE 17-11.** Patient with T2N0 squamous cell cancer of the soft palate before and after radiation therapy. This patient was treated with external beam radiation therapy to the primary site and both sides of the neck. The patient currently has no evidence of disease, more than 7 years after treatment.

primary RT. Stage I disease included 23 patients (16%) and stage II disease included 36 patients (25%). The 5-year initial and ultimate (i.e., after successful salvage) LRC rates for stage I were 84% and 89%, respectively. The 5-year initial and ultimate LRC rates for stage II were 85% and 88%, respectively. Specifically, the LC rates for both T1 and T2 were 90%. Nodal control rate at 5 years for N0 disease was 90%. The 5-year freedom from distant metastases rate was 95% for stage I and 97% for stage II. The 5-year DSS for stages I and II were 89% and 87%, respectively.[97] Figure 17-11 shows a T2 SCC of the soft palate before and after RT.

Iyer et al. reported on patients, with SCC of the soft palate, treated with primary surgery. With a median follow-up of 52 months, the 5-year DFS for stages I and II were 70% and 53%, respectively. Specifically, the 5-year LC for stages I and II were 85% and 84%, respectively. The 5-year regional control (RC) for stages I and II were 83% and 74%, respectively. The 5-year distant control (DC) for stages I and II were 96% and 81%, respectively. The 5-year DSS for stages I and II were 87% and 66%, respectively (Table 17.6).[98]

***Advanced-stage Disease.*** Chera et al. reported on 86 patients presented with advanced disease SCC of the soft palate. All patients underwent primary RT. Stage III disease included 23 patients (16%) and stage IVA/B diseases included 51 (35%) and 12 patients (8%), respectively. The 5-year initial and ultimate LRC rates for stage III were 66% and 96%, respectively. The 5-year initial and ultimate LRC rates for stage IVA were 85% and 88%, respectively, and for stage IVB were 43% for both. Specifically, the LC rate at 5 years was 67% for T3 and 57% for T4. Nodal control rates at 5 years were N1, 82%; N2, 68%; and N3, 71%. The 5-year rates of freedom from distant metastases were stage III, 100%; stage IVA, 93%; stage IVB, 69%; and overall, 94%. The 5-year DSS for stage III, IVA, and IVB were 88%, 57%, and 0%, respectively. In multivariate analysis, overall treatment time significantly affected local and ultimate LRC, and nodal stage significantly affected OS.[97]

Iyer et al. reported on patients with SCC of the soft palate, 81% underwent primary surgery, of whom 36% underwent surgery + PORT, and 19% underwent primary RT ± chemotherapy. With a median follow-up of 52 months, the 5-year DFS for stages III and IV were 54% and 36%, respectively. Specifically, the 5-year LC for stages III and IV were 88% and 54%, respectively. The 5-year RC for stages III and IV were 77% and 73%, respectively. The 5-year DC for stages III and IV were 72% and 83%, respectively. The 5-year DSS for stages III and IV were 64% and 55%, respectively, and for OS for stages III and IV were 55% and 37%, respectively.[98] In total, in the surgical cohort, 43% developed recurrent disease: 19% local recurrences, 20% nodal recurrences, and 12% distant

**TABLE 17.6 Five-year Oncologic Outcomes of Primary Surgery ± Postoperative Radiation Therapy in Soft Palate Cancer**

| | 5-yr Outcomes (%) | | | | | |

DFS, disease-free survival; LC, local control; RC, regional control; DC, distant control; DSS, disease-specific survival; OS, overall survival.

*Source:* From Iyer NG, Nixon IJ, Palmer F, et al. Surgical management of squamous cell carcinoma of the soft palate: factors predictive of outcome. *Head Neck.* 2012;34:1071–1080.

(c) 2014 Wolters Kluwer. All Rights Reserved.

metastases. Patients with early disease ($n$ = 90) had a DSS of 79%, whereas T1–2 but with neck-positive nodes ($n$ = 22) had a DSS of 56%. For OS and DSS, N classification was predictive of outcome. For LC and DC, margin status was a significant predictor, whereas the T classification was only a significant predictor for LC.[98]

Many single institutional reports have shown relatively similar outcomes.[99–108] In the modern era, results for loco-regionally advanced OPC are often combined for all primary sites, making it very difficult to extract the specific outcomes for each anatomic subsite. Most patients have primary lesions of either the tonsil or BOT, with fewer soft palate and pharyngeal wall lesions. Refer to the sections of this chapter titled "Selection of Therapeutic Modality—General Principles" and "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy" for additional data and discussion related to OPC, all sites combined. Chemo-RT is the mainstay of management of loco-regionally advanced OPC, and this is reviewed for OPC sites in the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy."

## Pharyngeal Wall Tumors

***Early-stage Disease.*** Treatment of pharyngeal wall tumors must address the primary site and both sides of the neck, including bilateral RP nodes. Hull et al. reported on 37 patients with pharyngeal wall tumors treated with primary RT. Five-year LC rates for T1 and T2 were 93% and 82%, respectively. On multivariate analysis, factors associated with improved LRC included twice-daily fractionation ($p$ = 0.0009), stages I to II disease ($p$ = 0.0051), and oropharyngeal primary site ($p$ = 0.0193). The same group previously reported the effect of the use of once-daily versus twice-daily fractionation on LC. The LC rates for patients treated with once-daily versus twice-daily fractionation were as follows: T1—100% versus 100% and T2—67% versus 92% ($p$ = 0.0009). These investigators also examined their outcomes as a function of RT technique. They found superior outcomes when using a more modern technique where there was more generous anatomic coverage of the prevertebral area and adjacent vertebral body. The LC rate for T1 was 100%. The LC rate for T2 was 57% using older techniques versus 100% for the modern approach, emphasizing the importance of including the entire prevertebral space into the target volume.[109,110]

Mendenhall et al. recently reported the results of primary RT. The 5-year LC and ultimate LC were: T1—93% and 93%, respectively; T2—84% and 91%, respectively. Multivariate analysis revealed stages I to II tumors, female gender, and altered fractionation were associated with improved LRC. The 5-year DSS and OS were as follows: stage I—88% and 50%, respectively; stage II—89% and 57%, respectively.[111]

Spiro et al. reported on 78 patients with posterior pharyngeal wall tumors treated with primary surgery ($n$ = 60) or primary RT ($n$ = 18). Survival was greater in those with stage I and stage II tumors, but the difference was significant only in comparison to those with stage IV disease. Local recurrence occurred in 16% and 21% for stages I and II, respectively.[112]

***Advanced-stage Disease.*** Hull et al. reported the outcomes of primary RT. The 5-year LC rates for T3 and T4 tumors were 59% and 50%, respectively. The LC rates for patients treated with once-daily versus twice-daily fractionation were as follows: T3—43% versus 80%; and T4—17% versus 50% ($p$ = 0.0009). These investigators also examined their outcomes as a function of RT technique. Similar to their finding for T2 disease, they found superior outcomes when using a more modern technique where there was more generous anatomic coverage of the prevertebral area and adjacent vertebral body. The LC rate for T3 was 46% for the older technique versus 73% for the modern approach. The LC rate for T4 was 29% for the older technique versus 75% for the modern approach, emphasizing the importance of including the entire prevertebral space into the target volume.[109,110] The current practice would employ IMRT, and issues of target coverage and spinal cord protection become easier to assure.

Mendenhall et al. recently reported the results of primary RT. The 5-year LC for T3 was 60% and T4 was 44%. Multivariate analysis revealed female gender, and altered fractionation were associated with improved LRC. The 5-year DSS and OS were the following: stage III—49% and 31%, respectively, and stage IV—35% and 21%, respectively. Fatal complications occurred in nine patients (5%).[113]

Spiro et al. reported on 78 patients with posterior pharyngeal wall tumors treated with primary surgery ($n$ = 60) or primary RT ($n$ = 18). Local recurrence occurred in 37% and 63% for stage III and IV, respectively. Neck failure was noted in 21% of patients. Distant metastasis was documented in 8%.[112]

Julieron et al. reported the outcomes for primary surgery ± RT. In their hands, primary surgery followed by RT produced the best outcomes. For combined therapy, the rate of local failure (LF) was 11% and the 5-year survival rate was 35%. In the group of patients who developed LF post primary RT, the 5-year survival rate was 16%.[114] In the modern era, results for loco-regionally advanced OPC are often combined for all primary sites, making it very difficult to extract the specific outcomes for each anatomic subsite. Refer to the sections of this chapter titled "Selection of Therapeutic Modality—General Principles" and "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy" for additional data and discussion related to OPC, all sites combined. Chemo-RT is the mainstay of management of loco-regionally advanced OPC, and this is reviewed for OPC sites in the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy."

## Tonsillar Region

***Early-stage Disease.*** Treatment of tonsil cancer must address the primary site as well as the regions of the neck at risk. There is a growing body of evidence to support the strategy of unilateral treatment to the ipsilateral neck alone, including the ipsilateral, lateral RP nodes.[115–117] Unilateral treatment provides the patient with a significant QOL advantage, both with respect to acute toxicity and late functional outcomes. Lesions that approach the midline or involve the tongue base or glossotonsillar sulcus are not good candidates for unilateral treatment and should be treated to both sides of the neck. Treatment planning must ensure protection of critical normal structures, which is easily achieved with image-guided IMRT. Treatment technique will be further described in Chapter 17, Part C.

Eisbruch et al. have demonstrated that patients treated unilaterally report less xerostomia and better QOL compared to those patients treated bilaterally, even with IMRT, which spares the contralateral parotid gland.[118] However, careful patient selection is required to minimize the risk for contralateral neck failure. Multiple reports document excellent outcomes using ipsilateral neck RT.

Jackson et al. report on 178 patients receiving ipsilateral treatment for tonsillar cancers. Patients presented primarily with T1–2 (66%) and N0 (57%) disease. The rates of LRC and contralateral neck recurrence by stage were as follows: stage I—91% and 0%, respectively; stage II—74% and 2%, respectively. None of the patients with N0 disease had experienced contralateral failure. The LC rate was 84% for T1–2.[115]

O'Sullivan et al. reported on 228 tonsillar carcinomas treated with ipsilateral RT. Eighty-four percent of patients had

(c) 2014 Wolters Kluwer. All Rights Reserved.

T1–2 tumors of which 70% with N0. At a median follow-up of 5.7 years, none of the patients with T1 or N0 lesions had experienced contralateral neck failure. The median 3-year LC rate for stages I and II were 91% and 76%, respectively. The 3-year median ipsilateral RC for stages I and II were 98% and 91%, respectively. For the whole cohort, the 3-year cause-specific survival was 76%. The only patients subsets with significant risk of contralateral neck failure (>10%) were those with tumor involvement of the medial one-third of palate or BOT.[116]

Kagei et al. reported 32 patients with SCC of the tonsil and soft palate treated unilaterally. Each tumor did not cross midline and demonstrated no obvious contralateral disease. With a median follow-up of 3.7 years, there were no contralateral neck failures.[119]

Levendag et al. reported on 190 patients with T1–3 N0–3 SCC of the tonsil and soft palate. All patients underwent primary RT followed by surgery or brachytherapy boost (BT). The tumor control rates after BT versus surgery at 5 years were 88% versus 88% for LC; 93% versus 85% for RC; 57% versus 52% for DFS; 67% versus 57% for OS; and 5% versus 6% for RF. They concluded that there was no need to treat the contralateral neck unless the tumor extends beyond the midline of the soft palate (uvula) or beyond the lateral one-third of the ipsilateral BOT.[120]

Hu et al. performed one of the few prospective trials assessing the safety of unilateral neck treatment.[117] The eligibility criteria required patients to have primary lesions >1 cm from midline, no involvement of the BOT, and PET-CT documentation of the absence of contralateral neck metastasis. With a median follow-up of 16 months, there were no failures in the contralateral neck. These criteria seem reasonable to use in making the decision to exclude the contralateral neck.

The oncologic outcomes for early-stage tonsil cancer with primary RT have been excellent. Mendenhall reported on 503 patients with tonsillar cancer, who underwent definitive RT. Five-year rates of LC were as follows: T1—88% and T2—84%. The ultimate LC rates (after salvage surgery) at 5 years were T1—94% and T2—91%. Five-year cause-specific survivals were as follows: stage I—100% and stage II—86%.[121]

It is important to recognize that the shift of patient characteristics toward younger, healthier, nonsmoker, more favorable prognosis of the HPV-related cancer, as well as the major advances in RT delivery, have had a major impact on outcomes and QOL in the modern era. Thus, current outcomes are much better than the prior era.[61,63,122–126]

Mourad et al. reported on 79 patients with SCC of the tonsil who underwent primary RT.[127] After a median follow-up of 56 months, the 5-year local control (LC), RC, DC, and OS for stages I/II combined were all 100%.

Garden et al. reported on 777 patients with OPC. The median follow-up was 54 months. The 5-year LRC, DFS, and OS rates were 90%, 82%, and 84%, respectively. Five-year DFS was 90% in never smokers with T1–2 disease. The 5-year DFS for N0 was 92%.[128] Table 17.7 shows the excellent outcomes of OPC as reported in the English literature. It is clear that the overwhelming majority of patients with early-stage tonsil cancer achieve excellent LRC with primary RT.

Primary surgical treatment is also an option for early-stage tonsillar cancer. Most surgical series report outcomes by T and N classification and is not always possible to determine the outcomes by overall stage. Thus, there are some limitations in the interpretation of the surgical literature related to this point.

The use of primary surgery, via conventional approach, as definitive treatment for early tonsillar disease is not reported frequently. However, excellent LC rates ranging from 80% to 90% have been reported.

Moncrieff et al. retrospectively reported on 92 patients with early-stage OPC, of whom 54% had tonsillar cancer. All patients underwent primary surgery, 76% underwent ND, and 62% underwent PORT or chemo-RT. Twenty-eight percent had T1 lesions, 72% had T2 lesions, and 52% were N0. The 5-year DSS was 83% and LC rate was 87%.[129]

Walvekar et al. reported on 49 patients with early-stage OPC, of whom 53% had tonsillar cancer. All patients underwent primary surgery, 94% underwent ND, and 33% underwent PORT or chemo-RT (8%). Thirty-five percent had T1 lesions, 65% had T2 lesions, and 42% were N0. The 3-year DFS and 5-year OS was 85% and 83%, respectively.[130] Table 17.8 shows the oncologic and functional outcomes of OPC status postsurgery and microinvasive surgery (MIS), including TLO, TLM, and TORS. The vast majority of patients underwent primary surgery and ND followed by adjuvant RT or chemo-RT based upon the pathological findings. If surgery is selected as the primary treatment, MIS is the preferred surgical approach.

Laccourreye et al. reported on 166 patients with SCC of the tonsil who underwent TLO. The 5-year LC rate was 89% for T1 and 82% for T2 lesions, respectively ($p = 0.02$).[25]

There has also been a growing interest in the role of TLM and TORS in the management of OPC.[28,29,131,132]

Grant et al. reported on 69 patients with OPC, of whom 41% were tonsil cancer. All underwent primary TLM, 86% underwent ND, and 26% had adjuvant RT. With a mean follow-up of 44 months, the 5-year LRC estimate for stages I and II disease were 90% and 73%, respectively. The 5-year OS estimate was 86%.[133]

Moore et al. reported on 66 patients who underwent TORS with a minimum of 2-year follow-up. Long-term gastrostomy tube use was required in 4.5% and long-term tracheotomy in 1.5%. Three-year estimated LC and RC were 97% and 94%, respectively. Two-year DSS and DFS were 95% and 92%, respectively.[134]

One of the strongest arguments for performing TLM or TORS is the potential to avoid RT and chemotherapy in properly selected, favorable patients. If negative margins are achieved and no other poor prognostic factors are noted in the specimen (lymphovascular invasion, perineural invasion, multiple positive lymph nodes, extracapsular extension), then adjuvant therapy can potentially be deintensified or eliminated. Thus, the patient may have the personal choice of selecting an algorithm that uses surgery to avoid chemotherapy or RT, or uses RT to avoid surgery. However, it must be pointed out that surgery alone generally does not address the RP nodes, which are at risk.

It is clear that excellent outcomes should be achieved with either primary RT or primary surgery for patients with early-tonsil cancer. In the best of circumstances, patients should be treated with single modality. Because there are options, and because these options require the patient to understand their risks and benefits, multidisciplinary evaluation is mandatory.

***Advanced-stage Disease.*** In the current era, patients with loco-regionally advanced disease are still highly curable. Excellent outcomes can be achieved in stages III, IVA, and IVB.[63,126] Most patients will require multimodality therapy. Concomitant cisplatin-based chemotherapy and RT (chemo-RT) has been the mainstay of treatment.[61,77,82,83,135,136] Primary surgical treatment is also an option, but will usually require additional treatment with RT ± chemotherapy.[85,137] Patients with stage III disease can be managed by single-modality therapy of primary RT or primary surgery, but the treatment of these patients must be individualized.

Treatment of loco-regionally advanced tonsil cancer involves management of the primary site and the regions of the neck at risk. As is the case with early-stage disease, unilateral treatment may still be appropriate, even in patients with ipsilateral nodal metastases.[116] O'Sullivan et al. report the results of 228 tonsillar carcinomas. Patients with stages III and IVA/B were included.

The vast majority of patients underwent TLM, TLO, or TORS followed by neck surgery (ND = neck dissection) and adjuvant therapy (e.g., radiation therapy [RT] or concurrent chemo-RT; CRT). BOT, base of tongue; KM, Kaplan-Meier; PPW, posterior pharyngeal wall; ISH, *in situ* hybridization; IHC, immune-histochemistry; PORT, postoperative RT; POcRT, postoperative chemo-RT; HPV, human papillomavirus; DSS, disease-specific survival; LC: local control; LRC: loco-regional control; DC: distant control; DFS: disease-free survival; OS: overall survival; LF: local failure; DM: distant metastasis; TNM: tumor, nodal, and metastasis classification; SS: statistically significant.

At a median follow-up of 5.7 years, the median 3-year LC for stages III and IVA/B were 79% and 70%, respectively. The 3-year median RC for stages III and IVA/B were 75% and 60%, respectively. Contralateral neck failure occurred in 3%.[116]

Jackson et al. report on 178 patients receiving ipsilateral treatment for tonsillar cancers. Sixty-three percent had stages III to IV disease. The rates of LRC and contralateral neck recurrence were as follows: stage III—51% and 4%; and stage IV—53% and 0%. Patients with N0 (57%) or N1 (30%) disease had contralateral failure rates of 0% and 4%, respectively. None of the 23 (13%) patients with N2–3 disease had contralateral failure.[115]

Likewise, Rusthoven et al. reported on 20 patients with well-lateralized, ipsilateral node-positive tonsil cancer, not involving midline structures (BOT or soft palate), treated with unilateral RT. Eighty percent were stage IV (N1—20%; N2a—5%; N2b—65%). None had contralateral neck failure.[124]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Chronowski et al. reported on 102 patients with SCC of the tonsil treated with unilateral RT. Patients had TX (17%), T1 (51%), or T2 (32%) disease, with Nx (2%), N0 (32%), N1 (23%), N2a (21%), or N2b (22%) neck disease. Sixty-one patients (60%) underwent diagnostic tonsillectomy before RT. Twenty-seven patients (26%) underwent excision of a cervical lymph node or ND before RT. Median follow-up for surviving patients was 38 months. LRC at the primary site and ipsilateral neck was 100%. Two patients experienced contralateral nodal recurrence (2%). The 5-year OS and DFS rates were 95% and 96%, respectively. The 5-year freedom from contralateral nodal recurrence rate was 96%.[125]

Hu et al. reported a prospective clinical trial including 22 patients with tonsil cancer who underwent unilateral RT: stage III—41% and stage IVA—59%. Twenty patients received platinum-based chemo-RT. Eligibility criteria mandated that all patients have primary lesions >1 cm from the midline, not involving the BOT, and a negative contralateral neck on clinical examination and PET-CT scan. At a median follow-up of 20 months, no patient experienced contralateral nodal failure. The 2-year actuarial oncologic outcomes were: LC—100%, ipsilateral RC—93%, distant metastasis rate—15%, and OS—88%. No patient had more than grade 1 xerostomia or chronic dysphagia. No patient required a PEG feeding tube.[117] It is clear that unilateral RT is an option, even in patients with loco-regionally advanced disease, as long as they meet the reasonable criteria in the series above.

Mendenhall reported on 503 patients with tonsillar cancer treated with primary RT. Five-year rates of LC were as follows: T3—78% and T4—61%. The 5-year ultimate LC rates (i.e., including surgical salvage) for T3 was 82% and for T4 was 68%. Five-year DSS were as follows: III—84%, IVA—73%, and IVB—46%. Absolute OS at 5 years were as follows: III—62%, IVA—57%, and IVB—33%.[121]

Mourad et al. reported on 79 patients with SCC of the tonsil who underwent primary RT. After a median follow-up of 56 months, the 5-year LC, RC, DC, and OS by stage were as follows: stages III to IVA—98%, 96%, 95%, and 88%, respectively; stage IVB—100%, 100%, 69%, and 66%, respectively. Among stage IVB patients, DC was significantly lower ($p = 0.01$) and a trend toward lower OS was noted ($p = 0.08$).[127]

The University of Florida data have the enormous advantage of large numbers, long follow-up and treatment performed consistently by experienced head and neck radiation oncologists. However, it is important to recognize that the shift of patients' characteristics, more favorable prognosis of the HPV-related cancer in younger patients with no or minimal smoking history as well as the major advances in IMRT planning and delivery (IGRT), has made a major impact on outcomes and QOL in the modern era. Thus, current outcomes are much better than the prior era due to these improvements. Table 17.7 shows the excellent outcomes of OPC as reported in the most recent studies.

Setton et al. reported on 442 patients with OPC, who underwent primary IMRT ± concomitant cisplatin-based chemotherapy. Stages III to IVA/B formed 94% of patients. The primary tumor subsite was the tonsil in 50%, the BOT in 46%, the pharyngeal wall in 3%, and the soft palate in 2%. Median follow-up among surviving patients was 37 months. The 3-year cumulative incidence of LF, regional failure, and distant metastasis was 5.4%, 5.6%, and 12.5%, respectively. The 3-year OS rate was 85%.[126]

Toledano et al. reported the results of the GORTEC 2004–03 study, which included 208 patients with SCCHN, of whom 56% were OPC and 71% were stages III to IV. All were treated with IMRT with concomitant chemotherapy. With a median follow-up of 25 months, the 2-year LRC and OS were 86% and 87%, respectively.[136]

Garden et al. reported on 777 patients with OPC, who underwent primary IMRT ± chemotherapy. With a median follow-up of 54 months, the 5-year OS, DFS, and LRC were 84%, 82%, and 90%, respectively. The 5-year DFS by N stage were as follows: N0—75%, N1/2a—92%, N2b/2c—80%, and N3—57%. A subset analysis showed that patients with level IV disease had a 60% 5-year DFS rate due to higher rate of distant metastasis.[128]

Multiple studies have documented the improved outcomes for patients who are HPV/p16 positive. Tables 17.7 and 17.8 summarize several important trials that emphasize this finding. Even for advanced-stage patients, oncologic and functional outcomes have been excellent.[61,65,123,138,139]

The technical aspects of RT management are reviewed in Chapter 17, Part C. In summary, IMRT is the mainstay of treatment and IGRT is an important complement to IMRT. The primary site and involved nodal areas receive 70 Gy in 7 weeks. The adjacent nodal areas generally receive an intermediate dose of 60 to 63 Gy, often by a dose-painting approach. Electively treated nodal regions such as low neck, lateral RP nodes, or contralateral neck nodes, generally receive 50 to 54 Gy.

Platinum-based concomitant chemotherapy with RT is the standard chemo-RT approach. Table 17.9 outlines a variety of protocols and their outcomes. The reader is referred to the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy" for the detailed review of chemotherapy management and outcomes. For patients who cannot receive cisplatin, alternate approaches such as carboplatin[140,141] or cetuximab[79] or even altered fractionation RT alone are considered. This is also reviewed in detail in the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy."

The general approach to the neck involves management with primary RT or chemo-RT. A PET-CT scan is done 3 months after the completion of treatment. An ND is done if there is evidence of residual disease. Neck management is discussed in detail in Chapter 14.

Recently, there has been a growing interest in incorporating MIS into the management algorithm of locally advanced OPC. MIS includes TLO, TLM, and TORS. There are multiple reports that have shown promising oncologic and functional outcomes via this approach. Noteworthy, the vast majority of patients who underwent MIS also underwent ND, and adjuvant RT or chemo-RT. Table 17.8 shows the oncologic and functional outcomes of OPC treated via MIS approaches.

Haughey et al. reported on 204 patients with stage III/IV OPC, of whom 48% had tonsil cancer. All patients underwent TLM and ND, 74% underwent adjuvant RT, of whom 22% required chemo-RT. With a median follow-up of 42 months, the 2- and 5-year OS rates were 89% and 78%, respectively. The overall LC was 97%. Long-term PEG dependency rates at 1-, 2-, and 5-year were 19%, 9%, and 4%, respectively.[142] Similar outcomes have been reported by other investigators.[26,131,133,143,144]

Moore et al. reported on patients with stage III/IV OPC, of whom 42% had tonsillar cancer and 89% were HPV/p16 positive. All patients underwent TORS and ND, 62% underwent adjuvant chemo-RT, and 21% underwent adjuvant RT alone. With a mean follow-up of 36 months, the 2-year DFS was 94%. The 4-year estimated LC and RC were 97% and 94%, respectively. The DFS was 96% and 83% for HPV-positive versus HPV-negative tumors, respectively ($p = 0.08$). Long-term PEG dependency was 4.5%.[134] Similar outcomes have been reported by other investigators.[28,132,145–148]

The use of primary TLM or TORS has demonstrated excellent oncologic and functional outcomes with low rates of PEG dependency and high QOL scores on questionnaire assessment. Most series reporting ≥2-year PEG dependency rates below 5% to 10%.[28,132,145,149] Similarly, the rates of PEG-dependence are

very similar for patients receiving surgery versus primary chemo-RT–based management, with estimated rate of <5%.[63,126,150] The outcomes are operator dependent, whether surgery or RT, with experience being a key factor in both oncologic and functional outcomes. See Tables 17.7 and 17.8 for further details of oncologic and functional outcomes for each modality.

## Base of Tongue

***Early-stage Disease.*** Early-stage BOT cancer is successfully treated with either primary RT or primary surgery. The results are equivalent for LC and OS. It is always preferred to use single-modality treatment in order to optimize both the oncologic and the functional outcomes. Treatment of BOT cancer must address the primary site as well as both sides of the neck and bilateral RP nodes.[41,47,50] Thus, RT has the advantage of comprehensively and simultaneously treating the primary site and all nodal areas at risk.

RT alone is very effective for patients with early-stage disease. Brachytherapy boost (BT) has been used by multiple investigators as a mechanism to increase tumor dose while significantly lowering dose to the salivary glands, the constrictors muscles, the larynx, and the surrounding mucosa. Table 17.10 summarizes the LC rates for BOT cancer treated with EBRT plus BT. Although there is no prospective trial, the data using BT has been consistently excellent. Patient selection is important, and a radiation oncologist with experience in BT must perform the procedure. As always, the decision to use any specific therapeutic approach should be individualized.

Data from numerous authors have shown that the LC for early-stage disease is in the range of 80% to 100% when treated

with combined RT and BT. Many centers, including our own, have used BT for patients with BOT cancers.[120,151–154] This approach has consistently yielded excellent outcomes from both the oncologic and functional prospective.[152] With the advances in RT techniques (IMRT, IGRT), changes in the patient characteristics (emergence of HPV/p16) and prognosis, it is legitimate to question whether BT should still be considered in the context of early-stage BOT cancer. There are ample reports in the literature that reveal excellent outcomes with primary RT, whether EBRT alone or EBRT with BT boost (Table 17.10). Whereas there is probably not an oncologic advantage for T1 lesions, the literature supports a potential LC advantage for T2 disease.[120,151–154] The use of BT allows considerable reduction (de-intensification) in the EBRT dose, from 70 Gy down to 50 to 54 Gy. This results in lower acute toxicity and minimal long-term swallowing dysfunction and xerostomia.[152] Of course, the use of BT involves short-term hospitalization, a temporary tracheostomy, and several days of continuous LDR-RT. This needs to be taken into account in making the best decision for the patient. A large percentage of current BOT cancer patients are healthy, young nonsmokers, who are able to tolerate this procedure well. Full informed consent is mandatory, as well as patient understanding of the options.

The authors' preferred strategy entails EBRT followed by an interstitial $^{192}$Ir implant as a boost to the BOT. The authors believe that this modality offers the greatest opportunity for excellent LC and best function results compared with either high-dose EBRT alone or to primary surgery. A BT boost to the BOT (20–30 Gy) is performed approximately 2 to 3 weeks after IMRT (50–60 Gy). The implant consists of $^{192}$Ir inserted via after-loading catheters placed with a looping technique (Fig. 17-12). As a safety precaution, a temporary tracheostomy is performed and maintained during the dwell time of the implant. A temporary nasogastric feeding tube is also used. Refer to Chapter 17, Part C, for RT techniques, where the details of contouring IMRT- and CT-based BT planning are reviewed.

Pernot et al. reported on 277 patients with SCC of BOT of whom 64% had T1–2 disease. The 5-year LC, DSS, and OS rates by T classification (T1, T2) were as follows: LC = T1—89%, T2—86%; DSS = T1—78% and T2—62%; OS = T1—62% and T2—53%. No local recurrence was detected after 3 years.[151] Multivariate analysis revealed that a treatment interval of <20 days between EBRT and BT and an overall treatment time of <55 days yielded better outcomes.[153]

While there are no randomized trials comparing BT to other approaches, there are comparative retrospective series that do compare approaches for early-stage patients. Housset et al. reported on 110 patients with early-stage BOT cancer (100% T1–2). Twenty-five percent underwent surgery and RT, 26% EBRT plus BT, and 49% underwent EBRT alone. With a median follow-up of 8 years, the LF rates were 43%, 21%, and 19% for EBRT alone, RT plus BT, and surgery plus RT, respectively.[155] The EBRT-alone patients had more favorable characteristics, highlighting the potential advantage of a BT boost in providing better oncologic outcomes. Sessions et al. reported on 262 patients with BOT cancer (26% stage I and 13% stage II), who underwent primary RT, primary surgery, or surgery plus RT. There was no significant difference in DSS or OS rates as a function of treatment modality. However, patients who underwent RT alone had improved capacity to swallow ($p = 0.001$), speak ($p = 0.01$), and work ($p = 0.001$) compared with surgery alone or surgery plus RT.[156]

MIS (TLM and TORS) has also gained interest in patients with BOT cancer. This would be especially true when surgery can be used as a single modality. As all patients with BOT cancer require treatment of the primary site, and both sides of the neck, surgical patients would require ND. A potential shortcoming of this approach related to the fact that the RP nodes are generally not addressed during these surgical procedures. This could leave the patient vulnerable to recurrence in this area. For example, Figure 17-13 shows a clinical example of RP nodal recurrence after TORS alone for BOT cancer. Thus, patient selection and

patient understanding of the various treatment algorithms is an absolute requirement to high-quality care.

The use of primary surgery requires a careful assessment of the resected specimen at both the primary site and the neck. Depending upon the pathologic finding, additional treatment may be indicated. Adverse pathologic features, such as inadequate surgical margins, perineural invasion, lymphovascular invasion, positive nodes, and extracapsular spread, would trigger the use of adjuvant RT or chemo-RT. One of the strongest arguments for performing TLM or TORS is the potential to avoid RT and chemotherapy in properly selected, favorable patients. If negative margins are achieved and no other poor prognostic factors are noted in the specimen, then adjuvant therapy may not be necessary. However, if the pathologic assessment triggers the need for adjuvant therapy, then the resultant management violates the principle of using single-modality therapy for early-stage disease. Thus, the patient may have the personal choice of selecting an algorithm that uses surgery to avoid chemotherapy or RT, or uses RT to avoid surgery.

It is difficult to partition the surgical data for early-stage versus advanced disease. In reality, the results of treatment are reported based upon the surgical and pathological findings rather than the clinical stage. Table 17.8 summarizes the surgical data including oncologic and functional outcomes.

Iyer et al. reported on 128 patients with SCC of the BOT, who underwent primary surgery. In the whole cohort, 16% underwent surgery only and 84% underwent surgery plus PORT. The clinical TNM classification was as follows: T1—18%, T2—41%, and N0—34%. With a median follow-up of 68 months, the 5-year DSS for surgery alone ± ND was 67%, and for surgery + ND + PORT was 100%. The 5-year DSS for T1 and T2 were 95% and 73%, respectively ($p = 0.001$). For the whole cohort, the 5-year OS and RFS rates were 60% and 61%, respectively. Multivariate analysis showed T classification is significant for local recurrence.[98]

Henstrom et al. reported on 20 patients with BOT cancer who underwent primary TLM and ND. Sixty percent underwent PORT and 20% underwent adjuvant chemo-RT. With a mean follow-up of 40 months, the 2- and 5-year OS rates were 90% and 83%, respectively. The 2- and 5-year DFS rates were 90% and 83%, respectively. The 2-year LC, RC, and DC rates were 84%, 100%, and 95%, respectively. Ten percent were PEG dependent.[144]

Moore et al. reported on patients with BOT cancer who underwent primary TORS and ND. Eighty-nine percent were HPV/p16 positive. Twenty-one percent underwent PORT and 62% underwent adjuvant chemo-RT. With a mean follow-up of 36 months, the 4-year DFS was 92%. The 4-year LC and RC were 97% and 94%, respectively. Five percent were PEG dependent.[134]

Thus, it is clear that a primary RT approach or a primary surgical approach can be used for early-stage BOT cancer. Primary RT has the advantage of being a single-modality therapy. Primary surgery is an alternative to primary RT, especially if surgery can be the only treatment. Both primary surgery and BT boost involve an inpatient hospital stay. Multidisciplinary evaluation and discussion of all treatment options is mandatory prior to embarking upon treatment and provides each patient with the best set of personalized options.

***Advanced-stage Disease.*** In the current era, patients with locoregionally advanced disease are still highly curable. Excellent outcomes can be achieved in stages III, IVA, and IVB.[126,128,154] Most patients will require multimodality therapy. Concomitant cisplatin-based chemotherapy and RT (chemo-RT) has been the mainstay of treatment.[61,77,82,83,135] Tables 17.7 and 17.9 summarizes the oncologic and functional outcomes of the concomitant chemo-RT approach.

Lawson et al. reported on 34 patients with SCC of the BOT, who underwent primary concomitant chemo-RT. Ninety-four percent were stages III to IV. With a median follow-up of 20 months, the 2-year LC and RC were 92% and 97%, respectively.[157]

Patton et al. reported on 89 patients with BOT cancer, who underwent primary concomitant chemo-RT including brachytherapy boost. Stages III and IV were 10% and 79%, respectively. TNM classification was T1—8%, T2—45%, T3—30%, T4—17%, and N2/3—80%. Patients were treated initially with EBRT to a median dose of 60 Gy followed by a brachytherapy boost (median dose = 18 Gy). Concurrent chemotherapy was given in 81%. Planned ND was performed in 79%. At a median follow-up of 38 months, 3-year LC was 97%, RC 96%, LRC 93%, DFS 88%, and OS 90%. The 3-year PEG-dependence was 4% and grade 2 xerostomia 5%.[154]

Cano et al. reported on 88 patients who underwent concurrent chemo-RT followed by BT boost. Eighty-one percent had positive nodes, 42% had T1–2, and 58% had T3–4. With a median follow-up of 3 years, the 3-year OS, LRC, and DSS rates were 81%, 80%, and 70%, respectively. The actuarial LC was 82% and DC was 90%.[158]

Platinum-based concomitant chemotherapy with RT is the standard chemo-RT approach. Table 17.9 outlines a variety of protocols and their outcomes. The reader is referred to the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy" for the detailed review of chemotherapy management and outcomes. For patients who cannot receive cisplatin, alternate approaches such as carboplatin[140,141] or cetuximab[79] or even altered fractionation RT alone are considered. This is also reviewed in detail in the section "Management of Advanced Stage Disease—Principles of Combining Chemotherapy and Radiation Therapy."

The general approach to the neck involves management with primary RT or chemo-RT. A PET-CT scan is done 3 months after the completion of treatment. An ND is done if there is evidence of residual disease. Neck management is discussed in detail in Chapter 14.

As mentioned in the above section on the early-stage disease, surgical outcomes have generally been reported as a function of surgical and pathological findings rather in clinical stage. The data from Henstrom and Moore have already been described,[144,159] and Table 17.8 summarizes the surgical data including oncologic and functional outcomes.

Díaz Molina et al. reported on 132 patients, of whom 93% had stage III/IV BOT cancer. All patients underwent primary surgery. Stages III, IVA, and IVB were 11%, 69%, and 13%, respectively. In the whole cohort, LC was 83%, RC was 89%, LRC was 85%, and DC was 93%. The 5-year DSS was 34% and was specifically 44% for stage III, 28% for stage IVA, and 12% for IVB ($p = 0.0004$). Multivariate analysis showed N2–3 ($p = 0.016$) and T3–4 ($p = 0.04$) are associated with worse survival. Four percent were PEG dependent.[160]

Similarly, Steiner et al. reported on 48 patients who underwent primary TLM (100%), ND (90%), PORT (48%), and adjuvant chemo-RT (25%) for stage III/IV BOT cancer. With a median follow-up of 47 months, the 5-year LC, DFS, and OS rates were 85%, 73%, and 52%, respectively. The LC and LRC rates were 80% and 72% for TLM + ND, respectively. The LC and LRC rates were 91% and 83% for TLM + ND and PORT or chemo-RT, respectively.[143]

## MANAGEMENT OF ADVANCED-STAGE DISEASE—PRINCIPLES OF COMBINING CHEMOTHERAPY AND RT

The rational for combining RT and chemotherapy is multifactorial. There are the independent mechanisms of cell killing that are synergistic. Moreover, chemotherapy has the capability to

(c) 2014 Wolters Kluwer. All Rights Reserved.

reduce the rate of distant metastases as well as contribute to improved LRC. The latter derives from the radiosensitizing effect of drugs, such as platinum compounds.[74,161]

The role of chemotherapy in multimodality treatment for advanced-stage OPC, although firmly established, presents several unresolved issues. Concomitant platinum-based chemoradiation (chemo-RT) is a standard primary treatment for advanced-stage OPC and for postoperative high-risk patients. Recent phase III trials comparing concomitant chemo-RT versus induction chemotherapy followed by chemo-RT did not show any advantage of induction chemotherapy in advanced-stage SCCHN.[94,95]

## Concomitant Chemotherapy and RT

***Chemo-RT.*** A landmark French intergroup (GORTEC 94-01) phase III randomized trial tested 226 patients with stages III (32%) and IV (68%) OPC. Patients were randomized to 70 Gy/7 weeks RT alone or the same RT with 3 cycles of concomitant carboplatin and 5-fluorouracil (5-FU). There was no difference in the incidence of grades 3 to 4 late toxicity (56% vs. 30%, $p = 0.12$). Treatment-related mortality was 1% in the chemo-RT arm versus 0% in the RT-alone arm. At a median follow-up of 5.5 years, the 5-year LRC was 47.6% versus 24.7%, $p = 0.002$, DFS was 26.6% versus 14.6%, $p = 0.01$, and OS was 22.4% versus 15.8%, $p = 0.05$ for patients in the combined modality arm versus RT arm, respectively. However, there was no difference in the rate of distant metastases, 18% versus 17%, respectively. On multivariate analysis, pretreatment hemoglobin levels <125 g/L, stage IV disease, and RT alone were independent prognostic factors of lower survival and LRF. The approximately 20% improvement in OS and LRC argues for the utilization of concomitant chemo-RT in the context of advanced disease OPC.[140,162–164] Noteworthy, this trial did not incorporate cisplatin, which is the most effective drug.

Table 17.9 shows the outcomes of a sampling of recent prospective randomized studies comparing RT alone to chemo-RT using platinum-based chemotherapy. As can be seen, the preponderance of the evidence reveals the superiority of chemo-RT. In the current era, cisplatin-based chemo-RT is the standard of care[165] for patients who are medically suitable to receive this therapy.

The Meta-analysis of Chemotherapy on Head and Neck Cancer (MACH-NC) included 93 randomized trials and 17,346 patients. This analysis showed that concomitant chemo-RT improved OS compared with RT alone in advanced disease by 6.5% at 5 years ($p = 0.0001$). This improvement was demonstrated irrespective of RT fractionation. Platinum-based concomitant chemo-RT was the most effective combination, with an absolute survival benefit of 9% at 5 years ($p = 0.01$).[74,76]

Blanchard et al. updated the MACH-NC by tumor site. They reported that the advantage of concomitant chemo-RT was present for all tumor locations with a 5-year absolute survival benefit of approximately 8% for OPC ($p < 0.0001$).[166]

Investigators have compared the outcomes of chemo-RT using standard fractionation RT (70 Gy/7 weeks) versus altered fractionation with a variety of accelerated RT techniques, including the concomitant boost. The RTOG 0129 phase III trial compared standard RT combined with 3 cycles of cisplatin (100 mg/m$^2$ × 3 cycles) versus accelerated concomitant boost RT (72 Gy/6 weeks) with 2 cycles of cisplatin (100 mg/m$^2$ × 2 cycles). There was no difference in the 5-year OS between these two arms: 59% versus 56% ($p = 0.18$), respectively.[61] Similarly, the GORTEC 99-02 study showed no difference in OS when accelerated RT plus 2 cycles of concomitant carboplatin + 5-FU were compared with standard fractionation RT concomitant with 3 cycles of the same chemotherapy regimen.[77]

Based on the aforementioned two studies, RTOG 0129 and GORTEC 99-02, it is reasonable to conclude that 2 cycles of concomitant chemotherapy may be adequate in the setting of concomitant altered fractionation RT. Likewise, both studies suggest that altered fractionation adds no benefit over standard RT in the context of chemo-RT. The current NCCN guidelines call for the use of standard fractionation IMRT with 3 cycles of concomitant cisplatin (100 mg/m$^2$ days 1, 22, and 43).[165] However, not all patients will be able to receive all 3 cycles of cisplatin. The impact of this is unclear, and patient safety generally dictates whether all 3 cycles can be given. It seems reasonable to the authors to drop the third chemotherapy cycle if the medical condition of the patient puts him/her at higher risk of life-threatening morbidity and/or mortality.

Concomitant chemo-RT is associated with serious treatment-induced morbidity and occasional mortality. It should only be advised for medically fit patients with good performance status. It has been reported that the incidence of concomitant chemo-RT-related death in the range of 1% to 9%.[164,167–169] Treatment sequelae are reviewed in detail in an upcoming section.

The toxicity of cisplatin-based concomitant chemo-RT has led investigators to explore potentially less morbid approaches. One such approach involves the use of biological agents that target the EGFR and more recently second-generation EGFR tyrosine kinase inhibitors (TKIs).[61,79,170–172]

Bonner et al. reported the results of a multicenter phase III study. Patients with advanced-stage SCCHN were randomly assigned to RT alone ($n = 213$) or RT plus weekly cetuximab ($n = 211$) at an initial dose of 400 mg/m$^2$ followed by 250 mg/m$^2$ weekly for the duration of RT. Sixty percent of the 424 patients enrolled in the study had OPC. With a median follow-up of 54 months, the addition of cetuximab provided a statistically significant improvement in the 3-year LRC (47% vs. 34%, $p < 0.01$), PFS (42% vs. 31%, $p = 0.04$), and OS (55% vs. 45%, $p = 0.05$). The greatest survival benefit was among patients with OPC, with a median survival of 66 versus 30.3 months.[79]

Ang et al. reported the results of the RTOG 0522 phase III trial (940 patients with locally advanced SCCHN) comparing concomitant chemo-RT (2 cycles of cisplatin concomitant with accelerated RT) and the same chemo-RT plus cetuximab. The 2-year PFS and OS rates were similar for both arms (64.3% vs. 63.4% and 79.7% vs. 82.6%, respectively). Likewise, no difference was observed for loco-regional relapse (19.8% vs. 24.5%) and distant metastasis rates (12% vs. 7.6%). The incidence rates of severe mucositis and in-field skin reaction were significantly higher in the chemo-RT plus cetuximab combinations arm (43% vs. 33% and 25% vs. 15%, respectively).[173]

These trials suggest that concomitant cetuximab-RT may be an alternative to concomitant cisplatin-based chemo-RT for patients who are not fit enough for cisplatin-based chemotherapy. Also, as pointed out in Table 17.9, carboplatin-based chemotherapy is an excellent alternative for cisplatin in this cohort of patients. At the current time, it does not appear that biologic therapy adds to the outcome with concomitant cisplatin-based chemo-RT. Current trials are exploring the comparison of concomitant platinum-based chemo-RT versus concomitant RT plus biological agents (i.e., cetuximab, lapatinib, panitumumab, zalutumumab, gefitinib, erlotinib, afatinib, lapatinib, bevacizumab, and bortezomib) but the results are not yet known.[171–177]

There are patients with stages III to IV disease who are not candidates for systemic therapy and need to be treated with RT alone. In this population, it is important to utilize the most effective RT regimen. Many studies have been done that explore a variety of fractionation schemes, in an effort to assess the potential benefits of altered fractionation.

Horiot et al. reported results of the EORTC 22791 randomized trial comparing hyperfractionated RT (HF) versus conventional fractionated RT (CF) in the treatment of 356 patients with T2–T3 N0–1 OPCs excluding the BOT. With a mean follow-up of approximately 4 years, HF improved 5-year actuarial LRC compared with CF (59% vs. 40%, respectively, $p = 0.02$) with a trend toward improved survival (38% vs. 29%, respectively, $p = 0.08$). T3 tumors benefited from HF but T2 lesions did not. The incidence of long-term grade ≥2 toxicity was no different between the two arms.[178]

RTOG conducted a landmark trial (RTOG 90-03) comparing multiple altered fractionated regimens for advanced disease SCCHN, of whom 60% was OPC. A total of 1,073 patients with were randomized to four arms: conventional fractionation, split-course accelerated fractionation (SAF), delayed concomitant boost (DCB), and HF. With a median follow-up of 23 months, the DCB and HF arms had significantly better 2-year LRC compared with CF (54.5% vs. 54.4% vs. 46%, respectively; $p = 0.05$, DCB vs. CF and $p = 0.045$, HF vs. CF) and trend toward improved DFS (39.3% vs. 37.6% vs. 31.7%, respectively; $p = 0.054$, DCB vs. CF and $p = 0.067$, DCB vs. CF) were seen in both the DCB and HF arms compared with CF. There was no difference in OS or long-term grade ≥3 toxicity.[179]

Overgaard et al. reported results of the Danish Head and Neck Cancer (DAHANCA) 6 and 7 trials, which randomized 1,476 patients with SCCHN to an accelerated versus CF protocol. Both arms were treated to a total dose of 66 to 68 Gy at 2 Gy/fraction. An oral dose of the hypoxic radiosensitizer nimorazole (1,200 mg/m$^2$) was administered with the first 30 fractions of RT. The accelerated regimen proved to be superior in terms of 5-year LC (76% vs. 64%, $p = 0.0001$), LRC (70% vs. 60%, $p = 0.0005$), and DSS (73% vs. 66%, $p = 0.01$) but without improvement in OS. Confluent mucositis was significantly higher in the accelerated group (53% vs. 33%, $p < 0.0001$), but 98% of both arms received the scheduled radiation dose. Late toxicity did not differ between the fractionation groups.[67] Several other randomized trials examining altered fractionation schemes have been reported to date, most of which also demonstrate an improvement in LC and LRC at the expense of increased acute toxicity, but without an impact on OS.[180–183]

Another issue that arises in the modern era is the role of altered fractionation schemes in the context of IMRT. Although the use of HF or accelerated treatment schedules with IMRT have been reported,[121,126,184,185] due to the expense of time and resources required with IMRT, most radiation oncologists have reverted to treating patients once a day. An alternative to twice-daily radiation is the delivery of a simultaneous integrated boost (SIB), wherein multiple targets are treated simultaneously with different prescribed doses. For example, the primary tumor and gross nodal disease may be treated to 66 Gy in 30 fractions (2.2 Gy/fraction), while at the same time, high-risk areas receive 60 Gy (2 Gy/fraction) and low-risk areas receive 54 Gy (1.8 Gy/fraction). Owing to the higher dose per fraction, however, this scheme may result in a greater risk of late morbidity.

As both the addition of concomitant chemotherapy and altered fractionated RT have been shown independently to improve outcome for patients with head and neck cancer, the present challenge is to find the optimal chemo-RT regimen(s) that offer high rates of LRC, are not unduly morbid, offer maximal preservation of organ function, and may be integrated with new biologic agents.

The RTOG (0129) has randomized patients with stages III to IV SCCHN to receive either standard RT (70 Gy/7 weeks) or accelerated RT (72 Gy/6 weeks through DCB), with both groups received concomitant cisplatin. The accelerated RT group received cisplatin 100 mg/m$^2$ on days 1 and 22, whereas the standard RT group received an additional cycle of cisplatin on day 43. The 5-year OS was 59% versus 56%, respectively, with no difference between both arms ($p = 0.18$).[61]

In conclusion, the body of data would seem to favor a generalized improvement in outcomes for loco-regionally advanced OPC with concomitant chemo-RT versus RT alone. The added toxicity of altered fractionation ± concomitant chemotherapy, and the lack of clear benefit, has led to more utilization of standard fractionation RT approaches (i.e., 1.8–2 Gy/fraction) via IMRT with concomitant chemotherapy (i.e., cisplatin 100 mg/m$^2$ days 1, 22, 43).

## Induction Chemotherapy

In most studies, the experimental rationale for induction chemotherapy has been threefold. First, systemic therapy may be used to suppress the development of distant metastatic disease in patients at high risk. Second, induction chemotherapy may help select patients for organ preservation with improved outcomes. Third, the response to induction chemotherapy may predict the oncologic outcome and may allow subsequent response stratification, intensification, or deintensification of definitive treatment. There is conflicting data on the role of induction chemotherapy in the management of locally advanced SCCHN, which will be discussed.

The major emphasis for the use of induction chemotherapy has been the exploration of this approach for patients with advanced disease, who are known to be at increased risk for distant metastases.[186] A body of literature emerged that explores a variety of induction regimens, the most notable being docetaxel plus cisplatin and 5-fluorouracil (TPF).[187] This led to the development of two pivotal studies that attempted to determine the place of induction chemotherapy in the management of patients with locally advanced disease.[94,95]

Cohen et al. reported the DeCIDE trial, where 280 patients with loco-regionally advanced disease, N2–3, were randomized to receive either induction TPF followed by concomitant chemo-RT versus concomitant chemo-RT alone. With a minimum follow-up of 24 months, there was no difference in OS between the two arms, although there was a significant difference in the cumulative incidence of distant metastasis.[94]

Haddad et al. reported the PARADIGM trial, where 140 patients with loco-regionally advanced disease were randomized to receive induction TPF followed by concomitant chemo-RT versus concomitant chemo-RT alone. There was no difference in OS or PFS.[95] In both trials, excellent OS was observed in all arms. The role of induction chemotherapy in the presence of concomitant chemo-RT remains investigational and should only be done in the context of clinical trials.

## Management of the Neck

Management of the neck is an important and complex issue in SCCHN and is discussed in detail in Chapter 14. The selection of treatment modality for the neck should be based upon the approach toward the primary tumor. In cases where surgery is the primary treatment modality, ND should be performed at the time of surgery, with the need for PORT or chemo-RT determined by pathologic findings. In OPC, however, which is most commonly treated with definitive chemo-RT, the surgical management of the neck remains a debated issue. For N0–1 patients, the probability of neck control after definitive RT or chemo-RT is very high. Therefore, patients do not require an ND unless there is evidence of persistent disease after treatment.[63,154,188] However, with increasing nodal disease, regional recurrence rates increase.[189,190] In the pre-chemo-RT era, it had long been recognized that patients treated with combined RT

(c) 2014 Wolters Kluwer. All Rights Reserved.

and surgery for N2–3 disease had lower neck recurrences than after either modality alone.[191,192] Historically, planned ND had been standard for patients with N2–3 disease.[87,193] However, in the current era of treatment with concomitant chemo-RT, the need for a planned ND has been questioned, particularly in the setting of a complete clinical response after definitive doses of RT.[194–196]

Historically, several investigators have advocated the incorporation of a planned ND, regardless of the response after chemo-RT,[197–203] whereas others preferred to reserve ND for those patients with clinical or radiographic evidence of residual nodal disease.[194,204–207] Recently, the use of PET-CT scans has aided in further refining the management of the neck. Liauw et al. analyzed the records of 550 patients with node-positive disease treated with RT or chemo-RT, with or without planned ND. Of 211 patients with CT scan imaging data available for review, 28% had a radiologic complete response (rCR). When correlated with the pathologic specimens, an rCR demonstrated a sensitivity of 96%, specificity of 24%, positive predictive value of 35%, and a negative predictive value of 94%. Among the 32 patients who did not undergo an ND after an rCR, the 5-year neck control rate was 97% (with salvage 100%). This was equivalent to those patients with a pathologically negative ND (5-year neck control 98%). There was no difference in cause-specific survival or OS between these groups.[208] Similarly, Yao et al. reported a series of 41 patients treated with definitive RT or chemo-RT who underwent posttreatment PET scans to assess response.[209] Patients' scans were correlated with biopsy or ND specimens. In this study, a negative PET scan (maximum standardized uptake value [SUV] < 3.0) was highly correlated with a negative pathologic examination, with a negative predictive value of 100%. Several studies support these findings, with a negative predictive value of PET scans after radiation of 83% to 97%.[210–213] Some studies, however, report significantly lower negative predictive values associated with post-RT PET scans (Rogers et al., 2004; Gourin et al., 2006).[213a,213b]

The concept of withholding planned ND in patients who experience CR to chemo-RT has continued to gain momentum over the last decade.[214] This has been extensively reviewed in Chapter 14, in the section "Role of Planned Neck Dissection for Patients with a Complete Response to Chemoradiotherapy." Corry et al. reported that all patients with N2/3 disease, who obtained a clinical and radiological CR to chemo-RT at 12 weeks post treatment, had RC, with a zero incidence of isolated neck failure, without a planned ND. These authors concluded that the use of planned ND in this patient subset cannot be justified. Hamoir et al. have recently reviewed the literature on this issue and reached a similar conclusion.[215]

It has therefore become the policy at the authors' institution to withhold ND in patients who achieve a clinical and radiologic (PET-CT) CR at 3 months after definitive chemo-RT. If clinical examination or PET-CT at 3 months post treatment suggests the possibility of residual disease in the neck, ND should be performed. Sometimes the PET-CT imaging is equivocal, and management must be individualized. In this setting, it is often helpful to perform a fine-needle aspiration biopsy from that suspicious node. ND is done if the biopsy is positive but may be withheld if the biopsy is negative. Clinical judgment should always prevail in making this decision. It is also imperative that patients are followed very carefully with frequent examinations and surveillance, especially during the first 2 years after treatment.[201]

## Postoperative RT ± Chemotherapy

In patients treated with a primary surgical approach, a careful examination of the resected specimen is essential to the determination of the need for adjuvant therapy. Chapter 1 reviews the pathologic details contained in the pathology report, and Chapter 3 reviews the important prognostic factors in detail.

The use of PORT can be triggered by findings at either the primary site or the neck. For the primary site, the key features are the tumor size, local invasiveness into adjacent structures (i.e., bone), adequacy of the resection margins, tumor grade, presence of lymphovascular and/or perineural invasion, and even tumor spillage or tumor multicentricity. Adverse features in any of these areas would trigger PORT.

Similarly, findings in the neck could trigger the use of PORT. Whereas patients with a single positive node and no extracapsular spread may not benefit from PORT, patients with multiple nodes should receive PORT and patients with positive margins and/or extracapsular spread should receive PORT with concomitant cisplatin-based chemotherapy.[216]

Several investigators examined the interval between surgery and RT. Bastit et al. reported no difference in LRC or OS in a retrospective study of 420 patients with OPCs who were treated with similar doses (59 Gy/6 weeks) either within ($n = 219$) or after 30 days ($n = 201$) of surgery.[217] However, Ang et al. report that among high-risk patients (positive margins, extracapsular nodal extension, or multiple lymph nodes), a duration of <11 weeks from the end of surgery to the end of RT resulted in better LRC ($p = 0.005$) and OS ($p = 0.03$) compared with those treated over a longer period.[218] Similarly, Rosenthal et al. reported a retrospective study on 208 patients treated with surgery and PORT (≥55 Gy) for SCCHN. With a median follow-up of 24 months, the actuarial 2-year LRC and OS were 82% and 71%, respectively. The total time from surgery to completion of RT (treatment package time) of <100 days was associated with improved LRC and OS ($p = 0.021$).[219]

The role of postoperative chemo-RT has been evaluated in locally advanced SCCHN. Two major phase III studies compared RT alone versus concomitant chemo-RT as adjuvant treatments after surgery in poor-risk SCCHN stages III to IV nonmetastatic patients. In both studies, a single-agent cisplatin, dose of 100 mg/m$^2$ on days 1, 22, and 43, was administered during PORT. Both the RTOG 9501 and the EORTC 22931 studies showed that the concomitant chemo-RT gave a significant benefit in DFS.[85,137] However, in the EORTC 22931 study, the OS showed significant improvement with chemo-RT versus PORT alone.[85] A subsequent joint analysis showed that the OS benefit of concomitant chemo-RT was significant only for patients with positive resection margins at the primary site and/or extracapsular spread in the neck.[220] These two pathological findings are the only criteria for selecting patients to treat with adjuvant concomitant chemo-RT.[220] It should be noted that combined treatment should only be delivered to patients with good performance status due to severe treatment-related toxicity. Because the aforementioned studies used high-dose cisplatin, this remains the standard regimen to be used postoperatively. However, the reported compliance analysis reveals that only 50% to 60% of patients were able to receive all three planned cycles in both studies. Recently, Cooper et al. reported the long-term follow-up of the RTOG 9501. With a median follow-up of 9.4 years, there was no significant differences in outcome However, analysis of the subgroup of patients who had either microscopically positive margins and/or extracapsular spread showed improved LRC and DFS with postoperative concomitant chemo-RT.[221] Table 17.11 shows oncologic outcomes in both RTOG 9501 and EORTC 2293.

## Recurrent Disease and Salvage

Loco-regional recurrences are seen in 15% to 50% of patients with SCCHN and this a major factor contributing to death from head and neck cancer.[137,222–227] Due to the heterogeneity of patients with loco-regional recurrence, it becomes impossible to

be dogmatic about treatment guidelines and approaches. A high level of individualized care is required, taking into account the disease extent, prior treatment constraints, the performance status of the patient, the ability to maintain QOL, and other appropriate factors. In general, the data support the conclusion that the best outcomes are achieved in patients who can undergo salvage resection, accompanied by re-irradiation and chemotherapy. Figure 17-14 outlines the NCCN 2012 guidelines for recurrent or persistent SCCHN.

Salama et al. reviewed the University of Chicago experience with recurrent disease and reported the best outcomes for tumor control in patients who had surgical resection, higher doses of re-irradiation, and chemotherapy.[228] Janot et al. reported a randomized trial of surgery ± chemo-RT for recurrent disease patients and reported better tumor control in those who received surgery plus chemo-RT.[229]

The restrictions imposed by prior RT have prompted the investigation of intraoperative RT (IORT) at the time of surgery, as a mechanism of safely escalating the dose of re-irradiation. Scala et al. reported on 77 patients with recurrent SCCHN, who were treated with high-dose-rate (HDR) IORT. With a median follow-up of 11 months, estimated 1-year OS was 66%, DFS 51%, in-field control (IFC) 65%, and DM 31%. Margin status impacted on IFC. In patients with negative versus positive margins, the 1-year IFC was 86% versus 56% ($p = 0.01$), respectively. The DFS was 66% versus 39% ($p = 0.05$) in patients with negative versus positive margins, respectively. Margin status did not impact upon OS or DM. Patients with IFC had improved OS.[230] Table 17.12

shows a selection of studies that highlight the positive outcomes that can be achieved with combined surgery, RT, and chemotherapy, including IORT, in the recurrent disease setting. Of course, as stated, treatment must be individualized.

## TREATMENT SEQUELAE AND COMPLICATIONS

Different modality treatment sequelae can be grouped into acute and late toxicities. Acute toxicity and management is discussed in detail in Chapter 10. In the current section, we present each modality late toxicity and its management.

### Surgery

Sequelae related to surgery can be clustered into intraoperative, immediate, and delayed postoperative complications. Traditionally, operative mortality for either primary tumor resection or ND has been low. Perioperative complications include infection, bleeding, nerve injury, cardiovascular, and pulmonary complications.[231,232] Delayed complications include fistula, flap loss, trismus, lymphedema, and shoulder muscle dysfunction after ND.[233,234] Locally advanced disease necessitates extensive resection that can affect speech and swallowing. Moreover, a laryngectomy may be required in very advanced disease in an effort to prevent aspiration, causing additional functional morbidity.[235]

As described in this chapter, there has been a growing interest in MIS for OPC. Currently, MIS is extensively reported within the head and neck literature, driven by the desire to offer a less morbid alternative to traditional surgery. These techniques have included TLO, TLM, and TORS, which dramatically reduce the surgical time and morbidity associated with the traditional resections.[26,28,131,132,236–239] Table 17.8 shows the oncologic and functional outcomes of several recent studies of OPC treated with either traditional surgery or MIS (i.e., TLO, TLM, and TORS). The vast majority of patients underwent TORS or TLM followed by ND and adjuvant therapy (e.g., RT or chemo-RT). In general, utilization of MIS has led to marked improvement in the QOL outcomes over traditional surgical approaches. Specifically, MIS is associated with relatively low rates of gastrostomy tube dependence and high QOL scores on questionnaire assessment.

### Radiation Therapy

The major sequelae of RT can be divided into acute and late toxicity. These depend on total dose, fraction size, prior or concomitant therapy (i.e., surgery or chemotherapy), and target volume. Refer to Chapter 10 for discussion of acute toxicity and supportive care management. The late toxicity of RT presents months to years after the completion of treatment and is often permanent. This includes xerostomia, altered taste, dysphagia, dysphonia, osteoradionecrosis, brachial plexopathy, carotid artery vasculopathy, soft tissue fibrosis, esophageal injury, hypothyroidism, and radiation-induced malignancy. Severe late toxicity is less common with current treatment techniques.

Xerostomia is the most common late toxicity of RT, which is due to loss of function of the salivary glands secondary to RT effects. Loss of saliva predisposes to mucosal fissures and ulceration. RT-induced xerostomia is dose dependent. A parotid gland mean dose of ≤26 Gy should be a planning goal if substantial sparing of the gland function is desired.[240] Moreover, mean

(c) 2014 Wolters Kluwer. All Rights Reserved.

doses of 40 to 50 Gy to a parotid gland typically causes >75% reduction in function.[170] There are different approaches to prevent xerostomia, including parotid-sparing IMRT, amifostine, and submandibular salivary gland transfer.

The development of IMRT and daily IGRT significantly decrease the incidence of RT-induced xerostomia. The Parotid-Sparing Intensity-Modulated Versus Conventional Radiotherapy in Head and Neck Cancer trial (PARSPORT) randomly assigned 94 patients with locally advanced SCCHN to either conventional 3D RT or IMRT. The trial utilized the Late Effects of Normal Tissues Subjective–Objective Management Analytic (LENTSOMA) subjective side-effect scale. At both 12 and 24 months, significant benefits were seen in recovery of saliva secretion with IMRT compared with conventional RT, as were clinically significant improvements in dry-mouth-specific and global QOL scores.[241] Toledano et al. reported the results of the GORTEC 2004–03 study. They utilized the RTOG-EORTC toxicity scales. At 18 months, grade ≥2 xerostomia was 16%. A mean dose to the spared parotid below 28 Gy led to significantly less grade ≥2 xerostomia (8.5% vs. 24%, $p = 0.03$). Grade ≥2 xerostomia increased by approximately 3% per Gy of mean parotid dose up to 28 Gy, and then 7% per Gy above 33 Gy.[136] Lee et al. reported that IMRT reduced severe late xerostomia from 67% to 12%.[150]

Amifostine role in preventing xerostomia is controversial. Brizel et al. randomized patients to receive RT alone or with IV amifostine before each RT dose. At 2 years, the incidence of grade ≥2 late xerostomia was improved (19% vs. 36%, $p = 0.038$).[242,243] In contrast, Buentzel et al. enrolled 132 patients in a multicenter randomized placebo-controlled study in which patient received either IV amifostine or placebo before receiving carboplatin-based chemo-RT. In this study, there was no difference in either grade ≥2 late xerostomia (37% vs. 24%, $p = 0.235$).[244] GORTEC group ran a prospective randomized study comparing IV versus subcutaneous (SC) amifostine administration. There was no difference in either compliance (70% vs. 71%) and the incidence of hypotension (3% vs. 1%). Of note, SC group had an increased incidence of rash (11% vs. 22%, $p = 0.02$) and local pain at the injection site (0% vs. 9%, $p = 0.0008$).[245]

The submandibular gland (SMG) provides approximately 70% of the unstimulated saliva. IMRT has been used to lower the RT dose to the parotid gland(s) to reduce long-term xerostomia. However, there is little experience with SMG-sparing IMRT. Mean RT doses to the SMG exceeding 39 Gy cause permanent ablation of both stimulated and unstimulated salivary flow. Attempts to do IMRT sparing SMG without impairing the oncologic outcome have been reported by many investigators.[111,246] An alternative approach to SMG sparing involves surgical transfer of the gland into the submental space before RT. Seikaly et al. reported 83% of the patients had normal salivary flow and improved swallowing outcomes.[247–249] Similarly, salivary sparing has been reported by other groups,[250,251] and in the RTOG 0244 multicenter phase II trial. Recently, Jha et al. reported that SMG transfer led to spare 74% of patients from RT-induced acute xerostomia.[252]

## Dysphagia

The development of IMRT significantly decreases the incidence of dysphagia. Eisbruch et al. reported that it is possible to reduce the mean V50 (percentage of volume receiving >50 Gy) to pharyngeal constrictors and the larynx via IMRT.[253] Setton and Lee et al. reported that IMRT reduced the PEG feeding tube rate from 21% to 3%.[126,150] Thus, RT technique is an essential ingredient to optimizing functional outcome.

The majority of patients receiving chemo-RT experience significant weight loss due to RT or chemo-RT–induced mucositis and dysphagia. Feeding tubes may limit malnutrition.[254] However, whether the prophylactic placement of feeding tubes is beneficial is controversial. A randomized study showed significantly higher QOL scores in the group who underwent prophylactic gastrostomy tube.[255] On the contrary, Chen et al. reported that due to disuse of pharyngeal musculature during RT, prophylactic gastrostomy tube placement led to increase dysphagia and ultimately higher rates of long-term gastrostomy tube dependence.[256] They retrospectively reported that prophylactic placement of a gastrostomy tube resulted in both a higher percentage of gastrostomy tube dependence at 1 year (21% vs. 0%, $p < 0.001$) and a higher rate of esophageal stricture (30% vs. 6%).[256] The importance of these issues led to the development of a specific instrument that measures the impact of gastrostomy tubes on the QOL.[257] However, the incidence of long-term gastrostomy tube dependence has declined dramatically in the recent years due to the wide use of IMRT and IGRT, with an estimated rate of <5% of patients who underwent concomitant chemo-RT.[63,126] Thus, RT technique and dose optimization have an important effect on the incidence and severity of dysphagia.

## Quality of Life

Harrison et al. retrospectively examined patients with SCC of the BOT who were treated with primary RT or primary surgery, comparing the QOL and functional outcome. Patients treated with RT had consistently better performance status and QOL scores. This was true for all early (T1–2) and advanced (T3–4) diseases. For surgery, functional status deteriorated significantly when comparing T1 to T2 and T3 to T4 lesions ($p = 0.0014$), consistent with the fact that larger tumors require more extensive surgeries.[258] In addition to QOL issues, Harrison et al. have examined the long-term socioeconomic outcomes for patients with cancer of the BOT who were treated with an organ-preservation approach. At a median follow-up of 5 years, patients' annual incomes were similar to those at the time of presentation. Of those working full-time, 72% were still in full-time work and 83% of those working part-time were in part-time work.[152,258,259]

Campbell et al. report a cohort of 111 patients who underwent surgery, RT, or surgery followed by PORT. The RT group had the least problems, followed by the surgery-only group, whereas the surgery plus RT group experienced the greatest impairment.[260]

Several investigators have studied the impact of cetuximab on QOL. No significant, incremental impact was noted for patients receiving cetuximab plus RT[79,261] or cetuximab plus chemo-RT.[262]

**Carotid artery vasculopathy** (i.e., ischemic stroke) can be a late complication of neck RT.[263–265] Multiple reports have shown that RT to the head and neck may cause carotid artery stenosis and increase the risk of ischemic stroke.[264–269] Table 17.13 summarizes recent reports on RT-induced carotid vasculopathy.

Carotid artery rupture (e.g., carotid blowout syndrome) is most common in the setting of a surgically exposed carotid artery with limited residual normal tissue to cover it, recurrent tumor, infection, or severe radiation damage.[270] Carotid blowout syndrome usually occurs proximal to the carotid bifurcation and is commonly associated with soft tissue necrosis in the neck and mucocutaneous fistulas. Powitzky et al. identified 140 patients with carotid artery events, of whom 60% had life-threatening hemorrhage that required emergency intervention.[271] Carotid blowout has been reported in the setting of recurrent disease with multiple courses of surgery, RT, and compromised wound healing.[272]

Soft tissue ulceration is an RT dose-dependent side effect that can occur anytime from 6 months to several years after RT. Usually, these ulcerations heal on their own, but it can take weeks or months. Meticulous local hygiene and pain control are the cornerstone of management. In refractory cases, hyperbaric (HBO) may be helpful in promoting healing.[273,274]

**TABLE 17.13 Summary of Recent Reports on RT-Induced Carotid Vasculopathy**

| Author | Institution | Nature of Study | Outcome |
|---|---|---|---|
| Dorresteijn (2002)[264] | Netherlands Cancer Institute | Retrospective study of 367 patients | 14 ischemic strokes = 15-yr cumulative risk of stroke of 12% |
| Smith (2008)[268] | M.D. Anderson Cancer Center | SEER and Medicare study | 9% increase in 10 year incidence of cerebrovascular events with RT (35%) vs. surgery (26%), No significant increase with surgery and adjuvant RT |
| Huang (2008)[269] | Mt. Sinai Medical Center | SEER and Medicare study | 2.5% increase in 10-yr rate stroke incidence with RT (10%) vs. (7.5%) without RT ($p = 0.01$). No significant difference in stroke mortality |

SEER, Surveillance, Epidemiology, and End Results; RICV, radiation-induced carotidvasculopathy.

**Osteoradionecrosis** (ORN) is exposed, irradiated bone in the absence of tumor after completion of RT.[275] ORN is a spectrum of bone injury, mainly to the mandible, that ranges from bone exposure to full-blown bone necrosis. The main risk factors include the RT dose to bone,[275–277] dental extraction/trauma, and poor dental hygiene. ORN occurs in <5% of cases.[63,126,136,154,278,279] Factors that increase the risk of ORN include volume of mandible treated with RT, RT dose, dose per fraction, and poor dental hygiene. ORN is discussed in more detail in Chapter 9.

The patient's perception of the impact of illness before, during, and after treatment is a major issue. Clearly, QOL issues must factor strongly into the decision-making process and selection of the appropriate management strategy. Measurement of QOL is ongoing activity and is a key component to current research protocols. There are many head and neck cancer–specific instruments that are reliable and well validated. See Table 17.14 for QOL measurements details.

**TABLE 17.14 Quality-of-Life (QOL) Measurements in Details**

| Reference Study/ Abbreviation | | Description |
|---|---|---|
| List (1990)[322] | PSS-HN | Performance Status Scale for Head and Neck Cancer; consists of three subscales: normalcy of diet, understandability of speech, and eating in public. Scores on each subscale range from 0 to 100, with higher scores indicating better performance |
| Bjordal (1992, 1994, 1999)[323–325] | EORTC QLQ-H&N35 | European Organization for Research and Treatment of Cancer QOL Questionnaire—Head and Neck–Specific Module; can be used in conjunction with the QLQ-C30. This scale includes items assessing symptoms and side effects relevant to patients with head and neck cancer and appears to be sensitive to temporal changes before, during, and after treatment with surgery, RT, and chemotherapy |
| Browman (1993)[55] | HNRQ | Head and Neck Radiotherapy Questionnaire; a patient-rated tool that measures early treatment-related effects in patients undergoing RT for HNC. It consists of 22 questions that cover symptoms related to six domains: oral cavity, throat, skin, digestive function, energy and psychosocial function |
| Hassan (1993)[326] Rogers (1998)[327] | UW-QOL | University of Washington QOL questionnaire; a self-administered scale consisting of 15 questions assessing nine domains: pain, physical appearance, activity, recreation, employment, chewing, swallowing, speech, shoulder function, and overall QOL |
| Portenoy (1994)[328] | MSAS | Memorial Symptom Assessment Scale; a comprehensive symptom measure that records prevalence of 32 physical and psychological symptoms commonly experienced by cancer patients, symptom characteristics, and measures of symptom distress |
| List (1996)[329] | FACT-H&N | Functional Assessment of Cancer Therapy–Head and Neck; consists of the FACT-G, to which an 11-item site-specific, head and neck cancer subscale, which evaluates the unique concerns of patients with head and neck cancer such as swallowing and chewing |
| Terrell (1997)[330] | HNQOLQ | University of Michigan Head and Neck QOL Questionnaire; a 20-item that covers four major domains, namely, pain, communication, eating, and emotion |
| Trotti (1998)[331] | QOL-RTI | QOL–Radiation Therapy Instrument; specifically addresses issues related to RT in patients with head and neck cancer. This instrument evaluates the impact of treatment on mucus production, saliva, taste, cough, and local pain |

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 17.14 Quality-of-Life (QOL) Measurements in Details (Continued)**

| | | |
|---|---|---|
| Hogikyan (1999)[332] | V-RQOL | Voice-related QOL measure; a 10-item, self-administered voice outcome measure. Scores are reported in two domains, social-emotional and physical functioning, and a total score, all ranging from 1 to 100. A higher score indicates better voice-related QOL |
| Chen (2001)[333] | MDADI | M. D. Anderson Dysphagia Inventory; a self-administered questionnaire that evaluates the impact of treatment-related dysphagia on QOL. This instrument includes global, emotional, functional, and physical subscales |
| Cella (2003)[334] | FHNSI | The FACT Head and Neck Symptom Index; a 10-item symptom index with items extracted from the FACT-H&N. The FHNSI was designed to allow rapid assessment of the most relevant disease symptoms. The FHNSI can be administered alone or scored using items embedded within the FACT-H&N (Yount et al., 2007) |
| Murphy (2010)[335] Cooperstein (2011)[336] | VHNSS | Vanderbilt Head and Neck Symptom Survey; to assess the physical and functional problems relevant to patients with head and neck cancer treated with chemo-RT. This 28-question survey has an emphasis on oral health outcomes, such as mucous production. Also, assesses other symptoms such as mucosal sensitivity, dental health, and trismus contains 50 questions and has been studied in the post-RT setting |

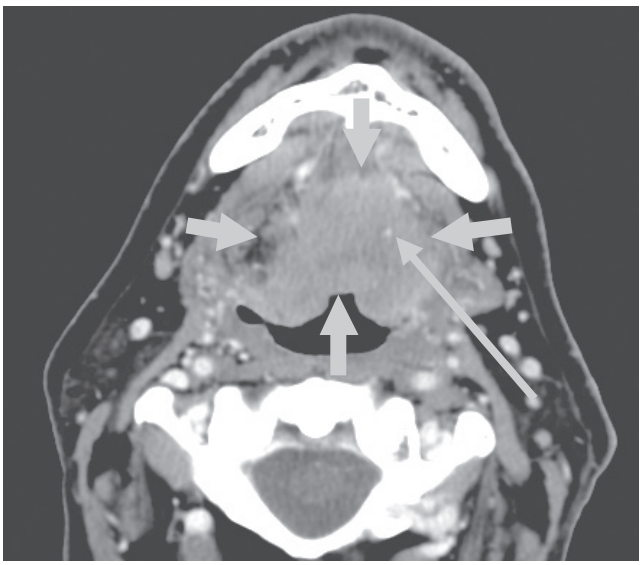
# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

The oropharynx provides a challenge to imaging because of its abundant lymphoid tissue, which normally enhances and has variable thickness. Small superficial mucosal tumors may not be seen on CT or MRI for this reason. Indeed, small lesions may not be seen with direct visualization if they are hiding within deep crypts in the lymphatic tissue. Therefore, tumor can only be reliably identified on imaging studies if it infiltrates into the deep soft tissue planes (Fig. 17-15). An additional challenge to CT imaging is streak artifact from dental hardware, which may necessitate changing the gantry angle to achieve adequate visualization of the entire oropharynx. Tongue motion and swallowing will degrade the images as well, which is certainly a problem for MRI, but is less of a problem with high-speed multidetector CT scanning. Suggested protocols are given in Figures 17-16 and 17-17.

Even though the superficial mucosal extent of a tumor may not be well seen with CT or MRI, both imaging modalities can readily identify invasion into the glossotonsillar sulcus, the intrinsic tongue, and the preepiglottic space (Fig. 17-18).[1] Lateral and posterior pharyngeal wall tumors can be easily overlooked radiographically, but imaging is good for assessing deep invasion into the parapharyngeal space (Figs. 17-19 and 17-20).

Soft palate tumors require coronal imaging for adequate assessment of possible bony invasion of both the hard palate and extension through the parapharyngeal space to the skull base



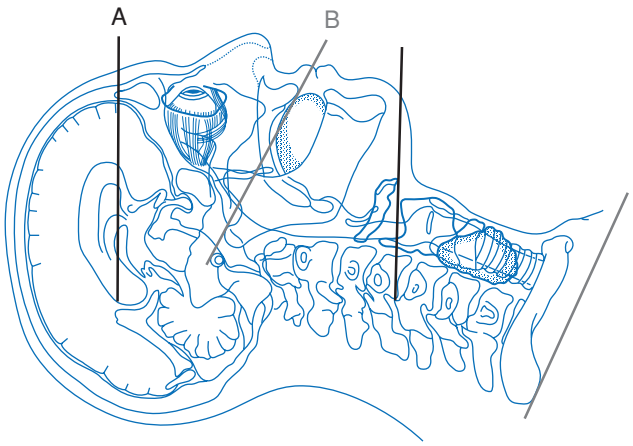


**FIGURE 17-15.** Axial contrast-enhanced computed tomography (CT) shows an aggressive tumor involving the tongue base (*short arrows*). Note that the tumor encases the lingual artery (*long arrow*).

Compare the normal greater and lesser palatine foramina on the right side for comparison. **D:** Axial contrast enhanced CT scan shows that the tumor has spread along V2 to the left pterygopalatine fossa (*arrow*).

(Fig. 17-21). MRI may be better for visualization of tumor extending along the tensor veli palatini and the levator veli palatini muscles to the skull base.

Primary tumors of the palatine tonsils are also difficult to detect on imaging studies before there is deep invasion. Once deep tissue plane invasion is present, multiplanar CT or MRI can document extension to the palate (Fig. 17-22), the tongue base, the masticator space (Fig. 17-23), and the mandible (Fig. 17-24).

In all cases of oropharyngeal squamous cell cancer, careful evaluation of the retropharyngeal space must be made to look for lateral retropharyngeal lymph nodes (Fig. 17-25), as these cannot be detected clinically and may be excluded from limited neck dissections for clinical N0 necks.[2]

Posttreatment imaging is challenging to interpret because of altered anatomy and scarring (Fig. 17-26). FDG-PET/CT is becoming increasingly used for follow-up 3 to 4 months after

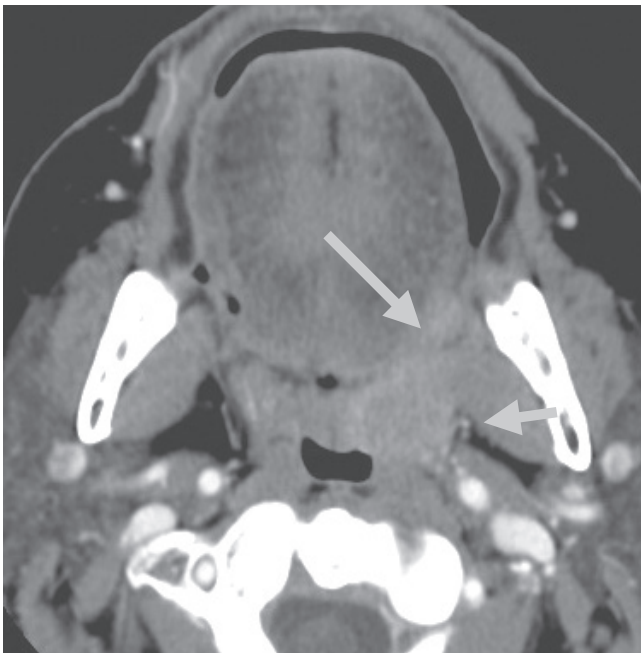

**FIGURE 17-24.** Axial contrast-enhanced computed tomographic (CT) scan shows the typical appearance of a left tonsillar carcinoma. There is deep extension into the parapharyngeal space (*short arrow*) and some anterior extension along the superior constrictor muscle (*long arrow*).

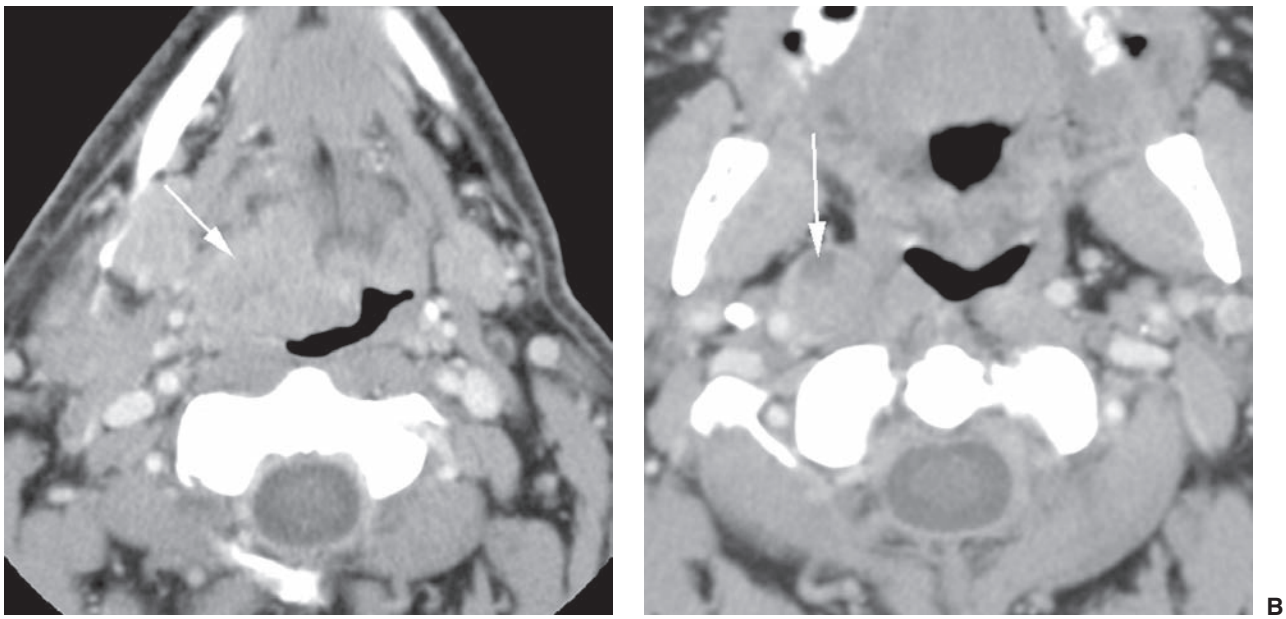

**FIGURE 17-25.** **A:** Axial contrast-enhanced CT scan shows an aggressive right tongue base squamous cell carcinoma (*arrow*). **B:** A positive right retropharyngeal lymph node is present (*arrow*).

completion of therapy. It is particularly useful because of its high negative predictive value.[3] When positive, the area with increased uptake can be biopsied to confirm recurrent tumor (Fig. 17-27). Recent studies are investigating whether higher standard uptake values (SUV) in the primary tumor or in lymph nodes have an ability to predict outcome.[4] This research may in time alter treatment regimens.

Surveillance scanning for patients with HPV-positive tumors may be different from patients with HPV-negative tumors because of their different biological behaviors, although this is still being investigated. Zhang et al.[5] found that a negative FDG PET/CT performed between 4 and 16 weeks after treatment had a 79% negative predictive value after 2 years of follow-up, indicating that those patients with a negative initial posttreatment scan were low risk for recurrence.

# PART C:
# Radiation Therapy Technique

Louis B. Harrison, James E. Dolan, Rudolph Woode, Waleed Mourad, and Kenneth S. Hu

## TONSIL

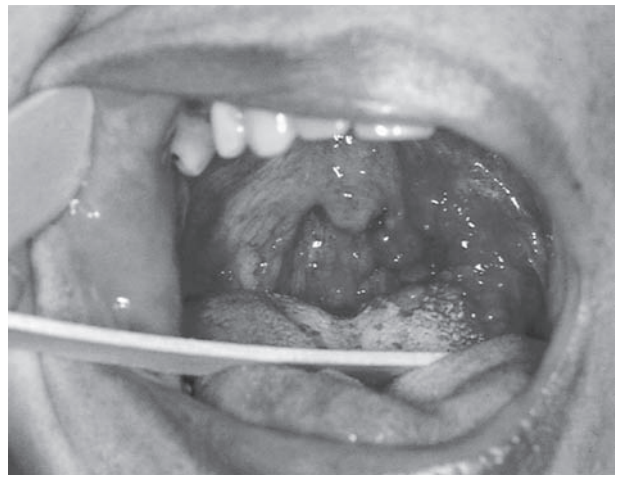
The chapter has provided extensive discussion about the relative indications for unilateral neck treatment versus bilateral neck treatment for patients with carcinoma of the tonsil. For unilateral treatment, either 3D conformal radiation therapy (3DCRT) or intensity-modulated radiation therapy (IMRT) can be used. Often, 3DCRT will allow the radiation oncologist to obtain excellent dose distribution with very acceptable normal tissue doses. The mere sparing of the contralateral neck and anatomical structures both reduces late toxicity and improves acute tolerance to treatment.

Figure 17-28 shows a patient with T2N0M0 squamous cell cancer of the left tonsil. As can be seen, excellent tumor coverage is obtained and key normal organs are well protected.

IMRT has been increasingly utilized for tonsil cancers. It is especially helpful in clinical situations where sparing of the contralateral parotid gland is appropriate or where the volume of normal tissue can be reduced with IMRT techniques. Figure 17-29 shows a patient with T1N0M0 squamous cell carcinoma of the right tonsil, treated with IMRT. The primary lesion receives the full therapeutic dose of 66 Gy in 33 fractions of 2 Gy each. The ipsilateral regional lymph nodes, including the ipsilateral lateral retropharyngeal nodes, receive elective nodal irradiation at 1.8 Gy/fraction. The contralateral neck and the contralateral parotid gland are spared. If there is a clinical indication to treat the contralateral neck electively (e.g., a primary lesion that extends within 1 cm of midline or involves the base of tongue, but the contralateral neck is clinically negative), then IMRT is used to keep the contralateral mean parotid dose ≤26 Gy (see technique for "Base of Tongue"). When IMRT is used, no bite block is used in order to maximize reproducibility and immobilization.

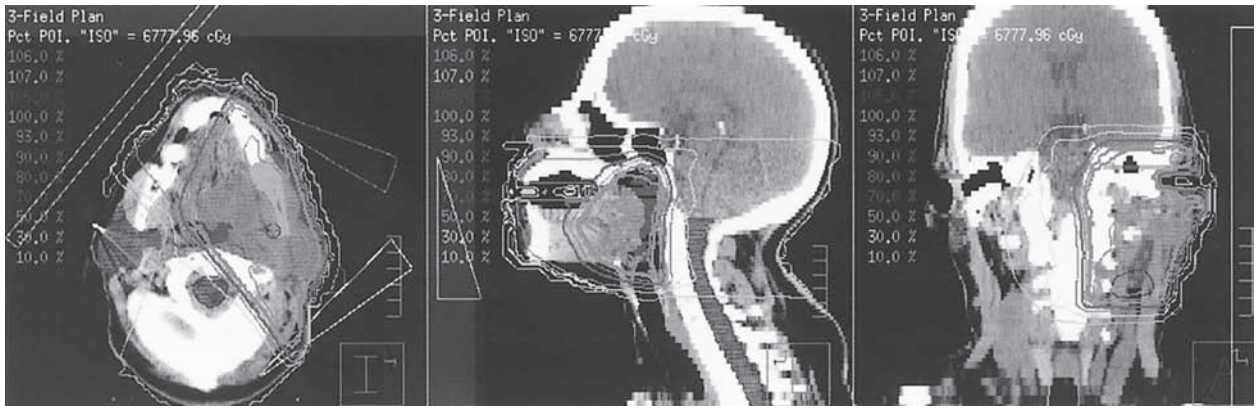
For patients with tonsil cancer and bilateral neck metastases, IMRT is used. The technique is similar for tonsil and base of tongue. Figure 17-30 shows a patient with cancer of the base of tongue and bilateral neck metastases. A similar technique would be used for a tonsil primary.

## BASE OF TONGUE



Patients with cancer of the base of tongue (Fig. 17-31) are treated to the primary site and both sides of the neck. As discussed in the chapter, authors' practice is to use an implant for the boost treatment. However, many centers do not incorporate brachytherapy and use an external beam boost.

IMRT is the standard approach for base-of-tongue cancers. Figure 17-31 shows the contours, dose distributions, and dose–volume histogram for a patient with T2N0M0 squamous cell carcinoma of the base of tongue. In this case, the primary site, as well as the bilateral neck nodes, receives 54 Gy in 30 fractions of 1.8 Gy. The contralateral parotid is relatively spared, as shown in the dose–volume histogram. However, because there are nodes near the parotid, the authors recommend caution about this. The low neck can be treated as part of the IMRT field or can be treated with a separate, anterior field, which also blocks the larynx in the upper midline. Treatment to the primary site is completed with an implant (Fig. 17-32). Figure 17-30 shows a patient with T4N2c squamous cell cancer of the base of tongue. This patient had disease extending into the upper portion of the larynx. An implant was not technically feasible, so IMRT was used for the entire course of treatment.



## SOFT PALATE

Patients with soft palate cancer are treated to the primary site and both sides of the neck. As with base of tongue, there are no data to support the concept of ipsilateral neck irradiation in these patients. Techniques are similar to those for base of tongue.

C

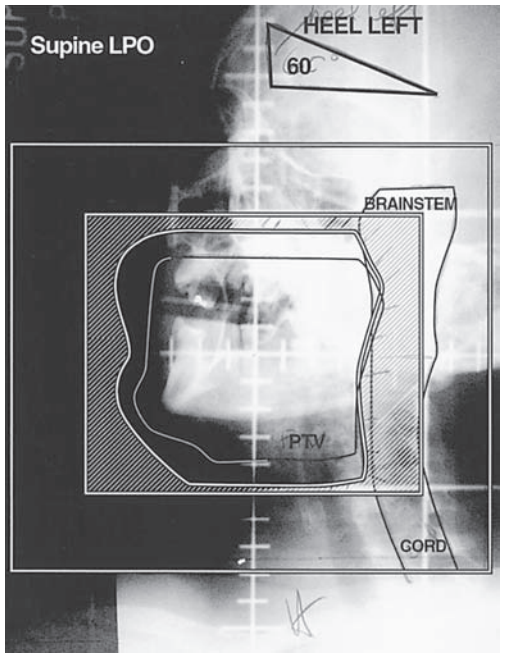

**FIGURE 17-28.** Tonsil cancer. Unilateral neck treatment technique. A patient treated with unilateral fields. This patient is a 50-year-old woman with a T2N0 squamous cell carcinoma of the left tonsil. The authors' plan is to treat this patient with definitive radiation therapy. **A:** This is a photograph of the primary lesion. It involves the tonsillar fossa, with involvement of the anterior tonsillar pillar and superficial involvement of base of tongue. **B:** This patient was treated with a three-field plan. This involves a wedged-pair plan, with a low-weighted right anterior oblique field, to help cover the tongue extension without overdosing the spinal cord. The planning tumor volume (PTV) is contoured. The primary site, extension along the soft palate, extension into the base of tongue, upper neck nodes, and retropharyngeal nodes are all included. An axial, sagittal, and coronal dose distribution shows that the PTV is well covered. The salivary gland tissue of the contralateral neck, especially the parotid gland, is well protected. **C:** Dose–volume histogram of this plan showing good coverage of the target volume and adequate protection of the surrounding normal tissue. The curves are depicting extremely low doses to the right parotid as well as the right and left retina. **D** to **F:** The simulation films showing the fields that were used. As mentioned previously, these consisted of a left anterior oblique (LAO), a left posterior oblique (LPO), and a lightly weighted right anterior oblique (RAO).

**FIGURE 17-29.** This patient had a T1N0M0 American Joint Committee on Cancer (AJCC) stage I squamous cell cancer of the right tonsil. The treatment plan was definitive external beam radiation therapy. The authors used intensity-modulated radiation therapy (IMRT) and did use a dose-painting technique. The high-risk PTV includes the primary site, which received 66 Gy in 2-Gy fractions over 33 fractions. The intermediate risk (interrisk) PTV includes the ipsilateral upper neck nodes and retropharyngeal nodes, as well as some additional safety margin around the primary site. This area received 1.8 Gy/fraction, so it received 59.4 Gy in total. The authors could have delivered only 54 Gy to this volume as it is treated electively. The low neck (right side only) was treated with a separate, AP field, to 50 Gy in 2 Gy fractions over 5 weeks. **A:** Isodose distribution displayed on an axial computed tomography (CT) used for treatment planning. This shows the primary site (high-risk PTV) as well as the electively treated ipsilateral regional nodes (interrisk PTV). The left (contralateral) parotid gland is spared completely. Care is taken to avoid hot spots, especially in the mandible. **B:** This figure was produced using the MIM-Vista system. It shows representative serial radiotherapy (RT) planning slices as well as representative contours.(a) Contour shows the upper limit of the ipsilateral retropharyngeal nodes. (b) Contour shows upper limit of the primary site contour, plus the added safety margin (interrisk PTV). (c) Contour shows high-risk and interrisk volumes, plus the contralateral parotid gland, which is spared. (d) Contour shows primary site (high-risk) and ipsilateral neck nodes (interrisk) as well as the spared, contralateral parotid. (e) Same as (d). (f) Same as (d). (g) Same as (d), without contralateral parotid. (h) Same as (g). (i) Inferior contour at level of hyoid bone showing the ipsilateral neck nodes contoured (interrisk PTV). **FIGURE 17-30.** This patient had a T4N2CM0 squamous cell cancer of the base of tongue. The primary lesion involved the base of tongue at the midline, extending to both sides of the tongue base, into the vallecula, and into the upper portion of the supraglottic larynx. We treated this patient with concomitant cisplatin and IMRT. The PTV70 includes the primary site as well as the involved lymph nodes on both sides of the neck. The PTV60 includes the remaining upper neck levels II and III. The PTV54 includes bilateral retropharyngeal nodes and the bilateral lower necks. A 9-field IMRT plan was used. The patient is free of disease at 2 years. **A:** CT slice through the superior aspect of the base of tongue at level of the uvula. The PTV70 and PTV54 are identified. Also identified are the right and left parotid glands and the constrictor muscles. **B:** Same CT slice as A except that the isodose lines are shown. The PTV contours have been removed for ease in optical display. The relative sparing of the parotid glands and constrictors is evident. **C:** CT slice through the base of tongue and neck at level II. The PTV70 includes the primary site as well as the involved lymph nodes in the left level II. The PTV60 expands upon the PTV70 and includes all of levels II and III bilaterally. Small portions of the inferior aspect of both the right and left parotid glands are also shown. **D:** Same CT slice as C except that the isodose lines are shown. The PTV contours have been removed for ease in optical display. The relative sparing of the parotid glands and constrictor muscles is evident. **E:** CT slice through the hyoid bone which shows the inferior aspect of tumor as it invades the upper larynx and epiglottic. The PTV70 contours this inferior tumor extension as well as lymph node involvement of bilateral neck nodes at levels II and III. The PTV60 expands upon the PTV70 as well as including all of levels II and III bilaterally. **F:** Same CT slice as E except that the isodose lines are shown, and the PTV contours removed as in prior figures. **G:** Midsagittal slice which shows PTV70 covering the disease in the base of tongue and upper larynx. **H:** Same midsagittal contour as G with PTV70 contour removed but showing isodose display. **I:** Coronal slice showing PTV70 including involved lymph nodes on both sides of the neck, PTV60 to include entire upper neck levels II and III, and both parotid glands. **J:** Same coronal slice as I with contours removed and isodose curves displayed. **K:** Dose–volume histogram for this patient using a 9-field IMRT plan.

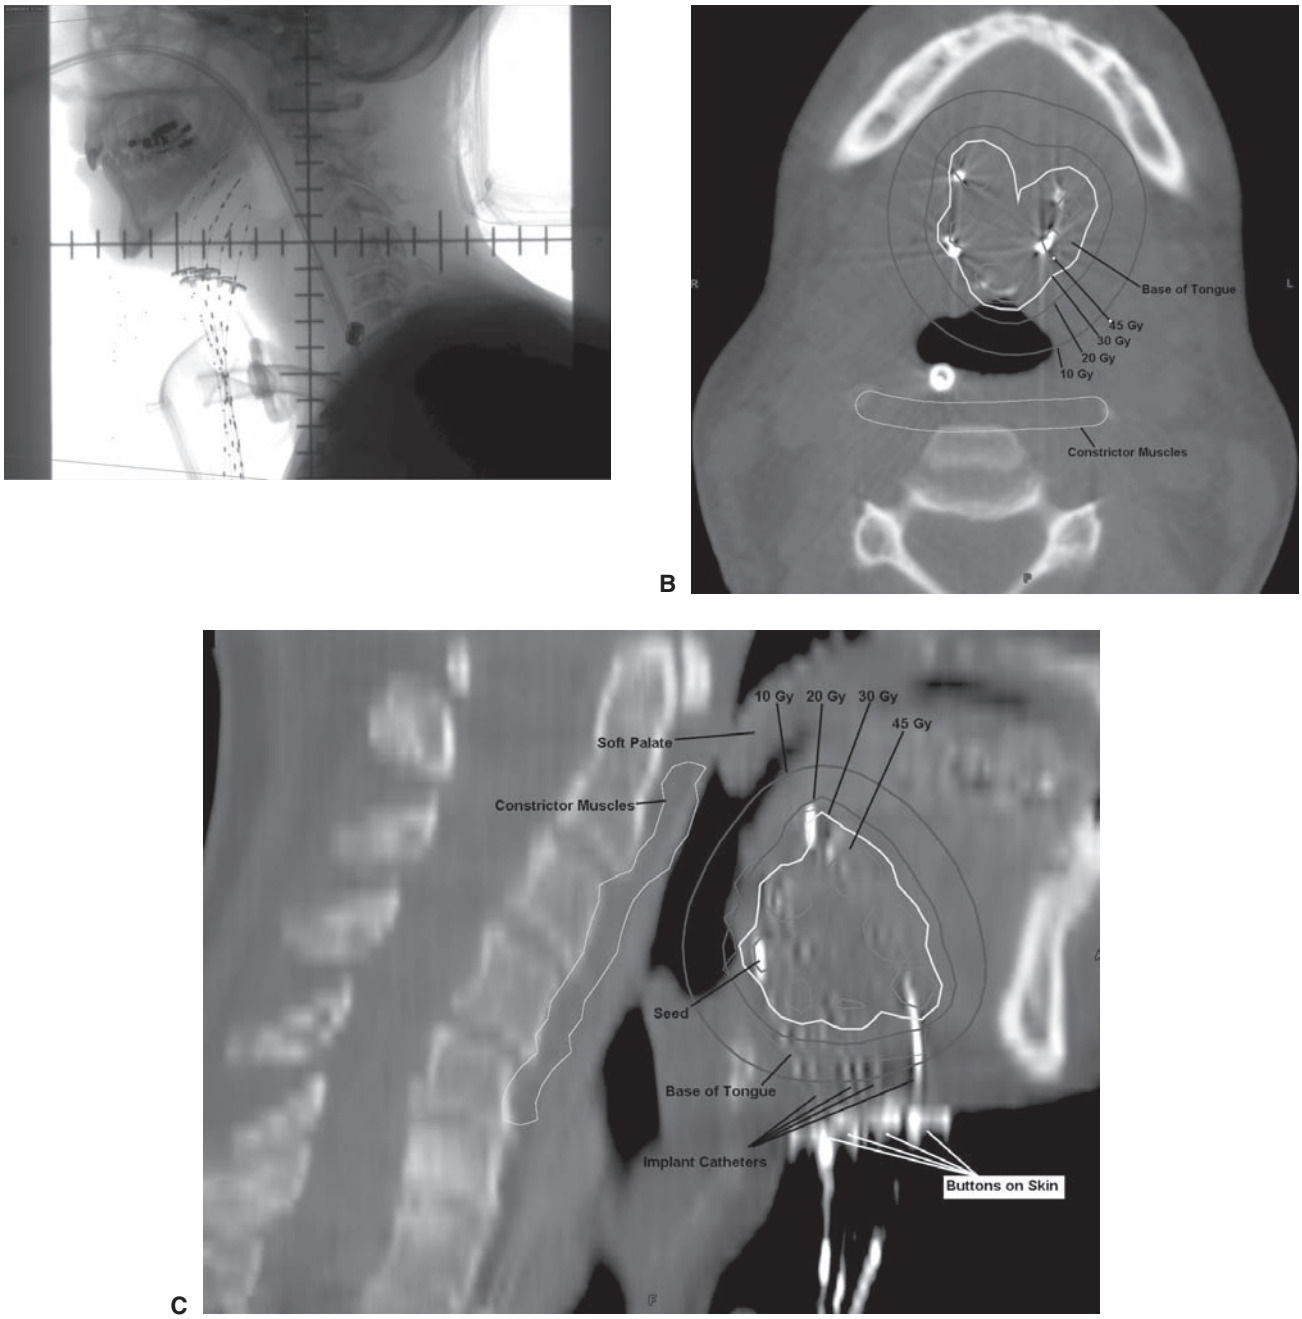

**FIGURE 17-32.** This patient had an iridium-192 ($^{192}$Ir) implant boost to the base of tongue. The patient had received intensity-modulated radiation therapy (IMRT) with concomitant chemotherapy, and the base of tongue received 5,400 cGy via IMRT. The involved lymph nodes were in the PTV70 and received 70 Gy via IMRT. This was accomplished using a dose-painting technique where the base of tongue was contoured as PTV54 and received 5,400 cGy in 6 weeks. The PTV70 received 70 Gy in 7 weeks. About 3 to 4 weeks after the completion of IMRT, the patient was brought to the operating room for the implant. **A:** Localization film showing looping implant of catheters through the base of tongue and exiting the anterior neck. **B:** CT slice through the base of tongue showing the contour of the base of tongue, the constrictor muscles, and isodose levels 3,000 cGy, 2,000 cGy, and 1,000 cGy. The dose rate is 900 cGy/day. Note the excellent sparing of the pharyngeal wall and constrictor muscles. **C:** Midsagittal CT slice showing the base of tongue, constrictor muscles, catheter loops and buttons, soft palate, and isodose levels 3,000 cGy, 2,000 cGy, and 1,000 cGy. Normal tissue sparing of the constrictor muscles, the pharyngeal wall, and the palate are nicely displayed.

# PART D:
# Surgical Technique

Vikas Mehta, and Robert L. Ferris

## INTRODUCTION

Over the last decade, technological advances in minimally invasive, transoral surgical techniques have revolutionized the treatment paradigm for oropharyngeal neoplasms. Since the early 1990s, due to evidence extrapolated from the VA larynx and RTOG 91-11 trial[1,2] for nonsurgical larynx preservation, primary surgical therapy was reserved for small tumors (<1.5 cm) of the posterior pharyngeal wall and the tonsils, carcinomas requiring bony resection or tumors not sensitive to radiotherapy. Organ-preservation protocols demonstrated not only that patients treated with primary radiation therapy had similar survival rates to upfront surgical therapy, but also that primary surgical patients were 10 times more likely to have severe morbidity or mortality.[3] The complications from traditional surgical methods were largely due to external surgical approaches, which required opening the pharyngeal and oral contents to the neck, with the patient often needing a tracheostomy and feeding tube. The addition of a mandibulotomy and/or glossotomy further increased postoperative speech and swallowing dysfunction, as well as cosmetic deformity.

With the sharp increase in the prevalence of human papillomavirus (HPV)–associated oropharyngeal squamous cell carcinoma (OPSCC), there has been a corresponding shift in the affected population to younger, nonsmoking patients.[4] Per the current practice guidelines, these HPV-positive patients undergo intensive chemoradiotherapy (CRT) protocols, just as their HPV-negative counterparts, but with drastically improved survival. The increased risk for these younger patients of long-term sequelae such as osteoradionecrosis, progressive dysphagia, fibrosis, aspiration, and radiation-induced malignancy has led head and neck surgeons to explore minimally invasive surgical techniques to minimize the morbidity of surgical resection and reduce the need for high-dose chemoradiotherapy. Additionally, the very good survival of patients with advanced OPSCC treated with CRT can be primarily attributed to increasing rates of HPV-positive disease. A multicenter phase III trial reported 3-year overall survival (OS), disease-free survival (DFS), and loco-regional control rates of 51%, 42%, and 66%, respectively, when treated with chemoradiation.[5] When the TAX 324 study, a phase III CRT trial of 264 patients with OPSCC, was stratified by HPV status, 5-year survival was 82% for HPV+ and 35% for HPV– patients.[6]

Both transoral laser microsurgery (TLM) and transoral robotic surgery (TORS) have demonstrated excellent oncologic results with good functional outcomes for oropharyngeal tumors,[7–10] leading to a change in the National Comprehensive Cancer Network 2011 guidelines to remove primary radiation therapy as the Category 2B preferred treatment for early oropharyngeal cancer.

For advanced, high-volume, or post-CRT recurrent oropharyngeal carcinoma, surgical resection via an external approach is often required. The choice of open surgical approaches depends on the location of the tumor and degree of bony involvement. The oropharynx contains structures crucial for deglutition, respiration, and phonation. There is no one approach that allows wide exposure with minimal morbidity. The three main routes are combined transoral/transcervical, transpharyngeal, and transmandibular approaches. Each has its own risks and sequelae to these vital structures. If necessary, a maxillectomy and/or mandibulectomy can be combined with any of the three techniques. Often, oropharyngeal resections will require flap reconstruction. This chapter will address the indications, advantages and disadvantages of the transoral and external approaches.

### Minimally Invasive Transoral Approaches

Minimally invasive surgical techniques have greatly expanded the scope of the transoral approach for oropharyngeal resections. Traditionally, transoral surgery was reserved for tumors <2 cm of the tonsil, the soft palate, and the posterior pharyngeal wall. Larger neoplasms or tumors of the base of tongue were difficult to access, especially at the deep margins. The use of endoscopes greatly improved transoral visualization of the oropharynx by magnification, tissue distention, and angled optics. Additionally, advancements in laser delivery systems and the wristed technology of the DaVinci robot have allowed increased freedom of motion in previously inaccessible subsites. These innovations have enabled surgeons to remove large neoplasms from the oropharynx with excellent oncologic control and functional outcomes.

### Transoral Laser Microsurgery

Transoral laser microsurgery was first introduced by Strong and Jako in 1972.[11] Despite promising initial results, it soon fell out of favor as an oncologic treatment option due to early difficulties with exposure and en bloc removal. In 1993, Steiner revolutionized the field of minimally invasive transoral surgery by presenting an article describing results with a piecemeal resection utilizing a tumor-splitting approach.[12] The splitting of the tumor in this dimension allowed much better assessment of the deep margins (Fig. 17-33). Steiner's report was followed by a rapid influx of evidence supporting the roles of TLM in treating cancer of the upper aerodigestive tract. Recent large cohort studies and multicenter case series have reported oncologic results for laryngeal and oropharyngeal neoplasms that are comparable to nonsurgical management, with improved functional outcomes and decreased health care costs (mean cost of US$3,281 for TLM compared to US$13,825 for XRT).[10,13–17]

While most of the supporting evidence for TLM is in early glottic cancer, there has been promising results with OPSCC over the last decade. In 2003, Steiner et al. reported on a cohort of 48 patients with OPSCC treated with TLM, of which 94% were stage III/IV.[18] Twenty-three of the 48 patients required therapy for either deep extension into the tongue base or positive resection margins. The 5-year local control for all T stages was 85% with no local recurrences in the T1 or T2 group and a 20% local recurrence rate for T3/T4 tumors. OS and DFS were 52% and 73%, respectively.

In a recent, multicenter, prospective study of primary, TLM-resected, stage III/IV OPSCC, 204 patients were reported.[10] Two- and 5-year estimates demonstrated an OS of 89% and 78%, DSS of 91% and 84%, and DFS of 85% and 74%, respectively. The survival results are comparable with studies using chemoradiation as the primary treatment modality, with improved functional outcomes. A recent CRT study ($n$ = 71) by Huang et al. with 32% of the tumors staged T3 and T4, showed a 3-year OS of 83% and a loco-regional control rate of 90%.[19] In the TLM study, with

**FIGURE 17-33.** A CT scan of a patient with a T3 tonsillar SCCA. The arrows depict the transoral laser microsurgical approach of a tumor debulking followed by radial incisions through the tumor to determine depth of resection circumferentially.

34% T3 and T4 tumors, the OS was 86% at 3 years and loco-regional control of 93%. The matched, chemoradiation group in this report had a long-term G-tube rate of 35% compared with 3.4% in the TLM study.

Studies have also indicated that TLM-based surgical treatment without adjuvant therapy can be used with excellent oncologic control for early T-stage OPSCC. In 2009, Grant et al. reported 69 cases of oropharyngeal carcinoma staged T1 to T4 (T1 = 25, T2 = 30, T3 = 12, T4 = 2) treated with TLM and a neck dissection, if indicated.[13] None of the patients received adjuvant radiation therapy, either because it was not indicated or the patient declined. Five-year OS was 86% with loco-regional control of 90% for T1 and 94% for T2. None of the T3 or T4 patients had a local recurrence. In terms of functional outcomes, none of the patients required a long-term feeding tube and 98% reported normal or near-normal swallowing, using the Salassa scale.

***Technique*** TLM is usually done with either a microscope-mounted carbon dioxide laser or a hollow-fiber carbon dioxide laser system. Exposure of the tumor is achieved with a variety of specialized endoscopes, and excision is performed either circumferentially (en bloc) or in a tumor-splitting fashion (Fig. 17-33), to ensure adequate surgical margins. Tumor mapping and margin status is typically performed using both frozen-section and permanent pathologic analysis. The reported complication rate of TLM is extremely low with the most common problem encountered being postoperative bleeding at a rate of 1.5% to 3%.[13,20] Contraindications to TLM include inadequate endoscopic access, which is unusual for oropharyngeal carcinomas, or projected unresectability because of a probable positive margin. Examples of an unresectable tumor are lateral extension of a tonsillar primary into the infratemporal fossa invading the great vessels or ventral extension of tongue base tumors into the anterior floor of mouth.

## Transoral Robotic Surgery

The first described use of robotics in head and neck surgery consisted of a robotic-assisted salivary gland resection and neck dissection in an animal model.[21] The elimination of hand tremor and superior, three-dimensional visualization were both described as significant advantages.[21] The feasibility of transoral robotic surgery was investigated at the University of Pennsylvania, first using a human cadaver,[22] followed by a supraglottic laryngectomy in a canine model.[23] Protocols were then established for positioning, use of 5-mm instruments, and hemostasis.[23,24] The first documented OPSCC TORS resection was in three patients with early T-stage, base of tongue SCCs. En bloc resection with negative margins was achieved in all three cases with no complications or change in swallowing function.[25]

In 2007, a case series of 27 patients with tonsillar SCC underwent primary resection with TORS.[26] The patients were mostly stage III/IVa.[24] Neck dissections were performed on 26 of the 27 patients with 24 of the patients having at least one positive node. The cervical lymphadenectomy was performed 1 to 3 weeks after the TORS procedure to minimize lymphedema in the oropharynx after TORS. Negative margins were achieved in all of the cases and there were no loco-regional recurrences during the 2-year study period with a minimal of 6-month follow-up. All of the patients who returned for evaluation (26 of 27) tolerated a regular diet without the need for a gastrostomy tube. Only one patient required a tracheostomy for preexisting sleep apnea, which was exacerbated by the surgical procedure.

Since 2007, several institutions have reported case series highlighting the efficacy of TORS for OPSCC.[9,27–31] These reports document excellent oncologic outcomes in patient series ranging from 20 to 47 patients. In the patient population presented by Moore et al.,[9] 12 of 45 patients (27%) were able to avoid adjuvant radiation, and at 1-year follow-up in this series, no local recurrences were detected. Weinstein et al.[31] reported a series of 47 patients with advanced OPSCC (stage III/IV). One patient had a positive margin (2%). DSS was 98% at 1 year and 90% at 2 years. Due to the TORS procedure, 18 of 47 patients (38%) avoided chemotherapy, and 5 patients (11%) did not require any adjuvant therapy. In a prospective, phase I single arm study,[32] 31 patients underwent TORS with selective neck dissection(s) (SND) with a 100% disease control rate and a 2-year PEG dependency rate of 0%. Seven patients avoided adjuvant therapy and 15 of the remaining 24 (62.5%) received radiation alone (60 Gy to the primary site and dissected neck, 54 Gy to the contralateral neck and retropharyngeal nodes) based on the lack of nodal extracapsular extension (ECE).

Functional outcome studies in OPSCC patients undergoing TORS resections have reported superior swallowing results when compared to published, organ-preservation protocols.[8,9,29,30,33,34]. In a direct comparison of TORS versus CRT with matched group of OPSCC patients at a single institution, TORS was associated with better short-term eating ability (swallowing score 72 vs. 43, $p = 0.008$), diet-tolerance (43 vs. 25, $p = 0.01$), and Functional Oral Intake Score (FOIS) (5.5 vs. 3.3, $p < 0.001$) at 2 weeks after completion of treatment.[33] At 12 months, the TORS group had returned to baseline swallowing status while diet and FOIS remained impaired in the CRT group. In a series of 45 patients, Moore et al. found that only 5 of 22 patients who had gastrostomy tubes required their use beyond 20 days and all patients had their feeding tubes removed by 4 months.[9] Dean et al. compared feeding tube dependence in patients undergoing TORS to those who had open surgery for post-CRT OPSCC failures and found that while 43% of the open salvage group were G-tube dependent at 6 months, none of the TORS patients required feeding tube supplementation. These early evaluations of the oncological and functional outcomes of TORS led to FDA approval of TORS

(c) 2014 Wolters Kluwer. All Rights Reserved.

for use in selected benign and malignant (T1/T2) tumors of the head and neck in December 2009.

***Technique.*** TORS is performed with exposure either using the Dingman or Feyh-Kastenbauer (FK) laryngeal retractor. Once adequate exposure is achieved, the robot is brought to the left side of the patient and the 0-degree (tonsillar fossa) or 30-degree (tongue base) binocular endoscope is positioned to allow optimal visualization of the tumor. Five-millimeter instruments are typically used with one being a grasper and the other arm holding monopolar cautery (Fig. 17-34). An assistant at the head of the bed helps with exposure, suctioning and, if necessary, hemostasis with bipolar cautery. The anatomic landmarks via a TORS approach have recently been well described for OPSCC tumors.[35] Once the tumor is removed, three-dimensional orientation of the specimen for pathologic evaluation is crucial. Reconstruction, if required, is then performed with the robot utilizing either a local flap or free tissue transfer. Most authors advocate the use of a hemostatic agent at the end of the procedure due to the difficulty in obtaining access if postoperative bleeding should occur. Fixation of the tumor to the lateral pharynx or the skull base, inadequate exposure, or presumed unresectability should discourage the surgeon from proceeding with a TORS approach.

## Traditional Transoral Excision

Proper patient selection is the most critical aspect in planning transoral excision using traditional methods. The surgeon must be able to adequately visualize the tumor through the oral cavity using a headlight throughout the procedure. This requirement effectively limits these procedures to T1/2 tumors involving the upper oropharynx: the tonsil, the soft palate, and the posterior pharyngeal wall (if the inferior aspect of the tumor does not extend beyond the tip of the epiglottis). Absolute contraindications to transoral excision include trismus, deep invasion by the tumor, and poor accessibility. These should be evaluated preoperatively through physical examination and imaging, but attachment to the deep vascular and soft tissue structures may be difficult to ascertain until the patient is under general anesthesia.

**FIGURE 17-34.** An intraoperative photo of a transoral robotic base of tongue tumor resection. A Dingman retractor is being used for exposure. The 5-mm monopolar cautery and Maryland forceps instruments are introduced into the operative field with the wristed technology allowing excellent transoral access to the oropharynx.

A high tooth profile, macroglossia, thick lips, or microstomia can all interfere with adequate exposure and are therefore relative contraindications.

Exposure of the tumor is the key step in performing a transoral excision of an OPSCC. An oral mouth gag (such as a McIver or Crowe-Davis retractor) is first inserted and suspended from a Mayo stand. If the tumor extends superiorly into the nasopharynx, red rubber catheters can be placed to retract the soft palate anteriorly and superiorly. Palpation of the tumor is then performed to assess the submucosal extent and attachment to deep structures. The tumor can be removed using either electrocautery or a handheld laser based on surgeon preference. If a handheld carbon dioxide laser is going to be utilized for resection, the use of a reinforced endotracheal tube is imperative. Usually, the initial mucosal cut is made as far posterior and inferior as possible since these areas will become difficult to visualize as the resection proceeds. Margins should be taken with at least 1 cm cuff of mucosa, and the deep margins should be checked frequently via palpation to ensure complete removal. The specimen should be oriented for pathologic analysis as a failure to orient often leads to unclear margin assessment. Finally, posterior pharyngeal wall defects can be left to heal by secondary intention after securing the edges to the prevertebral fascia or resurfaced with a split-thickness skin graft. The tonsillar fossa and soft palate can be primarily closed or left open. The reconstruction of larger defects will be discussed later in the chapter.

## Open Surgical Approaches

With increasing use of CRT and minimally invasive techniques, the need for external surgical approaches for OPSCC has steadily declined. For tumors with bony involvement or postradiation recurrences, however, an open surgical approach is often preferred, especially if microvascular reconstruction is required. The choice of open surgical technique depends on the size, location, and degree of bony involvement (Table 17.15). No external approach allows wide exposure with minimal morbidity. The transoral/transcervical, transpharyngeal, and transmandibular approaches each carries its own risk and damage to vital structures. If necessary, a maxillectomy and/or mandibulectomy can be combined with any of the three techniques.

## Transoral/Transcervical

The transoral/transcervical approach, also known as the "pull-through" procedure, involves prolapsing the contents of the oral cavity/oropharynx into the neck by releasing the oral cavity/orpharyngeal attachments to the mandible. The technique is limited to T1–3 tumor without mandibular involvement. In a series of 13 patients with OPSCC resected via this approach, the authors achieved negative margins with minimal postoperative morbidity.[36] The advantages include intact lip sensation and avoidance of a facial incision and/or mandibulotomy. Disadvantages include decreased exposure inferiorly, bilateral floor of mouth and tongue paresthesias, and communication of the oral cavity and the neck. Tumor excision begins with bilateral level I neck dissections, which helps identify the hypoglossal nerves, the lingual nerves, and the lingual arteries. Once the neurovascular structures have been isolated, the lingual mucosa of the floor of mouth is incised circumferentially taking care to leave sufficient cuff of mucosa on the mandible to facilitate closure. The lingual nerve and the sublingual gland are kept attached to the mandible. The extrinsic muscles of the tongue attached to the mandible are incised, and the tongue is delivered into the neck allowing access to the tumor.

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 17.15 Comparison of Various Open Surgical Techniques**

| Open Surgical Approach | Indications | Advantages | Disadvantages |
|---|---|---|---|
| Transoral/transcervical ("pull-through") | T1–3 tumors of the upper posterior pharyngeal wall, the tonsil, or the soft palate | Intact lip sensation, no external facial incision, avoidance of a mandibulotomy | Decreased exposure inferiorly, bilateral floor of mouth and tongue paresthesias |
| Transhyoid pharyngotomy | T1–4 tumors of the base of tongue, the tonsil, and the low posterior pharyngeal wall | Intact lip sensation, no external facial incision, avoidance of a mandibulotomy | Swallowing impairment, poor access to tumors involving the inferior pharynx, the skull base, and the pterygoid fossa |
| Lateral pharyngotomy | T1–4 tumors of the lower lateral and the posterior pharyngeal wall | Exposure to tumors extending inferiorly to the hypopharynx | Blind entry into the pharynx, which can compromise the oncologic resection, risks of injury to the superior laryngeal nerve, the hypoglossal nerve, and the lingual artery, poor access to the superior oropharynx |
| Median mandibulotomy ("Trotter procedure") | T1–3 tumors of the base of tongue, the upper posterior pharyngeal wall, the soft palate, and the nasopharynx | Preserves lip and tongue sensation, exposure to tumors extending superiorly to the nasopharynx | Poor lateral exposure, lip-split, mandibulotomy, and tracheostomy required |
| Lateral mandibulotomy | T1–4 tumors of the tonsil, the base of tongue, and the upper posterior pharyngeal wall | Access to superolateral oropharynx | Lip, tooth, and tongue parethesia and mandibular vascular compromise |
| Mandibulectomy | T1–4 base of tongue, tonsil, upper posterior pharyngeal wall, and soft palate | Resection of advanced tumors invading the mandible | Lip, tooth, and tongue parethesia, mandibular vascular compromise, requires reconstruction |

## Transpharyngeal

***Transhyoid Pharyngotomy.*** The transhyoid approach to the oropharynx is best utilized for primary or recurrent lesions of the base of tongue, the tonsil, and the low posterior pharyngeal wall. The suprahyoid pharyngotomy can be used for any T-stage tumors in these locations, but caution should be taken when addressing T4 tonsil lesions. These advanced tumors often involve the pterygoid musculature, the skull base, and/or the mandible, and a mandibulotomy is often required for proper excision. Additionally, tumors should not involve both lingual arteries, as the maintenance of vascularized tongue base musculature is vital to the closure for this procedure. Agrawal et al. presented a series of 41 patients who underwent the transhyoid approach for OPSCC and compared outcomes to a stage-matched OPSCC group of 41 patients resected via a mandibulotomy approach.[37] Margin status (9 vs. 11 positive), survival (47% vs. 45%), and long-term gastrostomy tube dependence (18% vs. 21%) were similar between the transhyoid and the mandibulotomy procedures. The major distinction between the two came when comparing incidence of osteoradionecrosis (ORN): 2% for the transhyoid group and 17% for the mandibulotomy patients. The advantages of the transhyoid approach are the avoidance of a facial incision and mandibulotomy. Disadvantages include communication of the pharynx and the neck, swallowing impairment, and poor access to tumors involving the inferior most portion of the pharynx, the skull base, and the pterygoid fossa.

***Technique.*** The first step in the procedure is to dissect the suprahyoid musculature from the hyoid bone and release the stylomandibular ligament. The hyoid is then either retracted inferiorly or resected depending on its degree of involvement. Agrawal et al. advocate for removal of the hyoid bone as it allows for greater ease of closure through increased rotation of the tongue base. The intrinsic muscles of the tongue can then be bluntly dissected from the hyoid bone and the hyoepiglottic ligament. The condensation of fibers in this ligament, the median glossoepiglottic fold, will then be identifiable. The pharyngotomy is then performed guided by either prior endoscopy or simultaneous transoral palpation to avoid violating the tumor. The pharyngotomy can then be widened for further access (Fig. 17-35). For base of tongue carcinoma, the tongue base is grasped and pulled anteriorly through the pharyngotomy to facilitate visualization. For cancers involving the tonsillar fossa, the base of tongue and the mandible are retracted anteriorly and the carotid sheath is separated from the pharynx up to the skull base. After resection of the lesion, the hyoid bone, if present, is resuspended to the remaining tongue base musculature or the mandible. If the hyoid bone has been resected, the strap muscles should be brought up to resuspend the larynx. These closure techniques not only serve to prevent fistula formation, but are also essential for avoiding aspiration.

***Lateral Pharyngotomy.*** The lateral pharyngotomy approach is rarely used alone. It is primarily utilized for lower lateral and posterior pharyngeal wall oropharyngeal neoplasms, although

(c) 2014 Wolters Kluwer. All Rights Reserved.

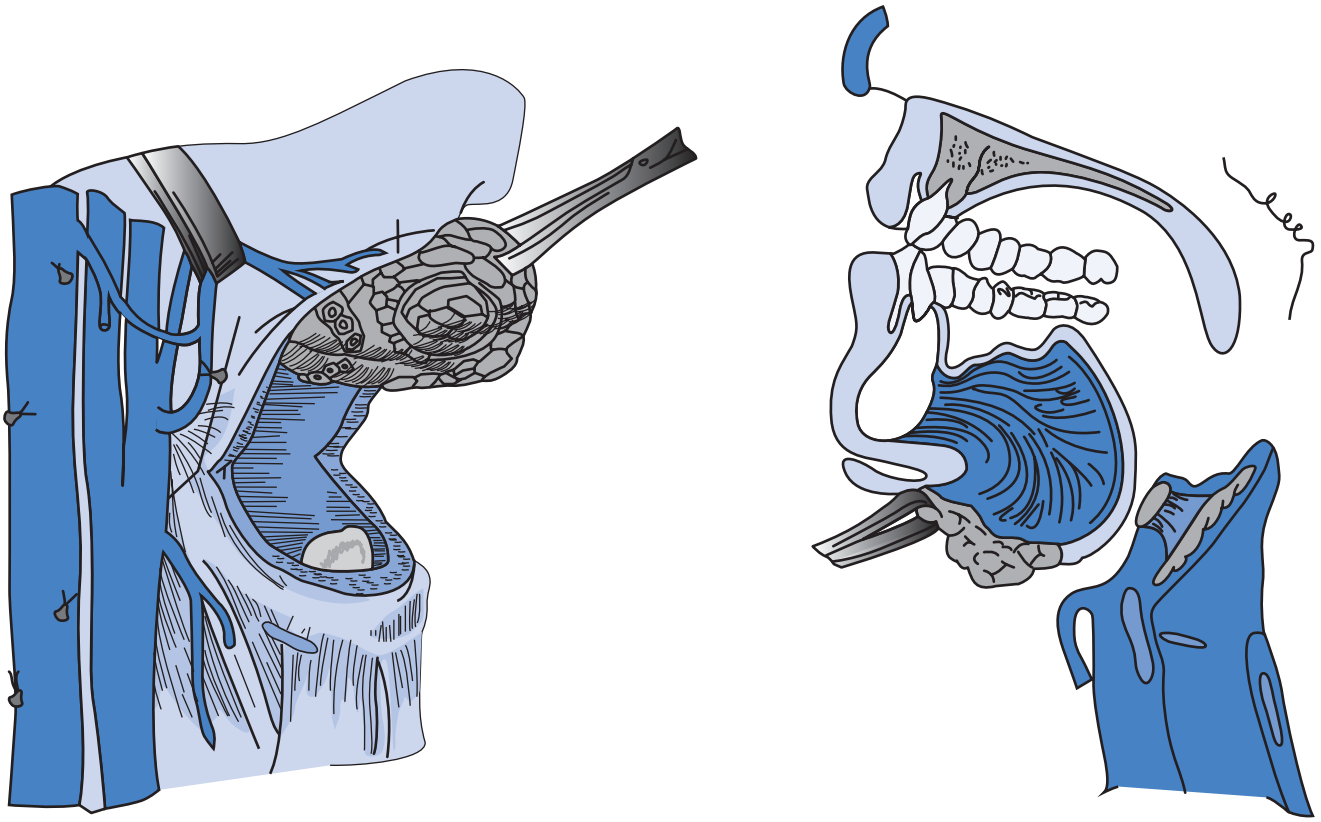

**FIGURE 17-35.** A suprahyoid pharyngotomy is depicted with retraction of the external carotid vessels. The tongue base has been grasped and delivered into the field for access to the base of tongue.

an extended lateral pharyngotomy has been described for lateral tongue base carcinomas and lesions involving the vallecula.[38] For wider exposure, the lateral pharyngotomy can be combined with a mandibulotomy or transhyoid pharyngotomy. Lesions that involve the oropharynx and spread into the hypopharynx are often amenable to resection through this approach. The major disadvantage to the lateral pharyngotomy is that it requires a blind entry into the pharynx, which can compromise the oncologic resection. Additionally, there are risks of injury to the superior laryngeal nerve, the hypoglossal nerve, and the lingual artery. Finally, lesions of the superior oropharynx are not well exposed through this approach.

***Technique.*** The procedure begins by exposing the carotid sheath and retracting its contents laterally to allow identification of the inferior constrictor muscle, as well as the superior pole of the thyroid gland and its vascular supply (Fig. 17-36). The superior laryngeal neurovascular bundle and the hypoglossal nerve are identified and preserved. The stage and site of origin of the primary cancer dictate the extent of the lateral pharyngotomy. The pharyngotomy can be extended superiorly to expose the nasopharynx or inferiorly to expose the cervical esophagus. A high pharyngotomy can be limited by the mobility of the superior laryngeal nerve and occasionally requires nerve transection for adequate exposure. The lateral third of the ipsilateral hyoid bone and the superior cornu of the thyroid cartilage can be removed and the thyrohyoid ligament can be transected in order to increase mobilization. The pharyngotomy location is identified by placing the index finger along the base of the tongue, inferior and posterior to the tonsillar fossa, and tensing the middle constrictor muscle/mucosa. Lesions extending to the superior aspect of the hypopharynx may require inferior extension of the pharyngotomy. The inferior constrictor muscle is incised over the posterior edge of the thyroid ala to expose the mucosa of the pyriform sinus, which is then dissected from the medial facet

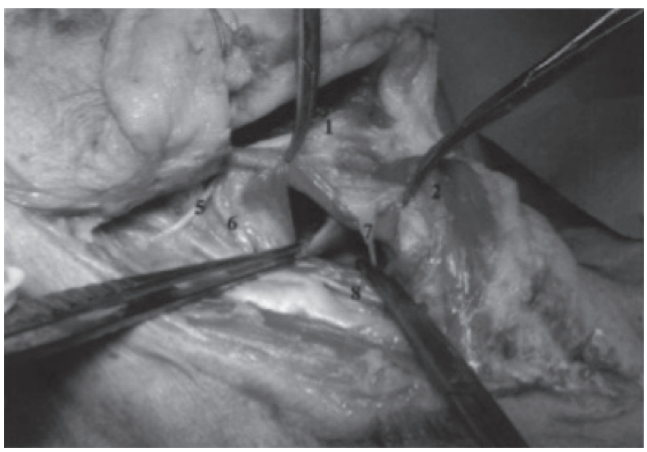

**FIGURE 17-36.** A lateral pharyngotomy has been performed with a lateral view of the epiglottis. 1, tendon of digastric muscle; 2, infrahyoid muscles transected from lateral horn of hyoid bone; 5, hypoglossal nerve; 6, lingual artery; 7, superior laryngeal nerve; 8, superior thyroid artery.

of the thyroid ala. The pyriform sinus pharyngotomy is opened with the mucosa under tension. After the extirpative surgery, the pharyngotomy is repaired with a double-layer closure technique.

## Transmandibular

***Median Mandibulotomy.*** Although uncommonly utilized in the modern era, the median labio-mandibulo-glossotomy (Trotter's procedure) has been historically advocated for lesions of the base of tongue, the upper posterior pharyngeal wall, the soft palate, and the nasopharynx. The approach can be combined with a palatal split making it a good choice for tumors extending superiorly. The major advantage to the Trotter's procedure is that it preserves sensation with good functional outcome. This approach, however, is mainly reserved for midline lesions, as the exposure laterally is poor. Another disadvantage is that it requires a lip-split incision, which is often noticeable, a mandibulotomy, which increases the risk of ORN, and a tracheostomy to protect the airway due to significant tongue edema.

A midline mandibulotomy is performed by exposing the mandible via a lip-splitting incision. Soft tissue flaps are elevated to the level of the mental foramen bilaterally taking care to avoid injury to the mental nerve. The periosteum is elevated only in the area where fixation plates will be placed. Once this is done, the screw holes are predrilled to reconstitute the patient's preoperative occlusion. The mandibulotomy is performed either in the midline between the two central incisors or in the paramedian position between the lateral incisor and the canine tooth. The tongue is then incised in the midline, which is usually a fairly bloodless plane. The incision is carried as far posterior as necessary to provide exposure. After resection of the lesion the tongue is reapproximated with a layered closure and the mandible is plated.

The median mandibulotomy can also be utilized with a mandibular swing to expose lesions of the entire tongue, the soft palate, the posterior pharyngeal wall, the tonsillar fossa, the retromolar trigone, and the infratemporal fossa. After the mandible has been split, the lingual floor of mouth mucosa on the side of the lesion is incised, the mylohyoid and digastric muscles are divided, and the mandible is retracted laterally. The disadvantages of this approach include the morbidity of a mandibulotomy, loss of sensation to the lateral tongue and the floor of mouth secondary to disruption of the lingual nerve, division of the muscular attachments to the anterior and medial aspects of the mandible, and limited exposure of the inferior posterior pharyngeal wall. If necessary, a cervical pharyngotomy can be combined with this approach to provide exposure to the lower posterior wall. Even this combined exposure, however, can be limited inferiorly by the hypoglossal nerve.

***Lateral Mandibulotomy.*** A lateral mandibulotomy can be used to access lesions of the tonsil, the base of tongue, the parapharyngeal space, and the upper posterior pharyngeal wall. The mandibulotomy is usually made posterior to the mental foramen, which results in disruption of the inferior alveolar nerve and the lingual nerve. These can be reapproximated post resection. Once the mandibulotomy has been performed, the soft tissues are released medially to allow the mandible to swing laterally. In general, this approach is not commonly used due to the sacrifice of lip, tooth and tongue sensation, as well as the potential risk of compromising the mandibular blood supply. The midline mandibulotomy usually offers equal surgical exposure with far fewer morbidities.

***Mandibulectomy.*** Finally, a mandibulectomy, or composite resection, is used when tumor invades the mandible (Fig. 17-37). Advanced tumors of the tongue, the tonsil, and the soft palate may all be addressed via this approach. A lip-split incision is then performed and a cheek flap is developed. The mental nerve is sacrificed and the periosteum elevated from the level of the mental nerve to the ascending ramus. The buccal mucosa is incised posteriorly to the retromolar trigone. When elevating the posterior aspect of the cheek flap, it is important to stay close to the ramus of the mandible as a more lateral excursion can injure the facial nerve. Once the mandible has been exposed, a mandibular reconstruction plate is fashioned with holes drilled on either side of the proposed mandibulectomy. There should be room enough for three holes on either side. Once the bony cuts are made, the lesion is excised. Wound closure depends on the chosen method of reconstruction.

**FIGURE 17-37.** Intraoperative photo of a patient with recurrent right tonsillar SCCA. A mandibulectomy was performed along with a hemipharyngectomy, hemiglossectomy, and floor of mouth excision. The tumor was dissected off the carotid vasculature which can be visualized medial to the pharyngeal defect. Microvascular reconstruction was required for closure.

(c) 2014 Wolters Kluwer. All Rights Reserved.

## Reconstruction

The oropharynx contains structures crucial for deglutition, respiration, and phonation making it imperative but difficult to reconstruct. With the advent of microvascular free tissue transfer, the reconstructive options available have increased significantly over the last three decades. A detailed discussion of all the techniques is beyond the scope of this chapter, but a brief outline of the options, as well as their advantages and disadvantages, are described below.

For limited defects, primary closure can be attempted provided it does not impair function or place the tissues under excess tension. Healing by secondary intention has gained resurgence in popularity as more OPSCCs are being treated with minimally invasive techniques. Several authors have reported good swallowing function, even after resection of large tumors.[9,30,31,34,39–41] Shallow defects can be reliably resurfaced with a split- or full-thickness skin grafts if placed in an adequate recipient bed.[42,43] Cicatricial scarring and relief of closure tension are alleviated by the use of a dermal graft. The graft's survival can be improved by the use of a bolster dressing and by not placing it on a previously irradiated recipient site.

The more commonly used local flaps consist of tongue rotational flaps, facial artery musculomucosal flap (FAMM), and palatal island flap. The tongue rotational flap provides enough vascularized tissue to close small to medium defects. The effect on the oral swallowing phase by harvest of this flap is unpredictable thereby limiting its use. The FAMM flap was first described by Pribaz et al.[44] and has been used for medium-sized defects of the soft palate, the tonsillar fossa, and the base of tongue with good reliability.[44–46] One-third of the patients will require a second stage to decrease bulk and improve mobility, although a harvesting modification has been proposed to exclusively utilize the FAMM in a single-stage fashion.[46] The palatal island flap is an axial flap based on the greater palatine vessels. The flap is hearty, easily accessible, and not technically challenging to harvest. It has a limited arc of rotation (which can be improved by drilling out the vascular supply) and can result in oropharyngeal narrowing.

Prior to the advent of free tissue transfer, regional flaps, including the pectoralis major flap, were the primary means of reconstructing large or through-and-through defects. The bulk of this flap, however, while occasionally helpful, is not often beneficial to functional pharyngeal reconstruction. Fasciocutaneous flaps are the most widely utilized reconstructive option for large pharyngeal defects with the two most common being the radial forearm free flap (RFFF) and anterolateral thigh (ALT) free flap due to their pliability and thickness. The RFFF is the workhorse for reconstruction in the oropharynx due to its demonstrated versatility, reliability, and ease of harvest. Simultaneous harvesting can be performed, donor site morbidity is low, and sensory reinnervation using the lateral antebrachial nerve has been well established and can improve functional outcome.[47] The ALT free flap, which is based on the branches of the lateral circumflex femoral artery in a more suitable option for larger defects where more soft tissue bulk or extensive carotid artery coverage, is needed. The harvest is more challenging than the RFFF due to the small caliber of the perforating vessels, but the donor site morbidity is low, a two-team approach can be used, and sensory reinnervation is also possible.[48] Additionally, successful inset of these flaps has been described using a transoral robotic approach, thereby obviating the need for an open approach to reconstruct these defects.[49–51]

If a bony defect is present, an osseocutaneous flap is often required for functional reconstruction. The fibula free flap, introduced by Taylor in 1978, has emerged as the most commonly used bone-containing free flap in head and neck reconstruction. It provides up to 25 cm of bone, which can support osteointegrated implants, and a skin paddle up to $10 \times 20$ cm. The thin, pliable skin can also be harvested as a sensory flap. The main limitation to the use of this flap is donor site morbidity related to vascular compromise after harvest. Careful preoperative assessment is required of the tibial arterial system. The RFFF can also be harvested with radial bone, but due to the poor bone quality and donor site morbidity, an osseocutaneuous RFFF is seldom chosen. Finally, if the lower extremity vascular supply is insufficient or if an extensive, complicated soft tissue defect exists, a scapula osseocutaneous free flap can be utilized. It can provide up to 15 cm of bone stock and can also support an independently vascularized bony segment at the tip of the scapula for simultaneous maxillary reconstruction. A large fasciocutaneous skin paddle can be included for larger defects and the donor site can be closed primarily. The major disadvantages include the complexity of the subscapular system and the inability to simultaneously harvest the flap and perform the oncologic resection.

## CONCLUSION

The changing demographics and good outcome of HPV-related oropharynx cancer and advances in minimally invasive, transoral surgical techniques have significantly impacted the therapeutic options available for this malignancy. Due to the rise of HPV-associated OPSCC, which has demonstrated improved survival and treatment response to both surgical and nonsurgical modalities, the focus has shifted from being able to cure patients to doing so in a manner that best preserves their long-term function. TLM and TORS have demonstrated excellent oncologic control for oropharyngeal neoplasms with minimal deficits in functional swallowing outcomes. There still remains a role for open surgical approaches primarily for surgical salvage or advanced-stage disease not amenable to transoral surgery or CRT. The use of free tissue transfer to repair large oropharyngeal and bony defects has greatly improved the quality of life for these patients. The ability to achieve reconstruction of the defect with a minimally invasive technique and provide sensory reinnervation with free flaps, as well as avoid the long-term sequelae of organ-preservation protocols, may further increase the role of surgery for OPSCC.

CHAPTER 18

# Cancer of the Larynx

## PART A:
## General Principles and Management

William M. Mendenhall, and John W. Werning

Cancer of the larynx represents about 0.8% of the total cancer risk in 2010 and is one of the most common head and neck cancers.[1] In 2010 in the United States, there were approximately 12,720 new cases of cancer of the larynx (10,110 men and 2,610 women) and about 3,740 deaths from laryngeal cancer.[1] Based on 1992 to 1997 US data at diagnosis, about 51% of the cases remain localized, 29% have regional spread, and 15% have distant metastases.[2] Cancer of the larynx is strongly related to cigarette smoking. The risk of tobacco-related cancers of the upper alimentary and respiratory tracts declines among ex-smokers after 5 years and is said to approach the risk of nonsmokers after 10 years of abstention.[3] The role of alcohol in inducing laryngeal cancer remains unclear.[4] Some evidence exists that heavy marijuana smoking may be associated with laryngeal cancer in young patients. The ratio of glottic to supraglottic carcinoma is approximately 3:1.

### ANATOMY

The larynx is divided into the supraglottic, glottic, and subglottic regions. The supraglottic larynx consists of the epiglottis, the false vocal cords, the ventricles, the aryepiglottic folds, and the arytenoids. The glottis includes the true vocal cords and the anterior commissure. The subglottis is located below the vocal cords (Figs. 18-1 and 18-2).[5]

The lateral line of demarcation between the glottis and supraglottis is the apex of the ventricle. The demarcation between the glottis and subglottis is ill defined, but the subglottis is considered to begin 5 mm below the free margin of the vocal cord and to end at the inferior border of the cricoid cartilage.

The vocal cords vary from 3 to 5 mm in thickness and terminate posteriorly with their attachment to the vocal process. The mucosa between the arytenoids is called the *posterior commissure*.

The outside shell of the larynx is formed by the hyoid bone, thyroid cartilage, and cricoid cartilage; the cricoid cartilage is the only complete ring. The more mobile interior framework is composed of the heart-shaped epiglottis and the arytenoid, corniculate, and cuneiform cartilages. The corniculate and cuneiform cartilages produce small, rounded bulges at the posterior end of each aryepiglottic fold.

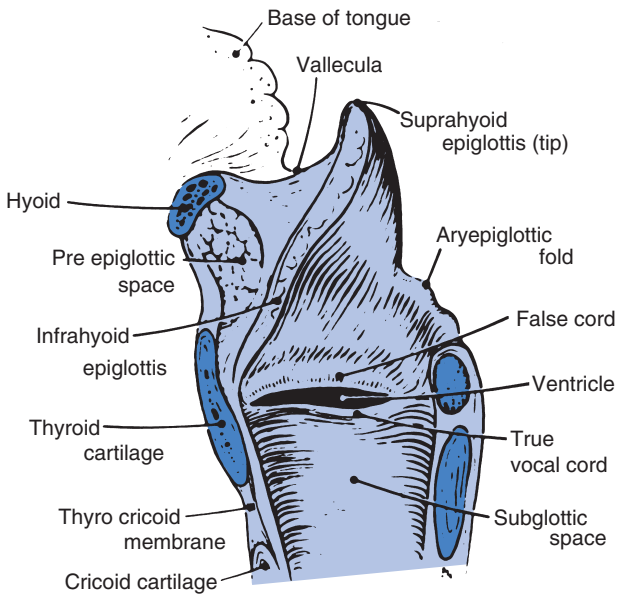

**FIGURE 18-1.** Diagrammatic sagittal section of the larynx. Note adjacency of the epiglottis to the preepiglottic space, and also note the proximity of the cephalic extent of this space to the base of the tongue. Finally, note intimate relationship of the subglottic mucosa to the cricothyroid membrane anteriorly. This is the point of exit for anterior cancers that are diverted caudally from the glottic level.

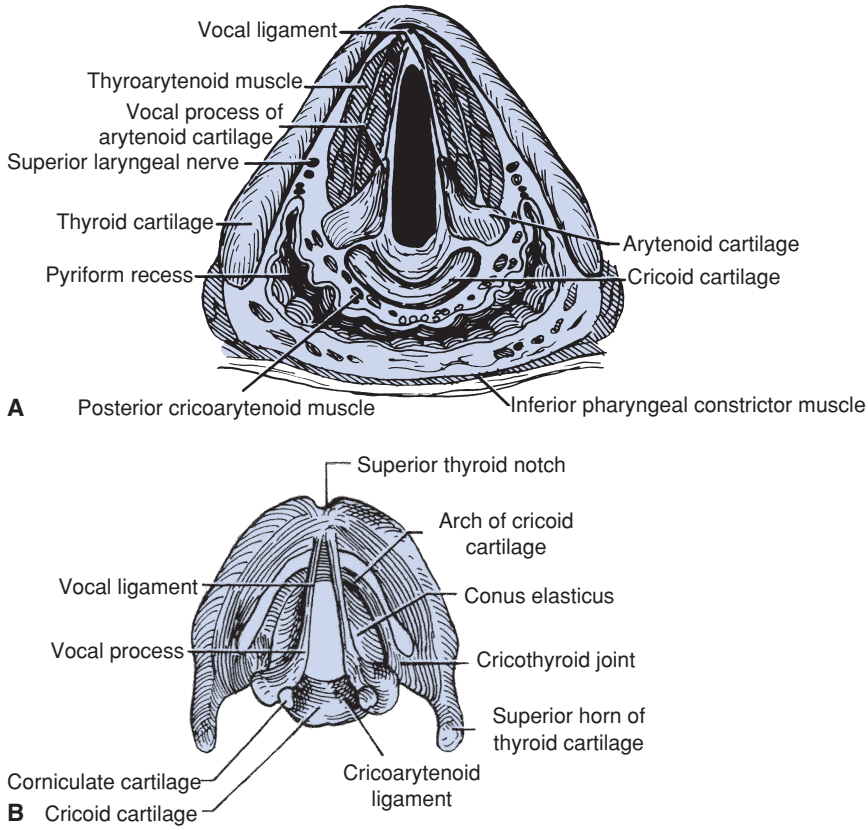

**FIGURE 18-2.** **A**: Cross-section of larynx at the level of the vocal folds. **B**: Framework of the larynx.

*Source:* Redrawn from Sabotta J. *Atlas der anatomie des menschen in 2 volumes.* 20th ed. Munich, Germany: Urban & Fischer Verlag; 1975 (**A**, Fig. 770; **B**, Fig. 761), with permission.

The thyroid and cricoid cartilages and a portion of the arytenoid cartilage are hyaline cartilage and may partially ossify with age, particularly in men. The epiglottis is elastic cartilage; ossification does not occur, and even focal calcification is rare.[6]

The external laryngeal framework is linked together by the thyrohyoid, cricothyroid, and cricotracheal ligaments or membranes (Figs. 18-3 and 18-4).[5]

The epiglottis is joined superiorly to the hyoid bone by the hyoepiglottic ligament. The epiglottis is attached to the thyroid cartilage by the thyroepiglottic ligament at a point just below the thyroid notch and above the anterior commissure. The arrangement of the ligaments that connect the cricoid and arytenoid cartilages and form the vocal ligaments, which are part of the true vocal cords, is shown in Figure 18-2B. The conus elasticus (cricovocal ligament) is the lower portion of the elastic membrane that connects the inferior framework. It connects the upper surface of the cricoid, the vocal process of the arytenoid, and the lower thyroid cartilage; its free border is thickened into the vocal ligament.

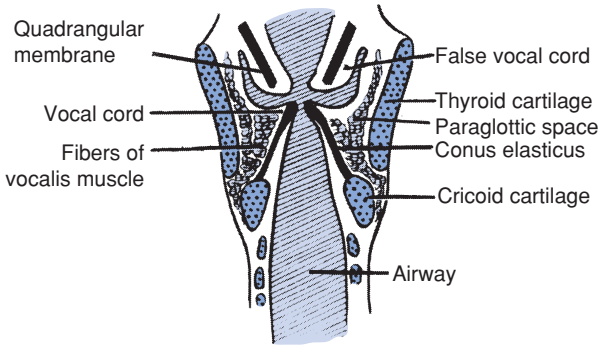

**FIGURE 18-3.** Diagram of the coronal view of the larynx. This rendition is taken through the middle one-third of the larynx, showing the fibrous barriers in both the supraglottic and the lower larynx, the intrinsic laryngeal muscles, and the thyroid and cricoid cartilages.

*Source:* Redrawn from Sabotta J. *Atlas der anatomie des menschen in 2 volumes.* 20th ed. Munich, Germany: Urban & Fischer Verlag; 1975 (Fig. 766), with permission.

The vocal ligaments and muscles attach to the vocal process of the arytenoid posteriorly and the thyroid cartilage anteriorly. The intrinsic muscles of the larynx, which primarily control the movement of the cords, are presented in Figures 18-2 and 18-3.[5] The extrinsic muscles are concerned primarily with swallowing. The cricothyroid muscle produces tension and elongation of the vocal cords and is innervated by the superior laryngeal nerve (Fig. 18-4).[5]

The preepiglottic and paraglottic fat spaces are, for practical purposes, one continuous space lying between the external framework of the thyroid cartilage and hyoid bone and the inner framework of the epiglottis and intrinsic muscles. Lam and Wong[7] showed that the thin, membranous septa located between the paraglottic and preepiglottic space are capable of holding a tumor in check to a limited degree. The space is traversed by blood vessels, lymphatic vessels, and nerves. Because few capillary lymphatics arise in this area, invasion of the fat space should only indirectly be associated with lymph node metastases. The fat space is limited by the conus elasticus inferiorly, the thyroid ala, the thyrohyoid membrane, the hyoid bone anterolaterally, the hyoepiglottic ligament superiorly, and the fascia of the intrinsic muscles on the medial side. Posteriorly, it is adjacent to the anterior wall of the pyriform sinus.

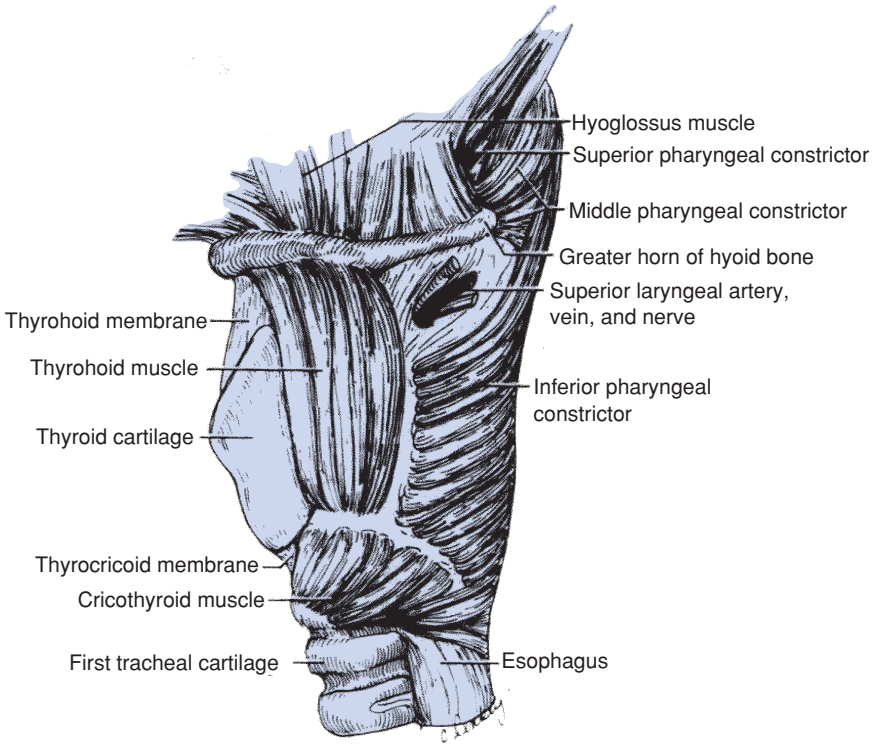

**FIGURE 18-4.** External view of the larynx.

*Source:* Redrawn from Sabotta J. *Atlas der anatomie des menschen in 2 volumes,* 20th ed. Munich, Germany: Urban & Fischer Verlag, 1975 (Fig. 744), with permission.

The laryngeal surface of the epiglottis and the free margin of the vocal cords are squamous epithelium, and the remainder is usually pseudostratified ciliated columnar epithelium. Beneath the epithelium of the free edge of the vocal cord is the lamina propria, which can be divided into three layers. There is no true submucosal layer along the free margin of the vocal fold.[8] The laryngeal arteries are branches of the superior and inferior thyroid arteries.

The intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve. The cricothyroid muscle, an intrinsic muscle responsible for tensing the vocal cords, is supplied by a branch of the superior laryngeal nerve. Isolated damage to this nerve causes a bowing of the true vocal cord; it continues to be mobile, but the voice may become hoarse.

The supraglottic structures have a rich capillary lymphatic plexus. The trunks pass through the preepiglottic space and the thyrohyoid membrane and terminate mainly in the subdigastric lymph nodes (level 2); a few drain to the middle internal jugular chain lymph nodes (level 3). There are essentially no capillary lymphatics of the true vocal cords. As a result, lymphatic spread from glottic cancer occurs only if tumor extends to supraglottic or subglottic areas. The subglottic area has relatively few capillary lymphatics. The lymphatic trunks pass through the cricothyroid membrane to the pretracheal (Delphian) lymph nodes in the region of the thyroid isthmus. The subglottic area also drains posteriorly through the cricotracheal membrane, with some trunks going to the paratracheal lymph nodes and others continuing to the inferior jugular chain (level 4).

## PATHOLOGY AND PATTERNS OF SPREAD

### Pathology

Nearly all malignant tumors of the larynx arise from the surface epithelium and therefore are squamous cell carcinoma or one of its variants. Carcinoma *in situ* occurs frequently on the vocal cords. Differentiating among dysplasia, carcinoma *in situ*, squamous cell carcinoma with microinvasion, and true invasive carcinoma is a problem that the pathologist and the clinician frequently confront. Most vocal cord carcinomas are well differentiated or moderately well differentiated. In a few cases, an apparent carcinoma and sarcoma occur together, but most of these are actually a spindle-cell carcinoma or so-called pseudosarcoma (i.e., squamous cell carcinoma with a spindle-cell stromal reaction). Verrucous carcinoma occurs in 1% to 2% of patients with carcinoma of the vocal cord. The histologic diagnosis is difficult and must correlate with the gross appearance of the lesion.

Small cell neuroendocrine carcinoma is rarely diagnosed in the supraglottic larynx, but it should be recognized because of its biologic potential for rapid growth, early dissemination, and responsiveness to chemotherapy. Minor salivary gland tumors arise from the mucous glands in the supraglottic and subglottic larynx, but they are rare.[9] Even more rare are chemodectoma, carcinoid, soft tissue sarcoma, malignant lymphoma, or plasmacytoma. Benign chondromas and osteochondromas are reported, but their malignant counterparts are rare.

### Local Spread

Although supraglottic and glottic lesions tend to remain confined to their original compartments, there is no anatomic barrier to growth from one area to the next. Glottic lesions tend to be slow growing, but as they increase in size, they extend to the supraglottic and subglottic areas. Supraglottic lesions do not often start near the vocal cords. Involvement of the cords on their external epithelial surface is a late phenomenon, but submucosal extension by way of the paraglottic area occurs earlier.

The fat space is an important avenue of submucosal tumor spread for infrahyoid epiglottis, false cord, and true vocal cord lesions. As the false cord and the true vocal cord lesions penetrate anteriorly and laterally, they encounter the tough perichondrium

(c) 2014 Wolters Kluwer. All Rights Reserved.

of the thyroid cartilage and may eventually be shunted by the conus elasticus (lateral cricothyroid membrane) out of the larynx via the cricothyroid space. Thyroid cartilage invasion usually occurs in the ossified section of the cartilage, commonly in the region of the anterior commissure tendon or the junction of the anterior one-fourth and the posterior three-fourths of the thyroid lamina.[10]

Fixation of the vocal cord from laryngeal cancer is usually caused by invasion or destruction of the vocal cord musculature, invasion of the cricoarytenoid muscle or joint, or, rarely, invasion of the recurrent laryngeal nerve. Perineural spread is uncommon.

## Supraglottic Larynx

***Suprahyoid Epiglottis.*** A lesion of the suprahyoid epiglottis may produce a huge exophytic mass with little tendency to destroy cartilage or spread to adjacent structures. Other lesions may infiltrate the tip and destroy cartilage. The destructive lesions tend to invade the vallecula and preepiglottic space, the lateral pharyngeal walls, and the remainder of the supraglottic larynx.

***Infrahyoid Epiglottis.*** Lesions of the infrahyoid epiglottis tend to produce irregular tumor nodules and simultaneously invade the porous epiglottic cartilage and thyroepiglottic ligament into the preepiglottic fat space and extend toward the vallecula and base of the tongue. The thick hyoepiglottic ligament is an effective tumor barrier. However, the tumor may present in the vallecula and base of tongue without involving the suprahyoid epiglottis.

Lesions of the infrahyoid epiglottis grow circumferentially to involve the false cords, aryepiglottic folds, medial wall of the pyriform sinus, and the pharyngoepiglottic fold. Invasion of the anterior commissure and cords and anterior subglottic extension usually occur only in advanced lesions. Infrahyoid epiglottic lesions that extend onto or below the vocal cords are at a high risk for thyroid cartilage invasion, even if the cords are mobile.[11]

***False Cord.*** Early false cord carcinomas, which are usually submucosal with little exophytic component, are difficult to delineate accurately. They involve the paraglottic fat space early in their development and may spread a considerable distance beneath the mucosa without producing physical signs. These carcinomas extend to the perichondrium of the thyroid cartilage quite early, but cartilage invasion is a late phenomenon. Extension to the lower portion of the infrahyoid epiglottis and invasion of the preepiglottic space are common. Submucosal extension involves the true vocal cord, which may appear normal. Vocal cord invasion is often associated with thyroid cartilage invasion. Submucosal extension to the medial wall of the pyriform sinus occurs early.

***Aryepiglottic Fold/Arytenoid.*** Early lesions of the aryepiglottic fold/arytenoid are usually exophytic. It may be difficult to decide whether the lesion started on the medial wall of the pyriform sinus or on the aryepiglottic fold. As the lesions enlarge, they extend to adjacent sites and eventually cause fixation of the larynx, which is usually a result of involvement of the cricoarytenoid muscle or joint or, rarely, invasion of the recurrent laryngeal nerve. Computed tomography (CT) may distinguish the cause of fixation. Advanced lesions invade the thyroid, the epiglottic, and the cricoid cartilages and eventually invade the pyriform sinus and postcricoid area.

## Glottic Larynx

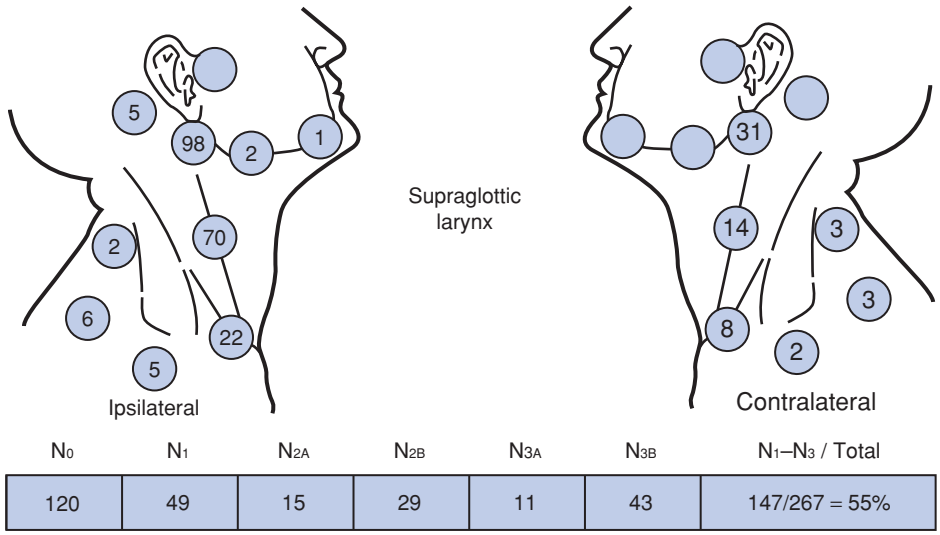
Most lesions of the true vocal cord begin on the free margin and upper surface of the cord. When diagnosed, about two-thirds are confined to the cords, usually one cord. The anterior portion of the cord is the most common site. Anterior commissure involvement, which is common, occurs when no tumor-free cord can be seen anteriorly. Small lesions isolated to the anterior commissure account for only 1% to 2% of cases. Extension to the posterior commissure is uncommon, occurring only in advanced lesions.

Tumors at the anterior commissure may extend anteriorly via the anterior commissure tendon (Broyles' ligament)[12] into the thyroid cartilage. Kirchner,[11] using whole organ sections, showed that such extension is unusual unless the tumor extends off the vocal cord onto the base of the infrahyoid epiglottis and suggested that the tendon serves as more of a barrier than an avenue of tumor spread. Early subglottic extension is also associated with involvement of the anterior commissure, and tumor may grow through the cricothyroid membrane.

Lesions that arise on the posterior half of the vocal cord tend to extend along the submucosa toward the medial side of the vocal process and invade the cricoarytenoid joint and posterior commissure; this spread is difficult to appreciate by clinical examination.

Subglottic extension may occur by simple mucosal surface growth, but it more commonly occurs by submucosal penetration beneath the conus elasticus. One centimeter of subglottic extension anteriorly or 4 to 5 mm of subglottic extension posteriorly brings the border of the tumor to the upper margin of the cricoid, exceeding the anatomic limits for a conventional hemilaryngectomy. Lesions may spread beneath the epithelium along the length of the vocal cord within Reinke's space.[13] As vocal cord lesions enlarge, they extend to the false cord, vocal process of the arytenoid, and subglottic region. Infiltrative lesions invade the vocal ligament and muscle and eventually reach the paraglottic space and the perichondrium of the thyroid cartilage. Advanced glottic lesions eventually penetrate through the thyroid cartilage or via the cricothyroid space to enter the neck, where they may invade the thyroid gland. Lesions involving the anterior commissure often exit the larynx via the cricothyroid space after they extend subglottically.[13]

A fixed cord that is associated with a lesion having <1 cm of subglottic extension and no false cord involvement does not ordinarily indicate invasion of the thyroid cartilage.[11] If the false cord is also involved, cartilage invasion is more likely.



## Subglottic Larynx

Subglottic cancers are rare. Most involve the inferior surface of the vocal cords by the time they are diagnosed, so it is difficult to know whether the tumor started on the undersurface of the vocal cord or in the subglottis. Because early diagnosis is uncommon, most lesions are bilateral or circumferential at discovery. They involve the cricoid cartilages in the early stage because there is no intervening muscle layer. Partial or complete fixation of one or both cords is common; misdiagnosis or diagnostic delay is frequent.

## Lymphatic Spread

The location and stage of neck nodes detected on admission for previously untreated patients with squamous cell carcinoma of the supraglottic larynx are given in Figure 18-5.[14] The disease spreads mainly to the subdigastric nodes (level 2). The submandibular nodes (level 1b) are rarely involved, and there is only a small risk of spinal accessory lymph node (level 5) involvement. The incidence of clinically positive nodes is 55% at the time of diagnosis; 16% are bilateral.[14] Elective neck dissection shows pathologically positive nodes in 16% of cases; observation of initially node-negative necks eventually identifies the appearance of positive nodes in 33% of cases.[15,16] Spread to the pyriform sinus, the vallecula, and the base of the tongue increases the risk of

lymph node metastases. The risk of late-appearing contralateral lymph node metastasis is 37% if the ipsilateral neck is pathologically positive, but the risk is unrelated to whether the nodes in the ipsilateral neck were palpable before neck dissection.

In carcinoma of the vocal cord, the incidence of clinically positive lymph nodes at diagnosis approaches zero for T1 lesions and 1.7% for T2 lesions.[17] The incidence of neck metastases increases to 20% to 30% for T3 and T4 lesions. Supraglottic spread is associated with metastasis to the jugulodigastric nodes. Anterior commissure and anterior subglottic invasion are associated with involvement of the midline pretracheal lymph nodes (Delphian nodes).

Lederman[18] reported a 10% incidence of positive lymph nodes in 73 patients with subglottic carcinoma.

## CLINICAL PRESENTATION

Carcinoma arising on the true vocal cords produces hoarseness at a very early stage. Sore throat, ear pain, pain localized to the thyroid cartilage, and airway obstruction are features of advanced lesions.

Hoarseness is not a prominent symptom of cancer of the supraglottic larynx until the lesion becomes quite extensive. Pain on swallowing, usually mild, is the most frequent initial symptom, often described as a sore throat. Some patients report a sensation of a "lump in the throat." Pain is referred to the ear by way of the vagus nerve and auricular nerve of Arnold. A mass in the neck may be the first sign of a supraglottic cancer. Late symptoms include weight loss, foul breath, dysphagia, and aspiration.

## DIAGNOSTIC EVALUATION AND CLINICAL STAGING

### Physical Examination

Flexible fiberoptic endoscopes are now used routinely as a complement to the laryngeal mirror examination. The mirror gives a larger image of the larynx or the hypopharynx than that obtained by direct laryngoscopy or fiberoptic endoscopy. The mirror often provides the best view of the posterior pharyngeal wall. The flexible fiberoptic laryngoscope is inserted through the nose and is useful in more difficult cases.

Determination of the mobility of the vocal cords frequently requires multiple examinations because the subtle distinctions between mobile, partially fixed, and fixed cords are often challenging, apparently changing from examination to examination. A cord that appeared mobile to the surgeon before direct laryngoscopy may exhibit impaired motion or even fixation after biopsy. Videostroboscopy is particularly useful for assessing vocal cord mobility.

Ulceration of the infrahyoid epiglottis or fullness of the vallecula is an indirect sign of preepiglottic space invasion. Palpation of diffuse, firm fullness above the thyroid notch with widening of the space between the hyoid and the thyroid cartilage signifies invasion of the preepiglottic space. The preepiglottic fat space is a low-density area on the CT scan, and changes resulting from tumor invasion are easily seen.

Postcricoid extension may be suspected when the laryngeal click disappears on physical examination. Postcricoid tumor may cause the thyroid cartilage to protrude anteriorly, producing a fullness of the neck.

Invasion of the thyroid cartilage remains a difficult clinical diagnosis. Localized pain or tenderness to palpation or a small bulge over one ala of the thyroid cartilage is suggestive.

### Radiographic Studies

Contrast-enhanced CT scan is the method of choice for studying the larynx. The CT scan should be performed before biopsy so that abnormalities that may be caused by the biopsy are not confused with tumor. CT is preferred to magnetic resonance imaging (MRI) because the longer scanning time for MRI may result in motion artifact.[19] CT slices 1 to 2 mm thick are obtained at 1 to 2 mm intervals through the larynx and at 3 mm intervals for the remainder of the study. The gantry is angled so that the scan slices are parallel to the plane of the true vocal cords. It is also necessary to obtain a CT scan of the entire neck to detect positive, nonpalpable lymph nodes. Positive retropharyngeal nodes

(c) 2014 Wolters Kluwer. All Rights Reserved.

may be present at diagnosis in patients with laryngeal cancer who have advanced neck disease.[20] Retropharyngeal adenopathy is often not apparent on physical examination but is usually apparent on the CT scan.

Contrast enhancement helps to outline the blood vessels and thyroid gland. The tumor often enhances, probably because of reactive inflammatory changes. In addition to CT, MRI may be obtained to define subtle exolaryngeal spread or early cartilage destruction. The value of MRI for detecting early cartilage destruction is open to speculation. Sagittal MRI may be useful in detecting early invasion of the base of the tongue.

Positron emission tomography (PET) is not routinely obtained. It may be useful to evaluate a questionable finding on CT or MRI if that finding would alter the treatment plan. It may also be useful to determine whether or not distant metastases exist in a patient with advanced neck disease, particularly if it involves low neck below Ho's line.[21]

## Glottic Larynx

Although the CT scan does not show minimal mucosal lesions, it is excellent for determining subglottic extension and extension anterior to the anterior commissure and is used in virtually all T1 and T2 lesions for these reasons alone. CT scanning is useful in the diagnosis of moderately advanced and advanced lesions; it is excellent for demonstrating extension outside the larynx into the soft tissues of the neck and has potential for determining thyroid or cricoid cartilage invasion, which tends to occur at the edges of the cartilage rather than on the faces. Early cartilage involvement is difficult to detect with axial scans, but it may be demonstrated by coronal or sagittal scanning techniques. If the low-density plane of the paraglottic space is intact, cartilage is probably not invaded by tumor. CT is also useful for evaluating the neck. Radiographically positive adenopathy may be appreciated that would otherwise be undetectable.

## Supraglottic Larynx

The CT scan provides an excellent means for viewing the preepiglottic and paraglottic fat spaces. Soft tissue extension into the neck or base of the tongue also can be seen. The CT scan is also useful for determining extension to the subglottic areas and to evaluate the neck.[6]

## Direct Laryngoscopy

Diagnostic procedures for laryngeal cancer at the University of Florida are summarized in Figure 18-6. A CT scan is usually performed, followed by direct laryngoscopy and biopsy. The ventricles, the subglottis, the apex of the pyriform sinus, and the postcricoid area must be carefully examined because these areas are not consistently seen by indirect examinations. Fiberoptic telescopes (0 degree and 30 degrees) are introduced through the laryngoscope for inspection of these areas. Endoscopic visualization facilitates the assessment of arytenoid fixation and involvement of the laryngeal ventricle, factors which must be considered before laryngeal preservation surgery is attempted. A generous biopsy specimen is taken from the obvious lesion; additional biopsies may be obtained from suspicious areas. In cases where the lesion is limited and superficial, directed biopsies that are guided by the surface appearance of the lesion may fail to detect foci of microinvasion, resulting in sampling error; thus, excisional biopsy should be considered whenever possible. Diffuse mucosal abnormalities suspicious for premalignancy should be endoscopically excised with the $CO_2$ laser or by using cold instrument dissection

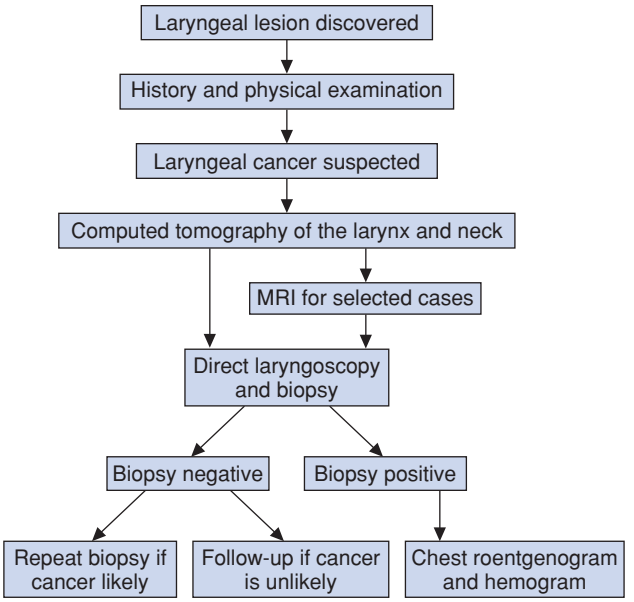

**FIGURE 18-6.** Algorithm for diagnostic evaluation of a laryngeal lesion. MRI, magnetic resonance imaging.

in lieu of crude vocal cord stripping to spare the superficial lamina propria, thereby optimizing postoperative voice quality.

## Clinical Staging

The 2010 American Joint Committee on Cancer (AJCC) staging system for laryngeal primary cancer is listed in Table 18.1.[22] T2 glottic cancers are stratified into those with normal (T2A) and impaired (T2B) vocal cord mobility. For lesions arising in the supraglottis, the sites of origin include the false cords, the aryepiglottic folds, the suprahyoid epiglottis, the infrahyoid epiglottis, the pharyngoepiglottic folds, and the arytenoids.

Only in the early T stages can one identify the specific site of origin with certainty. As the lesion enlarges, the site of origin is an educated guess based on the location of the greatest bulk of tumor. The major difference between the 1992 and 2010 staging systems is that a supraglottic cancer that invades the mucosa of the base of tongue and/or medial wall of the pyriform sinus can be staged as a T2 lesion. This has resulted in a reverse "Will Rogers effect" and negative stage migration such that the likelihood of local control for supraglottic cancer will likely be lower within each T stage while remaining the same overall. In contrast, invasion of the paraglottic space now upstages a T2 cancer to a T3. Parenthetically, we have evaluated the impact of paraglottic space invasion determined by pretreatment CT in a series of patients with T2 glottic cancers and found no significant adverse effect on local control after definitive radiotherapy (RT).[23] Additionally, T4 cancers have been stratified into T4A and T4B, which reflects the likelihood of achieving a complete resection.

# TREATMENT SELECTION: VOCAL CORD CARCINOMA

## Selection of Treatment Modality

In treating vocal cord carcinoma, the goal is cure with the best functional result and the least risk of a serious complication. Patients may be considered to be in an early group if the chance

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 18.1 2010 American Joint Committee on Cancer Staging System for Larynx Cancer**

| Tumor Stage | Characteristics |
|---|---|
| **Supraglottis** | |
| T1 | Tumor limited to one subsite of supraglottis with normal vocal cord mobility |
| T2 | Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx |
| T3 | Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex) |
| T4a | Tumor invades through the thyroid cartilage, and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus) |
| T4b | Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures |
| **Glottis** | |
| T1 | Tumor limited to vocal cord(s) (may involve anterior or posterior commissure) with normal mobility |
| T1a | Tumor limited to one vocal cord |
| T1b | Tumor involves both vocal cords |
| T2 | Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility |
| T3 | Tumor limited to the larynx with vocal cord fixation, and/or invades paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex) |
| T4a | Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus) |
| T4b | Tumor involves prevertebral space, encases carotid artery, or invades mediastinal structures |
| **Subglottis** | |
| T1 | Tumor limited to the subglottis |
| T2 | Tumor extends to vocal cord(s) with normal or impaired mobility |
| T3 | Tumor limited to larynx with vocal cord fixation |
| T4a | Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, esophagus) |
| T4b | Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures |
| **Regional Lymph Nodes (N)*** | |
| NX | Regional lymph nodes cannot be assessed N0; no regional lymph node metastasis |
| N1 | Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension |
| N2 | Metastasis in a single ipsilateral lymph node, 3–6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension |
| N2a | Metastasis in a single ipsilateral lymph node, 3–6 cm in greatest dimension |
| N2b | Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension |
| N2c | Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension |
| N3 | Metastasis in a lymph node, more than 6 cm in greatest dimension |
| **Distant Metastasis (M)** | |
| M0 | No distant metastasis |
| M1 | Distant metastasis |

**Note:* Metastases at level VII are considered regional lymph node metastases.
*Source:* American Joint Committee on Cancer. *Cancer Staging Manual.* 7th ed. New York, NY: Springer-Verlag; 2010:59–60, with permission.

of cure with larynx preservation is high, a moderately advanced group if the likelihood of local control is 60% to 70% but the chance of cure is still good, and an advanced group if the chance of cure is moderate and the likelihood of laryngeal preservation is relatively low. The early group may be treated initially by RT or, in selected cases, by partial laryngectomy. The moderately advanced group may be treated with either RT or partial laryngectomy with total laryngectomy reserved for relapse or by total laryngectomy with or without adjuvant postoperative RT. The obvious advantage of the former strategy, which we use at the University of Florida, is that there is a fairly good chance that the larynx will be preserved.[24] Although some patients may be rehabilitated with a tracheoesophageal puncture after laryngectomy, only about 20% of patients use this device long term and the majority use an electric larynx.[25] The advanced group is treated with total laryngectomy and neck dissection with or without adjuvant RT or by RT and adjuvant chemotherapy.[26] Data suggest that if patients whose tumors show a partial or complete response to two to three cycles of neoadjuvant chemotherapy are then given high-dose RT, the cure rates are comparable to those obtained with initial total laryngectomy.[27] Another less expensive and less toxic method to select patients likely to be cured by RT alone is to calculate the primary tumor volume on pretreatment CT or MR. Data indicate that primary tumor volume is inversely related to the probability of local control after irradiation.[28,29] Data indicate that whereas induction chemotherapy probably does not improve the likelihood of local–regional control and survival, concomitant chemotherapy and RT result in an improved possibility of cure compared with RT alone.[30–32] There is a subset of patients with high volume (>3.5 cc), unfavorable, advanced cancers who may be cured by chemoradiation but have a useless larynx and permanent tracheostomy and/or gastrostomy.[28] These patients are best treated with a total laryngectomy, neck dissection, and postoperative RT.

## Carcinoma *In Situ*

Lesions diagnosed as carcinoma *in situ* may sometimes be controlled by stripping the cord. However, it is difficult to exclude the possibility of microinvasion on these specimens. Recurrence is frequent, and the cord may become thickened and the voice hoarse with repeated stripping. Localized carcinoma *in situ* can also be excised using the $CO_2$ laser.

Early RT for carcinoma *in situ* often means a better chance of preserving a good voice, especially since many patients with this diagnosis eventually receive this treatment.[33]

Many patients with a diagnosis of carcinoma *in situ* have obvious lesions that probably contain invasive carcinoma. We have often proceeded with RT rather than put the patient through a repeated biopsy procedure.

## Early Vocal Cord Carcinoma

In most centers, RT is the initial treatment prescribed for T1 and T2 lesions, with surgery reserved for salvage after RT failure[34–36] (Fig. 18-7). Although hemilaryngectomy or cordectomy produces comparable cure rates for selected T1 and T2 vocal cord lesions, RT is generally preferred.[34,37] Supracricoid laryngectomy, as reported by Laccourreye et al.,[38] is a procedure designed to remove moderate-sized cancers involving the supraglottic and the glottic larynx. The larynx may be removed with preservation of the cricoid and the arytenoid with its neurovascular innervation, the defect is closed by approximating the base of the tongue to the remaining larynx. The oncologic and functional results of this procedure in selected patients are reported to be excellent. Transoral laser excision also may provide high cure rates for select patients with small, well-defined lesions limited to the mid-third of one true cord.[39–43]

(c) 2014 Wolters Kluwer. All Rights Reserved.

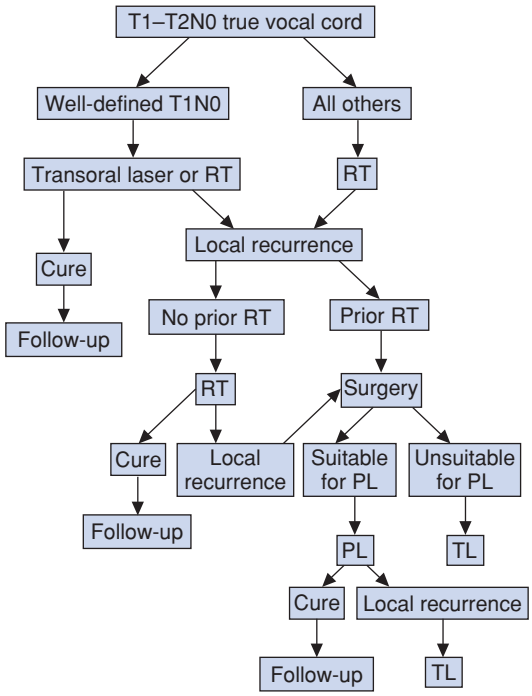

**FIGURE 18-7.** Treatment algorithm for T1–T2N0 squamous cell carcinoma of the true vocal cord. RT, radiation therapy; PL, partial laryngectomy; TL, total laryngectomy.

A small subset of transoral laser surgeons successfully use this technique in moderately advanced cancers.[34] The major advantage of RT compared with partial laryngectomy is better quality of the voice. Partial laryngectomy finds its major use as salvage surgery in suitable cases after RT failure. Even if the patient has a local recurrence after salvage partial laryngectomy, there is a third chance with total laryngectomy, which may still be successful.

Verrucous lesions have the reputation of being unresponsive to RT and, in some instances, converting into invasive, often anaplastic, metastasizing lesions. Partial laryngectomy is recommended for early verrucous carcinoma of the glottis, but RT is recommended if the alternative is total laryngectomy. We have observed typical verrucous lesions that have disappeared with RT and not recurred. O'Sullivan and associates[44] also have made this observation. Additionally, a variety of tumors that recur after unsuccessful treatment (with surgery, RT, and/or chemotherapy) are more likely to exhibit more aggressive behavior.

## Moderately Advanced Vocal Cord Cancer

Fixed-cord lesions (T3) may be subdivided into relatively favorable or unfavorable lesions. Patients with unfavorable lesions usually have extensive bilateral disease with a compromised airway and are considered to be in the advanced group. Patients with favorable T3 lesions have disease that is low volume (≤3.5 cc), confined mostly to one side of the larynx, have a good airway, and are reliable for follow-up. Some degree of supraglottic and subglottic extension usually exists. The extent of disease and tumor volume, in particular, are related to the likelihood of control after RT.[28]

The patient with a favorable lesion is advised of the alternatives of RT with surgical salvage or immediate total laryngectomy; the occasional patient may be suitable for a partial laryngectomy. Data suggest that the likelihood of local–regional control is better after some altered fractionation schedules compared with conventional once-daily RT.[32,45] Follow-up examinations are recommended every 4 to 6 weeks for the first year, every 6 to 8 weeks for the second year, every 3 months for the third year, every 6 months for the fourth and fifth years, and annually thereafter. The patient must understand that total laryngectomy may be recommended purely on clinical grounds without biopsy-proven recurrence and that the risk of laryngeal osteochondronecrosis is about 5%.

Evaluation of cord mobility after 50.4 Gy or at the end of RT has not been helpful in predicting local control.[29] Some patients in whom the vocal cord remained fixed have had local tumor control of the disease for 2 years or longer after RT.

The major difficulty in using RT for the more advanced lesions is distinguishing radiation edema from local recurrence during follow-up examinations.[46] Progressive laryngeal edema, persistent throat pain, or fixation of a previously mobile vocal cord frequently signifies recurrent disease in the larynx, although a few patients with these findings remain disease free with long-term follow-up.

Partial laryngectomy has been used by a few surgeons in the treatment of well-lateralized fixed-cord lesions. A permanent tracheostomy is usually required because a portion of the cricoid is resected, but a useful voice may be retained.[47]

## Advanced Vocal Cord Carcinoma

Advanced lesions usually show extensive subglottic and supraglottic extension, bilateral glottic involvement, and invasion of the thyroid, cricoid, and/or arytenoid cartilages.[10,48] The airway is compromised, necessitating a tracheostomy at the time of direct laryngoscopy in approximately 30% of patients. Clinically positive lymph nodes are found in about 25% to 30% of patients.

The mainstay of treatment is total laryngectomy, with or without adjuvant RT. The most frequent sites of local failure after total laryngectomy are the tracheal stoma, the base of tongue, the neck lymph nodes, and/or soft tissues of the neck. If the neck is clinically negative before surgery and if postoperative RT is planned, neck dissection may be withheld and RT may be used to treat both sides of the neck. However, in practice, most surgeons prefer to perform elective bilateral selective (levels II–IV) neck dissections in conjunction with a total laryngectomy for T3N0 or T4N0 laryngeal cancer, even if postoperative RT is planned. If the lymph nodes are clinically positive, a therapeutic neck dissection is performed at the time of laryngectomy.

The indications for postoperative RT include close or positive margins, significant subglottic extension (1 cm or more), cartilage invasion, perineural invasion, endothelial-lined space invasion, extension of the primary tumor into the soft tissues of the neck, multiple positive neck nodes, extracapsular extension, and control of subclinical disease in the opposite neck.[49,50] Preoperative RT is indicated for patients who have fixed neck nodes, have had an emergency tracheotomy through tumor, or have direct extension of tumor involving the skin.

Definitive RT is prescribed for the patient who refuses total laryngectomy or is medically unsuitable for major surgery.

As previously stated, there is evidence that two to three cycles of induction chemotherapy followed by RT in patients obtaining at least a partial response may provide a moderate likelihood of larynx preservation without compromising cure.[27] Data suggest that concomitant chemotherapy and RT is more efficacious than RT alone or induction chemotherapy followed by RT.[30,31] The optimal combination of concomitant chemotherapy and irradiation is unclear.[32]

A randomized intergroup trial (RTOG 91-11) compared three treatment arms: Arm A, three cycles of induction cisplatin and fluorouracil followed by RT in complete and partial responders; Arm B, RT and concomitant cisplatin (100 mg/m$^2$ on days 1, 22, and 43 of RT); and Arm C, once-daily RT (70 Gy in 35 fractions over 7 weeks) alone.[30] Five hundred forty-seven patients were

(c) 2014 Wolters Kluwer. All Rights Reserved.

randomized and followed for a median of 3.8 years; 518 patients were evaluable. The rates of larynx preservation were: Arm A, 72%; Arm B, 84%; and Arm C, 67%. The rates of larynx presentation were significantly improved for Arm B; there was no significant difference between Arm A and Arm C. The 5-year survival rates were similar for the three treatment groups: Arm A, 55%; Arm B, 54%; and Arm C, 56%. The likelihood of developing distant metastases was lower for the two groups of patients that received adjuvant chemotherapy.

# TREATMENT SELECTION: SUPRAGLOTTIC LARYNX CARCINOMA

## Selection of Treatment Modality

Patients with supraglottic laryngeal carcinoma may be considered to be in an early or favorable group suitable for RT or conservation laryngectomy or an unfavorable group often requiring total laryngectomy (Fig. 18-8).

## Early and Moderately Advanced Supraglottic Lesions

Treatment of the primary lesion for the early group is by RT or supraglottic laryngectomy, with or without adjuvant RT.[51] Transoral laser excision is effective in experienced hands for selected lesions and is currently preferred to open approaches by many surgeons.[40] Total laryngectomy is rarely indicated as the initial treatment for this group of patients and is reserved for treatment failures.

RT and partial laryngectomy are highly successful modes of therapy for early lesions.[51] Approximately 50% of supraglottic laryngectomies performed at the University of Florida have been

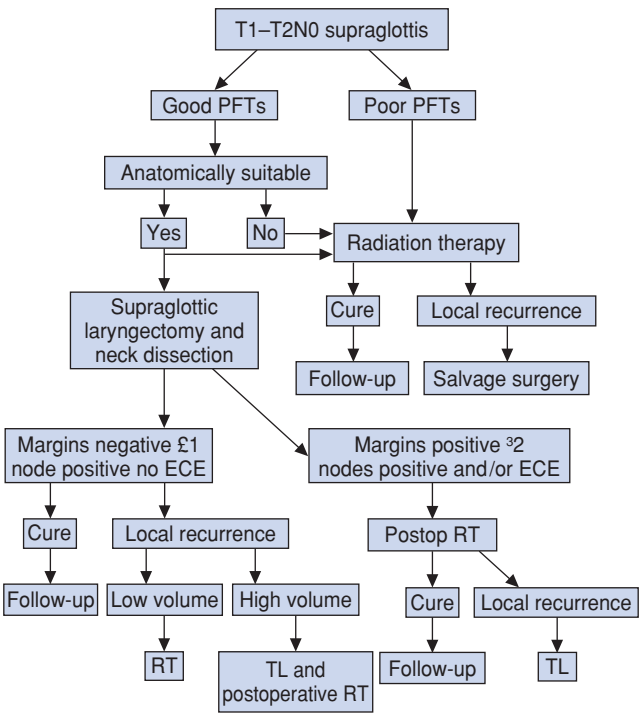

**FIGURE 18-8.** Treatment algorithm for T1–T2N0 squamous cell carcinoma of the supraglottis. PFTs, pulmonary function tests; ECE, extracapsular extension; RT, radiation therapy; TL, total laryngectomy.

followed by postoperative RT because of neck disease and, less often, positive margins.

The decision to use RT or supraglottic laryngectomy depends on several factors including the anatomic extent of the tumor, medical condition of the patient, philosophy of the attending physician(s), and the inclination of the patient and the family. Overall, about 80% of patients are treated initially by RT. Approximately half of the patients seen in our clinic whose lesions are technically suitable for a supraglottic laryngectomy are not suitable for medical reasons (e.g., inadequate pulmonary status or other major medical problems); these patients are treated with RT.

Analysis of local control by anatomic site within the supraglottic larynx shows no obvious differences in local control by RT for similarly staged lesions. Invasion of the preepiglottic space is not a contraindication to supraglottic laryngectomy or RT. Primary tumor volume based on pretreatment CT is inversely related to local tumor control after RT.[28] A large, bulky (>6 cc) infiltrative lesion, especially one with extensive preepiglottic space invasion, is a common reason to select supraglottic laryngectomy.

The status of the neck often determines the selection of treatment of the primary lesion. Patients with clinically negative neck nodes have a high risk for occult neck disease and may be treated by RT or supraglottic laryngectomy and bilateral selective neck dissections (levels II–IV).

If a patient has an early-stage primary lesion but advanced neck disease (N2b or N3), combined treatment is frequently necessary to control the neck disease.[26] In these cases, the primary lesion is usually treated by definitive RT, with surgery added to the treatment of the involved neck site(s). If the same patient were treated with supraglottic laryngectomy, neck dissection, and postoperative RT, the portals would unnecessarily cover the primary site and the neck. If the patient has early, resectable neck disease (N1 or N2a) and surgery is elected for the primary site, postoperative RT is added only because of unexpected findings (e.g., positive margins, multiple positive nodes, or extracapsular extension). Patients who have positive margins at the primary site after a partial laryngectomy should not have been treated surgically; the postoperative RT dose to the remaining larynx is likely to result in major complications requiring a permanent tracheostomy and/or gastrostomy. The usual indurations for postoperative RT are related to neck disease. The remaining larynx is treated to 55.8 Gy at 1.8 Gy per fraction and the involved neck is boosted to a higher dose as needed.[52]

## Advanced Supraglottic Lesions

Although a subset of these patients may be suitable for a supraglottic or supracricoid laryngectomy, total laryngectomy is the main surgical option. Selected advanced lesions, especially those that are mainly exophytic, may be treated by RT and concomitant chemotherapy[31] with total laryngectomy reserved for RT failures.

For patients whose primary lesion is to be treated by a total or partial laryngectomy and who have resectable neck disease, surgery is the initial treatment, and postoperative RT is added if needed. In practice, virtually all patients undergoing a total laryngectomy as the initial step in treatment have very advanced disease and require postoperative RT. If the neck disease is unresectable, preoperative RT is used. The indications for preoperative and postoperative RT have been previously outlined.

# RESULTS OF TREATMENT

## Vocal Cord Cancer

The local control and survival rates after treatment of early-stage glottic carcinoma are depicted in Tables 18.2–18.5.[34] Sengupta et al. recently reported on 37 patients treated at the University

of Florida with definitive RT for carcinoma *in situ* and observed the following 5-year outcomes: local control, 91%; local control with larynx preservation, 91%; and ultimate local control, 91%.[33] Chera et al. reported on 585 patients at the University of Florida for T1 to T2N0 glottic carcinoma and observed the following 5-year local control rates: T1A1, 95%; T1B, 94%; T2A, 81%; and T2B, 74%.[36] Hinerman et al. recently reported an update of the University of Florida experience treating fixed cord T3 glottic cancers with definitive RT and reported a 5-year local control rate after RT of 63%.[24] The local control and survival rates are similar for transoral laser excision, open partial laryngectomy, and RT. Larynx preservation rates are also comparable. Voice quality depends on the amount of tissue removed with partial laryngectomy and is probably similar for patients with limited lesions treated with transoral laser resection to those undergoing RT and poorer for patients undergoing open partial laryngectomy.[34]

Foote and coworkers[53] reported on 81 patients who underwent laryngectomy for T3 cancers at the Mayo Clinic between 1970 and 1981. Seventy-five patients underwent a total laryngectomy and 6 underwent a near-total laryngectomy; 53 patients received a neck dissection. No patient underwent adjuvant RT or chemotherapy. The 5-year rates of local-regional control, cause-specific survival, and absolute survival were 74%, 74%, and 54%, respectively. The results of definitive RT for patients with fixed cord T3 glottic carcinoma are depicted in Table 18.6[54] and are similar to the surgical outcomes reported by Foote et al.[53]

The survival and control rates of patients with T3 fixed-cord lesions treated at the University of Florida are presented in Table 18.7.[55] There was no relationship between subsequent local control and whether the vocal cord remained fixed or became mobile during irradiation. The incidence of severe complications, including those after the initial treatment and any later salvage procedures, was 15% after RT alone and 15% after surgery alone or combined with adjuvant irradiation. The vocal quality varied from fair to nearly normal.

The results of treatment of T4 vocal cord carcinoma in four surgical series and two definitive RT series are summarized in Table 18.8.[56] Hinerman et al. observed an 81% 5-year local control rate in 22 selected patients with favorable T4 cancers treated with definitive RT at the University of Florida.[24] Parsons and coworkers[57] reviewed the literature and reported a local control rate of 62% in a series of 87 patients treated with RT alone for T4 glottic carcinoma.

## Supraglottic Cancer

The proportion of patients suitable for a supraglottic laryngectomy is depicted in Table 18.9.[51] Depending on the referral patterns, a modest subset of patients is suitable for this operation.

The extent of neck disease for patients treated with either surgery or RT is shown in Table 18.10.[51] In general, patients treated with supraglottic laryngectomy appropriately have earlier stage neck disease and would be anticipated to have a lower risk of distant failure and improved survival. The local control rates after transoral laser, RT, and open supraglottic laryngectomy are summarized in Tables 18.11–18.13.[51] In general, the local control rates after transoral laser excision are fairly good for patients with T1 to T2 tumors and tend to deteriorate for those with more advanced disease. The local control rate for patients selected for open supraglottic laryngectomy are excellent. However, the incidence of severe complications tends to be higher after supraglottic laryngectomy compared with RT and transoral laser excision (Table 18.14).[51,58]

## Radiation Therapy Sequelae

The acute reactions from the treatment of early vocal cord cancer using a tumor dose of 2.25 Gy per day to administer a total dose 63 Gy (4 MV or 6 MV photons, five fractions per week) are relatively mild. During the first 2 to 3 weeks, the voice may improve as the tumor regresses. The voice generally becomes hoarse again because of RT-induced changes, even though the tumor continues to regress. A mild sore throat develops beginning at the end of the second week, but medication is usually not required. The voice begins to improve approximately 3 weeks after completion of treatment, usually reaching a plateau in 2 to 3 months. Patients with extensive lesions often recover a normal voice, although not as frequently as those with small tumors.

Edema of the larynx is the most common sequela after RT for glottic or supraglottic lesions. The rate of clearance of the edema is related to the RT dose, volume of tissue irradiated, addition of a neck dissection, continued use of alcohol and tobacco, and the

size and extent of the original lesion. Edema may be accentuated by a neck dissection and may require 6 to 12 months to subside.

Soft tissue necrosis leading to chondritis occurs in fewer than 1% of patients, usually in those who continue to smoke. Soft tissue and cartilage necroses mimic recurrence, with hoarseness, pain, and edema; a laryngectomy may be recommended as a last resort for fear of recurrent cancer, even though biopsy specimens show only necrosis.

Corticosteroids such as dexamethasone (Decadron) have been used to reduce RT-induced edema after recurrence has been ruled out by biopsy. If ulceration and pain occur, administration of an antibiotic such as tetracycline may help. Of 519 patients with T1N0 or T2N0 vocal cord cancer treated at the University of Florida, 5 (1%) experienced severe complications,[35] including total laryngectomy for a suspected local recurrence (1 patient), permanent tracheostomy for edema (3 patients), and a pharyngocutaneous fistula after a salvage total laryngectomy (1 patient).

In patients irradiated for supraglottic carcinoma, sore throat persist 1 to 2 months after completion of treatment. There is an associated dry mouth from RT of the salivary and parotid glands, a loss of taste, and a sensation of a lump in the throat. It is unusual for patients to require a tracheotomy before RT unless severe lymphedema develops at the time of direct laryngoscopy and biopsy. However, in patients who have recovered from the direct laryngoscopy and biopsy without obstruction, a tracheotomy has rarely been required during a course of definitive RT.

Patients treated twice a day with 1.2-Gy fractions (continuous-course technique) to a total dose of 74.4 Gy usually have more brisk acute reactions than those treated once a day with 2-Gy fractions. All patients are treated with continuous course; planned split course RT is associated with a higher risk of failure. Approximately 30% treated with twice-a-day RT require temporary gastrostomy feeding tubes because they have difficulty in swallowing.[59]

Examples of acute chondritis requiring discontinuation of treatment have not been seen, although most epiglottic lesions exhibit cartilage invasion.

The epiglottis, both suprahyoid and infrahyoid portions, remains thicker than normal for long periods of time, but this is not often associated with difficulty in swallowing, respiratory obstruction, or aspiration. The patient is cautioned to eat and drink slowly until the edema resolves. The false cord and arytenoids may develop some edema.

Lesions of the suprahyoid epiglottis frequently destroy the tip of the epiglottis, and it may require some time for the exposed cartilage to heal. Successful RT of infrahyoid epiglottis tumors is not associated with a high rate of necrosis, even though most of these lesions penetrate the porous epiglottic cartilage.

The incidence of severe late complications in 274 patients treated with RT alone or combined with neck dissection at the University of Florida was 4%.[51]

# MANAGEMENT OF RECURRENCE

## Follow-up Policy

Follow-up of patients with early lesions is planned for every 4 to 8 weeks for 2 years, every 3 months for the third year, and every 6 months for years 4 and 5, and then annually for life.

Follow-up of patients with early- and moderate-stage vocal cord or supraglottic larynx lesions treated by RT or conservative surgery is almost more important than the treatment itself because early detection of recurrence usually results in salvage that may include cure with voice preservation.[46] If recurrence is suspected but the biopsy is negative, patients are reexamined at 2- to 4-week intervals until the matter is settled. The value of follow-up positron emission tomography and CT scans for detecting early local recurrence is investigational.

The likelihood of salvage of a local-regional recurrence after total laryngectomy and adjuvant RT is very low.

An important goal of follow-up, in addition to detection of recurrent cancer and management of complications, is detection of metachronous second primary malignancy.[60] Wagenfeld and associates[61] studied 740 cases of glottic larynx cancer treated from 1965 to 1974 to determine the incidence of second respiratory tract malignancies. With a minimum follow-up of 5 years, 48 second respiratory tract malignancies occurred, although only 14 were expected. Twenty-five were in the lung, and 23 were scattered among other head and neck sites. Only 7 of the 23 second head and neck primary lesions resulted in death; these second lesions were frequently diagnosed in an early stage during routine follow-up for the glottic lesion.

Because the risk of a lethal lung primary lesion is nearly as great as that of dying of an early glottic carcinoma, it makes sense to obtain annual chest radiographs. Patients with supraglottic cancers who receive RT to the neck have a high risk of developing hypothyroidism and require monitoring of their thyroid functions every 6 to 12 months.[62]

## Glottic Larynx Carcinoma

Most recurrences appear within 18 months, but late recurrences may appear after 5 years.[63] With careful follow-up, recurrence is sometimes detected before the patient notices a return of hoarseness. There is often minimal lymphedema for 1 to 2 months after RT, which usually subsides or stabilizes. An increase in edema, particularly if associated with hoarseness or pain, suggests recurrence, even if there is no obvious tumor. Fixation of a previously mobile vocal cord usually implies local recurrence, but we have occasionally observed a patient who has experienced a fixed cord with an otherwise normal-appearing larynx and who has not shown evidence of recurrence. It may be difficult to diagnose recurrence if the tumor is submucosal. Generous deep biopsies are required. If recurrence is strongly suspected, laryngectomy may rarely be advised without biopsy-confirmed evidence of recurrence.

RT failures may be salvaged by cordectomy, hemilaryngectomy, or total laryngectomy. Biller and associates[64] reported a 78% salvage rate by hemilaryngectomy for 18 selected patients in whom irradiation failed; total laryngectomy was eventually required in two patients. Only two patients died of cancer. These investigators offered guidelines for using hemilaryngectomy: contralateral vocal cord is normal, arytenoid is not involved, subglottic extension does not exceed 5 mm, and vocal cord is not fixed. In our experience, 10 patients irradiated for T1 or T2 vocal cord cancers underwent a hemilaryngectomy following a local recurrence, and 6 were successfully salvaged.[17]

The rate of salvage by irradiation for recurrences or new tumors that appear after initial treatment by hemilaryngectomy is about 50%.[65] Patients who experience a local-regional failure after surgery and postoperative irradiation have a low chance of cure, particularly if the initial procedure was a total laryngectomy.

## Supraglottic Larynx Carcinoma

***Recurrence After Radiation Therapy.*** The overall likelihood of successful salvage after a local recurrence is about 50%; it is probably somewhat better for patients who initially have stages I to II disease.[46] Most patients require a total laryngectomy; a few

(c) 2014 Wolters Kluwer. All Rights Reserved.

are suitable for a voice-sparing procedure. Approximately one-third of patients sustain a major complication secondary to salvage surgery, usually related to poor wound healing.

When an isolated recurrence develops in a previously $N_0$ neck, patients have a 50% to 60% chance of cure by means of a salvage neck dissection.[66] The likelihood of salvaging a failure in a previously positive neck is remote.

The likelihood of cure after development of distant metastases is nil, and management is palliative with either supportive care or chemotherapy.

***Recurrence After Surgery.*** Patients who develop a low-volume local recurrence after a supraglottic laryngectomy may sometimes be successfully treated with RT. Patients with high-volume recurrences are best managed with a total laryngectomy and postoperative RT.

## SPECIAL ISSUES AND FUTURE DIRECTIONS

There are limited data pertaining to the use of chemotherapy alone as the initial step in treatment of patients with early-stage laryngeal cancer.[67,68] A small subset of patients may be cured with chemotherapy alone, thus sparing them the morbidity of RT and/or partial laryngectomy. A caveat is that the cure rates for patients with early-stage disease are already very high, the morbidity of chemotherapy may be more severe than that associated with conventional treatment, and >90% of patients must proceed to RT or surgery despite the chemotherapy (which probably does not enhance the likelihood of cure).

## ACKNOWLEDGMENT

We thank the research support staff of the Department of Radiation Oncology for their help with statistics, editing, and manuscript preparation.

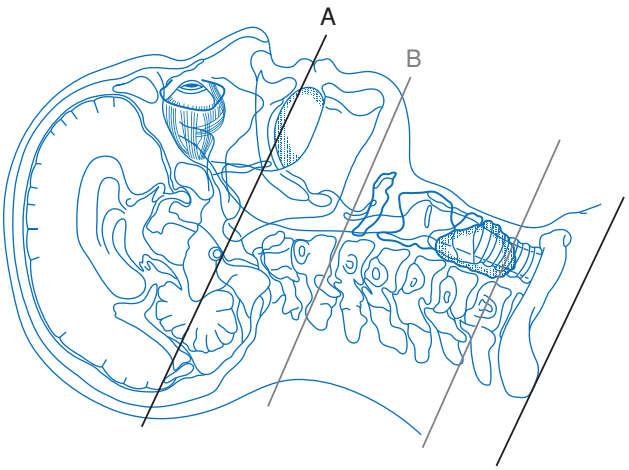
# PART B:
# Radiologic Imaging Concerns



Jeffrey A. Bennett

Imaging the larynx requires high speed because of the difficulties patients have with secretions and throat discomfort, which lead to frequent swallowing, coughing, and resultant motion artifact. Therefore, computed tomography (CT) is the imaging modality of choice, especially with the newer multidetector row helical or volumetric scanners. Very thin axial sections can be obtained, down to 0.5 mm, which allow outstanding quality of sagittal and coronal reformats. The axial images should be performed parallel to the true vocal cords to allow the best view of the anterior and posterior commissures. However, this is proving to be less important now, because many PACS software packages allow reformation of the images in any plane. This data manipulation can essentially "straighten out" the patient and optimize the imaging plane, no matter how the images were acquired. The long imaging time required for magnetic resonance imaging (MRI) often results in motion-degraded images, but in cooperative patients who are able to hold very still and not swallow for extended periods of time, MRI still provides better soft tissue differentiation. Since this scenario is infrequent, MRI is mostly reserved for problem solving in more advanced transglottic tumors, such as when there is a question of tracheal or esophageal invasion. Intravenous contrast is necessary for both modalities. Suggested protocols are given in Figures 18-9 and 18-10.

No matter which imaging technique is chosen, MRI or CT, the information obtained is critical in staging.[1] Imaging frequently upgrades clinically suspected low-grade tumor based on submucosal spread deep to the mucosal lesion visualized with endoscopy. As seen elsewhere in the head and neck, visualization of fat planes is critical to image interpretation (Fig. 18-11). In the larynx, obliteration of the paraglottic fat and preepiglottic fat are signs of tumor extension. At the level of the true vocal cords, normally no fat is seen in the paraglottic space, but at the level of the false cords a clear paraglottic fat plane should be seen. The anterior commissure is very thin, and normally minimal to no soft tissue should be seen at that location. Similarly, in the subglottic region, no soft tissue should be seen in the airway inside the cricoid cartilage. Soft tissue in these locations is a sign of tumor spread. Multiplanar imaging is helpful for determining the full extent of the primary tumor (Fig. 18-12).

Occasionally, gross morphologic changes to the larynx such as a laryngocele are caused by a tumor. A careful search for an obstructing mass should be performed when a laryngocele is encountered (Figs. 18-13 and 18-14).

Not uncommonly, the laryngeal cartilages will be seen to be sclerotic. There is frequently irregular ossification of the laryngeal cartilage, so asymmetries cannot be assumed to be tumor invasion of the cartilage. The best way to be sure that cartilage invasion has occurred is if tumor is seen on both sides of the cartilage (Fig. 18-15). The arytenoid cartilage is frequently sclerotic. Pathologic studies have revealed a 50% likelihood of microscopic cartilage invasion in a single sclerotic cartilage directly adjacent to the tumor. There is a >90% possibility of cartilage invasion if more than two adjacent cartilages are sclerotic next to the tumor. Cartilage sclerosis has been correlated with a poorer local control rate with radiation therapy.[2] Both CT and MRI can detect cartilage sclerosis, appearing solid bright on CT and black on MRI. Initial studies reported a higher specificity for cartilage invasion with CT compared to MRI.[3] A recent study was performed[4] to investigate the accuracy of MRI in predicting thyroid cartilage invasion and found that MRI overpredicts cartilage and thyroid gland invasion.

Examples of glottic squamous cell carcinoma spreading to the supraglottis and subglottic region are given in Figures 18-16 to 18-18.

Primary supraglottic tumors are sometimes difficult to see on imaging studies if they are superficial and low volume. Direct visualization often outlines the mucosal extent of disease. Imaging studies should focus on deep extension to the preepiglottic and paraglottic spaces, as well as spread to lymph nodes. Particular attention should be paid to level VI nodes and lateral retropharyngeal nodes (Fig. 18-19).

If paratracheal lymph node metastases are present, the patient carries a worse prognosis. These nodes can be detected with

both CT and MRI. One study showed a sensitivity and specificity of 70% and 36% for CT and 50% and 71% for MRI, when the node was >5 mm in its greatest axial diameter.[5] CT perfusion may provide additional functional information regarding the presence of tumor in lymph nodes.[6]

Follow-up imaging is of limited use for treated small mucosal early lesions, unless there are clinical symptoms of tumor recurrence, although CT has been demonstrated to be able to detect treatment failure before it is clinically suspected.[7] Radiation therapy produces posttreatment changes of edema and mucosal enhancement, and so careful comparison with the pretreatment study is necessary to assess for response (Fig. 18-20). Interpreting postsurgical changes requires an understanding of what was removed and where flaps have been placed. Often mucosal and submucosal soft tissue thickening is seen after surgery, and the initial posttreatment scan serves as a baseline for future follow-up. Scar tissue generally shrinks, and enhancement reduces over time, whereas tumor grows and enhances more over time. When present, special attention should be made to sites of anastomosis of the neopharynx and along the tracheostomy.

Posttreatment cartilage necrosis can often present diagnostic difficulty (Fig. 18-21). Fragmentation of sclerotic cartilage and tunneling through osseous segments are signs of radiation necrosis. If there is an associated soft tissue mass, this raises the suspicion for necrotic tumor. In these cases, FDG PET-CT at least 3 to 4 months after treatment completion may be helpful in directing a biopsy. A negative FDG PET is very encouraging in that there is no recurrent disease.

# PART C:
# Radiation Therapy Technique

William M. Mendenhall

## T1N0–T2N0 GLOTTIC LARYNX

The portals used to treat T1N0 and T2N0 glottic carcinomas are limited to the primary lesion. The risk of occult disease in the neck nodes is very low, even for patients with T2B tumors, and elective neck irradiation is not indicated.

Patients may either be treated in the lateral decubitus position with the fields set up daily by the physician using the anatomic landmarks or in the supine position with aquaplast to ensure accurate repositioning. Parallel-opposed fields are used and weighted 3:2 toward the side of the cancer, if it is lateralized. Weighting the fields reduces the dose to the contralateral posterior larynx. The field borders for a T1N0 cancer involving the anterior two-thirds of the cord are the middle of the thyroid notch, the bottom of the cricoid cartilage, 1 cm posterior to the thyroid lamina, and 1.5 cm fall off anteriorly (Fig. 18-22).[1] The fields are enlarged for T2 cancers depending on the sites of disease extension. Approximately 5% of the dose may be delivered with an anterior field centered over the tumor, with the patient in the supine position, in order to reduce the dose laterally. Patients are treated with $^{60}$Co, 4 MV x-rays, or 6 MV x-rays; the dose delivered to the tumor is similar for these beams.[2] Alternatively, patients may be treated with intensity-modulated radiation therapy (IMRT) to reduce the dose to the carotid arteries and reduce the long-term risk of stroke.[3] Patients with cancers that extend anteriorly though the cricothyroid membrane into the soft tissues of the neck may be underdosed with 6 MV x-rays. However, these lesions are T4 by definition, and the treatment techniques are addressed elsewhere.

Patients with T1 or T2 vocal cord cancer treated with once-a-day fractionation at the University of Florida are irradiated with 2.25 Gy fractions to 63 Gy for T1 and T2A cancers and 65.25 Gy for T2B lesions.

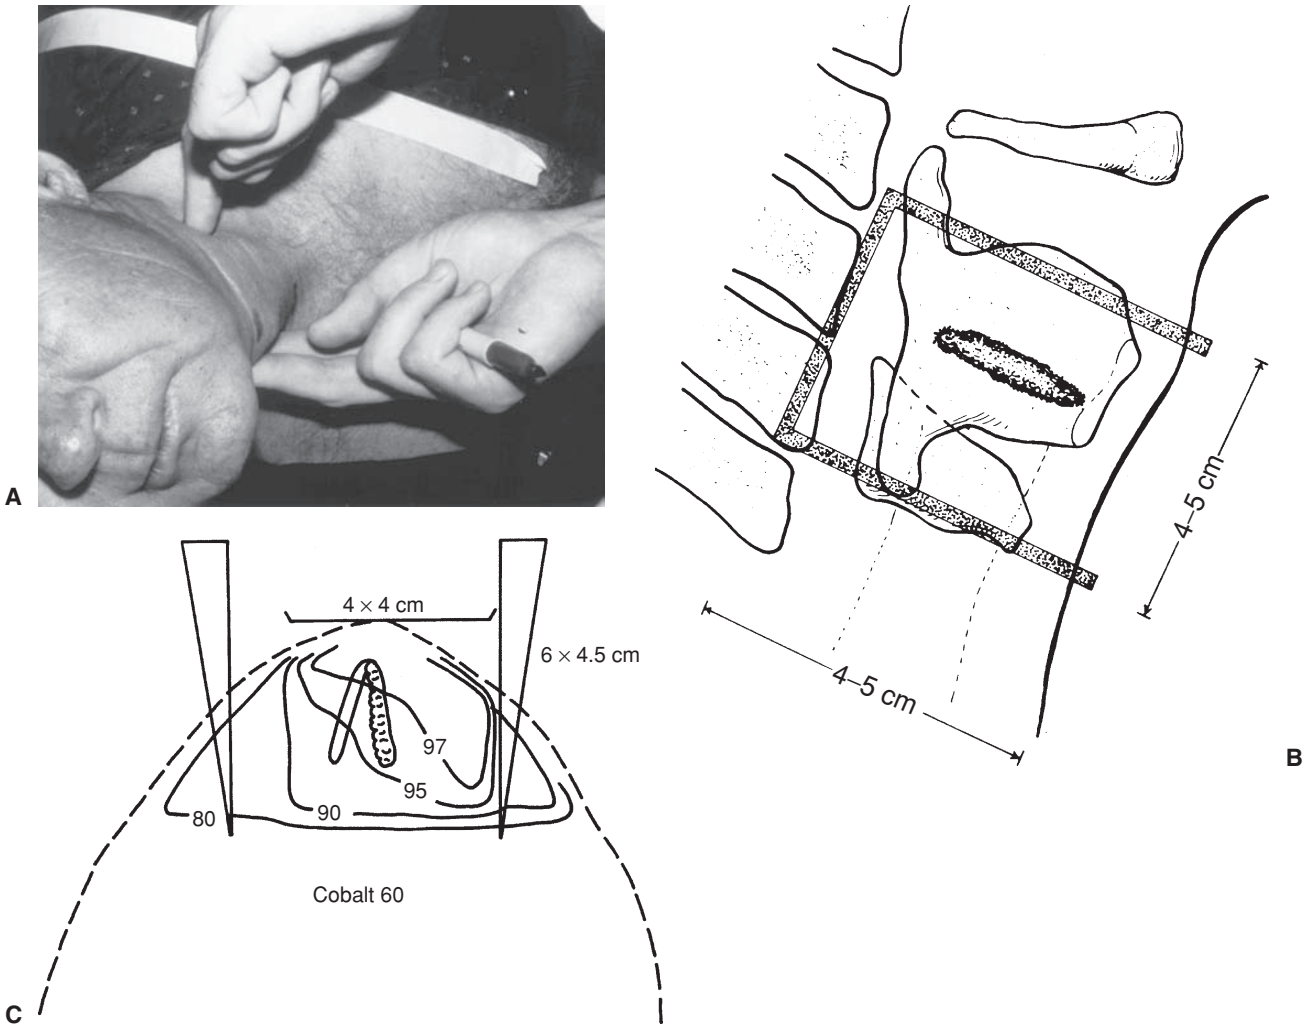

**FIGURE 18-22.** Radiation treatment technique for carcinoma of glottic larynx, stage T1–2. **A:** Patient is in lateral decubitus position. To locate the posterior border of the thyroid cartilage, fingers of one hand are positioned under the patient's neck and the larynx is lifted gently a few millimeters while the index finger of the other hand simultaneously locates the posterior edge of the thyroid lamina. **B:** For T1 cancer, the superior border of the field is usually at mid thyroid notch (height of the notch typically is approximately 1.0 cm or slightly more in male adults); for minimal lesions (e.g., carcinoma *in situ*), the bottom of the thyroid notch is chosen. If the ventricle or false vocal cords are minimally involved, the top of the notch (which corresponds to the cephalad portion of the thyroid lamina as palpated just off midline) is often selected; more advanced lesions call for greater superior coverage. If only the anterior half of the vocal cord is involved, the posterior border is placed at the back of the mid portion of the thyroid lamina. If the posterior portion of the cord is involved, the border is 1.0 cm behind the lamina. If the anterior face of the arytenoid is also involved, the posterior border is placed 1.5 cm behind the cartilage. If no subglottic extension is detected, the inferior border of the irradiation portal is at the bottom of the cricoid arch as palpated at the midline. If computed tomography demonstrates subglottic extension, the portal is adjusted accordingly. Anteriorly, beam fall off (by 1.5 cm) over patient's skin. **C:** The three-field technique (two lateral wedge fields and an anterior open field) is commonly used to treat vocal cord cancer at the University of Florida. Lateral fields are differentially weighted to involved side. The anterior field, which usually measures 4 × 4 cm, is centered approximately 0.5 cm lateral to midline in patients with one cord involved and typically delivers approximately 5% of total tumor dose (usually on last 2 treatment days) after treatment from the lateral portals is completed. The anterior portal is essentially a reduced portal that centers high dose to the tumor. The isodose line at which the dose is specified is that which covers gross disease. By appropriate field weightings, encompassing the tumor within 95% to 97% of maximum isodose line is virtually always possible.

## T1–T2N0 SUPRAGLOTTIC LARYNX

The risk of occult disease in the neck nodes is relatively high, even for early-stage lesions, so that the nodes at risk are treated bilaterally in conjunction with the primary malignancy. For patients with a clinically negative neck, the nodes at highest risk are those in levels II, III, and IV. Nodes in levels I, V, and VI, and the retropharyngeal lymph nodes are unlikely to harbor metastatic disease, and the fields are not enlarged to include these areas.

Patients are treated with parallel-opposed fields weighted to the side of the cancer, if it is lateralized. The fields usually extend from the bottom of the cricoid cartilage to 1 to 2 cm above the angle of the mandible, to the posterior of the spinous processes, and fall off 1.5 cm anteriorly, if the cancer extends to the anterior commissure and/or petiole. If not, a strip of anterior skin may be spared (Fig. 18-23).[4] The low internal jugular lymph nodes are included in a tight low neck field with a small, tapered, midline block (see Fig. 18-23).[4] The fields are reduced off the spinal cord at approximately 45 Gy, and a second mucosal reduction is performed at 60 Gy to encompass the initial gross disease, with a 1.5- to 2.0-cm margin.

Most patients treated at the University of Florida are currently irradiated at 1.2 Gy per fraction, continuous course, with a minimum 6-hour interfraction interval. The dose for T1 and T2 lesions is 74.4 Gy. The total doses for patients irradiated once daily at 2 Gy per fraction are 60 Gy for T1 cancers and 64 to 66 Gy for T2 cancers. All patients are treated with the continuous-course technique.[5]

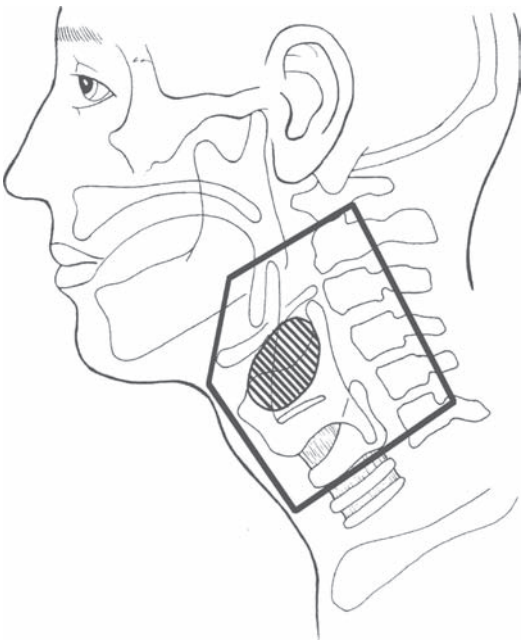

**FIGURE 18-23.** Example of a portal for a lesion of the lower epiglottis or false vocal cord and a clinically negative neck. The subdigastric nodes are included but not the junctional nodes. Depending on the anatomy and tumor extent, the anterior border may fall off (i.e., "flash") or a small strip of skin may be shielded.

*Source:* From Million RR, Cassisi NJ, Mancuso AA, et al. Management of the neck for squamous cell carcinoma. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach.* 2nd ed. Philadelphia, PA: JB Lippincott; 1994:75–143 (Fig. 6-52, p. 133), with permission.

IMRT is employed when there is a clear advantage compared with conventional field arrangements. IMRT is not employed to spare the salivary glands in patients with T1–T2N0 supraglottic carcinomas because most of the parotid glands are excluded from the initial parallel-opposed fields. The main reason to use IMRT would be to obtain an adequate inferior margin on the occasional patient with a low-lying larynx and a short neck where the inferior extent of the primary tumor cannot be included in the parallel-opposed lateral fields.

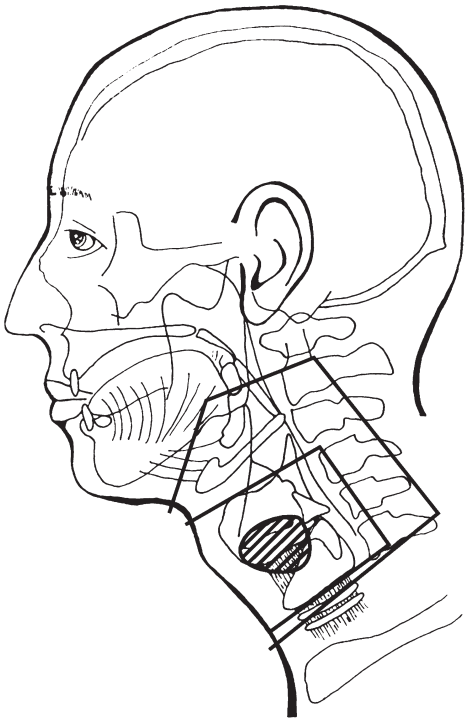
## T3–T4 GLOTTIC AND SUPRAGLOTTIC CANCERS

Patients with T3–T4 laryngeal cancers are treated with parallel-opposed portals weighted 3:2 to the side of the lesion, unless the cancer is midline or significantly crosses the midline necessitating 1:1 weighting. The initial portals extend from 2 cm above the angle of the mandible to the bottom of the cricoid cartilage, 1.5 cm anterior to the skin of the anterior neck, and to the posterior aspect of the spinous processes of the cervical vertebrae. The posterior border may be tight for patients with node-negative glottic cancer, where the risk of level V node involvement is minimal (Fig. 18-24).[6] A strip of skin may be spared for patients with supraglottic cancers depending on the anterior extent of the tumor. IMRT is usually not indicated for these patients because it is possible to exclude most of the parotid glands from the conventional fields. The fields are enlarged depending on the location of the primary tumor and neck disease. For example, the inferior edge of the field may be placed 1 to 2 cm below the bottom of the cricoid cartilage if there is subglottic extension. Because patients with positive neck nodes have an increased risk of retropharyngeal lymph node involvement, it is necessary to include the retropharyngeal lymph nodes at the level of the C1–C2 vertebral bodies in the initial portals. The fields are reduced off the spinal cord at approximately 45.0 Gy, and a second mucosal reduction usually occurs at about 60.0 Gy. If necessary, electron beam may be used to treat the posterior strip after reducing off the cord. The low neck is treated with an anterior field with a small, tapered, midline block.

Patients may be treated once daily or with an altered fractionation schedule.[7] The concomitant boost technique is currently employed at the University of Florida; gross disease receives 72.0 Gy in 42 fractions over 30 treatment days over 6 weeks, and moderate risk subclinical disease receives 49.5 to 54.0 Gy.[8] Alternatively, hyperfractionation may be employed to deliver 74.4 Gy in 62 twice-daily fractions. Clinically negative nodal regions that are treated include ipsilateral levels IB, II, III, IV, V, VI, and retropharyngeal nodes, as well as contralateral levels II, III, and IV.[8] Patients receive weekly concomitant cisplatin 30 mg/m$^2$ during the course of radiation therapy (RT). A computed tomographic (CT) scan is obtained 1 month after RT to determine whether a neck dissection is indicated.[9] An example of a patient treated with IMRT is shown in Figure 18-25.[8]

The portals used to treat patients after surgery, which would usually entail a total laryngectomy and neck dissection for patients with an advanced primary cancer are depicted in Figure 18-26.[10] The anterior field edge allows tangential irradiation of the skin of the anterior neck. The neck nodes are often positive, necessitating inclusion of the retropharyngeal and junctional nodes in the initial portals. The lower border of the lateral fields slants superiorly from anterior to posterior, and the central axis of the anterior low neck field is placed at the field junction, so

(c) 2014 Wolters Kluwer. All Rights Reserved.



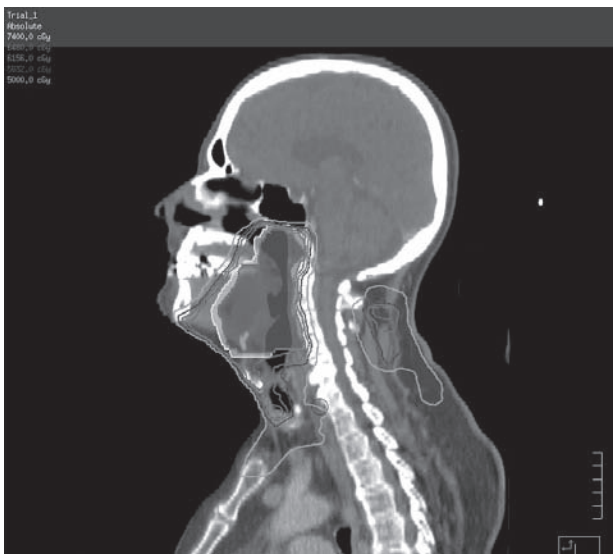


**FIGURE 18-24.** Portals for T3–4 lesions: The initial portal includes the jugulodigastric and mid jugular lymph nodes. In the N0 patient, the highest jugular lymph nodes near the base of the skull are at little risk of involvement. To ensure adequate coverage of the mid jugular lymph nodes, it is necessary to include the spinal cord in the treatment volume. The placement of the inferior border depends on the presence and degree of subglottic extension as determined by direct laryngoscopy and computed tomography and is commonly 1.0 to 2.0 cm below the inferior border of the cricoid cartilage; this line is slanted to facilitate matching with the anterior low neck portal. Anteriorly, the beam is allowed to "fall off" over the skin and subcutaneous tissues. The entire preepiglottic space is included within the initial treatment volume.

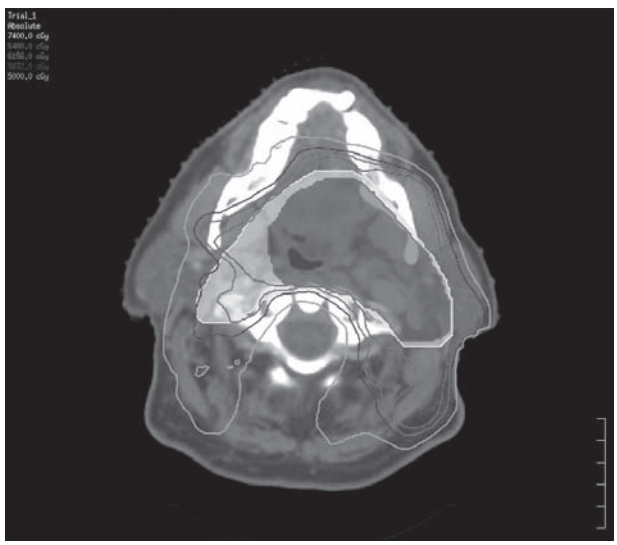
*Source:* Parsons JT, Mendenhall WM, Mancuso AA, et al. Twice-a-day radiotherapy for T3 squamous cell carcinoma of the glottic larynx. *Head Neck.* 1989;11:123–128 (Fig. 1, p. 124), with permission.



that dose to the spinal cord at the junction is low (Fig. 18-27).[11] This field-matching technique has been used for over five decades at the University of Florida, with a very low risk of radiation myelitis and a low risk of failure in the neck at the junction. Patients are treated with $^{60}$Co or 6 MV x-ray. Vaseline gauze bolus, 5 mm thick, is placed in the incision to ensure an adequate surface dose. The low neck node is given 50 Gy in 25 fractions specified at Dmax, after which the dose to the stoma may be boosted with an electron beam (usually 12 MeV), if there is subglottic extension.

IMRT may be employed postoperatively for the same indications as those used for patients treated with definitive RT. The fractionation schedule and whether concomitant chemotherapy is employed depends on the pathologic findings.

The technique employed for preoperative irradiation is the same as that used for patients treated with irradiation alone.

# PART D:
# Surgical Decision Making and Technique

F. Christopher Holsinger and Andrew J. McWhorter

Options for surgical treatment of early larynx cancer include open conservation laryngeal surgery (CLS) or transoral endoscopic resection, with either traditional "cold-steel" phonosurgery or transoral laser microsurgery (TLM). Although the use of open techniques has declined, the emergence of transoral endoscopic head and neck surgery (eHNS)[1] has rekindled interest in functional organ-preservation surgery of the larynx and has expanded the available multidisciplinary treatment options for patients. Chen et al.[2] recently found that among patients with early-stage cancer, those receiving primary surgery increased (from 20% in 1985 to 33% in 2007), whereas the use of RT decreased from 64% to 52%. However, for intermediate- and advanced-staged cancers, Hoffman described the opposite trend: a greater role for radiation and concurrent chemoradiation over these same decades.[3] This review of the National Cancer Database between the years 1985 and 2001 found a trend toward decreasing survival among patients with laryngeal cancer from the mid-1980s to mid-1990s. During these decades, the authors found a significant increase in chemoradiation, with a concomitant decline for the role of surgery.

Over this same time period, there has been a sea change within the field of head and neck surgery. For years, cancer surgery for tumors of the larynx has been synonymous with "total laryngectomy." However, now an array of new surgical approaches, including transoral minimally invasive surgery of the larynx, and supracricoid partial laryngectomy (SCPL) offer the potential to improve clinical outcomes, function, and quality of life.[4] Since these techniques are just now being routinely accepted and employed within the multidisciplinary paradigm, we review here the current role of surgery for patients with laryngeal cancer.

## ENDOSCOPIC RESECTION

### Vocal Stripping, Cold-Steel Resection, and Phonosurgery

Vocal cord stripping may still occasionally be performed for selected superficial, noninvasive lesions of the glottis.[5,6] In general, this previously accepted technique of vocal cord stripping has fallen out of favor due to the poor voice results that often accompanied these procedures. Early malignant tumors, and even extensive premalignant disease, may seem superficially invasive, by preoperative exam in the clinic, but in fact often have invasion of the vocal ligament.[7] Our improved understanding of the layered vocal fold from Hirano[8] and the refinement of microflap techniques have pushed this technique toward obsolescence. The stripping technique is rather imprecise in peeling away the epithelium in the layer of the superficial lamina propria. Failure to preserve this layer when possible, and in a nonuniform manner, has relegated its use to a vocal fold scar model for investigational studies. The more precise technique of microflap excision has proven to be voice preserving in many instances and successful in the treatment of precancerous lesions. Ossoff's work detailed the successful regression of preneoplastic lesions with serial microflap excision of dysplasia.[9]

***Technique.*** Rigid laryngoscopy in suspension under microscopic guidance is used for resection. Microlaryngeal instrumentation is used to sharply excise the tumor from the vocal folds. In the microflap technique, an incision is made lateral to the lesion, which is bluntly undermined and then sharply excised.

### Transoral Laser Microsurgery

In contrast to transoral cold-steel "phonosurgery," the concept of TLM encompasses the laser-based surgical resection of tumors of the larynx through the mouth. For the purposes of this chapter, we will limit this terminology to TLM of the larynx, but the technique can easily and reliably be applied to the oral cavity, oropharynx, and hypopharynx as well. TLM as a surgical approach is founded upon the historical evolution of the field of otolaryngology and reflects the practitioner's ability to look through the transoral window into the laryngopharynx and treat myriad conditions. Traditionally, TLM is done using a line-of-sight laser beam aided by a microscope. As the use of the operating microscope with the laser greatly facilitated complete tumor excision that was not possible with cold surgical techniques, advances in technology will likely continue to expand the repertoire of the TLM approach. With continued advances in lasers, robotics, and visualization technologies, TLM techniques will continue to evolve and improve.

In 1972, Jako and Strong published the first clinical experience using the carbon dioxide laser as part of transoral microsurgery for the treatment of benign and early malignant lesions of the larynx.[10] The technique was widely adopted among laryngologists, but failed to take hold within head and neck surgery. Steiner[11,12] and others in Europe developed this technique and made critical conceptual advances and improvements in instrumentation. Since then, TLM has played a much greater role within the multidisciplinary paradigm, and its use has been expanded for tumors throughout the upper aerodigestive tract and for more advanced-stage tumors.[12]

TLM may or may not entail a "piecemeal excision" of the laryngeal tumor. Small lesions can be removed *en bloc* or by dividing the tumor across its main axis. Although this approach violates Halstedian technique, advocates argue that by appreciating the unseen depth of the lesion, especially near critical and/or unique anatomy, an adequate oncologic resection can be achieved, while minimizing the sacrifice of surrounding normal structures. Using the operating room microscope, which provides magnification of 4× to 12×, the endoscopic surgeon can have significantly improved visualization and thus more detailed understanding of the interface between tumor and normal tissue.[13,14] By dividing the tumor, though, the surgeon must bear additional responsibility to provide adequate margins through close coordination with pathology—as well as close tumor surveillance postoperatively. In fact, in the largest series published on the role of margins in TLM, Jackel et al.[15] found that 30% of patients required some additional surgery for a variety of T1 to T4 tumors treated with TLM, mostly for inadequate margins on final histopathology, despite negative frozen sections. Most of these patients (82% of the re-resected specimens demonstrated no evidence of residual tumor) had similar rates of local control as those patients in whom revision was not necessary. This discordance suggests the inherent challenges associated with TLM and underscores close partnership with the surgical pathologist. However, patients with residual tumor after revision TLM showed a significant reduction in locoregional control as well as

(c) 2014 Wolters Kluwer. All Rights Reserved.

larynx preservation. However, in this study, overall survival was not significantly affected[15]; rather, there is a need for open surgery and salvage radiation therapy for these patients with positive re-resection margins.

Despite these concerns, TLM has outcomes comparable to open conservation surgery and radiation therapy for patients with T1 to T2 glottic cancer. Local control for T1 lesions was 77% to 92% and that for T2 tumors was 61% to 88%. After salvage therapy, an "ultimate" local control rate was well above 90% with 5-year disease-specific survival of 86% to 98%.[16–22] Authors quote high rates of overall larynx preservation, when TLM is selected as the first treatment modality with rates ranging from 90% to 99%,[16–19,21,22] although one group reported a larynx-preservation rate of 97% for T1 tumors and 82.5% for T2 lesions.[20] Critics of TLM point out that most of the literature is derived from single institutional retrospective reviews. However, there remains no NCI, or industry-funded cooperative group, or funding to support central data collection and prospective investigation.

Despite these current roadblocks to prospective clinical investigation, Hinni and his colleagues assembled in 2007 a multidisciplinary review of TLM in the treatment of advanced laryngeal cancer of stages T2 to T4. Two-year larynx preservation and local disease control rates were 92% and 82%, respectively. Five-year Kaplan-Meier estimates of overall survival were 55%, in keeping with results from the RTOG-911. A number of larger series such as this and other now appear to suggest that TLM for the treatment of larynx cancer has local control rates, and larynx preservation, on par with open approaches with better functional outcomes, and in properly selected patients on par with radiation therapy.

First and foremost, TLM represents a dramatic break from traditional compartmental or subunit surgery for the resection of laryngeal tumors. Yet this "precision medicine"[23] approach using transoral eHNS creates challenges in nomenclature and description of the TLM procedure performed. In this new approach, each endoscopic resection is personalized for the individual patient's tumor and is thus not removed in the traditional whole organ or compartmental fashion. In 2000, Remacle led the European Laryngological Society (ELS) effort to develop a classification system for the endoscopic resection of glottic cancer.[24] In this schema, endoscopic cordectomy is categorized into five types, ranging from subepithelial to anterior commissurectomy with bilateral anterior cordectomy, to "extended cordectomy," representing the full array of partial laryngectomies[24,25] (Table 18.15). In 2009, the ELS proposed a classification system for endoscopic supraglottic laryngectomy with four categories, ranging from limited excision to a lateral supraglottic laryngectomy[26] (Table 18.16).

Although TLM offers many advantages to the surgeon, there are also important limitations. First, not every patient may be a suitable candidate. Inadequate endoscopic exposure due to dental occlusal, deformity, retro- or micrognathia, or macroglossia may limit the number of patients eligible for endoscopic resection. Second, adverse tumor features, such as an endophytic growth pattern, perineural invasion, or occult extralaryngeal spread,[27,28] are associated with poor oncologic and functional outcomes. Previous radiation treatment may also be a relative contraindication. Although TLM may be effective in this setting, identification of tumor margins and prolonged mucosal healing are more difficult during endoscopic resection after radiation therapy.

Steiner et al.[29] reported on 34 patients with early- or advanced-stage recurrent glottic carcinoma after radiation therapy. Twenty-four patients (71%) were cured after one or more TLM. Patients with early-staged recurrent carcinomas had lower rates of local recurrences and salvage total laryngectomy than did patients with advanced recurrent cancers. However, in this experience, more than half of the patients required at least two TLM procedures to achieve disease control, underscoring the difficulty of this approach. Similarly, Quer et al. presented a series of patients treated with TLM for both supraglottic and glottic cancers, recurrent after radiation.[30] Although disease-free survival rate after 5 years was 100%, multiple procedures were required to achieve disease control. For these reasons, the role of TLM in the setting of surgical salvage after radiation should be carefully considered. For small limited recurrences (rT1), TLM may appear to offer good results. For more extensive recurrence after radiation, open surgery may be a better option. What is clear, though, is that TLM has its best role to play as primary, rather than salvage, therapy.

As primary treatment for laryngeal cancer, TLM is associated with several advantages in the short-term benefits (Fig. 18-28A,B). Tracheotomy is rarely needed. Swallowing dysfunction is rare, especially for patient undergoing endoscopic

resection for glottic cancer. These functional advantages are also associated with shorter hospital stays and lower costs of treatment.[31] In most cases, endoscopic surgery broadens the management possibilities for persistent or recurrent disease; salvage for failure after TLMs can be approached with further endoscopic, or open surgery, or with radiotherapy.[5,14]

***Technique.*** Using suspension direct microlarynoscopy, the carbon dioxide laser is used to transect the tumor to determine the depth of invasion. Using microlaryngeal instrumentation, it is then typically resected, either *en bloc*, or in the fashion proposed by Steiner,[32] maintaining orientation of the specimens removed in order to evaluate for margin status. The technique usually varies from traditional open CLS in following the tumor, rather than subscribing to the compartment resection theory of the larynx. Healing is by secondary intention, with contraction of the resected tissue, avoiding the need for reconstruction (Fig. 18-29).

## Conservation Laryngeal Surgery

CLS[33] represents a broad array of open surgical techniques, ranging from laryngofissure with cordectomy to supracricoid laryngectomy. In addition to achieving comparable rates of local control, with CLS, surgeons can achieve functional organ preservation by understanding the cricoarytenoid unit[34] (defined as arytenoid, cricoid cartilage, associated muscles, and corresponding innervation by the superior and recurrent laryngeal nerves) as the basic functional unit of the larynx, not the vocal cord alone.[33]

Rarely, laryngofissure with cordectomy may still be required, perhaps for patients with poor transoral exposure. The thyroid cartilage is divided to gain access to the endolarynx, and with wide visualization, the tumor is excised. Historically, postoperative tracheotomy was always required,[35] but Laccourreye et al. described a series of 33 patients where this was not needed: local control was 100%; 5-year survival rate 97%.[36]

Vertical partial laryngectomy (VPL), also known as hemilaryngectomy, is a time-honored approach to resecting an entire ipsilateral glottic larynx, including paraglottic space and corresponding thyroid ala, but preserving the ipsilateral arytenoid. Local control rates for T1 cancers range from 89% to 100%.[37–40] Involvement of the anterior commissure decreases local control; one study reported that anterior commissure involvement decreased local control from 93% to 75%. For tumors involving the anterior commissure or the anterior-most aspect of the contralateral vocal fold, an extended VPL or frontolateral vertical hemilaryngectomy can be done. Yet for larger T2 tumors, VPL may be less effective, with local control rates of 74% to 86%.[37–39,41] Ultimately, for preoperative decision making, T classification may be less effective than careful laryngoscopic exam: for instance, patients with significant extension to the subglottis or supraglottis, or without impaired vocal cord mobility may fare worse.

***Technique.*** Tracheotomy is performed separately from the incision for resection. The strap muscles are then reflected isolating the laryngeal cartilages. The outer perichondrium is then elevated and preserved overlying the ipsilateral thyroid cartilage. A midline vertical thyrotomy is performed, and resection is carried across the cricothyroid membrane and thyrohyoid membrane preserving the epiglottis. *En bloc* resection of the true vocal fold and paraglottic space along with thyroid cartilage is obtained. Reconstruction is performed with the preserved perichondrium and strap muscles to create a buttress for contact with the remaining contralateral vocal fold. These resections can be extended to include the contralateral true vocal fold or ipsilateral arytenoid.

In contrast to the VPL, the supraglottic laryngectomy (SGL) is also known as the "horizontal" partial laryngectomy. First performed in 1939[42] by Alonso from Uruguay,[43] SGL encompasses the resection of the entire supraglottis from hyoid to false cord, including the preepiglottic space, while preserving both true vocal cord and arytenoids. For properly selected patients, SGL

(c) 2014 Wolters Kluwer. All Rights Reserved.

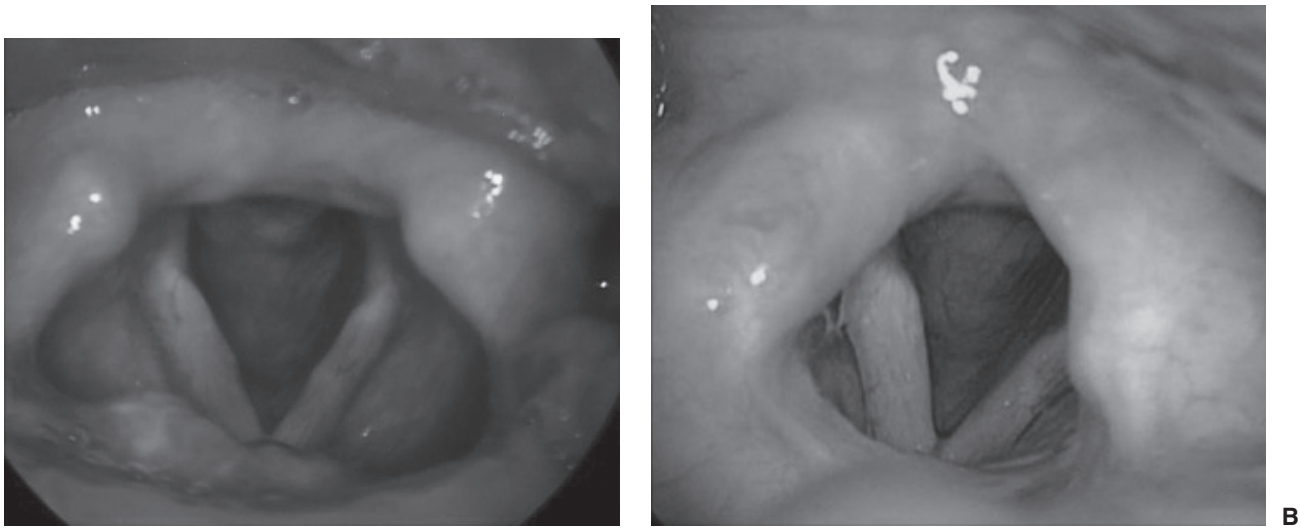

**FIGURE 18-29.** Transoral laser microsurgery for supraglottic laryngeal cancer. **A:** Preoperative laryngoscopy demonstrates a tumor of the infrahyoid supraglottic larynx in a 57-year-old female smoker with T2N0M0 squamous cell carcinoma. **B:** Postoperative view at 12 months.

achieves rates of locoregional control ranging from 92% to 100% for T1 lesions and 85% to 100% for T2 tumors.[44–47] Ogura[48] and others have described a variety of extended procedures, which range from procedures that include resection of the tongue base, arytenoids, aryepiglottic fold, or pyriform sinus. Contraindications include tumors that involve the glottis larynx, or extend to the thyroid, or cricoid cartilage invasion, tongue base, or the intrinsic deep-tongue musculature.[48,49]

***Technique.*** Tracheotomy is performed, followed by separation of the strap muscles, and isolation of the thyroid cartilage and hyoid bone. The hyoid is released from the suprahyoid musculature. The pharynx is entered in the vallecula, and the thyroid cartilage is transected immediately above the anterior commissure. Cuts are made through the apex of the ventricle, anterior to the body of the arytenoid resecting the false folds, the epiglottis, and the aryepiglottic folds, while including the preepiglottic space. Reconstruction is performed by closing the laryngeal remnant to the base of tongue and the strap muscles as a second layer of closure.

Though VPL and SGL have a long and rich history within the pantheon of CLS, the SCPL has gained popularity over the past decade. SCPL was first described in French by Majer and Rieder in 1959 while they were working in Vienna.[50] This novel approach advocated preservation of speech and swallowing via subtotal laryngectomy, by creating an impaction of the hyoid bone onto the cricoid cartilage, a "crico-hyoïdo-pexie."

Surgeons in France made critical technical refinements, namely, Labayle[51] working in Paris and J. J. Piquet working in Lille,[52] which led to wide adoption of SCPL. Laccourreye organized these disparate procedures as supracricoid partial laryngectomies and standardized their reconstructions as either cricohyoidopexy (CHP) or cricohyoidoepiglottopexy (CHEP).[53,54]

SCPL[34] involves the resection of both true and false vocal folds, the entire thyroid cartilage, both paraglottic spaces; the epiglottis may or may not be removed depending on tumoral spread. After SCPL, the laryngopharynx is reconstructed through either cricohyoidoepiglottopexy (CHEP) or a cricohyoidopexy (CHP), depending on the extent of resection (Fig. 18-30). For early- and intermediate T1–2 stage cancers, the 5-year estimates of local control range from 91% to 98%.[55,56] The most common complication is postoperative aspiration, occasionally leading to pneumonia.[57] Rates of permanent gastrostomy and/or tracheotomy are < 5% to 10%, as is postoperative mortality rate (1%–2%).[55,58] Severe postoperative morbidity usually develops when the SCPL is used as salvage therapy after radiation therapy. Although SCPL-CHEP can be used with some success after radiation therapy, good functional outcomes after radiation are more difficult to achieve when performing salvage SCPL-CHP. Much higher rates of local wound-healing complications[59] or rupture of the pexy are seen after RT.[60,61]

***Technique.*** Apron flap is elevated, and the strap muscles are divided in the midline released below the infrahyoidal and above the oblique line of the thyroid cartilage, thus isolating the hyoid, the thyroid, and the cricoid cartilages. The superior laryngeal nerves are preserved, and the thyrohyoid membrane is incised, releasing the thyroid cartilage superiorly. Inferiorly, the cricothyroid joint is disarticulated, preserving the recurrent laryngeal nerve, and the cricothyroid membrane incised releasing the thyroid cartilage inferiorly. The larynx is then entered through the vallecula or

across the petiole of the epiglottis depending on the location of the tumor (Fig. 18-31). For supraglottic tumors, the surgeon should encompass the epiglottis and the underlying preepiglottic space within this vallecular laryngotomy incision. For glottic tumors, the surgeon can preserve the epiglottis to assist in deglutition. Posterior incisions are made at the vocal process, down along the cricoid cartilage, preserving the lateral cricoarytenoid muscle, while resecting the paraglottic space (Fig. 18-32). Reconstruction is performed by "impacting" or suturing the cricoid to the hyoid with a #1 suture. This impaction creates a neoglottis with the arytenoids to the epiglottis (CHEP) or the base of tongue (CHP) (Fig. 18-33).

## Total Laryngectomy

Total laryngectomy is the gold standard of treatment for advanced-stage laryngeal cancer. First performed successfully by Billroth in 1863 for cancer resection, it was later modified to a one-stage procedure in the 1880s by Gluck and Sorenson.[62] It is used for advanced-stage tumors of the larynx, and for both oncologic and functional surgical salvage. The role of primary therapy with total laryngectomy has long been cast in a negative light due to the necessary rerouting of the trachea, and the stigma of a permanent stoma and voice loss. Today, it is used only for advanced-stage

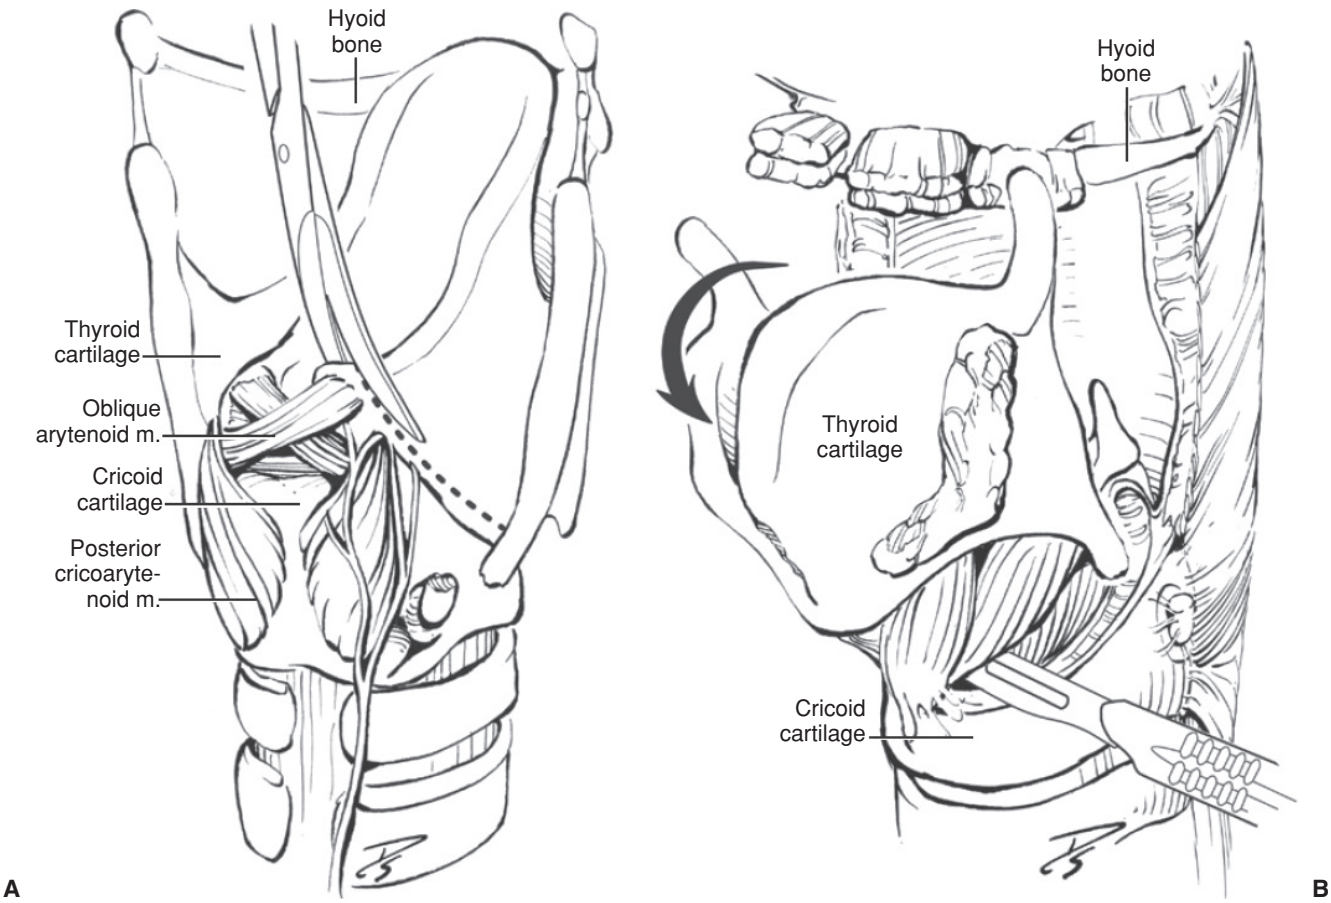

**FIGURE 18-32.** Schematic for laryngeal incisions for supracricoid laryngectomy (SCPL) for a glottic laryngeal tumor. **A:** After vallecular laryngotomy and the anterior release of the larynx, posterior incisions must be made through the base of the aryepiglottic folds, preserving the entire unaffected arytenoid cartilage, and separating the glottis with a final incision just anterior to the vocal process of the arytenoid. To clarify, the vocal cords are removed completely during SCPL. Shown here with scissors, cold-steel technique or monopolar cautery may be used. **B:** Then the remaining paraglottic space is removed with incisions placed just above the anterior border of the cricoid cartilage, hence the name of the procedure.

tumors not felt to be candidates of organ-preservation therapy, due to extensive thyroid cartilage invasion, extralaryngeal spread, or comorbidities that prevent nonsurgical therapy. Functionally, the rehabilitation of these patients has seen dramatic benefit from the extensive adoption of tracheo-esophageal speech and cricopharyngeal myotomy. Control rates for total laryngectomy are very good overall. Five-year disease-free survival for T3 glottic tumors treated with total laryngectomy range from 49% to 80%.[63–65] The 5-year overall survival is 54%.[66,67] For T4 tumors of the glottis, the 5-year overall survival after total laryngectomy ranges from 32% to 63%.[64,65,68]

Partial pharyngectomy with total laryngectomy is required for tumors with extension into the oropharynx or the hypopharynx. For small additional defect, this can be accomplished without the need for more than primary closure in reconstruction. The typical resection, however, only includes the hyoid and the laryngeal cartilages and is closed with primary reapproximation of the pharyngeal remnant on itself to create a neopharynx. Complications are most commonly wound infection and pharyngocutaneous fistula. Fistula rates can approach 50% in the postradiated patient.[69]

***Technique.*** An apron incision is made and the tracheotomy is typically delayed until the larynx is fully mobilized. The strap muscles are included in the resection, releasing the hyoid from the suprahyoid musculature. The trachea is isolated inferiorly, and the inferior constrictor is released from the thyroid cartilage bilaterally, with the thyroid gland mobilized contralaterally, and resected with the specimen for margin ipsilaterally. The pharynx is entered in the vallecula or lateral pharynx depending on the primary, and the cuts are made across the vallecula resecting the hyoid with the preepiglottic space, and all of the endolarynx with the arytenoids, the thyroid, and the cricoid cartilages. The pyriform sinuses are released from the thyroid cartilage to maximize the pharyngeal remnant for reconstruction of the neopharynx between the esophagus and the base of tongue. The inferior cuts are made through the trachea and separated through the parting wall with the esophagus (Fig. 18-34). Though still part of the ablative aspect of total laryngectomy, the surgeon must keep in mind how surgical resection anticipates alaryngeal voice restoration. Suspension of the trachea, wide maturation of the stoma, release of the sternal heads of the sternocleidomastoid muscle, cricopharyngeal/inferior constrictor myotomy, and primary tracheo-esophageal puncture all facilitate function postoperatively. The pharynx is closed on itself primarily using a running Connell stitch, ideally in a straight line, vertical closure.

## Radiation Salvage

Surgical salvage is performed for recurrent or persistent disease following organ-preservation therapy. CLS, transoral microsurgery, and total laryngectomy all have a role in posttreatment surgical salvage. Salvage surgery may also be performed to restore function due to chondroradionecrosis or severe dysphagia. Posttreatment surveillance can be challenging due to edema and mucosal

change that can mask recurrent disease. Despite close monitoring, reviews of RT failures in T1 and T2 laryngeal cancer have shown that nearly 70% of patients in whom the disease recurs require total laryngectomy as the only option for salvage treatment.[70,71]

Patient selection is critical to the successful performance on these procedures that are performed in lieu of total laryngectomy. Wound healing is prolonged in these patients, and exposed cartilage is less likely to be viable, leading to an increased incidence of wound complications and fistulae. Wider margins are required in the TLM procedures due to yet greater difficulty in determining tumor extent in the altered tissue and the opportunity for satellite lesions. Open conservation procedures have similar difficulties with decreased cartilage viability following surgery in the radiated field.

Quer et al. reported on 24 patients with recurrent supraglottic and glottic cancer who underwent salvage TLM.[30] The larynx was preserved in 18 patients (75%), and the disease-free survival rate after 5 years was 100%. Steiner et al.[29] described 34 patients with early (T1–2, $n = 21$) or advanced (T3–4, $n = 13$) recurrent glottic carcinoma after full-course RT. Twenty-four patients (71%) were cured after one or more TLM. With a median follow-up of at least 3-years, 15 (71%) of the 21 patients with early recurrent carcinomas (rT1–rT2) and 9 of the 13 patients with advanced cancer (rT3–rT4) remained disease free. Patients with early-staged recurrent carcinomas had lower rates of local recurrences and salvage laryngectomies than did patients with advanced recurrent cancers; the overall 3-year survival rate was 74%, and the 5-year survival rate was 53%.

Open conservation surgery can be even more challenging than TLM due to the wound-healing issues being compounded by the open approach. Although technically feasible, there has been less success with salvage vertical, partial, and supraglottic laryngectomy than when SCPL is performed. Laccourreye and others have successfully demonstrated the feasibility of SCPL salvage with good local control rates.[60,61] Laccourreye et al. initially reported this in 1996, with Kaplan-Meier 3-year actuarial survival and local control estimate of 83.3%.[60] Salvage total laryngectomy resulted in a 100% local control rate, while maintaining for the whole population a 75% laryngeal-preservation rate. Furthermore, these findings have been widely reproduced outside of France, with Luna Ortiz most recently finding an organ-preservation rate of 75%, and local control of 87%, with an overall 5-year survival of 50%.[72]

When patient selection precludes salvage partial larynegectomy for functional or oncologic reasons, total laryngectomy remains an excellent alternative. Again, there is a significant increase in the complication rates. Salvage total laryngectomy can also be utilized if conservation salvage efforts fail.

### Management of the Neck

New options for surgical management of the primary laryngeal tumor require us to revisit how we manage the neck. Regional lymphatic spread is uncommon for glottic cancer,[73] but is an important consideration for patients with supraglottic cancer. Even for N0 patients, 30% may occult lymphatic spread.[74] It is therefore recommended that the levels II to IV of the neck be addressed bilaterally for all supraglottic tumors, either surgically, or with postoperative radiotherapy.[75,76]

## FUNCTIONAL OUTCOMES AFTER FUNCTION-PRESERVING LARYNGEAL SURGERY

The reintroduction of surgery into the multidisciplinary paradigm, especially for early-stage disease, has introduced not only confusion and uncertainty, but also the opportunity to improve the care for patients with laryngeal cancer.

At present, there is no comparative level A evidence-based medicine comparing oncologic and functional endpoints after radiation therapy, open surgery, or transoral endoscopic surgery for laryngeal cancer. For each modality, much of the published literature is retrospective and confounded by selection bias, heterogeneity in study population, and inconsistency of outcome measures. So a consensus for how to treat the disease relies on physician preference and patient choice.

In the literature, there's a bias suggesting that radiation therapy results in better overall voice outcomes.[14] Sjogren et al. found no significant difference in posttreatment speech outcomes in T1a midcord glottic cancer treated either with laser excision or radiotherapy.[77] Voice-handicap index scores and perceptual, acoustic, aerodynamic, and stroboscopic analyses demonstrated no significant difference. Using a similar retrospective cohort design, Hirano

(c) 2014 Wolters Kluwer. All Rights Reserved.

et al. found an interesting discrepancy between a higher incidence of hoarseness, incomplete glottal closure, and altered vocal fold vibration with TLM, yet no difference in overall global voice function.[78] A series of additional reports demonstrate a similar equivalence in voice outcomes after either radiotherapy or laser surgery.[79,80]

Clearly though, case selection is important. For patients undergoing TLM, resections extending to or into the vocalis muscle ELS/Remacle I-c and beyond are associated with worse postoperative voice quality.[79,81,82] In view of these data, subepithelial and even subligamentous cordectomy may provide a good overall voice outcome. However, naturally, the more extensive and deep a soft tissue resection is required (> ELS/Remacle I-c), the less certain is the overall voice result. Involvement of the anterior commissure remains an issue of great interest and debate. Here also, both modalities may be associated with anterior glottis web remains, but the final impact of treatment on voice remains unknown.

For early- to intermediate-staged glottic laryngeal cancer, swallowing dysfunction is rare after TLM. For supraglottic cancers, aspiration must be expected at least in the short term.[83] However, for most patients, nasogastric tubes are usually removed within 3 weeks.[84] Without disrupting the supporting laryngeal musculature and superior laryngeal neural network, transoral endoscopic surgery is associated with a much faster return to normal deglutition, when compared to open SGL or SCPL. Sasaki et al. found that the glottic closure reflex returned within 72 hours after endoscopic SGL, compared with nearly 3 weeks for patients undergoing open SGL.[85] Similarly, after SCPL, most patients achieve full oral diets,[58,86–89] most within the first postoperative month.[58] For more advanced-stage patients, T stage and a history of previous radiotherapy were associated with the need for more long-term dysphagia, requiring gastrostomy.[83,90]

## CONCLUSION

Up-to-date multidisciplinary management of early and intermediate laryngeal cancer now includes several new surgical options.[91,92] In the absence of prospective clinical trials comparing surgery with radiotherapy to guide treatment decisions,[93] clinicians should offer the range of treatment options for patients. The largely retrospective literature suggests similar rates of local control and survival among these modalities, especially for T1 tumors.

CHAPTER 19

# Cancers of the Hypopharynx and Cervical Esophagus

## PART A:
## General Principles and Management

Tim J. Kruser, Nitin A. Pagedar, Henry T. Hoffman, and Paul M. Harari

## INTRODUCTION

Cancers of the hypopharynx and the cervical esophagus share a number of overlapping features with regard to risk factors, epidemiology, management, and treatment outcomes. The anatomy of this region is served by a rich lymphatic network; therefore, presentation with nodal metastases is commonplace. In addition, patients with hypopharynx and cervical esophageal tumors frequently present with advanced-stage disease and harbor medical comorbidities that may limit the feasibility of delivering aggressive cancer care. Therefore, despite therapeutic advances in recent years, oncologic outcomes in these tumors remain relatively poor. Although organ-preservation surgery may be feasible in selected early-stage tumors, surgical management more commonly requires radical surgery such as laryngopharyngectomy or pharyngolaryngoesophagectomy. These procedures result in significant functional impairment, as well as cosmetic changes, and therefore tumors of the hypopharynx and the cervical esophagus are commonly managed with radiation or chemoradiation in an effort to control tumor while preserving organ function.

Cancers of the hypopharynx and the cervical esophagus are commonly considered together, as they share many features, and tumor frequently extends from one anatomic region into the other. Cancers of the hypopharynx accounted for 5.2% of upper aerodigestive malignancies from 2000 to 2008.[1] Similarly, cervical esophageal cancer is rare, with only 2% to 10% of esophageal carcinomas occurring in the cervical location.[2] In a recent worldwide study of >4,500 esophagectomy patients, upper esophageal tumors accounted for only 4.1% of the cohort.[3] The relative rarity of these tumors lends itself to grouping them together in order to effectively study epidemiology, management strategies, and outcomes. However, randomized control studies specific to tumors of the hypopharynx and/or the cervical esophagus are rare; studies of these cancers are often retrospective, incorporating heterogeneous management strategies spanning many years, and in some cases decades. The relative rarity of these tumors leads to a paucity of large-scale clinical trials data with which to base treatment guidelines.

Cancers of the hypopharynx and the cervical esophagus are commonly associated with tobacco use.[4,5] In addition, patients are typically elderly, with dysphagia and weight loss as a result of their tumor burden and/or a poor baseline diet.[5,6] These matters complicate management decisions and delivery of effective therapy. Given the complexity of these tumors, the surrounding structures, and frequent patient comorbidities, management of patients warrants multidisciplinary management with evaluation by head and neck, reconstructive, and thoracic surgeons, medical oncologists, radiation oncologists, speech/swallow therapists, nutritionists, and social workers. Despite advances in the treatment of hypopharyngeal and cervical esophageal cancer, the overall outcome in these patients remains poor. Efforts to improve cure rates and reduce treatment-related morbidity, including the incorporation of molecularly targeted agents, remain vital for the future.

### Incidence, Etiology, and Epidemiology

In the United States, cancer of the hypopharynx and cervical esophagus account for <10% of the tumors of the upper aerodigestive tract.[7] Approximately 1,800 cases of hypopharyngeal cancers are diagnosed each year in the United States.[8] Tumors of the cervical esophagus account for 5.3% of all esophageal cancers,[7] which equates to roughly 900 of the nearly 17,000 esophageal cancer cases per year in the United States.[9] Squamous cell carcinoma (SCC) accounts for 95% of cancers in the hypopharynx and cervical esophagus, and the causative factors for SCC in these locations are shared.

The mean age of patients presenting with hypopharyngeal cancer is 65, with three-fourth of cases occurring in men. More than 90% of patients will report a tobacco history.[10] Alcohol consumption potentiates the carcinogenic effects of cigarette smoke; in combination, heavy tobacco and alcohol users are at

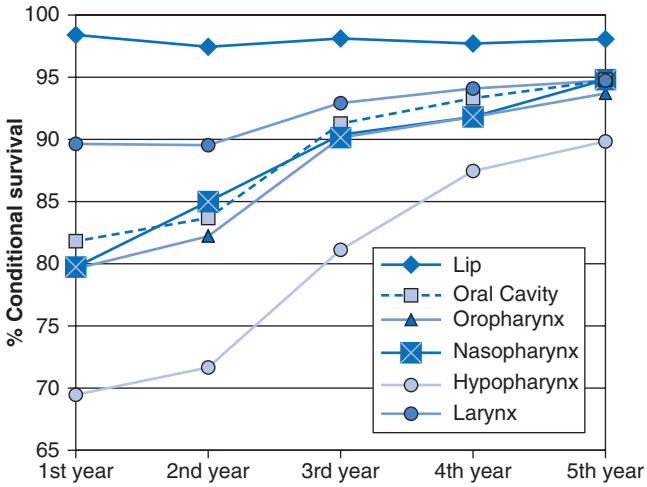

**FIGURE 19-1.** Conditional 5-year survival of head and neck cancers. A nearly 30% difference exists in survival through the first year, with hypopharynx cancers faring the poorest. Hypopharyngeal cancer patients continue to have lower rates of survival in years 2 to 5; secondary malignancies and comorbidities contribute to this phenomenon.

*Source:* Reprinted with permission from Cooper JS, Porter K, Mallin K, et al. National Cancer Database report on cancer of the head and neck: 10-year update. *Head Neck.* 2009;31:748–758.

up to 100 times elevated risk of developing tumors in the upper aerodigestive tract as compared with nonsmoking, nondrinking individuals. In addition to potentiating the effects of tobacco, a moderate to high consumption of alcohol can put nonsmoking individuals at a higher risk for hypopharyngeal and cervical esophageal cancers (Table 19.1).[7,11] Alcohol appears to have a stronger neoplastic effect in the hypopharynx than in the larynx, and dark liquor may carry a higher risk than light liquor.[12] In addition to tobacco and alcohol, gastroesophageal reflux, obesity, and achalasia can lead to higher rates of esophageal cancer.

As tobacco and alcohol are the major causative agents for tumors of the hypopharynx and cervical esophagus, field cancerization is a common phenomenon in these patients. The wide mucosal exposure to carcinogens results in a field of diseased mucosa characterized by high-grade dysplasia, giving rise to the index hypopharyngeal or cervical esophageal tumor. Therefore, these patients have high rates of synchronous and/or metachronous upper aerodigestive primary tumors. Approximately 10% of patients may be found to have synchronous primary tumors,[13] and up to 20% will develop a metachronous second primary tumor. Hypopharyngeal cancer patients have a worse overall survival than other malignancies of the head and neck due to the tendency for advanced disease at presentation.[10] In addition, even among survivors of the initial presenting lesion, survivorship is poorer in the following years; the fact that metachronous malignancies are more common in these patients than in other head and neck squamous cell carcinoma (HNSCC) patients contributes to this observation (Fig. 19-1). Counseling patients on smoking cessation can diminish treatment-related side effects, can minimize the risk of subsequent malignancies of the upper aerodigestive tract, and should be emphasized during the initial evaluation of these patients.

Occupational factors may also play a causative role in the formation of cancers of the hypopharynx and the cervical esophagus. Two European studies have shown that masons, iron workers, railway workers, cement industry workers, and rock diggers demonstrate high rates of cancer in the larynx and the pharynx,[14,15] suggesting that coal dust, steel dust, iron compounds, and fumes may contribute to carcinogenesis in these anatomic regions. In addition to occupational exposures, dietary factors can influence cancer rates in the hypopharynx and the cervical esophagus. High consumptions of salted foods and nitrosamines have been linked to esophageal SCC.[16] Although the incidence of esophageal SCC are approximately 2.5 to 5/100,000 for men in most areas of the world, rates in China, Singapore, Iran, former USSR, Chile, Brazil, Puerto Rico, Switzerland, France, and South Africa have been demonstrated to be much higher.[17] Dietary and occupational factors, as well as infection with the human papillomavirus (HPV) (see below), have been posited to account for these differences. One such example of a dietary risk for neoplasia is Plummer-Vinson syndrome, which is characterized by iron-deficiency anemia, hypopharyngeal webs, weight loss, and dysphagia. The syndrome is accompanied by an elevated risk of cancers in the postcricoid region.[7] This risk has been ameliorated by the addition of iron to flour in the northern Midwest United States and Scandinavian countries, where this syndrome was problematic.

The relationship between HPV infection and head and neck cancer has become well recognized in recent years, especially for cancers of the oropharynx. Epidemiologic studies have strongly suggested that HPV has a causative role in SCC of the base of tongue and the tonsil, with up to 60% to 70% of oropharyngeal SCC patients demonstrating evidence for HPV infection.[18] HPV positivity is a strongly positive prognostic factor in oropharyngeal SCC patients undergoing chemoradiation.[19] Whether HPV is similarly carcinogenic and/or prognostic in tumors of the hypopharynx and the cervical esophagus is less clear. Approximately 20% to 25% of hypopharynx cancer tumor specimens have detectable HPV DNA.[20,21] Additionally, the detection of antibodies against the HPV16 E6 and E7 antibodies is associated with an elevated risk of hypopharyngeal cancer,[22] suggesting a causal relationship. A large analysis of HPV rates in esophageal SCC showed the HPV can be detected by *in situ* hybridization in 23% of tumors, and in 15% by polymerase chain reaction.[17] A wide geographic variance in HPV detection was noted, with low detection rates in Europe and the United States and higher rates noted in high-risk areas for esophageal SCC such as China, Japan, and South Africa. However, while HPV-positive oropharyngeal patients are more likely to be younger and nonsmokers as compared with their

(c) 2014 Wolters Kluwer. All Rights Reserved.

HPV-negative counterparts, HPV-positive and HPV-negative esophageal cancer patients have been shown to have similar clinical risk factors.[23] Therefore, although current data are suggestive of a carcinogenic role for HPV in the hypopharynx and the cervical esophagus, prospective studies demonstrating that persistent HPV infections result in malignant transformation, such as those performed in uterine cervix cancer, may be necessary to confirm this suspicion.

## RELEVANT ANATOMY

The hypopharynx (sometimes referred to as the laryngopharynx) and the cervical esophagus are contiguous structures that collectively span from the hyoid bone to the thoracic inlet (Fig. 19-2). The hyoid bone demarcates the inferior border of the oropharynx, and the hypopharynx extends from the hyoid bone superiorly to the inferior border of the cricoid cartilage distally (approximately the level of the sixth cervical vertebral body). The cervical esophagus continues inferiorly from the lower edge of the cricoid cartilage to the thoracic inlet, approximated by the suprasternal notch.

The hypopharynx is composed of three primary anatomic subsites: the bilateral pyriform sinuses, the posterior pharyngeal wall, and the postcricoid region. Anteriorly, the aryepiglottic fold forms the border between the postcricoid hypopharynx and the supraglottic larynx; tumors of the aryepiglottic fold can be labeled of hypopharyngeal or of supraglottic larynx origin, depending on where the majority of the tumor bulk lies. The postcricoid region is composed of the mucosa overlying the cricoid cartilage and is bound by the posterior arytenoid cartilages and aryepiglottic folds superiorly and the cricopharyngeus inferiorly (Fig. 19-3).

The pyriform sinuses are bilateral conical structures with the open-ended bases superiorly at the level of the pharyngoepiglottic

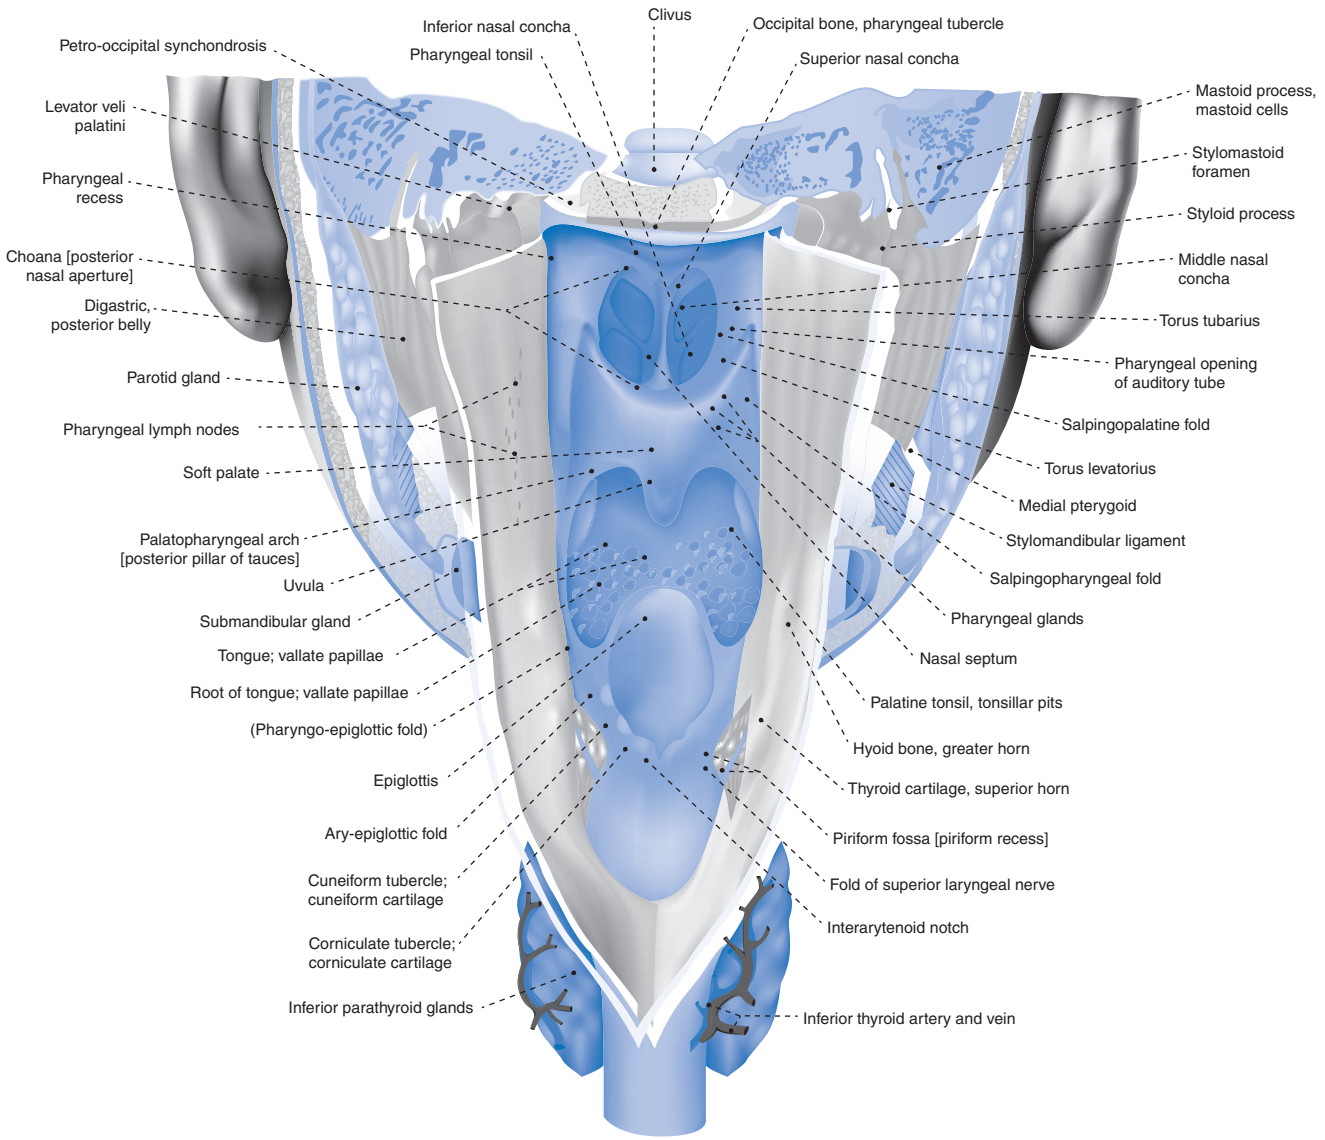

**FIGURE 19-2.** Posterior view of the larynx and hypopharynx as viewed by a posterior midline incision through the posterior pharyngeal wall, cricopharyngeus, and cervical esophagus.

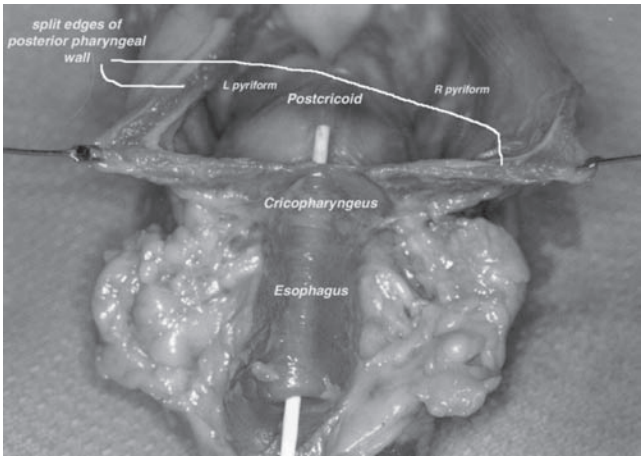

**FIGURE 19-3.** This anatomic specimen (with the posterior pharyngeal wall incised) allows a posterior view of the hypopharynx, demonstrating the three primary anatomic subsites (posterior pharyngeal wall, postcricoid region, and pyriform sinuses) of the hypopharynx.

fold, and the medial, anterior, and lateral walls narrowing inferiorly to form the apices, which extend slightly below the cricoid cartilage. The pyriform sinuses are open posteriorly and contiguous with the posterior pharyngeal walls. The internal branch of the superior laryngeal nerve pierces the thyrohyoid membrane, which surrounds the superior aspects of the pyriform sinuses laterally. Tumor involvement of the sensory component of this nerve, which synapses superiorly with the nerves of the external auditory canal in the jugular ganglion, can result in referred otalgia. The remaining sensation in this region is provided by nerve fibers of the glossopharyngeal nerve. The recurrent laryngeal nerve provides motor function to the cricopharyngeus muscle and the posterior cricoarytenoid muscles of the larynx, with remaining primary motor supply to the hypopharynx provided by the pharyngeal plexus.

The posterior pharyngeal wall is predominantly composed of squamous mucosa overlying the middle and the inferior pharyngeal constrictor muscles. The posterior pharygneal wall is separated from the prevertebral fascia by the retropharyngeal space; the mucosa overlying this region is thin and provides little barrier to direct tumor infiltration from the posterior wall to the prevertebral fascia. The distal fibers of the inferior constrictor coalesce to join the cricopharyngeus muscle, which serves as the junction between the hypopharynx and the cervical esophagus.

The cervical esophagus is lined by nonkeratinizing squamous mucosa overlying two muscular layers: an inner circular layer and an outer longitudinal layer. These muscles are striated in the upper third of the esophagus, whereas a gradual transition to smooth muscle occurs through the course of the thoracic esophagus. The cervical esophagus lies just posterior to the trachea, extending from the cricopharyngeus (C6 level) for about 4 to 5 cm to the thoracic inlet (suprasternal notch). Measured from the incisors (as commonly reported in endoscopic procedures), this ranges from 14 to 16 cm (cricopharyngeus) to approximately 20 cm. The tracheoesophageal grooves run laterally between these structures, and the recurrent laryngeal nerves and the paratracheal nodes are located in these grooves. The lateral lobes of the thyroid gland approximate the cervical esophagus and lie between the cervical esophagus medially and the carotid sheaths more laterally (Fig. 19-4). Vascular supply to the cervical esophagus is from branches of the inferior thyroid artery and veins, as well as ascending vessels along the thoracic esophagus. The sympathetic trunks and branches of the recurrent laryngeal nerves provide innervation.

There is a rich network of lymphatics that surround the hypopharynx and the cervical esophagus. From the hypopharynx, primary lymphatic drainage is to the jugulodigastric nodes (levels II–IV). Spinal accessory (level V) nodes are also at risk. Anterior lymphatic channels within the hypopharynx may drain from the pyriform sinuses directly through the thyrohyoid membrane along the path of the superior laryngeal artery. When tumors invade the posterior pharyngeal wall, lymphatic vessels passing through the inferior constrictor muscles place the retropharyngeal nodes at risk for involvement, including the most cephalad retropharyngeal nodes at the base of skull (nodes of Rouvière).

Lymphatic drainage from the cervical esophagus may mirror that of the hypopharynx and can pass superiorly toward the nodes surrounding the internal jugular vein. Lymphatics may also drain within the paratracheal and esophageal grooves to involve paratracheal lymph nodes. These lymph nodes are in the central compartment (level VI) and lie between the medial edge of the common carotid laterally, the trachea medially, inferior to the cricoid, and superior to the suprasternal notch. These paratracheal nodes are not usually included in a standard neck dissection and deserve consideration in hypopharyngeal and cervical esophageal tumors.[24] The paratracheal lymph nodes are contiguous with lymph nodes of the upper mediastinum inferiorly; the anatomic and radiographic border between these two regions is poorly defined. Nonetheless, caudal drainage from the hypopharynx and cervical esophagus can involve these lymph node basins, which may also warrant attention from surgeons and radiation oncologists.[25]

## NATURAL HISTORY, PATHOLOGY, PATHOGENESIS, AND PATTERNS OF SPREAD

### Natural History

Tumors of the hypopharynx and the cervical esophagus tend to present with advanced disease, usually including nodal metastases. A retrospective study from Washington University demonstrated that 87% of patients with pyriform sinus tumors and 82% of posterior pharyngeal wall tumors presented with either stage III or IV disease.[26] Similarly, a study of 107 patients with cervical esophageal tumors demonstrated that 79% of patients had stages III to IV disease.[27] Therefore, despite stepwise advances in the diagnosis and treatment of these tumors, outcomes remain disappointing. Hypopharynx cancers fare poorly as compared with patients with HNSCC in other tumor sites, with 5-year survival rates approximating 30% (Fig. 19-5).[8] Likewise, single institution reports have noted 5-year overall survival rates for cervical esophageal patients to range from 12% to 28%,[13,28,29] and cervical esophageal patients have demonstrably inferior outcomes to tumors located in the thoracic esophagus (Fig. 19-6).[3] A thorough understanding of the patterns of spread is essential to surgeons and oncologists in combating these aggressive tumors.

### Pathology

Historically, approximately 95% of tumors of the hypopharynx or the cervical esophagus are SCC. Recent analysis of the Surveillance, Epidemiology, and End Results (SEER) database from 2000 to 2008 support this claim, as 93.9% of hypopharynx cancers were SCC, whereas lymphoma, sarcoma, adenocarcinoma, and adenoid cystic carcinoma accounted for approximately 0.5% of cases each.[1] Similarly, the National Cancer Data Base (NCDB) Benchmark Reports evaluated 17,654 cases of hypopharyngeal cancer in the United States between the years of 2000 and 2008. More than 90% of cases were SCC.[30]

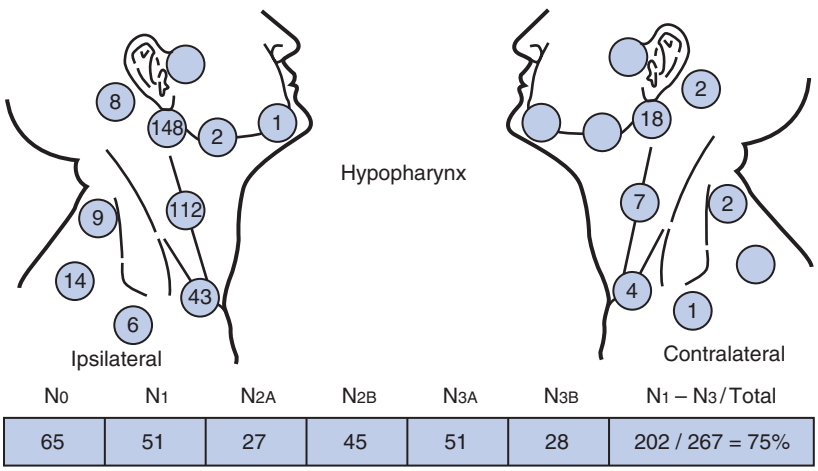
## Primary Tumor Location, Spread

Within the hypopharynx, tumor involvement of more than one subsite can cloud the ability of clinicians and/or radiologists to assign the tumor to a specific primary subsite. Within the Surveillance, Epidemiology, and End Results database from 2000 to 2008, 83% of tumors with known subsite arose within the pyriform sinus. The posterior pharyngeal wall accounted for 9% of primary tumors; the postcricoid was less commonly the primary site, accounting for 4% of tumors.[1] Cancers in the hypopharynx and cervical esophagus are prone to submucosal spread, though less so in the pyriform sinus than in other locations. Serial sectioning of surgical specimens has shown that 60% of hypopharynx cancers demonstrate significant subclinical spread, which can contribute to local failures following definitive management. Typical patterns of submucosal spread in such patients can include a range of 10 mm superiorly and 20 mm inferiorly.[31] Skip lesions from the hypopharynx therefore commonly involve the cervical esophagus. Cervical esophageal tumors are similarly prone to submucosal spread, especially caudally; up to 23% of cervical esophageal tumors may have clinical evidence of thoracic esophageal involvement at the time of diagnosis.[27]

Cancers originating in the pyriform sinus can infiltrate laterally to invade the posterolateral portion of the thyroid cartilage and/or the superior lobe of the thyroid gland. The medial wall is the most common site of involvement for pyriform sinus tumors, and tumor invasion in this location can result in invasion of the cricoarytenoid joint and/or muscle or the recurrent laryngeal nerve and may cause the vocal cord to become fixed. Superior extension may involve the aryepiglottic folds and arytenoids, and the paraglottic space is also at risk for involvement. Posterior pharyngeal wall extension is common as the tumor grows laterally.

Tumors primarily of the postcricoid area commonly extend inferiorly to involve the cervical esophagus, and circumferential growth frequently occurs, with invasion of the cricoid cartilage and cricoarytenoid muscle and resultant vocal cord fixation. These tumors are commonly extensive at presentation and portend a worse prognosis in comparison to tumors from other hypopharyngeal locations.[32] Tumors of the posterior pharyngeal wall tend to expand in the craniocaudal dimension, tracking submucosally in a superior fashion to the oropharynx or inferiorly to the cricopharyngeus and the cervical esophagus. Deep infiltration can involve the retropharyngeal space with access to the lymphatics in that region and subsequently into the prevertebral fascia.



Cervical esophageal tumors commonly extend into adjacent tissues at presentation.[13] Direct anterior extension can result in tumor involvement of the trachea, and involvement of the larynx and/or recurrent laryngeal nerve may result in vocal cord paralysis in approximately 10% of patients. Lateral extension into the thyroid gland is not uncommon, and possible posterior infiltration into the prevertebral fascia warrants careful evaluation on upfront diagnostic imaging. Thus, the extensive pattern of primary tumor infiltration in hypopharyngeal and cervical esophageal tumors can present considerable challenge in the effort to achieve clear surgical margins or achieve full dosimetric coverage with radiotherapy.

## Lymphatic Spread

A rich lymphatic network surrounds the hypopharynx and the cervical esophagus, and lymph node involvement occurs in the majority of tumors by the time of diagnosis. More than 50% of patients will present with clinically positive cervical lymph nodes at diagnosis. An additional 30% to 40% of N0 necks are found to show pathologic involvement when dissected electively,[33] rendering 65% to 80% of patients ultimately node positive.

The primary lymph node drainage of the cervical esophagus is to the paratracheal lymph node bed, and surgical series consistently demonstrate these lymph nodes to be most commonly involved, with approximately 40% to 70% of cases demonstrating metastatic involvement on pathologic analysis.[13,34,35] The general lymph drainage of the cervical esophagus is directed upward, and therefore levels III and IV of the neck are at the next highest risk, with levels II and V at lower but not negligible risk. Lymph node risk is associated with the length of the primary tumor, with lesions >5 cm showing lymph node involvement in 90% of cases.[36]

In patients with hypopharyngeal cancer, 50% to 80% of patients will have metastatic lymph node involvement. Jugular chain nodes (levels II–IV) as well as the retropharyngeal nodes are all at high risk for metastatic involvement. Lymphatics from the hypopharynx can drain anteriorly along with the lymphatics of the supraglottic larynx through the thyrohyoid membrane to primarily drain into levels II and III. Posterior lymphatics more commonly drain tumors of the inferior hypopharynx, penetrate the superior constrictor muscle, and drain to the lateral retropharyngeal and the paratracheal lymph nodes. Cross-draining lymphatics are present, and bilateral cervical node metastases are common (Fig. 19-7). In addition to the jugular chain lymph nodes typically addressed during neck dissection procedures, paratracheal lymph nodes are also at risk in hypopharynx cancer, with surgical specimens demonstrating involvement in 20% to 25% of cases[37,38] and warrant surgical consideration.

| N0 | N1 | N2A | N2B | N3A | N3B | N1 – N3 / Total |

### Distant Metastases

Cancers of the hypopharynx have higher rates of distant metastatic disease than do primary tumors of other HNSCC subsites.[39] Approximately 16% of hypopharyngeal cancer patients present with distant metastases at diagnosis.[40] Distant metastatic rates rise with time, especially in patients with residual or recurrent locoregional disease following initial therapy; rates of ultimate distant metastases have been reported up to 60% in older reports.[39] Data regarding initial metastatic presentation and ultimate metastatic risk with cervical esophageal cancer is less robust. Nonetheless, metastatic patterns of tumors from the hypopharynx and the cervical esophagus are similar, with the lung most commonly involved, followed in incidence by the mediastinal lymph nodes, the liver, and bone.

## CLINICAL PRESENTATION

Patients with cancers of the hypopharynx and the cervical esophagus initially develop nonspecific symptoms, which are commonly attributed to presumed infectious or gastrointestinal causes, leading to frequent delays in diagnosis. Therefore, the majority of patients will present with advanced local and/or regional disease. Presentations of hypopharyngeal and cervical esophageal tumors are similar, although cervical esophageal tumors tend to present earlier, as the lumen of the cervical esophagus is smaller than that of the hypopharynx. Dysphagia is the most common presenting symptom, present in up to 85% of cases, although a palpable neck mass is the most common physical finding.[13] Other common symptoms at presentation include odynophagia, weight loss, and neck pain. The majority of patients will note more than one of these symptoms by the time of diagnosis.[41] Rarely, early-stage tumors may be diagnosed in the evaluation of new-onset reflux symptoms.[10]

Other presenting symptoms can include unilateral ear pain (referred otalgia), classically seen in patients with tumors of the pyriform sinus. This results from involvement of the superior laryngeal nerve (a branch of the vagus nerve), which synapses with the auricular branch of cranial nerve X (the nerve of Arnold) in the jugular ganglion. Hoarseness can result from tumor infiltration into laryngeal structures or from involvement of the recurrent laryngeal nerve by tumors in the cervical esophagus or the postcricoid regions. Weight loss is common and is often substantial and can reflect poor nutritional status that may result from clinically significant dysphagia, alcohol dependency, and/or tumor-mediated cachexia/anorexia.

## DIAGNOSTIC EVALUATION AND CLINICAL STAGING

### Workup and Evaluation

Patients with tumors of the hypopharynx and/or the cervical esophagus should be evaluated in a multidisciplinary fashion, with input from surgeons, medical oncologists, radiation oncologists, speech-and-swallow specialists, social workers, dentists, nutritionists, and often specialists in alcohol and/or tobacco cessation. A detailed history should be elicited, with the nature and duration of symptoms documented, as well as the degree of weight loss. Assessment of dysphagia to both solids and liquids should be noted. Changes in voice quality and the complaint of referred otalgia are frequently present. Exposure in pack-years of cigarette smoking should be noted, as should the use of smokefree tobacco (chewing tobacco, snuff). Alcohol history should be elicited, with particular attention to current use, which may predispose patients to withdrawal.

The initial physical examination should indirect visualization of the full laryngopharyngeal axis. Given the high rate of second head and neck mucosal primaries, thorough attention to any other mucosal irregularities is warranted. Tumors of the pyriform sinus can be notoriously difficult to visualize; having the patients puff their cheeks (blow against closed lips) during nasopharyngolaryngoscopy can aid in visualization of the pyriform sinuses. In addition to the primary tumor (size, location, involved structures), particular attention should be paid to the mobility of the vocal cords with phonation, as this impacts tumor staging. Furthermore, the initial examination should include an assessment of dentition, particularly if (chemo)radiation is likely to be employed as a treatment modality. Unlike many tumors of the head and neck region, where indirect visualization may suffice, direct visualization under anesthesia is warranted in most tumors in these locations to fully delineate the extent of tumor spread and for biopsy confirmation of malignancy. An upfront thorough assessment of dentition allows for dental extractions, if needed, to be performed simultaneously while the patient is under anesthesia for tumor mapping under direct visualization (Table 19.2).

Physical exam should include assessment of cervical lymphadenopathy, providing a description of the size, location, number, mobility, and texture of suspicious lymph nodes. As all patients with biopsy-proven malignancies of the hypopharynx and/or the cervical esophagus warrant advanced radiographic imaging, fine-needle aspirate of enlarged lymph nodes to further confirm metastatic lymphadenopathy is rarely of value and should not be routinely performed.

Panendoscopy should be complemented by advanced imaging to assess the extent of the primary tumor and rigorously assess cervical lymph node chains for presence and/or extent of regional lymph node involvement. High-resolution computed tomography (CT) with contrast from the base of skull to below the clavicles is usually the imaging study of choice, although MRI can be utilized. A low threshold should be utilized in extending a CT through the lungs distally, as tumors of the hypopharynx and cervical esophagus have significant rates of pulmonary metastases at presentation. For the rare early-stage, lymph node–negative hypopharyngeal tumor, chest x-ray may suffice to rule out distant pulmonary metastases. Cervical esophageal tumors in particular commonly involve the lymph nodes of the upper mediastinum[25] and may have thoracic esophageal involvement,[27] and therefore CT imaging should routinely include the thorax in these patients.[18] FDG-PET (or PET-CT, with accompanying CT slice co-registration) is increasingly utilized in the upfront staging of tumors of the hypopharynx and the cervical esophagus. PET-CT allows for detection of distant metastases and provides information that may aide in the determination of lymph node malignant involvement. Furthermore, PET-CT imaging may influence radiation planning, in terms of field design and/or prescribed dose.[42] A recent prospective study of PET imaging in HNSCC tumor management included 46 patients with hypopharyngeal cancer. Therapeutic decisions were made with physicians blinded, and then unblinded, to FDG-PET imaging data. Tumor/node/metastases (TNM) staging was altered in 100 of 233 enrolled patients (43%), whereas PET altered the management of 32 patients (13.7%) (Table 19.3). This study, and similar experiences with PET imaging in HNSCC management support a role for PET-CT imaging in the upfront evaluation of patients with hypopharyngeal and cervical esophageal tumors. Worldwide, approximately 75% of oncologists utilize FDG-PET imaging in a proportion of esophageal cancer patients for staging purposes, with routine use slightly more common in North America than in Europe or Asia.[43]

Patients with cancers of the hypopharynx and/or the cervical esophagus commonly present with significant weight loss,

often as a result of progressive tumor-associated dysphagia and odynophagia. An assessment should be made of the patient's nutritional status, with attempts to correct nutritional deficits prior to the initiation of aggressive therapy. A nutritionist should be involved as a part of the multidisciplinary team. A percutaneous enteral gastrostomy (PEG) tube is commonly utilized. In surgical patients, a PEG tube is commonly placed at the time of surgery to allow for maintenance of nutrition during the postoperative recovery period. Whether upfront PEG tube placement should occur routinely in patients planning to undergo (chemo)radiation or should happen only in patients who demonstrate significant difficulties with maintaining weight and hydration during radiation is an area of debate. Patients with tumors of the hypopharynx and cervical esophagus tend to have more dysphagia, odynophagia, and prediagnosis weight loss than other HNSCC patients. Therefore, in our experience, the benefits of prophylactic PEG tube placement in terms of improved weight preservation and maintenance of hydration appear warranted for the majority of patients. Therefore, we routinely place PEG tubes during the pretreatment evaluation phase prior to chemoradiation.

**TABLE 19.3 Impact of FDG-PET on Staging and Management in 233 HNSCC Patients**

| Endpoint | Impact of FDG-PET |
|---|---|
| Discordant TNM stage | 100/233 (43%) |
| PET accurately upstaged | 30/233 (13%) |
| PET accurately downstaged | 17/233 (7.3%) |
| PET innacurately changed stage | 13/233 (5.6%) |
| No confirmed gold standard TNM | 40/233 (17%) |
| **Impact on patient management** | |

*Source:* Adapted from Lonneux M, Hamoir M, Reychler H, et al. Positron emission tomography with [18F]fluorodeoxyglucose improves staging and patient management in patients with head and neck squamous cell carcinoma: a multicenter prospective study. *J Clin Oncol.* 2010;28:1190–1195, with permission.

In addition to input from a nutritionist, a formal evaluation by speech-and-swallow therapists before initiation of therapy to assess baseline dysphagia is valuable. If swallowing dysfunction is noted, adaptive techniques may be taught to the patient to improve caloric intake and minimize aspiration risks. Although informal bedside assessment may be performed of swallow function, a more definitive fluoroscopic barium swallow study (videopharyngogram or oro-pharyngeal motility study [OPMS]) is usually preferable. Close posttreatment surveillance with a speech-and-swallow specialist familiar with the patient is important following definitive therapy.

All patients should undergo dental evaluation, with routing cleaning and Panorex imaging to assess for periapical abscesses, unerupted third molars, or other pathology prior to initiation of therapy. For patients who receive (chemo)radiation, long-term xerostomia may result and places patients at risk for accelerated dental decay. Therefore an assessment of teeth in poor repair that may warrant extraction is warranted, especially for any teeth that

(c) 2014 Wolters Kluwer. All Rights Reserved.

occupy a region likely to receive high-dose radiation. Upfront removal of such teeth in poor repair is preferable to subsequent removal following radiation, as manipulation of the teeth and sockets following radiation places patients at risk for osteoradionecrosis. Dental extractions should precede radiation by 10 to 14 days to allow for adequate healing. For patients who have teeth that will remain in place through radiation should receive custom fluoride carrier trays. Long-term use following radiotherapy of fluoride can minimize dental decay in the setting of postradiotherapy xerostomia.

Patients with hypopharyngeal and cervical esophageal cancers commonly have ongoing issues with alcohol addiction and tobacco dependency. Engagement with specialists for counseling and other methods to aide tobacco and alcohol cessation can be valuable. Medications such as the nicotine patch can be prescribed by surgeons and oncologists to assist patients with tobacco cessation. Additionally, many of these patients with benefit from input from social workers, as they often face issues such as financial difficulties, lack of transportation for appointments, and limited family/social support. A case manager or social worker can help these patients navigate the medical system and cope with these concerns through their cancer management.

## Staging

In 2009, the American Joint Committee for Cancer (AJCC) updated their staging system, releasing the 7th edition.[44] While the AJCC staging system provides a platform for grouping patients, in order to help guide discussions between physicians and for assessment of outcomes, patient factors include comorbidities, age, and motivation for organ preservation must be taken into account when considering management of an individual patient. For tumors of the hypopharynx, no significant changes were instituted in the 7th edition, with the exception that tumors extending to the esophagus are now T3 (previously T4a). T1 tumors are <2 cm in greatest dimension and limited to one subsite. T2 tumors measure between 2 and 4 cm, and/or invade more than on subsite of the hypopharynx or an adjacent site. Extension to the esophagus or fixation of the hemilarynx renders a tumor T3, as does size >4 cm. Tumor that invades either the hyoid bone, the thyroid gland, the central compartment soft tissue (prelaryngeal strap muscles and subcutaneous fat), or the thyroid and/or the cricoid cartilage is deemed moderately advanced local disease (T4a). Tumors are very locally advanced (T4b) if they invade the prevertebral fascia, involve mediastinal structures, or encase a carotid artery. Nodal staging and stage grouping is identical for hypopharyngeal cancer patients as to other HNSCC sites (excluding the nasopharynx).

For tumors of the cervical esophagus, major changes were implemented between the 6th (2002) and 7th (2009) editions of the AJCC staging based on a worldwide analysis of 4,627 patients with tumors of the esophagus and esophagogastric junction treated with surgery alone.[3,45] While the previous staging system was based only on tumor/node/metastases criteria, these analyses resulted in histology, grade, and location being incorporated into the stage grouping for 7th edition. T staging of esophageal tumors is based on depth of invasion and remains largely unchanged from the 6th edition of the AJCC staging system. As the vast majority of cervical esophageal tumors are SCC, the tumor (T) and the nodal (N) definitions for esophageal SCC are depicted in Table 19.4. It should be noted that only 4.1% of the tumors comprising the data set used for derivation of this staging system were located in the upper one-third of the esophagus, which would also include upper thoracic esophageal tumors.

Tis (*in situ*) is characterized by noninvasive high-grade dysplasia. T1a tumors invade the lamina propria or muscularis mucosae, with invasion of the submucosae staged T1b. T2 tumors invade muscularis propria, whereas T3 tumors invade adventitia.

**TABLE 19.4 T and N Staging for Esophageal Squamous Cell Carcinoma**

| Tumor Level of Invasion | T Descriptor |
|---|---|
| Noninvasive, high-grade dysplasia | Tis (*in situ*) |
| Invading the lamina propria or muscularis mucosal layers | T1a |
| Involving submucosa | T1b |
| Involving the muscularis propria | T2 |
| Involving the adventitia | T3 |
| Involving the diaphragm, pleura, or pericardium (resectable) | T4a |
| Involving aorta, trachea, vertebral body, other adjacent tissues (unresectable) | T4b |
| **Metastatic Lymph Node Burden** | **N Descriptor** |
| 1–2 lymph nodes | N1 |
| 3–6 lymph nodes | N2 |
| ≥7 lymph nodes | N3 |

*Source:* Adapted from Edge SB, Byrd DR, Compton CC, et al. *AJCC Cancer Staging Handbook.* New York, NY: Springer; 2010, with permission.

T4 tumors (invading adjacent structures) were split into T4a and T4b in the 7th AJCC system. T4a tumors are resectable tumors invading the pleura, pericardium, or diaphragm. T4b tumors are unresectable, invading other structures including the aorta, the trachea, and the vertebral body.

Nodal (N) staging also changed between the 6th and 7th AJCC staging systems for esophageal tumors. Previously lymph node staging was dependent on the location of lymph nodes, with lymph nodes in the cervical, scalene, internal jugular, periesophageal, and supraclavicular regions termed "regional" for cervical esophageal tumors. Currently, metastases in 1 to 2 regional lymph nodes renders a patient N1, metastases to 3 to 6 regional lymph nodes is N2, and involvement of 7 or more regional lymph nodes is N3. Regional lymph nodes are now designated as any nodes from the cervical nodes to the celiac nodes for all esophageal cancers, whereas previously cervical lymph nodes were deemed metastatic for thoracic esophageal tumors.

Grade and location now are also incorporated into AJCC staging for esophageal SCC, impacting the stage grouping in early-stage tumors (Table 19.5). Grade that cannot be assessed (grade x) and grade 1 tumors (well-differentiated) are grouped together, whereas grade 2 (moderately differentiated), grade 3 (poorly differentiated), and undifferentiated (grouped as grade 3 squamous) are grouped together. Furthermore, anatomic location impacts stage grouping. Tumors of the cervical esophagus are defined in this system as being bordered by the hypopharynx superiorly and by the thoracic inlet (sternal notch) superiorly, or from 15 to 20 cm from the incisors by endoscopy.[45]

# MANAGEMENT STRATEGIES AND TREATMENT PLANNING GUIDELINES

Historically, surgery has been a mainstay in management of cancers of the hypopharynx and cervical esophagus. This has typically involved sacrifice of the larynx, either via laryngo-pharyngectomy

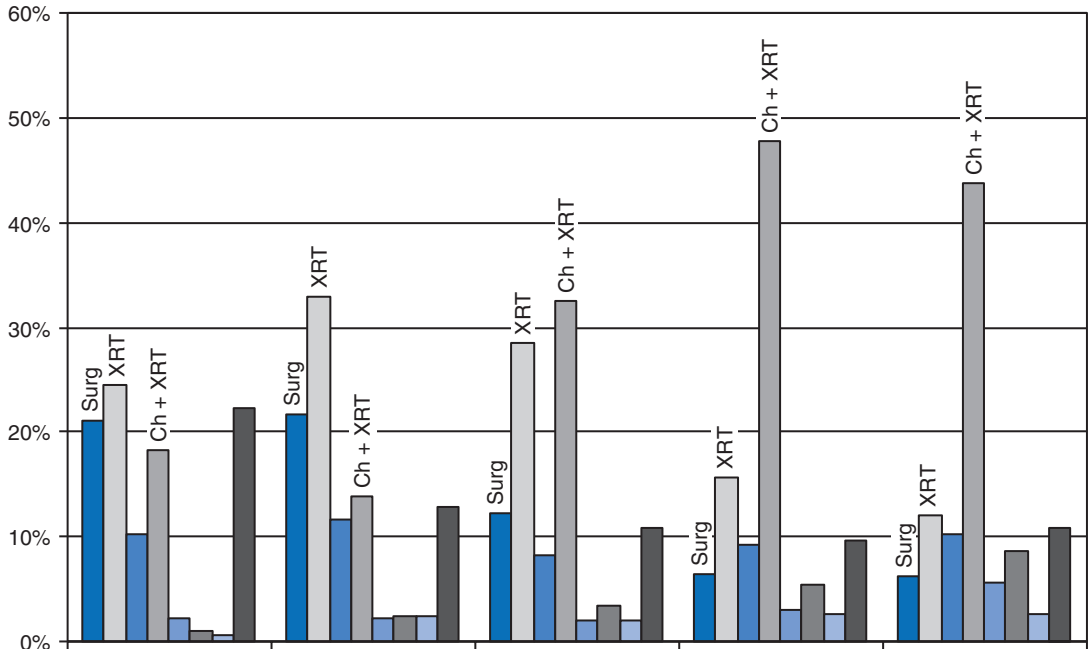
or pharyngolaryngoesophagectomy. However, in recent years, increasing efforts toward organ preservation have become more prevalent. As tumors of the hypopharynx and cervical esophagus tend to present with locally advanced and/or node-positive disease, these efforts at organ preservation most commonly involve chemoradiation for locally advanced disease (Fig. 19-8). However, more advanced surgical techniques may allow for organ preservation in those patients who present with early-stage disease amenable to larynx-sparing surgery. Nonetheless, radical surgery remains an important component of management and should be considered as an alternative to organ-sparing approaches, depending on the motivation of the patient for organ preservation and the patient's medical comorbidities. Active rehabilitation therapy in order to maximize eventual speech and swallow function must accompany all definitive management, regardless of the specific treatment approach. Rehabilitation and posttreatment surveillance are discussed at the end of this section.

## Hypopharyngeal Cancer Management



***Stages I to II Disease (T1–2, N0).*** A large analysis of 853 hypopharyngeal cancer patients revealed that approximately 84% of patients will present with either T3–4 and/or node-positive disease,[46] whereas a review of 1,210 hypopharyngeal cases diagnosed in 2003 through the NCDB identified only 150 (12.3%) of cases to be stages I to II.[30] Therefore, stages I to II hypopharyngeal cancer is a relatively rare clinical scenario. In general, curative radiation therapy is preferred as the definitive treatment approach for patients with early-stage hypopharynx tumors, as it provides a good chance for organ preservation. Alternatively, open or endoscopic surgery (partial laryngopharyngectomy) with ipsilateral or bilateral neck dissection may be performed (Table 19.6). More recently, transoral laser microsurgeries have been performed with promising results in selected early-stage lesions.

***Radiation Therapy.*** Radiation is commonly favored in stages I to II hypopharynx cancers, as surgery in this region often results in chronic aspiration due to injury/sacrifice of the superior laryngeal nerve. Additionally, given that concerning pathologic features (positive margins, node positivity, pathologic T3 or T4 status, perineural invasion, lymphovascular invasion) often prompt postoperative (chemo)radiation following surgery, definitive radiation may allow patients to forego the toxicities associated with multiple treatment modalities. However, for patients who receive definitive radiation, it is important for the head and neck surgeon to remain involved in the patient care. Endoscopic biopsy for detailed assessment of tumor extent may be necessary prior to definitive radiation, and the surgeon should remain involved in the multidisciplinary oncologic follow-up after treatment.

Radiotherapy for stages I to II hypopharygeal cancer classically consists of a 6-to-7-week course, with treatment delivered 5 days per week.[47–52] Lymphatic coverage from the skull base to the clavicle is routine for patients undergoing radiation for hypopharyngeal cancer. Conventional field design utilizes opposed lateral fields covering the primary tumor and upper neck regions matched to an anterior field covering low-neck and supraclavicular neck lymphatic regions. The superior border of the opposed lateral radiation fields should include jugular chain lymphatics to the base of skull, whereas inferiorly fields should extend to the lower aspect of the cricoid cartilage, unless more inferior coverage is mandated by extensive caudal tumor extension. Anteriorly, fields should flash skin at the level of the thyroid cartilage, and posterior borders should extend behind vertebral spinous processes, or further if needed to cover metastatic level V lymph nodes. Wedges or custom compensators should be used for the lateral fields to account for varying tissue thickness of the head and neck to maximize dose homogeneity. When the spinal cord reaches a dose of ≤45 Gy, shrinking-field techniques should be used to maintain the spinal cord dose below tolerance. Posterior neck electrons supplement dose to the posterior cervical lymph nodes, whereas 54 to 60 Gy should be delivered to the remaining lymphatics via lateral fields before final mucosal reductions are made to deliver 66 to 70 Gy to the primary tumor plus a margin (for T1 tumors) or 70 Gy for T2 tumors. Three-dimensional planning with intensity-modulated radiation therapy (IMRT) is now commonly utilized for radiotherapy in hypopharynx cancer and will be discussed further in the sections discussing management of locally advanced disease.

In patients with head and neck SCC undergoing definitive radiotherapy, rapid proliferation (repopulation) of tumor cells between radiation fractions can limit the effectiveness of radiotherapy. Intensified radiation fractionation schedules, including hyperfractionation and accelerated fractionation, have demonstrated improved local control rates for head and neck cancer patients in randomized studies. Hyperfractionation consists of twice-daily radiation treatments, separated by at least 6 hours (i.e., 1.1–1.2 Gy BID) and has shown promising results in early-stage tumors.[49,53] Accelerated fractionation (i.e., 6–7 fractions per week or concomitant boost regimens) also have shown demonstrable benefits in HNSCC radiation patients.[53–55] Recently, a meta-analysis examining multiple randomized control trials of altered fractionation versus conventional fractionation demonstrated an overall survival benefit with altered fractionation.[56] The benefit was greatest with hyperfractionation and was most pronounced in younger patients. Therefore in patients undergoing

radiation alone, especially for bulky T2N0 lesions, altered fractionation deserves consideration. Alternatively, concurrent chemotherapy may be considered for bulky T2 lesions to enhance locoregional control (see below sections for rationale).

***Larynx-preserving Surgery.*** Primary surgical management of patients with early-stage cancer of the hypopharynx is indicated in patients who refuse radiation, have had previous radiotherapy, or those patients in which organ preservation is feasible and postoperative radiation is unlikely to be used. As submucosal spread of tumor is common (making margin-negative resections difficult) and 30% to 40% of clinically N0 patients will have pathologically involved lymph nodes that may warrant postoperative radiotherapy, careful patient selection is necessary before attempting organ-preservation surgery. Additionally, adequate counseling on the possibility for adjuvant radiotherapy should be given to all early-stage hypopharyngeal cancer patients considering upfront surgical management, as a significant portion of patients will experience the side effects of both treatment modalities if upfront surgery is chosen. Additionally, the primary concern after organ-preserving surgery is dysphagia, and adjuvant radiation will commonly worsen swallow function due to radiation-induced edema and/or fibrosis. Given these considerations, all hypopharyngeal cancer patients should discuss treatment options with a multidisciplinary team of specialists before embarking on a treatment course.

Favorable areas for larynx-preserving surgeries include the upper pyriform sinus or posterior pharyngeal wall. Tumors causing impairment in vocal cord mobility, involving the pyriform apex, the postcricoid area, or the anterior wall of the pyriform sinus often require total laryngectomy, as do patients with poor lung function.[57] Cartilage invasion is also a relative contraindication to organ-conserving surgery in the hypopharynx. Supraglottic laryngectomy standardly encompasses the aryepiglottic fold and may be extended to resect the upper pyriform sinus. Small tumors of the posterior pharyngeal wall can at times be removed successfully by either an open approach or via endoscopic laser resection. If an adynamic and insensate free flap is utilized with an open approach, dysphagia (often requiring NPO status) is commonly encountered postoperatively.

Supracricoid hemilaryngopharyngectomy can be considered with selected T1–2 tumors of the aryepiglottic fold or upper pyriform sinus. Good pulmonary reserve is necessary before consideration can be given to this procedure. Free-flap reconstruction innovations may allow for retention of speech and swallow function after this procedure, despite extensive soft-tissue resection. Rigid cartilaginous support with temporo-parietal flap and radial forearm free flap can be utilized in cancers without involvement of the pyriform sinus apex or postcricoid region to retain function in selected patients.[58] Bilateral neck dissections (levels II–IV) should accompany most organ-preserving surgeries in hypopharygeal cancers; close-interval CT scan surveillance can be considered in select T1N0 patients.

Transoral methods, including transoral laser microsurgery (TLM) and transoral robotic surgery, have been recently employed in attempt to achieve margin-negative tumor resection while minimizing damage to adjacent normal tissues. With these approaches, neck dissection is often deferred until final margin analysis is performed on the primary tumor specimen, with delayed neck dissection performed if margins are negative, or more radical open surgery (or radiation ± chemotherapy) entertained when primary margins are positive. This approach may facilitate surgery without the need for tracheostomy and feeding tubes, and oncologic outcomes appear similar to open surgical approaches for appropriately selected T1–2 lesions. However, it should be noted that adjuvant (chemo)radiotherapy is utilized in the majority of T1–2 patients in reports of this approach.[59–62]

## Stages III to IVa Disease (T1–2, Node Positive, or T3-4a), Resectable

As discussed above, patients with early T-stage disease may achieve negative primary tumor margins via larynx-sparing surgical approaches. However, the presence of clinically apparent lymph node metastases at presentation suggests that adjuvant (chemo)radiation will be indicated following definitive surgical management in the vast majority of these patients (see indications in postoperative radiation section below), which can exacerbate swallowing complications of larynx-sparing surgical approaches. Patients with T3–4 hypopharyngeal tumors (and advanced T2 lesions) generally require laryngopharyngectomy for surgical management and adjuvant (chemo)radiotherapy. Therefore, given the need for radiotherapy and goals of organ preservation, definitive chemoradiotherapy is the treatment most commonly utilized in stages III to IV hypopharyngeal cancers (Fig. 19-8).[30] Induction chemotherapy can also be utilized and may be appropriate for some patients[63] prior to definitive therapy, with recent randomized trials showing benefits in terms of overall survival to three-drug induction regimens as compared with two-drug regimens.[64,65]

***Chemoradiation (± Neck Dissection).*** Desire for organ preservation in locally advanced disease is the primary indication for nonoperative management in patients who may be technically resectable. Other reasons to forego surgical management include medical comorbidities that preclude general anesthesia. Conventional radiotherapy, with or without chemotherapy, is utilized in this scenario and typically aims to deliver 70 Gy in 2 Gy daily fractions to gross disease, with 50 to 60 Gy delivered to areas at risk for microscopic disease. For patients with locally advanced hypopharyngeal cancer, three-dimensional CT-based planning has become routine. This technology allows for more accurate target volume delineation, as well as three-dimensional representations of dose distributions (Fig. 19-9).

In patients with good performance status and stages III to IV disease, concurrent systemic chemotherapy should be considered. Numerous randomized controlled trials in head and neck cancer radiotherapy have demonstrated benefits to concurrent chemotherapy,[66] and a recent meta-analysis demonstrated a 6.5% benefit in terms of overall survival with the use of concurrent radiosensitizing chemotherapy[67] (Fig. 19-10). This benefit was noted primarily in younger patients, and no benefit was demonstrated in patients above age 70; therefore, consideration to radiation alone should be given to elderly patients who are undergoing nonoperative management for locally advanced hypopharyngeal cancer. For patients who are not candidates for concurrent chemotherapy (renal insufficiency, poor performance status, elderly), altered fractionation can be considered (see above discussion in early-stage section). However, similar to analyses of concurrent chemotherapy, where a benefit was not demonstrable in patients above the age of 70, altered fractionation has not been shown to be significantly advantageous in patients above the age of 70 in meta-analysis.[56] For patients with modest performance status or the elderly, once-daily radiation schedules without concurrent chemotherapy offer a reasonable treatment option.

Molecularly targeted agents provide another alternative to concurrent chemotherapy in patients with locally advanced hypopharyngeal cancer. Inhibitors of the epidermal growth factor receptor (EGFR) such as cetuximab have the most mature clinical data supporting their use in such patients. A randomized, phase III study in advanced head and neck cancer patients (including the hypopharynx) of radiation alone versus radiation plus weekly cetuximab demonstrated a 10% overall survival benefit at 5 years for the patients treated with concurrent cetuximab.[68,69] Concurrent cisplatin exacerbates common

radiation-induced toxicities (mucositis, dysphagia) and causes other nonoverlapping toxicities (anemia, leukopenia, renal insufficiency, ototoxicity, nausea/vomiting), thereby limiting the ability of many patients to receive concurrent cytotoxic chemotherapy. In contrast, concurrent cetuximab was not demonstrated to worsen acute radiation-induced toxicities and therefore may be tolerated by patients unable to tolerate concurrent cisplatin with radiotherapy.

IMRT is now the dominant technique for radiation delivery in locally advanced head and neck cancer. IMRT can minimize dose to normal structures and diminish toxicity; this is particularly useful to avoid excessive radiation dose to contralateral parotid glands, minimizing late radiation-induced xerostomia. The best candidates for IMRT-mediated sparing of contralateral parotid radiation are those patients in whom the bulk of disease is well lateralized, that is, T1–3 primary lesions with ≤N2b neck disease. The cephalad margin of the N0 contralateral neck radiation can often be limited to the C1–2 interspace in such patients to facilitate parotid sparing.[70] Recently, a randomized control trial demonstrated the superiority of IMRT over conventional radiotherapy for parotid sparing in locally advanced oropharyngeal and hypopharyngeal cancer patients.[71] An avoidance goal of limiting the contralateral parotid to <24 Gy was utilized in the IMRT radiation plans, and this resulted in a reduction of grade 2 or worse xerostomia at 24 months from 83% (conventional radiation) to 29% in the IMRT patients. Improved quality-of-life (QOL) scores were observed in the IMRT patients, strongly supporting the use of IMRT in locally advanced hypopharyngeal cancer patients.

(c) 2014 Wolters Kluwer. All Rights Reserved.

For patients undergoing primary radiation or chemoradiation, consideration should be given to postradiation neck dissection. For patients with N0–N1 necks, postradiotherapy neck dissection is rarely utilized. Many institutions utilize postradiotherapy neck dissections for patients with N2–N3 neck disease in attempt to enhance regional disease control[72,73]; in such cases, radiation dose to gross nodal disease can be limited to 60 to 63 Gy. Alternatively, gross nodal disease can be carried to 70 Gy, with neck dissection utilized only for patients with concerning imaging findings on postradiation imaging studies. Increasingly, a PET-CT scan at 10 to 12 weeks in patients with N2–N3 disease who receive 70 Gy to the gross nodal disease is used for such an assessment, as studies have demonstrated that complete clinical response by this assessment has a very high negative predictive value.[74]

***Primary Resection and Postoperative Radiation.*** Total laryngectomy and partial pharyngectomy (laryngopharyntectomy) with bilateral neck dissections was the historical mainstay of treatment for locally advanced hypopharygeal cancer. While a minority of favorable T3 hypopharynx cancers presenting in the upper portion of the pyriform sinus may permit oncologic resection via extended supraglottic laryngectomy or extended vertical partial laryngectomy with free-flap reconstruction, the vast majority of T3–4 tumors require total laryngectomy.

When laryngopharyngectomy is undertaken, efforts are made to preserve a posterior strip of the hypopharynx to form the basis of a conduit for passage of food and saliva. Primary closure (such as over a nasogastric tube) of the hypopharyngeal mucosa is now discouraged when <3 to 3.5 cm of the posterior pharyngeal wall mucosa is available to be tubed on itself. Free-flap reconstruction with a pedicled or free flap to reconstruct the anterior and lateral walls of the hypopharynx results in superior swallow function most commonly in such cases. When the entire hypopharynx must be removed for bulkier tumors, a gap exists between the oropharynx and esophagus. In these cases, radial forearm free flaps, anterolateral thigh flaps, free jejunum, or pedicled myocutaneous free flap are methods that may provide for a tubed fasciocutaneous flap to reestablish continuity of the alimentary tract.

***Postoperative Radiation.*** The majority of advanced hypopharyngeal cancers that undergo upfront surgery warrant postoperative radiation. Indications for postoperative radiation include pathologic T3–T4 tumors, N2–3 nodal disease (>1 involved lymph node), positive margins, perineural invasion, tumor emboli in adjacent vasculature, or extracapsular extension (ECE) of an involved lymph node.[75] Traditional postoperative radiation delivers 54 to 63 Gy to volumes at risk for microscopic residual disease, with areas of known ECE or margin positivity boosted to 60 to 66 Gy. Shrinking-field techniques can be used with conventional radiation field design, such that the entire cervical nodal chains bilaterally, from the base of skull to the clavicles are included. As described above, IMRT techniques are now commonly employed for postoperative radiation to reduce normal tissue toxicities.

The addition of cisplatin chemotherapy to postoperative radiation has been demonstrated to improve outcomes in high-risk patients, however, at the expense of additional toxicity. Two randomized trials, one from the European Organization Research and Treatment of Cancer (EORTC) group and another through the Radiation Therapy Oncology Group in the United States, evaluated the addition of 100 mg/m$^2$ cisplatin every 3 weeks to postoperative radiation in patients with locally advanced head and neck cancer, including hypopharyngeal cancer patients.[76,77] Although the entry criteria for the respective trials differed somewhat, a subsequently published analysis of the combined data suggested that patients with ECE and/or positive margins were most likely to benefit from the addition of chemotherapy to postoperative radiation (Fig. 19-11).[78] Given an approximate doubling of grade 3 acute adverse effects seen with the addition of concurrent chemotherapy, careful clinical judgment regarding patients most likely to benefit from this approach is necessary.

***Induction Chemotherapy and Sequential (Chemo) Radiation.*** In patients who would require total laryngectomy for adequate surgical resection, induction chemotherapy can be utilized to facilitate organ preservation in some cases. A European study for patients with advanced tumor of the hypopharynx randomized patients to primary surgical resection with total laryngectomy with postoperative radiation versus induction chemotherapy with 5-florouracil (5FU) and cisplatin followed by definitive radiation. In the patients randomized to induction chemotherapy and radiation, two-thirds of patients who survived were able to preserve their larynx, and no differences in 5- or 10-year survival or progression-free survival were noted, establishing this approach as

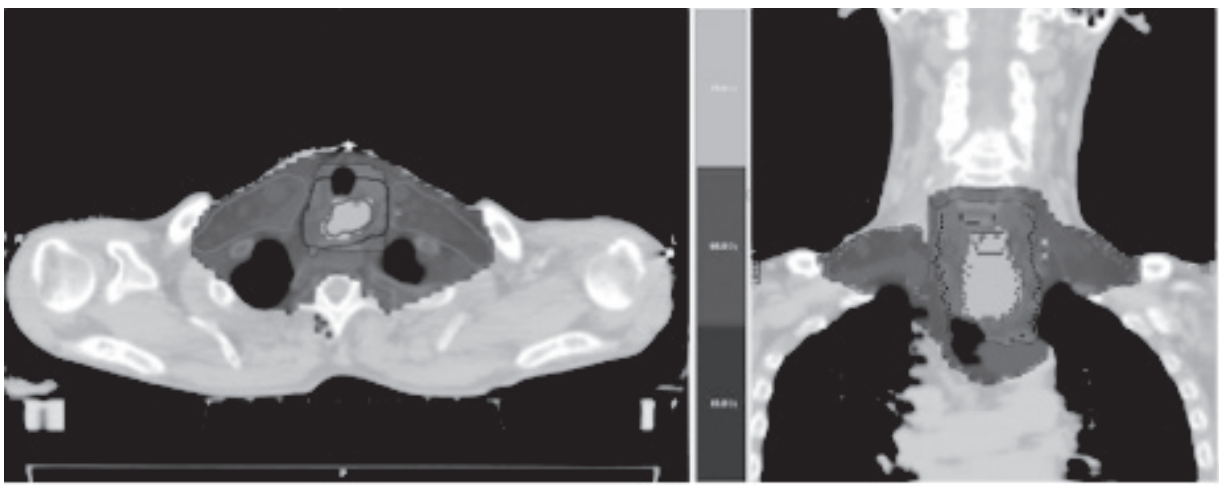

**FIGURE 19-11.** **(A)** Axial and **(B)** coronal representations of a patient with a T3N0 squamous cell carcinoma of the cervical esophagus treated with definitive chemoradiation. Helical tomotherapy was utilized to deliver 70 Gy to the primary tumor volume, 60 Gy to the high-risk clinical target volume, and 45 Gy to a prophylactic nodal volume, delivered with concurrent weekly cisplatin.

(c) 2014 Wolters Kluwer. All Rights Reserved.

an option for patients with advanced disease.[79] Cisplatin (P) and 5FU (F) in combination (PF) became a commonly used induction chemotherapy option.

Recently, the addition of docetaxel (T) to the backbone of cisplatin and 5FU (PF) has been studied in order to facilitate organ-preservation in patients with locally advanced cancer of the larynx or hypopharynx that would require total laryngectomy.[80] A French group randomized 213 patients to 3 cycles of induction PF or TPF. Response was assessed by laryngoscopy and CT/MRI imaging, and responders were treated with larynx-preserving (chemo)radiation, whereas nonresponders underwent laryngectomy and postoperative (chemo)radiation. TPF induction chemotherapy resulted in a higher tumor response rate (80% vs. 59%) than PF, allowing for a higher rate of laryngeal preservation (70% vs. 57%) at 3 years. Overall survival was 60% in both arms at 3 years.

***Unresectable, Nonmetastatic Disease.*** Patients with unresectable locoregional disease may warrant aggressive treatment with curative intent or may be best served by a palliative approach, with tumor burden, patient motivation, and performance status factoring into decision making. Curative-intent (chemo)radiation may be offered as above. For patients with high motivation and good performance status, induction chemotherapy followed by (chemo)radiation may be entertained. Two randomized studies have examined the addition of docetaxel (T) to the backbone of ciplatin and 5FU (PF) induction chemotherapy for patients with locally advanced, unresectable disease. TAX 323 was conducted by the EORTC and randomized such patients to induction TPF or induction PF, followed by definitive radiation alone.[65] TPF improved median overall survival as compared to PF. A similar study in the United States (TAX 324) randomized patients similarly to TPF versus PF induction chemotherapy, followed by definitive radiation with further concurrent chemotherapy (weekly carboplatin).[81] Improved overall survival was again demonstrated in the patients treated with TPF, and a subgroup analysis of patients with larynx and hypopharynx patients demonstrated improved survival as well as higher rates of laryngectomy-free survival.[82] These aggressive sequential therapy approaches may be considered in patients with good performance status, no contraindications to taxanes or platins, a high-tumor burden and/or advanced nodal disease.[63] However, these strategies are costly, toxic, and prolong the course of management. Randomized trials comparing these induction chemotherapy approaches with concurrent (chemo)radiotherapy have not yet been reported and will be important to determine the role for these regimens in the management in advanced head and neck cancer patients.

Patients with advanced disease and poor performance status who are not considered appropriate for aggressive radiation or chemoradiation can be offered palliative radiotherapy alone. Appropriate regimens include 4-5 Gy × 5 fractions over 1 to 2 weeks, which may be repeated 3 weeks later if initial tolerance is acceptable and response is seen. A comparative, nonrandomized study of palliative radiation regimens suggested that 3.7 Gy fractions twice daily × 2 consecutive days for 3 cycles every 2 to 3 weeks may offer similar palliation to other regimens, with less acute toxicity.[83]

## Cervical Esophageal Cancer Management

Large series evaluating management strategies for cervical esophageal tumors are lacking, and tumors in the cervical location comprise a small minority of cases enrolled in randomized studies evaluating management of esophageal cancers. Therefore, clear guidelines based on randomized data for management of tumors in this location do not exist. Pharyngolaryngoesophagectomy (PLE) with or without adjuvant radiotherapy has historically been the standard treatment approach for cervical esophageal tumors. However, given the impact of laryngectomy on QOL, concurrent chemoradiation with laryngeal preservation is commonly the preferred treatment approach for medically fit patients.[84] Many patients present with unresectable disease and/or metastatic disease, and aggressive treatment regimens may not be warranted in such patients.

***Resectable Disease.*** Large pattern of practice studies in the United States examining management of esophageal cancer have commonly excluded cervical tumors from their analyses.[85,86] Therefore, strong data of practice patterns in this rare tumor location are lacking, especially comparing upfront surgical treatment versus radiation approaches. However, oncologic outcomes appear to be similar between surgically treated patients and those managed with organ-sparing chemoradiation, with higher posttherapy QOL expected among the patients who can avoid pharyngolaryngoesophagectomy. When definitive radiation is delivered for curative intent, concurrent chemotherapy is indicated and is commonly utilized.[87]

***Chemoradiation.*** Practice patterns in esophageal cancer patients who are managed via nonoperative approaches have been heavily influenced by a randomized trial (RTOG 85-01) that randomized patients between dose-escalated radiation alone (64 Gy) versus chemoradiation utilizing 50 Gy with concurrent 5FU and cisplatin. Concurrent chemotherapy markedly improved the results; no 5-year survivors were seen in the radiation alone arm, whereas outcomes in the chemoradiation arm approximated surgical series (5-year survival of 26%).[88] Although cervical esophageal tumors were not enrolled, 88% of tumors in RTOG 85-01 were SCC, and therefore given the associated morbidity of operative management in cervical tumor locations, these results have been largely extrapolated to cervical esophageal tumors. Therefore, concurrent chemotherapy is most commonly employed with definitive radiation approaches for cervical esophageal tumors. Nonrandomized studies have shown survival outcomes following definitive chemoradiation in esophageal tumors to be similar to surgical series.[89–91]

Two approaches to definitive chemoradiation are commonly utilized. One approach is to treat cervical esophageal cancer with concurrent cisplatin and 5FU chemotherapy, as per RTOG 85-01. If this approach is chosen, valuable clinical trial data are available to guide radiation dosing. An intergroup phase III trial (INT 0123) randomized patients undergoing radiation with concurrent cisplatin and 5FU to a standard arm, with a dose similar to RTOG 85-01 (50.4 Gy), versus a dose-escalated arm treated with 64.8 Gy. Cervical tumors were enrolled in this study, and 86% of all tumors were SCC. Overall survival was not different between the standard arm and the dose-escalated arm (Fig. 19-12). Increased treatment-related deaths were noted in the dose-escalated arm, although this did not appear related to radiation dose as the majority of deaths on treatment in the dose-escalated arm occurred before patients received >50.4 Gy. Nonetheless, no differences were seen in cumulative local failure rates (Fig. 19-12), and therefore 50.4 Gy was felt to represent a standard dose when radiation was delivered with concurrent cisplatin and 5FU. Despite this, many current series specific to cervical esophageal tumors have reported radiation doses of 54 to 68 Gy with concurrent cisplatin and 5FU, with low rates of treatment-related mortality.[27–29,92] Although more advanced radiation delivery, including IMRT, may allow for safe dose-escalation beyond 50.4 Gy with concurrent 5FU and cisplatin, this approach should be undertaken cautiously. Alternatively, analogous to practice patterns in hypopharyngeal cancers, radiation may be delivered to doses of 60 to 70 Gy, with concurrent cisplatin chemotherapy.[28,93] A recent comparison of these two

approaches from Princess Margaret Hospital revealed similar oncologic outcomes between two cohorts of patients managed via these differing approaches.[28]

When designing radiation fields, careful review of endoscopic examinations, operative reports, and staging imaging studies is necessary. Additionally, the prospect of subclinical submucosal spread must be taken into account. Historical field design has encompassed a 5-cm margin in the cranial and caudal directions to cover possible submucosal spread,[90] with any boost dose delivered classically to a volume 2 cm above and below the gross tumor volume. More recent reports utilizing modern staging studies have limited the extent of normal-appearing esophagus and pharynx structures covered to 2 to 3 cm in the craniocaudal dimensions[27,28] (Fig. 19-13). With more advanced three-dimensional conformal techniques available in the modern era, efforts should be made to cover clinically negative bilateral supraclavicular lymph nodes and cervical neck level IV nodes, as well as the superior mediastinal (above the carina) lymph node basin with

prophylactic doses of approximately 50 Gy. Extension of prophylactic radiation volumes in the neck should extend at least one full cervical lymph node level at any area where clinically positive lymph nodes are located. Given the proximity of vital structures such as the spinal cord, the parotids, the submandibular glands, the brachial plexus, the heart, and the lungs, IMRT has been utilized and may offer advantages in treatment of cervical esophageal tumors in terms of normal tissue toxicity avoidance.[93]

***Surgery.*** Surgical treatment for malignancy of the cervical esophagus is markedly different from those tumors located in the thoracic esophagus. Cervical esophageal resections are difficult due to the proximity of the larynx, which hinders visualization and surgical access to the tumor. It may be difficult to obtain a negative resection margin while leaving a functional larynx, even for early-stage lesions. For this reason, resections frequently require concomitant laryngectomy. Furthermore, transcervical surgical access is limited below the thoracic inlet, potentially making it impossible to resect and reconstruct the inferior limit of a tumor. For this reason, esophagectomy is frequently required. PLE was first reported in 1960 by Ong and Lee[94] and has been the mainstay of surgical management for cervical esophageal tumors, even those that appear to be early-stage disease given the tendency for submucosal spread.

In addition to having a propensity for submucosal spread, extramural extension to adjacent structures is common. One study analyzing cervical esophageal cancer patients demonstrated clinical or pathologic involvement of surrounding structures in 55% of cases,[13] including neck soft tissue, the trachea, the prevertebral fascia, and the thyroid gland. As a result, 36% of resection specimens had positive margins upon pathologic analysis, highlighting the difficulty of resection in this anatomic region.

While radical resection at the primary site in effort to achieve margin-negative resection is a difficult operation, patients also additionally require unilateral or bilateral neck lymphadenectomy to address the likelihood of microscopic nodal disease spread. The primary lymph node pathway is to the paratracheal lymph nodes, and paratracheal lymph node dissection is necessary and carries attendant risks such as hypothyroidism and hypoparathyroidism.[24] Superior mediastinal lymph node dissection is warranted, as one-third of patients will have pathologic involvement of these lymph nodes.[25] Unilateral thyroid lobectomy or total thyroidectomy is usually performed, as the gland is often invaded.[95] Immediate reconstruction of the digestive tract must also accompany the resection and can be accomplished in several ways. However, this combination of these factors leads to long and difficult operations, which are associated with substantial morbidity.

Esophagectomy is traditionally performed with abdominal and cervical exposure, with or without thoracotomy. The literature suggests that the transthoracic approach is associated with lower risk of anastomotic leak and recurrent laryngeal nerve injury and higher lymph node yield. Meanwhile, the transhiatal approach, which avoids thoracotomy, is associated with shorter procedures and fewer respiratory complications; the transhiatal approach is used more commonly than the transthoracic approach in tumors of the cervical and upper thoracic esophagus.[96] More recently, thoracoscopic and laparoscopic techniques have been applied to esophagectomy in hopes of limiting perioperative morbidity. No definitive studies exist regarding the benefits of these "minimally invasive" approaches.[97]

Resection of cervical esophageal cancers requires immediate reconstruction to restore continuity of the digestive tract. In selected cases, cervical esophageal tumors that are well below the level of the cricopharyngeus may lend themselves to larynx-sparing, limited cervical esophageal resection, and reconstruction may be accomplished with fasciocutaneous free flaps[98] or with jejunal free flaps (Fig. 19-14A).[99,100] Jejunal free flaps require harvesting a section of jejunum,[101] with end-to-end jejunostomy, which can then be anastomosed in an end-to-end fashion with any remaining proximal esophagus or in an end-to-side manner with the hypopharynx; an end-to-end anastomosis is performed distally (Fig. 19-14B). Resections that include esophagectomy are usually managed with gastric pull-up, in which the stomach is brought through the posterior mediastinum and anastomosed to the upper resection margin. Anastomotic leak is a common and

troublesome complication after gastric pull-up, occurring in almost 10% of cases in one series.[102] A pectoralis major muscle flap can be used to cover the anastomosis to mitigate against morbidity from anastomotic leak.[103] Colon transposition is an alternative to gastric pull-up for reconstruction after esophagectomy and is preferred in some centers.

Lymph node dissection is indicated in the management of carcinomas of the esophagus. The jugular chains, central cervical, and mediastinal nodes are of particular importance. Kelley et al. reported that the central cervical compartment nodes were most commonly involved at 32%, followed by the jugular chain nodes at levels 3 and 4 (18% each), in a cohort of previously untreated patients.[13] Weber et al. reported a 71% incidence of central compartment nodal metastasis in patients operated for cervical esophageal cancer.[34] They advocated removal of the nodes in continuity with the hemithyroid to ensure completeness of dissection. The superior mediastinal nodes extend from the level of the sternal notch down to the level of the carina. Metastasis to the superior mediastinal nodes was reported by Hirano et al. in 33% of patients with cervical esophageal carcinoma, which increased to 56% in patients whose tumors extended into the thoracic esophagus.[25] A substantial portion of patients in this cohort had been treated with neoadjuvant chemotherapy.

For patients who undergo upfront PLE, the use of adjuvant radiation is an area of debate. Many patients will have significant morbidities associated with PLE and will decline or not be recommended to undergo adjuvant (chemo)radiotherapy. However, some data support the use of adjuvant radiotherapy. In a large series of patients with hypopharyngeal and cervical esophageal primary tumors undergoing surgical resection, 73% of patients received adjuvant radiotherapy. Postoperative adjuvant radiotherapy was a significant beneficial factor on multivariate analysis, as was hypopharyngeal tumor location, in this series.[104] However, more recent studies have been much more selective in the use of adjuvant radiation.[27,99] Current NCCN guidelines recommend postoperative chemoradiotherapy for R1 or R2 resections, but recommend observation for all margin-negative resections.[84] More trials to address the role for adjuvant therapy in this setting are unlikely given the shift to primary nonoperative management, and therefore individual patient and tumor factors must be utilized to guide the decision for adjuvant therapy should surgery serve as the primary oncologic modality.

***Unresectable Disease, M0 or M1.*** In patients with unresectable cervical esophageal tumor without distant metastases, definitive chemoradiation is preferred, as discussed above. Patients with distant metastases have incurable disease, and systemic therapy is preferred, unless local symptoms predominate and warrant palliative radiation. Current common regimens utilized in metastatic esophageal SCC include ECF (epirubicin, cisplatin, and 5FU), a flouropyrimidine (5FU or its oral equivalent, capecitabine) plus cisplatin, a fluoropyrimidine plus oxaliplatin (or irinotecan), or a taxane (paclitaxel or docetaxel) plus cisplatin.[84] Performance status and medical comorbidities should be incorporated into decision making, as many patients may be best served by best supportive care and hospice enrollment. Only patients with excellent performance status and easy access for frequent toxicity assessment should be considered for three-drug regimens.

***Posttreatment Surveillance and Rehabilitation.*** Patients with cancers of the hypopharynx and cervical esophagus remain at high risk for locoregional and/or distant metastases following definitive treatment, regardless of whether surgery and/or radiation is used for upfront management. Therefore, close posttreatment

(c) 2014 Wolters Kluwer. All Rights Reserved.

surveillance is of value and typically involves head and neck surgeons and radiation oncologists in a multidisciplinary fashion.

Initially, follow-up visits for surveillance of disease recurrence should occur every 1 to 3 months for the first year, every 2 to 4 months for the second year, every 4 to 6 months for years 3 to 5, and then every 6 to 12 months thereafter.[75,84] These visits should include detailed physical exam, usually to include flexible nasopharyngoscopy. Serum TSH should be assessed every 6 to 12 months if head and neck radiation was utilized. Guidelines regarding posttreatment imaging surveillance are not well defined. However, given that the majority of locoregional tumor recurrences that are destined to occur happen in the first 2 years following therapy, serial CT imaging studies every 3 to 6 months for the first 2 years is a reasonable approach. The focus of surveillance shifts from recurrence of the initial disease to second primary development as the time from initial treatment lengthens, and while routine imaging after 2 years is likely of marginal value, it should be considered as symptoms warrant, as delayed locoregional recurrences, second primaries, and/or distant metastases are not uncommon in these patient populations.[26] Assessment of posttreatment scans in hypopharyngeal and cervical esophageal cancer patients can be difficult, as soft tissue changes following surgery and reconstruction can be difficult to distinguish from recurrent disease. Additionally, postradiation edema and fibrosis can similarly mimic recurrent disease, and therefore the involvement of experienced head and neck radiologists is highly desirable.

In addition to oncologic surveillance, management of toxicities and rehabilitation play an important role in maximizing posttreatment QOL. Utilization of a head and neck nurse coordinator or similar case manager can help patients navigate through the acute phase of their toxicities and facilitate posttreatment rehabilitation efforts.[105] Regardless of the primary treatment approach long-term speech and swallow dysfunction are likely to some degree. Early and intensive involvement of speech and swallow therapists can mitigate the impact these changes can have on QOL and help to maintain nutrition and minimize the risks for complications such as aspiration pneumonia. Additionally, many patients will find themselves able to minimize use of tobacco and/or alcohol during their acute treatment course but remain at high risk of relapse in the months and years following treatment; continued involvement of experts in tobacco and alcohol cessation, as well as routine encouragement of these efforts, is of value.

# OUTCOMES AND RESULTS

Series analyzing outcomes of hypopharyngeal and cervical esophageal cancer treatments are limited. Few randomized trials of these tumor subsites exist, and they are often included in (but form a minority of) larger cohorts of head and neck and/or esophageal tumors for enrollment in clinical trials and/or retrospective reviews. Nonetheless, it is accepted that outcomes in these tumor sites are disappointing, in part due to their tendency to present with advanced disease. Furthermore, patients presenting with these tumors often have significant medical comorbidities and socioeconomic barriers that limit aggressive oncologic treatment, further confounding comparisons of treatment approaches. Additionally, medical comorbidities and the emergence of second primary tumors cloud interpretation of published series. With these caveats, published reports of outcomes of these patients are presented.

## Hypopharyngeal Cancer

Outcomes in hypopharyngeal cancers are poor in comparison with other head and neck cancers, with 5-year overall survival rates approaching 30% (Fig. 19-5). An analysis from the NCDB of hypopharnygeal cases diagnosed in 2003 demonstrates that at 5 years stage-specific overall survival rates were 51.3% for stage I (3.0% of cases), 34.8% for stage II (9.4% of cases), 34.8% for stage III (22.3% of cases), and 19.8% for the 65.3% of cases presenting with stage IV disease (Fig. 19-15).[30] This highlights the proportion of patients presenting with advanced disease and the poor prognosis in hypopharyngeal cancer. Poor prognostic factors include increasing age, with patients above 70 faring poorly compared with younger patients,[7,106] likely reflecting poor tolerance of aggressive treatment approaches. Women may have a better outcome than men,[32,107] though this may be due to more common presentation with earlier stage disease. Furthermore, tumors of the pyriform sinus fare better than those arising on the posterior pharyngeal wall or postcricoid region.[32,107,108]

### Stages I to II Disease (T1-2, N0)

***Radiation.*** Nonoperative management is often chosen for early-stage disease (T1–2, N0). With T1N0 lesions, 5-year disease-specific survival (DSS) of approximately 90% can be expected with definitive radiation, while T2N0 lesions may expect DSS of >70%. Recent selected studies are highlighted below.

Garden et al. reported the MD Anderson experience treating T1–2 hypopharyngeal cancers from 1976 to 1992 with radiation alone, using varying fractionation schemes to deliver doses ranging from 60 to 79 Gy to the primary tumor. More than half (52%) of the patients were clinically node positive, and a portion of the node-positive patients had surgical management of neck disease prior to radiation. Actuarial local control rates for T1 lesions at 2 years were 89% and for T2 lesions were 77%. While survival was not presented by stage (including neck metastases stratification), 5-year overall survival rates were 67% for T1 lesions and 46% for T2 lesions, including the node-positive patients.

Amdur et al.[47] analyzed outcomes in 101 patients with T1–2 cancers of the pyriform sinus treated with primary radiation at the University of Florida from 1964 to 1997. Again, node-positive patients were included in the analysis, and approximately half of patients had no staging CT scan performed prior to treatment. Despite this lack of modern staging, 73% of patients were node positive. Radiation was delivered either daily at 1.7 to 2 Gy to a mean of 66.9 Gy or twice-daily at 1.2 Gy BID to a mean of 74.7 Gy. Unilateral neck dissections following radiation were utilized in 43% of patients. Local control for T1 lesions was 89%, and ultimately 95% including those who underwent salvage surgery. Local control for T2 lesions was 82% and was 91% when salvage surgery was included. DSS rates at 96% for stages I to II, 62% for stage III, 49% for stage IVa, and 33% for stage IVb. Overall survival rates were 57% for stage I, 61% for stage II, 41% for stage III, 29% for stage IVa, and 25% for stage IVb, highlighting the competing medical comorbidities in these patients.

Ten Japanese institutions reported their combined outcomes in stages I to II hypopharyngeal cancers managed with definitive radiation from 1990 to 2001.[106] Approximately half (57/115) of the patients received concurrent chemotherapy. Median total dose for T1 lesions was 63 Gy in once-daily fractions and 63.5 Gy in BID fractionation schemes, while median doses for T2 lesions were 66 Gy in once-daily fractions and 70 Gy in BID fractionation schemes. Local control with voice preservation was achieved in 34/39 (87%) patients with T1N0 disease (including seven cases successfully salvaged after local recurrence), with these patients experiencing a 5-year DSS rate of 96%. T2N0 lesions fared worse, with 56/76 (74%) experiencing local control with voice preservation, and a 5-year DSS rate of 70%. Concurrent chemotherapy was demonstrated to be a significant prognostic factor for local control on multivariate analysis, as were age <70, T1 (vs. T2) primary, and better performance status. Strikingly, 65 (57%) of patients had either synchronous or metachronous malignancies.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Another Japanese group reported on 77 patients with stages I to II hypopharynx cancers treated with definitive radiation from 1988 to 2007.[108] Median radiation dose to the primary tumor was 66 Gy, and 66 patients (86%) had elective bilateral neck irradiation with a median dose of 40 Gy. Five-year recurrence-free survival and local control rates with laryngeal preservation were 57% and 70%, respectively. Five-year overall survival was 47%, whereas 5-year hypopharyngeal cancer specific survival was 74%. The majority of these patients (68%) were diagnosed without symptoms upon endoscopic examinations for other malignancies (most commonly esophageal cancer), and therefore nonhypopharyngeal cancer deaths were more common than hypopharyngeal cancer deaths in this series.

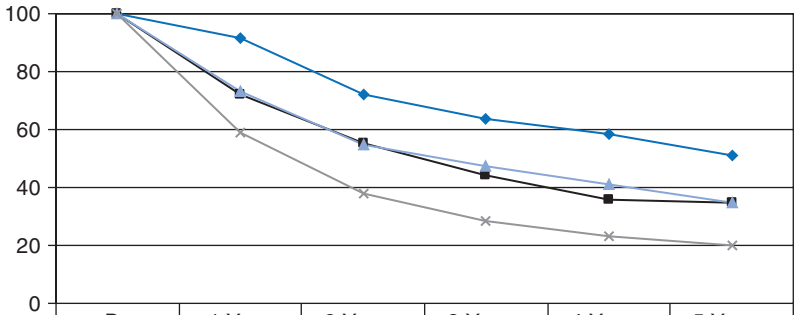
***Primary Surgery.*** Outcomes of patients treated surgically are difficult to summarize, as reports often include patients of widely variable stage, with differing proportions treated with larynx-sparing operations versus laryngopharyngectomy. Furthermore, endpoints between studies, use of adjuvant radiation, and time of endpoints reported vary widely between publications. Recently, TLM approaches have been used in selected hypopharyngeal cancers, with a potential for less invasive, more precise resection with lower morbidity and better QOL for surgically managed patients in comparison with open surgical approaches. Strict patient and tumor selection must be utilized, and given that margins of 15 to 20 mm are recommended for hypopharyngeal cases, TLM is not tenable in many patients, even with early T-stage lesions. Contraindications for TLM in cancers of the pyriform sinus include thyroid cartilage invasion, base of tongue and/or cervical space invasion, arytenoid involvement, and tumors crossing the posterior midline or involving the cervical esophagus.[109] Additionally, detailed knowledge of endoscopic anatomy, comfort with conventional surgery and microsurgery, and experience with the use of lasers are necessary skills for the endoscopic surgeon. TLM in combination with neck dissection and postoperative radiation as indicated can achieve results similar to (chemo)radiation in appropriately selected patients. Selected series utilizing TLM are summarized.

Steiner et al.[62] analyzed 129 patients with tumors of the pyriform sinus undergoing TLM from 1981 through 1996. Cases were pT1 in 24 patients, pT2 ($n = 74$), pT3 ($n = 17$), and pT4 ($n = 14$). The majority of patients ($n = 110$; 85%) received either a unilateral or bilateral delayed neck dissection, with 68% of cases ultimately node positive. Therefore, only 10 cases (7.7%) were stage I, 23 were stage II (18%), 26 were stage III (20%), and 70 cases (54%) were stage IV. Of the 33 stages I to II cases, only 6 (18%) received adjuvant radiation to the neck and primary, whereas 78 (81%) of the stages III to IV cases received adjuvant radiation, for indications of positive margins, ≥1 nodal metastases, or lymph nodes with ECE. The 5-year local control rate was 82% for stages I to II disease and 69% for stages III to IV patients, whereas overall neck failure rate was 14%; distant metastases developed in 14.7% of patients. Recurrence-free 5-year survival rates were 95% for stages I to II and 69% for stages III to IV, with overall survival rates at 5 years of 71% and 47%, respectively. Functional results were excellent, with all but 2 patients able to achieve oral intake, with median duration of nasogastric feedings of 7 days.

A smaller early series examining TLM in hypopharyngeal cancer reported outcomes in 29 patients.[110] Standard therapy consisted of TLM plus neck dissection and postoperative radiation. Five-year survival rates were encouraging in early-stage patients at 78%, but only 35% in the stages III to IV patients. However, functional outcomes were promising in this small series, with normal speech and swallowing reported in 100% of patients without local recurrence at 5 years.

Another German group performed TLM on 172 patients with hypopharyngeal cancers, with the vast majority ($n = 150$; 87.2%) having primaries in the pyriform sinuses.[61] Despite being candidates for TLM, only 15% of patients had stages I to II disease, whereas 85% had stages III to IV disease. Selective neck dissections were performed in 93% of patients, and 52% received postoperative radiotherapy. Five-year local control rates were 84% for pT1 tumors, 70% for pT2, 75% for pT3, and 57% for pT4a. Recurrence-free survival rates were 73% for stages I to II, 59% for stage III, and 47% for stage IVa. Second primary tumors developed in 44 patients (26%), resulting in 28 deaths. Consistent with the earlier report by Steiner, nasogastric tubes were needed by 80% of patients postoperatively, for a median of 6.5 days; only 6 patients (3.5%) required permanent gastrostomy tubes for long-term dysphagia. Postoperative edema, scar formation, or stenosis required repeat microlaryngoscopy in 6 patients (3.5%), and 7 patients required tracheotomies. Compared to radical surgery or open larynx-conserving experiences, oncologic outcomes appeared similar with lower morbidity and complication rates.

The largest reported experience of TLM in patients with only T1–2 primary tumors examined 119 patients.[60] TLM was able to achieve R0 primary resections in 101/119 (85%) of patients. The majority of patients (83.2%) received adjuvant neck dissections and/or postoperative radiotherapy. In patients with cN0 necks managed with neck dissection, 8 of 21 (38%) had occult neck disease. With a median follow-up of nearly 6 years, DSS was 83.7% in N0 neck cases, and 67.4% in node-positive cases. Tolerance of TLM in combination with adjuvant therapies was good, with permanent tracheostomy only needed in 2.5% of cases, and permanent gastrostomy tubes also needed in 2.5% of cases. Importantly, this series demonstrated the importance of negative margins, as DSS rates were significantly higher (77%) in R0 cases as compared with margin-positive cases (48%, $p < 0.001$).



## Stages III to IV Disease

***Chemoradiation.*** Single institution reports have demonstrated that 5-year overall survival rates of approximately 35% to 45% can be achieved with concurrent chemoradiotherapy in patients with advanced hypopharyngeal cancer, with approximately two-thirds of surviving patients expected to retain a functional larynx. These rates are slightly higher than those reported in cross-sectional analysis of outcomes in the NCDB (Fig. 19-15) as patients chosen to undergo chemoradiotherapy are generally of higher performance than unselected hypopharyngeal cancer cohorts. Results from recent series utilizing modern radiation techniques and concurrent chemotherapy in patients with advanced disease are summarized.

Lee et al.[111] analyzed a group of patients with stages III and IVa–b laryngeal ($n = 20$) and hypopharyngeal cancer ($n = 11$) all treated with IMRT and concurrent platinum-based chemotherapy at Memorial Sloan Kettering Cancer Center from 2002 to 2005. All patients had PEG feeding during treatment, and PEG tubes were routinely placed prophylactically. The 2-year local progression-free survival rate for hypopharyngeal patients was 73%, and the 2-year overall survival rate in these patients was 53%. The 2-year posttreatment PEG-dependency rate was 31% in hypopharyngeal patients, higher than that observed in the laryngeal cancer patients (15%), with severe stricture and significant dysphagia contributing to this observation.

A Taiwanese group reported on 94 patients with locally advanced hypopharyngeal cancer managed either via chemoradiotherapy ($n = 30$) or surgery plus adjuvant radiation ($n = 44$) between 1995 and 2004.[112] No significant differences in T or N staging or other patient characteristics existed between the surgical or chemoradiotherapy groups. No significant differences in overall survival or disease-free survival between the two groups were observed, with 3-year overall survival rates of 39% in the chemoradiotherapy patients and 44% in the surgery plus

**FIGURE 19-15.** Observed survival for hypopharyngeal cancer in the United States as calculated for new cases identified in the National Cancer Data Base in 2003. All pathologic types were included.

*Source:* Redrawn with permission from *National Cancer Data Base. Commission on Cancer. American College of Surgeons. Benchmark Reports,* accessed August 24, 2011. Staging according to 6th edition AJCC staging manual.

radiation group reported. Patients managed with surgery had a higher rate of local control, but approximately 70% of those surviving 2 years in the chemoradiotherapy arm were able to retain their larynx.

Liu et al.[113] treated 27 patients with concurrent chemoradiotherapy, with IMRT utilized in all patients. Early in the experience cisplatin days 1 and 29 with 5FU days 1 to 4 and 29 to 32 was given concurrently ($n$ = 6), but profound pharyngitis and esophagitis prompted a change to concurrent weekly cisplatin at 30 mg/m$^2$ for the latter 21 patients. The 5-year disease-free survival rate was 51%, whereas the overall survival rate was 35%, with a laryngeal preservation rate of 63%. Seven patients (26%) required a tracheostomy due to stridor with only two able to reverse to normal breathing; thus 5 of 27 (18.5%) had grade 3 laryngeal stricture. The authors concluded that IMRT with concurrent chemotherapy can attain high locoregional control rates and high functional laryngeal preservation rates, but late laryngeal stricture remains problematic.

Another Taiwanese report[114] compared outcomes in 33 patients treated with concurrent chemoradiotherapy with IMRT and outcomes of 14 patients treated with primary surgery. No patient and/or tumor factors were significantly different between the groups. The 5-year overall survival rates were not statistically different, observed at 44% for chemoradiotherapy versus 33% for those with primary surgery. Six patients in the chemoradiotherapy group underwent salvage surgery, such that 22 patients preserved a functional larynx. IMRT with concurrent chemotherapy was felt to preserve the larynx at high rates, without compromising survival as compared with primary surgical management.

***Surgery Plus Adjuvant Radiation.*** Oncologic outcomes of patients undergoing total laryngopharyngectomy plus adjuvant radiation are felt to be roughly equivalent to concurrent chemoradiation, with 5-year DSS rates of 40% to 50%. However, hypopharyngeal reconstruction presents a challenge with such approaches, and late complications and morbidity are problematic, including permanent gastrostomy tubes and significant strictures in a significant minority of patients, as well as the loss of natural voice. Thus, the use of open surgical techniques in hypopharyngeal cancer is declining.[115] Recent studies examining patients treated with primary surgery are presented, although limited by the trend toward nonoperative approaches in recent years.

A French group[104] reported on pharygolaryngectomy performed in 209 patients with either hypopharyngeal ($n$ = 131) or cervical esophageal cancers from 1982 to 1999. Methods of reconstruction to accompany pharyngolarygectomy varied; esophagectomy with pharyngogastric anastomoses were performed in 127 patients, free jejunal transfer in 77 patients, and total esophagectomy with pharyngocolic anastomoses in 5 patients. Of the hypopharyngeal patients, the vast majority were clinically T2 or T3 (85%), whereas clinical staging revealed node positivity in only 34%. Pathologic staging was not carefully reported, but ultimately 62% of patients were node positive, and 73% of patients were treated with postoperative radiotherapy. The 5-year survival rate was 29% for the hypopharyngeal cancer patients. No difference was noted between patients treated with either stomach interposition or jejunal transfer. Positive prognostic factors included R0 resection, postoperative radiotherapy utilization, and absence of surgical complications. Anastomotic leaks occurred in 47 patients (22.5%). The average time to resumption of oral feeding was 19.7 days, highlighting the severity of these operations, whereas mean hospital stay was 23.6 days. Late stricture occurred in 17 patients (8.5%).

Bova et al.[116] examined outcomes in 180 patients treated with pharyngolaryngectomy, all for hypopharyngeal cancer from 1979 to 2002. The majority (91%) had stages III to IV disease. The treatment paradigm in the reported patients was quite uniform, except that patients treated before 1990 received induction chemotherapy, but this practice was subsequently discontinued. Reconstruction involved a jejunal graft in all cases. Postoperative radiotherapy was utilized in 94% of patients, and all node-positive patients underwent neck dissections. Locoregional recurrence was low in this series at 18%, but 20% of patients developed isolated metastatic disease, whereas 16% developed second primary tumors. Therefore, the 5-year overall survival rate was 33%, whereas the DSS rate at 5 years was 52%. Functional outcomes, toxicities, and morbidity were not reported.

The experience of surgical management at Princess Margaret Hospital[117] included 66 patients treated with pharyngectomy as primary treatment. As nonsurgical management was favored at the institution, the indications for surgical treatment were

(c) 2014 Wolters Kluwer. All Rights Reserved.

previous head and neck irradiation ($n = 36$) or advanced primary disease ($n = 30$), where radiotherapy was felt unlikely to provide control. Five-year local and regional control rates (including salvage therapies) was 79% and 67%, respectively. The 5-year overall survival was 38%, and DSS was 45%.

## Cervical Esophageal Cancer

Pharyngolaryngoesophagectomy has traditionally served as definitive management for SCC of the cervical esophagus, but 5-year survival rates were approximately 15% utilizing this approach. Nonoperative management with chemoradiation is now commonly recommended given the substantial morbidity and poor oncologic outcomes associated with resection.[84] Outcomes of chemoradiotherapy are therefore emphasized, with 5-year overall survival rates of 25% to 40% expected in patients who are candidates for curative chemoradiation. Recent surgical series are also summarized.

***Chemoradiation.*** One of the earliest reports came from two Australian institutions, which analyzed 34 patients treated from 1991 to 1996 with chemoradiotherapy utilizing CT-based planning.[118] Shrinking-field technique was used to deliver at least 50 Gy to the tumor and draining lymph nodes, with the primary tumor receiving 61.2 Gy on average. All patients received concurrent chemotherapy, though the specific regimens were variable. Complete response rate was 91%, and ultimate local control was 88%. Actuarial 5-year survival was 55%, but no stage IV patients were included in the study, which may have contributed to these relatively good outcomes. Acute toxicity was acceptable, and late esophageal strictures were only significant (requiring dilations) in 5 patients (15%). Given these promising results, the authors concluded that concurrent chemoradiotherapy should be the preferred treatment for cancers of the cervical esophagus.

Bidoli et al.[119] reported on 106 patients with esophageal SCC treated with chemoradiotherapy. Thirty-two patients with cervical tumors were excluded from consideration of resection and were treated to 50 Gy, whereas a proportion of thoracic tumors were resected after 30 Gy. The nonsurgical patients (including the cervical tumors) had a better median survival (22 months) than the patients who underwent surgery (12 months). Of the cervical tumors, 7 of 32 (22%) required salvage surgery. The 10-year disease-free and overall survival rates for the cervical patients were 31% and 27%, respectively. The authors advocated that a nonsurgical approach should be strongly considered in patients where laryngectomy would be required given that 25% of patients achieved long-term survival with intact laryngeal function.

Subsequently, a Japanese report[120] examined 27 patients treated with definitive radiotherapy from 1988 to 2002. The mean radiation dose administered was 66 Gy, and concurrent cisplatin and 5FU was delivered in 23 (85%) of the patients. Actuarial overall survival at 5 years was 37.9%, whereas the disease-free survival rate at 5 years was only 13%, as 85% of patients ultimately experienced recurrence. Seven patients who received <60 Gy of radiation all failed locally, and 11 patients failed distantly.

MD Anderson Cancer Center reported their experience of 35 patients with SCC of the cervical or upper thoracic esophagus treated with chemoradiation, with a median dose of 50.4 Gy with concurrent 5FU-based chemotherapy. Complete response to chemoradiotherapy was documented in 63% of patients, although this rate was significantly higher in patients receiving >50 Gy (79% vs. 27%, $p = 0.003$). The 5-year rate of overall survival was 18.6%. Those with complete response had higher overall survival and cause-specific survival than those without complete response, and in patients receiving >50 Gy, 5-year overall survival was 29%. Therefore, chemoradiation with doses of 50 to 65 Gy was recommended by the authors for management of cervical esophageal cancer.

The Princess Margaret Hospital published their results of 71 patients treated with chemoradiotherapy.[28] Patients treated before 1997 to 2000 were treated with 54 Gy in 20 fractions without intentional elective nodal coverage, with concurrent cisplatin and 5FU chemotherapy. Patients treated from 2001 to 2005 were treated in a fashion more analogous to head and neck patients with elective nodal volumes treated to 50 to 56 Gy, and a boost to the gross disease to 70 Gy, delivered with concurrent cisplatin every 3 weeks. Only 50 patients were treated with curative intent, and the overall survival for this cohort was 28% at 5 years. No difference between the two treatment approaches was appreciated. Severe dysphagia requiring intervention (feeding tube, stent, or dilation) was common, afflicting 45% of the curatively treated patients.

***Surgery.*** Triboulet analyzed 78 patients who underwent pharyngolaryngectomy, with gastric replacement reconstruction used in 68 of the patients.[104] Average hospital stay for those with pharyngogastric anastomoses was 24.7 days. The majority of patients received postoperative radiotherapy, but despite these aggressive therapeutic measures, 5-year overall survival was only 14%. Pathologic T stage was shown to be prognostic, with T1 tumors showing a 33% 5-year overall survival, whereas no pT4 patients survived 5 years.

Another large series of 74 patients who underwent esophagectomy with or without laryngectomy demonstrated operative morbidity in 34% of patients, with in-hospital mortality rates of 4%.[121] The majority (80%) had tumors extending into the hypopharynx or thoracic esophagus, and 80% were stages T3 to T4. Only 16 patients (22%) received adjuvant radiation. Overall 5-year survival was 33%, with node negativity, stages I to II disease, and female gender being favorable prognostic factors. Significant complications occurred in 34% of patients, with graft necrosis in 20%. Larynx-preserving surgery was possible in only 32% of patients.

More recent studies have analyzed larynx-preserving esophagectomies for cervical tumors. Kadota et al.[99] reported outcomes in 32 patients with larynx-sparing surgery with jejunal transfer. Postoperative aspiration was absent or transient for the majority of patients, and mean time to oral intake was 12.5 days. Decannulation was achieved in all patients who underwent tracheostomy, and laryngeal function was fully preserved in all patients. Five-year disease-free survival was approximately 40%, with overall survival not reported. This approach may be utilized in patients with low cervical esophageal tumors, with more careful selection needed in patients with high tumors involving the hypopharynx.

Ott et al.[100] published results of 109 patients managed with limited resection and jejunal graft interposition from 1986 to 2006. The majority of patients (86%) received neoadjuvant chemoradiotherapy. Laryngeal preservation (complete or partial) was achieved in 85% of cases. Although the mortality rate was promising, with a 5-year survival rate of 47%, complications were high (74%), with anastamotic leak in 27% of patients, graft ischemia in 24%, and sternal osteomyelitis in 10%. Reoperation was performed in 29% of patients.

Two recent series have compared outcomes in patients managed either surgically or with primary chemoradiation. A Taiwanese study[92] examined 15 patients who underwent radical resection with reconstruction, and 14 patients receiving chemoradiotherapy from 2002 to 2007. No significant differences were noted in pretreatment patient characteristics. Surgery included bilateral neck dissections and adjuvant chemoradiation in cases of pathologic T3, N1, or M1a involvement. Chemoradiation consisted of 60 to 70 Gy with concurrent cisplatin and 5FU. Greater improvements in dysphagia scores were noted in patients undergoing surgery than patients receiving chemoradiation. Mean DSS

(c) 2014 Wolters Kluwer. All Rights Reserved.

times were not different in the surgical versus chemoradiation patients.

In a second, larger study, Tong et al.[27] reported outcomes in 107 patients with cervical esophageal cancer. Pharyngolaryngoesophagectomy was performed in 62 patients who had disease judged to be resectable, usually followed by adjuvant radiation. When surgery was declined or patients were too high of surgical risk, curative chemoradiation was offered to 21 patients; treatment was palliative in the remainder of patients. Of the patients receiving chemoradiation, 6 (29%) ultimately required salvage surgery. The median survival for surgical patients was 19.9 months, whereas it was 24.9 months in the chemoradiotherapy patients ($p = 0.39$). Median survival times for patients with other management strategies, including radiation alone, were all <10 months (Fig. 19-16), highlighting the dismal outcomes of patients not managed with either radical resection or chemoradiotherapy.

## Quality of Life

Treatment for hypopharyngeal and cervical esophageal tumors is accompanied by significant acute and long-term morbidity, with impact on patient appearance, speech, swallowing, and social functions. Therefore, assessment of organ preservation, functional status, and patient-assessed QOL must be considered in evaluating the overall efficacy of treatment approaches. Relatively few prospective studies with robust QOL analyses following treatment exist. In patients requiring surgery such as laryngopharyngectomy, functional deficits are predictable, whereas assessing the extent of functional organ preservation in patients undergoing either (chemo)radiation or larynx-sparing surgical procedures can be more difficult to quantitate. Regardless of the treatment approach, long-term speech and swallow rehabilitation efforts are warranted. Although data exist from some studies detailing impact of therapy on QOL in hypopharyngeal cancer patients, similar data are largely lacking for cervical esophageal patients.

A prospective study of QOL in head and neck SCC patients in Sweden demonstrates the substantial challenges for these patients. At diagnosis, hypopharyngeal cancer patients (as compared with other head and neck tumors sites) had the lowest social, emotional, and cognitive functioning, and the lowest global QOL scores.[122] When considering treatment options, the possibility of preserving laryngeal function must be considered. A controversial study by McNeil et al. administered a questionnaire to healthy subjects and found that some patients may accept a slightly lower chance for cure in favor of larynx-sparing approaches.[123]

Two recent similar studies by the same group in the Netherlands nicely demonstrate the impact of chemoradiotherapy or pharyngolaryngectomy on hypopharynx cancer patients. In the study performed in 73 patients who received chemoradiotherapy, toxicity was measured at 3, 6, 12, and 24 months after treatment.[124] QOL questionnaires were sent to long-term survivors, alive with a mean of 5 years after treatment. The mean overall score for vocal function demonstrated a mild-to-moderate voice handicap. Deficits were identified in physical, emotional, cognitive, and social functioning, with sticky saliva, weight loss, need for nutritional supplements, dry mouth, and trouble with social eating being the most problematic symptoms. These deficits demonstrate that organ preservation does not necessarily equate with preservation of high-quality organ function.

The sister study reporting on patients treated with pharyngolaryngectomy[125] demonstrated high complications rates (63% after jejunal grafts and 89% after gastric pull-up), but long-term QOL measures were good. Among the 21 patients alive at the time of the study, 14 returned QOL surveys. Satisfying scores were given for global health status and functional scales. The biggest factors negatively impacting QOL were smell and taste difficulties, speech problems, and sexuality problems.

Another recent report performed a matched-pair analysis of patients with advanced head and neck cancer undergoing operative or nonoperative management to evaluate long-term QOL.[126] Patients in the surgical arm demonstrated worse speech outcomes than those treated with chemoradiotherapy, but the overall QOL scores were similar, indicating that adjustment to loss of voice as well as other toxicities associated with chemoradiation may reduce the benefit of voice preservation on QOL. However, other studies have demonstrated better scores in terms of emotional and functional QOL measures in patients undergoing chemoradiation compared with surgery followed by radiation.[127] These studies demonstrate the complexity of QOL analysis following radical therapies for advanced head and neck cancer and highlight the need for prospective studies of QOL in these patients.

## Complications

***Surgical Management.*** Complications from surgery include anesthesia risk, bleeding, infection, and damage to structures in the surgical bed. When efforts are made to perform larynx-sparing procedures for hypopharyngeal cancers, significant dysphonia, aspiration, and refractory dysphagia requiring long-term gastrostomy feedings are not uncommon and may warrant completion laryngectomy. Laryngopharyngecomty is often accompanied by anastomotic leaks and fistulization. Graft necrosis can occur with free-tissue transfers. Stricture formation can occur late and may represent tumor recurrence.

The perioperative morbidity and mortality burden for cervical esophageal cancer is substantial with laryngopharyngoesophagectomy. One large population-based study recently reported a perioperative mortality rate of 4%.[128] A recent study reported a major complication rate of >40%[102] (Table 19.7). These can include pneumonitis, anastamotic leakage, pleural effusion, wound infection, and chylous fistula. Recurrent nerve palsy is common, as is stenosis requiring endoscopic dilation, both occurring in roughly 20% of patients.[100] Furthermore, significant dysphagia is common and problematic.

| Complications | Patients (n) |
|---|---|
| Pneumonitis | 23 (11.1%) |
| Anastomotic leakage | 19 (9.1%) |
| Pleural effusion | 15 (7.2%) |
| Wound infection | 8 (3.9%) |
| Chylous fistula | 4 (1.9%) |
| Heart failure | 4 (1.9%) |
| Hemothorax | 3 (1.4%) |
| Hemoperitoneum | 2 (1.0%) |
| Anastomosis stricture | 7 (3.4%) |
| Burst abdomen | 2 (1.0%) |
| Total | 87 (41.8%) |

***Radiation Therapy.*** Acute effects of radiotherapy to the head and neck region are predictable, including mucositis, fatigue, dermatitis, xerostomia, and loss of taste acuity. Mucositis is the most problematic of these, limiting oral intake leading to malnutrition and dehydration commonly in patients without enteral feeding tubes. Mucositis typically develops during the third week of radiation and is exacerbated by concurrent chemotherapy and/or altered fractionation radiotherapy courses. Nonprescription analgesics may be utilized first, in combination with maalidoben (liquid maalox, lidocaine, and diphenhydramine) to aide in alimentation, but narcotic analgesics are commonly necessary. Nausea is commonly encountered and further complicates dehydration and malnutrition, frequently warranting use of antiemetics.

Late effects of radiation include permanent xerostomia, which can cause difficulty with speech and accelerated dental decay. Trismus can result, causing difficulty with mastication. Dysphagia is common as a late side effect and warrants speech and swallow rehabilitation in the posttreatment phase. Many patients struggle to maintain a satisfactory body weight. Permanent gastrostomy tube dependence is more common with tumors of the hypopharynx and cervical esophagus than in other head and neck tumor sites and can be seen in approximately 15% of surviving patients.[111] Stricture is commonly encountered, especially in cervical esophageal tumors, with approximately 10% to 15% of patients requiring repeated dilation.[118] Hypothyroidism is a common side effect of radiotherapy in this region, and surveillance with laboratory tests in surveillance is warranted every 6 to 12 months.

## Management of Recurrence

Given the disappointing results of upfront therapy, regardless of primary modality, locoregional and distant recurrence is common in both hypopharyngeal and cervical esophageal tumors. Therefore, close posttreatment surveillance is indicated. Changes on endoscopic examinations and/or surveillance imaging that are concerning for recurrence prompt biopsy for confirmation of recurrence. Before entertaining aggressive salvage treatment, complete restaging is warranted, as patients with locoregional recurrence have high rates of simultaneous distant metastases. Many patients with recurrent disease, even without distant metastases, may not be candidates for aggressive local salvage therapy and may be best served with systemic chemotherapy and/or hospice enrollment with best supportive care measures.

***Salvage after Initial Radiotherapy.*** Salvage surgery remains an option for patients with recurrent disease after upfront (chemo) radiation. In general, recurrent disease will require extensive surgery including sacrifice of the larynx. However, TLM has been used successfully in select patients with low-volume localized disease[129] and may be considered.

In patients with more advanced recurrent disease following initial radiotherapy, salvage laryngopharyngectomy (with or without esophagectomy) can be entertained. These resections are technically challenging for the surgeon and present healing challenges to the patient, but selected patients may benefit from this approach. One series demonstrated a 5-year overall survival of 31% for patients undergoing salvage pharyngectomy for recurrent hypopharyngeal cancer, with locoregional control rates of 70%,[117] although perioperative complications were high. Similarly, long-term survival can be achieved with salvage esophagectomy following definitive chemoradiation, but this operation is risky with high rates of anastomotic leakage and in-hospital mortality.[130]

Traditionally, patients initially treated with radiation have not been considered for reirradiation to the head and neck. However, with the development of advanced, highly conformal radiation delivery systems, selected patients may be good candidates for high-dose reirradiation. Two prospective RTOG trials have recently demonstrated this approach to be feasible.[131,132] Recent experiences with IMRT have demonstrated that long-term disease control may be achieved in appropriately selected patients with acceptable toxicity.[133,134]

***Salvage after Initial Surgery.*** When larynx-sparing initial surgery was performed, salvage pharyngolaryngectomy may be feasible, accompanied by either gastric pull-up or jejunal transfer. In rare occasions, further organ-sparing surgery may be considered, particularly in patients initially managed without adjuvant radiation. If patients are to undergo further larynx-sparing surgery and have not previously received radiation, adjuvant radiation can be utilized.

Alternatively, if recurrence after surgery occurs in patients without a history of receiving radiation, high-dose (chemo)radiotherapy can be considered. More commonly patients will have received adjuvant radiation as part of their initial treatment package, and reirradiation should be avoided in the majority of these cases (see above discussion).

***Palliative Chemotherapy.*** A large proportion (25%–40%) of patients with cancers of the hypopharynx or cervical esophagus will ultimately develop metastatic disease. When this occurs, long-term survival is rare and treatment intent is palliative in nature. Distant metastases are often accompanied by local recurrence, and palliative short-course radiation should be considered for local pain, bleeding, or significant dysphagia limiting QOL. Palliative surgery can also be considered to alleviate local symptoms, and narcotic pain medications are often valuable.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Median overall survival for patients with metastatic head and neck cancer is 6 to 10 months.[135] In this situation, palliative chemotherapy can be considered in patients with good performance status, and single-agent cisplatin has been demonstrated to improve overall survival in head and neck cancer patients.[136] Historically, combinations of cytotoxic chemotherapies have not shown enhanced overall survival over cisplatin alone, and therefore they have not been commonly utilized.[137] Recently, however, randomized data have been published supporting the use of a triple-drug regimen in patients with recurrent or metastatic head and neck cancer, with (a) cisplatin or carboplatin (b) 5FU and (c) the anti–epidermal growth factor receptor monoclonal antibody cetuximab. In this setting, the addition of cetuximab to platinum and 5FU improved overall survival from 7.4 to 10.1 months,[138] and this regimen now has a category 1 recognition in the current NCCN guidelines.[75]

Chemotherapy options for recurrent esophageal cancer feature two-drug regimens. These regimens are commonly based on 5FU or capecitabine and platins (cisplatin or oxaliplatin). Randomized data supporting cetuximab use do not exist for tumors of esophageal origin to date, but biologic agents warrant continued investigation in these tumors given their dismal prognosis once metastatic.

## FUTURE DIRECTIONS

Cancers of the hypopharynx and the cervical esophagus present challenges to surgeons, radiation oncologists, and medical oncologists. As the majority of patients present with locally advanced disease, classical treatment approaches involve significant morbidity, and outcomes from an oncologic and functional standpoint remain disappointing in the majority of patients.

Advances in surgical techniques, such as the recent development of transoral laser techniques, may offer alternatives to the more aggressive traditional surgeries that involve laryngectomy and free-tissue reconstruction. In order to fully utilize these newer techniques, risk stratification for local recurrence following organ-preserving surgery must be more fully understood, in order to guide decisions regarding organ-preserving versus radical resection. Clinical experience, preferably in the form of prospective clinical trials, is also necessary to more uniformly guide the use of adjuvant (chemo)radiotherapy in patients treated using these more novel surgical techniques.

IMRT has significantly impacted the ability of the radiation oncologist to deliver high-dose treatment to the hypopharynx and the cervical esophagus while minimizing normal tissue toxicities. However, questions still remain regarding optimal target volumes, dose selection, and what chemotherapy should be delivered, especially for cervical esophageal tumors. Prospective clinical trials are difficult to perform in this setting, but are clearly indicated to address these issues.

Furthermore, there is increasing interest in the incorporation of biologic agents into the upfront and metastatic treatment paradigms for tumors of the hypopharynx and cervical esophagus. Ongoing preclinical and clinical work in these arenas will hopefully identify additional agents of value to patients afflicted with these aggressive malignancies.

# PART B:
# Radiologic Imaging Concerns

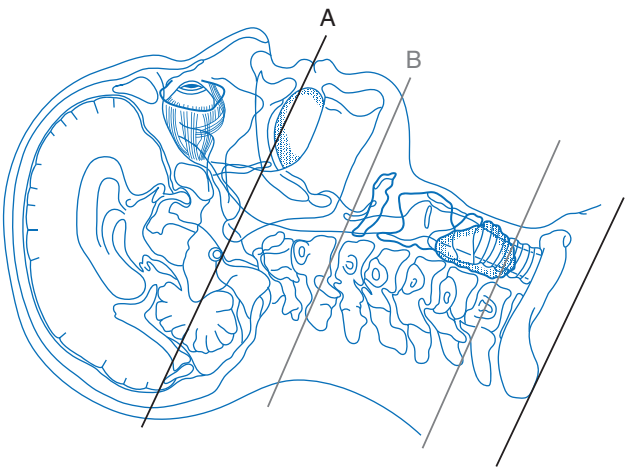
Jeffrey A. Bennett

Imaging of the hypopharynx is typically performed in a patient with persistent, often unilateral sore throat, dysphagia, glomus sensation, or otalgia after a tumor has been found by endoscopy. The endoscopist is usually able to map out the mucosal extent of the tumor, but the relationship of the tumor to the esophageal verge, postcricoid area, or piriform sinus apex may be difficult to determine. The submucosal extent of disease also cannot be determined by endoscopy. Computed tomography (CT) with intravenous contrast is the usual first imaging study performed. There is no longer a role for fluoroscopy with oral contrast in primary diagnosis, but video fluoroscopy is still performed, mainly in posttreatment patients for analysis of swallowing and to look for the presence of aspiration or a fistula. Suggested CT and magnetic resonance imaging (MRI) protocols are given in Figures 19-17 through 19-19.

As in other areas of the head and neck, the purpose of imaging is to determine the full extent of the primary tumor and to look for perineural spread in this location along recurrent laryngeal nerve, or superior laryngeal neurovascular bundle, or lymphatic spread, typically not only to levels II through VI, but also to the retropharyngeal nodes (Fig. 19-20).[1,2] In addition, the possibility for acute airway obstruction should be assessed. The airway may be at risk in the posttreatment setting as well, if there is radionecrosis of the cricoid cartilage.

CT and MRI can both provide information on spread of tumor to the larynx, the oropharynx, the paraglottic space fat, or the preepiglottic fat. Figures 19-21 and 19-22 show piriform sinus primary tumors with spread into the larynx. Figure 19-23 shows a postcricoid tumor extending to the esophageal verge. Figures 19-24 and 19-25 show primary cervical esophageal tumors.

CT and MRI are both somewhat limited in the detection of early cartilage invasion, as there is variability in the ossification of the cartilage, but CT might be slightly better because of the ability to acquire very thin, $< 1$ mm thick slices. MRI of this region is often degraded by motion artifact. Where MRI provides an advantage is in its superior soft-tissue differentiation in determining whether tumor abuts or invades the esophagus or the trachea.



Since esophageal cancers can be synchronous with other head and neck squamous cell carcinomas, the radiologist should search for other mucosal-based tumors when an esophageal tumor is found. One study by Wang et al.[3] showed 69 of 315 patients (21.9%) had synchronous head and neck squamous cell cancer and esophageal neoplasia. Drinking alcohol was a significant risk factor. Another study[4] found the risk of synchronous esophageal and head and neck squamous cell cancers to be rare for the oral cavity, but were more common in the larynx, the hypopharynx, and the oropharynx.

FDG-PET has limited use in mapping the primary tumor, but does have a role in the detection of an additional primary tumor such as lung cancer and may help to identify positive lymph nodes. Some studies suggest that higher standard uptake values within the primary tumor may correlate with increased radioresistance and may be a negative predictive factor,[5,6] but as yet this information has not been used to alter treatment plans.

Posttreatment surveillance imaging is aimed at early detection of recurrence[7] or metastatic spread to lymph nodes (Fig. 19-26). CT, MRI, or PET-CT are all viable modalities to use for follow-up imaging, and all can direct biopsies when there is a suspicion for recurrence. It is useful to have a baseline posttreatment imaging study at 3 to 4 months after completion of treatment so that comparison can be made on future studies to best interpret areas that scar, or are growing, and thus suspicious for recurrence. This is important as total laryngopharyngectomy may offer a chance of cure for some patients who have had voice-sparing treatment initially.

## PYRIFORM SINUS

Parallel-opposed portals are used to treat the primary cancer and both sides of the neck to include lymph nodes in levels II, III, IV, V, and the retropharyngeal nodes at the level of the C1–C2 vertebral bodies. It is difficult to detect subclinical disease at the pyriform sinus apex, which is located somewhere between the top and the bottom of the cricoid cartilage, even at direct laryngoscopy. Therefore, the inferior border of the initial portals is located 2 cm below the bottom of the cricoid cartilage. It may be difficult to obtain this margin if the patient has large shoulders and a low-lying larynx. If this is the case, the lateral portals are angled approximately 10 degrees inferiorly and the anterior portal used to treat the low neck is eliminated. The anterior field border may be placed just behind the skin of the anterior neck to avoid tangentially irradiating this area for patients with T1–T2 cancers and early-stage neck disease. The superior border is placed at, or just below, the jugular foramen, and the posterior border is placed just posterior to the spinous processes of the vertebral bodies (Fig. 19-27).[1] Reduction off the spinal cord is performed at approximately 45 Gy, and a second mucosal reduction occurs at 60 Gy. Electron beam is used to treat the posterior strips, if necessary, after reduction off the spinal cord.

Intensity-modulated radiation therapy (IMRT) may be employed to treat patients with a clinically negative neck or ipsilateral positive nodes to reduce the dose to the contralateral parotid to 26 Gy or less and to avoid a difficult match between the conventional lateral fields and the anterior low neck portal in the patient with a low-lying larynx and a short neck. Patients may be treated once daily or with an altered fractionation schedule.[2] The concomitant boost technique is employed at our institution and consists of 72 Gy in 42 fractions over 30 treatment days to gross disease (Fig. 19-28). Subclinical disease receives 49.5 to 54 Gy.[3] Alternatively, patients are treated to 74.4 Gy in 62 twice-daily fractions over 31 treatment days. Patients with a clinically negative neck receive elective RT to bilateral levels II, III, IV, V, and the retropharyngeal nodes.[4] Patients with ipsilateral positive nodes receive RT to ipsilateral levels IB, II, III, IV, V, VI, and the retropharyngeal nodes, as well as contralateral levels II, III, IV, VI, and the retropharyngeal nodes. Patients with stages III to IV cancers receive concomitant weekly cisplatin 30 mg/m$^2$. Those with positive nodes undergo a computed tomographic scan 1 month after RT to determine whether a neck dissection is indicated.[5]

The radiation therapy treatment technique after surgery that entails partial laryngectomy is as described above. The technique employed after a total laryngectomy is the same as that described in the "advanced larynx" chapter.

## PHARYNGEAL WALL

Because squamous cell carcinomas of the pharyngeal wall tend to spread submucosally, wide margins for the primary cancer are initially utilized. The portals are parallel opposed and usually weighted 1:1. The field margins for the initial fields usually extend to the bottom of the cricoid cartilage, 0.5 to 1.0 cm behind the skin of the anterior neck, the posterior processes of the vertebral bodies, and to (or just below) the jugular foramen. Because large tumors tend to extend posterolaterally around the vertebral bodies, the posterior border of the off-cord reductions is placed at the anterior edge of the spinal cord (Fig. 19-29).[6] The low neck is treated with an anterior field with a thin, tapered midline tracheal block. Electrons are used to treat the posterior strips after reduction off the spinal cord, if necessary.

As described in the pyriform sinus section, IMRT may be employed to reduce the dose to one or both parotids and/or avoid a difficult low neck match with conventional fields. The dose fractionation schedules are the same as those used for pyriform sinus malignancies. Patients with ipsilateral positive nodes receive elective RT to clinically uninvolved ipsilateral levels IB, II, III, IV, V, VI, and the retropharyngeal nodes, as well as contralateral levels II, III, IV, V, and the retropharyngeal nodes.[4] It may be difficult to treat patients with bilateral clinically positive nodes with IMRT and adequately spare the parotid(s).

## CERVICAL ESOPHAGUS

Anteroposterior opposed portals weighted anteriorly are used to treat the primary cancer of the upper mediastinum and the neck, if moderate-dose irradiation is planned prior to definitive surgery. The superior border is placed at mid mandible and splits the tragus; the neck is extended. The lateral borders include the supraclavicular fossae, and the inferior border is placed 5 cm below the inferior border of the primary cancer.

Treatment with high-dose irradiation alone or combined with adjuvant chemotherapy is more problematic because of

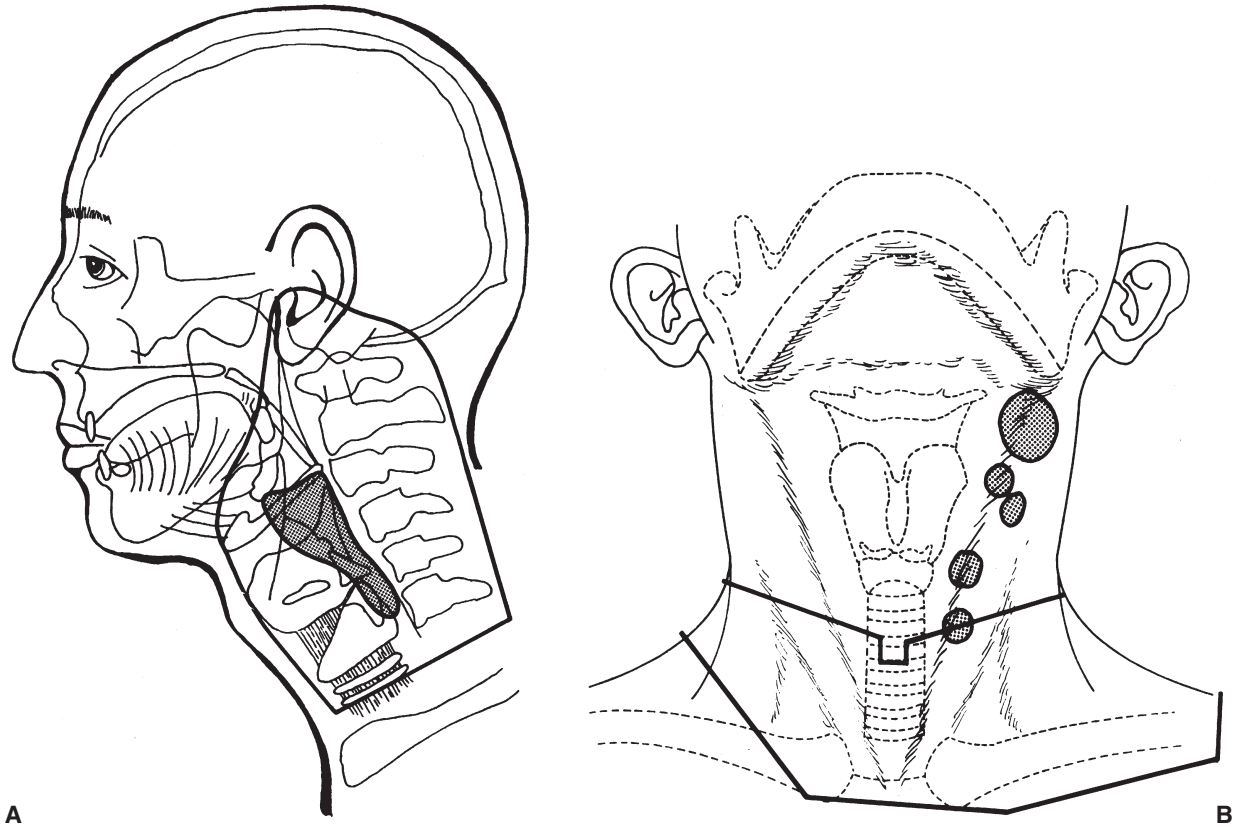

**FIGURE 19-27.** **A:** Portals used for the initial treatment volume in a patient with carcinoma (*stippled area*) of the pyriform sinus and a clinically negative neck. Superiorly, the portal covers the junctional and retropharyngeal lymph nodes. The submandibular nodes are not included, but the spinal accessory chain is included. Anteriorly, at least 1 cm of skin and subcutaneous tissues (as viewed from the lateral projection) is usually spared. The inferior border is 2 to 3 cm below the bottom of the cricoid cartilage and is slanted to facilitate matching with the low neck portal and to avoid irradiating the shoulders. The posterior field edge usually encompasses the spinous processes of the vertebral bodies. As treatment progresses, portal reductions are made to shield the spinal cord and to limit the volume of mucosa that receives high-dose irradiation. **B:** Anterior portal for treatment of low neck in patients with hypopharyngeal or laryngeal cancer. Low neck is irradiated bilaterally. Matchline is treated in primary portals, but excluded from low neck field. Usually, a $1 \times 1$ cm midline block is introduced at upper edge of field, except in postoperative patients in whom tracheal stoma is at risk. Each side of low neck portal is individualized according to risk and/or presence of lymph node metastases on that side.

the change in contour from the neck to the shoulders. Although several options exist, depending on the treatment planning and delivery system available, IMRT offers significant advantages compared with conventional techniques. The initial target volume includes the primary lesion with 5 cm distal and proximal esophageal and hypopharyngeal margins, respectively. The lymph nodes included are levels II, III, IV, VI, and the superior mediastinal lymph nodes. We currently use IMRT for all patients treated with definitive irradiation for cervical esophageal carcinoma. Subclinical disease is treated to approximately 45 to 50 Gy, and gross disease receives approximately 70 Gy. Patients may be treated once daily, or altered fractionation may be employed.

# PART D:
# Surgical Technique

Ramon M. Esclamado and Liana Puscas

## INTRODUCTION

Contemporary reconstruction of ablative defects of hypopharyngeal carcinoma remains clinically challenging. Successful and appropriate reconstruction requires a thoughtful analysis of many factors that will ultimately impact the choice of the reconstructive technique employed. Careful consideration should be given to reconstructive goals, oncologic outcomes, patient related factors, and comorbidities, the extent of the surgical defect, as well as the expertise and preferences of the reconstructive surgeon. Ideally, the reconstructive team will have available the entire armamentarium of reconstructive options and will utilize the technique that is best suited for the patient, that optimizes function, while minimizing both short-term morbidity, long-term disability, and expense.

The reconstructive goals are straightforward but elusive: to restore continuity of the alimentary tract so that a patient is able to eat a normal diet, while preserving laryngeal voice or restoring alaryngeal speech. Oncologic factors are essential to consider. Although primary and salvage hypopharyngectomy have comparable locoregional control rates and survival, overall and disease-specific survival remains poor.[1] Therefore, reconstruction should be single stage, have a low rate of fistula and delayed wound healing, allow for early resumption of deglutition and voice restoration, and have a low rate of delayed strictures, particularly if postoperative radiation is required. Since surgical ablation nearly always includes unilateral or bilateral neck dissection, the choice of reconstructive technique will in part depend upon availability and location of recipient vessels for free tissue transfer and should consider minimizing shoulder disability, particularly if the spinal accessory nerve has been sacrificed.

Patient-related factors and comorbidities must be recognized and considered to optimize outcomes.[2] In this era of concurrent chemoradiation therapy (CRT), iatrogenic hypothyroidism occurs in 48% of patients as early as 4 weeks posttreatment.[3] These patients can also be nutritionally or metabolically debilitated from alcohol and tobacco abuse, tumor burden and odynophagia, or from CRT. When primary surgery and reconstruction is contemplated, nutrition should be optimized; in the salvage setting, a preoperative TSH should be obtained. Diabetics should be carefully selected and managed in the perioperative period. Preoperative radiation, malnutrition, diabetes, and unrecognized hypothyroidism are known to increase fistula rates and delay wound healing.[4,5] Many patients have COPD, and consideration should be given to choosing donor sites that are not intra-abdominal to minimize postoperative pulmonary complications.

The extent of the surgical defect is a primary determinant of the selected reconstructive option. Defect classifications have been proposed,[6] but not universally adopted. The first

(c) 2014 Wolters Kluwer. All Rights Reserved.

consideration is whether all or part of the larynx has been preserved. Reconstruction will require, thin, pliable tissue that can be contoured so as not to obstruct the airway and suspended with little downward traction to preserve laryngeal elevation. If total laryngectomy is performed, the second consideration is whether the pharyngectomy is total, requiring a completely tubed reconstruction, or partial, which would allow a "patch" graft. The superior extent of the defect must also be evaluated because there is a caliber mismatch between the base of tongue/oropharyngeal defect compared with the esophageal lumen that is magnified when resection includes portions of the tongue or oropharyngectomy. Finally, one must consider if the inferior anastomosis can be performed in the neck. Hypopharyngeal cancer can have significant submucosal spread, and historically total esophagectomy was regularly used to obtain a 4 cm or greater inferior margin, which precluded a cervical anastomosis. However, it has been shown that a 2-cm inferior esophageal margin is adequate and facilitates utilizing less morbid reconstructive techniques.[7,8]

The experience and preferences of the reconstructive surgeon or team, and the availability of facilities to appropriately care for these patients cannot be overlooked. The literature abounds with studies espousing the superiority of one reconstructive technique over another, and there are benefits of expertise gained in performing a specific reconstructive technique repetitively so that errors in technique or judgment are minimized. Ideally, the reconstructive decisions take into account all of the above-mentioned factors, so that the reconstructive method chosen is best suited for the particular patient.

## RECONSTRUCTIVE OPTIONS

A variety of reconstructive options are available. The pertinent surgical anatomy, blood supply, harvesting techniques, and donor site management and complications have been well described and are beyond the scope of this chapter. The myriad of the most commonly used flaps are listed in Table 19.8, and it is important to understand the broad principles as to their advantages and disadvantages.

Regional flaps are either fasciocutaneous or myocutaneous. They are readily harvested, do not require microvascular expertise, and are fairly reliable. The muscle pedicle of myocutaneous flaps can provide additional carotid protection. They can have limited reach and arc of rotation and can be bulky and not as pliable in a three-dimensional reconstruction. The bulk and weight of the flap and pedicle could cause undue wound tension and increase the risk of wound complications.[9] When the skin paddle is extended beyond the normal vascular territory, there can be a partial flap necrosis. Fasciocutaneous flaps usually require a two-stage reconstruction to close a pharyngectomy defect, but are very useful in creating a controlled fistula to exteriorize a persistent fistula in an infected neck.

Revascularized (free) flaps are generally excellent options, although microvascular expertise is required, and operative time can be prolonged, but minimized with a two-team approach. Adequate recipient vessels are essential, and flap survival rates exceed 95% to 98%. A postoperative fistula with infected saliva draining over the vascular pedicle can cause late thrombosis, which is rare in pedicled flaps. The lack of a fixed pedicle allows three-dimensional positioning to minimize tension on the suture lines, and wound tension from downward traction can be minimized. The variety of donor sites allows selection of texture, bulk, and flap size to optimally reconstruct the defect.

**TABLE 19.8 Reconstructive Options for Hypopharyngeal Reconstruction**

| | Regional Flaps | Revascularized Flaps |
|---|---|---|
| Fasciocutaneous | Deltopectoral<br>Superior trapezius | Radial forearm<br>Anterolateral thigh<br>Lateral arm |
| Myocutaneous | Pectoralis major<br>Latissimus<br>Lower island trapezius | Rectus<br>Latissimus |
| Enteric | Gastric pull-up | Jejunum<br>Ileocolic |

## DEFECT RECONSTRUCTION AND RESULTS

As previously mentioned, the extent of the surgical defect is the primary determinant of the selected reconstructive option. Therefore, we will approach reconstruction of hypopharyngeal defects primarily by analyzing the defect, defining reconstructive goals, and looking at the advantages and outcomes of the most commonly used reconstructive options.

### The Partial Pharyngectomy Defect with an Intact or Partially Resected Larynx

The more common defect is a partial pharyngectomy defect with an intact larynx. A limited lateral wall defect can be closed primarily or with a thin pectoralis myocutaneous (PMC) flap. Since most defects involve the posterior hypopharyngeal wall with or without the lateral wall of the piriform sinus(es), the surgical goal is to provide thin pliable tissue. When partially tubed, the reconstruction should not obstruct the airway nor impair laryngeal elevation. The radial forearm free flap (RFFF) is ideal in this setting, since it is thin, pliable, and very reliable.[10] The disadvantages are that the donor site generally requires skin grafting or alloderm to close, the skin is nonsecretory, the flap cannot be used in the absence of an intact palmar arch, and if the patient is unwilling to accept the donor-site cosmetic result. Alternatives include the lateral arm[11] or the anterolateral thigh (ALT) fasciocutaneous free flaps.[12,13] Both of these flaps allow primary closure of the donor site, but can be quite thick and bulky, so the donor site must be carefully evaluated prior to its use. The free jejunal patch graft is a viable alternative and is the preferred option in many centers. It has the theoretic advantage of being self-lubricating, and both fistula and stricture rates are reportedly low when compared with RFFF. It does require a laparotomy, and there is the potential risk of aspiration of jejunal secretion. In a recent series of 43 patients, the flap success rate was 95%, the fistula rate was 11%, which all healed with conservative treatment, and all patients were tracheotomy independent. There were no instances of pneumonia from aspiration of jejunal secretions, and 95% of patients were eating and G-tube independent, usually within 2 weeks postoperatively.[14]

A partial pharyngectomy defect with a partial laryngectomy defect is more challenging. Usually, the hemilarynx and lateral wall of the pyriform sinus are absent with an intact cricoid arch. The reconstructive goals require restoration of glottic closure, and sensation to optimize airway protection, create an adequate airway, and preserve swallowing. Instinctively, one would want to recreate structure and restore the "volume" of the hypopharynx. However, restoring the natural contour of the hypopharynx with an insensate, adynamic flap may not be a good functional restoration when the hemilarynx is also reconstructed. One should consider

(c) 2014 Wolters Kluwer. All Rights Reserved.

insetting enough soft tissue to restore continuity of the hypopharynx so that tension is minimized to facilitate wound healing. However, the reconstruction should "obliterate" the involved lateral piriform wall so that the food bolus will preferentially be diverted to the normal, sensate, and contractile pharyngeal wall. Swallowing can then be facilitated with a "chin tuck" to the involved side to further open the normal side. Kim et al.[15] recently reported a series of 31 patients reconstructed with a RFFF for a vertical hemipharyngolaryngectomy for hypopharyngeal carcinoma. The palmaris longus tendon was included to reconstruct the glottis, and in 23 patients, the flap underwent sensory reinnervation to the superior laryngeal nerve. Eighty-eight percent of patients were able to meet all their nutritional needs orally, 2 patients (6%) developed glottic stenosis, marginal flap necrosis was seen in 2 patients (6%) that resulted in fistulas, and 88% of patients were eventually decannulated. If these results can be duplicated, the opportunity will arise for more patients to undergo laryngeal preservation procedures in selected hypopharyngeal cancers because the laryngeal defect can be safely and functionally reconstructed.

## The Total Laryngectomy with Subtotal Pharyngectomy Defect

This defect is the most amenable to obtaining a good functional outcome encountered in the reconstruction of hypopharyngeal or laryngeal carcinoma. A preserved posterior strip of mucosa is helpful because it avoids a complete circumferential closure and cicatricial contracture (especially at the cervical esophageal anastomosis, which is the most common site of strictures) (Fig. 19-30). At first glance, the decision making seems straightforward: primary closure or closure with a pectoralis flap? However, in an era when chemoradiation therapy is commonly employed as definitive oncologic treatment in an effort to preserve the larynx, surgery is more often utilized for salvage. The surgeon is faced with heavily radiated tissues and patients with comorbid conditions that impair wound healing. The challenges faced in this situation were highlighted in a recent study of patients undergoing salvage surgery for laryngeal carcinoma after failed radiation or chemoradiation therapy.[16] Patients reconstructed with a soft-tissue free flap had lower fistula rate (18%) compared with the primary closure group (50%); a lower rate of stricture formations (18% vs. 25%), and feeding tube dependence (23% vs. 45%). Therefore, more extensive laryngopharygectomy defects, particularly in the salvage setting, require soft-tissue reconstruction that minimizes wound tension so that fistulas and late strictures are minimized. The ability to restore voice with tracheoesophageal speech should be considered, and some authors feel that the type of flap used impacts long-term voice rehabilitation.[17,18] However, it is the first author's personal experience that the type of flap used has more impact when one is not able to preserve a normal vibratory segment of the upper esophagus between the TEP site and the distal end of the flap-esophageal anastomosis.

The first option to consider is a partially tubed pectoralis myocutaneous flap. This can be performed quickly by a single team of surgeons and has acceptable donor-site morbidity, and the muscle pedicle provides some protection to the great vessels. It is useful in a debilitated patient who is thin or if recipient vessels are poor or unavailable. The reported fistula rate is about 14%,[19] and all patients were G-tube independent. The pedicled latissimus or lower island trapezius flaps are options in the above situation when the pectoralis flap is unavailable, but these tend to be less reliable and require repositioning of the patient. A thick, bulky flap is a relative contraindication because it can be difficult to tube, may place undue tension on the pharyngeal anastomosis, and potentially obstruct the tracheostoma. There is also some evidence to suggest that PMC reconstruction compared with free flaps results in higher complication rates and G-tube dependence, and hospitalization is prolonged.[9]

The radial forearm free flap is an excellent choice in this setting because it is thin, reliable, and adequate soft tissue is readily harvested. In addition, a monitoring segment can be included in the flap design and placed in an exterior location in the neck to aid in monitoring of the pharyngeal flap, which may otherwise be difficult to assess on clinical exam (Figs. 19-31 and 19-32).

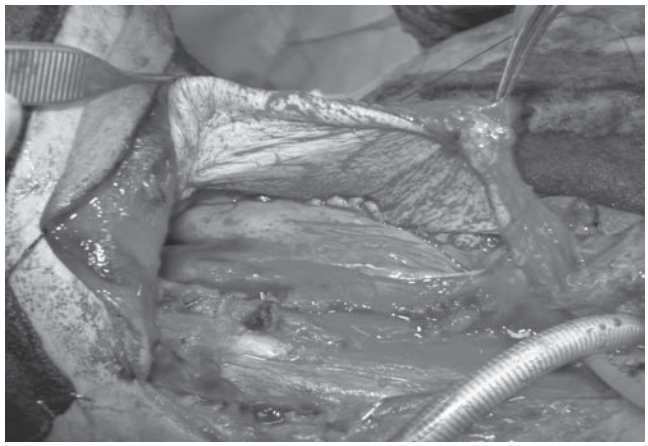

**FIGURE 19-30.** Pharyngeal reconstruction after total laryngectomy and partial pharyngectomy. (See color insert.)

**FIGURE 19-32.** Monitoring segment incorporated into neck closure.

**FIGURE 19-33.** Total glossolaryngeal defect with near total pharyngectomy.

In a salvage situation, it is important to remember that when a strip of native hypopharynx is present, all of the flap will be sewn to irradiated tissue that has impaired wound healing. Gentle handling of native tissues and using the curvature of needle when sewing will minimize tearing of the native mucosa. The use of interrupted vertical mattress sutures everts the edges to eliminate a potential "trough" in the suture line where saliva can leak, and utilizing a long-lasting absorbable suture has reduced the incidence of late fistulas.[8] Distal structures can be minimized by vertically incising the proximal esophageal segment to create a V-shaped defect and designing a complementary V-shaped tip to the free flap that is then inset into this gap to avoid a circumferential suture line. The ALT or lateral arm fasciocutaneous flap are also reasonable options[20] and have the advantage of primary closure of the donor site. Care must be taken in choosing these sites because the upper arm and thigh can be quite thick with an abundance of subcutaneous fat.

If the resection also includes a subtotal or total glossectomy defect with an intact pharyngeal strip of mucosa, consideration should be given to using a flap with enough soft tissue and bulk to restore tongue volume, and it is partially tubed to reconstruct the neogullet (Fig. 19-33). Our preference is to use the rectus myocutaneous flap based on the deep inferior epigastric artery and vein. The rectus flap has an abundance of skin that can be harvested with primary closure of the donor site and is usually bulky with a substantial fat component that does not atrophy; the anterior rectus sheath can be suspended on the mandible to minimize down traction and tension on the closure and has a long vascular pedicle with muscle to provide carotid coverage. If the rectus donor site is not available, the latissimus free flap is a good second option. It may require repositioning of the patient and generally has less subcutaneous fat so that the initial bulk may not be maintained as the muscle atrophies. However, the latissimus muscle atrophy can be compensated by reinnervating the thoracodorsal nerve to the stump of a hypoglossal nerve, if available. One can also gain additional bulk by designing the skin paddle more proximally and near the posterior axillary line, then harvesting the entire muscle, and folding it under the skin paddle to gain additional bulk.

## The Total Laryngopharygectomy Defect

Reconstruction of the total laryngopharygectomy defect has a wide variety of options and, as a corollary, the most controversy. The surgical goals include a single-stage reconstruction that restores continuity of the oropharynx to the esophagus and a low fistula and stricture rate and tolerates radiation therapy. The circumferential size mismatch between the oropharynx and the esophagus must be adequately addressed (Fig. 19-34). The ideal functional results are resumption of a regular oral diet, voice rehabilitation with a tracheoesophageal voice prosthesis, and minimal donor site morbidity.

Recent modifications of the U-shaped pectoralis myocutaneous flap introduced by Fabian[21] have important clinical application. The PMC flap is shaped into a U, and the lateral edges are sewn directly to the prevertebral fascia, which is allowed to granulate over a salivary bypass tube. Reported fistula rates are 20% to 25%, which usually close spontaneously, and swallowing outcomes are acceptable.[19,22] In a long-term follow-up study of 52 patients reconstructed in this manner, the disease-free survival was 17.3%, leading the authors to advocate for this option in patients that are debilitated or have significant comorbidities.[23]

The ongoing controversy in the reconstruction of this defect is whether a tubed fasciocutaneous or jejunal free flap is superior. The jejunal free flap has been the workhorse for many decades and is preferred by many surgeons because it has >95% success rate, its caliber is similar to the esophagus, fistula rates are low, it is secretory, and it can tolerate radiation doses of up to 65 Gy. Modifications have been made to compensate for the size mismatch of the jejunum circumference to the oropharyngeal closure, and this is usually readily corrected by spatulating the jejunum at its antimesenteric border. The disadvantages include the need for an intra-abdominal procedure, but can be harvested laparoscopically to minimize complications and a "wet" TEP voice, which is unsatisfactory in some patients.[24,25] This flap is very sensitive to ischemia, and late stricture can occur due to necrosis and late scar contracture of the muscularis mucosa, even though the serosa and mucosa appear intact. We prefer to tack the flap into position and then revascularize the flap when it is covered in iced saline laparotomy sponges. Final flap trimming and insetting is performed once the flap is revascularized. In a direct comparison in a single institution of PMC, ALT, and jejunal flaps, the fistula rate was 23.9%, 12.5%, and 4.6%, respectively. The late stricture rate was 27.2%, 12.5%, and 2.3%, respectively, leading the authors to conclude that the jejunal free

(c) 2014 Wolters Kluwer. All Rights Reserved.

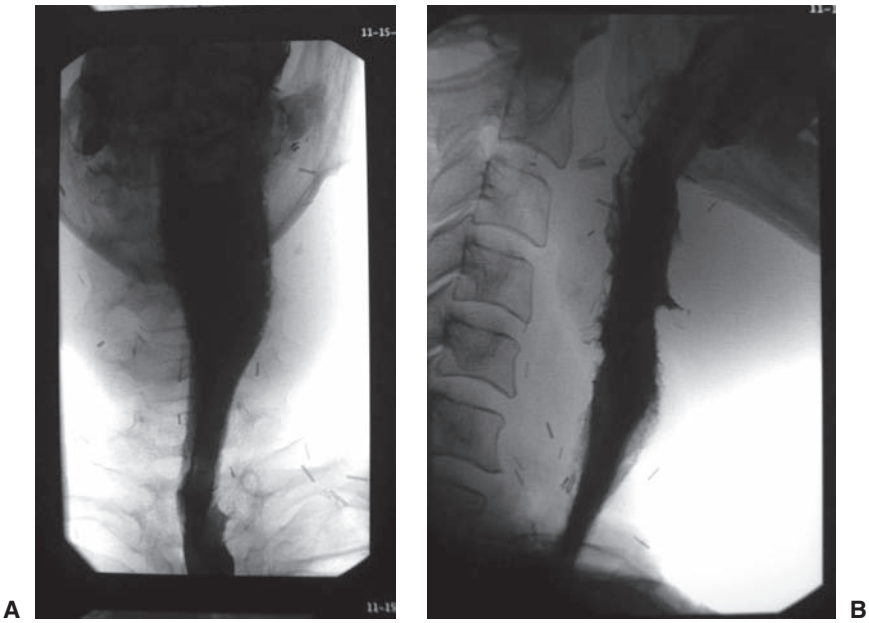

**FIGURE 19-34.** Postoperative swallow after reconstruction for total laryngopharyngectomy; anterior–posterior and lateral views.

flap provided the best functional outcome.[26] Early positive functional results are sustained with long-term follow-up. In a cohort of 19 patients who underwent total laryngopharygectomy, TEP and jejunal free flap reconstruction with a mean 4-year follow-up period, 18/19 were G-tube independent and 15/19 patients were using the TEP for communication. Poorer results with voice rehabilitation had been a shortcoming of the jejunal free flap, and the authors attributed the improvement in TEP voice to advances in prosthesis technology.[27]

Tubed fasciocutaneous free flaps are advocated by other centers because of less donor site morbidity, the availability of a larger volume of pliable tissue to reconstruct complex defects, and excellent functional outcomes. Fistula and stricture rates were initially worse, primarily because of three suture lines and the greater contraction of the skin–mucosa anastomosis versus a mucosa–mucosa anastomosis. After additional experience and modifications of technique, wound-healing complications and functional outcomes are at least equal to the jejunal free flap.[25] The tubed radial forearm free flap is an excellent option. In the authors' personal experience of 28 consecutive tubed RFFF for total laryngopharygectomy defects, flap survival was 100%; average length of stay was 8.0 days. There were two (8%) early fistulas and five (20%) late fistulas (>3 weeks). These late fistulas closed spontaneously within 1 to 2 weeks and were avoided in subsequent patients by changing the suture from vicryl to a slow absorbing suture. All patients resumed eating and were not using G-tubes, and 93% used TEP for communication.[28] Similar results were recently reported in a larger series of patients using the RFFF.[29] The disadvantage of the RFFF was the donor-site cosmetic defect from a large STSG, since often a large component of skin was harvested. The circumference mismatch was addressed by making the portion of the flap closer to the antecubital fossa wider than the distal part near the wrist, and the wider proximal part was used for the oropharyngeal defect. Alternatively, in some cases in this series, the flap could be "spiraled" to adjust for the circumference mismatch. Details of spiraling the flap is nicely outlined in a recent report using ALT free flaps.[20]

The ALT free flap is becoming a more popular option because it has the advantages of a fasciocutaneous flap, the donor site can often be closed primarily, and a large amount of tissue can be harvested to reconstruct complex defects of the pharynx and the external skin.[20] Each patient must be evaluated carefully because this flap can be quite thick and is difficult to tube in obese patients. In a single-institution comparison of ALT and jejunal free flaps, the ALT flap resulted in similar complication rates, shorter ICU and hospital stays, and better speech and swallowing compared with jejunal reconstruction.[17]

Reconstruction with the gastric pull-up continues to have its advocates because only one anastomosis is necessary, and the fistula rate may be better than the jejunal free flap or fasciocutaneous flaps. However, intra-abdominal complications can be significant, functional outcomes are worse, and vascular compromise of the stomach can be a devastating complication.[25,30] This should be reserved for when an esophagectomy is required for oncologic reasons.

## The Total Laryngopharyngoesophagectomy Defect

Fortunately, patients having to undergo this oncologic procedure are few, as survivorship is poor, and early mortality from a failed reconstruction is quite high. Patients with hypopharyngeal cancer that extends into the cervical esophagus require total esophageal resection when the inferior margin precludes a cervical anastomosis, regardless of the reconstructive method chosen. The gastric pull-up has been the reconstructive procedure of choice in this situation. When the anastomosis is high in the neck, care should be taken to ensure that the vascularity of the stomach is preserved and that the anastomosis is not under undue tension. If needed, a tubed free fasciocutaneous flap or jejunal flap can be interposed to bridge the oropharyngeal defect. Recently, a pedicled ileocolic flap has been described with reasonable functional success, although experience is limited with this procedure.[31]

## SUMMARY

In a disease with poor oncologic outcomes, it is essential to choose a reconstructive technique that will provide the patient with the fewest immediate complications so that hospital stay is minimized, long-term donor-site morbidity does not have a significant impact on quality of life, and functional outcomes

(c) 2014 Wolters Kluwer. All Rights Reserved.

maximize speech and swallowing. Advances in microvascular reconstruction have resulted in significant improvements in patient morbidity and functional outcomes. It is essential to use the reconstructive technique best suited for the individual patient to obtain the best result. Again, the reconstructive surgeon must carefully consider the reconstructive goals, oncologic outcomes, patient-related factors and comorbidities, and the extent of the surgical defect in recommending a procedure to a patient. The patient must have reasonable goals and expectations in understanding what can be accomplished with contemporary reconstruction so that the care of the patient is optimized.

# Cancer of the Nasal Vestibule, Nasal Cavity, Paranasal Sinuses, Anterior Skull Base, and Orbit: Surgical Management

Neoplasms of the nasal cavity, the paranasal sinuses, the anterior skull base, and the orbit represent a heterogeneous group of disorders that are associated with multiple challenges and historically poor outcomes. Several factors have been implicated in the overall poor prognosis of these lesions including aggressive growth patterns, proximity to critical neurovascular structures, nonspecific clinical presentation, and initial presentation with locally advanced disease. A multidisciplinary approach is often invoked for these lesions with the goals of oncologic control and preservation of organ function. The relative rarity and heterogeneous variety of these lesions have to date precluded the ability to perform large, prospective, randomized studies. The current treatment algorithms are based largely on the collective experience of single-institutional experiences.

The past decade has witnessed an evolution in the management strategies and outcomes for sinonasal and anterior skull base malignancies. Distinction in the clinical behavior and treatment sensitivity of the various histopathologies has resulted in more tailored therapy. Additionally, the well-defined principles of open extirpative surgery, including extended skull base approaches and craniofacial surgery, have led to an increasing range of treatment options for advanced lesions. Finally, the increasing collective experience with the techniques and outcomes of endoscopic surgery is rapidly defining its role in the surgical treatment of select sinonasal and anterior skull base neoplasms.

## ANATOMY—NASAL CAVITY AND PARANASAL SINUSES

A thorough understanding of the anatomy of the sinonasal cavity, the anterior skull base, and the orbit is fundamental in the treatment of these lesions. An abridged review is presented below. The bony landmarks of the facial skeleton are presented in Figure 20-1. The nasal cavity and the paired paranasal sinuses are air-filled cavities, surrounded by a bony-cartilaginous framework and lined by pseudostratified, ciliated columnar (respiratory) epithelium interspersed with goblet cells and basal cells (Fig. 20-2). Individual ciliated cells have approximately 50 to 200 cilia per cell, beating approximately 700 to 800 beats/minute and achieving a mucociliary clearance rate of 1 cm/minute. This physiology is easily impaired by the events that occur during cancer treatment including surgery and radiation therapy. The physiologic function of the sinonasal cavities include respiratory conductance of air flow, humidification and warming of inspired air, voice resonance, particle filtration, decreased skull weight, mediation of olfaction, absorption of midface and forehead trauma, and immune response to respiratory antigens. With regard to sinonasal neoplasms, the presence of compartmentalized, air-filled spaces allows for a period of unabated, local tumor growth with minimal, nonspecific symptoms and no significant findings on examination. This is one of the primary factors that predispose these lesions to a delay in diagnosis and advanced stage at initial presentation. Additionally, the intimate relationship of the sinonasal cavity to critical neurovascular structures, including the orbit, the internal carotid artery, and the intracranial cavity has significant implications on overall prognosis and treatment efficacy. In certain areas, the bony walls separating the sinonasal cavity from the orbit (lamina papyracea) and the intracranial cavity (anterior skull base) are thin and easily eroded by tumor (Fig. 20-3). Additionally, the presence of multiple adjacent foramina and canals allow tumor spread along preformed perineural and perivascular channels (Fig. 20-4). An understanding of these potential pathways is critical to defining the pathophysiology of tumor spread and is highlighted in the following paragraphs.

### Nasal Cavity

The nose consists of paired nasal apertures and cavities supported by a bony and cartilaginous framework. It is divided by the midline nasal septum (Fig. 20-5). The anterior most portion of the nasal cavity, termed the nasal vestibule, is lined by squamous epithelium and numerous hair follicles or vibrissiae. The remainder of the nasal cavity is lined by respiratory epithelium. The nasal cavity extends from the nasal vestibule anteriorly to the choana posteriorly. It is bounded by the columella and nasal septum medially and the lower lateral cartilages laterally. The floor of the nasal cavity corresponds to the hard and soft palate orally, whereas the roof corresponds to the cribriform plate intracranially. The paired choana open to the nasopharynx directly and are bordered by the medial pterygoid plates on each side. Olfactory epithelium is interspersed with respiratory epithelium along the superior aspect of the nasal septum, roof of the nasal cavity, and the superior and the middle turbinates. Olfactory nerve bundles pass through multiple perforations in the cribriform plate, providing a potential pathway for perineural spread of tumor intracranially.

The paired inferior, middle, and superior turbinates are bony projections lined by respiratory mucosa arising from the lateral

nasal wall. The inferior turbinates are independent osseous structures whereas the middle and superior turbinates are portions of the ethmoid bone. The area underneath each turbinate, termed meati, has important physiologic relationships. The lacrimal duct arises from the lacrimal sac in the inferomedial portion of the orbit, runs inferiorly along the medial-posterior surface of the maxilla, and empties through Hasner valve into the inferior meatus. The anterior paranasal sinuses composed of the maxillary, the anterior ethmoid, and the frontal sinuses physiologically clear their contents into the middle meatus. Similarly, the posterior ethmoid cells and the sphenoid sinus clear their contents into the superior meatus. The sphenopalatine foramen is located on the lateral nasal wall, inferior-posterior to the horizontal attachment of the middle turbinate, and transmits the sphenopalatine artery and vein from the pterygomaxillary space in addition to the nasopalatine and the superior nasal branches of the maxillary division of the trigeminal nerve.

The nasal septum is composed of a bony-cartilaginous wall sandwiched between two layers of tightly adherent mucopericondrium. The anterior quadrangular cartilage sits on the bony maxillary crest and articulates with the bony vomer posteriorly and the perpendicular plate of the ethmoid superiorly. In addition to providing structural support and normal nasal physiology, the nasal septum may act as a barrier for tumor transgression. Multiple neural and vascular sources supply the nasal septum. Arterial branches arise from both the external (sphenopalatine and facial arteries) and the internal carotid arteries (anterior ethmoid artery). Sensation is transmitted through both the ophthalmic (nasociliary nerve) and the maxillary (nasopalatine nerve) divisions of the trigeminal nerve.

## Maxillary Sinus

The paired maxillary sinuses represent the largest of the paranasal sinuses and most common site of sinonasal malignancy. These inverted pyramidal structures have a total volume of approximately 15 mm. Dynamic mucociliary clearance transports sinus secretions toward the natural ostium in the superomedial aspect of the sinus into the middle meatus of the nasal cavity. Obstruction of the ostium results in stasis of secretions and potential bacterial superinfection. Accessory openings, termed fontanelles, may also exist in approximately 25% of the population. The maxillary sinuses are bordered medially by the lateral nasal wall and the nasal cavity (maxillary and palatine bones), superiorly by the orbital floor and the infraorbital canal, anteriorly by the anterior face of the maxilla, inferiorly by the alveolar process of the maxilla, posterolaterally by the infratemporal fossa, and posteromedially by the pterygopalatine fossa (PPF). The base of the pyramid is the nasal surface and the tip points toward the zygomatic process. The anatomic proximity of the maxillary sinus to these structures predicates the patterns of spread for advanced lesions and has significant treatment and prognostic implications. Anatomic variations of the maxillary sinus include the presence of septations and hypoplasia of the maxillary sinus. The floor of the maxillary sinus is intimately related to the upper gingiva and the hard palate and is typically 1 to 2 cm below the level of the nasal cavity floor in adults. Tumor extension inferiorly to the alveolus and medially to the lateral nasal wall is relatively more favorable and amenable to *en bloc* resection.

## Ethmoid Sinus

The ethmoid sinus consists of multiple individual compartments and has been aptly termed the ethmoid labyrinth. Significant variability in the number, size, and pneumatization pattern of the ethmoid sinus cells has been described. Examples of this include aberrant pneumatization of ethmoid sinus cells within the inferior orbital wall (Haller or infraorbital cell), the frontal recess and sinus (frontal cell), the sphenoid sinus (Onodi or sphenoethmoid cell), and the middle turbinate (concha bullosa). The ethmoid sinuses are bordered by the middle and the superior turbinates medially, anterior face of the sphenoid sinus posteriorly, the lamina papyracea laterally, and the anterior skull base (fovea ethmoidalis) superiorly. The latter two boundaries are thin walled and easily breached by both neoplasm and surgical injury. In the normal configuration, there is an approximately 15-degree anterior-to-posterior down-sloping of the fovea ethmoidalis although variability in its height and slope exist. The periorbital perichondrium and dura of the anterior cranial fossa are tightly apposed to the respective bony walls and represent a natural barrier to tumor extension. The bony optic canal houses the optic nerve and may traverse immediately adjacent to the lateral border of the posterior ethmoid cells to a variable extent. The ethmoid sinuses are divided both anatomically and functionally into an anterior and posterior set of cells as demarcated by the ground (basal) lamella, the horizontal lateral bony attachment of the middle turbinate to the lamina papyracea. The paired anterior and posterior ethmoidal arteries traverse the roof of the ethmoid sinus. These vessels arise from the ophthalmic branch of the internal carotid artery. The anterior ethmoidal artery courses over the medial rectus muscle, penetrates the lamina papyracea, and courses the roof of the ethmoid sinus, posterior to the frontal. The posterior ethmoidal artery enters the orbit approximately 3 to 5 mm anterior to the optic foramen, emerges from the orbit approximately 12 mm posterior to the anterior ethmoidal artery courses across the roof of the posterior ethmoid cavity and terminates with the dural, the ethmoidal, and the nasal septum branches.

## Sphenoid Sinus

The sphenoid sinus is the posterior most extension of the sinonasal cavity and develops as a pneumatization of the sphenoid bone (Fig. 20-6). It is bordered by the posterior ethmoid cells and the sphenoethmoid recess anteriorly, the sella and the clivus posteriorly, the internal carotid artery and the cavernous sinus laterally, and the planum sphenoidale superiorly. The natural ostium of the sphenoid sinus is located in the superior meatus, bounded by the superior turbinate laterally and posterior-most extension of the nasal septum medially. The ostium is located two-thirds up the vertical height of the sphenoid sinus cavity. The pneumatization of the sphenoid sinus is variable especially with regard to the sella medially and floor of the middle cranial fossa laterally. Variant numbers and insertions of the intersinus septation may also exist. The optic nerves run in the superolateral aspect of the sphenoid sinus, and the carotid artery canal is located at the junction of the lateral and posterior walls of the sinus. Dehiscences of the bony coverings of the optic nerve and the internal carotid artery within the sphenoid sinus may exist.

## Frontal Sinus

The frontal sinus is the most anterior and superior extension of the sinonasal cavity. The majority of humans have two asymmetric frontal sinus cells separated by a thin septation. Variability exists in the degree of frontal sinus development with approximately 10% of the population lacking pneumatization of the frontal bone. The frontal sinuses empty into the inferomedial aspect of the sinus through the frontal recess into the middle meatus. The thicker anterior frontal table separates the frontal sinus from the soft tissue of the forehead. The thinner posterior frontal table separates the frontal sinus from the anterior cranial fossa.

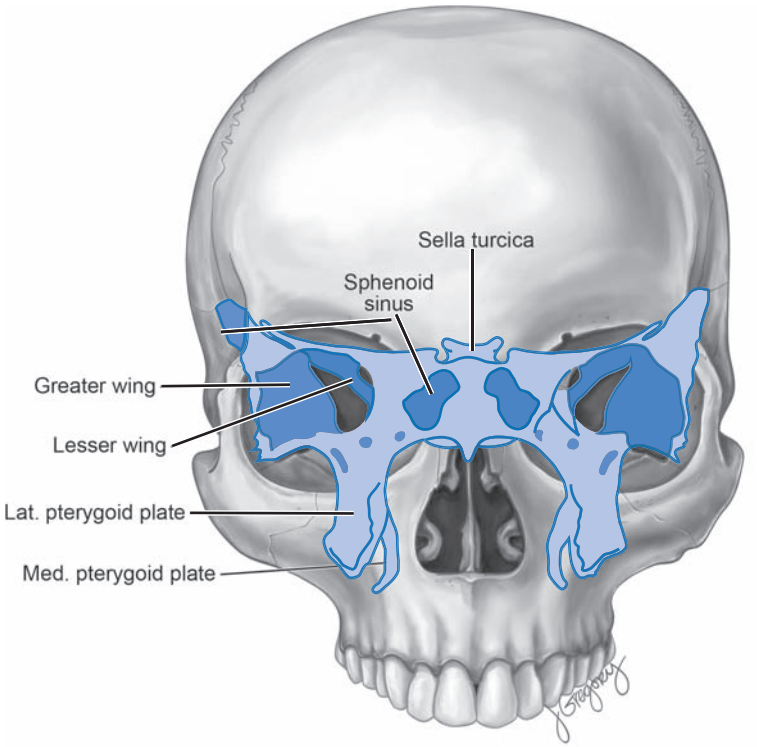

**FIGURE 20-6.** Schematic representation of the sphenoid sinus within the sphenoid bone.

## Sinonasal Lymphatics

The lymphatic drainage of sinonasal malignancies is based on the location of the primary site. In general, the lymphatics are profuse and two distinct patterns are described for the sinonasal cavity. The lymphatics originating from the anterior nasal mucosa and nasal vestibule pass through the first echelon facial, submandibular, and parotid lymph nodes and eventually continue to the jugulodigastric nodes. The majority of the nasal cavity and paranasal sinuses drain posteriorly to the retropharyngeal lymph nodes and eventually to the superior deep cervical chain.

# ANATOMY—ANTERIOR SKULL BASE

## Pterygopalatine Fossa

A description of the complex neurovascular relationships within the PPF is integral to an understanding of the pathophysiology and treatment concepts for tumors involving this area. Direct pathways between the PPF and the orbit, the middle cranial fossa, the infratemporal fossa, and the sinonasal cavities allow for contiguous spread. The fossa has the shape of an inverted pyramid. The anterior border is the posterior surface of the maxilla and the maxillary sinus cavity. The posterior border is composed of the base of the medial and lateral pterygoid plates and greater wing of the sphenoid (Fig. 20-7). The Vidian nerve enters the medial portion of the posterior PPF in the Vidian canal. The maxillary division of the trigeminal nerve exits the middle cranial fossa and enters the lateral portion of the posterior PPF through the foramen rotundum, courses through the PPF providing a branch to the pterygopalatine ganglion and reaches the inferior orbital fissure as the infraorbital nerve. The pterygoid plates and the pyramidal process of the palatine bones fuse to form the inferior aspect of the PPF. The greater wing of the sphenoid bone and the middle cranial fossa form the superior boundary of the PPF. The medial portion of the PPF is composed of contributions from the perpendicular plate of the palatine bone, the medial pterygoid plate, and the sphenoid bone. The sphenopalatine foramen within the medial wall of the PPF transmits the sphenopalatine nerve and sphenopalatine artery (branch of internal maxillary artery) into the nasal cavity. The PPF communicates laterally with the infratemporal fossa and the pterygomaxillary fissure. The contents of the PPF can be generally classified as an anterior vascular space housing the termination of the internal maxillary artery and its branches and a posterior neural space housing the maxillary division of the trigeminal and the pterygopalatine ganglion. The principal branches of the pterygopalatine ganglion are the Vidian nerve, maxillary nerve, and the lesser and the greater palatine nerves. The neurovascular structures of the PPF are embedded within fat.

## Anterior Sinocranial Junction

The anterior skull base separates the anterior cranial fossa from the sinonasal cavity. The complex anatomy of this area has critical physiologic and tumor-related implications. The osteology of this area encompasses contributions from the frontal, the ethmoid, and the sphenoid bones. The sagittal length of the anterior skull base spans the posterior table of the frontal sinus (anterior) to the planum sphenoidale and the anterior clinoid process (posterior) (Fig. 20-5). The frontal bones form the lateral bony boundaries including the superior orbital wall. This area houses the orbital portions of the frontal lobe. The central portion of the floor of the anterior cranial fossa is composed of portions of the ethmoid bone including the central crista galli dividing the paired cribriform plates. The falx cerebri separating the two cerebral hemispheres attaches to the crista galli. The depression of the cribriform plates represents the lowest and thinnest portion of the anterior cranial fossa and functions to transmit olfactory filia from the sinonasal cavity to the olfactory bulbs lying on the

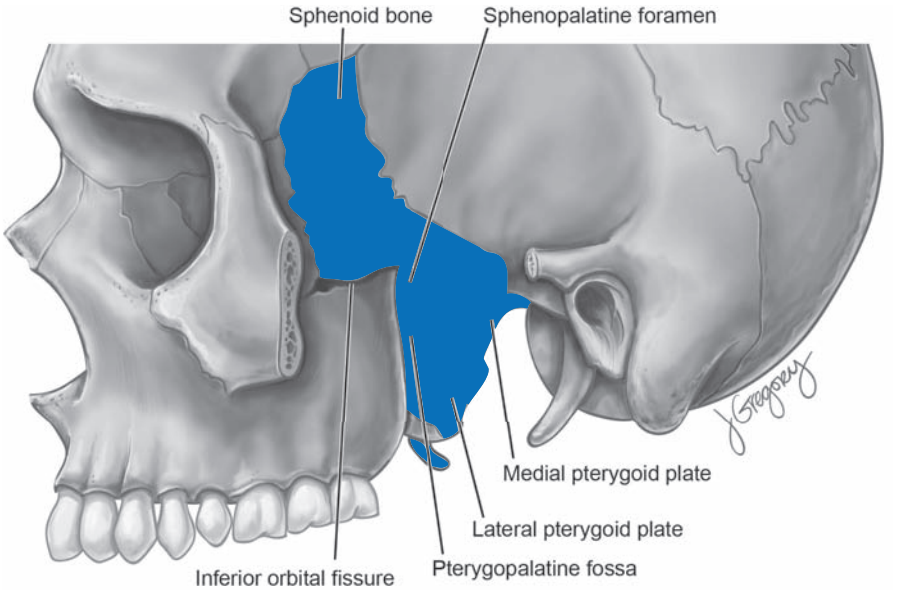

**FIGURE 20-7.** Bony relationships of the pterygopalatine fossa.

intracranial surface. The fovea ethmoidalis is immediately lateral to the cribriform plate. Variances in the difference in height between the cribriform plate and fovea ethmoidalis have been described, most notably in the Keros classification[1] (Fig. 20-8).

## ANATOMY—ORBIT

### Osteology

The bony orbit is pyramidal in shape with the anterior conjunctival surface (base) pointing to the posterior orbital apex (Fig. 20-1). Direct neurovascular communication and bony foramina have the potential to act as a route of transmission among the orbit, the paranasal sinuses, and the intracranial cavity (Fig. 20-9). The medial orbital wall extends from the anterior lacrimal crest to the orbital apex and separates the orbit from the ethmoid sinus. The thin-walled lamina papyracea comprises the anterior portion of the medial orbital wall, and the thicker sphenoid bone contributes to the posterior portion in the area of optic canal. The superior portion of the medial orbital wall transmits the anterior and posterior ethmoidal arteries through their respective foramina. The anterior ethmoidal artery pierces the medial orbital wall at the site of the frontoethmoid suture and then courses through the roof of the anterior ethmoid cells in the anterior ethmoidal sulcus, immediately posterior to the frontal recess. It enters the lateral lamella of the cribriform plate to supply the frontal sinus, the nasal septum, and the lateral nasal wall. A middle meningeal branch additionally enters the anterior cranial fossa. The floor of the orbit is composed of the orbital plate of the maxilla in addition to the zygoma and palatine bones and separates the orbit from the maxillary sinus. The infraorbital canal runs along the floor of the orbit and transmits the infraorbital artery and nerve to the cheek. The lateral wall of the orbit is formed by the zygoma anteriorly and the greater wing of the sphenoid posteriorly. The latter separates the orbit

from the middle cranial fossa. The superior and inferior orbital fissures in addition to foramina transmitting the zygomaticofacial and zygomaticotemporal arteries exist on the lateral orbital wall. The lateral orbital tubercle acts as an attachment point for multiple tendons and ligaments and is located on the lateral aspect of the lateral orbital rim, approximately 1 cm inferior to the frontozygomatic suture line. The orbital roof is composed of the orbital plate of the frontal bone and has variable pneumatization by the ethmoid and frontal sinuses. The trochlea exists in the anteromedial aspect of the orbital roof approximately 4 mm posterior to the orbital rim. The supraorbital notch or foramen transmitting the supraorbital neurovasculature exists at the boundary of the medial third of the orbital roof. A periosteal layer, termed the periorbita, lines the inner surface of the orbit and has complex attachments with various areas of the surrounding bone, the fascia layers of the orbit, and the dura surrounding the optic nerve.

## Orbital Apex and Neurovascular Anatomy

The orbital apex provides direct intracranial communication and is marked by the posterior portion of the inferior orbital fissure, the superior orbital fissure, and the optic foramen. The optic foramen acts as an opening into the optic canal for the optic nerve and ophthalmic artery. The canal itself is housed within the lesser wing of the sphenoid bone, separating the canal contents from the posterior ethmoid cells and the sphenoid sinus medially. The superior orbital fissure lies between the greater and lesser wings of the sphenoid and transmits the oculomotor nerve (III), the trochlear nerve (IV), the lacrimal, the frontal, and the nasociliary branches of the ophthalmic nerve (V1), the abducens nerve (VI), branches of the ophthalmic vein and sympathetic fibers from the cavernous plexus. The oculomotor nerve divides into a superior and inferior branch within the cavernous sinus. The maxillary division of the trigeminal nerve from the PPF, the infraorbital branch of the maxillary artery, and the inferior ophthalmic vein pass through the inferior orbital fissure in the posterior-lateral portion of the orbital floor.

The optic nerve is approximately 5 cm in length and 4 mm in diameter. It consists of four anatomic segments in its length from the optic chiasm to the globe: intracranial, intracanalicular, intraorbital and intraocular. A dural layer surrounds the majority of the nerve course. The arterial supply to the optic nerve is primarily from the central retinal artery, a branch of the ophthalmic artery.

The ophthalmic division of the trigeminal nerve provides sensation to the orbit. It enters the orbit through the superior orbital fissure and divides into the frontal, the lacrimal, and the nasociliary nerves. The frontal branch divides into the supraorbital and supratrochlear nerves and supplies the upper eyelid and the forehead. The lacrimal nerve carries postganglionic parasympathetic fibers and somatic sensory innervation to the lacrimal gland. The nasociliary branch has multiple complex branches including the long and the short ciliary nerve (sympathetic and parasympathetic for pupil reactivity), anterior and posterior ethmoid nerves, the infratrochlear nerve (sensation to medial lower lid, conjunctiva, lacrimal sac, and side of the nose).

The primary vascular supply to the orbit is the ophthalmic artery (Fig. 20-10). The artery arises from the internal carotid artery as it exits the cavernous sinus and enters the orbit through the optic canal. Multiple branches arise from the ophthalmic artery within the orbit. Branches supplying ocular function include the central retinal artery, the ciliary artery, and the collateral branches to the optic nerve. Nonocular orbital branches include the lacrimal artery, the muscular arteries, and the periosteal branches. Nonocular extraorbital branches include the anterior and the posterior ethmoid arteries, the supraorbital artery, the medial palpebral artery, the supratrochlear artery, and the dorsal nasal artery. Anastomoses between the ophthalmic branches and branches of the external carotid artery system exist, namely, the superficial temporal artery and the angular arteries. Additional anastomoses exist between the cavernous portion of the internal carotid artery and the ophthalmic artery via the inferolateral trunk. Anastomoses additionally exist with the internal maxillary artery via the middle meningeal artery. The infraorbital artery is a branch of the internal maxillary artery and enters the orbit

(c) 2014 Wolters Kluwer. All Rights Reserved.

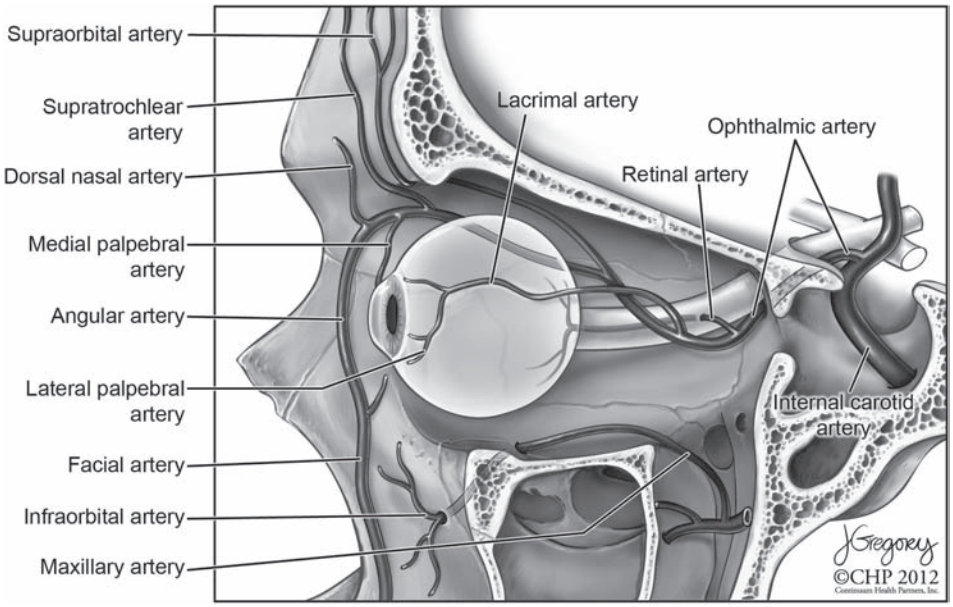

**FIGURE 20-10.** Lateral view of the primary arterial supply to the orbit.

through the inferior orbital fissure. It travels across the floor of the orbit and exits the skull at the infraorbital foramen. The venous supply to the orbit is represented in Figure 20-11.

## Extraocular Muscles

The annulus of Zinn is a ring of tight fibrous tissue at the orbital apex separating the superior orbital fissure into intra and extraconal spaces. The annulus acts as the origin site for the four rectus muscles (superior, medial, inferior, lateral) and the superior oblique muscle (Fig. 20-12). Innervation of the extraoccular muscles are conferred by the oculomotor nerve with the exceptions of the trochlear nerve (superior oblique muscle) and the abducens nerve (lateral rectus muscle). The innervation courses in the intraconal space and enters the muscles at approximately the posterior one-third junction. The medial and superior recti originate adjacent to the insertion of the annulus to the body of the sphenoid bone adjacent to the optic foramen. The medial rectus courses adjacent to the lamina papyracea before inserting on the globe, making it prone to surgical and traumatic involvement from injury to the lamina as well as contiguous spread from ethmoid sinus neoplasms. The superior rectus runs inferior to the levator palpebrae superioris before attaching to the globe. The latter forms an aponeurotic band in the region of Whitnall ligament and inserts onto the tarsal plate of the eyelid skin and the medial and lateral canthal tendons. The inferior rectus originates from a tendinous portion of the annulus that spans the body and greater wing of the sphenoid bone. The muscle runs close to the orbital floor, especially in its posterior course, intimating a relationship with maxillary sinus pathology. The lateral rectus

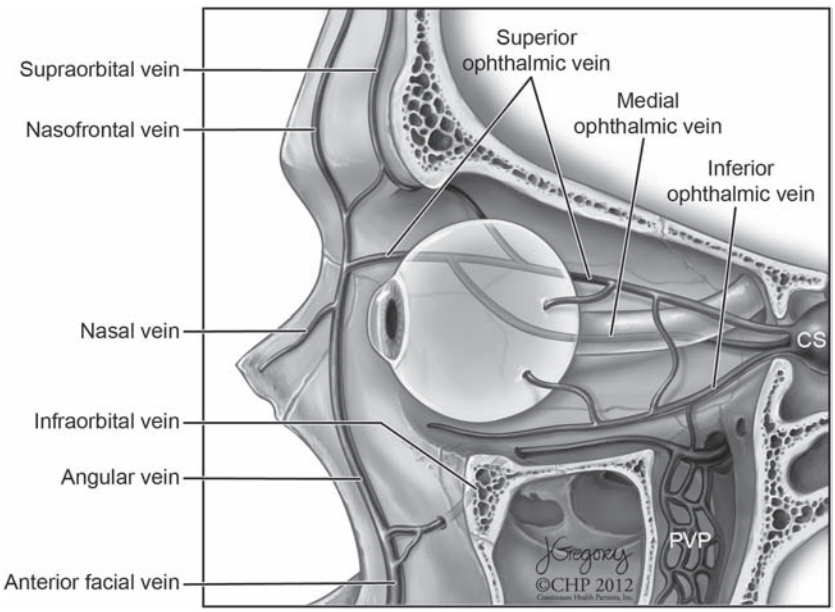

**FIGURE 20-11.** Lateral view of the primary venous supply to the orbit.

(c) 2014 Wolters Kluwer. All Rights Reserved.

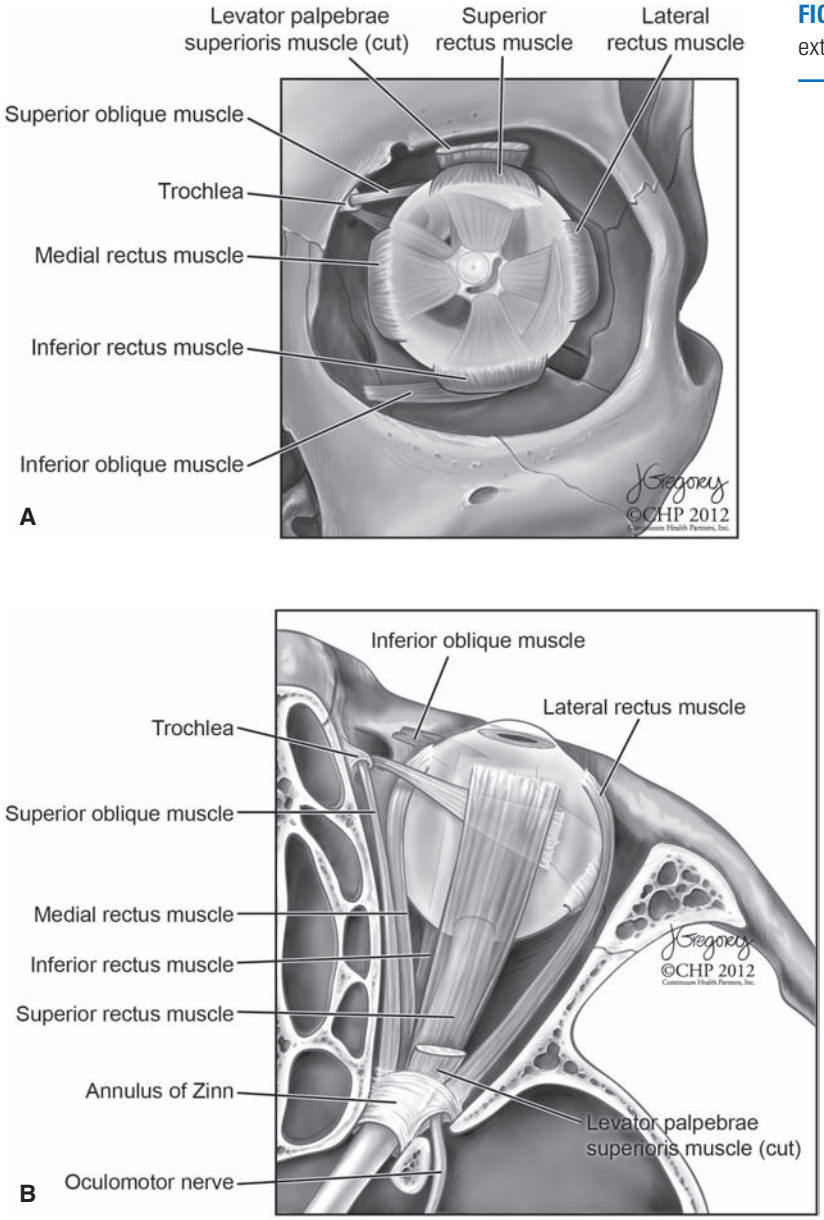

**FIGURE 20-12.** Frontal **(A)** and superior **(B)** views of the extraocular muscles.

originates from the body of the greater wing of the sphenoid near the lateral border of the superior orbital fissure and is separated from the optic nerve posteriorly by the ciliary ganglion. The insertion of the lateral rectus on the orbit is inferior to the lacrimal gland, the artery, and the nerve. The superior oblique muscle arises from the superomedial aspect of the annulus courses anteriorly through the trochlea before inserting in the posterolateral surface of the globe. The inferior oblique uniquely does not originate from the annulus of Zinn but rather arises from the periorbita of the inferomedial orbit lateral to the nasolacrimal duct. It courses lateral and posteriorly below the inferior rectus to insert on the inferolateral surface of the globe.

## Lacrimal Gland

The oval-shaped, bilobed lacrimal gland is located adjacent to the globe in the superior-lateral aspect of the orbit in a depression of the frontal bone termed the lacrimal gland fossa (Fig. 20-13). A pseudocapsule invests the gland. The orbital lobe of the lacrimal gland is approximately 2 to 3 times larger and is positioned posterior-superior to the smaller palpebral lobe. The two lobes are separated by the lateral horn of the levator aponeurosis, which along with Whitmall ligament and periostial fibers (Soemmering ligaments) provide support to the gland. Multiple excretory ducts exist for each lobe and ultimately pass through the palpebral lobe to reach the superior lateral conjunctival fornix, 5 mm above the superior tarsal margin. The boundaries of the lacrimal gland include the lateral rectus inferiorly, the orbital septum anteriorly, orbital fat posteriorly, and the globe medially. The serous function of the lacrimal gland is mediated by the columnar and myoepithelial cells that comprise the acini. The secretions formed in the acinar system drain into the intralobular space, followed by the interlobular space and ultimately into the main ducts. Arterial supply to the lacrimal gland is primarily from the lacrimal artery, a branch of the ophthalmic artery. Anastomoses between the lacrimal artery and the external

(c) 2014 Wolters Kluwer. All Rights Reserved.

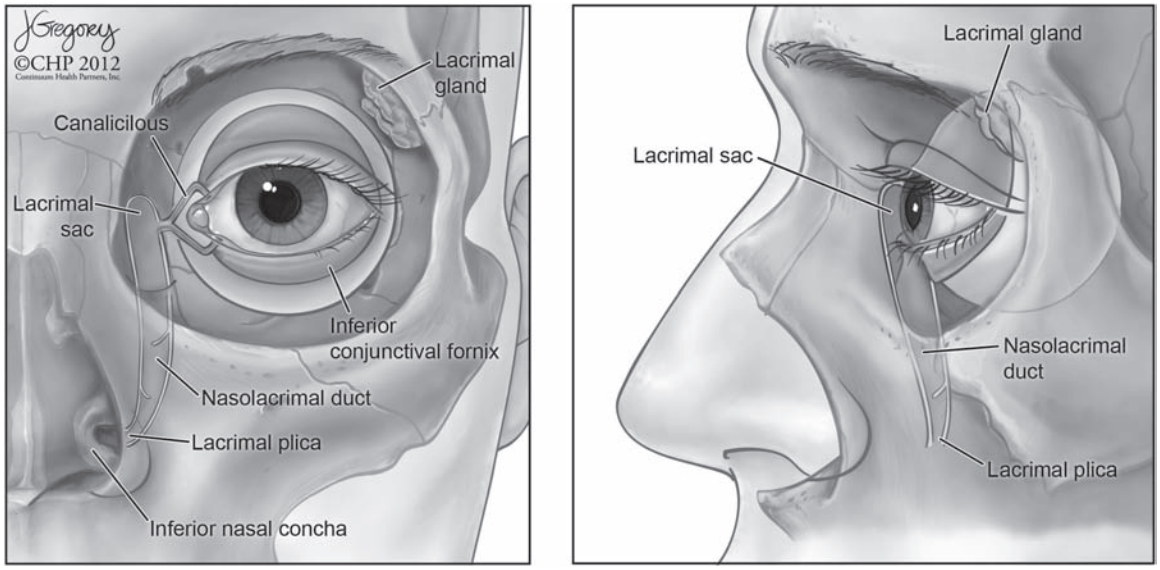

**FIGURE 20-13.** Schematic representation of the lacrimal system.

carotid artery system additionally exist including the middle meningeal artery, the anterior deep temporal artery, and, potentially, the infraorbital artery. Venous drainage is via the superior ophthalmic vein.

The complex pathway of the parasympathetic and the sympathetic innervations of the lacrimal gland initiates in the lacrimal nucleus in the pons and travels through the cerebellopontine angle as the nervus intermedius. The fibers course through the geniculate ganglion and exist as the greater superficial petrosal nerve. This merges with the deep petrosal nerve (sympathetic fibers from the internal carotid plexus) to form the Vidian nerve. Synapsing of the parasympathetic fibers occurs in the pterygopalatine ganglion. Postganglionic fibers travel via the zygomatic nerve and merge with the lacrimal nerve, a sensory branch of the ophthalmic division of the trigeminal nerve, prior to penetration of the lacrimal gland.

## Lacrimal Drainage System

Flow of tears away from the nasal bulbar conjunctival surface through the lacrimal system begins at the inferior and superior lacrimal puncta (Fig. 20-14). These openings into the lacrimal canaliculi face posteriorly toward the globe, are approximately 0.3 mm in diameter, and are separated by approximately 6 mm from the medical canthus. The puncta are positioned on an elevation termed the papilla lacrimalis. The paired upper and lower canaliculi traverse the distance from the puncta to the lacrimal sac. The canaliculi are lined by nonkeratinizing, stratified squamous epithelium surrounded by elastic tissue. The canaliculi have an initial vertical segment (2 mm) followed by an approximately 90-degree bend termed the ampulla and continue with the horizontal segment (8–10 mm). The common canaliculus is formed by the merger of the horizontal segments. The common

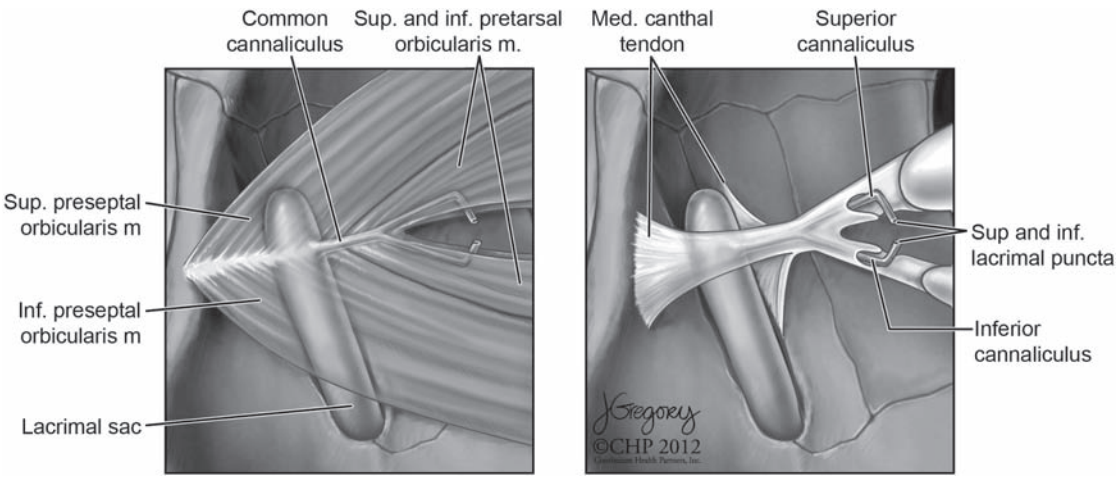

**FIGURE 20-14.** Schematic representation of the lacrimal drainage system.

(c) 2014 Wolters Kluwer. All Rights Reserved.

canaliculus pierces the lacrimal fascia to enter the lacrimal sac through the valve of Rosenmüller. The sinus of Maier is the dilation of the common canaliculus near the entrance to the lacrimal sac. The lacrimal fossa houses the lacrimal sac and is bounded by the anterior (frontal process of maxilla) and the posterior (lacrimal bone) lacrimal crests in the anterior-medial portion of the orbit. Visualization of the lacrimal sac through an intranasal approach, as is done in dacryocystorhinostomy, can be achieved by removal of the lacrimal bone in the superior aspect of the lateral nasal wall, anterior to the uncinate process. The lacrimal sac is divided into a superior portion termed the fundus and an inferior portion termed the body. The lacrimal fascia, an extension of the orbital periosteum, envelops the lacrimal sac and the nasolacrimal duct. Attaching fibers of the orbicularis oculi muscle are immediately deep to the fascia layer around the lacrimal sac. The nasolacrimal duct connects the lacrimal sac to the inferior meatus opening into the nasal cavity, termed Hasner valve. The nasolacrimal duct has a 12-mm superior intraosseous portion and a 5-mm inferior membranous portion and has a slight posterior-lateral trajectory as it enters the nose (Fig. 20-15). The approximate diameter of the duct is 1 mm. The lacrimal sac and the nasolacrimal duct are lined by stratified columnar epithelium with foci of ciliated cells and interspersed goblet cells.

## NASAL AND PARANASAL NEOPLASMS—NATURAL HISTORY, PATHOLOGY, PATHOGENESIS, AND PATTERNS OF SPREAD

### Natural History

Sinonasal malignancies are rare, comprising fewer than 3% of upper aerodigestive neoplasms. The most common malignancy, squamous cell carcinoma (SCC), has an estimated incidence of <1:100,000.[2,3] The rarity of these lesions limits epidemiologic data and formation of prospective, randomized treatment protocols. Hence, the literature on sinonasal malignancies is largely composed of single institutional, retrospective case series. The origin of these cancers is from the maxillary sinus in 60% to 70%, from the nasal cavity in 20% to 25%, and the ethmoid sinus in 10% to 15% of cases. Malignancies arising from the frontal and sphenoid sinuses are extraordinarily unusual, making up fewer than 5% of all cases. At presentation, the majority of lesions extend beyond the site of origin.[4,5] Sinonasal malignancy most commonly occurs in patients older than 40 years of age and has a slight male preponderance.[2–4]

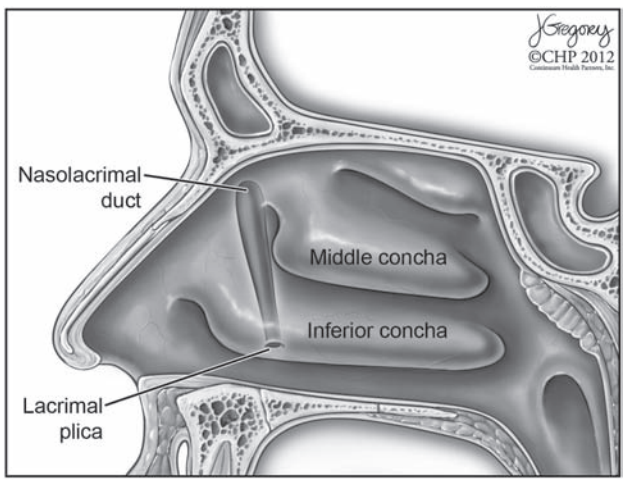

**FIGURE 20-15.** Sagittal orientation of the lacrimal duct.

The majority of treatment failures are related to local recurrence. Lymphatic metastasis at initial presentation for sinonasal malignancy is uncommon. At the time of initial diagnosis, a 10% to 20% rate of lymphatic involvement is noted in patients with carcinoma of the maxillary sinus. The incidence increases up to 35% during the course of the disease.[6–10] Lymphatic spread for lesions originating from the ethmoid sinus is less common and ranges from approximately 5% to 10%.[11–13] The propensity for lymphatic and distant spread of disease additionally varies based on the tumor histology and grade. The retropharyngeal location of the majority of lymphatics implies inaccessibility during routine examination and is evaluated by imaging studies. Additionally, the surgical treatment implications for this pattern of spread are significant as the first echelon nodes are not routinely accessible at the time of resection and are better addressed with radiation therapy. The unusual presentation of a sinonasal cancer with a cervical metastasis may portend a locally advanced lesion and/or aggressive histology.

### Benign Lesions

The differential diagnosis of sinonasal lesions is extensive and requires multimodality evaluation including endoscopic examination, radiography, and histopathology. Although this chapter primarily discusses malignancy, certain nonneoplastic processes can mimic the former and must be considered at the time of evaluation. One of the central challenges of successful detection of a sinonasal malignancy is differentiation from more common, inflammatory conditions including allergic rhinitis and sinusitis. Adding confusion to the issue is the frequent coexistence of sinusitis and neoplasm. Tumor growth may obstruct sinonasal outflow tracts and precipitate secondary infection. Older age at presentation, unilateral disease, symptoms, and examination findings consistent with aggressive behavior are more suggestive of malignancy and should increase clinical suspicion. These issues highlight the importance of close examination of preoperative imaging and collection of all sinus specimens for histology in patients undergoing surgery for presumed inflammatory sinusitis. An expanded discussion of two benign conditions, inverted papilloma and juvenile nasopharyngeal angiofibroma, is presented below given their clinical importance and the specific challenges associated with these lesions. The salient features of the other benign and inflammatory lesions that should be considered in the evaluation of a patient with a sinonasal lesion are presented in Table 20.1.

### Inverted Papilloma

Several different types of papilloma are identified in the sinonasal cavity. Squamous papilloma related to human papillomavirus (HPV) infection has a predilection for the nasal vestibule. Although local excision is considered curative, surveillance of the initial site and the remainder of the upper aerodigestive tract is required. Three different types of papilloma arising from the Schneiderian (respiratory) mucosa have been described. Although these lesions differ in their anatomic predilection and clinical behavior, the ultimate distinction requires histopathological analysis. Everted papilloma (fungiform) typically arise from the septum and are curable with local resection. Everted fronds of epithelium are noted on histology. Cylindric papillomas are rare and are similar in histology to everted papilloma. These latter two lesions are not felt to have significant malignant potential.

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 20.1 Benign Sinonasal Lesions**

| Diagnosis | Salient Features |
|---|---|
| Acute invasive fungal sinusitis | Immuno-compromised host including neutropenia and poorly controlled diabetes; rapid tissue destruction; invasive fungal forms on histology; treated with wide local debridement, systemic antifungal therapy and reversal of immuno-compromised state if possible |
| Allergic fungal sinusitis | Atopic and immuno-competent host; polypoid changes with potential for bony erosion and expansion; characteristic radiographic features, allergic mucin and histology; treated with endoscopic sinus surgery, anti-inflammatory therapy |
| Fungal ball (mycetoma) | Immuno-competent host; single affected sinus with potential for bony expansion; characteristic radiographic features; treated with endoscopic opening of the affected sinus and removal of lesion |
| Granulomatous disease (Wegener granulomatosis, sarcoidosis, mycobacteria, syphilis) | Diffuse mucosal inflammation, granulation, and potential for tissue destruction especially the nasal septum; histology and systemic evaluation required; treated with systemic therapy |
| Osteoma | Most common benign sinonasal tumor, primary tumor of mature lamellar bone with characteristic radiographic findings; may be silent or cause local symptoms and/or sinus obstruction; surgical removal if symptomatic, enlarging, or obstructive |
| Fibrous dysplasia | Replacement of normal bone by fibroblasts and collagen; characteristic radiographic appearance; generally observed |
| Pyogenic granuloma (lobular capillary hemangioma) | More common in females especially around pregnancy, most commonly located on the anterior septum and the inferior turbinates, frequently associated with recurrent epistaxis, treated with wide local excision |
| Neurogenic tumors (schwannoma and neurofibroma) | Arise from peripheral nerves; potential for malignancy (neurofibroma); characteristic radiographic appearance; surgery considered for enlarging or symptomatic lesions |

Inverted papilloma most commonly arise from the lateral nasal wall of the nasal cavity but may occur anywhere in the sinonasal tract. The overall incidence is estimated to be between 0.5 and 1.5 cases per 100,000 per year.[14,15] The etiology of inverted papilloma remains unclear and theories suggesting inflammatory and viral (HPV) origin have been described.[16,17] The name arises from the characteristic histological finding of infolded projections of the epithelium into the underlying stroma. Recurrence after treatment may occur in up to 20% of lesions even with aggressive initial surgery. The potential for synchronous or metachronous transformation to squamous cell carcinoma has been described. A wide range of transformation rates has been described, with the majority of series reporting a rate of approximately 10%.[18] There is some uncertainty of the number, however, because carcinoma *in situ* changes occur on the surface of the papillomas. To condemn such lesions as malignant papilloma may be an overstatement, especially since the percentage of them that go on to full-blown malignancies is unknown.

Although medial maxillectomy through a transfacial, lateral rhinotomy approach has historically been considered the treatment of choice for inverted papilloma, application of endoscopic techniques for resection of these lesions has demonstrated favorable results. Avoidance of an external incision is an obvious advantage over the more traditional procedures.[19–21] Additionally, the endoscopic approach can be tailored to the specific site and extent of lesion, allowing for complete tumor removal and preservation of functional sinus physiology (Fig. 20-16). Although unsubstantiated by conclusive data, most experienced endoscopic surgeons believe the critical factor associated with successful surgical management of inverted papilloma lesions is identification of the site of origin and drilling of the underlying bone. This is greatly facilitated with the panoramic visualization

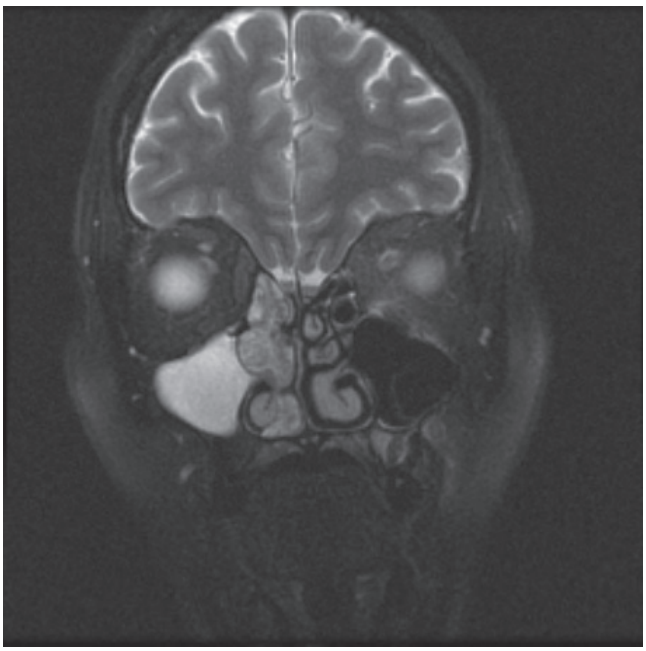

**FIGURE 20-16.** Postcontrast, coronal T-2 weighted MRI of a sinonasal inverted papilloma with involvement of the right nasal cavity, the middle turbinate, the infundibulum, and the ethmoid sinus. Postobstructive pattern without tumor involvement noted in the right maxillary sinus. This lesion is potentially amenable to endoscopic resection.

(c) 2014 Wolters Kluwer. All Rights Reserved.

provided by endoscopy. In a large meta-analysis of surgical treatment for inverted papilloma, Hwang et al. reported a lower rate of recurrence (12% vs. 20%) in patients treated endoscopically versus conventional surgical means.[22]

## Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) accounts for approximately 0.05% of all head and neck tumors and has an estimated incidence of 1:150,000.[23,24] These lesions occur exclusively in males and are most common in the second decade of life, likely secondary to androgen hormone responsiveness. The most common site of origin is the area around the sphenopalatine foramen and multiple potential patterns of local spread may exist. Medial spread occurs into the sinonasal cavity and nasopharynx with limited resistance. Lateral extension occurs into the pterygopalatine and infratemporal fossa. Posterior-superior growth may involve the sphenoid sinus and cavernous sinus. Erosion of the sphenoid bone may result in intraorbital and intracranial extension (middle cranial fossa). The most common presenting symptoms include nasal obstruction, epistaxis, facial pain, headache, and facial swelling. Symptoms related to orbital, sinonasal, and Eustachian tube mass effect may also occur. Endoscopic examination reveals a hypervascular appearing soft tissue mass.[23]

A combination of CT and contrast-enhanced MRI are used to characterize JNA lesions including the soft tissue extension, bony erosion, anterior bowing of the posterior maxillary wall (Holman-Miller sign), and vascularity (Fig. 20-17). The characteristic imaging studies combined with patient demographics is typically adequate for pretreatment diagnosis. Office-based biopsy is associated with the potential for extraordinary hemorrhage and should not be performed for suspected JNA. Histopathology from surgical specimens demonstrates a complex and heterogeneous proliferation of blood vessels with absent or thin elastic laminae and variably thick vascular walls. A background collagen matrix with spindle-shaped cells is noted around the blood vessels.[25] Extensive vascular arcades may be identified on angiography with the predominant vascular supply arising from the internal maxillary artery and a minor contribution possibly arising from the ascending pharyngeal artery, the internal carotid artery, and the contralateral external carotid artery system. Several staging systems have been proposed as described by Sessions, Chandler, and Fisch.[26–28] Staging is essential for reporting of treatment outcomes and possibly for predicting the prognosis for recurrence. For clinical purposes, the critical aspects of "advanced" disease that impact surgical planning include extension to the infratemporal fossa, the orbit, the cavernous sinus, and the middle cranial fossa.

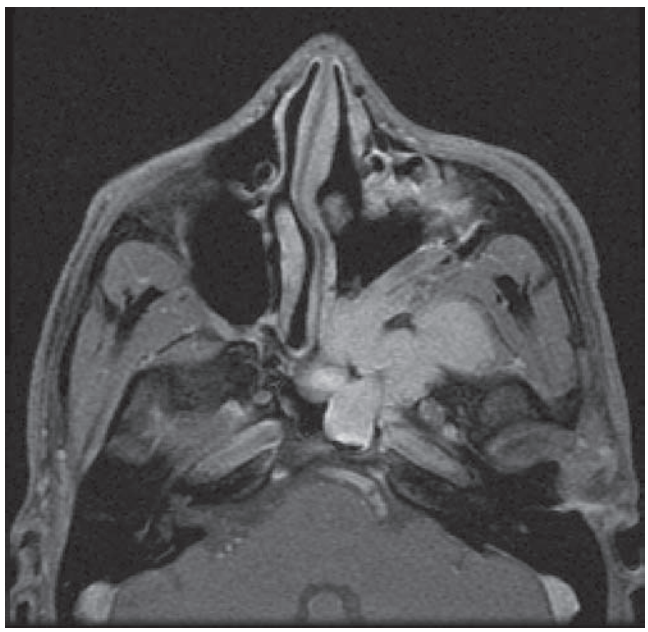

**FIGURE 20-17.** Axial postcontrast, fat-suppressed T-1 weighted image demonstrating a large, recurrent juvenile nasopharyngeal angiofibroma with multicompartmental involvement including the sphenoid sinus, the pterygopalatine fossa, and the infratemporal fossa.

Surgery represents the primary treatment modality for JNA. Although local control has been associated with radiation therapy, the potential long-term adverse effects in this young population (secondary malignancy, oribital and intracranial dysfunction) limit its use to unresectable and enlarging lesions.[29–31] Not surprising, given the complex anatomic location of JNA lesions, multiple surgical approaches have been described. The hypervascularity of these lesions is counteracted by presurgical angiography and emobilization. Choice of the available surgical approaches is based on the location and extent of the lesion. Open skull base approaches include midface degloving, facial translocation, lateral rhinotomy, transpalatal, craniofacial, and subcranial approaches. The application of expanded endoscopic techniques has rapidly emerged as a meaningful primary treatment modality for the majority of JNA lesions. Excellent tumor control rates have been reported from multiple centers with an overall favorable perioperative morbidity profile including decreased blood loss, shorter hospital stay, and avoidance of facial incisions. Lateral access to the infratemporal fossa and masticator space can be achieved with limited additional morbidity by the inclusion of a sublabial incision and a limited bony opening through the maxillary antrum.[32–36]

Regardless of the approach, a significant risk of recurrence is associated with JNA with reported rates ranging from 15% to 45%. The likelihood of recurrence correlates with the stage and location of the primary lesion especially if there is bony skull base involvement, prior history of recurrence, and an incomplete resection of both the soft tissue and bony components. Routine surveillance imaging with MRI scan is advocated to identify early recurrence of lesions.[37–39]

# MALIGNANT LESIONS

The World Health Organization has described a histological classification of primary sinonasal malignancies with categories based on the tissue type: epithelial, soft tissue, bone and cartilage, hematolymphoid, and neuroectodermal. More than 25 types are listed. The more common lesions are briefly discussed.[40]

## Squamous Cell Carcinoma

Squamous cell carcinoma is the most common sinonasal malignancy accounting for 70% to 80% of malignant tumors. The most common site of origin for sinonasal SCC is the maxillary sinus cavity, followed by the nasal cavity and the ethmoid sinus.[41–43] A possible association between tobacco inhalation and sinonasal SCC has been described,[44,45] although this is unclear. The potential malignant transformation of inverted papilloma, especially when recurrent, has also been well described[46–48] (Fig. 20-18). The majority of patients with sinonasal SCC present with advanced local disease (T3/T4). Although nodal disease is present at presentation in only 10% to 20% of cases, the incidence increases to 20% to 35% for recurrent lesions.[3,5,42,43]

(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 20-18.** Coronal noncontrast CT scan of a patient with sinonasal squamous cell carcinoma with orbital involvement in the setting of inverted papilloma.

A higher incidence of nodal metastasis is associated with SCC of the maxillary sinus cavity compared with other sinonasal sites.[49] The presence of nodal disease is a poor prognostic sign.

## Adenocarcinoma

Adenocarcinoma represents the second most common primary malignancy of the paranasal sinuses, accounting for up to 20% of lesions. These lesions are more commonly localized to the superior aspects of the nasal vault and ethmoid sinuses and have been associated with a history of industrial inhalant exposures, especially wood dust and leather.[50–53] The possibility of the combined carcinogenic effects of industrial chemicals and wood dust has been described by Wolf et al. in a study of dysplastic changes occurring in a cohort of factory workers.[54] Adenocarcinoma accounts for >50% of malignant lesions of the ethmoid sinus and has a propensity for intracranial spread.[55,56]

## Minor Salivary Gland Malignancies

Mucoepidermoid and adenoid cystic carcinomas originate in the minor salivary glands and can involve the paranasal sinuses. Together they make up fewer than 15% of all cases of salivary gland tumors.[57] As in other sites of the head and neck, adenoid cystic carcinoma of the sinonasal cavity has a propensity for perineural spread and delayed recurrence.[58] Despite aggressive surgery, positive histologic margins and skip lesions may occur.

## Neuroendocrine Tumors

Neuoendocrine lesions are theorized to arise from the neuroectoderm of the nasal cavity and include esthesioneuroblastoma, sinonasal undifferentiated carcinoma, small cell carcinoma, and neuroendocrine carcinoma. The prognosis for this group of disorders correlates strongly with histology[59]; esthesioneuroblastoma have the best prognosis and small cell carcinoma the worst. Histopathological differentiation of these lesions is challenging and is significantly aided by immunohistochemistry.

Esthesioneuroblastoma (olfactory neuroblastoma) arises from the neural crest cells in the olfactory epithelium of the superior nasal and sinus cavity. A bimodal age distribution is identified at 10 to 20 and 50 to 60 years of age. The gross morphology varies and may be either polypoid or sessile. A propensity for intracranial spread through the olfactory nerve bundles and the cribriform plate is noted. Cervical lymph node and distant metastasis (lung, bone) occur in 10% to 15% during the course of the disease and may be delayed.[60–66] Histopathology reveals rosettes of neuroblastoma cells with varying degrees of differentiation. Immunohistochemical staining with neural markers is positive for neurospecific enolase, S-100 protein, and neurofilament protein.

The Kadish staging system divides lesions into stage A (confined to the nasal cavity), stage B (involving the paranasal sinuses), stage C (extending beyond the sinonasal cavity), and stage D (regional or distant spread).[67] A large review in 1997 identified 945 cases of esthesioneuroblastoma published in the literature.[60] This and other reports have noted improved survival and disease control rates with combination radiation therapy and surgery. However, a significant incidence of local (50%–75%) and regional (20%–30%) recurrences is expected.[60] The correlation of overall outcomes to the histopathological tumor grade as described by Hyams et al.[64] has been reported in several independent series. Five-year disease-free survival rates are noted to be significantly improved in patients with low-grade (65%–80%) versus high-grade (12%–25%) tumors.[61–66] The greatest experience to date in the surgical management of these lesions is the craniofacial approach which addresses both the sinonasal and intracranial aspects of the tumor through *en bloc* resection. The collective experience of endoscopic resection of these lesions has suggested comparable early outcomes for select lesions.[68–78]

Sinonasal undifferentiated carcinoma (SNUC) is a unique tumor that is characterized by extremely malignant behavior with a propensity for local recurrence, distant metastasis, and poor overall survival. The diagnosis can be difficult given the rarity of these lesions and their histopathologic similarity to other poorly differentiated neuroendocrine tumors, such as high-grade esthesioneuroblastoma. Histopathology reveals poorly differentiated or undifferentiated small and medium-sized polygonal cells with vascular and perineural invasion, high mitotic rates, high nuclear to cytoplasmic ratios, and tissue necrosis. Positive immunohistochemical staining with epithelial membrane antigen and cytokeratin is noted. Although the ideal treatment for these lesions remains controversial, multimodality therapy including neoadjuvant chemoradiation followed by surgery in resectable cases may result in improved overall outcomes. Despite their overall poor prognosis, dramatic response to chemoradiation has been described.[79–82]

## Mucosal Melanoma

Mucosal melanoma constitutes approximately 3% of all sinonasal malignancies and 1% to 2% of all malignant melanoma. A significantly worse prognosis compared with cutaneous lesions is noted.[83,84] The most common sites are the nasal septum, the maxillary sinus, and the ethmoid sinus, respectively. Examination reveals a soft tissue lesion with variability in pigmentation. Melanin is identified in approximately two-thirds of lesions. Positive immunohistochemical staining for vimentin, HMB-45, and S-100 protein is confirmatory. Therapy typically involves a combination of wide surgical resection and radiation therapy. Long-term survival is poor with 5-year survival rates ranging from 10% to 47%. Negative prognostic factors include older age

(c) 2014 Wolters Kluwer. All Rights Reserved.

at presentation, poorly or undifferentiated histology, recurrent lesions, and occurrence of regional or distant spread.[83,85–87]

## Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is the most common sinonasal malignancy in children and is felt to arise from mesenchymal progenitor cells of skeletal muscle. The orbit is the single most common site of head and neck RMS with the nasal cavity and paranasal sinuses representing 14% and 10%, respectively, of head and neck sites of occurrence. The histological subtypes include embryonal, alveolar, and pleomorphic. Localization to the primary site and embryonal subtype appear to be favorable factors. The treatment for these lesions has evolved significantly over the past 40 years, largely due to the work of the Intergroup Rhabdomyosarcoma Study Group (IRSG).[88,89] Multimodality therapy including surgery, radiation, and chemotherapy is typically indicated.[88–91] The role of surgery may be limited to tissue diagnosis in patients with small, metastatic or unresectable lesions. In patients with localized and resectable disease, a wide local excision with preservation of function and cosmesis is generally advocated prior to chemoradiotherapy. The staging and outcomes following treatment for rhabdomyosarcoma are directly correlated to the adequacy of the surgical resection.[88–90] In patients with RMS of the sinonasal cavity, a high incidence of parameningeal involvement is noted. This is noted by the presence of cranial nerve palsy, skull base erosion, and intracranial extension of the tumor. The morbidity and overall poor outcomes of surgery in this area has prompted protocols based on chemoradiation without surgery as defined by the IRSG with 5-year survival rates of 74%.[91]

## Hemangiopericytoma

Hemangiopericytoma are rare vascular lesions arising from the pericytes of Zimmerman, found on the outside of capillaries. These lesions are felt to be low-grade malignancies. Although metastases from these lesions are rare, the propensity for aggressive local behavior and recurrence after inadequate resection has been described. The majority present with some degree of epistaxis and a soft, pale, rubbery lesion on endoscopy.[92,93] The majority of lesions are treated with aggressive local surgery with radiation reserved for unresectable disease.[94]

## Lymphoma

Lymphoma may primarily involve the sinonasal cavity and is more commonly of the non-Hodgkin variety. The symptom complex may correlate with the histological grade with low-grade lesions presenting as a nasal mass with obstruction and epistaxis and high-grade lesions presenting with local tissue destruction, cranial nerve paresis, and facial swelling. Destruction of the nasal septum by what was previously referred to as "midline lethal granuloma" likely represents T-cell lymphoma. The origin of these lesions from natural killer cells is suggested by their positive staining for CD56.[95–98] The role of surgery in sinonasal lymphoma is largely limited to tissue diagnosis and treatment relies on a combination of chemotherapy and radiation. The majority of patients present with only local, extranodal disease although both local and distant spread are possible. The overall prognosis is dependent on stage and grade with 5-year overall survival rates ranging from 25% to 65%.[99–101]

## Etiology and Pathogenesis

The pathogenesis in the majority of cases of sinonasal malignancy is unknown. Multiple inhalant exposures have been linked to an increased risk of sinonasal adenocarcinoma especially of the ethmoid sinus including wood dust, aflatoxin, heavy metals, industrial chemicals, and leather tanning.[54,102–104] The reported interval between exposure and occurrence of disease ranges from one to five decades. Although heavy tobacco and alcohol have not historically been implicated as risk factors for paranasal sinus malignancy, an association of tobacco exposure and sinonasal SCC may exist.[44,45] Additionally, the occurrence of synchronous and metachronous SCC in the setting of inverted papilloma has been well documented and may occur in up to 10% of cases.

## Patterns of Spread

The presence of advanced local disease at the time of initial presentation in the majority of patients with sinonasal malignancy is due in part to the readily accessible pathways for spread. The pattern of tumor extension to adjacent structures is based on multiple factors including the location of the original lesion, presence of preformed channels, and histopathology. Lesions originating from the nasal vestibule and the nasal cavity may spread to the nasal soft tissue, the lateral nasal wall, the nasal septum, or floor of the nasal cavity into the premaxilla. The propensity for perineural spread is noted in patients with minor salivary gland lesions, especially adenoid cystic carcinoma.

The pattern of spread from primary lesions of the maxillary sinus is variable and may involve any of the surrounding structures. The relatively thin anterior maxillary wall that separates the sinus from the soft tissues of the face may be eroded directly. Inferior spread will result in oral and dental symptoms and may occur either through direct bony destruction or the dental roots. Spread superiorly into the orbit may similarly occur through the infraorbital canal or destruction of the orbital floor itself. The area around the natural maxillary sinus ostium allows somewhat unimpeded spread of tumor into the nasal and the ethmoid cavity. From there, further spread intracranially may occur as in primary ethmoid lesions. Finally, lateral and posterior extension into the infratemporal and the pterygomaxillary fossa, respectively, may occur through direct bone erosion.

Involvement of surrounding structures is noted at the time of initial diagnosis in the overwhelming majority of patients with malignancies of the ethmoid sinus. Inferior spread into the nasal cavity and the maxillary sinus occurs with minimal impedance. Spread to the frontal and the sphenoid sinuses may similarly occur through the natural recesses. Intracranial extension involves either direct bony destruction or passage of tumor through preformed neurovascular channels. Areas of naturally thin bony separation, including the fovea ethmoidalis and the lamina papyracea, allow intracranial and intraorbital spread of ethmoid lesions. The cribriform plate can also allow intracranial spread through its multiple perforations that provide nasal entry for olfactory nerve projections. Lesions involving the ethmoid sinus can spread along the anterior and the posterior ethmoidal neurovascular bundles to the intracranial cavity. Extension to the middle cranial fossa from paranasal sinus lesions may occur through the orbital apex or the lateral sphenoid wall. Involvement of the orbital apex is particularly ominous given the intimate relationship of the optic canal and the superior orbital fissure to the intracranial cavity.

The frontal and the sphenoid sinuses are infrequently the initial site of sinonasal malignancy and are more commonly involved secondarily by spread from adjacent locations. The potential directions of spread from the frontal sinus may include the superior orbit, the anterior cranial fossa, and the facial soft tissue. The bony confines of the frontal sinus serve as barriers to this spread, but microscopic communications do exist including valveless emissary veins between the posterior frontal sinus and the anterior cranial fossa (Behcet plexus). The sphenoid sinus has numerous potential pathways of spread including anteriorly into the ethmoid sinuses and the nasal cavities, inferiorly into

(c) 2014 Wolters Kluwer. All Rights Reserved.

the nasopharynx, laterally into the cavernous sinus, posteriorly into the clivus and the brain stem, and superiorly into the sella and anterior and middle cranial fossas. The morbidity of this pattern of spread and associated treatment challenges highlight the poor prognosis of advanced disease in this area.

## NASAL AND PARANASAL MALIGNANCY—CLINICAL PRESENTATION, EVALUATION, AND STAGING

### Clinical Presentation

The nonspecific symptoms and rarity of sinonasal neoplasms present a diagnostic challenge. Distinguishing early symptoms from inflammatory sinusitis requires a high index of suspicion and a delay in diagnosis is not uncommonly seen. Evaluation of patients with suspected sinonasal neoplasms incorporates clinical history, physical examination, radiography, and histology. Concerning clinical features include new onset of sinonasal symptoms at an older age, unilateral nasal polyps and masses, and symptoms atypical of sinusitis including facial hypesthesia, epiphora, diplopia, and orbital proptosis. The clinical manifestations of a given lesion are dependent on its size, invasiveness, and location. Common early symptoms associated with nasal cavity lesions include unilateral nasal obstruction, nasal pain, rhinorrhea, and epistaxis. Symptoms representing extension beyond the paranasal sinus cavity suggest advanced disease. Orbital signs and symptoms include proptosis, epiphora, diplopia, and decreased visual acuity. Soft tissue involvement of the face may result in facial swelling, cheek pain, and infraorbital hypesthesia. Symptoms localized to the oral cavity include trismus, pain, and dental hypesthesia and may result from direct erosion into the oral cavity or extension into the infratemporal and PPFs. Loosening of teeth, malocclusion, or expansion of the premaxilla resulting in ill-fitting dentures may also occur. Additional findings include a neck mass indicative of nodal spread and serous otitis media for tumors extending to the nasopharynx with involvement or obstruction of the Eustachian tube.

### Evaluation

The algorithm for evaluation and diagnosis and sinonasal malignancies is presented in Figure 20-19. Following a detailed history, the initial evaluation involves examination of the nose, the sinus

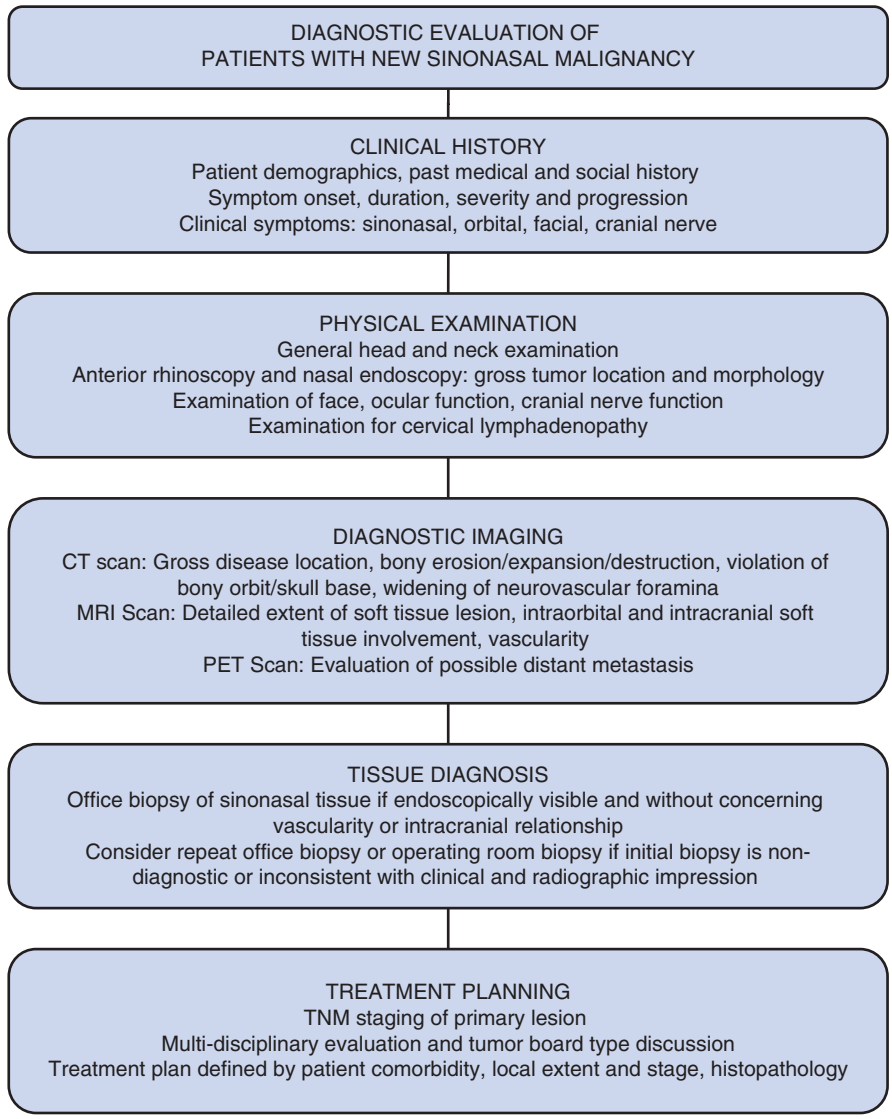

**FIGURE 20-19.** Algorithm for evaluation and diagnosis of sinonasal malignancies.

(c) 2014 Wolters Kluwer. All Rights Reserved.

cavity, the orbit, the face, the oral cavity, the cranial nerves, and the lymph nodes. Suspicious findings on endoscopy include unilateral, friable, and irregular changes of the mucosa. Unilateral nasal "polyps" should also raise suspicion for the possibility of malignancy. Lesions within the paranasal sinuses, however, are not directly visible unless they have extended beyond the sinus confines. Worrisome symptoms in the setting of a normal examination should prompt radiographic studies. Computed tomography (CT) and magnetic resonance imaging (MRI) provide complementary information in the evaluation of these lesions. Critical bony areas, including the walls of the paranasal sinuses, the skull base, the orbit, and the neurovascular foramina are best visualized by CT. Malignancy is suggested by erosion and destruction of bone in distinction to benign lesions which may result in bony expansion and displacement. Defining the soft tissue extent and distinguishing among neoplasm, mucosal edema, and retained secretions is, however, challenging with CT and is best achieved with gadolinium-enhanced MRI. Additionally, MRI is superior in identifying periorbital invasion and perineural spread for neurotropic tumors. Dural enhancement and intraparenchymal tumor extension are also better defined by MRI. The role of positron emitted tomography (PET) is still incompletely defined but may be useful in defining the extent of suspected metastases.

Histologic analysis of a suspected sinonasal lesion is critical in determination of ideal treatment modality and should be routinely performed prior to any intervention. Obtaining diagnostic tissue from a sinonasal lesion is associated with several challenges including the cavitary location, potential vascularity, and proximity to critical neurovascular structures. Office-based endoscopic-guided biopsies under local anesthesia may be performed after review of appropriate imaging studies for possible vascularity and intracranial extension of the tumor. Although the procedure has been shown to be overall safe, limitations in sensitivity and specificity do exist, likely related to sampling error. In patients with a suspicious lesion, extensive surgical biopsies may be appropriate in the setting of a negative office biopsy.[105,106]

## Staging

The 2009 American Joint Committee on Cancer (AJCC) staging of sinonasal malignancies incorporates a TNM classification scheme and is presented in Table 20.2.[107] Separate staging criteria for the primary tumor are described for maxillary versus nasal-ethmoid lesions. Specific staging of carcinomas arising from the frontal or sphenoid sinus is not addressed. The majority of patients present with advanced disease and the critical issue of resectability is suggested by the staging system as the distinction between stage T4a versus T4b. Although stage T4a is considered moderately advanced, lesions involving the orbit, soft tissue of the face, the pterygoid plates, the infratemporal fossa, the cribriform plate, the sphenoid sinus, and the frontal sinus are still often surgically resectable. In contrast, involvement of the orbital apex,

**TABLE 20.2 2009 American Joint Committee on Cancer Staging System for Sinonasal Malignancy**

**Primary Tumor (T)**

**Maxillary sinus**

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma *in situ*
- T1: Tumor limited to the maxillary sinus mucosa with no erosion or destruction of bone
- T2: Tumor causing bone erosion or destruction including extension into the hard palate and/or the middle of the nasal meatus, except extension to the posterior wall of the maxillary sinus and the pterygoid plates
- T3: Tumor invades any of the following: bone of the posterior wall of the maxillary sinus, the subcutaneous tissues, floor or medial wall of the orbit, the pterygoid fossa, or the ethmoid sinuses
- T4a: Tumor invades the anterior orbital contents, the skin of cheek, the pterygoid plates, the infratemporal fossa, the cribriform plate, the sphenoid, or the frontal sinuses
- T4b: Tumor invades any of the following: the orbital apex, the dura, the brain, the middle cranial fossa, the cranial nerves other than maxillary division of the trigeminal nerve ($V_2$), the nasopharynx, or the clivus

**Nasal cavity and ethmoid sinus**

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma *in situ*
- T1: Tumor restricted to any one subsite, with or without bony invasion
- T2: Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
- T3: Tumor extends to invade the medial wall or floor of the orbit, the maxillary sinus, the palate, or the cribriform plate
- T4a: Tumor invades any of the following: the anterior orbital contents, the skin of nose or cheek, minimal extension to the anterior cranial fossa, the pterygoid plates, or the sphenoid or frontal sinuses
- T4b: Tumor invades any of the following: the orbital apex, the dura, the brain, the middle cranial fossa, the cranial nerves other than $V_2$, nasopharynx, or clivus

extensive aspects of the intracranial cavity, the nasopharynx, or the clivus usually represent very advanced, and often unresectable, lesions. As with any staging system, there are a number of limitations of the current classification scheme including its uniform application to different histolopathologies with widely disparate behavior. Additionally, there may be a correlation between histolopathologic tumor differentiation and prognosis that is not addressed by the AJCC classification.

Lesions of the nasal vestibule are staged according to the 2009 AJCC system for primary cutaneous carcinomas excluding carcinoma of the eyelid: T1, tumor 2 cm or smaller in greatest dimension with fewer than 2 high-risk features; T2, tumor >2 cm

(c) 2014 Wolters Kluwer. All Rights Reserved.

or any size tumor with 2 or greater high-risk features; T3, tumor with invasion of the maxilla, the mandible, the orbit, or the temporal bone; T4, tumor with invasion of skeleton (axial or appendicular) or perineural invasion of skull base. High-risk features applicable to the nasal vestibule skin refer to depth of invasion, perineural invasion, or poorly/undifferentiated histology.[108]

Several prior classification schemes have been described in the past.[109–112] Ohngren highlighted the negative prognostic significance of posterosuperior extension of maxillary sinus lesions. This was defined in a practical way by a line, termed "Ohngren's line," drawn from the medial canthus to the angle of the mandible.[109] Lesions extending posterosuperior to this line are more likely to be associated with locally advanced disease including extension into the orbit and the pterygomaxillary fossa. Surgical respectability is additionally more challenging for lesions above "Ohngren's line." His classification scheme additionally incorporated histologic grading and the presence of metastasis.

# ORBITAL TUMORS

## Tumors of the Orbit

Primary tumors of the orbital cavity are relatively rare. A variety of benign and malignant histopathologies have been described (Table 20.3). A detailed description of the diverse array of lesions that may occur is beyond the scope of this chapter. Any of the different tissue types found in the orbit may represent the origin of a neoplastic lesion. Additionally, the origin of the primary lesion may be outside of the orbit itself, as is the case with sinonasal lesions extending to the orbit and with metastatic lesions. The variety and rarity of these lesions represent a clinical challenge in diagnosis and treatment. This is further compounded by the need to differentiate a neoplastic process from more common disorders including Graves' disease, inflammatory lesions (i.e., orbital "pseudotumor"), and infection. Stratification of the differential diagnosis is based on age onset, time frame of symptom progression, clinical characteristics, and imaging findings. The spectrum of possible symptoms reflects the location, invasiveness, and growth pattern of the lesion. Potential symptoms include proptosis and swelling, pain, epiphora, change in visual acuity, diplopia, and drooping of the eyelid. The physical examination of a patient with a suspected neoplasm encompasses evaluation of visual acuity, visual fields, globe position (proptosis), extraocular muscle movement, pupil response, and examination for any visible lesions. Proptosis is the most common finding and is identified when the globe protrudes >18 to 20 mm beyond the orbital rim or if there is a >2 mm asymmetry between the two globes. Imaging studies including a combination of CT and MRI are useful for defining the anatomic relationships of the lesion and providing possible diagnostic characteristics including vascularity and surrounding bony changes. The role of pretreatment biopsy for primary orbital lesions is patient specific. Although FNA or open biopsy is indicated for most lesions, two important exceptions exist. Patients with radiographic evidence of vascular lesions should not undergo FNA given the risk of hemorrhage. Additionally, open biopsy is contraindicated in patients with suspected pleomorphic adenoma of the lacrimal gland given the risk of tumor seeding of the surgical field.

**TABLE 20.3 Common Benign and Malignant Orbital Lesions in Children and Adults**

| Benign and malignant orbital tumors | |
|---|---|
| Benign tumors in children | Dermoid or epidermoid cyst |
| | Neurofibroma |

| | Cutaneous malignancy (squamous cell, basal cell) |
| | Fibrous histiocytoma |

## Tumors of the Lacrimal Gland

Primary tumors of the lacrimal gland account for approximately 5% to 25% of all orbital neoplasms. Twenty percent of these are related to epithelial lesions, and the remaining 80% are represented by inflammatory and lymphatic lesions. Of the primary epithelial neoplasms, approximately half are benign and half are malignant.[113–115] Several classification schemes have been described including those of the 1980 World Health Organization and those related to salivary gland disorders.[116,117] The most common benign neoplasm is pleomorphic adenoma and, as in their counterparts within the salivary glands, malignant transformation may occur. Up to 90% of lesions involve the orbital lobe. Primary resection through a lateral orbitotomy approach is indicated for the majority of these lesions.[118,119] Other benign tumors of the lacrimal gland include oncocytoma, myoepithelioma, hemangioma, dacryops, and dermoid cyst. The most common malignant neoplasm of the lacrimal gland is adenoid cystic carcinoma. Rarer lesions include malignant mixed tumor, adenocarcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, squamous cell carcinoma, and lymphoma. Adenoid cystic carcinoma is associated with a poor overall prognosis with the most common cause of death secondary to intracranial disease.[120–122]

Clinical presentation of lacrimal gland tumors includes presence of a visible mass, proptosis, pain, and restriction in ocular movement with diplopia. Decreased visual acuity, optic disc

(c) 2014 Wolters Kluwer. All Rights Reserved.

swelling, and loss of trigeminal sensation are less common and may be associated with more advanced or more aggressive histopathology. CT imaging of suspected lacrimal gland neoplasms may help to differentiate a benign from a malignant process. Findings concerning for malignancy include irregular bone invasion and destruction, invasion of adjacent soft tissue structures, irregular surface, and calcification within the primary lesion.

## Tumors of the Lacrimal Drainage System

A variety of neoplasms may affect the lacrimal drainage system, with approximately 70% malignant in nature. The different histopathologies can be classified based on the tissue of origin: epithelial (70% of cases), mesenchymal (12% of cases), lyphoid (11% of cases), malignant melanoma (4% of cases), and other histopathologies (1% of cases).[123] Secondary lacrimal tumors may originate from other orbital structures, surrounding skin, sinonasal cavities, and rarely metastatic sites. Inflammatory lesions may additionally present with mass effect and may be confused for neoplasm. The most common epithelial neoplasms of the lacrimal system include papillomas, oncocytomas, benign mixed tumors, and fibrous histiocytoma.[124,125] The majority of benign neoplasms of the lacrimal drainage system can be managed by wide local excision.

Malignant neoplasms involving the lacrimal system may similarly arise from primary or secondary tissues of origin. Primary epithelial lesions include squamous cell carcinoma, transitional cell carcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, and adenocarcinoma. Nonepithelial lesions include lymphoma and malignant melanoma. Management of primary malignancies is complex and individualized. Local resection of the lacrimal apparatus through a lateral rhinotomy approach may be indicated for localized lesions and when adequate clearance of margins can be achieved. Extensive resection including exenteration and inclusion of adjuvant therapy is indicated for more advanced disease.[124,125]

# TREATMENT OF NASAL AND PARANASAL SINUS MALIGNANCY

## General Considerations

The multidisciplinary team approach to the treatment of sinonasal neoplasms includes head and neck surgery, neurosurgery, radiation oncology, medical oncology, neuroradiology, ophthalmology, plastic surgery, and prosthodentics. Given the complexity of these lesions, the strategy is most effectively developed in a multidisciplinary tumor board. Treatment is based on the location, stage, and histology of the lesion (Fig. 20-20). Additionally, the presence of patient comorbidities may alter treatment planning given the physiologic stress associated with surgery, radiation therapy, and the increasing use of chemotherapy. In patients with histologically confirmed benign lesions, complete gross tumor removal with minimization of morbidity is typically indicated. Radiation therapy may be considered in select cases including unresectable lesions or unacceptable surgical morbidity. Surgery for malignancy is challenging given the need for complete tumor removal, the proximity of critical neurovascular structures, and need for functional and cosmetic restoration.

The contraindications to surgery remain controversial and may potentially include extensive involvement of the nasopharynx and the clivus precluding complete resection, especially when associated with internal carotid involvement. Bilateral orbital cavity or optic nerve involvement additionally represents a contraindication to surgery given the poor prognosis and the morbidity involved with surgery of this area. Involvement of the internal carotid artery represents a relative contraindication to surgery. Tumor involvement of either the brain or the cavernous sinus represents a poor prognostic sign and denotes an aggressive lesion. Although extension to these structures has traditionally been considered unresectable, surgical treatment has been described.[126] In contrast to primary brain malignancies, brain involvement from a sinonasal origin may spread in a continuous

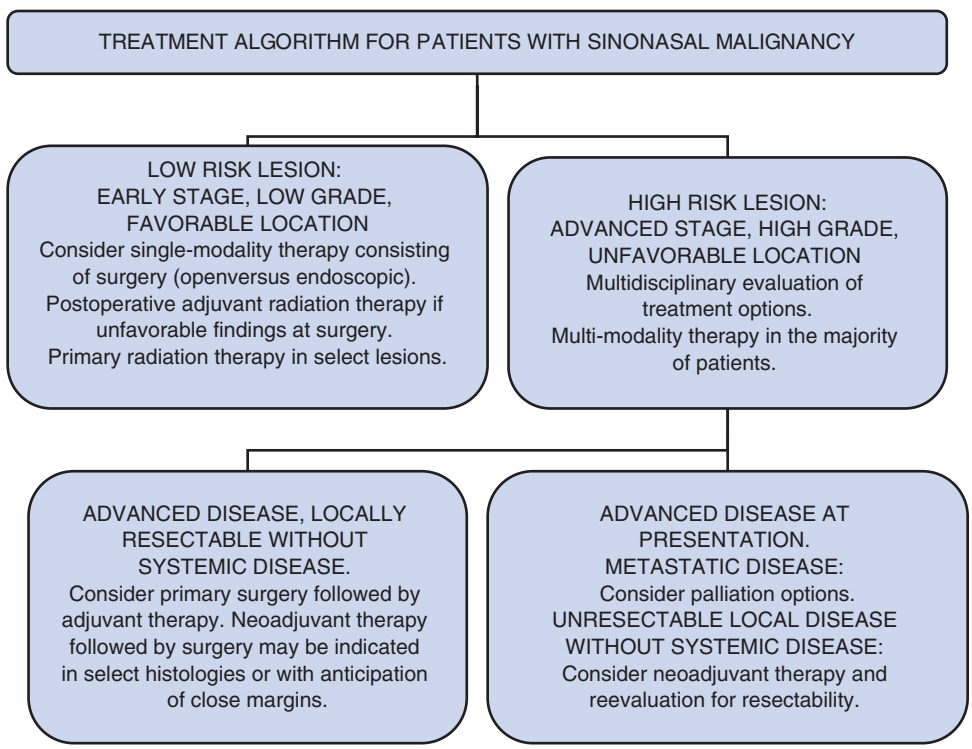

**FIGURE 20-20.** Treatment algorithm for patients with a new diagnosis of sinonasal malignancy.

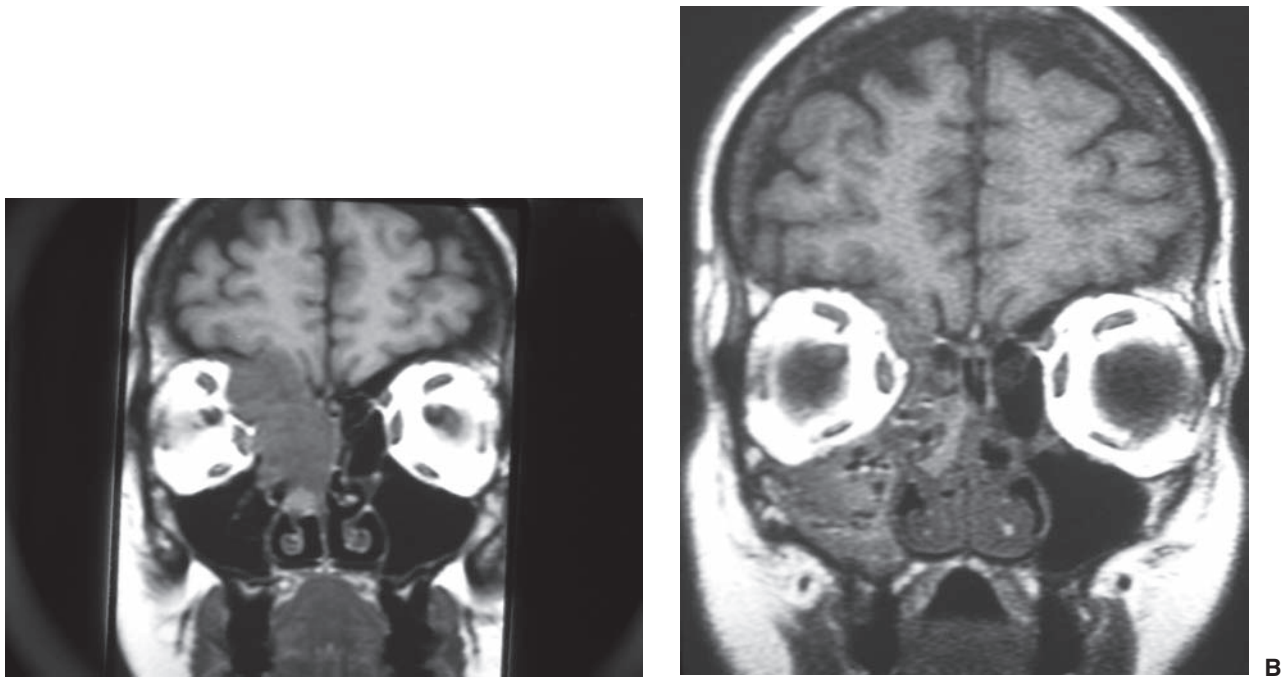
(c) 2014 Wolters Kluwer. All Rights Reserved.

manner, reinforcing the possibility of local resectability. Multifocal leptomeningeal disease, however, may also occur and would be considered unresectable. Additionally, resection of a portion of the gyrus rectus of the frontal lobe may result in minimal functional deficits. In contrast, surgical resection of the cavernous sinus is extremely challenging given the presence of extensive venous network, the internal carotid artery, and multiple cranial nerves. Given the high morbidity and overall poor outcome of lesions involving the cavernous sinus, only selective lesions should be considered surgical candidates. The limits and indications for brain or cavernous sinus resection, however, are not clear, remain controversial, and are dependent on the specific clinical situation and the experience of the surgical team.



Regardless of the approach, tumor-free margins are essential in surgery for these malignancies. Given the overall poor prognosis, potential for aggressive behavior and limitations of therapy for recurrent disease, an optimum result requires an aggressive initial surgical treatment. The goal of negative margins typically requires multiple frozen section specimens at the time of surgery and extension of the resection to include positive areas. This is especially challenging in surgery for sinonasal malignancy. The majority of lesions are locally advanced at the time of initial presentation and have complex three-dimensional patterns of spread. Additionally, the neurotropism of certain lesions with the occurrence of skip lesions is responsible for residual disease potential despite negative histologic margins. Finally, the greatest obstacle to performing a wide local excision is the proximity of a given tumor to multiple critical neurovascular structures.

Early lesions (T1, T2), especially of the anterior nasal cavity and maxillary sinus, that are amenable to wide local excision may be treated with surgery alone. Multiple factors must be considered if surgery without radiation is planned for a small lesion including the anatomic confines of the tumor, the robustness of the resection, and the histolopathologic findings at the time of surgery including neurovascular extension. In patients who are poor surgical candidates secondary to medical comorbidities, such lesions may alternatively be treated with radiation therapy alone. The majority of patients, however, present with locally advanced disease and benefit from multimodality therapy including surgery, radiation therapy, and, possibly, chemotherapy. Patients with advanced, but resectable, disease are treated with surgery followed by radiation. In patients with unresectable disease, combined chemotherapy and radiotherapy are indicated with consideration of subsequent surgery when there is a positive response to treatment (Fig. 20-21). The role of chemotherapy in patients with resectable disease, however, is not clear and is largely dependent on histopathology. For example, chemotherapy is incorporated in the initial treatment protocol in the majority of patients with sinonasal undifferentiated carcinoma and rhabdomyosarcoma.

Given the overall low incidence of nodal involvement (<20% at presentation) in patients with sinonasal carcinoma, treatment of the neck is indicated only with clinically or radiographically positive disease. The management of the neck in patients with locally advanced disease without evidence of neck disease is not clear. A 20% overall incidence of nodal involvement during the course of treatment has been described and suggests the possible need for additional management of the neck. Possible strategies include observation alone, staging neck dissection at the time of initial surgery or elective radiation therapy to the neck. The latter approach is supported by the significantly lower incidence of both lymph node failure and distant metastasis in patients who received elective radiation therapy to the neck.[7,8,13]

## Surgical Therapy

If resectability is suggested by preoperative assessment, the surgical planning involves determination of the tumor boundaries and reconstructive requirements. The surgical procedure

A B

**FIGURE 20-21.** Squamous cell carcinoma of the ethmoid sinus with intracranial and intraorbital extension **(A)**. Significant reduction of the tumor volume noted following induction chemo-radiation **(B)**.

(c) 2014 Wolters Kluwer. All Rights Reserved.

for sinonasal malignancies can be classified based on the approach and the anatomic boundaries of the resection. The transfacial approach may incorporate variations of several different facial incisions. The lateral rhinotomy incision begins adjacent to the medial eyebrow, extends halfway between the nasal dorsum and the medial canthus running inferiorly along the lateral aspect of the nose at the boundary of the aesthetic subunits and terminates around the nasal ala. The lateral rhinotomy incision allows for adequate exposure of the nasal septum, the medial maxilla, the ethmoid sinus, the sphenoid sinus, and the medial orbital wall. Extension of the lateral rhinotomy to incorporate incisions of the upper lip and lower eyelid is termed the Weber-Ferguson incision and additionally allows for exposure of the inferior and the lateral maxilla, the nasal floor, the lateral orbit, and the infratemporal fossa (Fig. 20-22).

The midfacial degloving allows for exposure of the entire bony midface without external facial incisions. A sublabial incision allows for subperiosteal elevation of the soft tissues over the anterior maxilla. Exposure of the nasal cavity involves a combination of a complete transfixion and intercartilagenous and pyriform aperture incisions with dissection of the nasal soft tissue. Transcranial approaches may incorporate a bifrontal craniotomy or subcranial approach. The versatility of the midfacial degloving allows for exposure of the nasal cavity, the nasopharynx, and the maxillary sinus. With additionally bony removal, the exposure can be extended to the pterygomaxillary space and the infratemporal fossa.

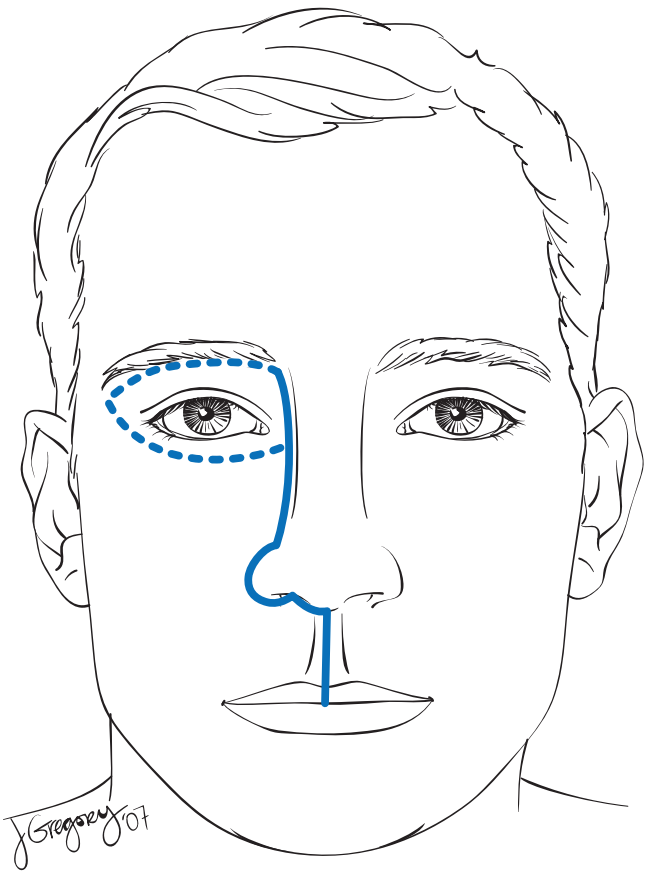


**FIGURE 20-22.** The lateral rhinotomy incision (*solid line*) can be extended to encompass the orbit (*dashed line*) as indicated.

## Medial Maxillectomy

Medial maxillectomy allows for *en bloc* resection of the lateral nasal wall including the inferior turbinate and the ethmoid sinus, and the medial orbital wall if necessary (Fig. 20-23). Following either a lateral rhinotomy or a Weber-Ferguson incision, a facial flap is elevated off the anterior maxilla. The angular vessels are identified medial to the medial canthus and ligated. The periosteum over the anterior face of the maxillary sinus is elevated with identification and preservation of the infraorbital nerve. The medial canthal ligament is mobilized in a subperiosteal fashion and reapproximated at the end of the case to the area of the nasofrontal suture line with a nonabsorbable suture. The bony lateral rhinotomy cuts can be made either with an osteotome or powered drill and extends from the pyriform aperture to the frontal process of the maxilla. In patients where preservation of the orbit is anticipated, the medial orbital perichondrium is elevated off the lamina papyracea. The anterior and posterior ethmoidal arteries are controlled by surgical clips or bipolar. The lacrimal fossa may either be spared or is usually incorporated to the resection. The orbital contents are then retracted laterally while the medial orbital wall and the ethmoid sinuses are opened. Orbital retraction is maximized by transecting the proximal nasolarcrimal duct adjacent to the lacrimal sac. An inferior bony cut is made along the nasal floor from the pyriform aperture to the posterior maxillary wall. The posterior dissection is performed last as the exposure of this area is limited. Curved scissors may be used to separate the surgical specimen from the posterior maxillary wall. The surgical area is packed with packing material. Depending on the origin and extent of the lesion, this may be modified to incorporate less tissue. For example, the lateral nasal wall and the inferior turbinate alone may be resected for limited disease.[127,128] The management of the lacrimal duct during this surgery is variable. Transection of the duct without a formal reconstruction results in recannulation and normal tear drainage in the majority of patients. If ductal obstruction is a concern, a stent may be passed through the lacrimal system and left in place for 4 to 6 weeks as is done following dacrocystorhinostomy. Adequate exposure of small lesions localized to the nasal septum can be achieved either through a lateral rhinotomy, alarotomy, or midface degloving approach. These lesions may additionally be amenable to endoscopic resection.

## Infrastructure Maxillectomy

Infrastructure maxillectomy is indicated for lesions confined to the floor of the maxillary sinus, the hard palate, and the premaxilla, traditionally described as tumors below Ohngren line. The area of resection encompasses the maxillary floor, the gingival arch, the hard palate, and the lower lateral nasal wall (Fig. 20-24). These lesions more commonly arise from the oral cavity with secondary involvement of the maxillary sinus. In locally advanced lesions, the tumor may extend to involve the nasal cavity and the facial soft tissues. If the preoperative imaging suggests no significant involvement superior to the maxillary floor, a sublabial incision alone may be adequate. The osteotomy cuts are tailored to the extent of the lesion and may encompass the entire length of the premaxilla. Multiple reconstructive options are possible including free tissue transfer with an osteocutaneous free flap or placement of an obturator. Preservation of the soft palate promotes improved speech and swallowing function. A temporary prosthesis may be placed at the time of surgery and promotes rapid return to function.

## Radical Maxillectomy

Radical maxillectomy is indicated for locally advanced carcinoma of the maxilla with major involvement of the maxilla, the pterygomaxillary fossa, the orbit, and the ethmoid sinus.

(c) 2014 Wolters Kluwer. All Rights Reserved.

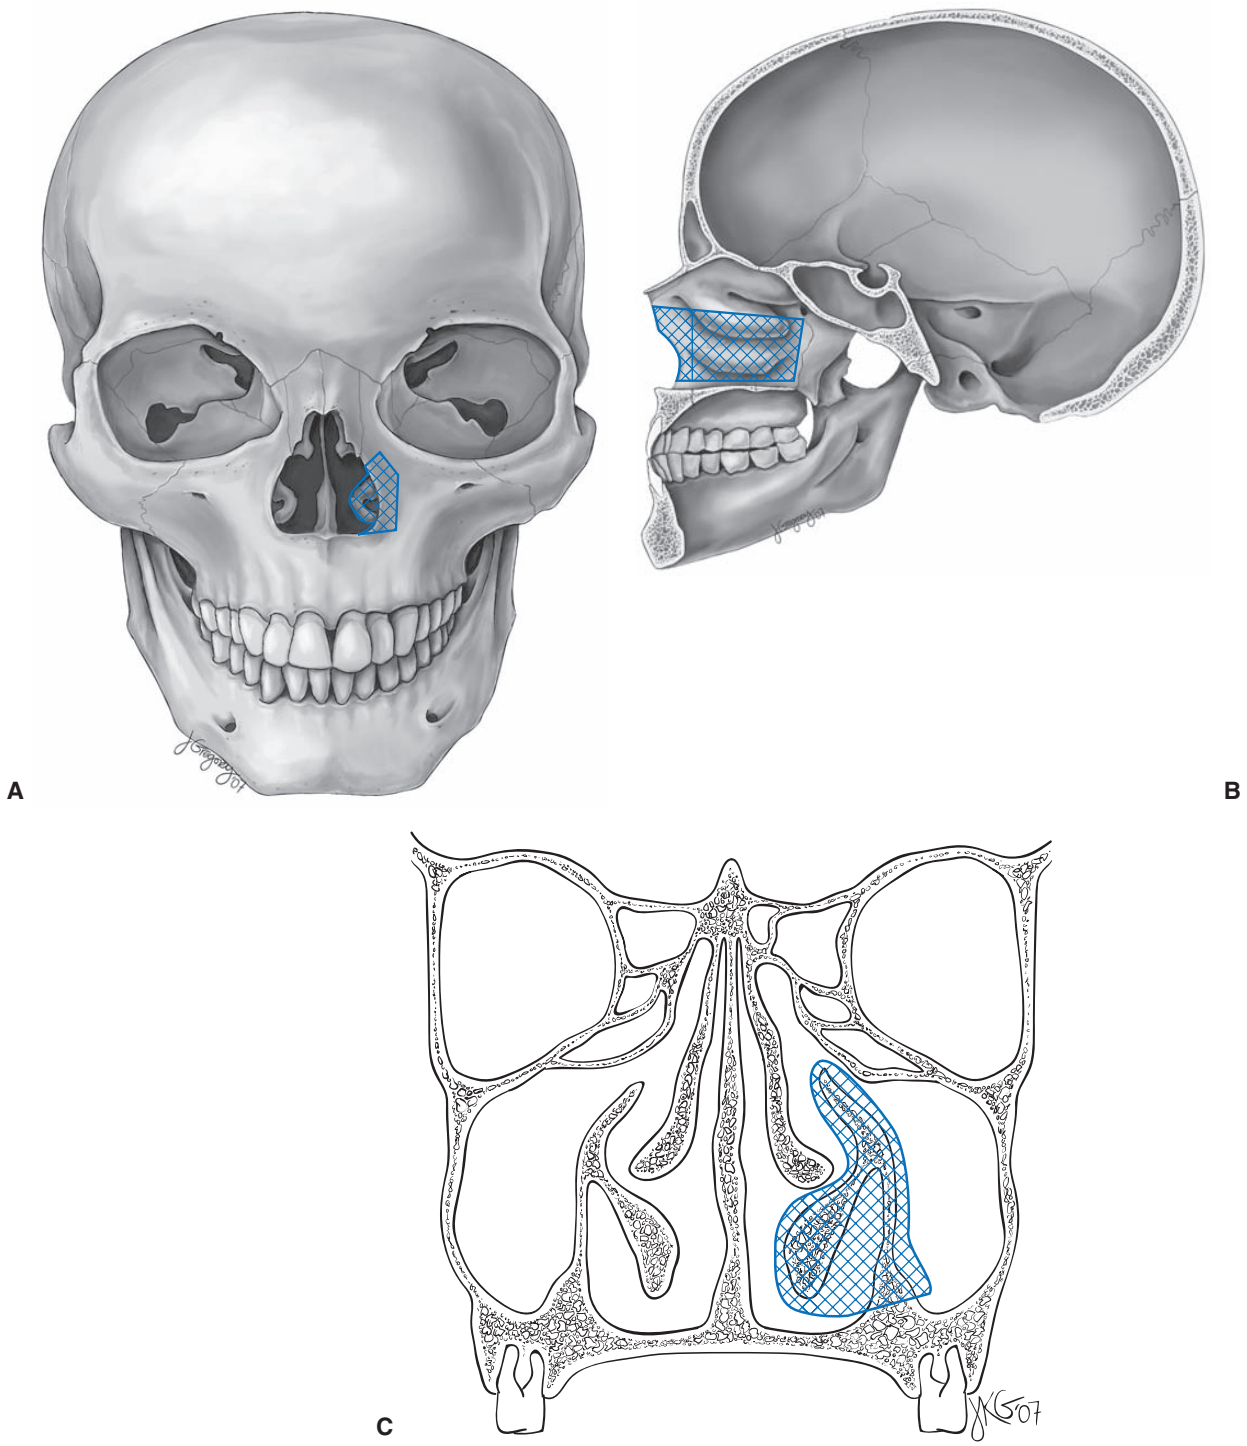

**FIGURE 20-23.** Frontal **(A)**, sagittal **(B)**, and coronal **(C)** views of the medial maxillectomy margins including the lateral nasal wall, the nasal floor, and the inferior turbinate. The margins of the resection can be extended to include portions of the lamina papyracea, the inferior orbital wall, the ethmoid sinus, the nasal septum, and the posterior maxillary wall as indicated.

A Weber-Ferguson incision is used for exposure of the anterior maxilla, the nasal bones, and the ethmoid sinus and may be extended to encompass the orbit. In patients where an orbital-sparing procedure is proposed based on preoperative imaging, the medial and inferior orbital walls are inspected during the time of surgery to confirm lack of involvement. Following the elevation of a facial flap, multiple bony cuts are made to mobilize the maxilla at the malar bone, the zygomatic arch, the hard palate, and the nasal process of the maxilla (Fig. 20-25). If possible, preservation of a portion of the premaxilla facilitates fitting of a prosthesis. The superior bone cuts are performed to encompass the ethmoid sinus at the frontoethmoid suture and necessary portions of the bony

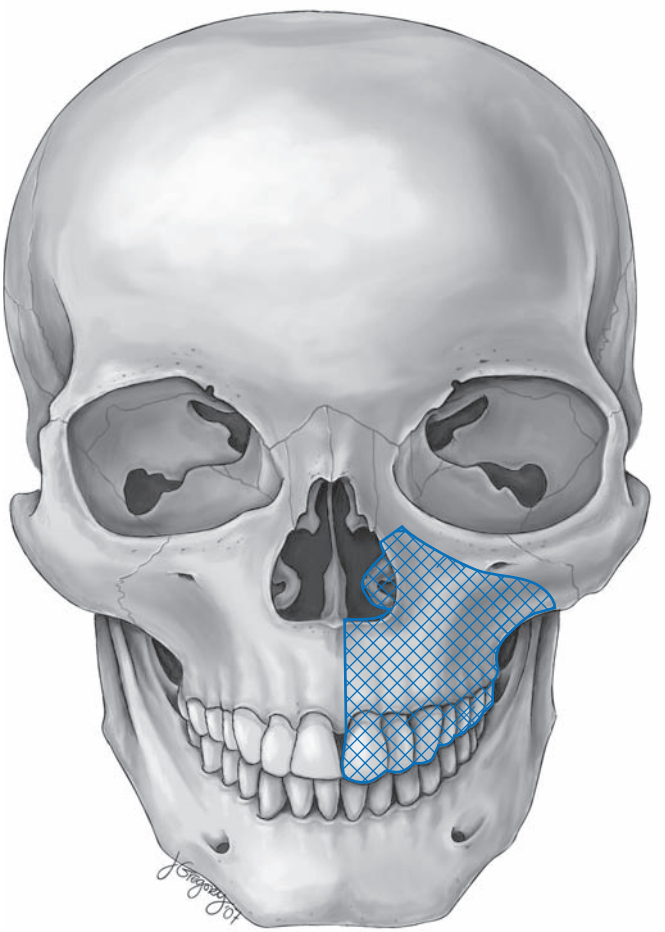

**FIGURE 20-24.** The surgical margins of the infrastructure maxillectomy include the upper gingiva and the dentition, the hard palate, the soft palate, the floor of the maxillary sinus, and the lateral nasal wall. Tumors amenable to this approach are often of oral cavity origin with extension superiorly.

orbit. The posterior cuts are based on the extent of tumor and can encompass either the posterior wall of the maxillary sinus alone or include the pterygoid plates. Anterior tumor extension may result in a partial or total defect of the nose. This may be addressed with a complex reconstruction or a prosthesis. Free flap reconstruction of the defect may also be performed depending on the reconstructive issues. The wound is packed and a temporary prosthesis should be placed. This approach may also include the ethmoid roof, the orbital contents, and the pterygomaxillary fossa as indicated by the location of the tumor.

## External Ethmoidectomy

External ethmoidectomy may be performed through a Lynch or lateral rhinotomy incision. This approach may be used for open excision of ethmoid sinus lesions and the medial orbital wall (Fig. 20-26). The exposure is limited notably in the area of the skull base and is indicated only in small, well-delineated lesions. The indications for this approach may also have become more limited with the increasing role of endoscopic surgery for small lesions. Surgical injury to the frontal recess predisposes to stenosis and chronic frontal sinusitis. Long-term stenting may help prevent this complication. Management of the lacrimal duct as

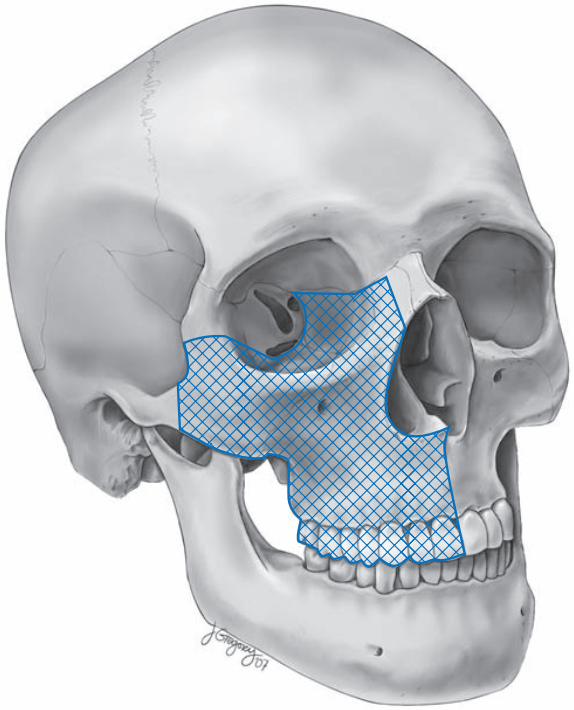

**FIGURE 20-25.** A radical maxillectomy is indicated for locally advanced carcinoma of the maxillary sinus and encompasses the anterior maxilla, the lateral nasal wall, the lamina papyracea, the inferior orbital wall, and the ethmoid sinus. Orbital exenteration may be performed through this approach as indicated.

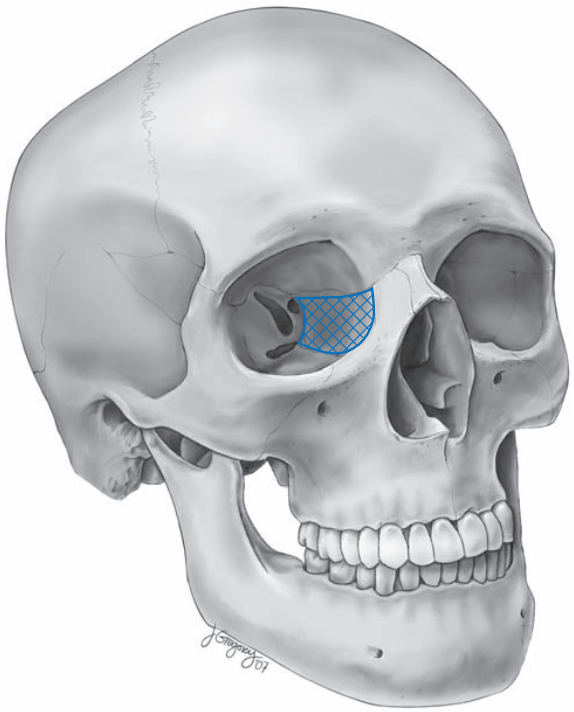

**Figure 20-26.** The indications for the external ethmoidectomy are limited to well-defined lesions confined to the ethmoid sinus and the lamina papyracea.

(c) 2014 Wolters Kluwer. All Rights Reserved.

discussed previously may be required to prevent postoperative stenosis and epiphora.

## Craniofacial Resection

Craniofacial resection represents a major advancement in the surgical treatment of tumors involving the anterior skull base. It is indicated for tumors of the nasal cavity and the ethmoid and the frontal sinuses involving the skull base. This requires a dedicated team approach with head and neck surgery and neurosurgery. Through a combination of a facial and craniotomy approach, an *en bloc* resection of the anterior skull base including the fovea ethmoidalis, the cribriform plate, the planum sphenoidale, the ethmoid and the frontal sinuses, and the superior aspect of the nasal septum is performed. Inclusion of the orbit and the dura is also possible if necessary (Fig. 20-27). Contraindications

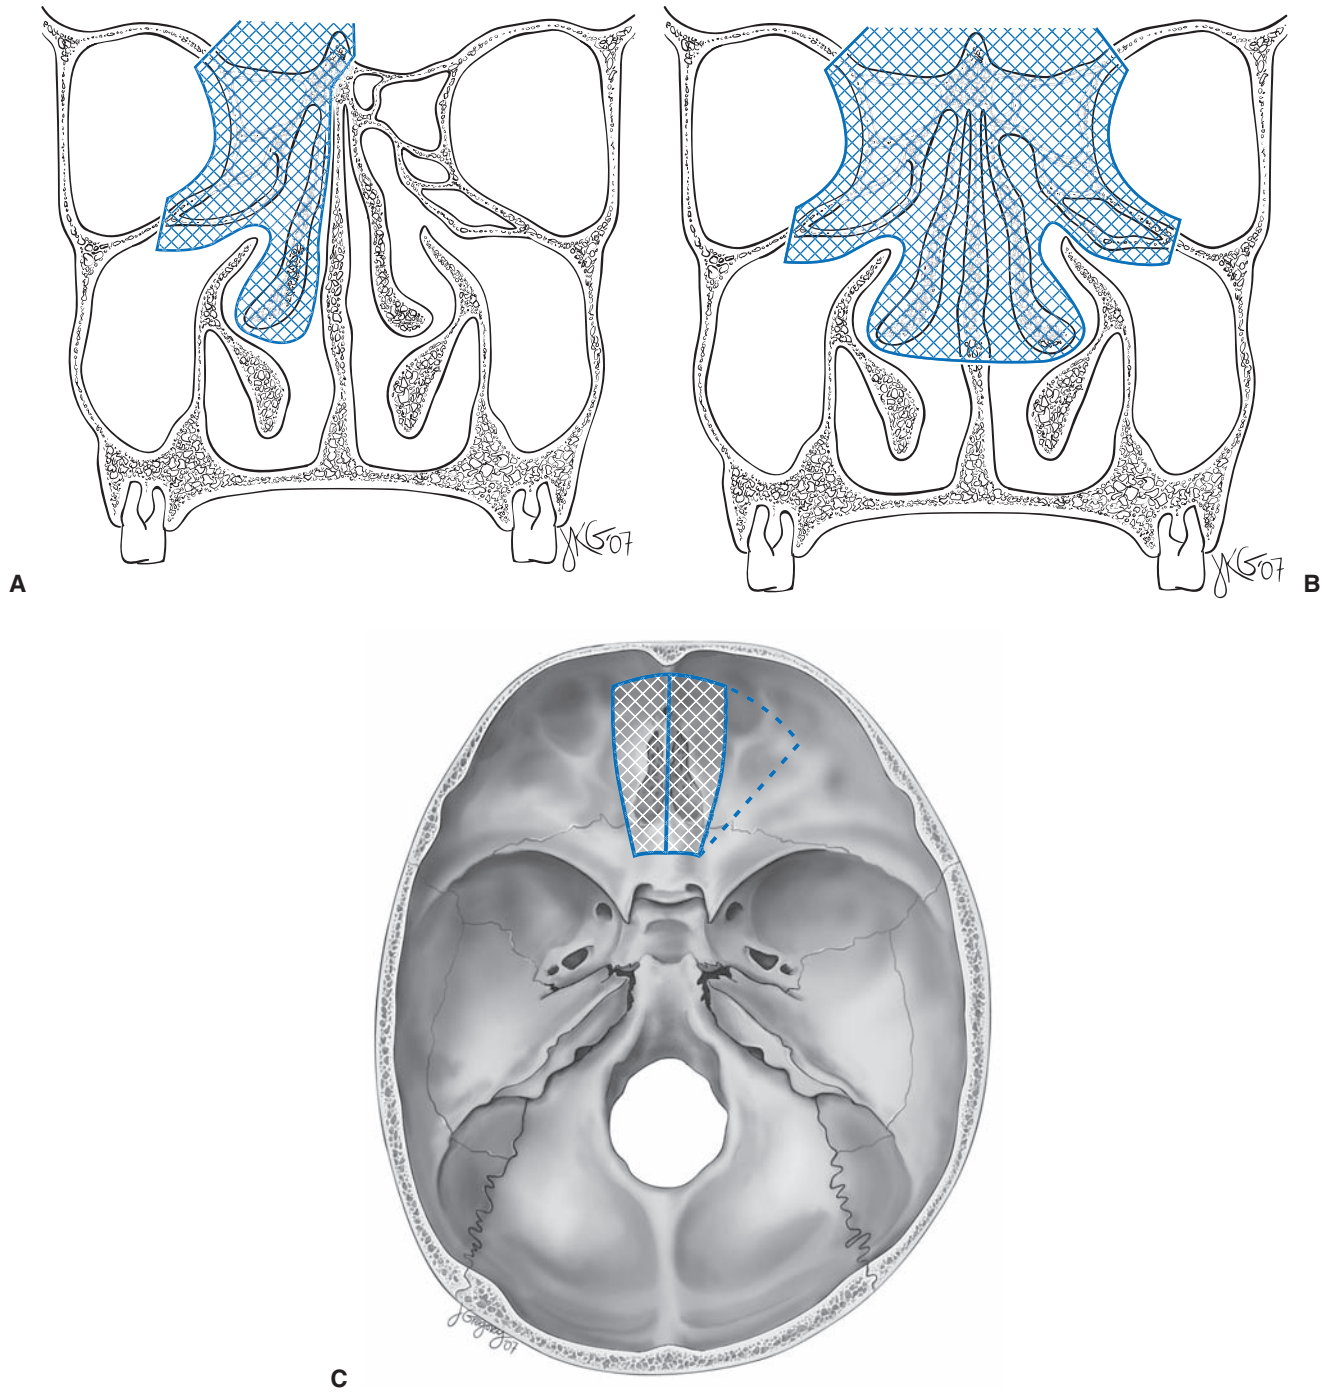

**Figure 20-27.** The external bony margins of the craniofacial approach are shown in Frontal 3. The coronal views of the unilateral **(A)** and the bilateral **(B)** approach demonstrate the areas encompassed with the resection including the anterior skull base, the ethmoid complex, the nasal septum, the middle turbinates, and the lamina papyracea. The intracranial component **(C)** traditionally encompasses the cribriform plate and the fovea ethmoidalis but can be extended laterally (striped margins) to incorporate the superior orbital wall and posteriorly toward the sella.

(c) 2014 Wolters Kluwer. All Rights Reserved.

may vary according to the histopathology and experience of the surgical team. Major involvement of the clivus, the cavernous sinus, or the brain parenchyma are typically considered contraindications to surgery.

The sinonasal portion of the procedure is performed initially to delineate the tumor margins from below and to minimize the duration of an open intracranial cavity and frontal lobe retraction. The sinonasal component can be approached in a variety of ways including through a lateral rhinotomy, midfacial degloving, or possibly endoscopic approach. The lateral margins are defined with exploration of the orbit, usually toward its apex. Appropriate extracranial osteotomies are performed according to the extent of the necessary resection.

The intracranial component is approached through a bicoronal incision, preferably behind the hairline. Elevation is performed in the subgaleal plane with preservation of the superficial temporal (anterior branches), supraorbital, and supratrochlear neurovascular bundles. A separate inferiorly based pericranial flap is developed and preserved for reconstruction. A frontal bone plate is removed for exposure of the intracranial cavity (Fig. 20-28).

Retraction of the frontal lobe allows for wide exposure of the anterior cranial floor. Complete anosmia results from the bilateral transection of olfactory fibers, which is often necessary for exposure. Retraction trauma of the frontal lobe should be minimized. The intracranial components of the tumor margins are delineated and drilling of the floor of the anterior cranial fossa proceeds according to the extent of skull base involvement. The tumor may be removed *en bloc* by working above and below the skull base during mobilization. The posterior limits of the resection through this approach are the anterior clinoids and the internal carotid artery.

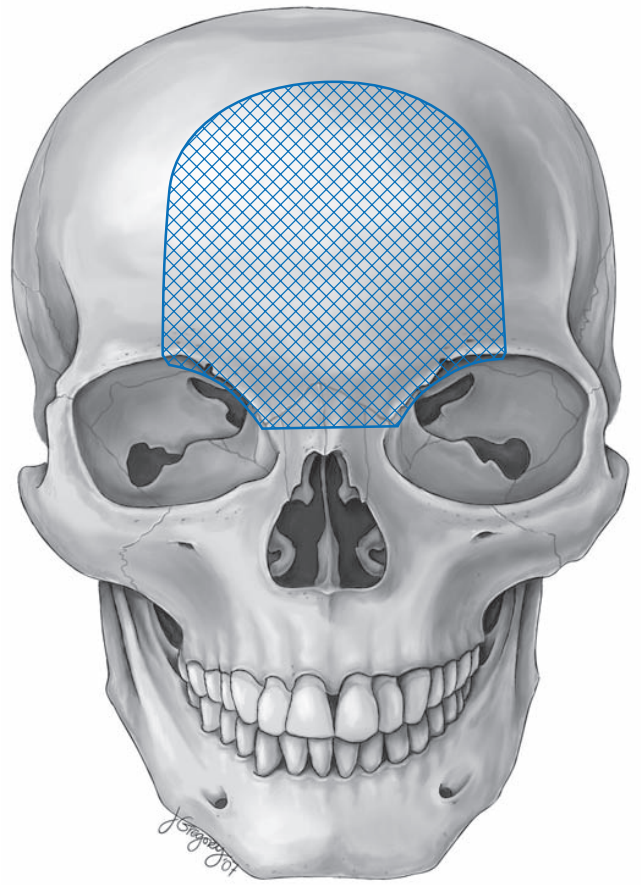

**Figure 20-28.** Craniotomy for intracranial portion of the craniofacial approach.

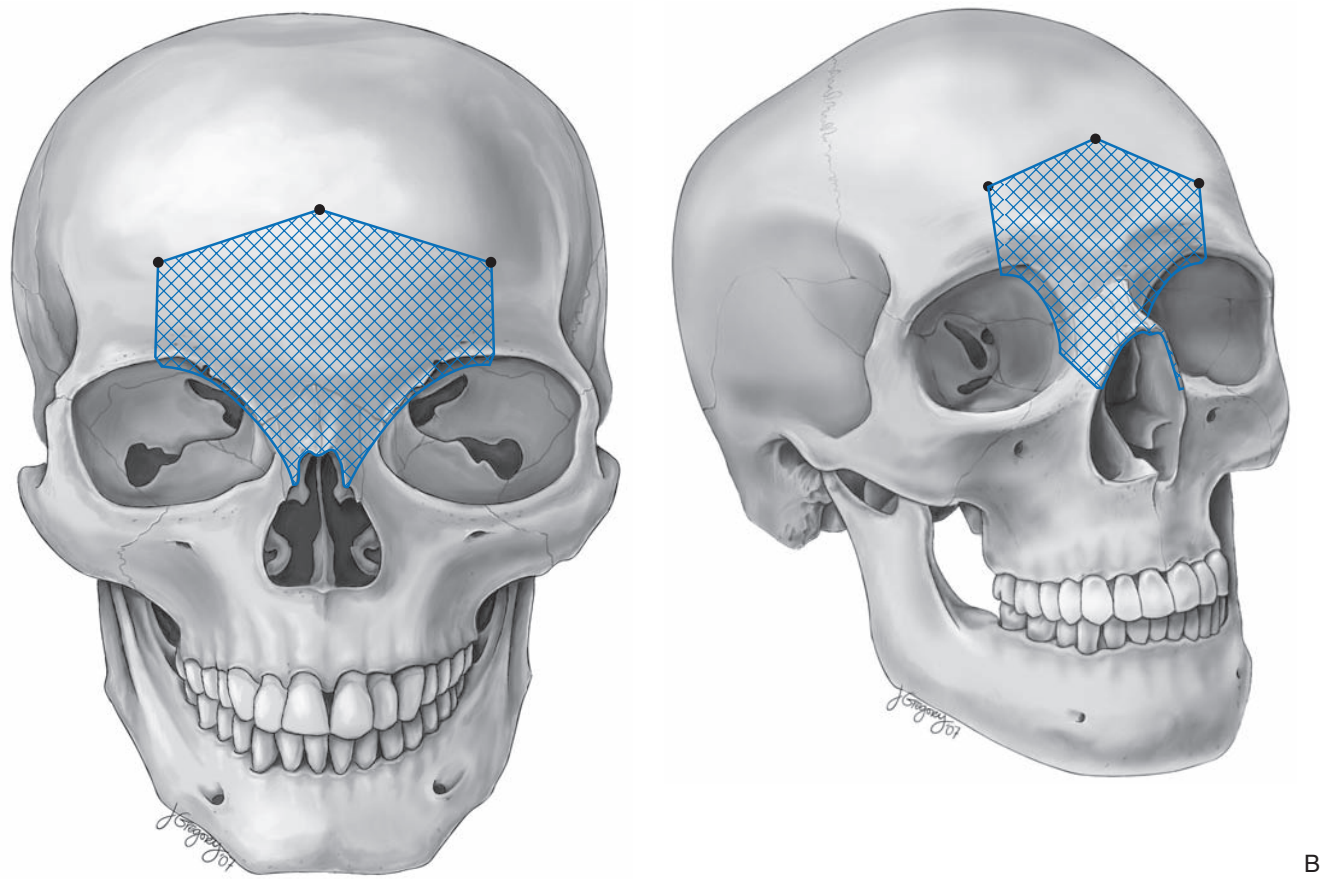
The major challenge associated with reconstruction following craniofacial resection is the need for a watertight separation between the intracranial and sinonasal cavities. Inadequate reconstruction may result in significant morbidity including cerebrospinal fluid (CSF) leak, pneumocephalus, meningitis, brain abscess, and death. The exposure afforded by this approach, however, offers versatile reconstructive options. Typically, the defect closure is accomplished with the previously mobilized vascularized pericranial flap. Free allografts of dermis have also been quite successful. In patients with an extensive defect, a soft tissue–based free tissue flap (e.g., rectus abdominus free flap) may be inset for reconstruction. Bone grafts are usually not necessary. The reconstructed floor of the anterior cranial fossa is temporarily supported from below with nasal packing. Spinal drainage is also used to decompress the CSF during the postoperative period.



## Anterior Subcranial Approach

The subcranial approach addresses the anterior skull base from an anteroinferior approach. Frontoethmoid and orbital osteotomies provide exposure to the anterior skull base with the advantage of minimal retraction of the frontal lobes. The more inferior angle of approach provides excellent exposure of the fovea ethmoidalis, the cribriform plate, and the orbital roofs (Fig. 20-29).

The technique involves a bicoronal incision, elevation of a subgaleal flap to the level of the frontozygomatic suture lines laterally, and the pyriform aperture and rhinion in the midline. The periorbital plane is developed along the superior and lateral aspects of the orbit, thereby exposing the bony superior orbital rims and frontonasal area. The placement of the osteotomy sites is based on the location and extent of the lesion. The initial anterior cuts for the bone flap are placed along the frontal bone, the medial orbital wall, and the nasomaxillary grooves. The posterior, vertical aspect of the bone flap is based on the location of the tumor. In patients in whom the posterior table of the frontal sinus is to be incorporated into the resection, the posterior osteotomy is made anterior to the table. In patients in whom this area is not involved with tumor, the entire frontonasal segment including the posterior table is removed as a single bone flap. During the elevation of the bone flap, care is taken to protect the dura and the frontal lobe.

Following removal of the bone flap, the olfactory filaments and the dura are separated from the skull base. The subsequent tumor resection involves circumferential definition of the desired margins in an anterior to posterior direction. The resection is tailored to incorporate the fovea ethmoidalis, the cribriform plate, and the medial and the superior orbital walls. Posterior extension of the resection may be extended to include the sphenoid sinus and the clivus as indicated. Adequate reconstruction following the subcranial approach is critical given the potential for postoperative CSF leak. In patients with small- to medium-sized dural defects, a tissue graft consisting of autologous fascia, synthetic dura, or a dermal allograft with tissue sealant may be adequate. Extensive defects may require an inferiorly based pericranial flap. Well-designed reconstruction of the bony framework is required for maximal cosmetic and functional outcome. Reconstruction of the medial orbital walls may be performed with free cartilage or bone grafts in cases in which an extensive portion of the orbital wall and the periorbita are resected. Replacement of the nasofrontal bone flap is optimized by predrilling the micro and miniplate screws at the time of initial flap design. The medial canthal ligaments are repositioned with a nonabsorbable suture anchored to the bone flap.[129–131]

## Surgery and Management of the Orbit

The extent of orbital resection indicated for sinonasal lesions has undergone evolution over the past several decades and remains a source of discussion. In a series published in 1985, Ketcham and Van Buren reported a significant improvement in overall survival when the orbit was resected at the time of the initial surgery.[132] Improvements in radiation therapy coupled with the significant morbidity associated with orbital exenteration for a questionable improvement in outcomes has resulted in a trend toward orbital preservation. The decisions regarding management of the orbit in patients with primary sinonasal and skull base neoplasm are highly complex and individualized. The factors that impact treatment decisions include the histology, extent, and location of the lesion, patient comorbidities, and overall prognosis (Fig. 20-30). For low-grade lesions abutting the lamina papyracea without radiographic or intraoperative evidence of periorbital invasion, the orbit may be spared. High-grade lesions or a greater degree of invasion including involvement the orbital apex, the extraocular muscles, the orbital fat, and a significant portion of the eyelid represent indications for orbital exenteration.[133,134] Preoperative treatment with radiation and possibly chemotherapy may result in tumor retraction from previously involved orbital contents. This may then allow an orbit-sparing procedure. An algorithmic approach is presented in Figure 20-30. In addition to the histology of the lesion and imaging findings, the decisions regarding orbital management may necessitate intraoperative biopsy of the periorbita to define the presence or absence of tumor.

The various surgical approaches for orbital neoplasms that preserve ocular function can be classified based on the trajectory of the approach. In orbit-sparing procedures, the various approaches can be extended and combined to allow for more complete exposure and mobilization of the orbital contents. The exposure associated with a number of these approaches is limited and may be most appropriately applied to purely orbital benign and small malignant neoplasms and for biopsy purposes.

The lateral approach begins with a lateral canthotomy incision, mobilization of the temporalis muscle, and exposure of the lateral orbital wall. The lateral canthal tendon is divided and the periorbita is elevated allowing for osteotomies to mobilize the lateral orbital rim. The posterior extent of bone exposure is flexible and can be extended to the superior orbital fissure and the skull base. Incision of the lateral periorbita allows for exposure of extraconal lesions of the lateral compartment. Laterally based intraconal lesions require either retraction or detachment of the lateral rectus.

Several incisions allow for access to the medial orbit. A vertical incision (Lynch) can be made 6 to 7 mm medial to the medial canthal tendon to allow for elevation of the medial orbital periostium. Retraction of the orbital contents allows for visualization of the medial-most aspect of the orbit. The addition of an external ethmoidectomy allows for increased exposure. Retraction or displacement of the medial rectus is required for intraconal lesions. A transcaruncular, conjunctival incision and dissection posterior to the lacrimal sac is an alternative option for entrance to the medial orbital compartment. Finally, the endoscopic transethmoid approach

(c) 2014 Wolters Kluwer. All Rights Reserved.

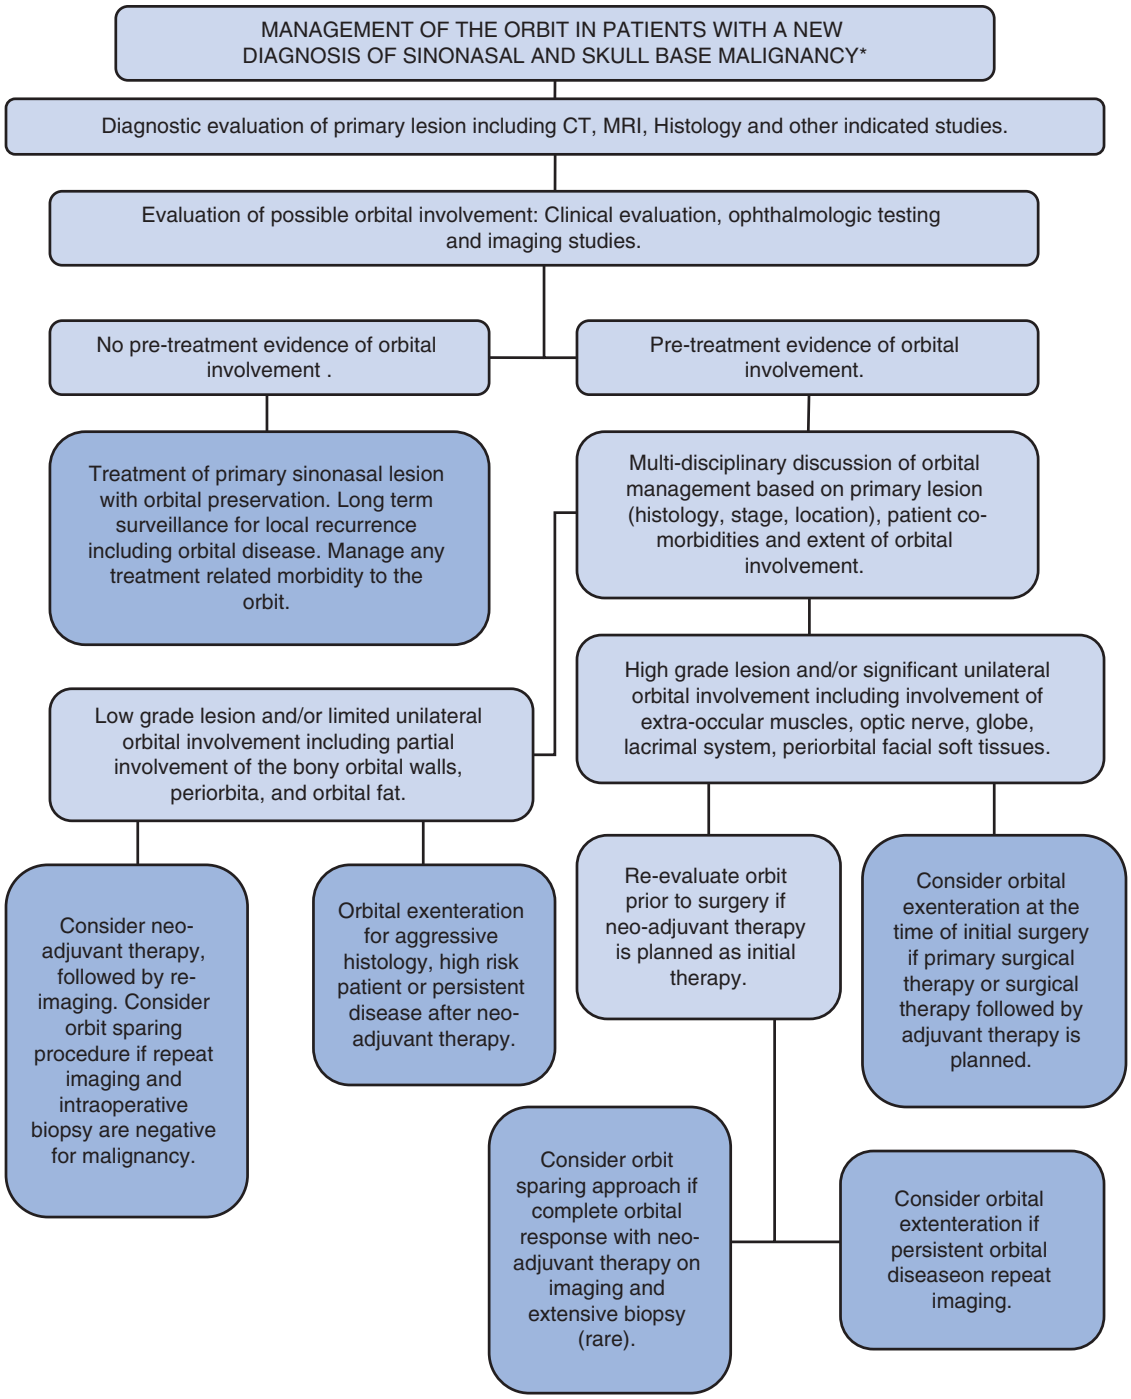

**Figure 20-30.** Algorithm for management of the orbit in patients with primary sinonasal and anterior skull base malignancy.

to the medial orbit allows for avoidance of facial incision and retraction of orbital structures. This technique has been successfully described for orbital decompression and resection of benign lesions.

Open access to the inferior orbit is planned according to the anterior-posterior location of the lesion and the extent of planned resection. For anterior lesions, a transconjunctival approach affords visualization of limited lesions in the inferior orbit and the orbital floor. For posterior and more extensive lesions, removal of the orbital floor through the maxillary antrum may be performed. This allows for visualization along the entire length of the inferior orbit. Intraconal access requires retraction or disinsertion of the inferior rectus muscle.

A purely superior approach can be accessed through either an eyelid fold or infra-brow incision. A periosteal dissection allows for visualization of peripheral and bony lesions. The transseptal approach involves incision of the skin, orbicularis muscle, and orbital septum to access the superior extraconal space including the area of the lacrimal gland. Greater visualization of the superior-medial orbital contents can be gained by mobilization of the lacrimal sac, ligation of the anterior and the posterior ethmoid arteries,

(c) 2014 Wolters Kluwer. All Rights Reserved.

and retraction of the orbital contents. A frontal craniotomy allows for wide exposure of the superior orbit for more extensive lesions.

Enucleation is primarily indicated for intraocular malignancies that involve the globe but allow for preservation of the orbital suprastructure. The procedure involves circumferential incision of the conjunctiva around the corneal limbus followed by transaction of the insertions of the extraocular muscles. Rotation of the globe at this point allows for visualization and transection of the optic nerve approximately 3 to 4 mm away from the globe. The Tenon capsule and conjunctival layers are closed. An orbital prosthesis may be implanted if single-stage reconstruction is planned.

Orbital exenteration is performed for lesions that are not amenable to orbit-sparing therapies. The standard exenteration procedure involves resection of all of the orbital soft tissue structures and the eyelid skin. Variations including preservation of the eyelids and various soft tissue components can be tailored based on the extent of the lesion. The procedure commences with a circumferential incision around the orbit, either around the eyelid skin or at the eyelash margin. A plane superficial to the orbicularis oculi muscle is elevated to the orbital rims. The medial and lateral canthal tendons are detached. The periosteum is incised and circumferentially dissected. The lacrimal apparatus is mobilized and divided from its nasal component. The orbital contents are now fully mobilized and are transected posteriorly at the orbital apex. Minimal traction and early ligation of the optic nerve and the ophthalmic artery decrease the risk of vagal response and hemorrhage, respectively. Additional removal of the orbital walls and combination with transcranial and transfacial approaches can be used for more extensive lesions. Reconstructive options of the orbital cavity include delayed healing with granulation tissue, placement of a skin graft, and placement of either a pedicled or free soft tissue flap.

## Principles of Reconstruction

The goals of reconstruction include a rapid return-to-normal function and adequate cosmetic appearance with minimal morbidity. The complex physiology, extensive nature of the surgical defect, stresses created by mastication and normal sinonasal function, and presence of contaminated and irradiated field create specific challenges. Fabrication of an oral prosthesis for the maxillary defect allows for rapid rehabilitation and direct inspection of the tumor site. This may be combined with relining of the sinus with a skin graft or temporoparietal rotation flap. Alternatively, free flap reconstruction results in closure of the defect with vascularized bone and soft tissue that may be contoured and allows for osseointegrated dental implants. Options for this include fibula, scapula, or iliac crest. In patients undergoing orbit-sparing procedures, reconstruction of orbital wall defects is critical. Functional and cosmetic optimization of the orbit requires symmetric positioning of the globe, restoration of normal intraorbital volume, and preservation of extraocular muscle function. Multiple reconstructive options are available including free tissue transfer, rotational flaps, bone grafts, and placement of synthetic graft material. If orbital exenteration is necessary, the resultant cavity can be filled with temporalis muscle flaps, temporoparietal fascia flaps, or free flaps. Placement of osseo-integrated implants allows for better postoperative prosthesis rehabilitation.

## Endoscopic Surgery

The past 15 years has witnessed the rapid development of advanced endonasal, endoscopic approaches for a variety of sinonasal lesions. The foundations of these techniques are based on endoscopic surgery for inflammatory sinus disease. With technological improvements in instrumentation and visualization including angled endoscopes, image guidance, and powered instruments, more complex procedures such as CSF leak closure, orbital decompression, and approaches for benign intracranial lesions (i.e., pituitary adenoma) are now routinely performed endoscopically. The theoretical advantages of endoscopic surgery, in general, include its minimally invasive nature, avoidance of facial incisions, and improved panoramic visualization of the entire surgical field including surgical margins and critical neurovascular structures. To date, the paradigm for a number of different sinonasal lesions has shifted such that endoscopic surgery is the mainstay in surgical therapy. This includes endoscopic surgery for benign sinonasal neoplasms such as inverted papilloma[22,135–138] and juvenile nasopharyngeal angiofibroma[36,38,39] as well as repair of CSF leak.[139–142] The lower perioperative morbidity for these lesions coupled with outstanding short- and long-term surgical outcomes support the role of endoscopic surgery. Endoscopic surgery also appears to have a well-defined role in certain aspects of sinonasal malignancies including biopsy of suspicious lesions,[105,106] palliation of unresectable disease[143] and excision of small, well-demarcated tumors.

Extension of endoscopic surgery for management of sinonasal malignancy has been the subject of a great deal of interest and debate. The benefits outlined above for benign and inflammatory pathology also theoretically apply for endoscopic surgery for malignancy. The focus of debate centers on the oncologic outcomes associated with endoscopic surgery. Although an equivalent rate of gross tumor removal with frozen section confirmation of margins can be achieved endoscopically in selective cases, the main theoretical distinction between endoscopic and open surgery for malignancy is the inability to perform an *en bloc* excision for locally advanced disease. The oncologic implications of piecemeal versus *en bloc* tumor resection for malignancy require systematic examination as it represents a significant deviation from the traditional principles of surgical oncology. The potential for tumor seeding and inadequate margins of resection are potentially increased with piecemeal resection. This is further compounded by the fact that the majority of treatment failures for sinonasal malignancy are local in nature, emphasizing the need for adequate initial resection. However, *en bloc* resection may not be possible even with open approaches in patients with advanced lesions, including intracranial extension.

The primary advantages of endoscopic surgery include the potential for decreased perioperative morbidity, improved visualization of cavitary areas, and decreased manipulation of critical neurovascular structures. The avoidance of facial incisions, elevation of facial flaps, and open transfacial approaches implies improved cosmesis and faster postoperative recovery. In patients with limited intracranial involvement, the bony skull base and dura may be addressed entirely with the endoscopic technique, thereby avoiding the need for craniotomy and frontal lobe retraction. Additionally, visualization with straight and angled endoscopes allows for panoramic visualization of the tumor and surrounding neurovascular structures throughout the procedure. This contrasts with open surgery where visualization of certain aspects of the tumor, notably the superior and posterior margins is limited until the end of the procedure and is often deeply recessed in the surgical field.

Oncologic resections extend the techniques used in endoscopic surgery for benign sinonasal and intracranial pathology. The surgery can be conceptually divided into the stages of treatment planning, tumor exposure, resection, and skull base reconstruction. Treatment planning, as in all sinonasal malignancies, is complex and requires a multidisciplinary consideration of the role of the various surgical and adjuvant therapy options. If surgical resection is indicated, the critical question of whether endoscopic surgery is appropriate is based on both the tumor characteristics and the expertise of the surgical center. Given the complexity of the surgical challenges encountered during approaches for malignancy combined with the potential for neurovascular

(c) 2014 Wolters Kluwer. All Rights Reserved.

complications and negative impact on outcomes of an incomplete resection, these surgeries should be performed in centers with the appropriate expertise. Careful consideration of contraindications to endoscopic surgery should be considered preoperatively including involvement of the facial soft tissue, extensive orbital cavity requiring exenteration, extensive maxillary involvement necessitating maxillectomy, anterior and far lateral involvement of the frontal and the maxillary sinuses, extensive intracranial involvement, and far lateral extension into the pterygomaxillary and the infratemporal fossa. Intracranial extension, however, does not necessarily represent a contraindication as the lesion may be managed entirely through an endoscopic procedure or a combined endoscopic-transcranial approach. Endoscope-assisted surgery which combines the exposure of open surgery with the visualization of endoscopic surgery is also possible.

The technical challenges associated with endoscopic resection of sinonasal malignancies are best addressed by a team approach with expertise in advanced sinonasal and intracranial pathology. General principles include wide endoscopic exposure, two- or four-handed surgical dissection, and incorporation of multiple surgical tools including powered instrumentation and image guidance. The resection progresses through stages including demarcation of gross tumor involvement, central debulking, mobilization of critical neurovascular structures, and clearance of the tumor margins. Serial frozen section confirmation of the margins is critical. The various endoscopic procedures available can be divided based on the target of the resection and the approach necessary to reach this location. Several descriptions of a compartmentalized approach to the various lesions have been described.[144–146] The approaches describe the different sinonasal cavities that are traversed including transnasal, transsphenoidal, transmaxillary, and transethmoidal approaches. Following opening of the various sinonasal passages, the approach is further expanded to encompass the necessary aspects of the intracranial and the skull base cavities. The transnasal corridor does not traverse any of the paranasal sinuses and can be used to target the medial aspects of the nasal cavity (nasal turbinates, nasal septum, chaona), the midline of the anterior skull base (cribriform fossa), and the nasopharynx. Extension posteriorly into the transsphenoidal corridor allows for exposure of the sella, the suprasella, and the sphenoidal clivus. Transmaxillary approaches allow for access to the inferior orbit, the PPF, the infratemporal fossa, and the middle cranial fossa. Transethmoid approaches allow for exposure of the lateral aspects of the skull base including the fovea ethmoidalis, the anterior cranial fossa, and the medial orbital wall. These approaches are often combined for sinonasal lesions to allow for a complete circumferential exposure and clearance of margins. Advanced endoscopic techniques and instrumentation are available for tumor removal.

Following tumor resection, skull base reconstruction is performed. This aspect of the surgery has critical importance in order to prevent postoperative CSF leak and associated sequelae, promote healing of the surgical cavity, restore sinonasal physiology, and allow for tumor surveillance. This is additionally associated with a number of technical challenges if a purely endoscopic approach has been used, including the cavitary, three-dimensional nature of the dissection, the presence of a large surgical defects with high-volume intraoperative CSF leak, the limited ability to directly instrument the reconstruction site as can be done with open surgery, and the stresses applied to the repair site from intracranial pressure, gravity, and normal sinonasal function. The primary goal of reconstruction is the re-creation of a separation between the sinonasal and the intracranial cavities. A number of options exist including various combinations of free tissue/synthetic grafts and vascularized pedicled grafts including the nasal septal flap. Expertise in applying the various techniques for skull base reconstruction is a requisite aspect of endoscopic skull base surgery to achieve a high rate of successful repair at the time of initial surgery. Overall, a low incidence of postoperative CSF leak has been reported in multiple independent series.[147–150]

## Complications

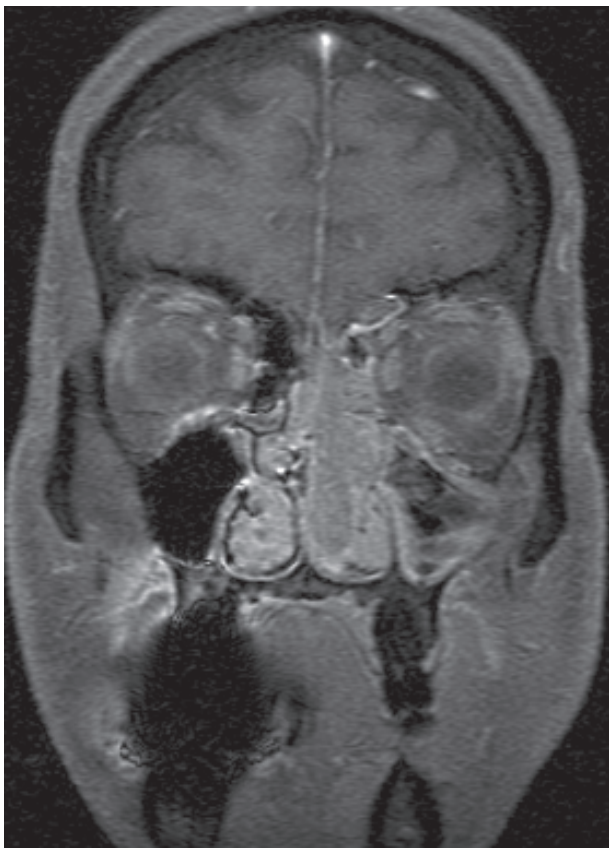
The major complications following surgery for sinonasal malignancy can be divided into systemic, local, and neurovascular. The combination of extensive surgery and older age is associated with an increased risk of perioperative medical morbidity including cardiovascular events, pneumonia, and deep-vein thrombosis. These issues may be minimized with dedicated nursing protocols. Postoperative epistaxis may be brisk and may arise from several named neurovascular bundles including the internal maxillary artery, the sphenopalatine artery, and the ethmoidal arteries. The wound is typically packed at the conclusion of the case for prevention, but the bleeding event may be delayed until the time of pack removal. Treatment options for persistent epistaxis include replacement of the packing, surgical exploration, or interventional radiographic embolization in refractory cases. Facial and sinonasal wound infections are uncommon, likely secondary to the extensive vascular supply to this area. Optic nerve injury resulting in blindness may occur secondary to direct surgical trauma, ischemia from devascularization, or increased intraorbital pressure. CSF leak occurs from persistent communication between the sinonasal and intracranial cavities and may secondarily result in meningitis. This is compounded in patients with a large defect where a one-way flow of air may result in tension pneumocephalus and rapid neurologic deterioration. Urgent treatment is required and may involve placement of a burr hole followed by surgical exploration of the reconstruction site. In patients with a low-volume CSF leak, a trial of lumbar drainage, bed rest, and head of bed elevation may be initially employed. Surgical exploration and repair of the defect site is indicated if the leak persists. Local infections may be minor if confined to the sinonasal cavity or severe if intracranial. The latter may result in meningitis, epidural, or subdural abscess. Broad-spectrum antibiotics and abscess drainage, if present, are indicated. Carotid artery injury and intracranial bleeding are rare, but potentially catastrophic events. Frontal lobe edema and contusion occurs in patients with transcranial surgery and extensive brain retraction. This may result in altered neurocognitive function and seizures. Cranial nerve injury is dependent on the extent of the surgery and may be greatest in patients undergoing surgery of the cavernous sinus.

# OUTCOMES

A definition of the outcomes following treatment for sinonasal malignancies is challenging given the overall low incidence of these lesions, heterogeneous histopathologies, and nonuniform treatment protocols. Adequately powered, case-controlled or prospective, randomized studies are challenging given these issues and would best be addressed with multi-institutional treatment protocols. The current understanding of the efficacy of various treatment options is instead largely pooled from the various single-institutional experiences. The majority of these reports are retrospective in nature which introduces significant issues in the interpretation of the available literature. For example, although higher rates of local disease control and survival have been suggested for surgery alone or surgery with radiotherapy compared with radiation alone, a significant selection bias likely exists. Patients receiving radiation alone likely had more advanced disease and may have been considered palliative.

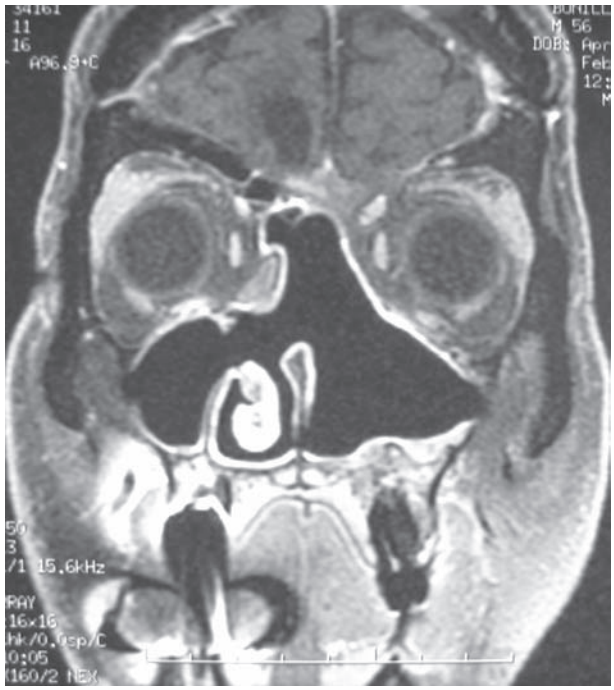
Although single-modality therapy may be indicated in early lesions (T1),[41] the majority of patients present with advanced local disease. Multimodality therapy incorporating at a minimum

(c) 2014 Wolters Kluwer. All Rights Reserved.



radical surgery combined with external beam radiation is advocated for the majority lesions. There have, however, been isolated reports of favorable outcomes following radical surgery alone. Terz et al. described a 72% 3-year and 50% 5-year survival in a case series of 28 patients with T3 and T4 paranasal sinus malignancy treated with radical craniofacial surgery including resection of the anterior and the middle cranial fossa, the orbit, and the soft tissues of the face. Three deaths were attributed to the surgery.[151] Similar outcomes with surgery alone, however, have not been reproduced and most centers routinely use postoperative radiation therapy.

The improved outcomes of radiation therapy combined with surgery versus either modality alone have been reported in multiple independent series.[152–155] The timing of radiation therapy with respect to surgery remains controversial. Radiation therapy with or without chemotherapy prior to surgery may result in shrinkage of the tumor and improve resectability for advanced lesions.[156,157] The possibility of improved ability to spare structures such as the orbit has also been discussed for this approach[158,159] but remains controversial. The surgical extent should be based on pretreatment imaging as the results of less aggressive resection do not seem favorable.[160,161] The local control and survival outcomes are significantly improved if no viable tumor is identified at the time of surgery.[162] Conversely, radiation therapy following radical surgery may improve eradication of microscopically positive margins. Additionally, since the concern for tissue healing is less pronounced with radiation therapy following surgery, a higher total dose may be considered. The impact of recent advances in radiation therapy, including conformal radiotherapy and intensity-modulated radiation therapy (IMRT) offer the hope of more directed therapy and preservation of critical structures[163] including orbital function.



The outcomes of craniofacial resection for paranasal sinus malignancies involving the anterior skull base reflect the challenges associated with these lesions. The majority of ethmoid sinus lesions present with skull base involvement at initial presentation. Multimodality therapy with surgery and radiation is indicated in the majority of the lesions. Inclusion of chemotherapy may also be indicated in advanced esthesioneuroblastoma.[164,165]

In a multi-institutional review of 334 patients with paranasal sinus malignancies excluding esthesioneuroblastoma, Ganly et al. reported 5-year overall, disease-specific, and recurrence-free survival rates of 48.3%, 53.3% and 45.8%, respectively. Rates of perioperative mortality of 4.5% and complications of 32.9% were noted. The complications associated with this cohort included local wound, central nervous system, systemic, and orbital complications. The presence of medical comorbidities, prior radiation therapy, positive surgical margins, various histologic subtypes, and intracranial tumor involvement were identified as independent risk factors.[166] Similar outcomes have been reported in other, smaller series.[56,167,168] Suarez et al. identified histology, recurrent lesions and involvement of the brain, orbital soft tissue, and sphenoid sinus as negative prognostic factors.[169]

The treatment paradigm for esthesioneuroblastoma varies depending on the size of the lesion and the institutional philosophy. For localized lesions (Kadish A and B), multiple case series have reported favorable long-term results with surgical resection followed by radiation therapy[61–66] (Fig. 20-31). The overall prognosis is poor in patients with local-regional recurrence or distant

A

B

**Figure 20-31.** Pretherapy **(A)** and 10-year follow-up **(B)** coronal MRI of an esthesioneuroblastoma treated with craniofacial resection followed by radiation therapy.

spread. A standardized protocol for advanced lesions has been described by the University of Virginia and involves presurgical radiation therapy (50 Gy) for patients with Kadish stage A–C disease. Chemotherapy (cyclofosphamide and vincristine) is additionally given for patients with Kadish C disease prior to radiation therapy to minimize tumor burden. Craniofacial surgery is performed following chemoradiation. Five- and 10-year survival rates of 81% and 54%, respectively, have been reported following this protocol.[170] As mentioned earlier in this chapter, the olfactory apparatus, intracranial extension, and paranasal sinus components of the tumor should be resected in continuity.

The outcomes following therapy for sinonasal melanoma remain poor overall. Several single-institutional case series over the past two decades have reported 5-year survival rates ranging from 10% to 47%. The majority of these patients were treated with aggressive surgery followed by radiation therapy.[83,85,86,171,172] Ganly et al. used the same multi-institutional database described above to report outcomes following craniofacial for surgery for melanoma with 3-year overall, disease-specific, and recurrence-free survival rates of 28.2%, 29.7% and 25.5%, respectively.[173]

The role of chemotherapy in sinonasal malignancy has been limited to date, but may develop an increasing role in the future. The utility of chemotherapy is strongly related to the histology of the lesion and with a clear role in sinonasal lesions that are both drug sensitive and have a propensity for regional and distant spread. Appropriate lesions may include sinonasal undifferentiated carcinoma, lymphoma, and rhabdomyosarcoma.[79,99–101] The efficacy of chemotherapy for the common sinonasal malignancies including squamous cell carcinoma remains unclear. To date, there have been few reports addressing this issue. Lee et al. reported a series of 19 patients with advanced paranasal sinus carcinoma treated with a combination of surgery and chemoradiation with 16 patients additionally receiving induction chemotherapy with cisplatin and 5-fluorouracil. The 10-year disease-free survival and local control rates were 66.6% and 76.1%, respectively.[162] Samant et al. reported a 53% 5-year survival rate in 19 patients with advanced paranasal sinus malignancies treated with neoadjuvant radiochemotherapy consisting of 50 Gy and 3 to 4 doses of intra-arterial cisplatin followed by surgery.[174]

The outcomes following endoscopic surgery for sinonasal malignancy is an active area of clinical investigation and has important implications in defining its indications and limitations. Several centers have described favorable early results with endoscopic management of selected sinonasal malignancies.[68–78,175–177] The greatest experience to date is with esthesioneuroblastoma, and favorable early results in selected lesions have been reported.[68,69–73] The majority of these patient series involved early-stage (Kadish A and B) lesions. The past 5 years has witnessed a growing body of literature describing favorable outcomes following endoscopic surgery for other malignant histologies. Goffart et al. reported 2- and 5-year survival rates of 73.1% and 52.3%, respectively, in 78 patients undergoing endoscopic surgery for sinonasal malignancy including adenocarcinoma, SCC, and esthesioneuroblastoma.[178] Lund et al. reported an 88% rate of survival at last follow-up in 49 patients undergoing endoscopic surgery for sinonasal malignancy including adenocarcinoma, malignant melanoma, and esthesioneuroblastoma.[179] Favorable tumor control and improved perioperative morbidity were described by Nicolai et al. in a single-institutional experience in the management of ethmoid sinus adenocarcinomas. The 25-year duration of this case series reflects the authors' evolution from craniofacial to endoscopic resection for these tumors.[76] In a case series of 120 patients with multiple histologies treated over a 15-year period at MD Anderson, Hanna described overall favorable outcomes for patients undergoing purely endoscopic and cranioendoscopic surgery. An 85% rate of local disease control was noted with a mean follow-up period of 37 months.

The overall positive outcomes associated with endoscopic surgery for sinonasal malignancy must be tempered by the relatively limited collective experience and duration of follow-up. In general terms, the application of endoscopic surgery for sinonasal malignancies requires ongoing critical analysis. These procedures should be done on a selective basis and by experienced practitioners after careful consideration of potential contraindications.

## FUTURE DIRECTIONS

Neoplasms of the nasal cavity and paranasal sinuses represent a challenging group of disorders. The rarity of these lesions, advanced stage at presentation, critical neurovasculature of the involved anatomy, and aggressiveness of the various histopathologies have traditionally resulted in poor overall outcomes. However, an evolving understanding of the clinical behavior and treatment response of the various lesions has resulted in more sophisticated treatment options and the promise of improved outcomes. Given the rarity of these lesions, continued scientific reporting is imperative to further the collective body of knowledge, likely in the form of pooling of data from individual centers that would allow for sophisticated statistical analysis of the epidemiology and treatment outcomes of these rare lesions. Ideally, the implementation of prospective, multi-institutional protocols may allow for a critical examination of treatment efficacy, as has been done for rhabdomyosarcoma. The roles of diagnostic and treatment advances include PET, IMRT, and proton beam therapy are still inadequately defined and need further study. In the future, biomolecular markers may allow for more directed, "customized" therapy. However, given the diverse spectrum of histopathologies, future studies with adequate patient sample size would be necessary to justify dramatic changes in the treatment protocols. Finally, the application of endoscopic surgery for sinonasal malignancy is an area of active debate. Multiple advances in the technique are the subject of active exploration including application of various forms of powered instrumentation, three-dimensional endoscopy, and robotic surgery. However, the most critical questions that have only been partially answered to date involve the indications, limitations, and outcomes of endoscopic surgery for sinonasal malignancy.

CHAPTER 21

# Cancer of the Nasal Cavity and Paranasal Sinus: Radiation Therapy and Chemotherapy Management

## PART A:
## General Principles and Management

Nancy Lee, Nadeem Riaz, and Allen M. Chen

Carcinomas arising from the nasal cavity and the paranasal sinuses are rare tumors of the head and neck accounting for approximately 3% to 5% of all upper respiratory tract malignancies and <1% of all new cancers.[1] They are twice as common in males as in females and typically occur after 40 years of age.[2,3] Owing to their inconspicuous locations along the anterior skull base, these tumors generally present at advanced stages unless the cancer impinges on vital organs or extends from the maxillary sinus to the nasal cavity producing subsequent symptoms of epistaxis or obstruction. Because these tumors frequently involve multiple adjacent sites, determination of the exact site of origin may be difficult. Similarly, treatment decisions have historically been complicated by the close proximity of these cancers to critical normal tissue structures such as the optic pathways and the brainstem.

Owing to the rarity of paranasal sinus or nasal cavity tumors, published clinical outcomes are largely limited to retrospective reviews of single institutional experiences. Additionally, the heterogeneity of these study populations with respect to both clinical presentation and treatment strategy often makes drawing definitive conclusions challenging. For instance, primary sites and different histological subtypes are often grouped together, which lead to some confusion in comparing treatment results across series. Moreover, the proportion of patients treated by a nonsurgical approach in these studies can vary greatly. In general, early-stage cancer is often successfully managed with surgery alone, whereas more advanced disease requires the addition of postoperative radiotherapy.[4–9] In select situations, chemotherapy has been added to postoperative radiotherapy as adjuvant treatment. The use of primary radiotherapy has been reported in older series but with apparently higher treatment-related complications, perhaps due to the inability to give adequate dose to the gross disease without having to compromise the surrounding normal tissues. Because these tumors are often surrounded by multiple critical normal tissues, such as the optic structures and the brainstem, delivery of a high therapeutic dose to gross disease is often difficult and maximal tumor resection should be attempted whenever possible before radiation therapy. However, for patients who are medically or surgically inoperable, definitive radiotherapy with or without chemotherapy is a feasible alternative approach, although reported outcomes have been less favorable.[10]

Intensity-modulated radiation therapy (IMRT) offers the potential to reduce dose to critical structures while maintaining desired doses to the targeted tumor volume through inverse planning and the use of optimized nonuniform beams.[11] As a result, a higher tumoricidal dose of radiation can be administered while minimizing the dose delivered to the surrounding normal tissues.[12] Although numerous treatment-planning studies have demonstrated through dosimetric comparisons that IMRT can offer a superior dose distribution for the treatment of tumors of the nasal cavity and paranasal sinuses in comparison to three-dimensional (3D) conformal and conventional methods,[13,14] several recently published articles suggest that the theoretic advantages associated with this technique do indeed translate into tangible benefits for patients treated in the clinical setting[5,15–17] directly compares 3DCRT to IMRT patients in paransal patients. Although most of these single-institutional series are limited by relatively short follow-up, the preliminary data with respect to both efficacy and toxicity are encouraging. In this chapter, the authors will discuss the management of cancer of the nasal cavity and paranasal sinuses using radiation therapy with or without chemotherapy.

## CLINICAL PRESENTATION

The diagnosis of cancer of the nasal cavity and paranasal sinuses is often delayed for considerable periods of time due to the lack of specific symptoms.[4,18] Early symptoms are vague and can mimic sinusitis. Unilateral nasal obstruction, chronic unilateral nasal discharge, and intermittent epistaxis can result from nasal cavity tumors. Other less common symptoms include headache, epiphora, and localized pain. Diagnosis can often be delayed

(c) 2014 Wolters Kluwer. All Rights Reserved.

further because these patients have a history of nasal polyps, which produce similar symptoms. Tumors of the maxillary antrum also tend to remain silent until they extend outside the sinus. As a result of tumor extension to the premaxillary region, patients can complain of facial pain, numbness, localized swelling, nasal obstruction, and epistaxis. Nasal obstruction from tumor extension to the nasal cavity and tumor extension into the orbit causing ocular problems such as epiphora, proptosis, diplopia, eye pain, and inner canthal mass are the most common symptoms of ethmoid sinus tumors. Sixth nerve palsy, severe morning headaches, and diplopia are common symptoms for primary sphenoidal tumors. Lastly, frontal sinus tumors can present with bilateral swelling of the glabella and the supraorbital ridge and with frontal pain.

Cervical lymph node metastases on initial clinical presentation are uncommon with an incidence of approximately 10% to 15%. Depending on the histological subtype and extent of the primary tumor, the incidence ranges from 20% to 44%.[19–21] Distant metastasis at the time of diagnosis is rare.

## PATHOLOGY

Squamous cell carcinoma (SCC) or one of its variants is the most common histological subtype, making up 80% to 85% of all neoplasms of the nasal cavity and paranasal sinuses. Minor salivary gland tumors such as adenoid cystic carcinoma and adenocarcinoma comprise approximately 10% to 15% of all neoplasms in this region. Mucoepidermoid carcinomas are extremely rare. Adenocarcinoma can also represent a metastasis, most often from the kidney, the breast, or the lung. Although malignant melanoma accounts for approximately 10% to 15% of nasal cavity cancers, it is rare in the paranasal sinuses. Other less common histological subtypes include undifferentiated carcinoma, plasmacytoma, lymphoma, esthesioneuroblastoma, sarcoma, and inverted papilloma. Undifferentiated carcinomas have an extremely poor prognosis with up to 90% of patients dying within the first year from either extensive local or metastatic disease. Although histologically benign appearing, inverted papilloma often has a very aggressive clinical course even in the absence of malignancy. It is associated with SCC in 10% to 15% of cases.[18,22]

## STAGING

Nasal cavity and paranasal sinus tumors are staged according to the current seventh edition of the American Joint Committee on Cancer (AJCC) TNM (tumor, node, metastasis) staging system. Within the paranasal sinuses, frontal and sphenoid sinuses are rare and not formally staged according to the AJCC TNM staging system. Magnetic resonance imaging (MRI) in addition to computed tomography (CT) is very useful as part of the staging workup as it can potentially differentiate between tumor and sinusitis. Table 21.1 contains the details of the staging system.

## RADIATION TECHNIQUES

Over the last several decades, a remarkable evolution of radiotherapy techniques for the treatment of nasal cavity and paranasal sinus cancer has been witnessed. Reported techniques have included conventional radiotherapy using two-dimensional (2D) imaging to three-dimensional conformal radiotherapy (3D-CRT) using CT simulation, to more recently, IMRT with dose painting. Proton beam has also been utilized for the treatment of these tumors but its use is limited to few centers.

**TABLE 21.1 Seventh Edition of AJCC Staging for Nasal Cavity and Paranasal Sinus Cancer**

| | |
|---|---|
| **Primary Tumor (T)** | |
| **Maxillary sinus** | |
| TX | Primary tumor cannot be assessed |

Conventional 2D radiotherapy techniques typically incorporate the use of a three-field technique with two lateral wedged fields and an anterior field. Because the dose required for treatment ranges from 66 to 70 Gy, significant toxicity can result from the excess radiation delivered to adjacent structures, especially optic structures, in which threshold doses for toxicity are below 60 Gy.[8,23] Notably, with the introduction of 3D-CRT, the dose inadvertently given to the surrounding normal tissues can be significantly reduced without compromising delivery of high doses to the target volume. However, this technique relies significantly on the expertise of the radiation oncology and physics team, and careful manipulations with dose distributions are needed to optimize delivery of a high dose to the target while minimizing dose to critical structures.[5,24,25] More recently, advances in radiation technology have resulted in additional refinement of 3D-CRT with the development of IMRT.[16] IMRT utilizes a computer dose distribution optimization process to deliver the radiation dose to the tumor while minimizing the dose delivered to the surrounding normal structures. The delivery of IMRT is based on the use of multileaf collimators (MLCs) and allows for painting or sculpting of dose distribution with superb precision resulting in a rapid dose fall-off near normal tissue. Although several different treatment planning systems are available, the basic principles underlying this technology are similar.[11] The technical aspects of IMRT are discussed further in Chapter 5.

Tumors of the skull base, including those involving the nasal cavity and the paranasal sinuses, appear to be especially well suited to the use of IMRT, given the irregular contours of these cancers and the presence of vital structures in this region such as the brainstem, the optic nerves, the optic chiasm, and the spinal cord. Multiple dosimetric studies have eloquently shown that improved dose distributions with increased dose delivery to the tumor target while minimizing the dose delivered to the surrounding normal tissues can be achieved with IMRT when compared with conventional radiotherapy[13,26] (Fig. 21-1). From a practical standpoint, the dose delivered to the optic pathways can be reduced selectively by IMRT, which has the potential to save binocular vision particularly for patients who have extensive and large-volume disease in the paranasal sinuses. Preliminary clinical data from several centers have demonstrated minimal toxicity from IMRT when compared with the historical series where the toxicity rates can be as high as 35%.[15,27,28] In a longitudinal analysis of 127 patients treated with radiation therapy from 1960 to 2005 at the University of California, San Francisco (UCSF), the incidence of grade 3 and 4 late ocular toxicity among patients treated with CRT, 3D-CRT, and IMRT was 20%, 9%, and 0%, respectively.[15] In another series from Memorial Sloan-Kettering Cancer Center, none of the 85 patients who underwent postoperative radiotherapy treated with CT simulation developed grade 3 to 4 late complication of the eye with a median follow-up of 60 months among surviving patients.[5,29] Other series have shown similar results in terms of the reduction of late complications due to radiotherapy. As more centers publish their experience with IMRT in the treatment of paranasal sinus cancer, it is hopeful that the late complication rates continue to decrease. In addition to its ability to spare the organs at risk, IMRT can potentially increase disease control as a result of improvement in tumor coverage and by allowing the delivery of higher radiation doses than with conventional technique.[13]

## ANATOMY AND PATTERNS OF SPREAD

### The Nasal Cavity

The anterior, the superior, the inferior, and the posterior borders of the nasal cavity are located at the limen nasi, the base of skull (the frontal sinuses, the cribriform plate, and the ethmoid air cells), the hard palate, and the choanae, respectively (Fig. 21-2). The limen nasi is the line of transition from the skin to the mucous membrane. The septum divides the nasal cavity into right and left halves and attaches to the perpendicular plate of the ethmoid bone posteriorly (Fig. 21-3). The medial walls of the maxillary sinuses define the lateral borders of the nasal cavity. The nasopharynx is located directly behind the nasal cavity. There are three turbinates or conchae (superior, middle, and inferior), which protrude downward and medially from the lateral wall into the nasal cavity, forming the superior, middle, and inferior meatus. Superiorly, the cribriform plate contains the branches of

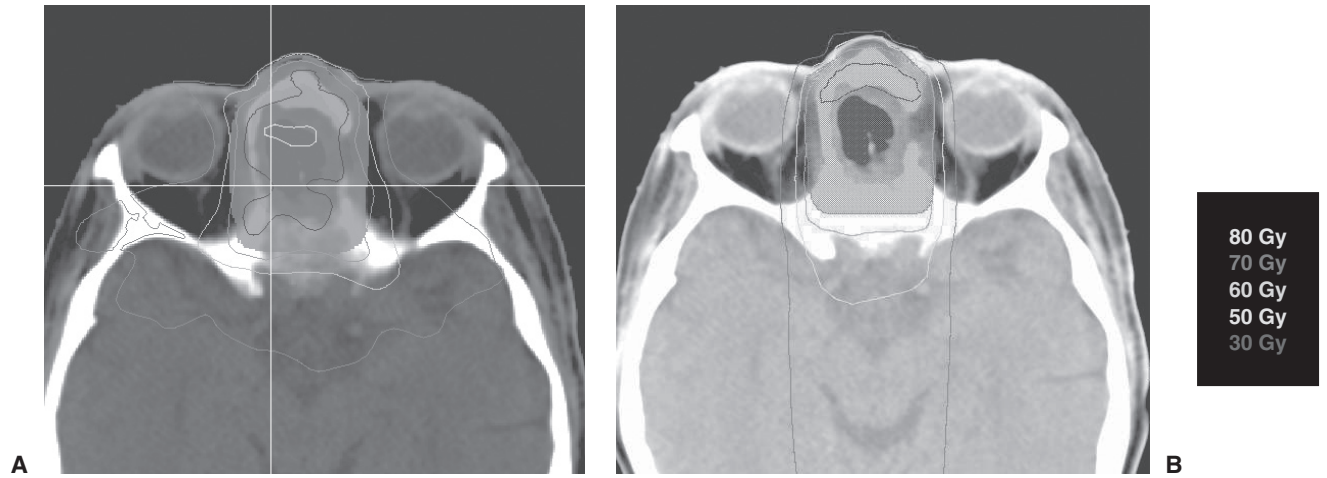

**FIGURE 21-1.** An example of an ethmoid sinus tumor being planned using **(A)** IMRT and **(B)** 3D-CRT. Notice that the 70-Gy isodose line (dark blue) coverage is superior in the IMRT versus the 3D-CRT plan. In addition, there is superior sparing of the optic chiasm when compared with the 3D-CRT plan. IMRT, intensity modulated radiation therapy; 3D-CRT, three-dimensional conformal radiotherapy. (See color insert.)

the olfactory nerve, which innervates the superior nasal concha and upper third of the septum.

Nasal cavity tumors tend to spread by local extension into adjacent bones and sinuses because the bony partitions between the nasal cavity, the sinuses, the orbits, and the cranial vault are quite thin and offer little resistance to cancer infiltration. Nasal cavity tumors can also destroy the septum and invade through the nasal bone to the skin. Lateral wall tumors can spread to destroy the medial maxillary sinus wall and invade into the maxillary antrum, whereas tumors arising in the middle meatus invade first the ethmoid sinus and then the orbit. The sphenoid sinus and the nasopharynx are also sites of tumor extension particularly in more advanced cases. The cribriform plate serves as an avenue for cancer spread to the anterior cranial fossa. Minor salivary gland tumors, particularly adenoid cystic carcinoma, have a higher chance of perineural spread. Commonly involved nerves for perineural spread include olfactory nerves, infraorbital nerve, and the nerves within the superior orbital fissure.

Regional lymph node metastasis occurs in <5% at presentation and approximately 10% of patients have distant metastases. Lymphatic drainage is to the retropharyngeal lymph nodes and the cervical chain. One series from MD Anderson Cancer Center (MDACC) of 51 patients showed a 6% nodal relapse in the subdigastric region in patients who did not receive elective nodal irradiation.[30]

## Esthesioneuroblastoma

Esthesioneuroblastoma, also commonly known as *olfactory neuroblastoma*, was initially described in the early 1900s and remains a relatively rare disease accounting for approximately 1% to 6% of all nasal cancers.[31–33] Arising from the olfactory mucosa, it frequently invades the paranasal sinuses, the orbits, and the skull base. Compared with other tumors located in this site, esthesioneuroblastoma is more likely to spread intracranially through the cribriform plate. Nasal obstruction, epistaxis, nasal discharge, pain, visual changes, facial numbness, or a neck mass are symptoms on presentation. Cervical nodal metastases have been reported to range from approximately 17% to 27% of the patients on presentation although distant metastases have been in the order of 10% to 40%.[31] Although different staging systems have been proposed, the Kadish staging system is the most commonly used[34] (Table 21.2). Because esthesioneuroblastoma typically expresses a variety of neuroendocrine markers such as neuron-specific enolase, chromogranin, and synaptophysin, immunohistochemistry can facilitate its diagnosis.

## The Ethmoid Sinus

The ethmoid sinus contains several small cavities, namely, the ethmoid air cells located between the medial wall of the orbit and the lateral wall of the nasal cavity (Figs. 21-4 and 21-5). The ethmoidal sinuses are divided into anterior, middle, and posterior groups of air cells, where the middle group opens directly into the middle meatus. These groups are distinguished from each other on the basis of their sites of communication with the nasal cavity. The lamina papyracea, a porous bone, separates the ethmoid sinus from the orbital cavity and is a source of tumor spread.

Tumors confined to the ethmoid sinus without any involvement of the surrounding structures and sinuses are extremely rare. Tumor extension to the ipsilateral nasal cavity, the maxillary sinus, the orbit, the sphenoid, the anterior cranial fossa, the frontal sinus, and the nasopharynx are common. Contralateral spread to the opposite ethmoid sinus is infrequent and reported to be approximately 10%.[22] Tumors can extend to the orbit through the lamina papyracea and superiorly into the anterior cranial fossa through the cribriform plate, particularly esthesioneuroblastoma. If the dura is compressed but not involved with tumor, it does not portend the poor prognosis when compared with tumor extension with histologic involvement of the dura.

Lymphatic spread is reported to be 3% to 7%.[22] Approximately 10% of the patients subsequently present with nodal failure when the lymph nodes are not electively radiated.

## The Maxillary Sinus

The maxillary sinus is shaped like a pyramid where the base separates the maxillary sinus from the nasal cavity (Figs. 21-6 and 21-7). The floor of the maxillary sinus is composed of the alveolar process, and it resides inferior to the floor of the nasal cavity, particularly for the edentulous patients. Superiorly, the floor of the orbit forms the roof of the maxillary antrum, which contains the infraorbital canal. The apex extends to the zygomatic bone. The facial wall is the anterior boundary of the maxillary sinus. Posteriorly, the infratemporal wall borders the infratemporal and the pterygopalatine fossae. Tumors gain access to the base of the skull when they spread posteriorly into these structures.

The Ohngren line, a theoretic plane joining the medial canthus of the eye with the angle of the mandible, divides maxillary sinuses into a suprastructure and an infrastructure.

Tumors can invade the nasal cavity through the medial wall, can involve the maxillary gingiva, may spread to the infratemporal fossa or the pterygopalatine fossa, or invade the orbit by direct superior extension through the ethmoids. In some sense, the pattern of spread of maxillary sinus cancer can vary depending on the site of origin within the antrum. Tumors in the suprastructure can extend to involve the nasal cavity, the ethmoid cells, the orbit, the pterygopalatine fossa, the infratemporal fossa, and the base of the skull. The routes of spread for infrastructure lesions include the hard palate, the alveolar process, the gingivobuccal sulcus, the soft tissue of the cheek, the nasal cavity, and the pterygoid fossa.

Lymphatic drainage ranges between 10% and 20%[20] The incidence can be as high as 30% for poorly differentiated histology. Approximately 10% to 15% will develop nodal relapse if elective lymph node irradiation is not done. When patients relapse in the lymph node region, they are rarely cured and also have high rates of distant metastases. The rate of distant metastasis is approximately 15% to 25%.[19]

## The Sphenoid Sinus

The sphenoid sinus is a midline air cavity within the body of the sphenoid bone. It is located anterior to the clivus, posterior to the superior meatus of the nasal cavity, and medial to the cavernous sinuses (Figs. 21-2 to 21-5). The sphenoid sinus is divided by a septum into the right and left sphenoid sinuses. The septum is often incomplete or very thin and is rarely in the anatomic midline. The pituitary fossa and the optic chiasm lie above and the nasopharynx lies inferior to the sphenoid sinus. Tumors can spread to the cavernous sinus and intracranially to the anterior or the middle cranial fossae. There can be involvement of the adjacent ethmoid sinuses, the clivus, the sella turcica, the nasal cavity, the nasopharynx, and the orbit.

## The Frontal Sinus

The frontal sinuses lie between the outer and inner tables of the frontal bone representing an extension of anterior ethmoidal cell (Figs. 21-2 and 21-8). The two frontal sinuses are irregularly shaped and asymmetric and are separated by a thin bony septum. The sinuses lie above the orbits and drains into the maxillary sinus through the frontal nasal duct.

# TARGET DETERMINATION AND DELINEATION

Understanding the patterns of failure for nasal cavity and paranasal sinus cancers is essential for adequate target determination and delineation. Before delineation of the target, determination

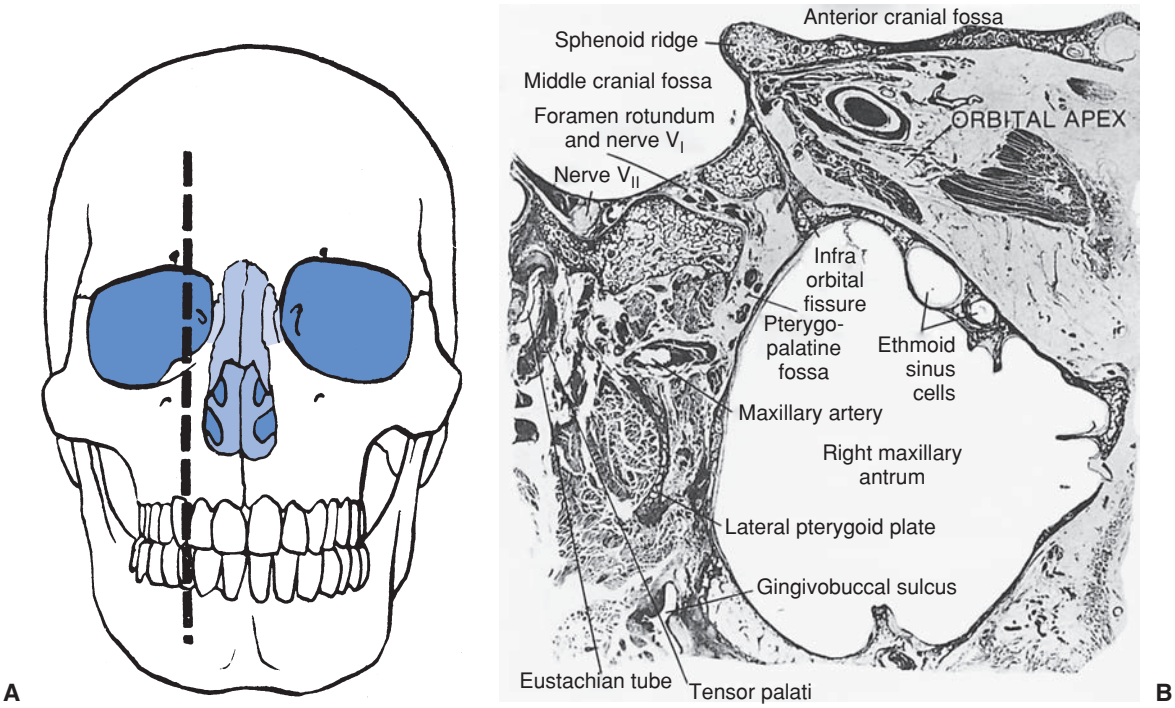

**FIGURE 21-7.** **A:** Sagittal section through the antrum and the apex of the orbit. **B:** The orbital apex communicates with the pterygopalatine fossa by way of the infraorbital fissure. Extension of antral tumor through the posterior wall provides access to the middle cranial fossa along the cranial nerves and the vascular foramina.

*Source:* From Bridger MWM, van Nostrand AWP. The nose and paranasal sinuses—applied surgical anatomy: a histologic study of whole organ sections in three planes. *J Otolaryngol.* 1978;7(suppl 6):1–30, with permission.

of proper sites to be irradiated must be considered. For example, for patients with tumors at risk for perineural spread such as adenoid cystic carcinomas, the planned target volume should include the neural pathways up to the cranial nerve ganglion at the base of skull.

For definitive treatment, the gross tumor volume (GTV) is outlined by using all available imaging, that is, MRI and/or positron emission tomography (PET). MRI fusion with treatment planning CT scan can further aid in the delineation of the GTV. Unless contraindicated, every patient should undergo MRI due to the complex anatomy of this region as MRI is superior in differentiating between mucous versus tumor as well as visualizing more clearly the different nerve pathways. One study from Hokkaido University School of Medicine compared clinical outcomes among 82 patients who underwent CT-assisted planning to those of 88 patients who had no such treatment planning.[35] The investigators found that the combined use of CT and the shell for immobilizations in treatment planning allowed greater accuracy in tumor coverage. Multivariate analysis for predicting significant prognostic factors confirmed the critical role of CT in terms of overall survival and primary tumor control. Notably, the actuarial 5-year survival rate was improved by 10% in patients who underwent CT-assisted treatment planning with a particular improvement observed among patients whose tumors were located adjacent to critical organs at risk such as the brain and eye. The clinical tumor volume (CTV) is defined as the GTV plus microscopic spread of the tumor. Typically, this involves one or more adjacent sinuses. The planning target volume (PTV) typically includes a margin ranging from 3 to 5 mm surrounding the CTV. Each institution should have its own set of guidelines on the margin needed to account for patient motion and daily setup errors. For postoperative lesions, the CTV is defined as the postoperative bed which should include previous sites of gross disease as depicted from preoperative imaging, as well as the entire postoperative bed (Fig. 21-9). Areas with positive margins and/or gross residual disease should receive a higher dose, although every attempt to achieve gross total resection is needed to maximize local control.[36] Due to the possibility of surgical seeding, postoperative CTV should also include all tissue planes surgically violated.[37,38]

## REGIONAL LYMPH NODE IRRADIATION

For patients treated with radiation therapy for carcinomas of the nasal cavity and the paranasal sinuses, uncertainty exists regarding the optimal treatment volume, particularly with respect to irradiation of the neck for patients without clinical evidence of nodal involvement. This issue is especially pertinent because the proportion of patients with clinical evidence of lymph node metastasis at presentation is relatively low, ranging from 3% to 25%, depending primarily on the histological subtype and location of the primary tumor.[19,39,40] Presently, elective neck irradiation (ENI) is controversial and indications for its use differ both within and between institutions.

Over the last couple of decades, studies attempting to identify groups of patients who may benefit from ENI have been published. Although several small historic series had suggested that

The middle turbinate appears to arise from the roof of the nasal cavity near the septum, which is the appearance during physical examination.

*Source:* From Bridger MWM, van Nostrand AWP. The nose and paranasal sinuses—applied surgical anatomy: a histologic study of whole organ sections in three planes. *J Otolaryngol.* 1978;7(suppl 6):1–30, with permission.

ENI was not necessary due to the low incidence of nodal relapse among patients with carcinomas of the nasal cavity and the paranasal sinuses, investigators from MDACC reported a nodal relapse rate of 38% among 73 patients treated for maxillary sinus carcinomas with squamous cell and undifferentiated carcinomas.[39] A subsequent analysis from Loyola University demonstrated a 29% rate of nodal recurrence among 42 patients and recommended routine ENI for those with SCC of the maxillary sinus.[19]

More recently, investigators from Stanford University and UCSF demonstrated a 5-year actuarial nodal relapse rate of 12% among 97 patients treated for maxillary sinus carcinoma.[19,20] On the basis of observation that all patients who failed in the neck had T3 or T4 cancers, the authors recommended ENI for these subsets of patients. University of Florida concurred with Stanford on their series of SCC of the maxillary sinus. The authors recommended that at least ipsilateral ENI be done for T3 or T4 N0 disease and

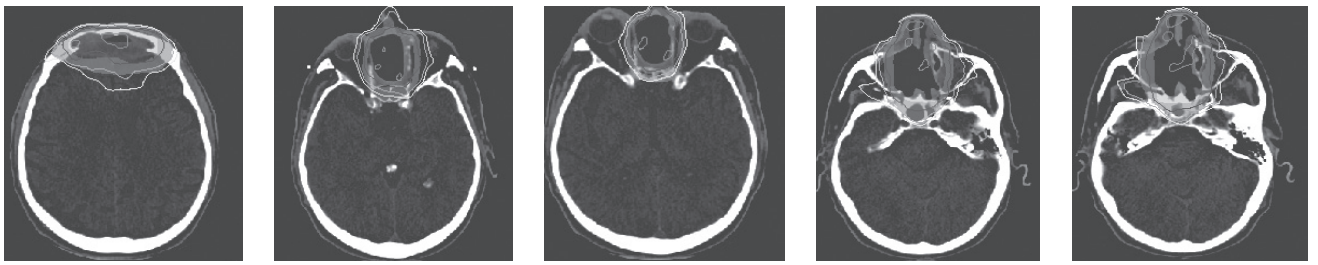

**FIGURE 21-9.** An example of different axial slices showing contours of a patient with ethmoid sinus tumor who underwent craniofacial resection. that bilateral ENI should be offered to patients with very large or recurrent primaries that cross the midline. The authors further noted a neck failure in a patient with T2 N0 disease and recommended that ENI should also be considered for early-staged T1–2 N0 patients.[41] Due to the relative rarity of patients with nonmaxillary sinus and nonsquamous cell cancers, the data reporting on ENI in this setting are extremely limited. However, a recent report from the University of Florida showed that the rate of nodal relapse was 27% among patients with esthesioneuroblastoma, thereby suggesting that ENI may be of benefit.[21] However, others have challenged the need of ENI for patients who presents with N0 esthesioneuroblastoma as effective salvage can be done at a later time when patients do recur in the neck.[42] Unlike SCC, SNUC, or esthesioneuroblastoma, ENI is not recommended for adenocarcinoma with N0 disease. In one study reporting on 47 patients with adenocarcinoma of the ethmoid sinuses, no patients experienced nodal relapse.[43] Similarly, a series from France showed neck irradiation is not needed for N0 disease in their experience with 95 patients with ethmoid adenocarcinoma.[44]

## RADIATION THERAPY TECHNIQUE—DOSE SPECIFICATIONS

IMRT has been shown to improve coverage while limiting the dose to the surrounding normal tissues by several institutions when compared with conventional radiotherapy techniques. Compared with historical controls, the authors reported more encouraging local control rates when paranasal sinus tumors are treated with IMRT.[5,13,16,17]

Different institutions have different guidelines regarding dose specifications. For definitive cases, treatment plans are generally designed to provide a dose of 70 Gy in 2 Gy to 2.12 Gy fractions to 95% or more of the gross disease. This is known as the $PTV_{GTV}$. A dose of 59.4 to 63 Gy is prescribed to 95% or more of the high-risk CTV, namely, $PTV_{CTV\ high\ risk}$. A low-risk CTV can also be prescribed, as determined by the treating physician, where 95% or more receives 54 to 56 Gy. This is known as the $PTV_{CTV\ low\ risk}$. For postoperative cases, the dose delivered to the high-risk CTV can range from 60 to 66 Gy, whereas the low-risk CTV receives typically 54 Gy. Examples of sample treatment plan can be found in Figures 21-9 and 21-10. For critical normal structures, dose constraints are designed to limit the maximum dose to 54 Gy for the brain stem and the optic nerves, 54 Gy to the optic chiasm, 45 Gy for the spinal cord, and 60 Gy for the temporal lobes. Table 21.3 lists dose specifications and normal tissue dose volume constraints.

## TREATMENT RESULTS

### The Nasal Cavity

The preferred treatment approach for cancer of the nasal cavity is surgery with or without radiotherapy, except for small lesions where radiotherapy and surgery are equally effective.[4] The choice of one modality over another is contingent upon the size, location, and the potential cosmetic outcome of treatment. Posteriorly located lesions are treated best by surgery, whereas anteriorly located lesions are best served with brachytherapy. Of note, although definitive radiotherapy yields a high cure rate for small nasal cavity SCCs, complications as a result of high doses of radiotherapy such as optic nerve injury can occur. One series from MDACC treated 45 patients with curative intent.[30] Eighteen patients were treated with radiotherapy alone of which brachytherapy was used in five. Postoperative radiotherapy was given to the remaining 27 patients. Thirty-one patients had lesions located in the lateral wall or floor of the nasal cavity, and 14 lesions were located in the nasal septum. SCC comprised 67% of the cohort. The 5- and 10-year disease-specific survival and overall survival rates were 83% and 69% versus 80% and 58%, respectively.

Several others also published their outcomes with survival rates up to 75%[30,45–47] (Table 21.4). Patient population varies among these series but, in general, small lesions involving the nasal septum are best cured with radiotherapy, particularly brachytherapy.

## Esthesioneuroblastoma

Due to the rarity of this disease, no prospective studies are available to determine the optimal treatment. In one series, combined modality treatment consisting of surgery and postoperative radiotherapy has demonstrated greater benefits when compared with single-modality therapy where the recurrence-free survival is 92% in those who underwent surgery followed by adjuvant radiation versus 14% surgery alone versus 40% radiation alone.[48] The 5- and 10-year overall survival rates were 74% and 60%, respectively. The traditional postoperative radiotherapy dose ranges from 50 to 66 Gy. An analysis of the Surveillance, Epidemiology, and End Results (SEER) database showed that for the 511 olfactory neuroblasoma cases, 5-year overall survival stratified by treatment modality was 73% for surgery with radiation, 68% for surgery alone, 35% for radiation alone, and 26% for neither surgery nor radiation. There was a significant overall survival difference between the four treatment groups with a $p < 0.001$.[49] In general, most series favor surgery followed by postoperative radiotherapy for Kadish A lesions where the disease is limited to the nasal fossa and Kadish B lesions where the disease extends to the paranasal sinuses. For the patients with disease extension beyond the paranasal sinuses, chemotherapy (i.e., cisplatin, etoposide, doxorubicine, vincristin cyclophasphamide) is often added to surgery and radiation.[50] Cisplatin and etoposide chemotherapy has been used successfully in conjunction with proton beam radiotherapy (equivalent to 68 Gy of photon irradiation) in a small series of nine patients with success. Eight out of nine patients have been controlled with a median follow-up of 20.5 months. Longer follow-up will be required to determine the long-term success rate.[32]

Whereas most centers advocated surgery followed by postoperative radiotherapy in the treatment of esthesioneuroblastoma, some centers prefer preoperative radiotherapy plus chemotherapy as a complement to radical craniofacial resection, attempting to reduce the tumor burden before surgery. Polin et al.[51] reported 34 consecutive patients with biopsy-proven esthesioneuroblastoma who underwent preoperative radiation therapy with or without chemotherapy followed by surgical resection. Patients received 50 Gy along with either single-agent cyclophosphamide, vincristine, or in combination with Adriamycin. The overall 5- and 10-year survival rates were 81% and 54.5%, respectively. The results are impressive as 23 patients had Kadish C disease. In light of all these promising results, a recent meta-analysis of results from different centers showed that the 5-year overall and disease-free survival averaged 45% and 41%, respectively.[33] In terms of the surgical approach, a recent meta-analysis has shown that endoscopic sinus surgery achieved comparable survival to open surgery and the authors suggest that it is a valid treatment method. However, prospective studies should be done to validate this finding.[52]

Several prognostic factors are noted for esthesioblastoma. Female patients and patients older than 50 years of age have a worse prognosis.[53] Overall survival is worse with those who present with node-positive disease versus those with node-negative disease (29% vs. 64% at 5 years). Patients who present with a high Hyams grade (defined by examining the histologic features such as having a lobular architecture, neurofibrillary background, rosettes, nuclear pleomorphism, mitosis, necrosis, and calcification of the tumor) did significantly worse in one series when compared with low Hyams grade, 36% versus 81% 5-year overall survival.[54] The failure rates are in the range of 24% to 75% with the 5-year overall survival rates ranging from 60% to 78% (Table 21.5). A multicenter retrospective review showed T1–3, N0, R0/R1 resection, and at least 54 Gy of postoperative radiation therapy in multivariate analysis, were independent factors predicting the outcome in olfactory neuroblastoma.[55]

## The Paranasal Sinus

Local disease progression and recurrence constitute the predominant patterns of failure for patients treated for carcinomas of the nasal cavity and the paranasal sinuses. The fact that most patients with uncontrolled tumor growth at the primary site will ultimately die of their disease is a testament to the paramount importance of local control. With the reported rates of 5-year overall survival ranging from 27% to 54%, it is clear that treatment results remain suboptimal and that considerable room exists to improve outcomes.[7,39,56]

Owing to their rarity, the literature to date reporting on patient outcomes after treatment for carcinomas of the paranasal sinuses and the nasal cavity are largely limited to retrospective single-institutional reports. Although some generalizations regarding treatment can be made based on these data, comparisons between series are complicated by the tremendous amount of heterogeneity with respect to such factors as therapeutic strategy, stage, histology, and disease site. Furthermore, it is unknown how potential imbalances in seemingly important prognostic variables such as intracranial invasion, orbital infiltration, and cranial nerve involvement influence treatment results.

The most consistently identified factor predicting for improved survival among those treated for carcinomas of the nasal cavity and the paranasal sinuses is gross total tumor resection. Among 127 patients treated at UCSF, the 5-year local control was 65% for those treated with postoperative radiation therapy after gross total resection compared with 44% among those who underwent postoperative radiation therapy in the presence of macroscopic disease.[15] In another study from the Netherlands, the addition of debulking surgery before radiation therapy dramatically improved 5-year overall survival from 9% to 60%.[57] The other variable which has been consistently demonstrated to correlate with outcome is tumor extent, with most studies confirming that patients with T1–2 tumors having superior rates of local control and overall survival compared with those with T3–4 tumors.[58–60] Because the vast majority of patients present with locally advanced cancers, additional data analyzing prognostic factors such as intracranial invasion, cranial nerve involvement, dural attachment, and orbital infiltration—all of which would currently categorize a tumor as T4 in the current AJCC staging system—is urgently needed. Although the AJCC staging system published in 2002 attempted to address this by dividing cases into T4a (resectable) and T4b (unresectable), it is still unclear how this distinction may influence prognosis. Mendenhall et al. reported their experience from the University of Florida and found that the probability of local control and cause-specific survival is better after surgery and radiation compared with definitive radiation.[61] However, there is still a need to improve the efficacy of treatment for this disease despite surgery being the preferred treatment and providing the best results, even accounting for the inherent bias in patient selection as discussed above.[62]

Despite the biases discussed earlier, several large series reporting treatment results are particularly instructive. Investigators from Memorial Sloan-Kettering Cancer Center recently analyzed 85 patients with carcinomas of the nasal cavity and the paranasal sinuses uniformly treated by gross total resection followed by postoperative radiation therapy and reported a 5-year local control of 62%.[5] On multivariate analysis, squamous cell histology and involvement of the cribriform plate predicted for an increased likelihood of local recurrence. In another series from Washington University, the 5-year local control was 58% among 106 patients treated by radiation therapy alone or combined with surgery for paranasal sinus cancer.[7] Likewise, investigators from UCSF reported a 5-year local control rate of 62% among 127 patients treated by radiation therapy with or without surgery from 1960 to 2005.[15] Although most of the patients included in the above-mentioned series had maxillary sinus cancers and squamous cell histology, the respective proportions nevertheless ranged from 43% to 76% and 53% to 82%, respectively. These differences are potentially significant because other studies have suggested that patients with maxillary sinus tumors have better outcomes than those whose primary tumors arise from the ethmoid, the frontal, and the sphenoid sinuses. The infrequency of the latter as well as the difficulty in determining the exact site of origin make drawing definitive conclusions problematic.[8,43,63] Similarly, others have shown that patients with nonsquamous cell histologies have improved outcomes compared with those with SCC of the nasal cavity and paranasal sinuses. Although a study from the University of Florida reported a very encouraging 5-year local control rate of 70% among 78 patients treated with radiation therapy, this study was notable for its large proportion of patients with adenocarcinoma.[8]

More recently, studies have attempted to evaluate the significance of radiotherapy technique on patient outcome, particularly with the widespread acceptance of 3D-CRT and IMRT. Using 3D conformal techniques, investigators from the University of Michigan reported a 5-year local control rate of 65% among 24 patients treated through surgery and postoperative radiation therapy.[64] Although this finding suggested that 3D radiation therapy improved local control compared with historic controls, a study from France showed that 14 of 25 patients experienced local recurrence after 3D-CRT with or without surgery for carcinomas of the paranasal sinuses.[65] However, it must be noted again that attempts to draw comparisons between respective series are complicated by the wide variability in surgical and radiation techniques employed across institutions. Tables 21.6 and 21.7 are selected treatments results from different institutions focusing on maxillary sinus and ethmoid sinus tumors.

Regarding IMRT for the nasal cavity and the paranasal sinuses, investigators at UCSF reported on 36 patients, 32 of whom were referred after gross total resection, treated between 1998 and 2004.[16] With a median follow-up of 39 months, the 2- and 5-year estimates of local control were 62% and 58%, respectively. The authors concluded that IMRT did not appear to improve disease control, but the low incidence of complications was encouraging. An important finding from this study was that all failures occurred within the high-dose region and that no geographic misses or marginal failures were observed. Investigators from Belgium similarly reported a 4-year local control of 68% among 39 patients treated with IMRT in the postoperative

setting.[66] A study from Stanford of 52 patients treated with IMRT demonstrated a 25% rate of local failures, with 12 of 13 failures being in-field.[37] There were six regional failures, of which four were out-of-field regional failures; however, all four of these patients had received bilateral nodal irradiation and all four were extranodal recurrences. An example of a patient with nasal cavity and maxillary sinus tumor who underwent postoperative IMRT is shown in Figure 21-11.

Although some have shown that the addition of chemotherapy to radiation therapy has the potential to improve local control and/or overall survival for patients with carcinomas of the nasal cavity and paranasal sinuses, the published data are limited to small, single-arm studies on highly selected patients.[67–69] Similarly, although strategies such as altered fractionation, brachytherapy, and particle beam therapy have been proposed as a means of improving the therapeutic ratio, their use is largely considered investigational.

Lastly, the question of whether advances in surgical and radiation therapy technique have contributed to improvements in clinical outcome remains somewhat controversial. A recent meta-analysis of 154 publications demonstrating survival rates of 28%, 36%, 43%, and 51% among patients treated in the 1960s, 1970s, 1980s, and 1990s, respectively, suggested that outcomes have improved over time.[70] However, a review of the UCSF experience did not corroborate this finding and instead suggested that the lack of improvement was due to underlying selection bias with the observation that cases referred for definitive therapy have become more complex with innovations in skull base surgery and radiation therapy delivery methods.[15]

## Sinonasal Undifferentiated Carcinoma

Primary sinonasal neuroendocrine tumors can be divided into four major histologic phenotypes: esthesioneuroblastoma (discussed in preceding text), sinonasal undifferentiated carcinomas (SNUC), neuroendocrine carcinoma, and small cell undifferentiated carcinoma.[71] SNUC portend a poor prognosis owing to its high rates of locoregional failures as well as distant metastases. Early reports on patients with SNUC were dismal.[72–74] An international collaborative study reporting on the results of craniofacial resection for malignant paranasal sinus tumors reported a 5-year overall survival rates of 0% for the undifferentiated

tumors.[56] Investigators have suggested that the poor outcomes in these series could have been attributed to the lack of chemotherapy or the inclusion of small cell histologies, as recent data are more promising.[71] Rischin et al.[75] have reported promising results with chemoradiation for SNUC patients. In their series, 10 patients of whom 9 had T4 disease underwent three cycles of induction platinum and 5-flurouracil followed by concurrent chemoradiation using cisplatin. With a median follow-up of 43 months (range, 8–101 months), the 2-year progression-free and overall survival rates were 43% and 64%, respectively. Rosenthal et al.[71] also reported a 5-year overall survival rate of 64.2% for patients with SNUC histology in their cohort of sinonasal neuroendocrine tumors. Some investigators also have used superselective high-dose cisplatin infusion with concomitant radiotherapy and achieved promising results where a majority of the patients with advanced cancer of the nasal cavity and the paranasal sinuses are cured while their organs are preserved. None of these patients underwent surgery. In this series, almost 20% had undifferentiated tumors.[76] The authors from University of Michigan showed that in their 13-year experience of 19 SNUC patients, local control was best among those treated nonsurgically, although statistically nonsignificant. The survival remains dismal at 22% at 5 years. The authors concluded that although it is possible that upfront radiation or chemoradiation will lead to better local control rates, surgery remains a mainstay of treatment.[77] Chen et al. has shown in their series that gross total resection should be the goal of all treatment whenever possible. With a median follow-up of 58 months among living patients, the 5-year local control rate was 74% for those who had gross tumor resection compared with 24% with subtotal tumor resection.[36] An example of treatment planning for a patient with T4 SNUC is shown in Figure 21-12.

## COMPLICATIONS OF TREATMENT

For patients treated with radiation therapy for malignancies of the nasal cavity and the paranasal sinuses, the high doses required to achieve local control coupled with the proximity of disease sites to sensitive normal tissue have historically been associated with a high incidence of treatment-induced morbidity. In particular, the location of these tumors in relation to the optic pathways, central nervous system, and bony structures has raised concerns regarding the potential development of such complications as blindness, brain injury, and osteoradionecrosis. In analyzing the frequency and severity of clinical complications reported across the literature for patients treated with radiation therapy for tumors of the paranasal sinuses and the nasal cavity, it is important to recognize that most publications have focused on those treated using conventional techniques.

Investigators from Keio Hospital in Japan reported a 25% incidence of radiation retinopathy and a 7% incidence of neovascular glaucoma among 25 patients treated for malignancies of the nasal cavity and the paranasal cavity.[78] Another study from Hokkaido University Hospital in Japan observed a 28% incidence of ocular complications among 115 patients who survived >2 years after radiation therapy with or without surgery for carcinoma of the maxillary sinus.[79] Investigators from the Netherlands noted that 19 of 73 patients (26%) developed visual complications including 3 patients who required enucleation due to infectious causes and 15 patients who developed blindness.[57] A study from Florida detected a 27% and 6% incidence of unilateral and bilateral blindness, respectively, among 78 patients treated by conventional radiation therapy techniques for carcinomas of the paranasal sinuses and the nasal cavity. In this same study, the authors reported that osteoradionecrosis developed in 6 of 78 patients.[8]

The data on neurocognitive functioning after radiation therapy for malignancies of the nasal cavity and the paranasal sinuses is more limited. Investigators from the MDACC analyzed 19 patients and found that memory impairment developed in 80% of patients during the follow-up period, with one-third of patients having difficulty with motor functioning and coordination.[80]

Although several studies have suggested that newer techniques such as IMRT have the potential to reduce complications, careful attention to targeting and dose constraints are essential to minimized radiation-induced complications.[81–83] In the UCSF series reporting on 36 patients treated using IMRT, reported acute complications included mucositis, conjunctivitis, keratitis, cellulitis, dacrocystitis, and parotiditis—all of which resolved with conservative management.[16] In the late setting, no patients experienced a complete loss of vision as a result of treatment with reported side effects including chronic xerophthalmia, chronic lacrimal stenosis, cataract formation, Eustachian tube dysfunction, and radiation necrosis of the gyrus rectus muscle resulting in gaze limitation. A longitudinal analysis of the UCSF experience showed that the incidence of grade 3 or higher late complications differed significantly among patients treated with conventional radiation therapy compared with those treated by 3D-radiation therapy and IMRT. For instance, 13% of patients treated with IMRT developed any grade 3 or higher late complication compared with 22% and 54%, respectively, of patients treated using 3D-radiaiton therapy and conventional radiation therapy, respectively.[15] Investigators from Belgium found that there is a high rate of radiation-induced hypopitutitarism after high-dose radiotherapy and therefore recommend endocrinologic surveillance for these patients. Thirteen of the 21 patients evaluated at the late morbidity clinic had hormonal disturbances of whom 24% had definitive evidence of hypopituitarism with multiple homonal definciencies.[84]

Further studies focusing on time-dose factors, particularly with respect to ocular and central nervous system toxicity, are needed to better delineate the optimal treatment parameters for patients undergoing radiation therapy for carcinomas of the nasal cavity and paranasal sinuses. It is likely that with increased understanding of the tolerance levels of normal tissue combined with continued improvements in image-based radiation therapy, treatment-related complications will continue to decline. Among long-term survivors, studies evaluating the incidence of pituitary dysfunction should be performed given the intricate relationship between the hypophysis and the base of skull. Formal ophthalmologic and auditory testing should also be considered in the prospective setting for patients treated for carcinomas of the nasal cavity and the paranasal sinuses.

## CHEMOTHERAPY

Chemotherapy has been used as a single agent for recurrent disease or as a radiosensitizer for unresectable SCC of the nasal cavity or the paranasal sinuses. Cisplatin-based chemotherapy is the most commonly used regimen and preliminary results have been promising.[85,86] Harrison et al. reported a series of 20 patients with T4 malignant skull base tumors, in which case high-dose cisplatin at 100 mg/m$^2$ was given on days 1 and 22 of radiation therapy using a delayed accelerated fractionation to a total dose of 70 Gy. With a median follow-up of 11 months, the 2-year local progression–free, distant metastases–free, and overall survival rates were 94%, 57%, and 80%, respectively.[10] The authors subsequently published a prospective phase II trial using the same treatment regimen for T4 unresectable tumors of the head and neck. With a minimum follow-up of 3 years and a mean follow-up of 45 months, the 3-year overall local control was 58% and 78%, respectively, for tumors of the paranasal

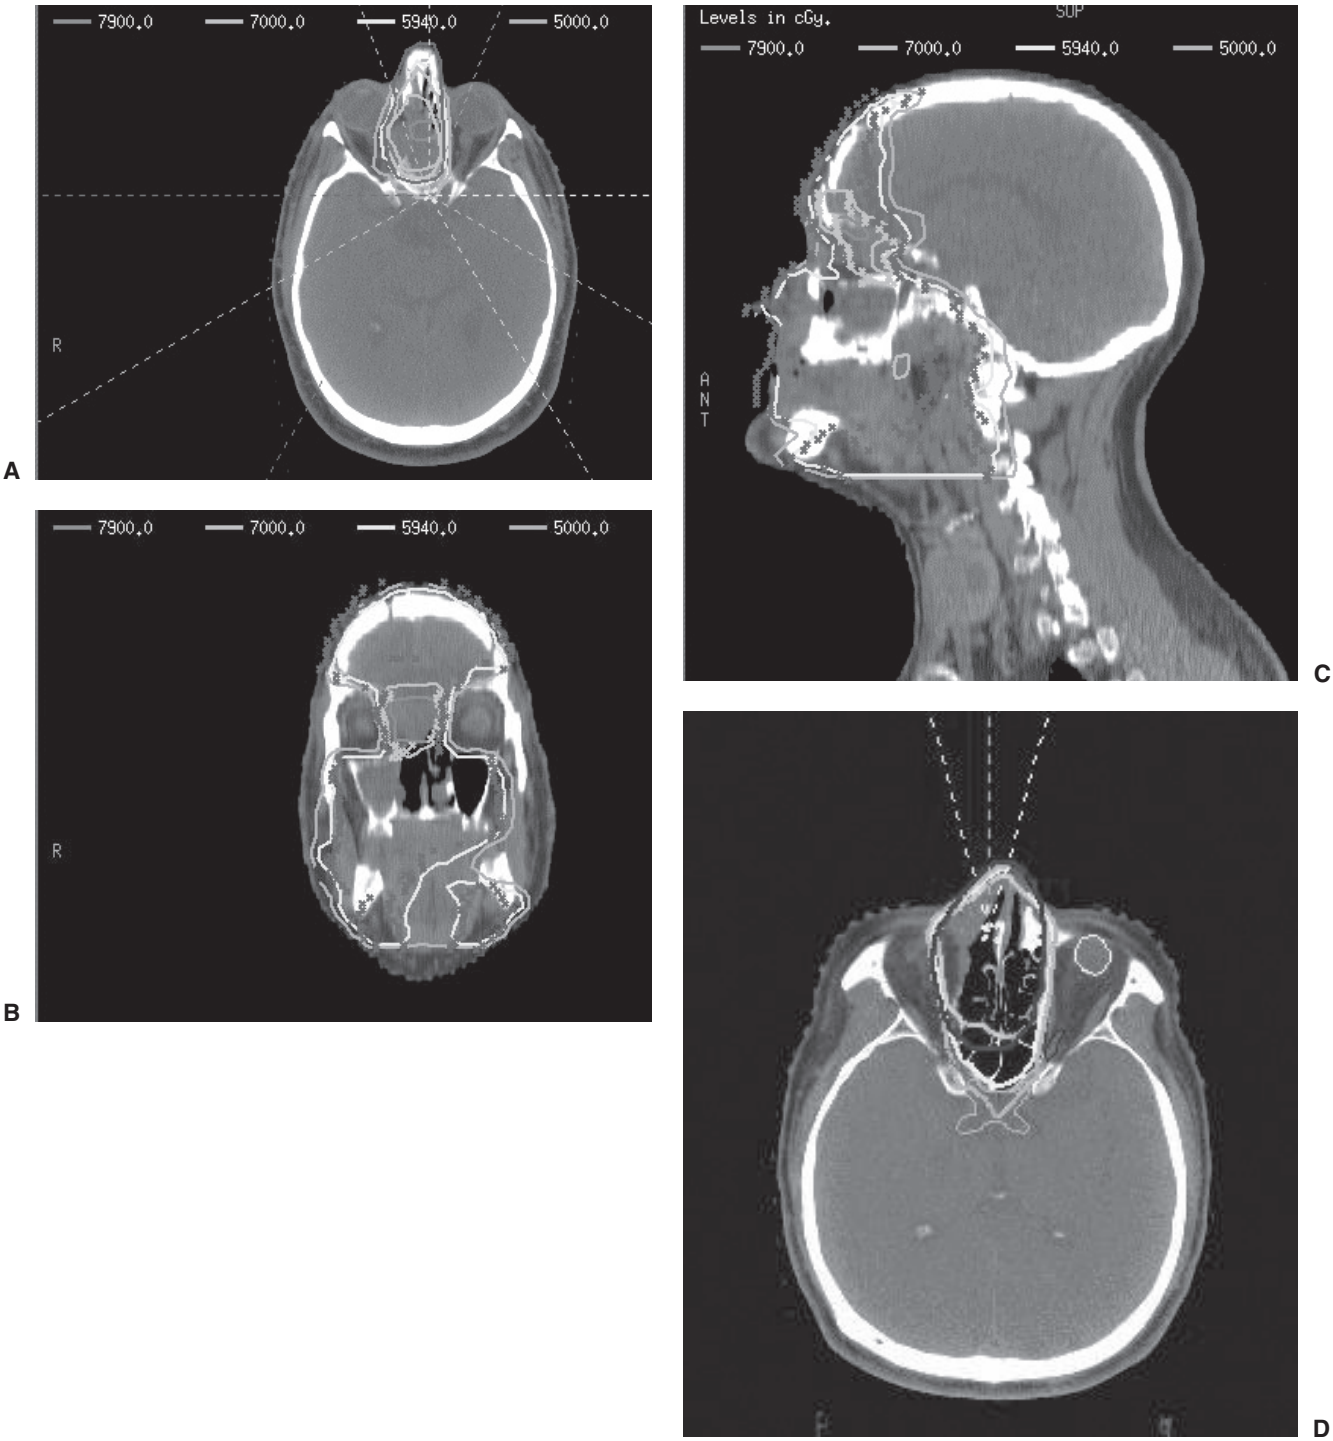

**FIGURE 21-12.** An example of a patient with sinonasal undifferentiated carcinoma where the tumor extended through the cribriform plate into the anterior cranial fossa. Despite two attempts at surgery, there was still gross residual disease. **A:** Notice the conformal dose distribution surrounding the gross tumor while sparing the optic structures. **B:** Axial view. **C:** Coronal view. **D:** Sagittal view. (See color insert.)

sinus. For all patients, the distant metastases–free rate was 56%.[87] Intra-arterial 5-fluorouracil chemotherapy as a radiosensitizer in an attempt to reduce the extent of surgery has been reported by Japanese.[88] Other investigators have also reported high tumor response using highly selective intra-arterial infusion of cisplatin-based chemotherapy.[89] Madison et al.[90] reported 11 cases of advanced sinonasal carcinomas of which the majority are T4 disease. Patients were treated with selective intra-arterial cisplatin with concurrent radiation therapy followed by conservative craniofacial resection. The mean follow-up was 57.2 months (range: 12–95 months). The overall 5-year survival was 81% with a 67% progression-free survival. In light of the

(c) 2014 Wolters Kluwer. All Rights Reserved.

above-mentioned available data along with the ability to target more precisely with IMRT, a new concept worthy of investigation is to use chemotherapy and definitive dose IMRT for advanced tumors involving the skull base where the alternative is extensive surgery requiring orbital exenteration. This concept of organ preservation is not new, and with the advent of highly conformal techniques such as IMRT, it is anticipated that the complication rates will decrease without compromise in locoregional control.[15] Lastly, chemotherapy has also been used as a palliative modality with modest efficacy in patients with present with esthesioneuroblastoma with intracranial metastases. However, median survival is poor at 10.5 months.[91]

## Proton Beam Radiotherapy

Proton beam radiotherapy has been used to treat tumors at the Massachusettes General Hospital (MGH) for >50 years. The rationale for using protons for skull base tumors is to deliver high doses of radiation with minimal doses delivered to the surrounding normal tissues. Proton radiation with its superior physical properties known as the Bragg peak can minimize the exit dose to the normal tissue beyond the target while achieving excellent coverage of the target.[92] Truong et al. reported the MGH experience of 20 patients with primary sphenoid sinus cancer that underwent proton beam to a median dose of 76 Gy equivalent. With a median follow-up of 27 months, the 2-year local, regional, and freedom from distant metastasis rates were 86%, 86%, and 50%, respectively. The disease-free and overall survival rates were 31% and 53% at 2 years, respectively. Brain invasion and involvement of the oropharynx and the anterior cranial fossa are important prognostic factors and portended worse outcomes.[93] From the same institution, protons resulted in a 5-year disease-free and overall survival rates of 90% and 85.7%, respectively, for esthesioneuroblastoma. No patients from their series suffered any severe radiation toxicity. The authors concluded that esthesioneuroblastoma can be safely and effectively be treated with craniofacial resection followed by proton beam irradiation.[94]

High-dose conformal proton beam results in a very encouraging local control for patients with adenoid cystic carcinoma of the skull base with a 5-year local control of 93%. In this series, approximately 50% of the patients had biopsy only. Overall, proton beam seems promising; however, complete surgical resection is still predictive of improved disease-free survival and decreased rate of distant failures among 102 patients with locally advanced sinonasal cancers treated with proton beam with or without surgery.[95] Now with more centers having the capabilities of delivering proton radiotherapy, prospective cooperative trials should be conducted to measure the true efficacy of protons versus IMRT.

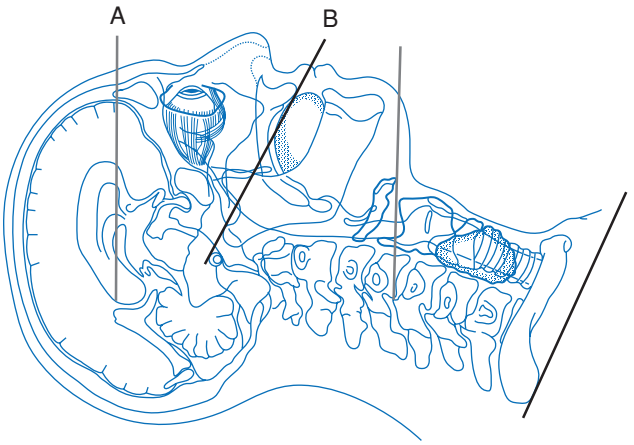
# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett



Imaging is critical in cases of cancer of the nasal cavity and paranasal sinuses, and computed tomography (CT) and magnetic resonance imaging (MRI) are complementary in evaluating lesions extending to the skull base and the orbit.[1,2] Both modalities are good at differentiating benign mucosal disease from more aggressive disease.[3] CT is typically performed first because of its speed and superior ability to show bony detail and destruction. CT must be performed with very thin sections, down to 0.5 mm, and reconstructed in bone and soft tissue algorithms. It is no longer necessary to acquire direct coronal CT images because the speed of imaging limits motion artifact, and very good quality coronal and sagittal reformations can be obtained from the very thin axial data. Both CT and MRI should be performed with contrast when a mass is suspected or known.[4] A combination of CT to evaluate bone and MRI to evaluate tumor versus obstructed mucosal disease has been shown to be essential.[5,6] Suggested protocols are given in Figures 21-13 and 21-14. The value of FDG PET-CT in the initial workup of sinonasal tumors is still being debated. These studies have a high negative predictive value, which is very useful for evaluation of tumor recurrence. However, the high rate of false-positive studies require the results to be viewed with caution.[7]

The approach to interpreting the images, as in other regions of the head and neck, is to determine the full extent of the primary tumor and to determine the presence of perineural and lymphatic spread.

In the nasal cavity and paranasal sinuses, a description of the local extent of a tumor includes a discussion of the amount of bone destruction present in the nasal cavity, facial bones, and sinuses and whether some of the abnormalities seen are a result of obstructed mucosal drainage, such as mucocele formation (Fig. 21-15) rather than tumor. Occasionally, imaging features will suggest a certain histology, such as lymphoma when the tumor is low signal on T2-weighted images and restricts on diffusion-weighted sequences, but usually determination of histology is reserved for the biopsy results. Both MRI and contrast-enhanced CT can demonstrate features of hypervascular tumors, showing large flow voids on MR and large vascular pedicles on

CT angiography. These findings can warn the surgeon to expect bleeding during biopsy or resection.

The amount of spread of tumor beyond the nasal cavity and sinuses is critical to the surgical approach and for determining whether postoperative radiation therapy is necessary. Tumor can cross the cribriform plate or paranasal sinuses to involve the intracranial compartment. In these cases, MRI should be performed to determine whether intracranial disease is confined to the extradural space, involves the dura, has spread through the dura to involve the arachnoid and the pial membranes, or invades the brain (Figs. 21-16 through 21-19).

The extent of orbital involvement determines whether the eye can be spared. CT is better at determining the extent of orbital bony destruction or erosion, and MRI is usually superior to determine

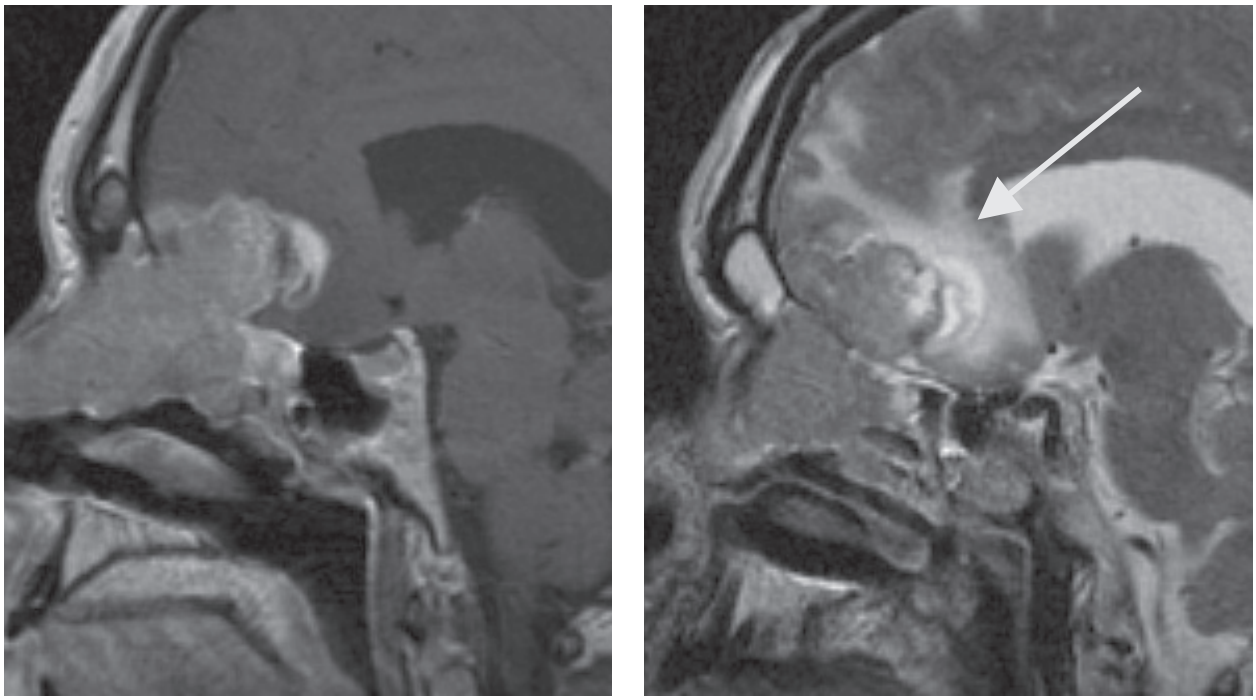

**FIGURE 21-19.** Intracranial involvement with brain invasion. **A:** Sagittal contrast-enhanced T1-weighted (T1W) image shows intracranial extension of a large sinonasal carcinoma. **B:** Sagittal T2W image demonstrates brain edema (*arrow*) indicative of invasion of the pial covering of the brain.

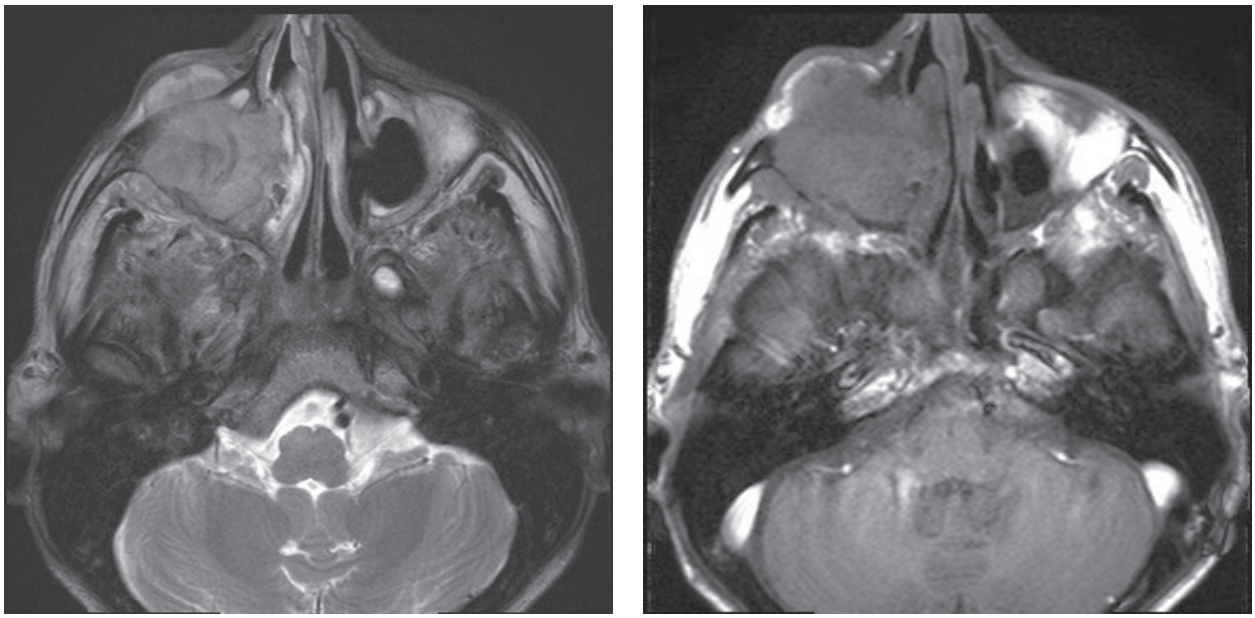
whether tumor has invaded the extraconal fat, the extraocular muscles, and the intraconal fat (Fig. 21-20). Fat suppression is essential when evaluating the orbit with MRI. Preseptal soft tissue tumor spread can affect the eyelid. Involvement of the lacrimal gland and nasolacrimal duct should be described when present.

Tumor can spread posteriorly to involve the nasopharynx and can also spread to the premaxillary fat, the retroantral fat, the infratemporal fossa, and the masticator space. Perineural spread can occur from any of these sites. Perineural spread of tumor can be seen with both CT and MRI, but MRI is preferred.



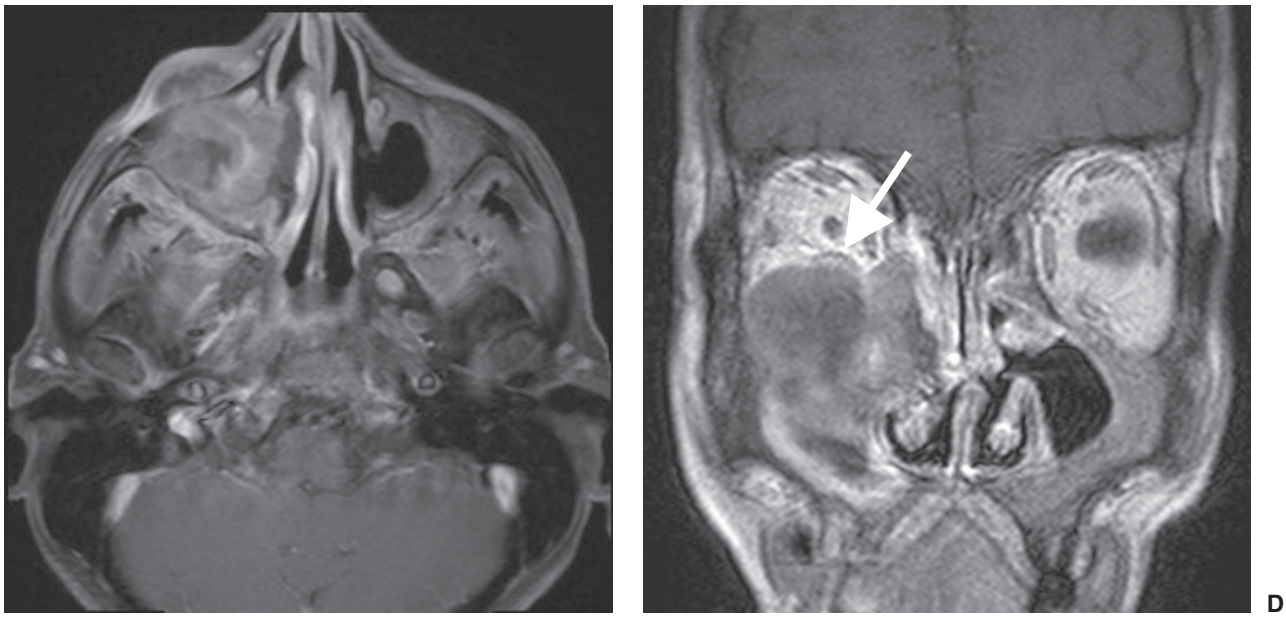


**FIGURE 21-20.** Squamous cell carcinoma (SCC) of the maxillary sinus. **A:** The tumor is intermediate to slightly high signal on T2-weighted (T2W) sequences. **B:** The tumor is intermediate signal on noncontrast T1W sequences. **C:** The fat-suppressed T1W images show that the tumor heterogeneously enhances. **D:** The coronal images demonstrate that the tumor erodes through the floor of the orbit and is indistinct from the inferior rectus muscle (*arrow*).

**FIGURE 21-20.** *Continued*

When maxillary sinus tumors spread to the cheek, perineural spread along the superficial musculoaponeurotic system should be sought. In nasal cavity tumors, spread can occur along the olfactory nerve through the cribriform plate. Spread along the branches of the trigeminal nerve must be described. Perineural spread can often be seen in the pterygopalatine fossa, and from there tumor can spread through foramen rotundum to Meckel cave and the cavernous sinus, through the vidian canal, or inferiorly along the greater and lesser palatine neurovascular bundles (Figs. 21-21 through 21-23).

Lymphadenopathy should be looked for in the facial, the parotid, the retropharyngeal, and the cervical lymph nodes.

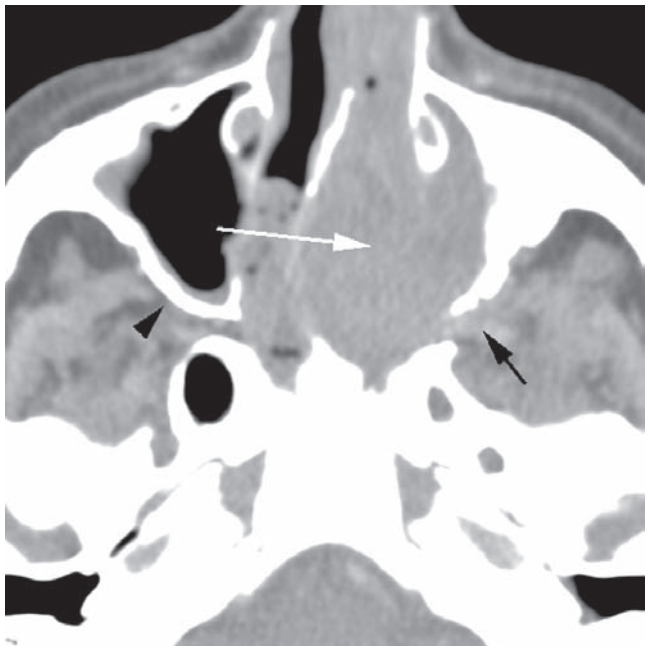

**FIGURE 21-21.** Axial contrast-enhanced CT scan shows a large nasal cavity carcinoma (*white arrow*) extending through the sphenopalatine forman into the pterygopalatine fossa (*black arrow*). Compare the normal retroantral fat pad on the right (*black arrowhead*).

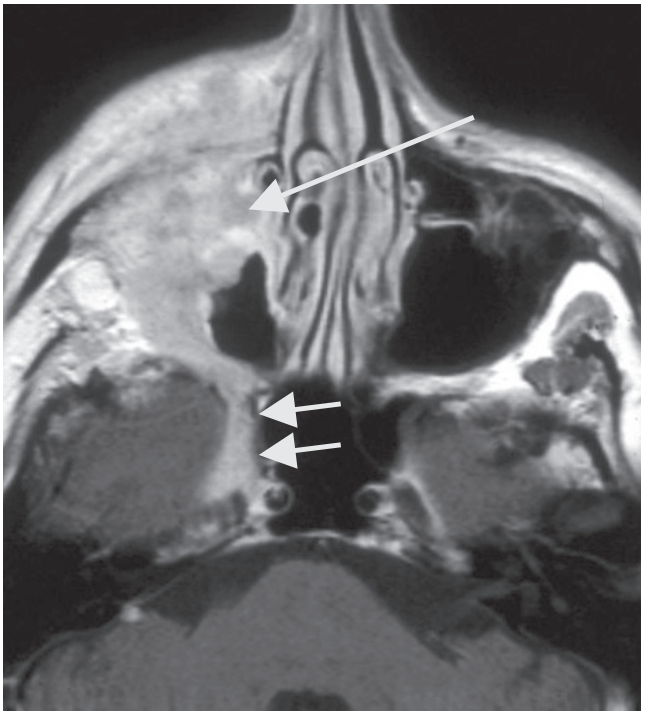

**FIGURE 21-22.** Perineural tumor spread. Axial contrast-enhanced T1-weighted (T1W) image shows an aggressive maxillary sinus carcinoma (*long arrow*). The tumor is extending retrograde along V2 into the cavernous sinus (*short arrows*). The deep extension of this tumor is clinically occult and imaging is necessary to determine that there is extension into the cavernous sinus, thereby staging this tumor as T4.

# PART C:
# Radiation Therapy Technique

Louis B. Harrison, James E. Dolan, Rudolph Woode, and Kenneth S. Hu

Intensity-modulated radiation therapy has become the standard of care for the delivery of radiation therapy for cancers of the nasal cavity and the paranasal sinus complex. The close proximity of vital structures such as the orbital contents; ocular structures such as the retina, the optic nerve, and the lens; the brain stem; and the optic chiasm, all represent challenges.

Like any other anatomic area, it is important to assess the gross tumor volume (GTV) and the clinical tumor volume (CTV). However, the authors do not use a routine volume expansion to determine the planning target volume (PTV). The PTV design must be individualized for each patient, as the closeness of key structures factor into this determination. The opportunity to use image-guided radiation therapy (IGRT) has added to the radiation oncologist's ability to design highly restricted PTVs and use daily imaging to verify position and fields and be tighter with margins. There is no general formula beyond observing the daily setup accuracy with IGRT, making the necessary shifts, and diligence to the interfaces between normal tissue and tissue at risk.

Basic technical issues are addressed in the body of the chapter in the section "Target Determination and Delineation" as well as "Radiation Therapy Technique—Dose Specification." In this section, we will show several specific patient examples, along with the figures that show the anatomical distribution of tumor, the PTV, and the isodose display (Figs. 21-24 and 21-25). We will also show the dose–volume histogram display, so the doses to both target and vital normal organs can be reviewed.

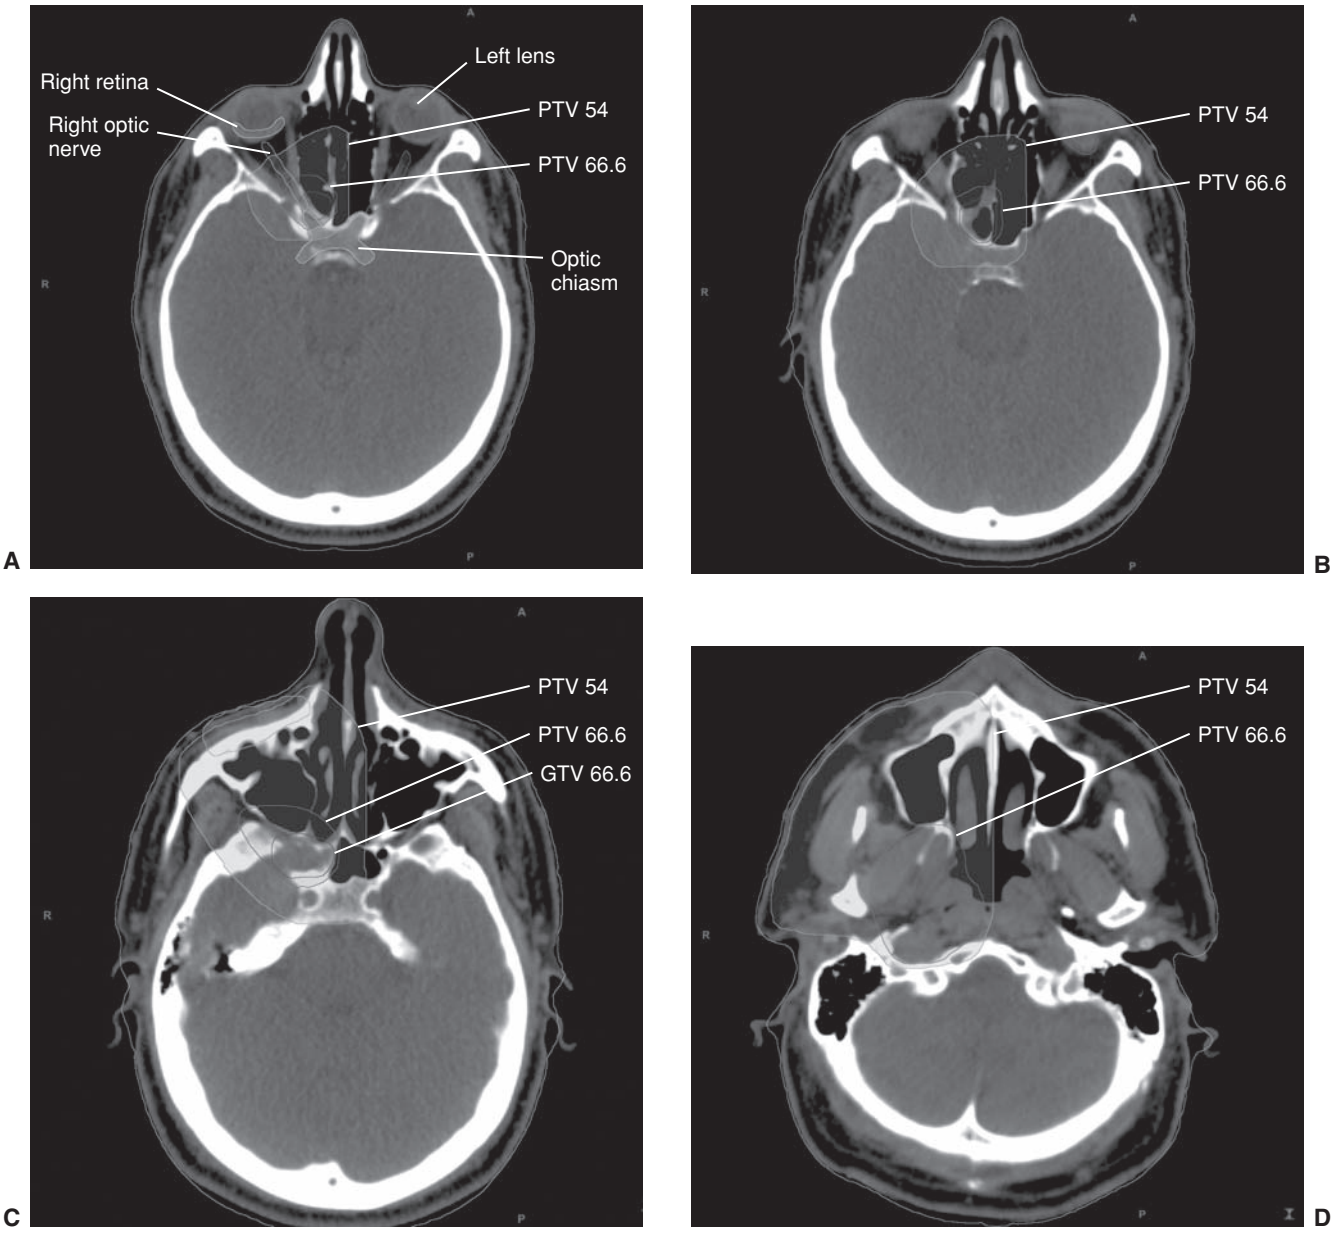

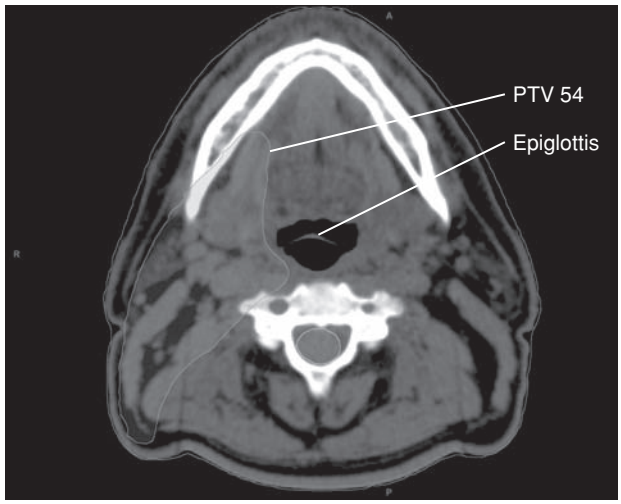

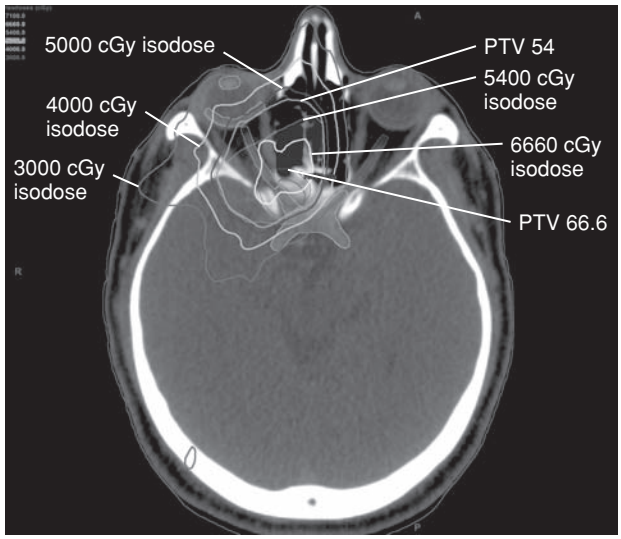

**FIGURE 21-24.** A 60-year-old male with a poorly differentiated carcinoma arising from the right side of the skull base. The tumor involves the sphenoid sinus, the ethmoid sinus, and the posterior aspect of the maxillary sinus and invades the posterior aspect of the right orbit. Tumor is very close to the right optic nerve as it enters the optic chiasm. The tumor did extend to the posterior nasal cavity. The stage was T4N0M0 AJCC stage IV. **A:** CT planning slice showing the optic chiasm, the right optic nerve, the retina, PTV 66.6, and PTV 54. The total dose used was 66.6 Gy at 1.8 Gy/fraction to the primary tumor volume plus margin (PTV 66.6). PTV 54 is an expansion of PTV 66.6. Care is taken to respect the anatomy as there is also a risk of total blindness due to the location of tumor near the optic chiasm. **B:** CT cut through the orbit showing PTV 66.6 and PTV 54. **C:** CT cut through the infraorbital area showing PTV 66.6, GTV 66.6, and PTV 54. Due to disease extent, PTV 54 is generous at this level, to include the entire right maxillary sinus and the nasal cavity with anterior expansion to the skin. **D:** CT cut through the midface showing PTV 66.6 involving the right pterygoid muscles, the pterygoid plates, and the most posterior nasal cavity. Again, PTV 54 represents a generous expansion to cover the entire right maxillary sinus, the anterior cheek/face, the skull base, the nasal cavity, and the preauricular area. This expansion covers routes of local disease progression and surrounding lymphatics. **E:** CT cut through the neck which shows PTV 54 including the neck nodes. Due to the advanced nature of the primary site, we delivered elective neck irradiation of 54 Gy at 1.8 Gy/fraction to the right-sided retropharyngeal nodes, as well as right levels 2, 3, and 4. **F:** Isodose distribution similar to Figure 1A above, showing coverage of PTV 66.6 with the 6,660 cGy isodose curve and coverage of PTV 54 with the 5,400 cGy isodose curve. The tightness of the coverage is noted due to the critical anatomy. The 5,000, 4,000, and 3,000 isodose lines are shown, which help protect the optic chiasm. **G:** Sagittal isodose display showing good coverage of PTV 66.6, PTV 54, protection of the spinal cord, the oral cavity, and the brain. **H:** Coronal dose distribution showing isodose display covering PTV 66.6 at the skull base; PTV 54 is well covered including the upper neck and the retropharyngeal nodes. **I:** Dose–volume histogram showing strong target coverage of PTV 66.6 and PTV 54, and respected tolerances of vital structures like the brain stem, the spinal cord, the optic chiasm, and the retina. A portion of the right optic nerve and the optic chiasm get higher doses because they are within PTV 66.6, as tumor is in these locations.

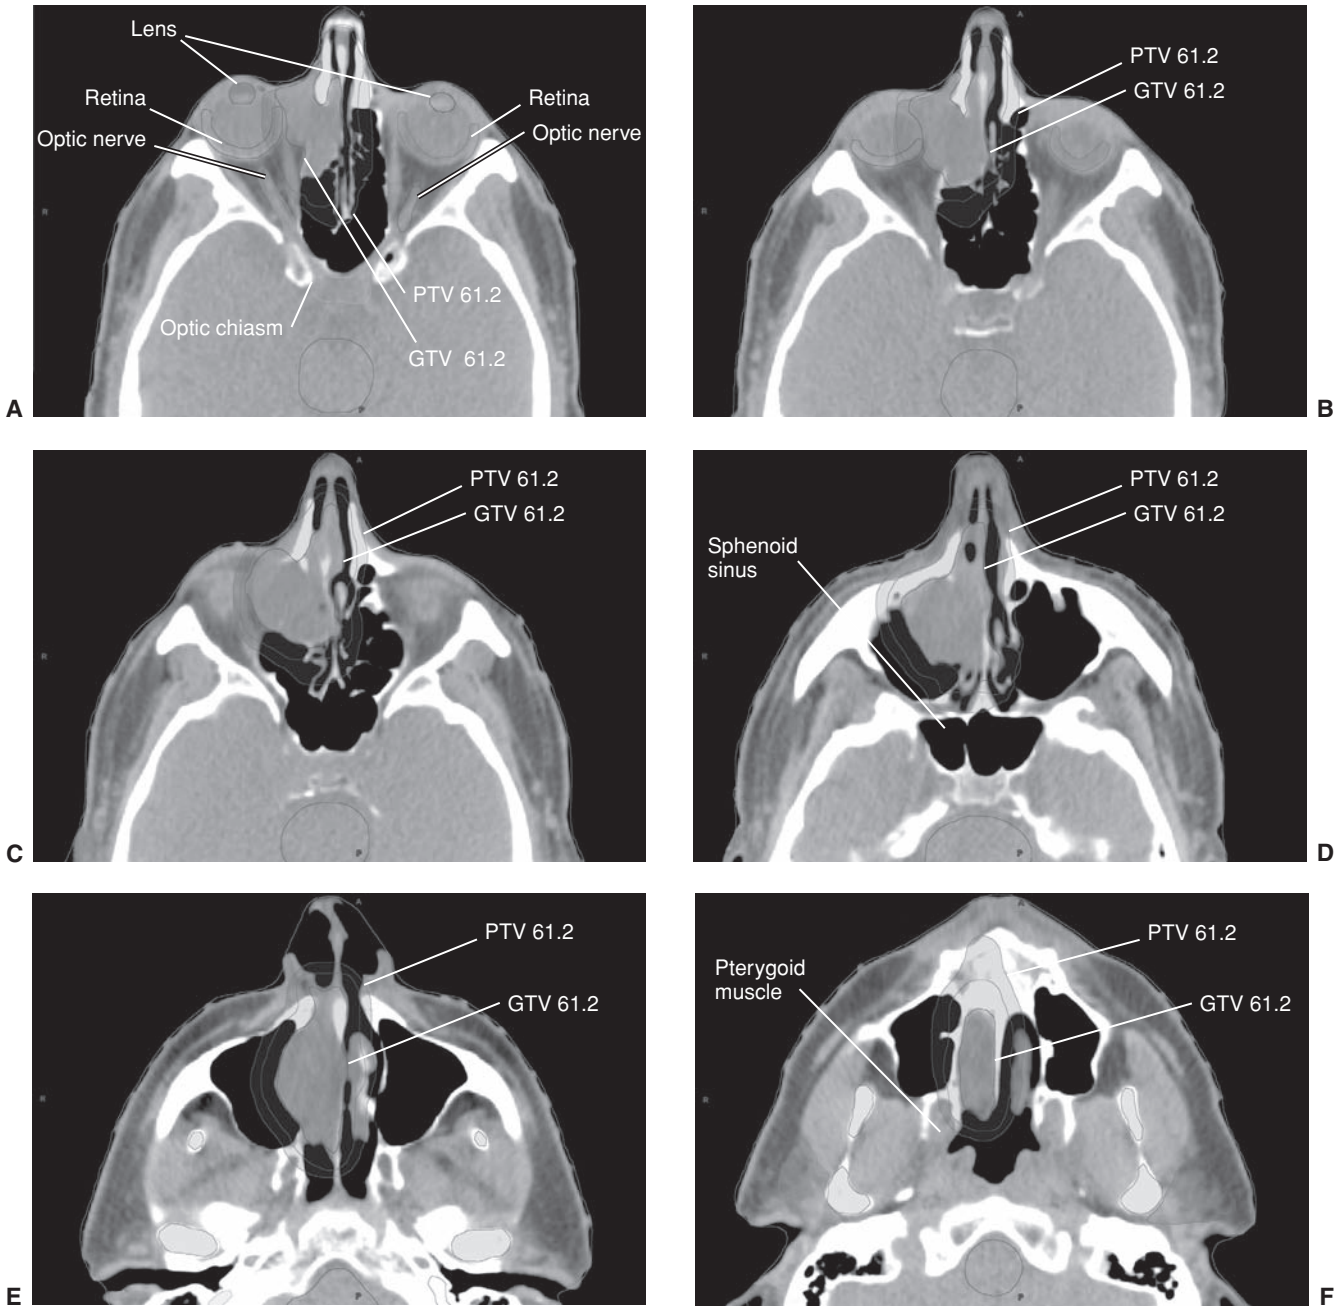

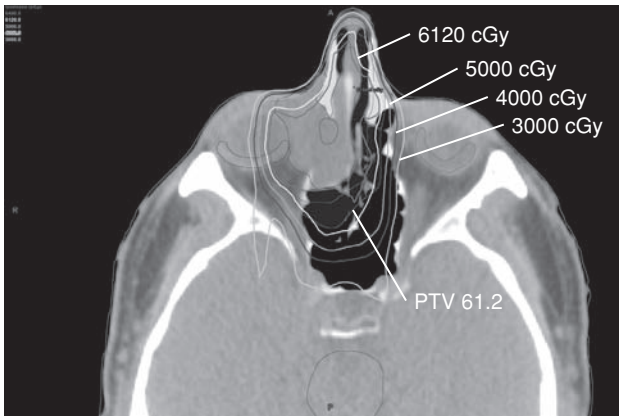

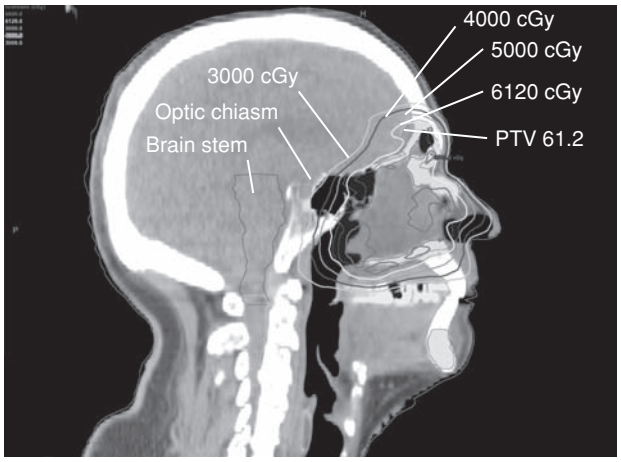

**FIGURE 21-25.** A 67-year-old male with a sinonasal undifferentiated carcinoma (SNUC) involving the right nasal cavity, the maxillary sinus, and the ethmoid sinus with disease beginning to encroach on the medial aspect of the right orbit. Our approach to SNUC involves initial concomitant chemotherapy and IMRT, followed by a planned resection which spares the orbital contents. Here, the primary tumor is represented by PTV 61.2. The planned, preoperative dose is 6,120 cGy at 180 cGy/fraction. **A:** CT planning slice showing the optic chiasm, the optic nerves, the retinas and the lenses, as well as PTV 61.2. The planned total dose is 6,120 cGy at 180 cGy/fraction. Note the care in the PTV expansion to try to respect the adjacent right optic nerve and the contralateral left optic nerve. **B:** CT cut through the orbit showing PTV 61.2 and GTV 61.2. Note that PTV 61.2 extends to skin surface at the medial aspect of the orbit. **C:** CT cut through the inferior orbit showing PTV 61.2 and GTV 61.2 with tight medial margin to respect the orbit. **D:** CT cut through midface showing PTV 61.2 and GTV 61.2 involving the right nasal cavity and the adjacent maxillary sinus. Note the entire nasal cavity is included in PTV 61.2, but the sphenoid sinus is not involved and not included. **E:** CT cut through the nasal cavity showing PTV 61.2 and GTV 61.2, which are becoming smaller as we move inferiorly. **F:** CT cut at the inferior nasal cavity showing PTV 61.2 and GTV 61.2 as they continue to get smaller. Note the PTV expansion respects the adjacent right pterygoid muscles, which are not involved. Avoiding high dose to these muscles helps to avoid trismus. **G:** Isodose distribution similar to Figure 2B above, showing coverage of PTV 61.2 with the 6,120 cGy isodose line. Note the steep dose gradient and the adjacent 5,000 cGy isodose line. This tight dose distribution is essential to optimizing both oncologic and functional outcome. **H:** Sagittal isodose display showing good coverage of PTV 61.2 with the 6,120 cGy isodose line. With dose fall off, note the protection of the optic chiasm and the brain stem. **I:** Dose–volume histogram showing strong target coverage of PTV 61.2 and respected tolerances of vital structures like the brain stem, the optic chiasm, the optic nerve, and the retina.

CHAPTER 22

# Cancer of the Nasopharynx

## PART A:
## General Principles and Management

Kenneth Hu, Anthony T.C. Chan, Peter Costantino, and Louis B. Harrison

### EPIDEMIOLOGY

The global incidence of nasopharyngeal carcinoma (NPC) is 84,400 new cases annually with 51,600 deaths.[1] It is an endemic disease in Southern China, with incidence rates of 15 to 50 per 100,000 persons, making it the third most common cancer in men.[2–5] However in the West, where it is associated with risk factors that are common to other cancers of the head and neck, NPC is a rare disease.[5,6] There is an intermediate incidence in populations in Alaskan Eskimos and in the Mediterranean basin.[4] The incidence rate rises after age 20 years and decreases after age 60 years, with a male–female ratio of 3:1. The median age of presentation is 40 to 50 years, which is significantly younger than that of other head and neck cancers.[2,4] Young adults and children comprise up to 1% of all patients. However, in non-Asian areas (e.g., Northern/Central Africa), younger patients between 10 and 20 years comprise up to 15% of cases. In the United States, there is four- to sevenfold increased risk of NPC among southern Black children compared with the Caucasian population.[7–10]

### ETIOLOGY

Unlike squamous cell carcinomas at other sites in the head and neck, the etiology of nasopharynx carcinomas is not usually related to tobacco and alcohol use, but is multifactorial with viral, genetic, and environmental factors.[3,11,12] Genetic, behavioral, and environmental cofactors are implicated as suggested from decreasing rates of cancer among successive generations of Chinese migrants to the United States and increased risk of NPC among people usually considered low risk who are born and raised in an endemic area.[13–15] Carcinogens related to diet (salted fish high in nitrosamine), poor hygiene, poor ventilation, smoking, and use of nasal balms have been implicated.[4,16] Genetic risk factors involving the HLA-A2, B-17, B246, and BW58 have been associated with increased genetic susceptibility whereas the A11, B13, and B22 loci have been associated with a decreased risk.[4,16] There has been a 40% drop incidence of new cases in Hong Kong from 33.1/100,000 in 1976 to 1990 to 19.5/100,000 during 1996 to 2000, pointing to the importance of environmental etiologic factors.[3] For nonendemic cases, traditional risk factors such as smoking and alcohol have been identified.[17,18]

Viral etiology has clearly been implicated in the majority of nasopharynx cancers. For endemic undifferentiated NPC, there is a strong association with Epstein-Barr virus (EBV), a human B-lymphotropic herpesvirus that is implicated in a variety of tumors,[19] and it is proposed that EBV plays a key role in NPC pathogenesis as EBV is consistently detected even in the earliest NPC lesions (severe dysplasia and CIS) with clonal viral genomes and latent-membrane-protein (LMP 1 oncoprotein) expression,[20] whereas EBV infection is not detected in normal nasopharyngeal epithelium.[21]

EBV is more commonly associated with WHO type II/III, where as a smaller proportion of type I is EBV associated. Conversely, there is a growing recognition that type I has a greater association with HPV compared with type II/III.[22] HPV-associated nasopharynx carcinoma were found to involve tumors that extended to the oropharynx and postulated to represent primary oropharynx tumors. In this study, p16 was positive in all HPV ($n = 3$) positive NPCs but none of the EBV-associated nasopharynx cancers ($n = 34$) and felt to be an important molecular tool to differentiate between an HPV- versus EBV-driven tumor.[23]

As early detection of NPC may be crucial to achieve better outcome of patients, serological markers have been developed taking advantage of the presence of EBV in the tumor. Tumor markers may be useful for early detection, diagnosis, prognostication and monitoring of treatment response. All serological markers of NPC have been based on the detection of antibodies to EBV[24] or on the detection of EBV genetic materials.[25,26] These markers may not be applicable to the patients with WHO type I well-differentiated squamous cell carcinoma. Immunoglobulin A (IgA) antibody titres to the viral capsid antigen of EBV has been widely used as a marker with a sensitivity of 80% to 90%.[24,27,28]

(c) 2014 Wolters Kluwer. All Rights Reserved.

The detection of plasma tumor-associated EBV DNA using polymerase chain reaction assays has opened up new possibilities in the detection and management of nasopharynx cancer. Lo was the first to quantitate plasma levels of EBV DNA using a PCR technique and detected EBV DNA in the plasma of 96% (55/57) with nasopharynx cancer versus 7% of control patients (3/43).[25] Plasma EBV DNA correlates with tumor staging, survival, and recurrence.[25,29,30] It has a diagnostic sensitivity of 96% and specificity of 93%.[25,31] A recent publication demonstrated that the combined interpretation of EBV DNA with UICC staging improved risk discrimination in early-stage disease.[32]

Pretreatment levels are associated with tumor volume[33] with prognostic implications beyond anatomic staging[32] and elevated posttreatment EBV DNA levels associated with higher risk for recurrence, distant metastasis, and poorer disease-free and overall survival whereas clearance of EBV DNA to undetectable or low posttreatment levels are associated with clinical remission.[29,32,33,34,35] Several groups have shown that patients can be stratified by pre- and posttreatment EBV levels into distinct survival groups with posttreatment EBV plasma levels as the major factor impacting on survival. For patients with undetectable posttreatment plasma EBV, a high pretreatment level prognosed a worse overall (87% vs. 71%) and relapse-free survival (86% vs. 76%) compared with low pretreatment levels.[36]

Harmonization of the plasma EBV DNA assay is crucial before it is accepted for routine clinical use as there are varying sensitivities of the assay depending on the part of the EBV viral genome that is detected. Most commonly the BamH1-W assay yields the highest concentrations due to multiple copies of this in different EBV genomes compared with single copy of other genes that have been tested including EBNA01, polymerase-1, or latent membrane protein-2. Even with the same target and assay conditions, the concentration can vary significantly and there is also a high degradation rate that depends on the age of the blood specimen.[36] The RTOG is attempting to standardize the assay prior to proceeding to use it as a stratification factor for adjuvant treatment.

# GROSS AND MICROSCOPIC ANATOMY

## Gross Anatomy

The nasopharynx is a cuboidal cavity located behind the choanae of the nasal cavity (Fig. 22-1). It is composed of two lateral walls with a roof which slopes downward toward the posterior pharyngeal wall down to the level of the uvula. The soft palate forms the floor. Behind the roof and posterior pharyngeal wall are the clivus composed of the basisphenoid, basiocciput, and anterior arch of the atlas. In the lower part of the lateral wall, the superior constrictor muscle sends its fibers posteriorly to attach to the basisphenoid. Between the upper border of the superior constrictor muscle and the skull base is the pharyngobasilar fascia with the Eustachian tube lodged between the medial pterygoid plate and the superior constrictor muscle. The posterior lip of the opening of the Eustachian tube is the torus tubarius behind which is a mucosal fold called the fossa of Rosenmüller. The cartilaginous part of the Eustachian tube enters the lateral pharyngeal wall through a muscle opening called the sinus of Morgagni. This serves as an easy source of entry/exit for nasopharynx cancer.

The nasopharyngeal lymphoid tissue or adenoid is concentrated in the nasopharyngeal roof and other lymphoid aggregates exist about the tubal openings. Adenoidal tissue in the pharyngeal bursa along the roof can result in inflammation or Thornwald cyst formation. The sensory nerve supply to the postnasal space is provided by the glossopharyngeal and the maxillary nerves. Multiple foramina are adjacent to the nasopharynx including the foramen lacerum at the roof with fibrocartilage that is a minimal barrier of entry into the middle cranial fossa for cancer, the foramens juglare, the ovale and the spinosum as well as the carotid and the hypoglossal canals.

## Microscopic

The epithelial lining of the nasopharynx is composed of three basic cell types with a pseudostratified columnar epithelium predominant at birth, a squamous cell type present in adulthood as well as an intermediate pseudostratified cuboidal type which exists in the transition zones between the first two. In the adult, the squamous cell type comprises 60% of the lining of the anterior wall and 80% to 90% of the posterior wall whereas the respiratory type comprises one-third of the anterior wall, 15% to 20% of the posterior wall and about half the area of the lateral walls.[4] The intermediate epithelium is most susceptible to oncogenesis as the areas of the nasopharynx where cancers originate correspond to the same areas that have the greatest amount of the intermediate type. The most common sites of origin are the lateral walls including the fossa of Rosenmüller, the posterior wall, and the anterior walls in descending order.[4]

# PATHOLOGY

## Classification and Histology of NPC

***Diagnosis.*** Tumors arise from the nasopharyngeal epithelium and may present as frank tumor with ulceration or as occult submucosal lesions. Diagnosis is made by pathologic confirmation usually by biopsy. Biopsy may show solid sheets, irregular islands, dyscohesive sheet, and trabeculae of tumor with interspersed lymphocytes and plasmas cells.[5] Undifferentiated subtype is characterized by syncitial appearing large tumor cells with scant cytoplasm and indistinct borders, round to oval vesicular nuclei, and large central nucleoli. Differentiated subtype shows cellular stratification and pavementing with plexiform growth similar to transitional cell carcinomas with less prominent nucleoli.

Immuhohistochemistry shows virtually all tumor cells staining strongly for pan-cytokeratin (AE1/AE3) and high-molecular-weight cytokeratins.[5] Nearly all nonkeratinizing tumors, including differentiated and undifferentiated subtypes, will show EBV viral infection, best detected by *in situ* hybridization for EBV encoded early RNA localized in the nuclei of tumor cells.

Fine-needle aspiration (FNA) of a neck node showing clusters of cohesive tumor cells with vesicular nuclei and prominent nucleoli that is cytokeratin positive and leukocyte common antigen (LCA) negative can detect an occult nasopharyngeal primary or residual/recurrent disease.[37] Fine-needle aspiration has a diagnostic sensitivity of 70% to 90%.[5] Cytologic examination of nodes shows a background of lymphocytes and plasma cells with irregular clusters of large cells with overlapping vesicular nuclei and large nucleoli. The diagnosis is confirmed by *in situ* hybridization for EBV and immunostaining for cytokeratins, which rules out a diagnosis of lymphoma.

***Classification.*** According to the World Health Organization (WHO) classification of head and neck carcinomas, NPCs encompass (keratinizing) squamous cell carcinoma, nonkeratinizing carcinomas, and basaloid squamous cell carcinoma.[38] Prior designations for these tumor types are no longer used and included WHO I for squamous cell carcinomas, WHO II for nonkeratinizing carcinoma (also previously referred to as transitional cell carcinoma), and WHO III for undifferentiated carcinoma; the latter also previously referred to as lymphoepithelioma, Schminke-type lymphoepithelioma, and Regaud-type lymphoepithelioma.[38]

(c) 2014 Wolters Kluwer. All Rights Reserved.

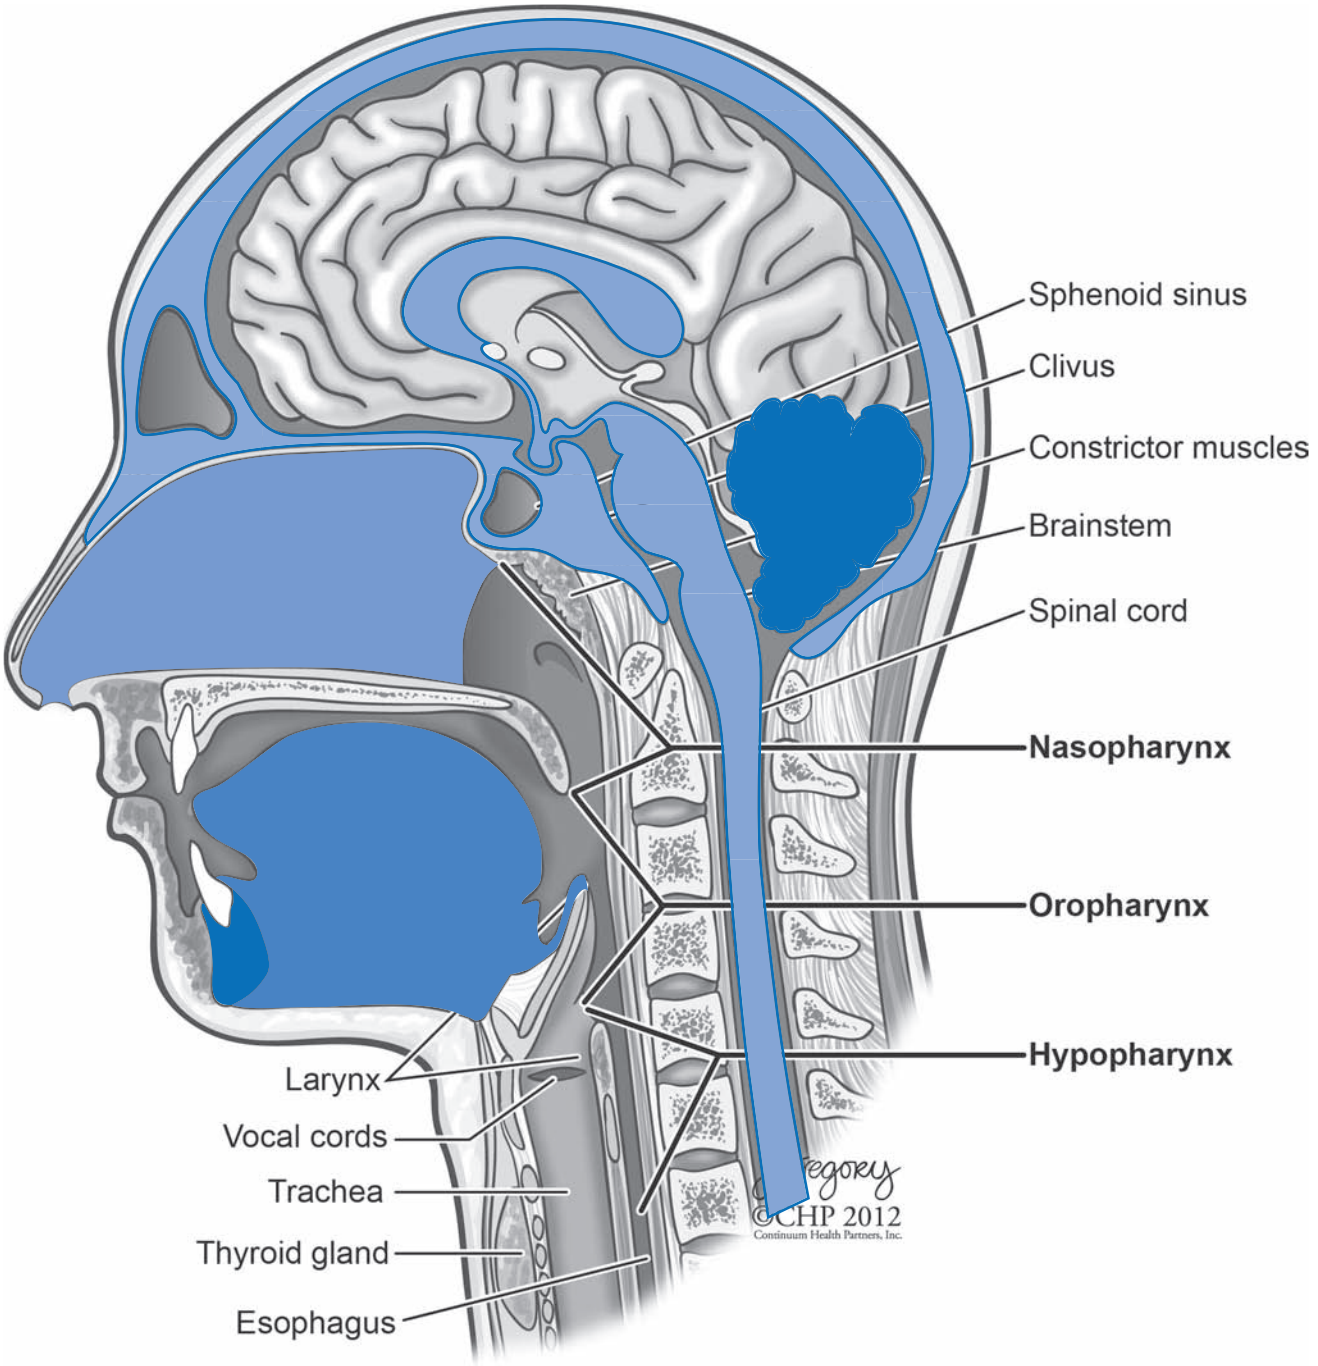

**FIGURE 22-1.** Anatomy of head and neck region and location of the nasopharynx.

The squamous cell carcinomas include well-, moderately and poorly differentiated carcinomas. Keratinizing carcinomas comprises <0.3% in southern China and about 3% in Hong Kong[2,3] but about 25% of all NPC in North America and has a conventional keratinization pattern with intercellular bridges, squamous pearls and graded as well, moderately, or poorly differentiated. It is associated with a desmoplastic response due to invasive growth.[5] It rarely occurs in patient younger than 40 years. These carcinomas are not associated with EBV.[38]

The category of nonkeratinizing carcinomas is subdivided into differentiated and undifferentiated types. The nonkeratinizing carcinoma, differentiated type shows little to absent keratinization and typically lacks a desmoplastic response. It represents about 12% of all NPCs both in Hong Kong and in North America[5,39] and has a growth pattern similar to transitional carcinoma of the bladder with stratified cells well-delineated from the surrounding stroma. Growth may be papillary or plexiform. This tumor type may show prominent cystic degeneration with associated necrosis, and such lesions may metastasize to the cervical neck as cystic metastatic carcinoma. The nonkeratinizing carcinoma, differentiated type, is associated with EBV.[38]

(c) 2014 Wolters Kluwer. All Rights Reserved.

The nonkeratinizing carcinoma, undifferentiated type represents 60% of all NPC in adults and is the most frequent type in the pediatric population. The cells of undifferentiated carcinoma have prominent eosinophilic nucleoli with dispersed to vesicular-appearing nuclear chromatin and a round nucleus often with prominent eospinophilic nucleoli.[5] In contrast to the other NPC types, the cell margins of this carcinoma are often indistinct creating a syncitial growth pattern. A prominent benign lymphoid component is usually present, and despite invasive growth there is often an absence of a desmoplatic response. As such, in the face of a prominent lymphoid cell proliferation that may overrun the neoplastic cells and the absence of a desmoplastic response, it may be difficult by histologic evaluation to identify the presence of invasive carcinoma. In this setting, the use of cytokeratin staining will greatly facilitate the identification of the malignant cells. Furthermore, the cytomorphologic features of the neoplastic cells as well as the tendency to grow in a dyscohesive manner may result in diagnostic confusion with a non-Hodgkin's malignant lymphoma. Since the neoplastic cells are of epithelial origin, they will be immunoreactive for epithelial markers (e.g., cytokeratins) and negative for lymphoid markers (e.g., leucocyte common antigen, others). The nonkeratinizing carcinoma, undifferentiated type can have a syncitial growth with cohesive cells (Regaud type) or a diffuse cellular infiltrate with independent, dyscohesive cells (Schmincke type). The growth characteristics of a given neoplasm has no bearing on the diagnosis, therapy, or prognosis of these neoplasms, and these two have no distinctly different clinical behavior compared with each other.[5] The nonkeratinizing carcinoma, undifferentiated type is highly associated with EBV.[38]

All three histologic types stain positive for cytokeratin and negative for leukocyte common antigen. Also, these three types may overlap with each other in up to 26% of cases[40] but the tumor will be classified according to the dominant component.

The categories have distinct clinical implications.[40] Undifferentiated NPC has a predilection for dissemination to regional nodes and distant sites and are radioresponsive. The keratinizing squamous cell carcinomas behave like those in other head and neck sites, typically occurring in patients 40 years or older and associated with a smoking/drinking history.[6] Nasopharyngeal squamous cell carcinomas tend to present with more locally advanced primary tumors with fewer involved nodes and metastases than the nasopharyngeal nonkeratinizing carcinomas but with increased radioresistance compared with the other two.[40–44] Overall survival is lower for patients with nasopharyngeal squamous cell carcinomas compared with those with nasopharyngeal nonkeratinizing carcinoma, undifferentiated type.[40,45–47] Five-year disease-free survival is reported to be 15% to 42% lower with squamous cell carcinoma versus nonkeratinizing carcinoma, undifferentiated type.[41,43,48] The nonkeratinizing carcinoma, differentiated type is clinically more similar to nonkeratinizing carcinoma, undifferentiated type than to squamous cell carcinoma and are associated with elevated EBV serology.[49]

Basaloid squamous cell carcinoma, a high-grade variant of squamous cell carcinoma, can rarely occur as primary tumor of the nasopharynx. It is morphologically identical to the same tumor more commonly occurring in other head and neck sites, such as the hypopharynx (pyriform sinus) and larynx. Histologically, the tumor is infiltrative composed of lobules, festoons, trabeculae, and solid foci of pleomorphic, mitotically active basaloid cells with pale-staining nuclei, interspersed with variable amounts of mucoid matrix or hyaline material. Comedo necrosis is common. Neurotropism is often identified. An identifiable squamous cell carcinoma, either in the form of invasive carcinoma or *in situ*, is often identified but may be absent. When present, it usually is limited in extent and represents a minor component in this carcinoma. Immunohistochemical staining is consistently reactive for epithelial markers including cytokeratins (AE1/AE3, CAM5.2, CK903, others) and epithelial membrane antigen. Neuroendocrine markers, including chromogranin and synaptophysin, are typically absent but in rare case may be positive. Melanocytic markers are negative.

Carcinomas histologically similar to nasopharyngeal nonkeratinizing carcinomas, differentiated and undifferentiated types, have been found in other head and neck sites including the oropharynx, the Waldeyer ring,[50] the larynx,[51] the thymus,[52] and the major salivary glands.[53] These "lymphoepithelial carcinomas" are infrequent (e.g., <5% of base of tongue and tonsil carcinomas), but their biologic behavior and response to treatment qualifies them further as carcinomas of nasopharyngeal type. The role of EBV in some of these carcinomas is strongly suggested by serologic profiles, presence of EBV-associated nuclear antigen in the carcinoma cells, and by high levels of viral genomes in the DNA.

## Signs and Symptoms

***Patterns of Spread and Clinical Presentation.*** NPC, especially of the WHO types II and III, usually arises in the region of the fossa of Rosenmüller.[4] The primary tumor may extend anteriorly into the nasal cavity, superiorly into the floor of the sphenoid sinus, anterosuperiorly into the posterior ethmoid air cells and the orbits, laterally into the parapharyngeal space and the pterygoid muscles, superiorly into the foramen lacerum and the sphenopalatine fossa, and inferiorly into the oropharynx (Fig. 22-2).[38] Tumor extension through the fibrocartilage of the foramen lacerum enables direct entry into the cavernous sinus and the middle cranial fossa, resulting in cranial neuropathy including diplopia due to involvement of cranial nerve VI as well as facial pain and paresthesias due to infiltration of the branches of cranial nerve V. Involvement of cranial nerves III and IV indicates more advanced disease along the cavernous sinus (Fig. 22-3). Tumor extension into the parapharyngeal space and involve cranial nerves IX, X, and XI, thus producing a jugular foramen syndrome.

First echelon lymphatic spread most commonly involves the superior jugular, the retropharyngeal, and the posterior cervical chain nodes.[38] Ninety percent of patients will have clinical evidence of unilateral nodal involvement whereas 50% will have bilateral lymphadenopathy. Involvement of the upper jugular and the posterior chain nodes are usually painless unless very large. However, retropharyngeal lymph node metastasis, when extensive, produces a characteristic syndrome of pain referred to the ipsilateral neck, ear, head, forehead, and the orbit. It may be associated with a stiff neck or pain upon neck flexion.

Patients most commonly present with a painless neck mass in more than one-third, whereas other common manifestations including hearing loss or ear drainage in about one-quarter and nasal bleeding or obstruction. Nasal symptoms including breathing obstruction, epistaxis, and discharge can occur. A small proportion of patients may present with cranial nerve deficit, most commonly involving the cranial nerves VI and V (V2 most commonly). Patients may also present with facial pain, headaches, or neck discomfort. Proptosis will occur when cancer invades through the posterior portion of the orbit. Trismus is an indication of the pterygoid muscle invasion.

Physical examination includes inspection of the nasopharynx, either indirectly with a mirror or preferably by direct visualization through a fiberoptic endoscope. The tumor usually appears as an asymmetric mass with telangiectasia on its friable surface and is centered in the fossa of Rosenmüller. Depending on the size of the primary tumor, distortion of the soft palate can occur. Straw-colored serous otitis media is usually unilateral. The earliest signs of cranial nerve involvement are usually extraocular muscle dysfunction, especially lateral rectus palsy, and signs of trigeminal nerve involvement such as hyperesthesia and atrophy of masticatory muscles.

(c) 2014 Wolters Kluwer. All Rights Reserved.

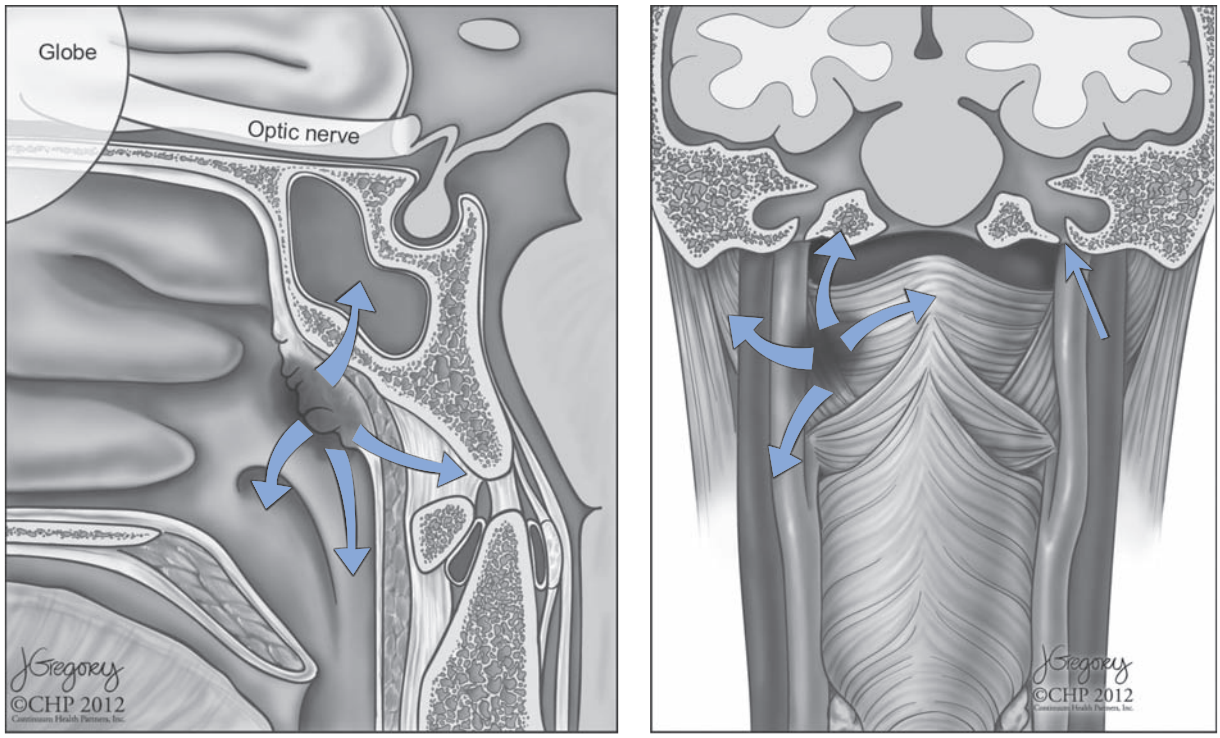

**FIGURE 22-2.** Patterns of spread in sagittal and coronal views. Potential areas of spread include superiorly into the sphenoid sinus/clivus, anteriorly into the nasal cavity/maxillary sinus, posteriorly into the prevertebral muscles and prepontine cistern as well inferiorly into the oropharynx. Note proximity of the brain stem, the spinal cord, and the visual pathways as well as the superior and the middle constrictor muscles. Lymphatic spread to the jugular and the retropharyngeal nodes is common.

For patients in whom the tumor in the nasopharynx is clinically obvious, biopsy can usually be done under the topical anesthetic by topical anesthetic applications through the nasal cavity. Sometimes, however, no primary lesion is evident in the nasopharynx but NPC is suspected on the basis of the presence and location of the cervical lymph nodes. In such cases, fine-needle aspiration cytology will usually establish whether the cell type is consistent with NPC.[37] Usually, clusters of cohesive tumor cells with vesicular nuclei and prominent nucleoli that stain for cytokeratin are present. If it is, radiologic assessment of the nasopharynx may indicate a target lesion for biopsy at examination under anesthesia. If not, a core biopsy of an involved node will provide tissue for fluorescent *in situ* hybridization (FISH) analysis to detect EBV viral genome constituents in the neoplastic cells, which is sufficient to establish the diagnosis of NPC.

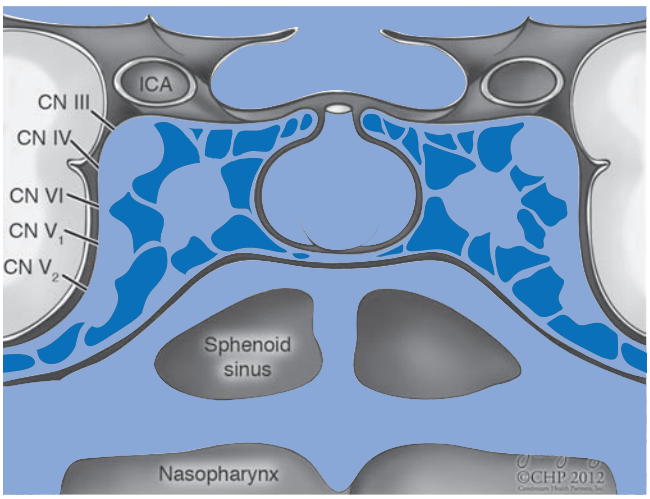

**FIGURE 22-3.** Anatomy of the cavernous sinus showing position of the cranial nerves in relationship to the nasopharynx. Cranial nerve V2 and V1 are in closest proximity to the skull base, while involvement of cranial nerve III and IV indicate advanced involvement of the cavernous sinus.

## CLINICAL EVALUATION AND STAGING

Clinical staging begins with examination by indirect mirror exam and direct endoscopy of the nasopharynx, particularly the fossa of Rosenmüller, and the roof as well as areas of potential spread including the nasal cavity and the oropharynx (Fig. 22-4). Inspection of the posterior pharyngeal wall may reveal bulging suggestive of bulky retropharyngeal nodes. Palpation of the neck nodes is essential especially of the posterior cervical and the upper jugular nodes. Neurologic examination of all cranial nerves is required.

Radiologic examination of the nasopharynx, its surrounding soft tissue, cavities, osseous structures, and lymphatics requires computed tomography (CT) evaluation of the face, the paranasal sinuses, the skull base, and the neck. CT provides excellent evaluation of the draining nodal basins as well as detection of bone invasion of the floor of the sphenoid sinus, the adjacent middle cranial fossa, the clivus, and the pterygoid plates. It provides good soft tissue delineation of tumor

(c) 2014 Wolters Kluwer. All Rights Reserved.

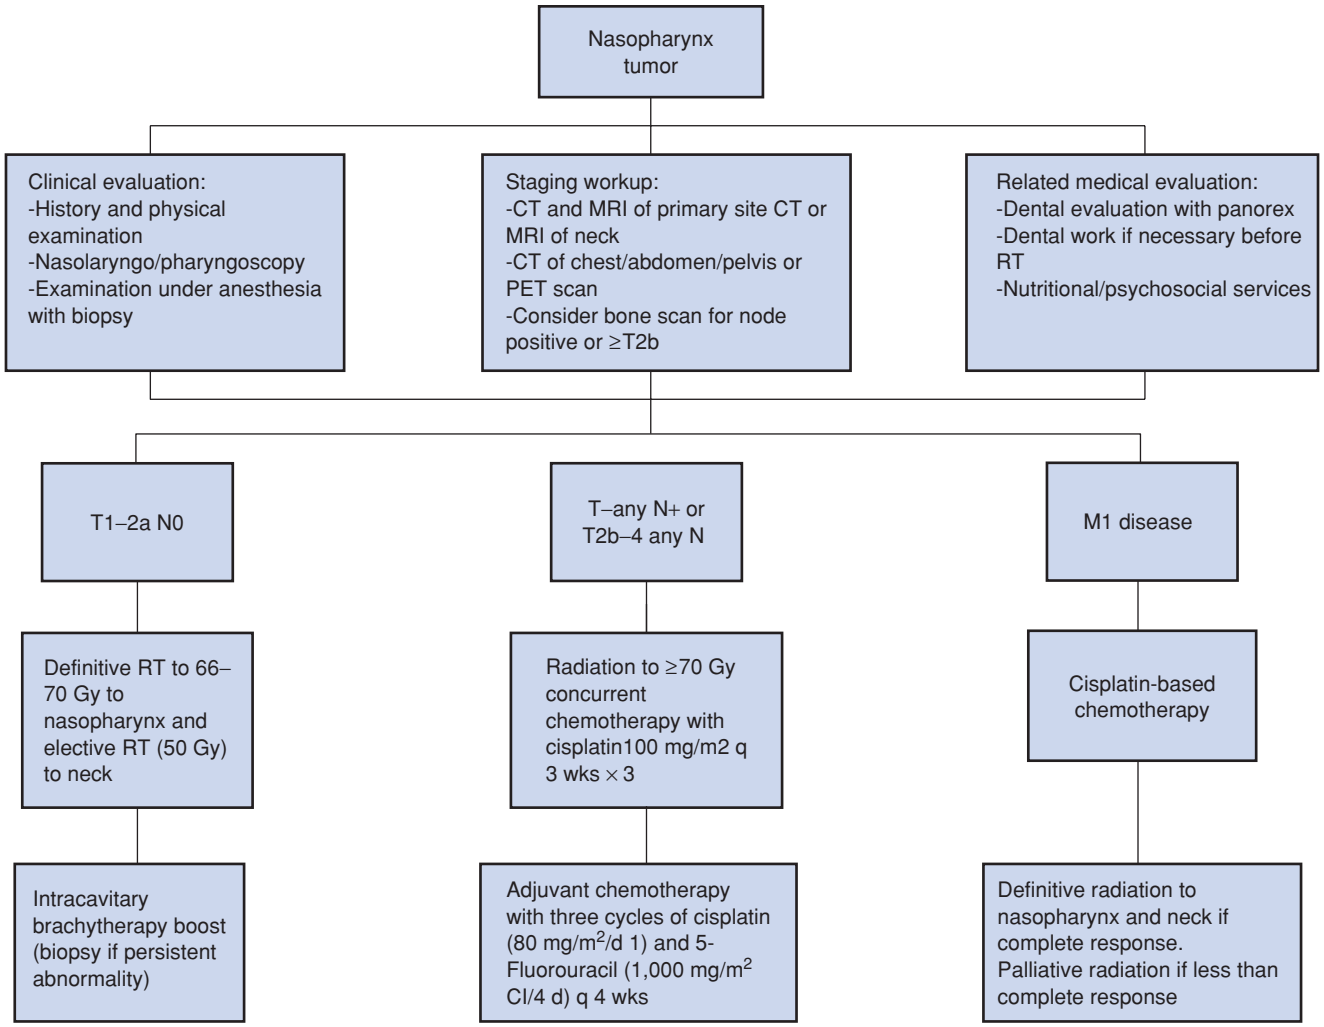

**FIGURE 22-4.** Algorithm for the workup and management of nasopharynx cancer.

extension through the foramen lacerum into the middle cranial fossa, laterally into the parapharyngeal space, anteriorly into the nasal cavity and the maxillary sinuses, inferiorly into the oropharynx, and anterolaterally into the ethmoids and the orbit. Magnetic resonance imaging (MRI) allows superior soft tissue delineation of tumor involvement into the sinuses where it can discriminate between mucus secretions and tumor, as well as evaluate intracranial extension of the prepontine area, the cavernous sinus, and the Meckel cave. MRI can also detect infiltration of the clivus more accurately than CT.[54] It is also useful in the tracking of perineural spread to the skull base foramina and the pterygopalatine fossa area. Moreover, MRI offers superior multiplanar imaging in identifying the course of spread. Evaluation of the jugular chain, the posterior cervical, and the retropharyngeal nodes is crucial given the propensity of early nodal involvement. CT of the neck with contrast is usually the primary imaging modality that is important; however, PET imaging is complementary.

The majority of patients with NPC present with locoregionally advanced disease, and at least one-fifth will have occult distant metastases (DM).[55,56] Sites of predilection for metastatic spread most commonly include in order of greatest frequency: bone, the lung, and the liver.

## Staging

The current staging system is the seventh edition of the American Joint Committee on Cancer[57] and represents the outcome of an evolution of 20 different systems and an international consensus of different staging systems used by the International Union Against Cancer (UICC) system and the AJCC and that used in Southeast Asia according to Ho as well as prognostic factors culled from clinical data from the Asian databases, primarily from Hong Kong.[58] The seventh edition has led to modifications from the sixth edition in both T and N staging. Most importantly, for early-stage tumors, those involving the oropharynx or the nasal cavity have been down staged from T2a to T1. Regarding nodal staging, the presence of unilateral or bilateral retropharyngeal nodes <6 cm are classified as N1. Thus, stage T2aN0 (IIa) patients from the sixth edition are now stage I whereas T2bN0-1 (AJCC stage IIB) are now stage II (T2N0-1). The sixth edition and fifth editions are identical with regard to nasopharynx staging. A comparison of the fourth (1992) versus sixth (2002) edition of the American Joint Committee on Cancer staging is shown below[59] (Table 22.1). It incorporates the importance of parapharyngeal extension especially in the T2 group as well as a nodal staging system that is distinct from that of other head and neck tumor

(c) 2014 Wolters Kluwer. All Rights Reserved.

## TABLE 22.1 Comparison of the 6th and 7th American Joint Committee on Cancer (AJCC) Staging Systems

T Stage

| AJCC 7th edition (2010) | AJCC 6th edition (2002) |
|---|---|
| T1: Tumor involving nasopharynx with or without extension into oropharynx or nasal cavity | Tumor confined to nasopharynx |
| T2: Tumor involving soft tissue with parapharyngeal extension | T2a: Tumor involving oropharynx or nasal cavity<br>T2b: Tumor involving parapharyngeal space |
| T3: Tumor involves bony structures and/or paranasal sinuses. | Same |
| T4: Tumor with intracranial extension or involvement of the cranial nerves, infratemporal fossa, hypopharynx, orbit or masticator space. | Same |

Parapharyngeal involvement is defined as the posterolateral spread of tumor beyond pharyngobasilar fascia. This corresponds to the line drawn from the medial pterygoid plate to the lateral aspect of the carotid artery. Tumor spread beyond the anterior surface of the lateral pterygoid muscle, lateral extension beyond the posterolateral wall of the maxillary antrum or involvement of the pterygopalatine fissure defines masticator space invasion.

7th Edition Nodal:

Regional Nodal staging is unique for nasopharynx cancers compared to other head and neck squamous cell cancers:

N1: Unilateral nodes up to 6 cm or less in greatest dimension without supraclavicular fossa involvement. Unilateral or bilateral retropharyngeal nodes up to 6 cm.

N2: Bilateral nodes up to 6 cm or less in greatest dimension without supraclavicular fossa involvement.

N3: Nodes >6 cm or involvement of the supraclavicular fossa.

N3a: >6 cm

N3b: Extension to the supraclavicular fossa.

The supraclavicular fossa is a 3-point area outlined as Ho's triangle: 1) superior margin of the sternal end of the clavicle, 2) superior margin of the lateral end of the clavicle and 3) point where neck meets shoulder.

6th Edition Nodal Staging is the same as 7th edition except retropharyngeal nodes not specified.

7th Edition Staging:

| | | | |
|---|---|---|---|
| 0 | Tis | N0 | M0 |

sites. Also of importance is that the sixth edition downstages N1 patients from stage III in the fourth edition to stage IIb, which is relevant in evaluating the Intergroup 0099 study which enrolled AJCC fourth edition stage III/IV patients.[60]

Teo reported that parapharyngeal extension is the strongest independent prognosticator for distant metastasis and survival in 903 NPC patients in patients without cervical nodal disease or skull base/cranial nerve palsy.[61] Chua further detailed that the extent of parapharyngeal extension impacted both on local control (LC) and distant metastasis in 364 patients.[62] The incidence of parapharyngeal extension was 73% and degree of extension subgrouped into grade 1 (poststyloid), grade 2 (prestyloid), and grade 3 (masticator space) (Fig. 22-5). Patients with no or grade 1 extension had better 5-year LC (87% vs. 72%, $p < 0.0001$) and lower 5-year distant metastasis (13% vs. 32%, $p = 0.0002$) compared with those with grade 2/3 extension, respectively. The increased risk for local failure with advanced parapharyngeal extension was seen in T2 but not in T3 patients. The increased risk for distant metastasis with advanced parapharyngeal involvement was independent of nodal status and was independently prognostic in N2 and N3 patients.

## Clinical Prognostic Factors

Early stage, female gender, nonkeratinizing histology, and younger age predict a more favorable outcome.[16,40] Patients with haplotype Aw33-C3-B58/DR3 have a poorer prognosis compared with those with A2-Cw-11Bw46/DR9.[4,16] Staging with MRI predicts a better outcome given the improved tumor delineation.[63] Tumor volume based on CT showed an independent prognostic factor of treatment outcome beyond the Ho staging system, but a small study showed the tumor volume derived from MRI was not.[64,65] Serum LDH was predicted for DM in two studies.[54,66] Serum EBV markers are clearly an important predictive and prognostic factors that are to be explored to tailor management in upcoming trials (see "Etiology").

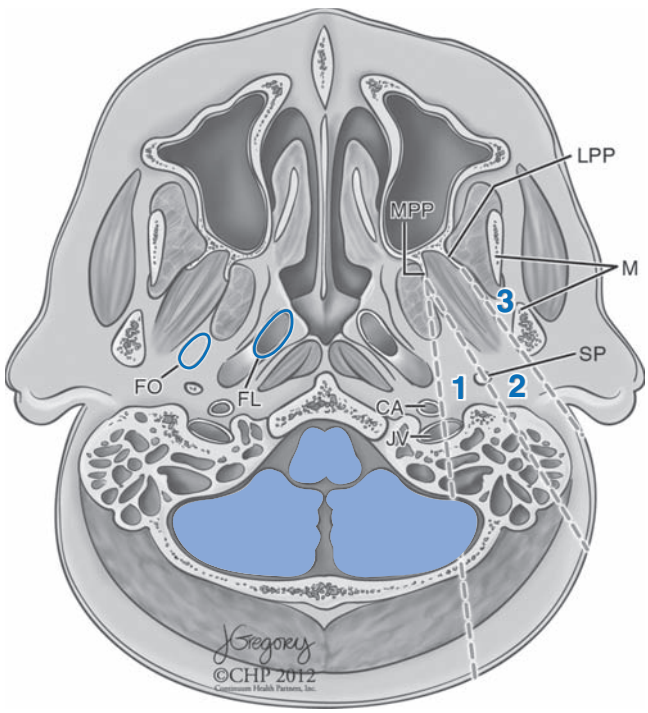

**FIGURE 22-5.** Schematic diagram outline the grading of parapharyngeal extension by nasopharyngeal carcinoma. Grade 1: extension into the retrostyloid space as it invades past the line between the medial pterygoid plate (MPP) to the internal jugular vein (JV), Grade 2: extension in to the prestyloid space at it extends past the line between the medial pterygoid plate and the styloid process (SP) and Grade 3: extension into the masticator space as delineated by extension beyond the line between the lateral pterygoid plate (LPP) and the posteromedial margin of the ascending ramus of the mandible (M).

# MANAGEMENT STRATEGIES

NPC is a highly radiosensitive head and neck cancer that can be treated effectively with radiation therapy (Fig. 22-4). Radiation therapy has been the mainstay treatment as it is able to cover the large areas of potential locoregional spread in a comprehensive manner. Nasopharynx cancers are located in a highly enriched lymphatic drainage area that favors early regional spread to the retropharyngeal and cervical nodes both unilaterally and bilaterally. The primary tumor exists in an occult location with a strong inclination to invade the skull base, surrounding sinuses, nerves, and soft tissue spaces before presenting clinically. Advances in radiation delivery, imaging, integration of chemotherapy, standardization of an internationally agreed upon staging system, improvement of multidisciplinary care as well as increased scientific exchange have led to significant advances in tumor control and quality of life (QOL).

In general, patients with early-stage tumors are amenable to treatment with radiation therapy alone with high rates of locoregional control, whereas those with T3/T4 lesions or significant nodal disease require more intensive treatment as outcomes with radiation therapy alone lead to higher rates of locoregional failure and DM. For the latter group, multiple large trials testing the addition of chemotherapy either sequentially concurrently or both with radiation therapy have been evaluated. Dose escalation and improved conformality of radiation therapy using a wide variety of techniques appear to improve outcomes. Altered fractionation has been explored as well as new biologic agents. For patients with recurrence after standard radiation, the role of surgical salvage and reirradiation have been explored.

## Patterns of Failure

Patterns of spread include invasion into adjacent soft tissues, paranasal sinuses, skull base as well as spreading intracranially (Fig. 22-2).[38] Potential areas of microscopic spread include the sphenoid sinus, the foramen ovale and the petrous tip, the posterior third of the nasal cavity/the maxillary sinus, the clivus, and the parapharyngeal space/the pterygoid fossa. Critical normal structures which are adjacent to the target volume and with tolerance doses that must be respected include the brain stem, the spinal cord, the optic nerve, the chiasm, the lens, the temporomandibular joints (TMJs), the cochlea, the vestibulocochlear nerves, the oral mucosa, and the external auditory canal. Most common sites of primary tumor spread based on MRI imaging of 308 patients have been reported (Table 22.2).[38]

## Radiation Technique

Radiation treatment of nasopharynx cancer is technically challenging due to the proximity of tumors to critical structures including the spinal cord, the brain stem, the temporal lobes, the optic pathways as well as structures important for QOL and function such as the masticatory/the constrictor muscles, the temporomandibular joint, the salivary glands, and the auditory nerves. These tumors often wrap around the brain stem in a

concave manner as they spread into the parapharyngeal space, as well as intracranially through the skull base, the foramina, and along the nerves. As such, they may extend too close to critical adjacent structures for an adequate tumoricidal dose to be delivered depending on the treatment technique.

Radiation therapy treatment has improved vastly from the initial use of orthovoltage/radium sources, block-shaped beams, and plain film–based imaging with large setup uncertainty, to high-energy linear accelerator with dynamic leaf collimation and more sophisticated CT-based treatment planning with precise setup and immobilization.[67] The evolution in treatment planning has provided for better targeted radiation delivery and dose escalation from 50–60 to 80 Gy.[68–70]

For many years, two-dimensional (2D) technique had been the mainstay of treatment and continues to remain so for many centers with good LC for early-stage cancers.[67,71] Traditional 2D treatment planning involves parallel opposed lateral fields and a low anterior neck field. After an initial phase in which the brain stem and the cord are in the treatment field, shielding of these structures is required to maintain the dose within tolerance, potentially compromising dose to areas of tumor that extend to the skull base, the parapharyngeal area, or intracranially. Simultaneously, normal structures such as the parotids and the constrictor muscles are unavoidably treated with high doses.[72,73] In addition, 2D technique does not account for tissue inhomogeneities that exist in the paranasopharyngeal area including the air cavities, multiple bony interfaces and variation in contour, and head and neck separation.[74]

Incorporation of volumetric imaging for treatment planning is crucial for improved dosimetry. Jian reported that the use of CT for 2D treatment planning was critically important to define an adequate clival margin, which was one of the most important factors for locoregional control in patients treated with radiation.[75] Since the 1990s, technologic advances in treatment planning systems incorporating CT have led to the development of conformal therapies such as three-dimensional conformal therapy (3D CRT)[74] and intensity-modulated radiation therapy (IMRT), which have enhanced dose conformality, improved dose homogeneity, permit dose escalation while simultaneously decreasing dose to normal tissue to lessen chronic toxicities.[76–78]

3D-CRT exploits the spatial relationship between tumor and normal tissue by manual selection of beam angle with a beam eye's view and through an iterative process of beam weighting with correction of tissue inhomogeneities to achieve optimization. It has been estimated that 3D-CRT can increase the mean tumor dose by >10% and potentially increasing tumor control probability by 15% without added normal tissue complications.[74]

IMRT represents a major advance beyond 3D-CRT, adding an extra degree of freedom to treatment planning by modulating the dose intensity within each beam to generate virtually any shape of dose distribution. Instead of manually changing beam weighting and angles as with 3D-CRT, the IMRT planner sets the dose to the target volumes, assigns normal tissue penalties/constraints, and selects the number of beams/beam angles at the outset for delineated structures, before an inverse treatment planning system attempts to satisfy these criteria through a least-squares, cost-function optimization process.[78–80] Adjustments of the number of beams/constraints/penalties refine the plan further. Dose gradients of 5% per millimeter can be achieved with a dose uniformity of 10% or less within the PTV.[79]

A crucial component toward achieving the maximal therapeutic benefit from conformal therapy is accurate delineation of the tumor volumes and adjacent critical structures. The appropriate dose and treatment margin to cure the tumor must be weighed against the potential to cause permanent toxicity. It requires not only precise visualization of gross tumor based on clinical and radiologic evaluation, but also a comprehensive understanding of potential areas of spread locally and regionally. If too precise, the probability of a geographic miss of occult disease increase which may be further magnified if small errors in reproducing patient setup occur. Thus, high-resolution imaging becomes a prerequisite toward achieving that goal. The latter should include both transverse and coronal CT cuts. Fusion with MRI or PET/CT as well as viewing in coronal and axial planes to accurately follow tumor spread three dimensionally is crucial.

## Dose Prescription

The standard radiation dose prescribed to the primary site in nasopharyngeal cancer in most centers is an equivalent of 70 Gy over 7 weeks. Doses of 66 to 70 Gy are given to involved nodes, and clinically uninvolved nodes typically receive 50 Gy in 5 weeks whereas intermediate risk areas for subclinical disease receive 60 Gy. With IMRT, dose painting is possible in which differential doses to various target volumes are delivered simultaneously. Typically, higher doses per fraction (212–220 cGy/fraction) are delivered to areas of gross disease are delivered while lower dose (180 cGy/fraction) are delivered for areas at risk for occult disease.[76,81,82]

Kam demonstrated that superiority of IMRT-based plans compared with 3D-CRT and 2D technique of Ho in three different but common clinical stages: early stage (T1N0), a tumor with parapharyngeal extension and significant nodal disease (T2bN2), and a tumor with intracranial extension T4N2.[81] All patients were treated to a final prescription dose of 66 Gy with standard dose constraints to the normal tissue. CTV included potential sites of microscopic disease as described above and GTV with at least 1-cm margin except a 5-mm posterior margin. A 3-mm margin was added to the CTV for the PTV. A total of 66 Gy in 33 fractions was prescribed to the gross volume whereas 60 Gy in 33 fractions was prescribed to cover areas at high risk for microscopic disease. In the Ho technique, the initial phase to 40 Gy is composed of opposed laterals with a low anterior neck, followed by a cone down to the primary with the addition of an anterior field to the opposed laterals with blocking of the pituitary, the optic nerve, and the tongue. The 3D technique comprised initial opposed laterals to 40 Gy, followed by six to eight coplanar beams as a 3D cone down. The IMRT plan consisted of seven coplanar beams. In the dosimetric comparison of the three techniques for the early-stage (T1N0) scenario, IMRT did not improve target coverage or dose, but better spared dose to the parotid (dose to 50% [D50] was 31 Gy [IMRT] vs. 50 Gy [3D-CRT] vs. 57 Gy [2D]) and the TMJs (D50 was 31 Gy [IMRT] vs. 64 Gy [3D-CRT] vs. 59 Gy [Ho-2D]). In the case of the tumor with parapharyngeal extension, the IMRT plan showed improved tumor coverage (D95 of PTV was 68 Gy [IMRT] vs. 64.8 Gy [3D-CRT] vs. 57.5 Gy [2D]). In the third scenario of intracranial extension of tumor, IMRT improved both PTV coverage (D95 of PTV was 67.5 Gy [IMRT] vs. 62 Gy [3D-CRT] vs. 55 Gy [2D]) and normal tissue sparing of the brain stem (maximum dose was 48 Gy [IMRT] vs. 65 Gy [3D-CRT] vs. 64 Gy [2D]) and temporal lobes (maximum dose was 46 Gy [IMRT] vs. 57.5 Gy [3D-CRT] vs. 66.5 Gy [2D]). Furthermore, in the IMRT-treated patients with T2b or T4 disease, an additional 3D boost of 14 Gy increased the probability of normal tissue complications primarily to the parotid gland by 20% but <1% to the brain stem, the spinal cord, and the TMJ. The latter data demonstrate the potential of IMRT to permit safe dose escalation to 80 Gy.

## Radiation Therapy Only

Outcomes after radiation therapy alone using conventional fractionation and 2D technique have shown generally good locoregional control rates for early-stage tumors but suboptimal outcomes for locoregionally advanced tumors. After conventional radiation, local failure occurs in 5% to 25% for T1–2 and 20% to 56% for T3–4 tumors (Table 22.3).[43,63,68,83–87] Improvements in outcomes using 2D technique have resulted from better staging, comprehensive radiation coverage, improved imaging, use of a simulator, mobilization, a high-output linear accelerator, customized blocks, accurate dose calculation, verification films, training of radiation technical staff, addition of boost techniques, and integration of chemotherapy for locoregionally advanced cases.[67,68,88–90]

One of the largest North American series of nonendemic patients was reported by the MD Anderson Cancer center on the outcomes of 378 patients treated from 1954 to1992 with primary radiation therapy.[68] Three-quarters were of Caucasian origin and 51% with WHO I histology whereas 41% were lymphoepitheliomas. The median age of patients was 52 years with 74% male and three-quarters presented with stage IV disease (AJCC, 1992). Patients were treated to doses ranging from 60 to 72 Gy depending on T stage with dose escalation for all T stages in the more modern eras (61 Gy [1954–1971] → 67 Gy [1972–1982] → 70 Gy [1983–1992]) as well as a transition from multifield 2D technique at the primary site in nearly two-thirds at the beginning of the study period to opposed laterals for nearly all patients during the latest period. At a median follow-up of 10 years, the 5-/10-year actuarial rates of local, regional control, and overall survival were 71%/66%, 84%/83%, and 48%/34%, respectively. LC was increased over 20% for tumors with lymphepithioloma versus squamous cell histology ($p < 0.0001$) with a trend toward improved control with higher doses ($p = 0.09$). The 5-/10-year actuarial rates of grade 3 to 5 late complications were 16%/19%. The incidence of treatment-related mortality was 3% (primarily spinal cord and cranial nerves) with virtually all cases occurring before 1971. There was a strong influence of treatment technique with incidence of grade ≥3 late complications highest in the three-field technique (AP/lats) versus 25% with opposed laterals ($p < 0.0001$).

The largest series of endemic patients treated with conventional fractionation and 2D technique was reported by Lee on the outcomes of 2,687 consecutive patients treated at multiple institutions in Hong Kong from 1996 to 2000.[91] The breakdown of patients were as follows: stage I: 7%; stage II: 41%; stage III: 25%; and stage IV: 28%. Patients were treated to a median total dose of 66 Gy and 90% were treated with the 2D technique of Ho. About 55% had additional boost treatment with external beam or brachytherapy. About one-fourth received chemotherapy (14% concurrent, 9% sequential). At a median follow-up of 3.4 years, 5-year local, nodal, and distant failure-free survival rates were 85%, 94%, and 81%, respectively. Five-year progression-free, overall, and cancer-specific survival were 63%, 75%, and 80%, respectively. Five-year LC by T stage were as follows: T1: 91%;

**TABLE 22.3 Local Control by Tumor Stage after Conventional Radiation Therapy**

| | T1 (No. of Patients) | T2 (No. of Patients) | T3 (No. of Patients) | T4 (No. of Patients) |
|---|---|---|---|---|

T2: 87%; T3: 80%; and T4: 77%. Five-year regional control by N stage were as follows: N1: 95%; N2: 92%; and N3: 83%. Among stages I to II patients, 5-year distant metastasis–free survival (DMFS) was 90% versus 81%, for those with locoregional control versus those with locoregional failure. For stage III to IV, the corresponding 5-year DMFS was 75% versus 65%, respectively. The results of this period (1996–2000) were compared with 5,037 patients treated from 1976 to 1985 and showed significantly better LC (85% vs. 66%, nodal control 94% vs. 67%, distant-free survival 81% vs. 62%, and overall survival 80% vs. 52%). Better imaging (CT/MR vs. plain radiography/tomography) and radiation delivery technology (linear accelerator) and use of conventional fractionation are identified as the most important factors for the improvement. The one-third of patients staged by MRI (860/2,687 = 32%) achieved better overall survival regardless of stage compared with those staged only by CT (stages I–II 93% vs. 83%, $p = 0.001$ and stages III–IV 72% vs. 63%, $p = 0.001$). MRI-staged patients had better LC (T1–2: 91% vs. 87% and T3–4: 83% vs. 76%).

## NECK CONTROL

In contrast to carcinomas at other head and neck sites, neck disease is managed with primary radiation regardless of N stage. Regional control with primary radiation therapy is excellent regardless of N and T stage. Regional control rates of 80% to 90% for N1–2 are the rule after definitive radiation without chemotherapy and 70% to 80% for N3.[68,85,91,92] In the MD Anderson series reported by Sanguinetti, regional control for 378 patients treated from 1954 to 1992 was 83% at 5 years for the entire group and by N stage (AJCC, 1992). Five-year actuarial rates were as follows: 95% (N0), 94% (N1), 91% (N2a), 80% (N2b), 77% (N2c), and 71% (N3).[68] The series from Washington University reports regional control of 98% for N0–1, 71% for N2, and 64% for N3.[92] Patients with recurrent disease to the neck after definitive radiation are treated with salvage neck dissection.

## CRANIAL NERVE IMPROVEMENT AFTER RT

Due to the proximity of the nasopharynx to the skull base and the cavernous sinus, a small but significant group of patients can present with cranial neuropathy from 11% to 29% in some series.[93,94] In a study of 93 patients who presented with CN palsy, 70% of patients showed improvement after definitive radiation therapy.[95] The most common cranial nerve palsies involved CN V (38%), CN VI (26%), CN XII (11%), and CN III (9%). Upon completion of RT, the complete recovery rate was 51% and partial recovery rate was 19%. At 6 months, the rate improved slightly to 58% complete recovery and 17% partial recovery. Patients with parasympathetic nerve, CN II, IX, and XI palsies showed complete recovery rates of 100% (3/3), 100% (2/2), 87% (7/8), and 100% (1/1), respectively, whereas the rate of complete recovery was worst for CN VII and XII (40% [2/5] and 40% [8/20], respectively). For the most common palsies, the complete recovery rate of CN V and CN VI were 44% (29/66) and 50% (23/46), respectively. Pretreatment duration of >3 months was associated with worse recovery of CN function (62% vs. 88%, $p = 0.002$) than those with a shorter period of cranial nerve palsy.

### Dose-response Effect of RT

The preponderance of retrospective data reports that dose escalation above 66 Gy improves LC.[43,70,71,83,88,89,92,96–99] However, some have shown no relationship.[90,100,101] The lack of consistency is likely related to confounding factors including small patient numbers, historic bias in which patient outcomes are compared over long periods of time, different staging systems, improved conformality of treatments with 3D planning, brachytherapy and stereotactic radiation, better target identification with improved imaging such as MRI, use of altered fractionation regimens, and integration of chemotherapy.[63,68,90]

Vikram reported on 107 nasopharynx patients treated with definitive radiation alone using consistent staging and treatment techniques.[83] More than half had T4 lesions and 87% with stage IV disease. Radiation was delivered with a 3-field technique to doses ranging from 40 to 77 Gy to the primary site with conventional fractionation. Minimum follow-up of at least 2 years was achieved in 98 of the 107 patients. Fifty-five patients relapsed, of whom 60% relapsed at the primary site. Patients receiving 57 to 67 Gy were at increased risk for local failure compared with those treated to 67 to 77 Gy (local failure: 43% [26/60] vs. 28% [12/43], $p = 0.08$, respectively). The dose response was especially pronounced for T4 lesion (local failure 46% [11/24] vs. 7% [1/14]). Patients having treatment breaks of >3 weeks had increased local failure (67% vs. 34%, $p < 0.05$) compared with those treated without such breaks and higher dose did not appear to compensate for the treatment break. Patients receiving the higher doses without treatment break had LC of 84%.

In a large multicenter pooled analysis of 2,426 patients treated in five Hong Kong regional centers, the benefit of escalation of dose beyond 66 Gy is evident.[102] All centers used the same 2D technique according to Ho. All patients received 66 Gy with external beam radiation and about two-thirds ($n = 1,572/2,426$) received a boost dose. Boosts doses and technique depended on the tumor stage. For T1/T2a tumors, intracavitary boost was favored ($n = 146$, 10 Gy/2 fractions or 18–24 Gy/3 fractions) although some were boosted with 2D EBRT ($n = 61$, 15 Gy/3 fractions). All T2b–4 tumors were boosted with EBRT as follows: ipsilateral 3D posterior oblique boost ($n = 211$, 20 Gy/10 fractions and $n = 634$, 10 Gy/5 fractions) for T2b tumors and 2D boost ($n = 487$, median dose 10 Gy/fractions) for T3/T4 tumors. The boost was planned for most T2b/T3/T4 tumors and given to T1–T2a if biopsy residual disease remained after initial treatment. About 20% ($n = 511$) received chemotherapy with 12% receiving concurrent chemotherapy. Median follow-up was 4.2 years. Both early-stage T1–T2 and advanced tumors (T3–T4) treated with radiation alone benefited from an RT boost above 66 Gy, but not patients treated with chemotherapy regardless of T stage. For T2b patients, a 20-Gy boost was superior to 10 Gy in decreasing local failure. Although the impact of boost on long-term morbidity was not reported, no excess mortality were attributable to RT complications.

A steep dose–response relationship for LC was demonstrated in the range from 65 to 85 Gy of physical dose delivered and for biologic equivalent dose (BED) 10 Gy from 80 to 125 Gy.[103] The data suggest a 15% decrease in local failure for every additional increase in 10 Gy BED 10 corrected for treatment time. However, dose escalation beyond 72 Gy using 2D technique is associated with significantly higher incidence of chronic toxicity such as hearing impairment, trismus, and temporal lobe necrosis based on a retrospective analysis of 849 consecutively treated patients in a single institution.[104]

An attempt to dose escalate using a 3D boost after initial 2D treatment was reported.[69] Sixty-eight patients were treated with initial 2D technique up to 50.4 Gy followed by a 3D boost to 7,020 to 7,560 cGy (median dose 70 Gy). Lateral fields were prescribed to midplane whereas the boost was prescribed to an isodose curve. The mean dose to the PTV was on average 13% higher with the 3D portion compared with the 2D technique. About half of patients received concurrent cisplatin chemotherapy. At a median follow-up of 42 months, the 5-year LC was 77%, regional control was 97%, and progression-free survival

(c) 2014 Wolters Kluwer. All Rights Reserved.

was 56%. These did not appear to have dramatically improved compared with a historic group of 33 patients treated with 2D technique at the same institution. However, the dose escalation was modest, the patient cohorts were small, and it is unclear how similarly imaged and staged was the historic control compared to the reported group.

## Brachytherapy

Dose escalation using adjuvant brachytherapy have primarily been confined to early-stage tumors which can be encompassed adequately by the dosimetry. The combinations of external beam and brachytherapy approach have included (a) external beam doses of 60 to 70 Gy with HDR brachytherapy of 12 to 18 Gy in 3Gy BID fractions,[105] (b) 60 to 62.5 Gy EBRT combined with brachytherapy boost of 18 to 24 Gy/8 Gy × 2 to 3 weekly fractions,[61] (c) 64.8 to 68.4 Gy of EBRT followed by brachytherapy boost of 5 to 16.5 Gy in 1 to 3 fractions,[106] and (d) 64 Gy → 7 to 10 Gy intracavitary boost (Table 22.4).[97]

The literature supports the benefit of brachytherapy in decreasing local failure by 50% for T1–2 patients treated with radiation alone with modestly improved disease-free survival.[102] The largest series is reported by Teo in a retrospective analysis of 743 patients with T1–2 cancers all treated with the Ho 2D technique.[102] One-hundred eighty-eight received brachytherapy (18–24 Gy in 3 fractions over 2 weeks) plus EBRT whereas 555 received EBRT alone. EBRT was delivered to a dose of 60 Gy in 4 weeks in the majority of patients. Neoadjuvant chemotherapy was delivered in 13% of patients. Brachytherapy was delivered within 4 to 6 weeks after EBRT for persistent disease in 126 patients (24 Gy) and as adjuvant (18 Gy) to complete responders in 62 patients. Median follow-up was 79 and 88 months in the brachytherapy arm and EBRT-alone arms, respectively. At 5 years, the brachytherapy group had fewer local failures (5.8% vs. 11.7%, $p = 0.013$) and lower disease-specific mortality (12.2% vs. 15.2%, $p = 0.08$) compared with the EBRT-alone group. No difference in regional failure (8% in each arm) or DM (13% in each arm) are reported. Multivariate analysis showed the independent benefit of brachytherapy in decreasing local failure. The two groups showed comparable chronic radiation complications. However, patients receiving brachytherapy had an increased incidence of nasopharyngeal ulceration and necrosis occurring in 6% versus 0.2% in the EBRT-alone arm.

Levandag reported on 42 patients treated from 1991 to 1995 with EBRT and high-dose rate brachytherapy.[105] The patient population consisted of 12 T1–2 and 30 T3–4 AJCC (1992) tumors, of whom 32 were N2 or greater. Patients with T1–3 tumors were treated with 60 Gy EBRT followed by 18 Gy brachytherapy given in 3Gy BID fractions, whereas T4 patients were treated with 70 Gy followed by 12 Gy brachytherapy in 3 Gy BID fractions. One of 42 received induction chemotherapy. The brachytherapy group was compared with a historic cohort of 109 patients treated from 1965 to 1991 with EBRT alone ($n = 69$) or chemotherapy with EBRT ($n = 40$). T1–2 tumor comprised 59% (64/109) of the historic group whereas 58% (63/109) were N2 or greater. The median dose of EBRT in the EBRT-alone group was 70 Gy and in the chemotherapy group was 64 Gy. Overall, the addition of brachytherapy was well tolerated except for the development of late grade 3 mucosal toxicity consisting of synechiae of the nasal cavity requiring surgical correction. At a median follow-up of 2.6 years, 3-year LC was 86% in the brachytherapy group and 3-year DFS was 71%. These outcomes were significantly superior to the corresponding outcomes in the nonbrachytherapy group (3-year LC 60% [$p = 0.004$] and 3-year DFS 52% [$p = 0.005$], respectively). Patients receiving induction chemotherapy had the worse LC (3-year 54%) versus the EBRT-alone group (3-year 64%). The American Brachytherapy Society recommends the applicator developed by this group.[107] The applicator can be positioned against the roof of the nasopharynx closer to where tumor originates, unlike pediatric endotracheal tubes which may sit on the soft palate away from the recurrent tumor.

## Stereotactic Radiosurgery and Radiation Therapy

Brachytherapy offers an excellent approach to escalate dose for early-stage lesions. However, for more advanced lesions where coverage with brachytherapy is suboptimal, alternative methods using stereotactic approaches have been used to provide highly conformal radiation with sharp fall off of dose to surrounding normal tissues.

The role of SRS boost after EBRT was reported for 23 patients.[108] EBRT doses of 66 Gy/33 fractions were delivered (64.8–70 Gy) in 23 patients. Fifteen received cisplatin-based chemotherapy. Twelve patients were T4. An SRS boost using frame-based linear accelerator technique to deliver an additional median dose of 12 Gy (range 7–15 Gy). At a mean follow-up

**TABLE 22.4 Local Control after Combined External Beam Radiation and Brachytherapy**

| Author | No. of Patients (% T1/2) | Median F/U (mo) | EBRT Dose | BT Dose | LC | Toxicity from BT |

(c) 2014 Wolters Kluwer. All Rights Reserved.

of 21 months LC was 100% whereas two patients developed a regional recurrence and seven had distant metastasis. No complications caused by SRS were reported.

An update was reported by Le on 45 patients treated with a stereotactic radiosurgery (SRS) boost after EBRT to a dose of 66 Gy.[109] Of the 45 patients, 22 had T3–4 tumors and 23 had N2 disease or greater. EBRT was delivered with 2D technique in 38 patients and IMRT in 7. Thirty-six patients received concurrent chemotherapy per the Intergroup 0099. SRS was delivered to a median dose of 12 Gy with Linac-based technique in 33 and cyberknife in 12 patients. At a median follow-up of 35 months, LC was 100% at 3 years whereas the incidence of metastasis was 31%. Regional failure occurred in three patients, one of whom was salvaged with neck dissection. No acute toxicity was reported from the SRS although long-term toxicity included cranial nerve palsy in four patients, temporal lobe necrosis in three patients, and retinopathy in a patient with cranial neuropathy.

## Stereotactic Radiation Therapy Boost

Sixty-four patients were treated with conventionally fractionated radiotherapy to 64.8 to 68.4 Gy with chemotherapy given in 81% as induction (22%) or concurrent (59%) followed by stereotactic radiation therapy (SRT) (12–15 Gy boost in 3 fractions).[110] At a median follow-up of 31 months, the LC was 93%, regional control was 91%, freedom from distant metastasis was 90%, and overall survival was 85%. No grade 4 acute or chronic radiation-related complications were reported.

***Toxicity.*** The primary acute complications during external beam radiation include mucositis, odynophagia, lymphedema, alteration of taste, xerostomia, fatigue, loss of appetite, dermatitis, alopecia, serous otitis media, and thrush.[90,111,112]

Long-term toxicities include xerostomia, lymphedema, fibrosis, osteoradionecrosis, soft tissue necrosis, cranial neuropathy, carotid artery stenosis, temporal lobe necrosis, pharyngeal stricture, dysphagia, feeding tube dependence, trismus, otitis media, tympanic membrane perforation, deafness, hypopituitarism, hypothyroidism, and dental caries.[90,111–114]

Analysis of 849 consecutively treated nasopharynx patients at a single institution treated with 2D radiation therapy without chemotherapy showed that EBRT doses >72 Gy resulted in a higher incidence of hearing impairment, trismus, and temporal lobe necrosis.[104] Patients were treated with EBRT combined with brachytherapy boost to total doses of 68.4 to 79.8 Gy. At 5 years, 90% had xerostomia, 54% had hearing impairment, 52% had tinnitus, 32% had otorrhea, 25% had neck fibrosis, 21% had Lhermitte sign, 12% had trismus, and 6% had temporal lobe necrosis (including 6% of cases associated with severe symptoms—seizure, debilitation, and change of consciousness). Hypopituitarism is detected in up to 25% of patients with most having hypogonadism or hyperprolactinemia without the need for hormonal replacement.[81] Hypothyroidism is also possible after neck irradiation.[81] Doses >72 Gy was associated with incontinence. Other chronic complications include dysphagia, lymphedema, carotid artery stenosis (8%–16%),[115] osteoradionecrosis of the mandible (up to 2%), cranial nerve palsy in 2% to 6%, and pharyngeal stricture in 2%.[90,111,112]

Patients with temporal lobe necrosis can demonstrate impairment of cognitive function including verbal ability, visual memory, language, abstract thinking, and motor ability based on a comprehensive battery of neuropsychologic testing of 53 patients performed at least 1 year after radiotherapy.[116–118] Lee reports that patients at risk for temporal lobe necrosis were those undergoing dose-escalation with an external beam parapharyngeal boost of 5 Gy (5-year incidence 8.3%) and in those undergoing accelerated radiotherapy in the setting of concurrent chemotherapy (5-year incidence 2.7%).[119] Patients treated to mean temporal lobe dose >22 Gy had higher rates of TLE compared with those with below (2.2% vs. 0%). Neurocognitive dysfunction including short-term memory loss and language abilities was increased if the mean dose to the temporal lobe was >36 Gy.[120]

With regard to deafness, patients who received a dose of >50 Gy had a higher risk whether treated by conventional radiotherapy alone (18% vs. 7%) or in the setting of concurrent chemoradiation (22% vs. 14%).[121] The incidence of cranial neuropathy was 1.7%, that of soft tissue ulceration was 1.2%, and that of hypopituitarism was 9.7% (6.7% hypothyroidism) with no statistical difference between those receiving radiotherapy alone versus concurrent chemoradiation.

***IMRT and Xerostomia.*** One of the primary benefits of IMRT radiation has been the amelioration of chronic xerostomia, the most common QOL complaint after head and neck irradiation affecting the sense of comfort, taste, dental hygiene, and swallowing. Both objective and subjective data have been established. Liu reported the time frame for parotid salivary flow recovery using sialoscinitigraphy in 45 NPC patients treated with IMRT with a component of the dose delivered with 3D (9–20 Gy) technique or high-dose rate brachytherapy (7 Gy/2 fractions).[122,123] The dose to 50% of the parotid volume was constrained at 35 Gy. Objective flow was analyzed by serial scialoscintigraphy pre-RT, and 1, 6, 12, and 18 months post radiation. The LENT/SOMA scale assessed subjective salivary function. At a median follow-up of 37.5 months, objective salivary flow remained decreased during the first year compared with the baseline, but after 1 year, flow recovered such that there was no significant difference from the baseline at 12 and 18 months. Mean parotid doses >38 Gy impacted on the preservation of parotid function. There was significant correlation ($p = 0.024$) between subjective and objective salivary function at 12 months. At 1 year, 47% reported grade 2 or greater xerostomia based on the LENT scale (grade 2 partial but persistent dryness, grade 3 complete dryness but not-debilitating). These results are comparable with those reported with the UCSF experience. Lee reported a grade 2 xerostomia rate of 2% at 2 years using RTOG scale after IMRT and that a the mean dose to 50% of the parotid volume was 34 Gy.[82]

Two randomized trials for early-stage nasopharynx cancer treated with radiotherapy alone showed a benefit of IMRT over conventional techniques to preserve salivary function. Kam showed the incidence of observer-rated xerostomia to be decreased from 82% to 39.4% ($p = 0.010$). However, patient-reported xerostomia was not statistically improved. Pow showed improved parotid sparing and QOL in patients treated with IMRT compared with conventional technique.[124]

***IMRT and Hearing.*** Although the adverse impact of radiation on salivary gland function is well appreciated, the impact of radiation on auditory function is not broadly recognized. In covering the skull base and the posterior cervical nodes, the auditory structures are at risk. These include the cochlea and the eighth cranial nerve, especially as cisplatin, an ototoxic chemotherapy agent, is given with radiation therapy. To that end, the mean dose tolerance for sensorineural hearing loss has been shown to be 48 Gy.[125] Bakst reported that 1 of 25 patients had grade 3 hearing loss at a median audiogram follow-up of 14 months with a mean cochlear dose of 43 Gy.[126]

***IMRT and QOL.*** The ability of IMRT to optimize tumor control and decrease toxicity enables endpoints to optimize patient QOL to be measured such as a patient's physical functioning as well as emotional and psychosocial well-being. A QOL analysis of 237 patients treated from 1996 to 2003 who were cancer free from their NPC for minimum of 2 years was performed.[127] Eighty-five patients

(c) 2014 Wolters Kluwer. All Rights Reserved.

received conformal therapy consisting of 52 patients treated with IMRT and 33 with 3D-CRT. One Hundred and fifty two patients received conventional treatment (2D only or 2D with 3D boost). The two groups had no statistically significant differences noted in distribution of clinical stages or sociodemographic characteristics. The EORTC core (QLQ-C30) and head and neck module (QLQ-H&N35) QOL questionnaires were performed as a longitudinal cross-sectional analysis. Patient receiving conformal RT had significant improvement in global QOL, all functional scales and six core symptom scales (fatigue, nausea, pain, dyspnea, insomnia, and appetite loss) as well as 12 head and neck symptom scales (pain, swallowing, sense, speech, social eating, social contact, teeth, mouth opening, xerostomia, sticky saliva, coughing, and feeling ill). Patients in the conformal group experienced a clinically significant improvement (mean score >10 points) in global QOL, pain, speech, xerostomia, appetite, social eating, feeling ill, and dental QOL. No significant differences were noted between 3D versus IMRT nor did 3D boost to an initial 2D plan improve QOL. Those who received conformal RT had a 2.70-fold lower probability of reporting high levels of xerostomia (relative risk 0.37 [0.20–0.66]). On logistic regression analysis accounting for education level, income, employment, and comorbidity, radiation technique retained a significant association with global QOL.

***Altered Fractionated Radiation.*** The role of altered fractionated radiation in NPC has been investigated. As demonstrated in RTOG 90-03 and DAHANCA trials, altered fractionated radiation using accelerated radiation by concomitant boost (AFX-CB), DAHANCA regimen (six conventional treatments/week), or hyperfractionation improves locoregional control and disease-free survival compared with conventionally fractionated radiation therapy (CFRT).[128,129] Similar to treatment of nonnasopharyngeal head and neck cancers where CFRT with concurrent chemotherapy has now been established as standard of care,[130,131] the role of altered fractionated radiation remains to be defined.[132–134]

Early experience reported the benefit of altered fractionated radiation therapy compared with conventional treatment. Wang reported a benefit using split-course accelerated radiation for T3 and T4 nasopharynx cancers treated at Massachusetts General Hospital with improved 5-year LC compared with historic controls treated with conventional therapy (77% vs. 45%).[135] For all patients, the twice-daily fractionation had improved 5-year LC (69% vs. 60%, $p = 0.008$) and 5-year disease-free survival (69% vs. 49%, $p = 0.0001$) compared with a historic control treated with conventional fractionated radiation.

Jen reported a single-institution experience exploring the efficacy of hyperfractionated BID radiation in 88 patients with nasopharynx carcinoma.[136] All patients were treated with using primarily 2D technique with cobalt or 6 to 10 MV photons. Eighty-eight patients with stage III/IV nasopharynx cancer received hyperfractionation ($n = 76$) to 1.2 Gy BID or split-course accelerated radiation ($n = 12$) with 1.6 Gy BID. A median dose of 78 Gy (64–82 Gy) was delivered. These patients were compared with 134 patient treated with conventional fractionation to a dose of 70 Gy in 8 weeks. Chemotherapy was integrated into treatment in 2 of 88 BID patients and 60 of 134 CFRT patients, the latter group receiving primarily adjuvant chemotherapy (90%, 54/60). Groups were well balanced with regard to age, gender, T, N, and overall stage. At a median follow-up of >70 months, there was a trend toward better locoregional control in patients receiving altered fractionated radiation compared with conventional treatment (83% vs. 67%, $p = 0.055$) with improvement in disease-specific survival (70% vs. 60%, respectively) but no difference in overall survival (62% vs. 58%, $p = 0.41$). Acute grade 3/4 mucositis was increased 59% versus 21%, $p < 0.0001$ and moist desquamation (21% vs. 14%, $p = 0.04$) in patients receiving BID radiation, respectively. The primary increased long-term toxicity experienced by BID patients over the CFRT group was temporal lobe necrosis (3% vs. 0%, $p = 0.06$) and was confined primarily to the split-course accelerated BID patients. For T4 patients, LC was only 35% to 45% regardless of fractionation whereas it was excellent for T1–3 patients (82%–97%). The authors conclude that given the small patient numbers and the confounding effect of differences in chemotherapy, a benefit of hyperfractionated radiation may be born out in a larger trial.

Lee reported on the efficacy of a DAHANCA-type accelerated radiation regimen using 6 fractions per week on 158 consecutive patients treated to 66 Gy/33–37 fractions and compared them with a cohort of 167 consecutive patients treated to the same dose with conventional fractionation of 5 fractions/week prior to the change in treatment policy. All were treated with the Ho 2D technique.[137] Parapharyngeal boost (10 Gy) was given in 101 patients in the accelerated versus 80 patients in the conventional arm. Cisplatin-based chemotherapy was given to 41 patients in the AF arm and 13 patients in the CFRT arm. Patients in the AF group had higher progression-free rate (74% vs. 63% at 3 years, $p = 0.02$) and a 25% improvement in LC for T3–4 patients (87% vs. 62%, $p < 0.01$) but not for all patients (83% vs. 77%, $p = 0.07$). No difference in disease-specific survival (86% vs. 80%, $p = 0.39$) or overall survival could be detected (81% vs. 78%, $p = 0.9$). Although acute grade 3+ complications were increased in the accelerated arm (primarily mucositis 71% vs. 13%, $p < 0.001$), no significant increase in late complication was observed (20% vs. 15% at 3 years, $p = 0.19$). The promising outcomes for T3–4 patients from this treatment regimen led to its study in a four-arm randomized trial evaluating the role of DAHANCA versus conventional fractionation and role of concurrent chemotherapy versus radiation alone in a $2 \times 2$ format.[138]

***Randomized Studies of Altered Fractionated Radiation Therapy.*** A two-arm study of 159 patients with nodal disease up to N1 with maximal nodal size ≤4 cm in size were randomized to receive conventionally fractionated radiation (60 Gy/4 weeks) alone or split-course accelerated treatment (20 Gy/8 fractions/2.5 weeks QD → 22.4/1.6 Gy BID/9 days → 28.8 Gy/18 fractions/11 days). Total dose was 71.2 Gy in the altered fractionation arm.[139] Both arms could receive an additional parapharyngeal boost of 14 Gy in 4 fractions. Both arms used the 2D technique of Ho. At a median follow-up of 59 months, no significant difference was noted in LC (85% vs. 89%, respectively), distant metastasis (overall survival [87% vs. 85%] and relapse-free survival [77% vs. 85%, $p = 0.141$]) in arm I versus II, respectively. The accelerated arm did significantly increase total iatrogenic CNS complication affecting the temporal lobe, cranial nerves, and brain stem/cord (49% vs. 23%) and more often caused neck fibrosis, trismus, and hypopituitarism. The trial was terminated early because of the increased temporal lobe necrosis (29% vs. 16%) in the altered fractionation arm.

# CHEMOTHERAPY MANAGEMENT STRATEGIES

## Chemotherapy for Locoregionally Advanced Disease

Although excellent outcomes are obtained for treatment of early-stage disease with radiotherapy alone,[68,85,88,89,96,98,140] 20% to 60% of patients with advanced-stage disease experience locoregional failure after radiotherapy alone[68,85,88,89,96,98,140,141] and high rates of DM (50%–70%)[63,142–144] with 5-year overall survival of 28% to 56%.[89,98,145–147]

For advanced-stage NPC, the specific aims of integrating systemic chemotherapy with chemotherapy are twofold: improving LC of the primary tumor and prevention of subsequent DM. With

(c) 2014 Wolters Kluwer. All Rights Reserved.

the continued improvement in radiation therapy techniques and hence better LC, DM has increasingly become the predominant cause of treatment failure in NPC.[148] Systemic therapy has been integrated with radiation in various combinations of induction, concurrent, and adjuvant regimens. There has been continued debates based on theoretical grounds that concurrent chemoradiotherapy improves LC by radiosensitization whereas neodjuvant and adjuvant chemotherapy improves DM by eradicating micrometastases. However, based on clinical trial results, this has not been a consistent finding, with neoadjuvant treatments being beneficial in improving LC, whereas concurrent treatments resulted in improvement of DM in several of the studies. Hence, chemotherapy can clearly play a dual role of radiosensitization as well as eradication of occult micrometastases, and the optimal strategy is likely to be one that enables delivery of maximal drug-dose intensity without a significant negative impact on radiation therapy delivery and related toxicities.

Cisplatin-based regimens have been found to be the most effective, and over the past two decades, multiple phase III trials have been reported for both endemic and nonendemic nasopharynx cancer populations.[60,143,147] However, the optimal timing, dosing duration, and regimens of chemotherapy drugs to be combined with radiation therapy remain to be defined.

## Concurrent Chemotherapy

In North America, the standard of care was established by the landmark Intergroup Study 0099.[60] One hundred forty-seven patients with stage III/IV (AJCC, 1992, 5th ed.) tumors were randomized to conventional fractionated radiation therapy (CFRT) to 70 Gy alone versus CFRT concurrent with 3 cycles of CDDP (100 mg/m$^2$ q3 weeks) followed by adjuvant CDDP/5-Fluorouracil (5FU) (80 mg/m$^2$ and 1,000 mg/m$^2$ × 4 days, respectively) for 3 cycles in a phase III randomized study.[29] Results at a median follow-up of 32 months showed improved locoregional control (crude locoregional failure 14% vs. 41%) and fewer DM (crude distant metastasis 13% vs. 35%) which translated into an approximate 30% to 40% increase in 3-year progression-free (69% vs. 24%, $p < 0.001$) and overall survival (76% vs. 46%, $p < 0.001$). The worse grade 3/4 acute toxicity was increased in the chemoradiation arm (76% vs. 50%) with a higher incidence of grade 3/4 leukopenia and vomiting. Compliance to the planned regimen was suboptimal as only 63% were able to complete all 3 cycles of concurrent cisplatin with an additional 23% able to complete 2 concurrent cycles whereas 27% were unable to complete the chemoradiation program. Only 60% of patients received two to three planned cycles of adjuvant chemotherapy. Importantly, 33% did not receive any adjuvant chemotherapy. The accrual goal was 270 patients. However, the trial was stopped early after interim analysis showed an increased risk of death in the radiation alone arm with a hazard ratio of 3.28. A follow-up analysis with 185 patients including those excluded initially due to missing documentation confirmed the 3-year overall and progression-free survival benefit of the chemoradiation arm (76% vs. 46%, $p < 0.001$ and 66% vs. 26%, $p < 0.001$, respectively).

The trial has been criticized for having small patient numbers and apparently poorer outcomes in the CFRT-alone arm compared with historic results as well as the concern that its results based on one-fourth of patients who were WHO type I histology may not be extrapolated to endemic patients where there is a distinct predisposition for WHO type II, and III carcinomas.[149]

Several pivotal trials conducted in Asia have confirmed the benefit of concurrent chemoradiation or concurrent chemoradiation followed by adjuvant chemotherapy. Wee reported on a randomized trial of 221 patients all treated with conventional radiation to 70 Gy in 7 weeks half randomized to radiation alone and the other half to concurrent cisplatin (25 mg/m$^2$ on days 1–4 on weeks 1, 4, and 7) followed by adjuvant cisplatin 20 mg/m$^2$ days 1 to 4 and 5FU (1,000 mg/m$^2$ day 1–4) for 3 cycles.[150] At a median follow-up of 3.2 years, the concurrent arm versus radiation-alone arm showed superior 3-year overall survival (80% vs. 65%, $p = 0.0061$) and decreased distant metastasis (2-year 13% vs. 30%, $p = 0.0029$), respectively. Unlike the Al-Sarraf trial, no difference in locoregional control was shown.

Chan reported on a phase III trial involving two major institutions in Hong Kong randomizing 350 locoregionally advanced patients to 6 weekly doses of cisplatin (40 mg/m$^2$) during radiation compared with radiation therapy alone.[151,152] The 5-year overall survival was improved from 58.6% to 70.3% and after adjusting for significant prognostic factors, the difference in overall survival was significantly in favor of concurrent cisplatin-radiation ($p = 0.049$). This outpatient regimen was well tolerated with only 5.1% of the patients requiring nasogastric tube-feeding. In endemic areas of NPC where supportive therapy is not as readily available and where acceptance of enteral feeding is lower, this regimen has been widely accepted as standard practice.

Lin reported on a phase III trial of 284 stage III/IV endemic patients randomized to 2 cycles of chemotherapy (CDDP 20 mg/m$^2$ days 1–4 and 5FU 400 mg/mg$^2$ × 4 days, continuous infusion, weeks 1 and 5) concurrent with conventional radiation and compared with patients receiving the same radiation treatment alone.[153] No adjuvant chemotherapy was given. At a median follow-up of 65 months, the concurrent arm showed increased 5-year overall survival (72% vs. 54%, $p = 0.0022$) and 5-year LC (89% vs. 73%, $p = 0.0009$) with a trend toward decreased distant metastasis (21% vs. 30%, $p = 0.0577$) compared with radiation alone. Compliance to chemotherapy was 94%. Patients receiving chemotherapy had increased leukopenia and emesis. No treatment associated mortality was reported on either arm.

A subsequent analysis of the aforementioned trial according to risk stratification was reported.[154] Patients were categorized as high risk ($n = 165$) if they satisfied one of the following criteria: (a) nodal size >6 cm, supraclavicular node involvement, T4N2 (AJCC 5th ed.) or multiple neck nodes with one node >4 cm or low risk ($n = 119$) if they satisfied none. Concurrent chemoradiation improved outcomes for low-risk patients with no obvious benefit for the high risk. Among the low-risk patients, the concurrent chemoradiation arm improved LC (95% vs. 77%, $p = 0.0012$), distant metastasis–free survival (90% vs. 78%, $p = 0.0282$), progression-free survival (87% vs. 62%, $p = 0.0003$), and overall survival (75% vs. 68%, $p = 0.0003$) over radiation alone. For the high-risk patients, there was no significant difference in LC (75% vs. 68%, $p = 0.25$), distant metastasis–free survival (60% vs. 60%, $p = 0.55$), progression-free survival (44% vs. 43%, $p = 0.39$), and overall survival (56% vs. 46%, $p = 0.18$) in patients receiving concurrent chemoradiation versus radiation alone. The authors conclude that the addition of neoadjuvant or adjuvant chemotherapy should be considered for high-risk patients.

Lee reported the preliminary results of a two-arm NPC-9901 Trial by the Hong Kong Nasopharyngeal cancer study group randomizing 348 T1–4N2–3 patients to the Intergroup 0099 regimen versus radiation alone.[155] One hundred seventy-six received conventional fractionated radiation therapy alone versus 172 patients undergoing the Intergroup 0099 regimen of concurrent chemoradiation followed by 3 cycles of adjuvant chemotherapy. At a median follow-up of 2.3 years, the chemoradiation arm achieved improved locoregional control (92% vs. 82%, $p = 0.005$), failure-free survival (72% vs. 62%, $p = 0.027$) but no improvement in distant metastasis–free survival (76% vs. 73%) or overall survival (78% vs. 78%). Acute and late toxicities were increased in the chemoradiation arm (84% vs. 53%, $p < 0.001$) and (28% vs. 13%, $p = 0.024$), respectively.

(c) 2014 Wolters Kluwer. All Rights Reserved.

A 5-year update of the NPC 99-01 trial was reported by Lee. At a median follow-up of 5.9 years, in patients receiving chemotherapy, there was a 12% improvement in 5-year freedom from relapse (67% vs. 55%, $p = 0.014$), 9% increase in 5-year progression-free survival (62% vs. 53%, $p = 0.035$), and a 10% improvement in 5-year locoregional control 88% versus 78%, $p = 0.005$. However, there was no difference in incidence of distant metastasis at 5 years (26% vs. 32%, $p = 0.32$) or overall survival (68% vs. 64%, $p = 0.22$). The lack of statistically significant improvement in overall survival despite improved disease-free survival was due to an increase in nonnasopharyngeal cancer–related deaths (infection, secondary malignancy, and suicide) (8.1% vs. 3.4% $p = 0.015$) and treatment-related mortality (1.7% vs. 0% $p = 0.015$) in patients receiving chemotherapy. Chemotherapy increased acute toxicity (83% vs. 53%, $p < 0.001$, primarily hematologic and nausea) but not chronic toxicity (30% vs. 24%, $p = 0.30$). Subset analysis suggested that stage III patients benefited the most from chemotherapy with respect to better survival (hazard ratio = 0.64, $p = 0.09$) whereas stage IVA/B patients had a locoregional control benefit. Similar to the Intergroup 0099 study, only 60% were able to complete all 3 cycles of cisplatin (compared with 63% in Intergroup 0099); however,76% were able to complete all adjuvant cycles compared with 55% in the Intergroup 0099.

Lee reported on a $2 \times 2$ phase III (NPC 99-02) study of 189 patients with T3–4N0–1 patients determining the benefit of concurrent with adjuvant chemotherapy versus radiation alone and the role of accelerated radiation given in 6 weeks versus conventional fractionation in 7 weeks (*Radiother and Oncol*. 2011;98:15–22).[155a] The chemotherapy tested was the Intergroup 0099 regimen and the accelerated regimen consisted of six treatments per week similar to the scheduled pioneered by the Danish cooperative group (DAHANCA). At a median follow-up of 6.3 years, patients receiving accelerated radiotherapy and chemotherapy had the highest 5-year failure-free survival (88%) compared with those treated with conventional radiotherapy and chemotherapy (65%, $p = 0.027$) and compared with the accelerated radiotherapy–alone group (56%, $p = 0.001$). Improvement of overall survival was increased 85% versus 66% with a trend toward significance ($p = 0.058$). Both locoregional control and distant metastasis–free survival was highest in this arm (90% and 5%, respectively). There was a non–statistically significant increase in chronic toxicity (36% vs. 20%, $p = 0.25$) especially grade 3 neck fibrosis (16/44 vs. 0/51 in the conventional fraction with chemotherapy) and death due to non-cancer-related causes (9% vs. 2%, $p = 0.62$).

A pooled analysis of NPC 99-01 and NPC 99-02 comprising 441 patients evaluated the benefit of chemoradiotherapy using the intergroup regimen versus radiation alone. The median follow-up was 6.1 years. By intent-to-treat analysis, the chemoradiotherapy arm had improved failure-free, locoregional control, and disease-specific survival without improvement in overall survival. By actual treatment, three patients in the chemoradiation arm did not receive chemotherapy whereas three patients in the radiation only received chemotherapy. Despite the adjustment, the two groups remained well balanced for patient characteristics. If analyzed by actual treatment received, those undergoing chemoradiotherapy had improved survival compared with those treated with radiotherapy alone (5-year overall survival 72% vs. 63%, $p = 0.037$). Multivariate analysis showed that those patients receiving 2 or 3 cycles of cisplatin during radiotherapy had improved locoregional control and overall survival compared with those receiving 0 to 1 cycles whereas those receiving 2 to 3 cycles of adjuvant chemotherapy had improved distant metastasis–free survival. Subset analysis revealed that the survival benefit was significant for stage III patients (12% increase in 5-year overall survival, $p = 0.047$) but not stage IV (7% increase in 5 years, $p > 0.19$), suggesting that the intergroup regimen is best for intermediate-stage patients and that more intensive treatment may be needed in those with the most advanced disease.

## Benefit of Concurrent Chemoradiation for Stage II Cancer

Moreover, the benefit of concurrent chemoradiation over radiation alone for stage II patients has been confirmed in a randomized trial conducted at the Sun-Yat Sen University in Guangzhou, China.[156] Two hundred thirty endemic patients with WHO II/III were randomized to receive radiation therapy to a dose of 66 to 68 Gy with or without weekly cisplatin (30 mg/m$^2$). Patients were treated without CT-based planning but with diagnostic MRI for determination of pretreatment tumor location as well as post-treatment surveillance. Stage II was based on a Chinese staging system, and when restaged according to AJCC, approximately 13% (31/230) were reclassified as III. Based on the restaging, there was an imbalance biased against group receiving chemoradiation with a greater percentage of stage III or N2 (16% vs. 10%) and a lower percentage of node-negative patients (10% vs. 15%) compared with radiation alone. At a median follow-up of 60 months, the addition of concurrent chemotherapy increased 5-year overall survival (86%–95%), progression-free survival (from 79% to 88%,), and distant metastasis–free survival (84% to 95%) but no difference in locoregional control (91% vs. 93%). Acute toxicity was increased primarily grades 3 to 4 mucositis (from 32.5 to 45.6%, $p = 0.04$), grade 3/4 nausea/vomiting (0% to 8.6%, $p = 0.001$) and grade 3/4 leucopenia/neutropenia (0% to 12.9%, $p < 0.001$). No patients experience treatment-related mortality. Compliance to at least six doses of CDDP was 78% with 26% completing seven doses. No statistically significant differences in chronic morbidity was reported especially with regard to grade 3/4 deafness (9.5% vs. 7%) or skin fibrosis (2.6% vs. 1.8%). The benefit of weekly cisplatin in this trial suggest a subset of patients who have a low-volume of occult distant metastatic volume who may not need adjuvant chemotherapy and challenges the uniform recommendation of the Intergroup 0099 regimen for stage II patients. Also the authors suggest that the lower dose of weekly cisplatin (30 mg/m$^2$) may be better tolerated than the 40 mg/m$^2$ dosing used in the Chan trial in which 44% were able to tolerate six doses.

Alternative concurrent platinum regimens have been explored in phase II studies including the use of weekly oxaliplatin (70 mg/m$^2$) in a small randomized study found to be safe with improved survival compared with radiation alone[157] and another trial of weekly carboplatin compared with weekly cisplatin study showing no difference in overall or disease-free survival at 2 years.[158]

## Altered Fractionated Radiation Therapy and Concurrent Chemotherapy

Given the results of the randomized NPC 99-02 trial showing that integrating accelerated radiation therapy (six treatments per week) with concurrent chemotherapy followed by adjuvant chemotherapy yielded the best locoregional control and lowest incidence of distant metastasis in patients with T3–4N0–1, the role of altered fractionation in the treatment of nasopharynx cancer with chemotherapy remains to be defined as the NPC 99-02 did not complete accrual. Several groups have evaluated other altered fractionation radiation such as accelerated radiation with delayed concomitant boost and hyperfractionation.

Delayed concomitant boost radiation with concurrent cisplatin followed by adjuvant chemotherapy according to Intergroup 0099 was reported in a phase II study.[159] Forty-five patients with newly diagnosed stage IIa to IV NPC (66% T3/4 and 55% N2/3) were treated with AFX-CB to 70 Gy/6 weeks (BID RT last 2 weeks

(c) 2014 Wolters Kluwer. All Rights Reserved.

with a 3D-conformal plan, 6-hour interfraction interval) with 2 to 3 cycles of concurrent CDDP (100 mg/m$^2$) on days 1, 22, and 43 of radiation followed by adjuvant 5FU/CDDP for 3 cycles. All patients completed the prescribed chemoradiation regimen, and 84% completed 2 to 3 cycles of adjuvant chemotherapy. At a median follow-up of 27 months (3–78 months), the 3-year actuarial LC, regional control, locoregional control, freedom from distant metastasis, disease-free survival, and overall survival were 95%, 98%, 93%, 94%, 86% and 87%, respectively. Among 29 T3/T4 patients, LC was 93%. Major grade 3 acute toxicities include mucositis (59%), dysphagia (41%), vomiting (20%), and anemia (4.5%). Ninety percent of patients received erythropoietin support and near 20% required blood transfusion. Late toxicities included grade 3 tinnitus in 1, grade 2 serous otitis in 1, osteoradionecrosis in 1, brain necrosis in 2, and grade 2 xerostomia in 80%.

Wolden et al. reported the MSKCC experience using the same chemoradiation regimen in the treatment of locally advanced nasopharynx cancer (54% T3/4 and 54% N2–3) and compared the results with a historic control treated with CFRT (31% T3–4 and 22% N2–3).[160] With a median follow-up of 42 months, their 3-year actuarial LC was 84%, progression-free survival was 66%, and overall survival was 84% for patients treated with AFX-CB. Comparison with patients treated with CFRT showed superior 3-year LC (89% vs. 74%, $p < 0.01$), disease-free survival (66% vs. 54%, $p = 0.01$), and overall survival (84% vs. 71%, $p = 0.04$) in the AFX-CB cohort. This was despite a selection bias against the altered fractionation group, which had a greater proportion patient with T3/T4 (54% vs. 32%), N2/N3 (44% vs. 22%), and stage III/IV (78% vs. 51%) disease compared with CFRT group. Acute grade 3 mucositis was increased in the accelerated arm compared with the CFRT (84% vs. 43%, $p < 0.001$) as well as need for gastric tube (46% vs. 20%, $p < 0.01$).

Hyperfractionated radiation concurrent with CDDP-based chemotherapy was used to treat locally advanced nasopharynx cancers.[161] Forty-eight patients with T3 or T4 (1997 AJCC) were treated with 1.2 Gy BID (74.4 Gy total; 1-week break after 3.5 weeks of radiation) with concomitant CDDP (100 mg/m$^2$) alone ($n = 28$) or CDDP (60 mg/m$^2$)/5FU (600 mg/m$^2$ × 5 days) ($n = 16$) on weeks 1 and 6 of radiotherapy followed by adjuvant CDDP/5FU for 2 to 3 cycles. Three-dimensional treatment planning was used after an initial standard three-field technique. Eighty-eight percent of patients were able to complete their treatment within 8 weeks. At a median follow-up of 57 months, the 3-year locoregional control was 93%, disease-free survival was 71%, and overall survival was 72%. For T4 patients, the 3-year corresponding LRC, DFS, and overall survival were 91%, 62%, and 63%, respectively. Comparison at the same institution of T4 NPC patients treated with conventional fractionation and concurrent chemotherapy demonstrated improvement in 3-year locoregional control (89% vs. 72%, $p = 0.2$) and disease-free survival (66% vs. 35%, $p = 0.14$) favoring those treated with hyperfractionation.

In summary, the role of altered fractionated radiation with concurrent chemotherapy appears to improve outcome but if given with conventional radiation delivery technique, the toxicity may be prohibitive. However, with newer conformal techniques such regimens may be delivered with acceptable toxicity. The patient population which best benefits from such treatments remains to be defined.

## IMRT and Concurrent Chemoradiation

IMRT allows even more conformal dose distributions to be obtained than is possible with 3D technique.[79] IMRT may be particularly relevant to patients with T3/T4 with intracranial or skull base invasion due to proximity of critical structures such as the optic nerves/the chiasm, the brain stem, and the spinal cord.

## Single-institutional Experience with IMRT

Multiple centers report significant series of nasopharynx patients treated with IMRT (Table 22.5). The IMRT experience from University of California, San Francisco (UCSF) for nasopharynx cancer has been discussed in multiple reports. Sultanem et al.[76] reported their initial experience on 35 patients treated between April 1995 and March 1998. A later report on 67 stage I to IV nasopharynx cancers showed a favorable experience.[82] Gross tumor and positive lymph nodes were treated to a dose of 65 to 70 Gy at 2.12 to 2.25 Gy per fraction over 6.5 weeks whereas high-risk or electively treated nodes were simultaneously treated using l.8 to 2.0 Gy to a dose of 60 and 50 Gy, respectively, using a standard fractionation scheme. Thirty-nine percent (26/67) received a brachytherapy boost to a dose of 5 to 7 Gy whereas 75% (50/67) received cisplatin-based chemotherapy. At a median follow-up of 31 months, the 4-year estimates of LC, local-regional control, metastatic disease–free survival, and overall survival were 97%, 98%, 66%, and 88%, respectively. Grade 3/4 acute toxicities were seen in 24% and grade 3/4 late toxicities in 12%. At 24 months, only one of the 41 (2.4%) evaluable patients had grade 2 or higher xerostomia, demonstrating significant sparing of the salivary glands. The crude incidence of the worst acute grade 3/4 toxicity was 24% with mucositis, the most common side effect, and worst grade 3/4 late toxicity was 12%, primarily xerostomia. With a mean dose of 34 Gy delivered to the parotid

glands, the incidence of grade 2 xerostomia at 2 years was 2%. A later report of 118 patients treated between 1995 and 2003.[162] At a median follow-up of 30 months, the 4-year actuarial LC, regional control, and distant metastasis–free survival were 96%, 98%, and 72%, respectively, whereas overall survival was 74%.

Wolden reported the MSKCC experience using IMRT for 74 nasopharynx patients who were treated with accelerated radiation by delayed concomitant boost ($n$ = 59) or dose painting with once-daily fractionation ($n$ = 15).[163] All patients were treated to a total dose of 70 Gy. Patients in the accelerated radiation by delayed concomitant boost (AFX-DCB) were treated at 180 cGy once a day during the first 4 weeks then twice a day during the last 2 weeks with 180 cGy in the A.M. and 160 cGy in the P.M. fractions. Patients in the dose painting were treated with 2.34 Gy to the GTV for 30 fractions. Sixty-nine patients received concurrent and adjuvant platinum-based chemotherapy similar to that in the Intergroup 0099 trial. Patient characteristics were as follows: 72% males, 35% Caucasian, 32% Asian, WHO II/III 95%, T3/4 51%, II/IV 77%. At a median follow-up of 35 months, the 3-year actuarial LC was 91%, regional control was 93%, distant metastasis–free survival was 78%, progression-free survival was 67%, and overall survival was 83%. Six patients recurred locally and all of them had T3–4 disease. The local failure rate for patients with T3/4 disease was 16% (6/38) whereas none with T1–2 disease failed. Five of the 6 patients failed in field whereas the other patient was a T4 patient who failed both within and beyond the high-dose volume adjacent to the brain. The mean number of adjuvant chemotherapy cycles received was 2.5.

A follow-up report of 25 patients treated with IMRT using the dose-painting technique confirmed excellent 3-year LC (91%), freedom from distant metastasis (91%) and overall survival (91%). However, 12% of patients developed temporal lobe necrosis at a median follow-up of 33 months and this dose-painting regimen was not recommended.[126]

Kam reported on the efficacy of IMRT in 63 newly diagnosed NPC patients treated with IMRT.[81] Patient characteristics were as follows: 51% T3/4, 57% stage III/IV, 76% males. Patients were treated to a dose of 66 Gy to the GTV, 60 Gy to the PTV, and 54–60 Gy to the clinically negative neck. Brachytherapy boost (12 Gy/4 fractions/2 weeks) was given to all 20 T1–T2a patients whereas additional external beam boost (8 Gy/4 fractions) was given to 15/42 T2b–T4. Thirty percent (19/63) received induction ($n$ = 3) or concurrent chemotherapy (weekly cisplatin). At a median follow-up of 29 months, the 3-year LC, regional control, distant metastasis–free survival was 92%, 98%, and 79%, respectively. Three-year overall survival was 90%. All four patients who failed had T3–4 disease and had not received boost therapy. On multivariate analysis, dose escalation above 66 Gy was associated with improved progression-free and distant metastasis–free survival. Acute side effects included grade 3 mucositis in 41% with a need for tube feeding in 8%. Chronic grade 2 to 3 xerostomia at 3 months was 57% and at 2 years was 23%. Long-term grade 3 hearing impairment occurred in 13%.

Xiao reported on 68 patient treated with an alternative IMRT prescription dose regimen of 68 Gy in 30 fractions with dose-painting elective areas of 54 Gy in 30 fractions using a simultaneous boost technique. Two cycles of cisplatin (80 mg/m$^2$) were given on week 1 and 4 of radiotherapy. At a median follow-up of 54 months, the 5-year LC was 95% with 5-year disease-free and overall survival of 77% and 75%, respectively. Acute toxicity was not reported. Patients were followed for a minimum of 48 months to assess longer toxicity. Twelve patients developed temporal lobe injury ($n$ = 11) or brainstem injury ($n$ = 1). The authors note that such patients had advanced disease extending intracranially or to the skull base. Thus, for such patients, such a fractionation regimen may not be optimal for patients with advanced tumors.

## RTOG Multi-institutional Phase II Study

A phase II trial to assess the feasibility of IMRT treatment in a multi-institutional setting was investigated in RTOG 0225. Patient were treated with the Intergroup 0099 regimen if advanced stage. Sixty-eight patients with stage I to IVB were enrolled with 94% WHO types II and III. The target delineation as prescribed in the protocol was delivered in 84%. The 2-year locoregional control, distant metastasis–free survival, and overall survival were 89%, 85%, and 80%, respectively. Acute grade 4 toxicity occurred in 12% primarily leucopenia ($n$ = 4), mucositis ($n$ = 3), anorexia ($n$ = 3), hyponatremia ($n$ = 2), and neutropenia ($n$ = 2). Treatment-related morality occurred in 4% due to febrile neutropenia ($n$ = 1), pneumonitis ($n$ = 1), and esophagitis ($n$ = 1). Incidence of xerostomia at 1 year was as follows: grade 2: 14%; grade 3: 3%; and grade 4: 0%. Currently, even patients with stage III/IV typically attain LC rates of 90% or greater, regional control rates of 95%, whereas distant metastasis remains the dominant pattern of failure occurring in up to 25%.

## Adjuvant Chemotherapy

Adjuvant chemotherapy is often poor tolerated by patients deconditioned after radiation therapy with or without chemotherapy. Although seven published randomized trials have included the use of adjuvant chemotherapy, two studies addressed solely the use of adjuvant chemotherapy after radiation alone. Both studies were negative and are discussed below.

The role of adjuvant therapy after radiation therapy was evaluated in a randomized phase III study.[164] One hundred fifty-seven patients with stage IV cancers all were treated with standard radiotherapy to 70 to 72 Gy and then randomized to no further treatment or 9 weekly cycles of 5FU/leucovorin/CDDP after radiation therapy. At a median follow-up of 49.5 months, there was no statistical difference in 5-year overall survival (60.5% vs. 54.5, $p$ = 0.5) or relapse-free survival (49.5% vs. 54.4%, $p$ = 0.38) in the no adjuvant vs. adjuvant chemotherapy arms, respectively. Patients received adjuvant chemotherapy did have a lower rate of distant metastasis (36% vs. 20%, $p$ = 0.03 respectively). The treatment was relatively well tolerated with a 2% incidence of grade ≥3 leukopenia. However, 34% refused adjuvant chemotherapy.

Rossi et al. randomized two hundred twenty-nine patients to 6 cycles of adjuvant vincristine, doxorubicin, and cyclophosphamide compared with no adjuvant therapy for patients who have achieved a complete response to radiation therapy. At a median follow-up of 32 months, there was no difference in overall survival or relapse-free survival. A major limitation of this study was the choice of a non-cisplatin-containing regimen.[143]

## Benefit of Adjuvant Chemotherapy after Concurrent Chemoradiation

Chen reported on a phase III randomized trial testing the benefit of adjuvant chemotherapy in patients treated with concurrent chemoradiation.[165] Two hundred fifty-one stage III/IV nasopharynx patients were all treated with weekly CDDP (40 mg/m$^2$) with conventional radiation to a total dose of 66 Gy. More than two-thirds of patients were N2/3 and >70% were T3/4. Adjuvant chemotherapy comprised CDDP (80 mg/m$^2$) and 5FU (800 mg/m$^2$) given every 4 weeks for 3 cycles. Forty percent to 45% were able to complete the prescribed concurrent chemotherapy with median total dose delivered of 240 mg/m$^2$ in both arms whereas in the adjuvant arm, 63% were able to complete all 3 cycles while 18% received no chemotherapy. The most common grade 3/4 acute toxicity during adjuvant therapy was

(c) 2014 Wolters Kluwer. All Rights Reserved.

stomatitis 21%, nausea 11%, vomiting 10%, and neutropenia 10%. At a median follow-up of 38 months, the 2-year failure-free survival rate was no different in those receiving adjuvant chemotherapy (86% vs. 84%, $p = 0.13$). Likewise, the incidence of distant metastasis at 2 years was not statistically different (13% vs. 18%, $p = 0.12$). The trial has been criticized as being underpowered to show equivalence.

The use of adjuvant chemotherapy after radiation is not recommended and its benefit after concurrent chemoradiation is undergoing reevaluation. Future studies are underway to integrate serum EBV DNA levels to select a high-risk subpopulation which may benefit from standard or intensified systemic treatment.

## Induction Chemotherapy

The advantages of induction chemotherapy include (a) better tolerance and compliance to chemotherapy in patients who are treatment-naïve, (b) a higher chance of eradication of micrometastases, and (c) *in vivo* testing of chemosensitivity by evaluating clinical response. The theoretical disadvantages include (a) delay in initiation of definitive radiation therapy and (b) accelerated tumor repopulation and hence increased radioresistance.

Three large randomized studies of induction chemotherapy before radiation alone conducted by the International Nasopharynx Cancer Study Group,[166] the Asian-Oceanian Clinical Oncology Association,[167] and the Sun Yat-sen University of Medical Sciences in Guangzhou[168] reported improved relapse-free survival but no overall survival benefit after 2 to 3 cycles of induction consisting of (a) epirubicin, CDDP, and bleomycin;[166] (b) epirubicin and CDDP;[167] or (c) CDDP, 5FU, and bleomycin[168] in advanced-stage NPC patients. Induction chemotherapy improved LC compared with radiation alone. In the International NPC Study Group study, there were 9% treatment-related deaths in the induction arm which suggest that any possible survival benefit may be offset by the increased treatment-related mortality.

## Induction and Concurrent Chemoradiation

Numerous phase II studies have been reported testing the benefit or feasibility of induction chemotherapy prior to concurrent chemoradiation.

In a pilot study reported by Rischin,[169] 35 patients with locoregionally advanced NPC cancer were treated with 3 cycles of induction chemotherapy consisting of epirubicin (50 mg/m$^2$), CDDP (75 mg/m$^2$), and continuous infusion 5FU (200 mg/m$^2$) for 3 cycles/weeks. This was followed by conventionally fractionated radiation to a reduced dose of 60-Gy 2 Gy/fractions with CDDP 20 mg/m$^2$/days × 5 days on weeks 1 and 6 of radiation. Seventeen patients were treated with conventional technique whereas 18 were treated with conventional technique to 36 Gy followed by arc technique for the final 24 Gy. Forty percent were stage IV by UICC 5th Edition criteria and 74% had WHO type III histology. At a median follow-up of 43 months, only 6% (2/35) failed locoregionally (l local, 1 regional), 6% failed distantly whereas the actuarial 4-year progression-free survival and overall survival were 81% and 90%, respectively. All patients completed induction chemotherapy and 97% completed chemoradiation. Acute toxicities during induction chemotherapy included grade 3/4 neutropenia in 31%, grade 3/4 stomatitis in 11%, and grade 3 vomiting in 26% with no febrile neutropenic episodes. During concurrent chemoradiation, acute toxicities included grade 3 mucositis (31%), grade 3 dermatitis in 23%, grade 3/4 vomiting in 23%, and febrile neutropenia in 6%. Anemia occurred in 63% with grade 2/3 in 9%. Common late toxicities included grade 2 to 3 xerostomia in 100%, hearing loss in 50% (primarily WHO type II 32%), and peripheral neuropathy in 24%. These single-institution results appeared to be about 10% better than the Intergroup trial with respect to progression-free survival (4-year 81% vs. 3-year 69%) and overall survival (4-year 90% vs. 3-year 78%).

Four other phase II studies demonstrated similarly encouraging results.[170–173] Chan et al. reported 2-year overall and progression-free survival rates of 91.8% and 78.5% using 2 cycles of induction weekly paclitaxel and 3 weekly carboplatin followed by concurrent weekly cisplatin-radiation therapy.[173] The same group recently demonstrated in a phase II study that patients randomized to receive induction taxotere and cisplatin followed by concurrent weekly cisplatin and radiation had improved overall survival at 3 years (94% vs. 68%, $p = 0.012$) and 3-year progression-free survival (88% vs. 60%, $p = 0.12$) compared with those treated with concurrent chemoradiation only (Chan, *JCO.* 2002; 20:2038–2044). Hui reported on a phase II randomized study of 65 patients treated concurrent weekly cisplatin and radiation with or without 2 cycles of induction taxotere and cisplatin.[174] The endpoint was toxicity. The study concluded that induction chemotherapy was feasible without compromise of concurrent chemotherapy. Three-year overall survival was increased from 68% to 94% ($p = 0.012$).

In contrast, Fountzilas reported on a Hellenic Cooperative Oncology Group phase II randomized study comparing induction chemotherapy with CDDP, epirubicin, and taxol for 3 cycles followed by concurrent weekly CDDP with radiation compared with concurrent chemoradiation alone. One hundred forty-one stages IIB to IVB patients were enrolled with 86% in the induction arm completing the neoadjuvant chemotherapy. At a median follow-up of 55 months, no difference in 3-year progression-free (64.5% vs. 63.5%, $p = 0.708$) and overall survival (67% vs. 72%, $p = 0.652$) was noted. Grade 3/4 toxicity from induction chemotherapy were infrequent. Huang reported a Chinese trial of 408 patients who all underwent induction carboplatin/floxuridine and then randomized to radiation alone or radiation with carboplatin. The addition of carboplatin yielded no survival or locoregional control benefit.[175] Xu reported on a randomized trial showing no difference in survival for patients treated with neoadjuvant chemotherapy followed by radiotherapy versus concurrent chemoradiation.[176]

Multiple other induction regimens prior to concurrent chemoradiation have been studied as nonrandomized phase II or phase I studies using taxol/carboplatin,[177] nedaplatin/5FU,[178] taxol/cisplatin,[179] TPF,[180,181,182] and taxotere/platinum/xeloda[183] have been evaluated.

## Phase III Trials

Currently, five phase III studies testing the benefit of induction chemotherapy followed by concurrent chemoradiation versus concurrent chemoradiation alone are underway (Table 22.6).[184] One of the five compares the Intergroup 0099 regimen directly to an induction regimen followed by concurrent chemoradiation using the same chemotherapy but reversing the sequencing. The study conducted by the Hong Kong group (HKNPCSG 0501) is a three-arm trial which also investigates the benefit of capecitabine over 5FU as well as accelerated radiation (DAHANCA type) compared with conventional fractions. Four of the trials have concurrent chemoradiation alone as the standard arm without adjuvant chemotherapy. Of these four, three are designed using weekly cisplatin during the radiation whereas one is every 3-week cisplatin. Two trials explore the benefit of induction TPF which have been shown to improve survival in nonnasopharyngeal head and neck cancer.[185,186]

## Meta-analysis

Meta-analysis of eight randomized trials with 1,753 patents comparing chemotherapy and radiation to radiation therapy alone reported a hazard ratio of 0.82 ($p = 0.006$) favoring chemotherapy

and corresponding to a 6% absolute 5-year survival benefit.[132] Concurrent chemotherapy provided an absolute event-free survival benefit of 10% at 5 years. Induction chemotherapy improved event-free survival (HR = 0.82 [CI 0.67–0.97]) but not overall survival (HR = 0.99 [CI 0.8–1.21]). The survival benefit of chemotherapy was most pronounced for WHO type I tumors (HR = 0.30 [CI 0.15–0.59]) but also for WHO types II and III (HR 0.85 [CI 0.73–0.98]).

Meta-analysis of seven randomized trials of 1,608 endemic patients showed a survival benefit of concurrent chemoradiation over radiation alone (hazard ratio at 3- and 5-year of 0.61 and 0.74, respectively).[187] Concurrent chemoradiation also decreased locoregional failure (3-year HR = 0.67 [CI 0.49–0.91]) and distant metastasis (HR = 0.71 [CI 0.58–0.88]). Five of the seven trials also incorporated CDDP/5FU adjuvant chemotherapy after concurrent chemoradiation. Distant metastasis was also decreased in those trials incorporating concurrent and adjuvant chemotherapy compared with radiation alone to a similar degree (HR = 0.71 [CI 0.54–0.92]). The benefit of adjuvant chemotherapy beyond concurrent chemotherapy was not reported in this population-based meta-analysis.

## Follow-up

Standard follow-up as recommended by NCCN guidelines include history and physical every 1 to 3 months the first year after treatment, 2 to 6 months the second year, and 4 to 8 months years 3 to 5 with imaging every 6 months, as well as regular thyroid function testing every 6 to 12 months in addition to speech and swallowing evaluation.

The potential of surveillance with posttreatment plasma EBV DNA in endemic patients has been reported in a single-institution study at Taichung Veterans Hospital in Taiwan. A prospective study of 245 nasopharynx carcinoma patients who achieved clinical remission were followed with serial plasma EBV DNA levels every 3 to 6 months as well as annual anatomic imaging of the head and neck area (MRI or CT), bone scan, and chest radiography. A total of 36 patients were found to have elevated plasma EBV DNA levels (>0 copy/mL) and underwent PET/CT. An additional five were felt to have clinical signs concerning for recurrence but whose plasma DNA EBV were negative. All 36 patients with elevated EBV DNA had recurrence subsequently detected on PET/CT whereas none of those with negative EBV DNA recurred. Patients with distant metastasis had higher median levels compared with those with locoregional failure only (median 1531 vs. 625 copy/mL, $p = 0.08$). The cost of a EBV DNA level reduced cost of surveillance 77% to 88% compared with one in which serial PET/CT were to be used for surveillance. The value of surveillance plasma EBV DNA remains to be validated.

## Secondary Primary Tumors

In contrast to other head and neck sites with incidence of secondary malignancies of 5% to 7%/year,[188] the incidence is markedly lower after treatment for NPC. The incidence of secondary malignancies was examined in 326 consecutively treated patients with definitive radiation therapy.[189] At a median follow-up of 5.6 years, the annual rate was 1.0% and the 5-year cumulative incidence was 5.8%. Two-thirds of secondary malignancies were aerodigestive tract tumors (lung in 44% and head and neck in 44%). All tumors were histologically distinct from the index nasopharyngeal cancer. Advanced age (age > 50 years) appeared to be associated with SPT development 11% versus 3% at 5 years for those aged >50 versus <50, respectively. The actuarial incidence of in-field SPT was 1.2% at 5 years with an annual rate of 0.35%.

## Salvage Therapy

***Salvage of Persistent Disease after External Beam Radiation Therapy.*** About 7% to 13% of patients may have persistent disease after EBRT alone[63,190,191] with failure rates of about 39% to 60% in such patients.[63] Leung reported on the use of salvage brachytherapy for locally persistent NPC in 87 patients treated with HDR-brachytherapy from 1990 to 1998.[191] Persistent disease was documented by biopsy 3 to 6 weeks after EBRT (median time 6 weeks). The EBRT dose was 65 to 66 Gy delivered with the Ho 2D technique with parapharyngeal boost (10 Gy/4 fractions) in patients with parapharyngeal involvement. No patients received concurrent chemotherapy. Initial T stage was as follows: T1: 19 patients; T2: 48 patients; and T3: 20 patients. Patients received 22.5 to 24 Gy in 3 fractions spaced 1 week apart using cobalt or iridium sources. The 5-year LC was 85% and disease-specific survival was 77%. Outcomes were compared with 383 patients treated with radiation alone. Brachytherapy improved LC in T1 and T2 patients but not T3 with 5-year LFFS as follows for brachytherapy patients: T1, T2, and T3 were 97%, 88%, and 67%, respectively, compared with 84%, 80%, and 63%, respectively, in the EBRT-alone patients. The iridium-treated patients showed better LC than the cobalt-treated patients, especially in the T1–2 (95% vs. 77%, $p = 0.03$, respectively). Complications attributed to brachytherapy included soft tissue necrosis in two patients within 6 months of treatment, both of whom healed, and perforation of the nasal septum with bilateral optic nerve atrophy in one patient.

Yan reported on a randomized study of 78 patients with T1–3 NPC tumors treated to 70 Gy to the nasopharynx and then biopsied within 2 weeks after EBRT.[192] Of the 30 positive patients, 16 were randomized to receive an external beam boost 20 Gy in five fractions versus the 14 who were randomized to observation. Local recurrence was 6% versus 36% in patients receiving

(c) 2014 Wolters Kluwer. All Rights Reserved.

additional EBRT versus those observed. Thus, boost with either EBRT or brachytherapy can salvage a significant percentage of those with persistent disease.

***Salvage of Recurrent Disease.*** Locoregionally recurrent disease after previous radiation therapy presents a challenging situation which requires multidisciplinary evaluation. Multiple surgical and radiation approaches are feasible salvage options particularly for the early-stage recurrences. With more advanced disease, options are usually limited to external beam radiation techniques with integration of chemotherapy. Neck dissection is routinely incorporated in patients with resectable nodal recurrence.

When local failure occurs, the chance for LC with subsequent treatment varies widely with reported 5-year control rates of 15% to 60%.[193–199] Prognostic factors important for LC and survival that are consistently reported from single institutional series include the stage of the recurrent tumor (T1–2 have more favorable outcomes), interval from previous radiation treatment (>2 year interval from previous radiation), and whether the chronology suggest persistent versus recurrent disease.[193–199] In general, for patients undergoing reirradiation, doses of >60 Gy are required for effective chance of salvage.[193–198] Patients with persistent disease do better than those with recurrent. The series are too limited and fraught with selection bias to make definitive conclusions as to which treatment should be recommended. The best salvage treatment must be individually tailored.

***Salvage Reirradiation.*** Dose escalation in patients undergoing reirradiation is important. A prospective, randomized study of dose escalation using 2D technique followed by boost delivery with 3D radiotherapy for patients with locally recurrent NPC showed a LC benefit for higher dose.[200] Thirty-six patients with >6 month interval from previous radiation (68–72 Gy) with local recurrence without nodal or distant metastasis were all treated with 2D EBRT to 54 Gy and then randomized to receive 3D-CRT boost doses of 16 Gy, 20 Gy, and 24 Gy in 4 Gy fractions/3× week. The median time to recurrence was approximately 3 years, and 56% had tumor confined to the nasopharynx. The dose allowed to the spinal cord and the brain stem was 15 to 20 Gy after previous treatment to 40 Gy. At a median follow-up of 27 months, 3-year local recurrence-free survival were 37%, 28%, and 72%, respectively, with the higher dose showing a statistically significant increase in LC ($p = 0.047$). No difference in 3-year overall survival was noted, 72%, 59%, and 82%, respectively, nor was any incidence in distant metastasis. The 3-year overall survival and incidence of distant metastasis for the entire three cohorts were 65% and 10%, respectively. One patient in the highest dose group had a fatal bleed, but there appeared to be no increase in grade 3/4 acute toxicities in the highest dose group. Late toxicities for the entire group included a 67% with trismus, 31% with posterior cranial nerve damage, 61% with tooth decay, and 8% with temporal lobe necrosis.

The addition of brachytherapy as a component of reirradiation appears to be important (Table 22.7). The role of brachytherapy was examined in 91 patients with recurrent nasopharynx cancer who were treated with reirradiation.[197] Eight patients were treated with brachytherapy alone (24–45 Gy in 3–10 fractions), 42 with EBRT (median dose 50 Gy) + brachytherapy (14.8 Gy in fractions), and 41 with EBRT alone (median dose 57.3 Gy). The breakdown of recurrent T stage were as follows: rT1: 37; rT2: 14; and rT3: 40. Fifty-eight percent of local recurrences were within 2 years of completion of initial radiation therapy. Neoadjuvant chemotherapy was given in 19%. Patients receiving EBRT+ brachytherapy had better LC compared with EBRT-only patients (57% vs. 34%, $p = 0.003$); however, there was a greater proportion of T3 patients in the EBRT arm. If only rT1–2 patients were analyzed, the EBRT+ brachytherapy showed a trend toward improved LC compared with EBRT alone (72% vs. 54%, $p = 0.13$). Fifty percent of patients treated with brachytherapy alone achieved LC. For all patients, the local failure-free survival for rT1, rT2, and rT3 were 64%, 62%, and 18%, respectively. Total dose >60 Gy and low rT stage were found on multivariate analysis to predict for tumor control.

One of the earliest reports advocating reirradiation as a salvage option was reported from the Massachusetts General Hospital (MGH). Wang reported the outcomes after reirradiation of 51 recurrent nasopharynx patients treated from 1950 to 1981.[193] The mean time from previous treatment to recurrence was 18 months. Patients were treated with 40 Gy EBRT followed by two brachytherapy boost of 10 Gy using $^{137}$ Cesium. EBRT alone to 66 Gy was used for T3/4 lesions. The 38 (33 T1–2, 5 T3–4) patients who received ≥60 Gy had a better 5-year survival than the 13 receiving <60 Gy (45% vs. 0%, $p = 0.0001$, respectively). Among patients receiving >60 Gy, the 5-year overall survival for T1–2 was 38% and 15% for T3/4 lesions. Patients who developed recurrence >24 months after initial treatment had better 5-year survival compared with those with a shorter time of relapse (66% vs. 13%, $p = 0.005$, respectively). The incidence of

long-term toxicities were reported to be 8% and included cranial neuropathies, osteoradionecrosis of the skull base, mucosal necrosis, trismus, and soft palate fibrosis.

Others have reported similar findings. Pryzant reported a 5-year LC of 35% and overall survival of 21% in 53 patients with best LC in those undergoing EBRT followed by brachytherapy.[194] Hwang showed a 5-year survival of 37% in 74 patients after reirradiation.[201] Lee reported a small series from UCSF of 12 recurrent cases treated with external beam 30 to 42 Gy with 5 to 7 Gy boost with HDR intracavitary brachytherapy or 10 to 54 Gy LDR.[195] The majority of patients were ethnic Chinese and all patients had WHO II or III histology. At a median follow-up of 50 months, the 5-year LC was 64% and overall survival was 91%. Three patients developed complication including osteoradionecrosis, stricture, and trismus.

The largest series of reirradiated patients was reported by Lee on a series of 706 patients with locally recurrence treated with EBRT with or without brachytherapy from 1976 to 1985.[196] Recurrent T1 comprised 40% of patients whereas 21% were T2. The 5-year overall survival for rT1 and rT2 were 27% and 17%, respectively, whereas survival was only 4% in rT3 or rT4. Late toxicity was 24% with a treatment mortality of 1.8%.

***Toxicity from Reirradiation and Brachytherapy.*** The incidence of severe complications is related to the total cumulative doseof external beam radiation. Patients receiving cumulative doses of external beam radiation >100 Gy had a higher incidence of severe complications (39% vs. 4%, $p = 0.066$) compared with those receiving <100 Gy. Such toxicities included cranial nerve damage, trismus, lymphedema, otoxicity, and temporal lobe necrosis.[194] The authors recommend limiting reirradiation doses of 20 to 30 Gy with EBRT followed by brachytherapy boost of 40 to 50 Gy. A 61% incidence of severe complications is reported by Teo, who attempted salvage therapy of 54 to 60 Gy followed by brachytherapy boost of 10 to 24 Gy in patients who previous received 60 to 62.5 Gy/24 to 29 fractions with possible additional treatment with parapharyngeal boost 20 Gy/10 fractions and/or brachytherapy 24 Gy/3 fractions.[198] Toxicities include soft tissue and bony necrosis, fistula formation, and cranial nerve damage. Complication rates reported by Leung were severe as nearly three-quarter of patients had a major complication with 50% having central nervous system complication at 5 years.[197] Temporal lobe necrosis occurred in 28% of EBRT-treated patients. Trismus was noted in 30% and deafness in 20%.

***IMRT for Recurrent Tumor.*** Lu reported the use of IMRT for reirradiation of recurrent nasopharynx cancer. Forty-nine patients with recurrent cancers were treated with IMRT to doses of 68 to 70 Gy at the primary site and 60 Gy to involved nodes. Mean doses to the brain stem, the spinal cord, the optic pathways, and the temporal lobes ranged from 20 to 28 Gy. T1–2 tumors comprised 13 of the patients while N0–1 comprised 46 patients. No comment is made about previous radiation doses or interval since initial treatment. Three patients with involved nodes were treated with chemotherapy after IMRT. The median time to recurrence after initial treatment for the study group was 19.5 months. At a median follow-up of 9 months, locoregional control was 100%, and 3 patients developed metastatic disease. Acute grade ≥3 toxicity was 4%, and tumor necrosis was noted in 29% without associated mucosal ulceration or bleeding.

Chua reported the results of reirradiation using IMRT for 31 patients with locally recurrent nasopharynx cancer.[202] rT3 or T4 comprised 74% (23/31) of the patients. Median time from the first course of treatment was 51 months. Median prescribed dose was 54 Gy (50–60 Gy) with induction chemotherapy in two-thirds and SRS boost (8.6–12.5 Gy) in one-third. At a median follow-up of 11 months, 1-year LC was 56% and overall survival was 63%. Local progression-free survival was 100% in 17 patients with rT1–3 tumors versus 35% in rT4. The 1-year actuarial rate of grade 3 or greater late toxicity was 25% (cranial neuropathy, otoxicity, and brain necrosis). Grade 3 to 4 toxicity occurred in 25% and included cranial neuropathy, neuropathy, otoxicity, and brain necrosis. Ototoxicity was most common and occurred in 42%. These results are preliminary and need longer follow-up before any assessment of efficacy and toxicity can be concluded.

## NASOPHARYNGECTOMY

With modern imaging, surgical technique, and supportive care, salvage nasopharyngectomy represents a good alternative to consider. Retrospective series reported LC in the 40% to 67% with best outcomes for early-stage patients.[203–205] Multiple surgical approaches are considered depending on tumor location. Subtotal nasopharyngectomy can be undertaken via a transpalatal approach with centrally located small tumors, with a maxillary swing approach for more extensive tumors and anterolateral approach with facial translocation for advanced tumors. An anterior and/or middle fossa resection is indicated when the tumor extends superiorly to involve the infratemporal fossa or the cavernous sinus.

Fee reported on 37 patients treated with nasopharyngectomy with or without RT.[204] Twenty-two patients with rT1 and 5 patients with rT2 were included. Mean time to recurrence after radiation was 29 months, and a median dose of 68 Gy was delivered. Patients underwent transpalatal, transmaxillary, or transcervical resection with or without neck dissection. Eight were treated with additional radiation for positive margins. At a median follow-up of 5.2 years, 5-year LC was 67%, 5-year disease-free survival was 52%, and overall survival was 60%. Five-year overall survival was 73% for rT1, 40% for rT2, 14% for rT3, and 0% for rT4. Corresponding 5-year LC was 77%, 40%, 57%, and 0%, respectively. Fifty-four percent had surgical complications with one perioperative death from carotid artery injury and one patient with pharyngeal plexus paralysis with resultant dysphagia. Transitory complications included osteoradionecrosis/osteomyelitis, palatal fistulas, thyroid storm, and pneumonia.

King reported on 31 patients (94% rT1 or rT2) undergoing nasopharyngectomy with 70% receiving postoperative radiation.[203] Five-year overall survival was 47% and LC was 43%. Complications included palatal defect in 55%, trismus in 48%, otitis media in 65%, dysphagia in 39%, and nasal regurgitation in 26%. Wei reported a 43% tumor control at 2.5 years in 45 patients with recurrent NPC undergoing nasopharyngectomy.[205]

Teo reported on 123 patients with locally recurrent NPC treated with reirradiation ($n = 103$) or nasopharyngectomy ($n = 20$).[198] rT1 and T2 comprised 44% of EBRT treated patients and 75% of surgery patients of whom 70% received postoperative radiation. At a median follow-up of 20 months, 5-year overall for all patients was 8% and 5-year LC was 15%. Survival was 26% for rT1, 8% for rT2, and 3% for rT3. Survival appeared to better in patients receiving nasopharyngectomy and post-op RT versus RT alone. At 2 years, freedom from further relapse was 40% of the 20 resected patients versus 20% for reirradiated patients. Among rT1–2 patients, nasopharyngectomy appeared to be superior to radiation. Temporal lobe necrosis occurred in 24%, trismus 70%, and hearing loss in 56%.

Chua showed no difference in survival in surgically treated patients ($n = 12$) compared with those treated with RT ($n = 94$) despite a selection bias in favor of surgery.[206] Five-year overall survival for T1/T2 was 57%. Thirty-four percent had neurologic complication with 30% incidence of trismus.

## Stereotactic Radiosurgery

SRS represents another option for salvage. Forty-eight patients with local failures were treated with SRS between 1996 and 2005 using a linac-based system with single or multiple isocenters.[207] A median dose of 12.5 Gy was delivered. At a median follow-up of 54 months, the LC was 47%, and 5-year overall survival 47%. Neuroendocine complication occurred in 27% without treatment-related deaths. Time interval from initial treatment, recurrent T stage, prior treatment failures, and tumor volume were significant predictive factors of LC and survival.

Cmelak reported the outcomes of 8 patients with recurrent nasopharyngeal cancers who had recurred 6 to 96 months after previous EBRT (58.2–79.2 Gy) and treated with SRS for 12 lesions (one patient had three separate lesions).[208] Patients were treated to a median SRS dose of 18 Gy (15–20 Gy). At a median follow-up of 17 months, about 7 of 12 lesions remain controlled locally. One patient experienced a facial nerve palsy 1 month after treatment.

## Fractionated SRT

Ahn reported the outcomes of 12 recurrent disease patients treated with fractionated SRT alone delivering a median total dose of 54 Gy in 2.5 to 3.0 Gy fractions.[209] Three patients received chemotherapy and one underwent debulking surgery. At a median follow-up of 13 months, the LC and survival at 2 years was 92% and 60%, respectively. One patient died of radiation myelopathy and six developed DM.

## SRS and Intracavitary Brachytherapy

Thirty-six patients with locally recurrent rT1 ($n$ = 19) or rT2 ($n$ = 17) were treated with SRS and intracavitary high-dose rate brachytherapy.[210] Eighty-six percent had locally recurrent disease (disease recurrence >4 months after previous EBRT). Median target volume was 36.3 cc (10.3–856.2 cc). Patients received 18 Gy of linac-based SRS to the 90% isodose followed by two intracavitary boosts of 6 Gy given a week apart. At a median follow-up of 4.2 years, the 5-year actuarial LC was 65% (rT1: 82%; rT2: 49%). Five-year overall and disease-free survival was 57% (rT1: 78%; rT2: 39%) and 62% (rT1: 80%; rT2: 48%), respectively. Complication-free survival rate was 31% at 5 years and consisted primarily of trismus (20%), cranial nerve palsy (20%), palatal fibrosis (17%), and osteoradionecrosis (17%) and temporal lobe necrosis (8%). No treatment-related mortality was reported.

## Interstitial Implant

Interstitial implant may offer higher and better accuracy of dose delivery to the recurrent tumor. Several interstitial series report excellent control that appears higher than intracavitary brachytherapy alone. However, this may be due to patient selection of more favorable lesions. The interstitial implants may be permanent or temporary and may be placed with exposure of the nasopharynx by soft palate retraction or via a transpalatal approach.

Gold-grain implants have been reported to offer favorable outcomes.[211,212] Fifty-three patients with recurrent or persistent tumors underwent gold-grain implant with a split palate direct visualization approach.[211] The 5-year LC was 63% and overall survival 56% in patients with rT1. The 5-year overall survival was 72% in those with persistent versus 54% in recurrent disease. Late complications comprised primarily headache in 28%, palatal fistula in 19%, mucosal necrosis in 16%, and neurologic complications in 12%.

Syed reported on 41 patients treated with interstitial implants and intracavitary brachytherapy alone for either recurrent ($n$ = 34) or new primary nasopharynx cancers ($n$ = 7) having received previous external beam radiation to the head and neck.[199] A mean dose of 50 to 58 Gy was delivered without external beam radiation using a temporary afterloading interstitial [192] Ir implant and an intracavitary applicator. Hyperthermia was used in about half of patients (21/41) with 8 patients receiving chemotherapy prior to implant and 17 patients received concurrent chemotherapy with 5FU and/or cisplatin. At a median follow-up of 7 years, the LC at 5/10 years was 59%/49%, overall survival 30%/20% and disease-free survival of 41%/34%. There were four perioperative deaths related to myocardial infarction, pneumonia, stroke, and cardiopulmonary failure. One patient died of massive epistaxis 9 months after treatment. About 45% experienced late complications including soft tissue necrosis (14%), dysphagia (11%), soft palate atrophy (11%), and nasal crusting (11%).

## Chemotherapy for Recurrent and Metastatic Disease

NPC is highly chemosensitive, and there has been multiple phase II trials demonstrating response rates of 50% to 90% to first-line combination chemotherapy, all of which containing platinum.[213–220,151,213–223] There has not been any phase III trial to compare between these multiple regimens, and hence the choice of chemotherapy regimen is currently based more on toxicity profile and reported response rates from phase II trials. Phase II studies using >2 drug combinations have generally been associated with a higher complication rate[224–228] although a recent study from Singapore using paclitaxel, carboplatin, and gemcitabine appears to be well tolerated.[229] Short of randomized phase III data, current options of first-line chemotherapy will be cisplatin in combination with infusional 5FU, paclitaxel, or gemcitabine. Newer chemotherapeutic agents demonstrating activity for NPC include irinotecan, capecitabine, docetaxel, vinorelbine, and oxaliplatin.[230–234] Combination first-line studies are ongoing.

## Long-term Survivors after Chemotherapy for Metastatic Disease

Several retrospective series have reported long-term survivors after systemic chemotherapy in metastatic NPC. The Institute Gustav-Russy series reported 20 survivors of >36 months after achieving complete response to chemotherapy.[235] The Hong Kong NPC Study Group series reported that patients with lung metastases only had a more favorable survival outcome after systemic chemotherapy compared with patients with other sites of failure.[148] Hence an aggressive approach to manage metastatic NPC patients with a good performance status is recommended, especially if the metastasis is confined to the intrathoracic site.

# FUTURE DIRECTIONS

## Targeted Therapy

***Epidermal Growth Factor Receptor (EGFR).*** EGFR is highly expressed in NPC and two recent reports demonstrated that EGFR expression is an independent predictor of poorer clinical outcome in NPC.[236,237] The activity of the monoclonal antibody against EGFR, cetuximab, has been investigated in a multicenter phase II study in combination with carboplatin in patients with recurrent or metastatic NPC who progressed within 6 months of platinum-based chemotherapy.[238] Thirty percent of the patient population had received >2 lines of prior chemotherapy. There were seven partial responses (11.7%) and 29 stable disease (48.3%) giving a combined clinical benefit of 60%. The toxicities were mild, and

(c) 2014 Wolters Kluwer. All Rights Reserved.

hence anti-EGFR therapy has significant activity in heavily pretreated metastatic NPC. Cetuximab is now being investigated in locally advanced NPC in combination with cisplatin-RT.

The EGFR tyrosine-kinase inhibitors gefitinib and erlotinib are both being tested in phase II trials in metastatic NPC. The preliminary result of a phase II study of gefitinib in patients who progressed after 1 to 2 lines of chemotherapy (at least one line containing platinum) for metastatic or locoregionally recurrent NPC has been reported.[239] Gefitinib was well tolerated and achieved stable disease for >6 months in 2 out of 11 evaluable patients, with no partial responders. Single-agent anti-EGFR therapy appears to be insufficient to achieve clinical response and ongoing studies combining these agents with chemotherapy in a sequential manner is ongoing. EGFR and Co × 2 are frequently overexpressed in NPC and there may be synergism between Co × 2 and EGFR inhibitors.[240] Investigators from Singapore are testing the combination anti-EGFR and Co × 2 inhibitor approach using celecoxib and gefitinib.

***Vascular Endothelial Growth Factor (VEGF).*** Overexpression of VEGF and its receptor VEGFR-1 and VEGFR-2 occurred in 60% to 90% of NPC biopsies and have been reported to be associated with regional and DM and poor survival outcome.[241–244]

Preclinical studies demonstrated promising activity targeting angiogenesis in NPC cell lines and xenograft.[245–247] Evidence of coexpression of c-kit and stem cell factor in NPC biopsies provide further support for the use of multitargeted tyrosine kinase inhibitors in NPC.[248] In a phase I study of the multitargeted receptor tyrosine kinase inhibitor sunitinib, one NPC patient demonstrated significant tumor shrinkage and necrosis.[249] A phase II study evaluating sunitinib is ongoing.

With the demonstrated survival benefit of bevacizumab (monoclonal antibody against VEGF) in multiple solid tumors including colon, lung, and breast cancer and the knowledge that NPC patients with elevated VEGF have a higher likelihood of DM and poorer survival. The RTOG conducted a phase II trial to determine the feasibility of the addition of bevacizumab during the concurrent and adjuvant phase of the Intergroup 0099 regimen in 44 patients. The dose limiting toxicity evaluated with grade 3 hemorrhage. No grade 3 hemorrhage was reported although 20% experienced a grade 1/2 hemorrhage while 9 patients had grade 4 hematologic toxicity. Seventy percent of patients received all 3 cycles of adjuvant chemotherapy. At a median follow-up of 2.5 years, the 2-year locoregional control was 84% and 2-year DM was 9% with a 2-year overall survival of 91% (Lee, *Lancet Oncol.* 2012;13:172–180).

## Epigenetic Therapy

CpG promoter methylation and histone deacetylation play crucial roles in the transcriptional regulation of gene expression in the EBV genome.[250] Silencing of the immunodominant EBV nuclear antigen (EBNAs-2, 3A, 3B, 3C) expression through methylation may serve as a target for epigenetic therapy using DNA methyltransferace (DNMT) inhibitors. In patients with EBV-positive malignancies who have failed conventional treatment, a clinical trial of the DNMT inhibitor Azacitidine was conducted aiming at the demethylation of EBV promoters and also upregulating expression of the silenced viral antigens.[251] In the 5 patients with adequate pre- and posttreatment biopsies, demethylation to varying degrees of all the latent and early lytic EBV promoters was demonstrated. Viral gene reexpression was observed in one antigen by immunohistochemistry. This pioneering study demonstrated for the first time that demethylation of tumor DNA in patients can be achieved using azacitidine. A follow-up study combining the histone deacetylase inhibitor SAHA with azacitidine is ongoing.

## Immunotherapy

EBV is ubiquitous in undifferentiated NPC, and hence the viral antigens expressed by the tumor provide potential targets for immunotherapy.[252–255] Adoptive therapy using cytotoxic T cells (CTLs) have been highly successful in treatment of EBV-associated, posttransplant lymphoproliferative disease (PTLD), which express the immunodominant EBV nuclear antigens EBNA 3A, 3B, and 3C. In contrast, NPC express a restricted set of less immunogenic viral antigens EBNA1, LMP1, and LMP2.

## Adoptive Therapy

The first pilot study to treat NPC using adoptive T-cell therapy was reported by Chua et al.,[256] where autologous EBV-transformed B-lymphoblastoid cell line (LCL) reactivated T cells were generated *in vitro* and used to treat four advanced cases of NPC. No adverse events occurred and infusion of CTL was associated with reduction of plasma EBV load. However, there was no evidence of tumor regression.

The use of autologous EBV specific CTL for NPC has since been evaluated in two clinical trials with 10 patients treated in each study.[257,258] Both studies demonstrated that EBV targeted autologous CTL is safe, induces LMP2-specific immune response, and is associated with objective response and control of disease in advanced NPC. Interestingly, Comoli et al. also reported the adoptive transfer of an allogeneic EBV specific CTL in one patient with relapsed NPC resulted in temporary stabilization of disease. Local tumor biopsy showed increase in tumor infiltrating CD8 T cells.[259] Taken altogether, the result of these studies showed that it is feasible to boost EBV-specific immune response in NPC patients and provide further rationale to explore EBV as a target for immunotherapy.

## Vaccination

A vaccine consisting of dendritic cells pulsed with peptides derived from LMP2 has been evaluated in 16 patients with local recurrence or distant metastasis after conventional treatment.[260] Peptide-specific T-cell response were elicited or boosted in nine patients and partial tumor reduction was observed in two patients. A vaccination trial is ongoing using a modified vaccinia virus expressing an EBNA1-LMP2 fusion protein to elicit CD4+ and CD8+ T cell against two EBV proteins expressed in NPC patients.[261] Alternatively, an LMP-based polyepitopte vaccine has also been developed for EBV-associated Hodgkin disease and NPC.[262,263]

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

Cancer of the nasopharynx is staged differently than other pharyngeal primaries in that more emphasis is placed on tumor extension to other spaces than on size. Therefore, it is critical that imaging clearly shows the full extent of the primary lesion. As with other mucosal tumors, endoscopy can show the mucosal extent of the tumor very well, but deep tumor invasion requires imaging. Extension to the nasal cavity or oropharynx as well as parapharyngeal invasion classifies the tumor as T2 (Fig. 22-6). A T3 lesion involves bony structures and/or the paranasal sinuses. The tumor is upstaged to T4 if there is intracranial extension, involvement of the cranial nerves, the infratemporal fossa, the hypopharynx, the orbit, or the masticator space (Fig. 22-7). Because of the importance of detecting soft tissue invasion, intracranial extension, and perineural spread, magnetic resonance imaging (MRI) is preferred to computed tomography (CT) for imaging of nasopharyngeal cancers.[1–4] However, care must be taken with fat suppression as this often produces artifacts at air-bone interfaces at the skull base. CT is not without benefit as it is very good at showing cortical bone erosion.

Usually, the diagnosis of nasopharyngeal cancer is known at the time of imaging, but occasionally it is found incidentally when imaging patients with unilateral serous otitis media and Eustachian tube dysfunction, otalgia, sore throat, or cranial neuropathies. When a tumor is discovered, it is essential to describe its pattern of spread and full extent so that the patient can be correctly staged and treated appropriately. Often both CT and MRI are obtained and these certainly give complementary information. Usually, the neck is scanned with CT to evaluate lymphadenopathy as the addition of a neck MR adds significant time and expense to the MR study. Suggested protocols are given in Figures 22-8 and 22-9.

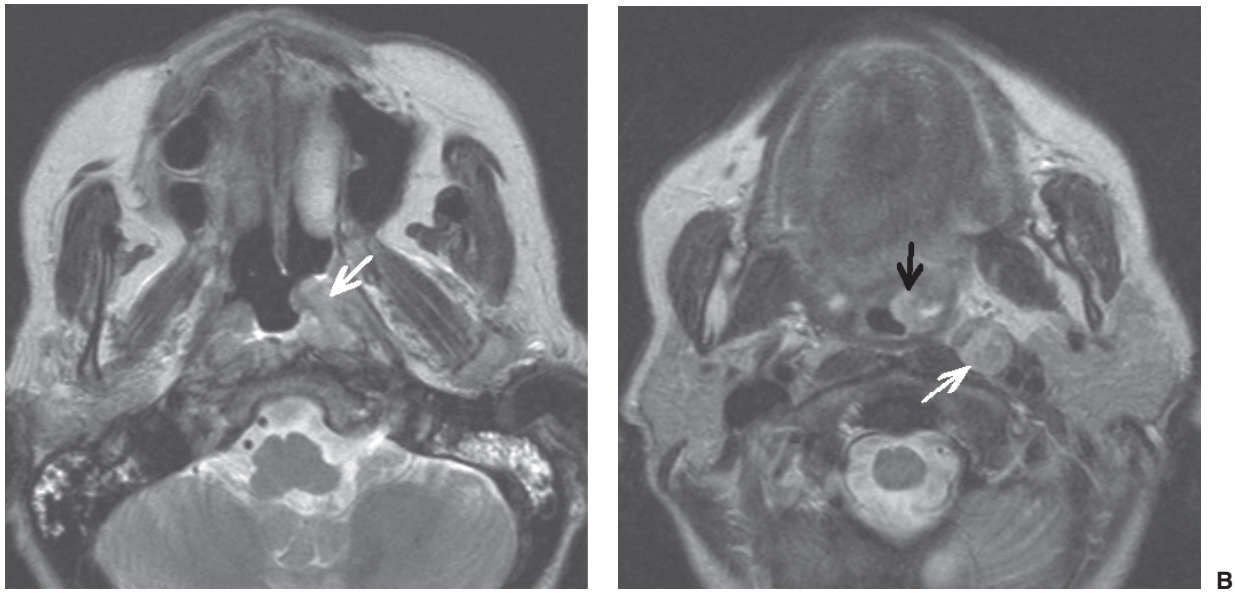

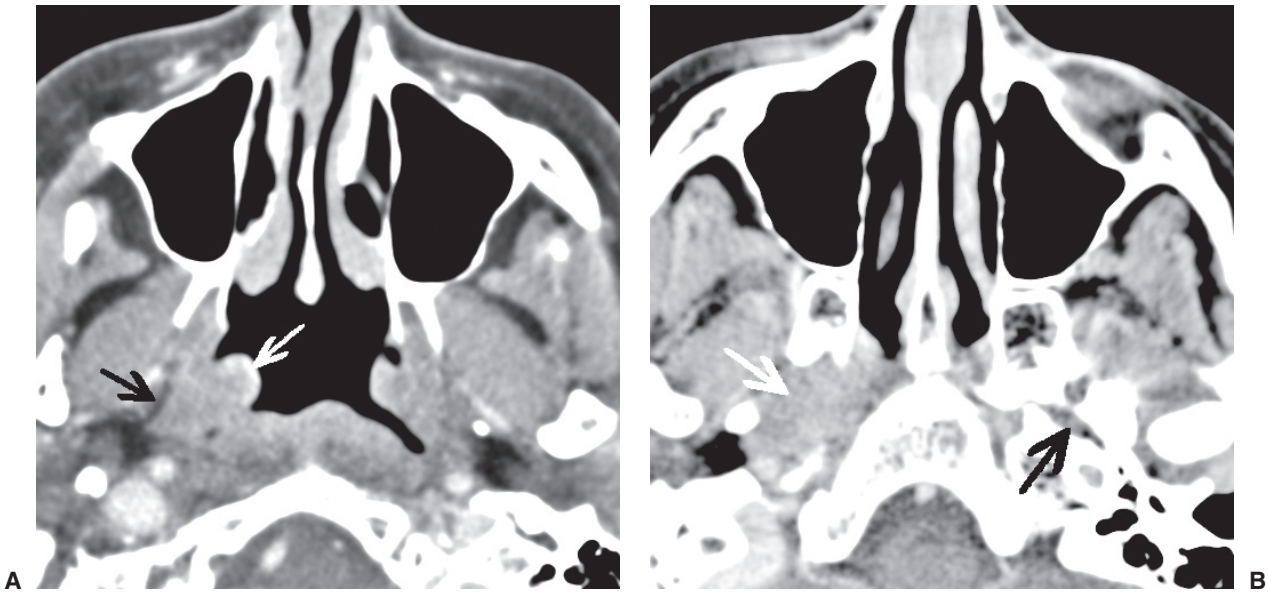

**FIGURE 22-6.** **A:** Axial T2-weighted MR image shows an infiltrating mass (*arrow*) in the left nasopharynx which has expanded the torus tubarius and obstructed the Eustachian tube orifice. No extension is seen into the parapharyngeal space fat. **B:** Axial T2-weighted MR image inferior to shows extension of tumor along the lateral pharyngeal wall into the oropharynx (*black arrow*). This stages the tumor as T2a. A positive left lateral retropharyngeal lymph node is well demonstrated (*white arrow*).

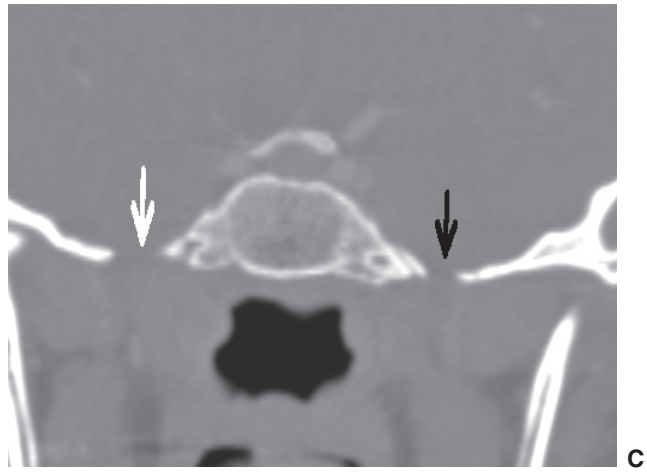

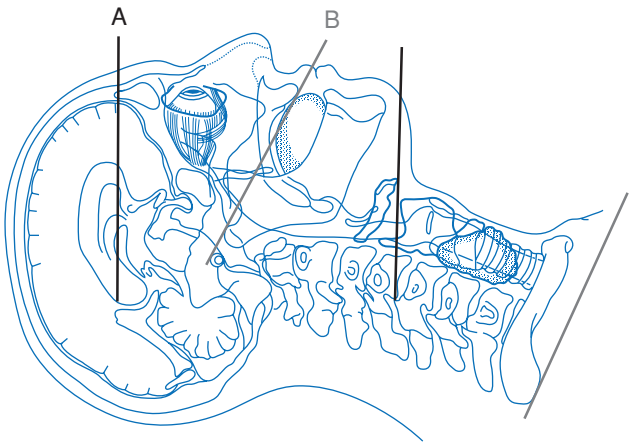

**FIGURE 22-7.** **A:** Axial postcontrast CT scan shows a right nasopharyngeal mass (*white arrow*). Note the preservation of fat in the parapharyngeal space deep to the pharyngobasilar fascia (*black arrow*). **B:** Axial postcontrast CT at the level of the temporomandibular joints shows that the tumor has spread superiorly (*white arrow*) and has destroyed bone at the petrous apex in the region of the foramen lacerum. Note the normal foramen lacerum on the opposite side (*black arrow*). **C:** Coronal reformat of the CT scan with bone windows shows enlargement of the right foramen ovale (*white arrow*) compared with the normal left foramen ovale (*black arrow*). At this point, an MRI would be warranted to look for more proximal spread of tumor along V3 to the trigeminal ganglion.

Nasopharyngeal carcinoma can arise from any of its mucosal walls and occasionally will arise deep within the crypts of the adenoids where it may hide from the endoscopist leading to the diagnosis of unknown primary. However, when found, the unknown primary is more often discovered in the oropharynx or piriform sinuses.

Tumor can spread in all directions from the nasopharynx. Inferior extension is common into the lateral oropharyngeal wall or the palatine tonsil. This spread may be submucosal. Apparent bulky inferolateral spread may in fact be due to large lateral retropharyngeal nodes which are commonly involved (Fig. 22-10). Anterior spread through the posterior choana into the nasal cavity is usually seen in large tumors and is often detected clinically (Fig. 22-11).

Lateral spread to the parapharyngeal space is usually through the gap in the pharyngobasilar fascia called the sinus of Morgagni. Once in the parapharyngeal space, tumor can grow laterally into the infratemporal fossa and the masticator space (Fig. 22-12), or superiorly to the skull base (Figs. 22-13 and 22-14). In addition, from the parapharyngeal space, the tumor can extend along the trigeminal nerve to the skull base (Fig. 22-15).

Direct invasion of the skull base is primarily at the central and posterior skull base (Fig. 22-16). Invasion into the sphenoid

(c) 2014 Wolters Kluwer. All Rights Reserved.

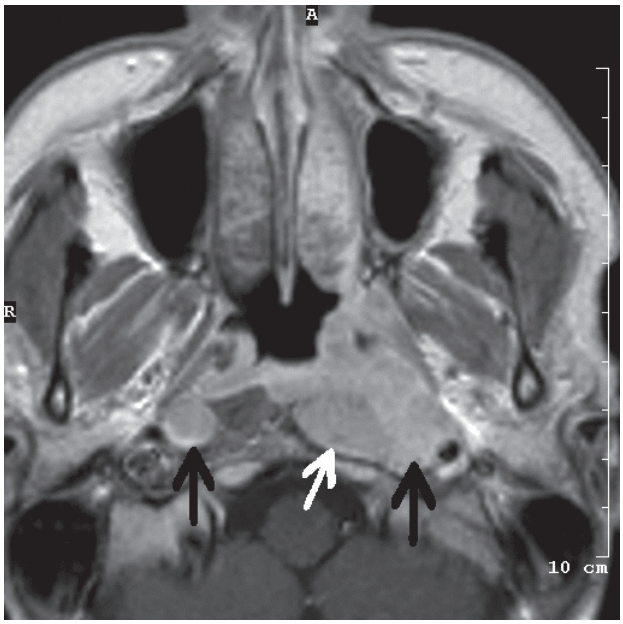

**FIGURE 22-10.** Axial T1-weighted postcontrast MRI shows a large left nasopharyngeal squamous cell carcinoma. There is apparent posterolateral extension into the retrostyloid parapharyngeal space. However, this is actually a positive lateral retropharyngeal lymph nodes with extracapsular spread and a positive right retropharyngeal node is also present (*black arrows*). Tumor has grown posteriorly to invade the prevertebral space with involvement of the flexor muscles of the neck (*white arrow*).

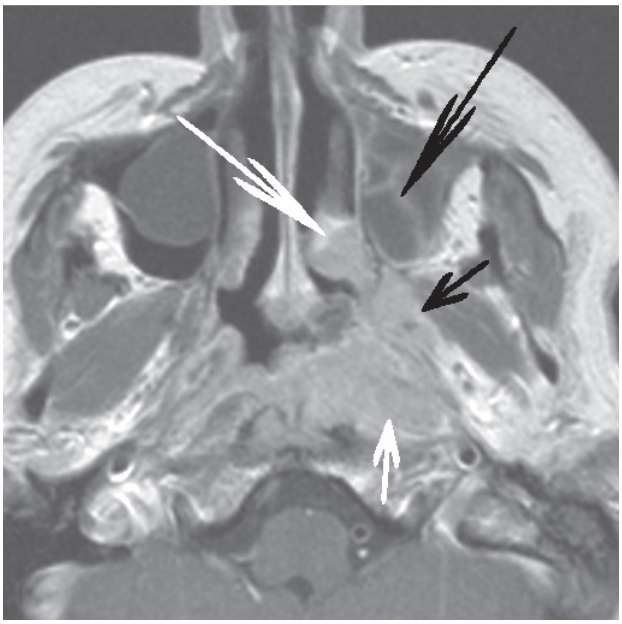

**FIGURE 22-11.** Axial T1-weighted contrast-enhanced MRI shows an infiltrating mass in the left nasopharynx (*short white arrow*) that has spread anteriorly through the posterior choana to invade the nasal cavity. The left superior turbinate is involved with tumor (*long white arrow*). Tumor has spread laterally into the parapharyngeal space (*short black arrow*). Notice the different signal of mucosal disease in the maxillary sinuses where there is reactive mucosal enhancement (*long black arrow*).

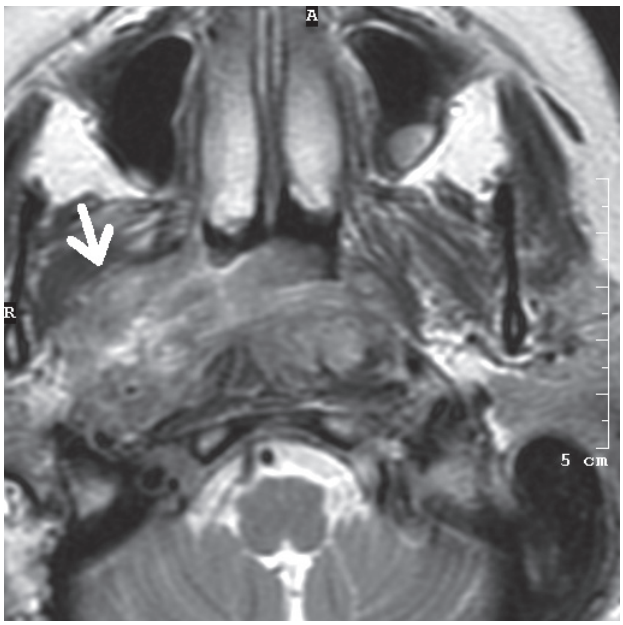

**FIGURE 22-12.** Axial T2-weighted MRI shows lateral spread of a nasopharyngeal mass into the masticator space where the pterygoid muscles have been invaded (*arrow*) resulting in trismus.

sinus is common. Direct extension to the petroclival fissure and region of the foramen lacerum is also common. Tumor can also spread along the tensor veli palatini muscle and the levator veli palatini muscles to encroach on the skull base.

The lymphatic plexus in the nasopharynx is very extensive which is why even small nasopharyngeal tumors often present with extensive lymphadenopathy. The spread pattern is to the lateral retropharyngeal nodes and then inferiorly to level 2 through 5. Bilateral positive lymph nodes are not uncommon.

A recent positron emission tomography (PET)/CT study investigated a measure of the heterogeneity of fluorodeoxyglucose (FDG) uptake in nasopharyngeal cancers and found a correlation with maximum SUV, tumor volume, and T category.[5] The tumors with greater FDG uptake heterogeneity were more aggressive. This may be another quantitative factor along with maximum SUV uptake that might help determine tumor aggressiveness and may help predict patient survival.

Posttreatment follow-up scanning is typically performed with CT or MRI and may require a baseline posttreatment scan performed 3 to 4 months following completion of therapy and subsequent surveillance scans to look for nodular growth suggestive of tumor recurrence. FDG-PET has not had established accuracy in the assessment of recurrence of the primary lesion. This may be because of the normal high FDG uptake in the adjacent brain and poor spatial resolution. A negative PET scan 3 to 4 month after treatment is still very encouraging. FDG-PET is still excellent for the detection of lymphadenopathy (Fig. 22-17) and distant disease.

# PART C:
# Radiation Therapy Technique

Kenneth S. Hu, Louis B. Harrison, James E. Dolan, and Rudolph Woode

As discussed in the body of Chapter 22, intensity-modulated radiation therapy (IMRT) has been shown to produce extremely high rates of local and regional control. Indeed, in the IMRT era, local failure for nasopharyngeal carcinoma (NPC) has become increasingly uncommon. No doubt, the ability of the radiation oncologist to encompass the entire disease extent, while maintaining protection of the adjacent vital structures, is core to the success achieved with IMRT.

IMRT also allows the opportunity for some dose reduction to the parotid glands. Care must be taken while contouring the neck nodes and the parotids because there can be nodes near the glands. In the authors' experience, although some parotid sparing is usually feasible, it is not as complete as it is for other sites. This may reflect the authors' conservatism in our contouring and treatment delivery. IMRT is very much physician dependent, and the authors recognize that variations in contouring and delivery will occur from one radiation oncologist to another, and from one center to another.

Figure 22-18 shows a clinical example of a patient with NPC treated with IMRT. The authors' technique generally involves seven fields for the primary site and upper neck, matched to a low neck field. Careful contouring of the primary site (including extension to the parapharyngeal space, the skull base, and any intracranial extension), the regional lymphatics (including the retropharyngeal nodes), and nearby vital organs (the optic chiasm, the spinal cord, the brain stem, the parotid glands, and any other organ dictated by the extent of disease) are crucial.

Figures 22-19 through 22-25 show a second patient and some added technical details. This patient is a 34-year-old Asian female who presented with rhinorrhea, epistasix, bussing in the right ear, and headache. Figure 22-19 shows the Positron emission tomography (PET)-computed tomography (CT) with the PET component beside the CT component, for ease in visual display. Disease extends into the oropharynx and involves bilateral retropharyngeal nodes. This patient was treated with IMRT. Figure 22-20 shows isodose display through the superior nasal cavity, at the inferior orbital level. Figure 22-21 shows a CT cut and isodose display at the level of the maxillary sinuses. The skull base, the superior nasal cavity, the maxillary sinus, and the pterygopalatine fossa were included in the intermediate risk CTV and treated to 5,400 cGy in 6 weeks. The temporal lobes and the brain stem are contoured in Figure 22-20 and the right cochlea is seen in Figure 22-21.

Figure 22-22 shows the isodose display through the nasopharynx. The gross tumor volume (GTV) is shown as the inner contour. The planning target volume (PTV) margin was 3 mm expansion on the GTV. An intermediate risk CTV was added to an additional minimum 5-mm margin which included the entire right parapharyngeal space and part of the left parapharyngeal space. Figures 22-23 and 22-24 show isodose displays through the oropharynx and neck. The GTV covers the primary disease extension as well as the involved lymph nodes. The oral cavity is contoured in Figure 22-23B in an effort to spare the minor salivary gland tissue.

Figure 22-24 shows the isodose display through the neck at the level of the larynx. The relative sparing of the larynx and the constrictor muscles is demonstrated, which is a key ingredient to a successful IMRT plan. The GTV is also shown correlating with an involved level 3 node. The brachial plexus is also protected.

Figure 22-25 shows the dose–volume histogram. There is good target coverage and good protection of all appropriate normal structures.

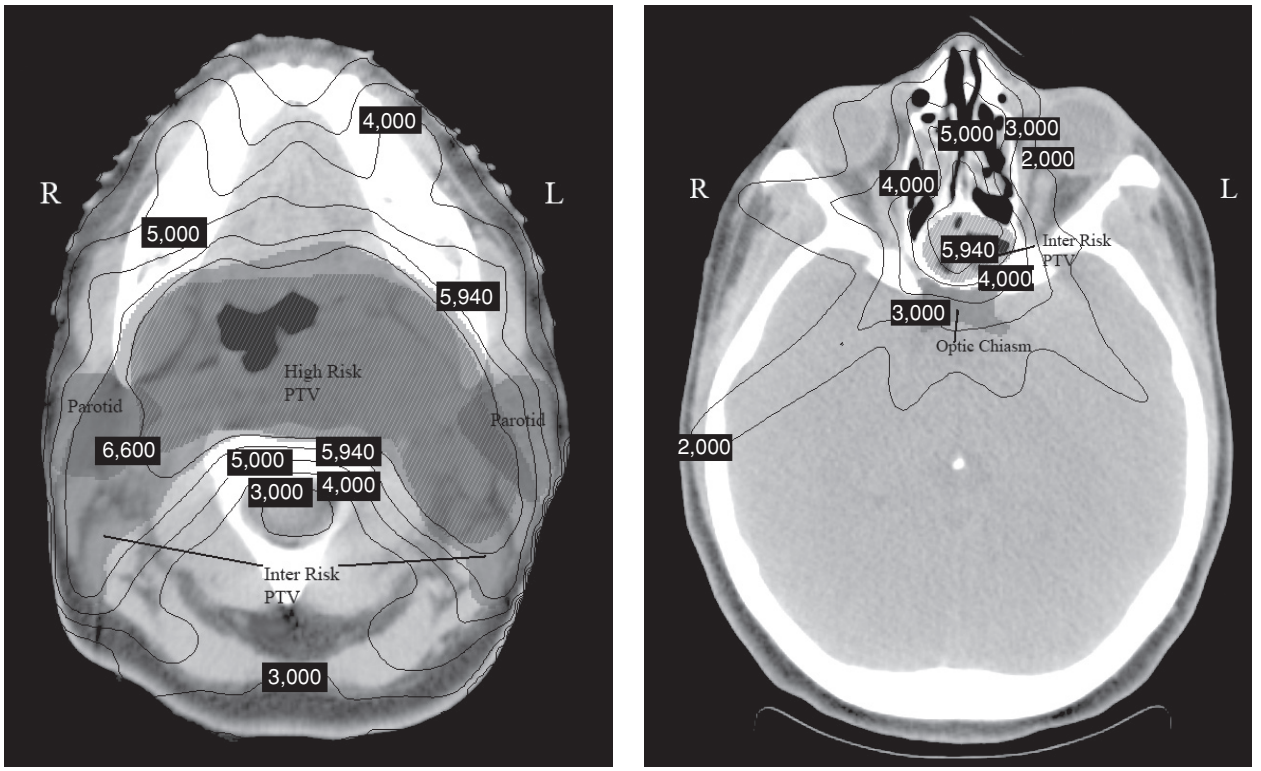

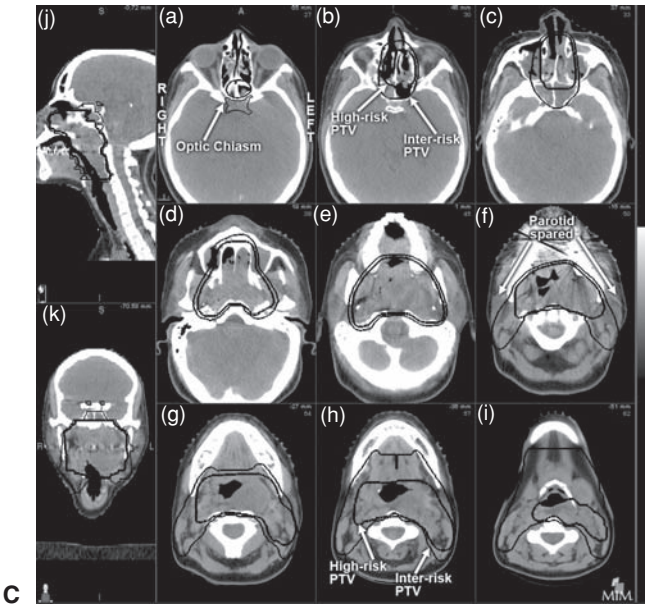

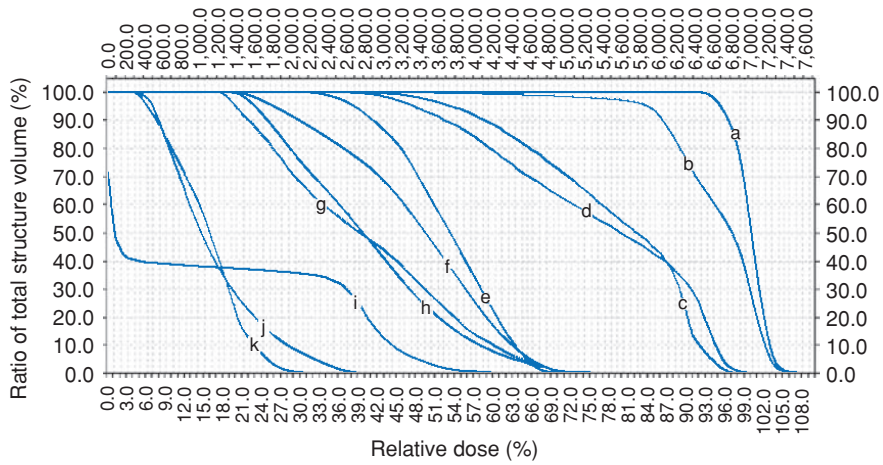

**FIGURE 22-18.** This patient had a T3-N2-M0 American Joint Commission for Cancer (AJCC) stage III squamous cell cancer of the nasopharynx. Positron emission tomography (PET)-computed tomography (CT) revealed the primary tumor mass occupying the nasopharynx with bone erosion through the floor of the sphenoid sinus and with extension into the oropharynx. There was left-sided retropharyngeal adenopathy and bilateral cervical adenopathy at level II. There was no evidence of distant metastases. The treatment plan utilized intensity-modulated radiation therapy (IMRT) with concomitant and adjuvant chemotherapy. The prescription dose to the high-risk PTV (primary site and all known nodal disease) was 6,600 cGy, and the intermediate risk PTV (safety margin around gross disease and adjacent, uninvolved nodal stations) received a minimum of 6,000 cGy. Care to protect the optic chiasm, the brain stem, the spinal cord, the bilateral retinas, and the parotid glands (spared to a lesser extent due to nodal involvement) are demonstrated in the dose–volume histogram. **A:** Isodose distribution displayed on an axial CT used for treatment planning. This shows the high-risk PTV, the interrisk PTV, both parotid glands, and the spinal cord. The high-risk PTV is well covered by the 6,600 cGy isodose, and the interrisk PTV is well covered by the 5,940 cGy isodose. A dose-painting technique was used which delivered 200 cGy/fraction to the high-risk PTV and 180 cGy/fraction was used for the interrisk PTV. Sometimes, the authors do increase the daily dose to the high-risk PTV beyond 200 cGy, but elected not to do so in this case. The patient was 19 years old and the volume was fairly large. **B:** Isodose distribution at a superior aspect of the axial CT used for treatment planning. It shows the sparing of the optic chiasm, which was of great importance to this patient. She made it explicitly clear that she would rather lose her life than her vision. There were secretions in the sphenoid sinus that represent the upper borders of the interrisk PTV. This area was not hypermetabolic on PET-CT. Most of it was encompassed by the 5,940 cGy isodose, although extra caution was taken due to her concerns about vision. **C:** This figure was produced using the Mim-Vista system. It shows representative serial radiation therapy (RT) planning slices as well as representative contours. (a) Contours show the upper limit of the interrisk PTV (extra safety margin around high-risk PTV including nonhypermetabolic secretions in the sphenoid sinus) as well as the optic chiasm. (b) Contours show the interrisk PTV and the superior limit of high-risk PTV. (c) Contours show high-risk and interrisk PTV. The authors' practice is to add additional safety margin around the high-risk PTV and include that in the interrisk PTV. Note that the entire sphenoid sinus is included in the interrisk PTV in this cut. (d) High-risk and interrisk PTV. (e) Same as (d). (f) Same as (c). The uninvolved regional neck nodes are part of the interrisk PTV. There is relative parotid sparing. (g) Same as (f). The involved regional neck nodes are part of the high-risk PTV. The uninvolved nodes are part of the interrisk PTV. (h) Same as (g). (i) Same as (g). This is the inferior cut, at level of the hyoid bone. The low neck is treated with an anteroposterior (AP) low neck field. (j) Midsagittal contour showing high-risk and interrisk PTV. (k) Coronal reconstruction showing high-risk and interrisk PTVs and extreme lateral aspects of the optic chiasm. **D:** Dose–volume histogram.

# PART D:
# Surgical Technique

William Ignace Wei and Jimmy Yue Wai Chan

## INTRODUCTION

The primary treatment modality for cancer of the nasopharynx is radiotherapy for early-stage diseases and concomitant chemotherapy and radiation for advanced-stage diseases. Surgical resection of cancer of the nasopharynx is only applicable when the cancer persists or recurs after the initial treatment.[1] For a group of 246 patients who underwent salvage nasopharyngectomy with a median follow-up of 38 months, the 5-year actuarial control of disease was 74% and the 5-year disease-free survival was 56%. Tumor size of <1.5 cm and negative resection margins were the two independent factors that affected the local tumor control and survival.[1]

The nasopharynx is located at the central skull base that anatomically is in the centre of the head and it is >10 cm from the skin surface from all directions. It is difficult to expose this region adequately for surgical resection of the tumor comfortably; this is particularly so when the lesion is malignant and has potential to infiltrate nearby structures.

Currently, there are two surgical techniques commonly employed for the resection of cancer of the nasopharynx.

1. Maxillary swing approach to expose the nasopharynx and the central skull base so that the malignant tumor in the region can be resected with adequate margin.[2]
2. The palate was split to expose the cancer in the nasopharynx and the tumor resection was carried out with the Da Vinci Robot.[3]

The maxillary swing approach originated from the observation that during maxillectomy for carcinoma of the maxillary antrum, the nasopharynx was widely exposed when the maxilla bone was removed. The anterolateral approach to the nasopharynx was thus developed; the maxillary antrum including the lateral walls and the floor attached to the anterior cheek flap could be swung laterally as an osteocutaneous flap to expose the pathology in the nasopharynx. After removal of the pathology, the maxillary antrum was returned to its original position and fixed to the rest of the facial skeleton (Fig. 22-26).

The surgical approach involves a Weber Ferguson facial incision as in maxillectomy, incision on the palate, osteotomies of the anterior wall, medial wall of the maxillary antrum, and lower portion of the zygomatic arch. The pterygoid plates are also separated from the maxillary tuberosity. This anterolateral approach exposed the nasopharynx and its vicinity from the side of the swing. With the removal of the posterior part of the nasal septum, the contralateral nasopharynx can be exposed. Persistent or recurrent cancer of the nasopharynx after chemoradiation can be removed adequately, and if there are paranasopharyngeal lymph nodes, these can be resected under direct vision. With the wide exposure of the nasopharynx and its vicinity following the maxillary swing approach, the internal carotid artery lying in the paranasopharyngeal space could be identified with palpation and vision, thus avoiding its injury during tumor extirpation; this is particularly important during the dissection of the paranasopharyngeal lymph node.[4] A microvascular free flap could also be employed to cover the exposed vessel and the raw area following removal of tumor in the nasopharynx. With this additional new vascular supply, further adjuvant therapy could then be considered.[5]

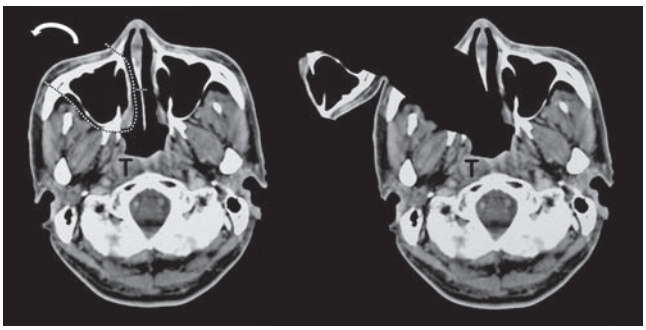

**FIGURE 22-26.** Schematic computed tomography. **Left:** Dotted line marks the osteotomy, the posterior part of the nasopharynx is removed to increase the exposure of the contralateral nasopharynx. **Right:** The maxillary antrum attached to the anterior cheek flap is swung laterally as one osteocutaneous complex, exposing the nasopharynx and a small tumor (T).

The morbidity associated with the operation was acceptable. The facial scar usually heals well and becomes less obvious with time. The development of significant trismus in patients who had previous radiation could be managed with passive mechanical stretching and this frequently improves the trismus. With the resection of the Eustachian tube, the patient develops serous otitis media on the side of the swing and this results in deterioration of hearing acuity.

The Da Vinci Robot have been reported for the resection of recurrent nasopharyngeal carcinoma. With the splitting of the palate, the tumor in the nasopharynx is exposed. It is, however, difficult to employ the ordinary instruments to resect the tumor en bloc with a good resection margin. With the versatility of the endowrist of the Da Vinci Robot and the 3D camera, adequate resection is possible with splitting of the palate. The location and the size of the tumor are determinants for a successful resection. Those tumor of around 1 cm diameter, not deeply infiltrative and located in posterior wall, not extending laterally beyond the floor of pharyngeal recess, have a better chance of being resected completely with the robot. The morbidities associated with this split palate approach are limited, patient might develop palatal fistula as the patient had previous radiation with or without chemotherapy. Exposure of the raw area in the nasopharynx following resection might lead to the development of osteoradionecrosis of the skull base bone.

## PREOPERATIVE PREPARATION AND ANAESTHESIA

For patients undergoing the resection of persistent or recurrent cancer in the nasopharynx, full cardiopulmonary assessment is essential to evaluate whether he or she can stand the procedure

(c) 2014 Wolters Kluwer. All Rights Reserved.

as the blood loss might occasionally be significant, especially with the maxillary swing procedure. The interalveolar distance should be at least 3 cm wide as otherwise it is difficult to raise the palatal flap transorally and to insert the curved osteotome to separate the pterygoid plates from maxillary tuberosity. A significant degree of trismus will also prevent the insertion of the robotic arm transorally for tumor resection. The interalveolar distance also prompts the anaesthetist to consider the appropriate route to insert the endotracheal tube. An upper alveolar dental plate is fabricated for each patient before the maxillary swing procedure; this is used to clip onto the teeth on the upper jaw upon return of the swung maxilla, ensuring correct repositioning and precise dental alignment.

Preoperative evaluation of the extent of persistent or recurrent cancer of the nasopharynx is mandatory before surgical resection. In addition to a full clinical examination, an endoscopic examination of the nasal cavities, the nasopharynx, and the oropharynx together with a cross-sectional imaging study such as computed tomography or magnetic resonance imaging is required to determine the extent of the cancer in the nasopharynx. Magnetic resonance imaging with contrast evaluates the proximity of the tumor to the internal carotid artery and possible involvement of soft tissue in the regions, such as the paranasopharyngeal lymph nodes. Computed tomography with bone window should be carried out to see whether the clivus or skull base bone is affected. For more extensive tumor in the nasopharynx or patients with both recurrent tumor in the nasopharynx and cervical lymph nodes, a positron emission tomography is indicated to rule out distant metastasis.

## SURGICAL TECHNIQUE

### Maxillary Swing Procedure

The operation is carried out under general anesthesia with the patient in supine position. The head is placed on a soft head ring to allow mobility and there is no need for any support behind the shoulders to extend the neck, unless a neck dissection or neck exploration is also planned. Endotracheal intubation is carried out through the mouth if possible as this avoids disturbance of pathologies in the nasopharynx. A temporary tracheostomy is then carried out and the endotracheal tube is withdrawn. The tracheostomy is optional as the procedure can be carried out with the transoral endotracheal tube in position. The presence of the tube, however, interferes to a certain extent the raising of the palatal flap and the osteotomy of the hard palate.

At the completion of the operation, the nose and the nasopharynx is usually packed with ribbon gauz and the discharge from the raw surface and the oropharynx might lead to partial airway obstruction. A temporary tracheostomy aids to maintain the airway. If this is not done following the endotracheal intubation at the start of the operation, it is usually carried out at the completion of the procedure. Endoscopic examination to confirm extent of the persistent or recurrent tumor in the nasopharynx was carried out before starting the operation.

Protective eye ointment is used in the contralateral eye, which is drafted off the operative field. The oral cavity and the nasal cavities are irrigated with copious amount of antiseptic solution such as chlorohexidine. Preoperative intravenous antibiotics are given, which usually include a metronidazole for anaerobic bacteria and a cephalosporin for aerobic bacteria.

The Weber Ferguson facial incision is used as, for maxillectomy, the horizontal limb of the incision is placed at about 5 mm below and parallel to the lower eyelid margin. The incision over the lip is designed to be zigzag to prevent postoperative contracture (Fig. 22-27) and the horizontal limb curves down laterally along the skin crease to stop at about 0.5 cm above the lower edge of the zygomatic arch. Tarsorraphy is done for the eye on the side of the swing to avoid inadvertent trauma to the cornea.

**FIGURE 22-27.** The facial incision is marked, with the incision over the lip in zigzag form.

The lip incision on the lingual surface continues to extend posteriorly to stop between the two central incisors. The palatal wound is a curved incision placed at a distance of 0.5 mm from the teeth margin, and it is continued posteriorly until the last molar tooth and then continued laterally behind it to stop just before reaching the buccal mucosa (Fig. 22-28). This allows the elevation of soft tissue and mucoperiosteum over the hard palate as a palatal flap with blood supply from the opposite mucosperiosteum of the hard palate and the soft palate.[6]

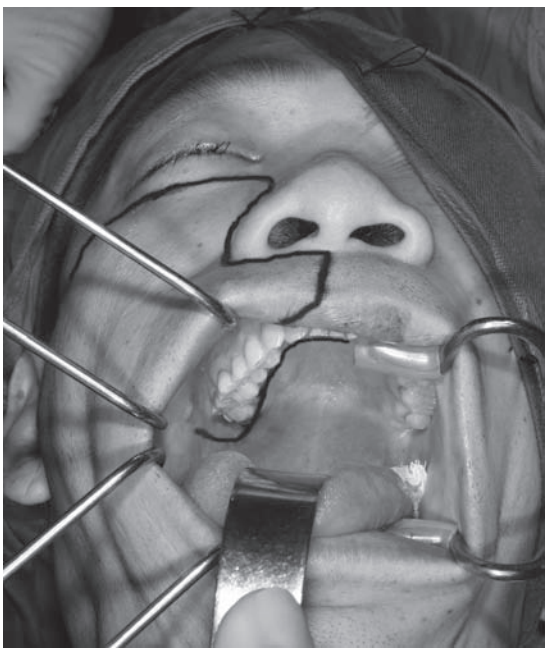

**FIGURE 22-28.** The palatal incision is marked, goes along the lingual aspect of the upper alveolar margin, and curves laterally behind the last molar tooth.

(c) 2014 Wolters Kluwer. All Rights Reserved.

The skin incision over the face goes through the skin, the subcutaneous tissue, and also the orbicularis oris muscle. The thin muscle is lifted together with the facial skin until the orbital rim is reached. The orbital septum should not be cut, or else the periorbial fat will be herniated into the wound. Although it is not harmful to the patient, it could be a nuisance during the elevation of the facial flap. The skin incision over the lip is continued and the orbicularis orris muscle is divided in the line of skin incision.

The horizontal limb of the facial incision goes down to the anterior wall of the maxilla, and limited amount of soft tissue over the anterior wall of the maxilla is elevated to expose a strip of bone for osteotomy. This osteotomy site is 0.5 cm below the orbital rim and frequently goes through the infraorbital foramen. The infraorbital nerve and the vessels are identified and divided. This reduces blood loss when the oscillating saw cuts through the infraorbital foramen. This osteotomy divides only the lower half of the zygoma (Fig. 22-29).

In preparation of the midline osteotomy, soft tissue and mucoperiosteum over the hard plate have to be lifted off the bony hard palate. The palatal incision goes down to hard palate bone, and the soft tissue together with the mucoperiosteum is lifted with a sharp periosteal elevator. The greater palatine vessels coming through the palatine foramen are seen. These should be divided and the palatal flap can then be raised further medially across the midline and posterior to the posterior edge of the hard palate. The attachment of the soft palate on the hard palate is divided with diathermy and the nasal cavity is entered.

A cured osteotome is inserted into the groove between the maxillary tuberosity and the pterygoid plates. The groove lies behind the hamulus which is lying posteromedial to the molar tooth. The osteotome has to be curved so that when it is placed in the groove and driven by the mallet, hitting on its head, it goes vertically upward separating the posterior wall of the maxillary antrum from the pterygoid plates (Fig. 22-30).

Before the start of the osteotomy, a four-hole titanium plate is placed across the osteotomy line on the anterior wall of the maxilla. Holes are drilled and screws are inserted and then removed. These preosteotomy-drilled holes will ensure accurate position of the maxilla bone when it is returned to its original site after tumor resection and fixed with the plate and the screws. The osteotomy over the anterior wall is carried out by an oscillating saw with a thin, long blade. The anterior wall of the maxilla is cut and this osteotomy extends laterally horizontally until the middle portion of the zygomatic arch and then turned downward. Only the lower part of the zygomatic arch is divided and thus, after completion of the osteotomy, the inferior orbital rim remains attached to the zygoma.

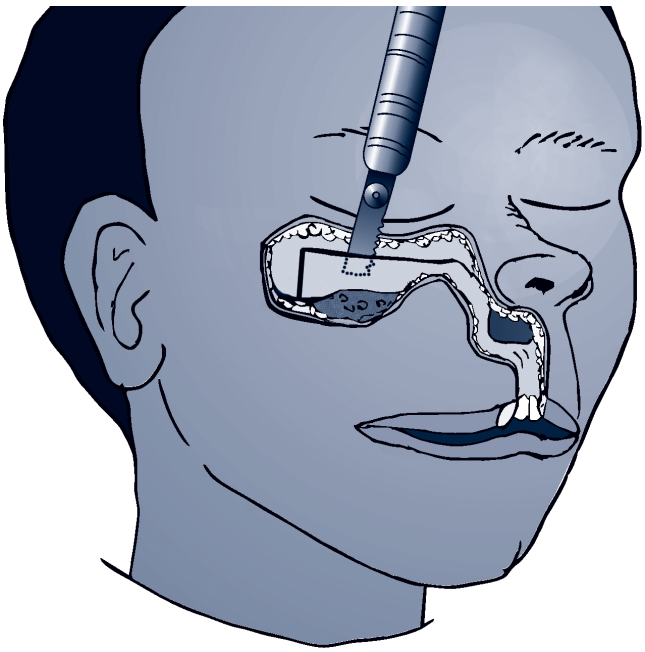

**FIGURE 22-29.** The horizontal osteotomy is shown to go through the anterior wall of the maxilla.

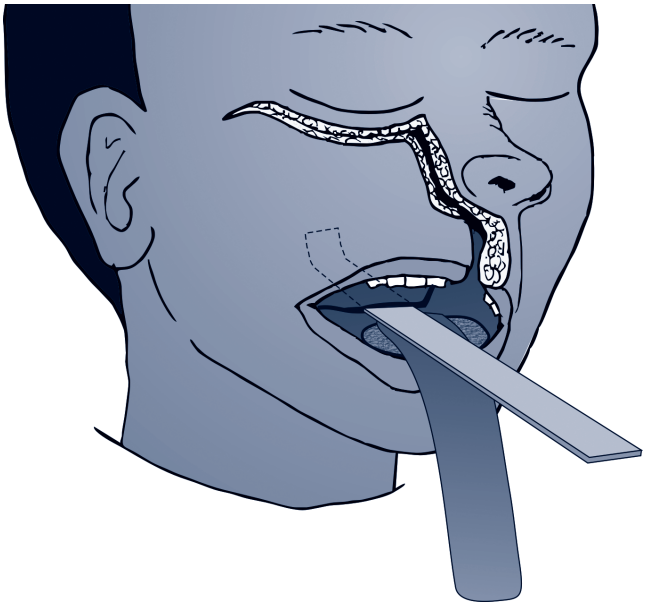

**FIGURE 22-30.** A curvedosteotome is inserted behind the maxillary tuberosity to separate it from the posterior wall of the maxillary antrum from the pterygoid plates.

The soft tissue over the midline is elevated to expose the underlying bone, in preparation for a midline osteotomy. Sometimes, the patient may have a high nasal spine, and this can be removed with a burr or a rongeur creating a flat bone surface where the titanium plate is placed. Holes are drilled and screws are inserted and removed similar to the procedure applied on the anterior wall of the maxilla.

An oscillating saw divides the hard palate from anterior to posterior in a straight line. The lifted palatal flap is retracted from the path of the osteotomy and protected. This osteotomy cuts through the entire length of the hard palate and lower part of the nasal septum if there is septal deviation. The blood loss is minimal with this osteotomy, and so it is carried out as the first osteotomy. Then the osteotomy of the anterior wall of the maxilla is carried out with the long, thin blade. The blade goes through the antrum and divides the lateral wall on its way until it reaches and cuts the posterior wall. The last osteotomy goes through the medial wall of the antrum. This is placed above the inferior turbinate and below the middle turbinate.

After the completion of the osteotomies, the maxilla bone drops down, but remain attached to the anterior cheek flap (Fig. 22-31). The whole osteocutaneous complex is retracted laterally to expose the nasopharynx and the paranasopharyngeal space (Fig. 22-32). With this exposure, persistent or recurrent cancer in the nasopharynx and the paranasopharyngeal lymph nodes can be removed together with the Eustachian tube under direct vision.

(c) 2014 Wolters Kluwer. All Rights Reserved.

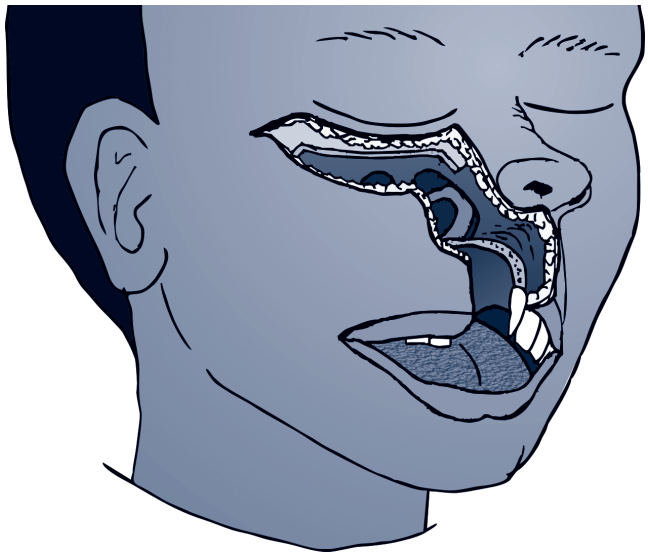

**FIGURE 22-31.** After completion of the osteotomies, the maxilla drops down but remains attached to the anterior cheek flap.

With the osteocutaneous complex including the maxilla swung laterally, the tumor in the nasopharynx with its surrounding tissue is adequately exposed and can be removed with conventional surgical instruments such as scissors, diathermy, and the like. The pterygoid plates together with the pterygoid muscle can be removed to improve exposure of the paranasopharyngeal space on the side of the swing, and any pathologic lymph nodes if present in the region can be removed under direct vision. The internal carotid artery lying outside the pharyngobasilar fascia is situated posteriorly or posterolaterally to the paranasopharyngeal lymph node. Sometimes, it could be adherent to the lymph node following radiotherapy. With this wide exposure, the carotid artery can be located with palpation of its pulsation and thus safeguarded during resection of the paranasopharyngeal lymph node.

When the pharyngobasilar fascia has to be resected with the tumor or the paranasopharyngeal lymph node, the petrosal part of the internal carotid artery will be exposed. This can be covered with a microvascular free muscle flap to prevent subsequent carotid artery rupture.

The frequently employed free muscle transfer are the rectus abdominis or the vastus lateralis muscle of the anterolateral thigh. The pedicle is delivered through a tunnel made above the oropharynx to the upper neck. The artery of the flap is joined to the facial or the superior thyroid artery and the venous return is anastomosed to a tributary of the internal jugular vein. The transferred muscle is covered by mucous membrane within a short period, and this avoids the crusting when skin is used to cover the wound in the nasopharynx.

Increased exposure of the contralateral nasopharynx is achieved following the removal of the posterior part of the nasal septum. Lesion that has extended across the midline can be resected up to the medial edge of the Eustachian tube of the opposite side. Following this wide exposure, en bloc resection of the nasopharyngeal carcinoma can be carried out and the resection includes the Eustachian tube crura. The inferior turbinate on the side of the swing is removed and the mucosa covering it is taken off. This mucosal sheet is laid onto the raw area in the nasopharynx as a free mucosal graft. This graft frequently survives and this facilitates healing; even if it does not survive, it acts as a temporary dressing for the wound in the nasopharynx.

After tumor extirpation and covering the raw area over the nasopharynx, the maxilla is returned to its original position. A few holes are drilled on the posterior edge of the hard palate, and sutures passing through these holes attach the soft palate to the hard palate. A hole is drilled on the base of the nasal bone, and a corresponding hole is drilled on the superomedial part of the anterior wall of the maxilla. A size 26 wire is passed through these holes. The intraoral placement of the prefabricated dental plate ensures accurate repositioning of the maxilla.

While the maxilla is maintained in position with the hand, the two titanium plates are placed over the zygoma and the midline where screw holes was predrilled, and the screws are inserted (Fig. 22-33). The wire on the superomedial angle of the anterior wall of the maxilla is also tightened to give additional support.

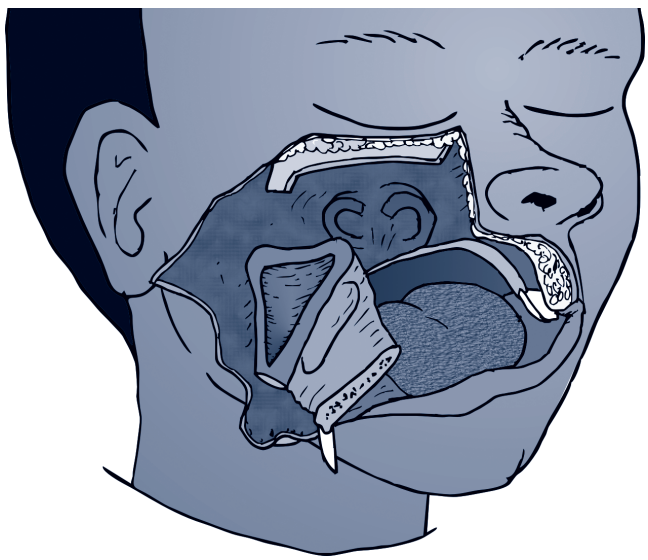

**FIGURE 22-32.** The osteocutaneous complex is swung laterally to expose the nasopharynx and its vicinity.

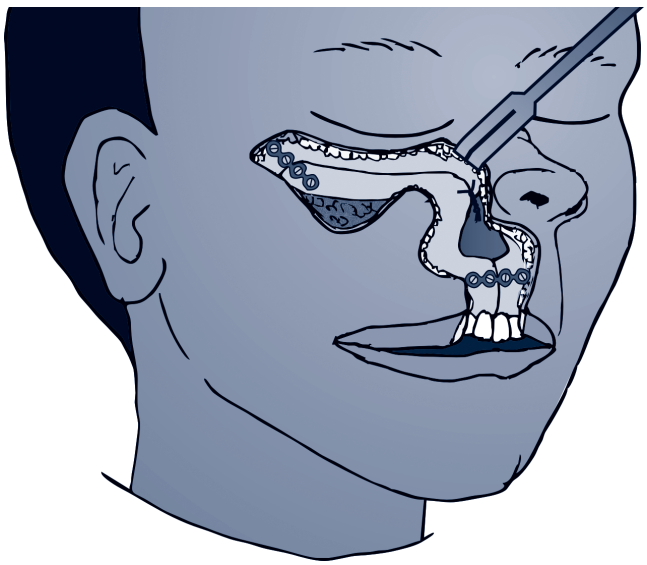

**FIGURE 22-33.** The maxilla is returned to its original position and fixed to the facial skeleton with two titanium plates.

(c) 2014 Wolters Kluwer. All Rights Reserved.

The dental plate is then removed and the palatal flap is returned. Two to three sutures are used to fix the posterior part of the flap to the alveolar margin, and the dental plate is reinserted to keep the palatal flap in position. This dental plate is normally removed on the third day after operation. Nasal cavity is packed with antiseptic ribbon gauz, and the facial wound is closed in layers.

## Nasopharyngectomy with the Da Vinci Robot

When robotics is used for transoral resection of pathologies in the oropharynx, the robot is docked from the caudal aspect of the patient. When employed for resection of tumor in the nasopharynx, the robot is docked from the cephalic direction.

The operation is carried out under general anesthesia with the patient in supine position, and ventilation is maintained with a nonkinking endotracheal tube, which is preferably placed over the central lower lip. A Dingman mouth gag is inserted and maintained in position with a pneumatic holding device (Aesculap AG, Tuttlingen, Germany). The soft palate is split in the midline with the incision placed at the base of the uvula. The incision extends onto the mucoperiosteum over the hard palate. The split soft palate and the mucoperiosteum of the hard palate are retracted with stay sutures to expose the nasopharynx with the lesion. The Da Vinci surgical robot, model S (Intuitive Surgical Inc., Sunnyvale, California) is docked from the cephalic aspect of the operating table and the 12-mm dual-channel endoscope is introduced transorally. This allowed good visualization of the lesion in the nasopharynx including both fossae of Rosenmüller.

The Maryland forceps, 5 mm in diameter, is mounted to the left robotic arm and a spatula dissector of scissors with monopolar diathermy is mounted to the right robotic arm. The incision around the tumor is performed with the diathermy, and this incision goes through mucosa and prevertebral muscle. The crura of the Eustachian tube cushion should be included in the resection together with the tumor. The tumor and its surrounding tissue are then lifted with the Maryland forceps while the diathermy cuts and cauterizes the tissue deep to the undersurface of the tumor. The pathology with a margin of soft tissue is removed en bloc. The internal carotid artery is not exposed or seen during dissection.

When the sphenoid sinus has to be entered to increase the resection margin, this can be done with power instruments under endoscopic guidance before docking the robot.[7]

Following resection of the tumor, the defect in the nasopharynx becomes a slanting trough; the deepest part is bone followed by the prevertebral muscle, the submucosa, and then the mucosa of the nasopharynx. A free mucosal graft is taken from the posterior oropharyngeal wall to be placed over raw area in the nasopharynx as a free graft. This is secured with the balloon of a urinary catheter as posterior nasal packing. The palatal wound is closed in layers, and a nasogastric tube is inserted for feeding.

CHAPTER 23

# Basal and Squamous Cell Skin Cancers

## PART A: General Principles and Management

Louis B. Harrison, Par S. Mehta, Matthew Halpern, and Desiree Ratner

Nonmelanoma skin cancers (NMSCs) are the most frequently occurring cancers in the United States, with basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs) being the most common histologies. More than 1 million cases are expected annually in the United States, and the incidence has been rising rapidly over the last decade.[1] The head and neck are the most common sites of presentation, accounting for >80% of all basal and SCCs.[2] These lesions are typically slow growing and infrequently metastasize. If neglected, they can cause significant local destruction and invade critical structures. These lesions can cause significant morbidity, especially cosmetic deformity. Metastasis can occur and can be life threatening. Treatment of these cancers is important, and multidisciplinary considerations are essential.

## EPIDEMIOLOGY

### Basal Cell Carcinoma

BCCs are thought to originate from pluripotent cells in the basal layer of the epidermis. Although formal statistics are not maintained for the incidence of BCCs of the skin, the American Cancer Society estimates 800,000 to 900,000 BCCs in the United States per year,[1] equating to 300 to 350 per 100,000 patient years. The incidence is significantly higher with increased age and is much greater in Whites than in African Americans. Men are also more likely to develop BCCs than are women. The incidence of BCC has also increased approximately 100% in the last decade, but still account for <1% of cancer deaths.[3] Whites in the United States have a 30% lifetime risk of developing a BCC, and those previously diagnosed with a BCC have a 35% to 50% chance of developing a second tumor over a 5-year period. BCCs are typically present over sun-exposed areas of the skin, accounting for the increased incidence in the head and neck. Geographic location also plays a significant role, with the highest incidence worldwide in Australia.

### Squamous Cell Carcinoma

Cutaneous SCC is a malignant tumor of epithelial keratinocytes and represents the second most common form of skin cancer. This neoplasm was first described in the literature in 1775 by Sir Percival Pott, who noted the relationship between scrotal carcinoma and exposure to chimney soot. Although most of the cases are easily treated with a high cure rate, a subset of tumors will behave more aggressively and recur or metastasize, resulting in most NMSC mortalities in the United States.[4]

The precise incidence of SCC is difficult to ascertain because the National Cancer Institute only collects data on tumors of the genitalia. Epidemiologic studies suggest, however, that in the United States, the rate approaches 100 to 150 cases per 100,000 persons per year. The age-specific incidence among persons older than 75 years is increased by a factor of 10.[4–8] In addition, it appears that this rate has increased by 50% to 200% over the last 10 to 30 years.[4–6,8–10] Geographic variations in sun exposure also contribute to differences in regional incidence data, with rates in Arizona of approximately three to six times those reported in more northern areas.[11] Similarly, in Australia, incidence rates are significantly elevated relative to the United States, with 1% to 2% reported most recently.[12]

## RISK FACTORS

### Basal Cell Carcinoma

Exposure to ultraviolet radiation is recognized as the major etiology of BCC, with ultraviolet B (UVB) more implicated than ultraviolet A (UVA). Ultraviolet radiation induces covalent bonds in DNA between adjacent pyrimidines, resulting in mutagenic lesions if not repaired. Both cumulative exposure and less frequent but intense exposure to direct sunlight are implicated in the pathogenesis of BCC. The amount of ultraviolet radiation exposure is especially important for patients with Fitzpatrick skin types I–II.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Exposure to ionizing radiation is also a risk factor for developing BCC. This increase is limited to the surface area exposed to radiation therapy. Lichter et al. showed in a population-based case-control study that the relative increase in incidence of BCC was 3.3 in skin previously irradiated for acne treatment, with lower increase in patients receiving radiation therapy for malignancies, at 2.0.[13] Lower-dose exposure to ionizing radiation is associated with more mutagenesis and may account for this discrepancy, and this study showed that there was no increase in the incidence of NMSC in adjacent areas of nonirradiated skin.

Other risk factors include chemical carcinogen exposure with arsenic or coal tar, and immunosuppression. Smoking and human papillomavirus (HPV) infection are also risk factors for development of BCC,[14] with smoking likely functioning as a carcinogen.

Each of the aforementioned risk factors is thought to contribute to genetic mutations responsible for BCC. Several pathways have been implicated, most commonly mutations in tumor suppressor genes. The *p53* mutations are the most common genetic aberrations involved in NMSC, although more common in SCC than in BCC. *p53* plays an important role in apoptosis, and effects of involvement of ataxia-telangiectasia mutated gene (ATM gene), *p38*, and mitogen-activated protein (MAP) kinases in the phosphorylation of *p53* serine residues are seen in response to ultraviolet radiation.[15] Exposure to ultraviolet radiation can result in the loss of Fas ligand interaction, with resulting accumulation of *p53* mutations in the skin.

Mutations in the patched tumor suppressor gene also play a role in the development of BCC.[16] Located on chromosome 9, the *PTCH1* gene is a component of the sonic hedgehog (SHH) signaling pathway and encodes for a transmembrane protein which, along with another transmembrane protein, smoothened, inhibits transcription factors regulating genes involved in tissue morphogenesis. This pathway is implicated in the increased incidence of BCC seen in genetic syndromes, including Gorlin syndrome and xeroderma pigmentosum, as well as sporadic BCC.[17]

Gorlin syndrome (basal cell nevus syndrome) is a rare autosomal dominant disorder, with a prevalence of approximately 1 in 100,000 found mostly in whites.[18,19] Patients with this disorder have a variety of clinical abnormalities, including early development of multiple BCCs, palmar and plantar pitting, craniofacial abnormalities, and bifid ribs. These patients are also at increased risk of medulloblastoma with a 3% to 5% incidence.[20]

Xeroderma pigmentosum is characterized by a deficit in nucleotide excision repair. This results in accumulation of defects induced by exposure to ultraviolet radiation and an increase in BCC. Xeroderma pigmentosum clinically presents with excessive skin reaction to sunlight, photosensitivity, multiple solar keratoses, and skin cancers.

## Squamous Cell Carcinoma

Table 23.1 lists known risk factors for the development of SCC. UVA (320–400 nm) and UVB (290–320 nm) result in thymidine dimer DNA mutations in the *p53* tumor suppressor gene and is the most common cause of SCC.[21–23] The highest risk exists among people with light skin, hazel or blue eyes, and blonde or red hair, and in those with chronic accumulated lifetime sun exposure.[24,25] Not surprisingly, the use of oral methoxsalen in combination with ultraviolet A radiation (PUVA) for the treatment of psoriasis and other conditions has been definitively associated with an elevated risk of SCC.[26,27] Ionizing radiation including x-rays, gamma rays, and grenz rays used either therapeutically or as occupational exposures also contribute to the risk of SCC.[28] This risk is directly related to the cumulative dose of radiation.[28] There are several genodermatoses that predispose individuals to SCC. In oculocutaneous albinism, patients have absent or decreased production of protective melanin resulting in increased SCC in sun-exposed areas.[29] Patients with xeroderma pigmentosum are deficient in the enzymes responsible for repairing ultraviolet-induced DNA damage and develop skin cancers beginning from an early age. Other inherited conditions associated with SCC include Ferguson-Smith syndrome and dystrophic epidermolysis bullosa.[30] HPV is associated with SCC development, especially with the periungual and genital regions. This is particularly evident in patients with epidermodysplasia verruciformis and in patients with HIV who develop the verrucous carcinoma subtype of SCC.[31,32] Multiple chemical exposures are associated with SCC development, including arsenic and polycyclic aromatic hydrocarbons.[21] Patients who are immunosuppressed are also at an increased risk of developing SCC. In particular, solid organ transplant recipients have a 40 to 250 times increased incidence of SCC compared with the general population.[33] In fact, the ratio of SCC to BCC is reversed in organ transplant recipients.[21] Patients with AIDS have a slightly increased risk of SCC, with a particular increase in anal lesions that are notable for a more aggressive clinical course.[30] SCCs are also known to occur more commonly in areas of skin affected by chronic inflammation, including ulcers (so-called Marjolin ulcers), osteomyelitis, radiation dermatitis, and vaccination scars, and a variety of inflammatory conditions such as discoid lupus erythematosus, lichen sclerosis, lichen planus, and cutaneous tuberculosis.[21] Infection with HPV has also been definitively linked to the development of nongenital SCC. In particular, HPV types 5, 16, and 18 have been shown to have increased oncogenicity relative to other subtypes.[34] Although the specific pathway by which HPV induces carcinogenesis has not been determined, it is known that HPV infection results in synthesis of the viral proteins encoded by the *E6* and *E7* genes that bind and inactivate the *p53*, *pRB*, and *Bak* tumor suppressor genes.[35] In addition, it appears that infection with HPV alone is insufficient to produce SCCs and that cocarcinogens such as ionizing radiation or ultraviolet radiation are required to produce malignant transformation.[36] It also appears that HPV infection in the setting of immunosuppression leads to carcinogenesis as evidenced by the increased risk of SCC and cutaneous warts in organ transplant recipients.[37]

## PREVENTION

Duration and intensity of sun exposure has been associated with both BCC and SCC.[38] BCC is more associated with recreational exposure, whereas SCC is more often associated with occupational exposure.[39] Prevention of both types of NMSC can be achieved by limiting overall exposure, as well as using protective clothing to minimize exposed areas. Regular use of sunscreen is a cost-effective approach to skin cancer prevention in subtropical settings.[40] The efficacy of sunscreens in reducing photocarcinogenesis and photaging is widely documented.[41] In August 2007, the FDA proposed an amendment to update sunscreen-labeling regulations, whose major points included limiting SPF labeling to 50+ for products with SPF values of 60 and higher, addition of a 4-star UVA protection rating system, approval of new combinations of sunscreen ingredients, and improved usage directions placed on approved products.[42]

## CLINICAL PRESENTATION AND HISTOLOGY

### Basal Cell Carcinoma

Unlike SCC of the skin, there are no precursor lesions associated with BCC. Patients typically present with a slow-growing, nonhealing papule, most commonly of the head and neck, although multiple clinical variants exist. Locally advanced tumors can show symptoms of disease progression into adjacent structures, including numbness, pain, and weakness.

There are several histologic subtypes of BCC, with nodular, superficial, and micronodular being the most common (Fig. 23-1).[43] Other less common variants include infiltrative, basosquamous, morpheaform, and clear cell.[44]

Nodular-type BCC resembles a translucent papule with telangiectatic-rolled borders, often with a central ulcer (Fig. 23-2). When these tumors are neglected, they may become large and exophytic (Fig. 23-3). Histologically, these lesions have islands of tumor cells encased in a mucin-rich stroma. When pigmented, these tumors can often be confused clinically with melanoma. However, the melanocytes have a benign histologic appearance. Nodular BCC tends to be slow growing and is rarely associated with aggressive disease.

Superficial-type BCC presents as red, scaly lesions, often on the trunk or extremities, which may be confused clinically with eczema or psoriasis. They are also less aggressive clinically, but may become large when neglected, forming crusted, scaling erythematous patches. These lesions are also associated with younger women. Unlike nodular subtype, which increases in incidence with advancing age, the superficial subtype tends to peak and then steadily decrease into the late 70s.[2]

The morpheaform BCC, also described as sclerosing type, presents as flat, indurated, whitish, ill-defined plaques. As they enlarge, they often become depressed and resemble a scar and, because of this subtle clinical appearance, may not be diagnosed until they are relatively large. The morpheaform histology is associated with small islands of tumor cells with dense fibrosis. At the periphery, there is often microscopic extension into the surrounding dermis. This histologic subtype is among the more aggressive BCCs.

Tumors with mixed histologies should be treated as tumors of the more aggressive subtypes. This includes patients with basosquamous carcinomas, which behave more like SCC. Infiltrative BCCs are also more aggressive than the more common nodular and superficial subtypes.

### Squamous Cell Carcinoma

SCCs are believed to arise primarily from precursor lesions known as *actinic keratoses* (Fig. 23-4). These scaly 1- to 3-mm, pink, skin-colored, or brown papules have a characteristic rough

**FIGURE 23-3.** Basal cell carcinoma of the antihelix. Central erosion of the lesion is characteristic and referred to as a *rodent ulcer*.

texture and are oftentimes more easily palpated than visualized. These lesions commonly occur in a typical sun-exposed distribution, including the face, scalp, and dorsal hands. Histologically, actinic keratoses consist of atypical keratinocytes confined to the basilar layers of the epidermis with overlying parakeratosis. Estimates of the rate of progression to SCC vary from 0.025% to 20% per year.[45,46]

SCC *in situ* (Bowen disease) presents as solitary, well-demarcated, pink, brown, or erythematous scaly plaques. Most commonly, these lesions occur in sun-exposed areas. Erythroplasia of Queyrat is SCC *in situ* occurring as smooth red plaques on the glans penis of uncircumcised men. Histologically, SCC *in situ* is characterized by keratinocyte atypical that involves the full thickness of the epidermis, but does not penetrate the basement membrane. SCC *in situ* may progress to invasive disease if not treated completely.[28]

Invasive SCCs are commonly scaly, pink- or skin-colored papules, or plaques that occur on the head, neck, trunk, and other sun-exposed areas. Patients may complain of pruritus, pain, or bleeding, with mild trauma to affected areas. Biopsy reveals keratinocyte atypia that traverses the basement membrane and involves the dermis and underlying structures. Tumors may be well differentiated, with minimal cytologic atypia, obvious keratinization, or they may be poorly differentiated with significant atypia and mitotic figures seen, with immunohistochemistry required for diagnostic confirmation.

Verrucous carcinoma is an uncommon variant of SCC that is characterized by a slow growth rate and exophytic, wart-like clinical appearance. This tumor occurs most commonly in the oral cavity (oral florid papillomatosis), anogenital region (giant condyloma of Buschke-Lowenstein), and the plantar surfaces of hands and feet (carcinoma cuniculatum).[28] It is associated with multiple HPV subtypes, including HPV 6, 11, 16, and 18.[47] Unlike other SCCs, irradiation is specifically contraindicated for verrucous carcinoma because it can result in increased tumor aggressiveness.[48]

Keratoacanthoma (Fig. 23-5) is a more common variant of SCC that presents as a rapidly growing solitary papule or nodule with a central keratin plug. These lesions are believed to regress without treatment in 6 to 9 months and most closely resemble well-differentiated SCC on histology.[49] Ultimately, however, the diagnosis of keratoacanthoma requires clinicopathologic correlation, and indeterminate lesions should be regarded as SCC for treatment purposes because metastasis has been reported in rare cases.[50]

## NATURAL HISTORY

### Basal Cell Carcinoma

Most BCCs are localized at presentation. Growth of these tumors is slow, estimated at 5 mm or less per year for the vast majority of tumors, but neglected tumors can become quite large. With adequate treatment, the recurrence rate is <10%, but more advanced lesions are associated with lower cure rates. The histology of the tumor may also predict the natural history. Sexton et al. examined 1,039 patients with BCC and noted that negative margins were achieved in >93% of patients with nodular or superficial tumors, compared with 81.4% for micronodular, 73.5% for infiltrative, and 66.7% for morpheaform histologies.[43] Location of the primary tumor is also important for prognosis. Tumors along the H-zone (Fig. 23-6) include the nose, nasolabial regions, upper lip, columella, periauricular skin, and frontozygomatic areas. These locations are associated with deeper invasion and higher recurrence rates.[51] This zone is also a cosmetically

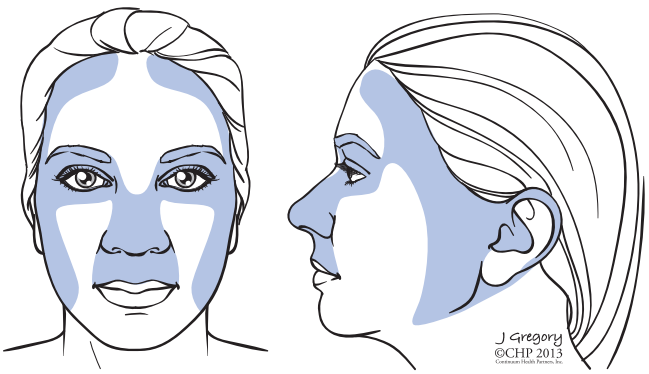

**FIGURE 23-6.** Anatomic depiction of the "H-zone" including areas associated with higher recurrence rates.

| Recurrent |

prominent region where cosmetic results of treatment are particularly important. Local extension is through pathway of least resistance, including fascial planes, periosteum, perichondrium, and nerve sheaths. High-risk features of BCC are shown in Table 23.2. The primary tumor stage may be the most significant factor in determining the progression of disease. BCCs rarely metastasize to lymph nodes or distantly, and most cases are associated with T3 or T4 tumors. In addition, locally advanced tumors are more likely to have perineural invasion, which can result in cranial nerve palsies. Periorbital lesions have potential for invasion into the ethmoid sinuses and subsequently to the base of skull. The incidence of nodal metastases from BCC is exceedingly rare, between 0.01% and 0.5%, and associated with high-risk tumor features.[44,52] However, the prognosis is poor after spread of disease, with median survivals between 8 months to 3 years. Distant spread of disease is to the lymph nodes, followed by bone, the lung, and the liver.

## Squamous Cell Carcinoma

Most patients with cutaneous SCC have an excellent prognosis. Invasive SCC does, however, have the potential to recur and metastasize. Although estimates vary, the approximate 5-year recurrence rates for primary cutaneous lesions is reported to be 8%, whereas the 5-year metastasis rate is 1.4% to 6%.[53–55] In 1992, Rowe, Carroll, and Day reviewed all relevant studies on recurrence and metastasis rates of SCC from 1940 to 1992 (Table 23.3). Large lesions (>2 cm) have been reported to metastasize at a rate of 30%.[53] Rapidly growing lesions on the eyelid or ear are also thought to be more aggressive and may metastasize in up to one-third of cases.[56] Similarly, rates of metastasis are relatively high for lesions on the ear (11%) and the lip (13.7%), with associated 5-year survival rates that range from 25% to 40%.[28,57–59] It should be noted that with improved abilities to diagnose and treat SCC, current rates of recurrence and metastasis may be lower than previously reported, but more recent prospective studies have not been performed.

Several histologic features may portend a worse prognosis. Depth >4 mm, extension into the reticular dermis or subcutaneous fat, and involvement of underlying fascia, muscle, bone, or cartilage are all associated with a greater risk of metastasis.[60] Lesions that are poorly differentiated behave more aggressively and metastasize three times as often as well-differentiated tumors.[53] Perineural invasion, in which tumor cells invade and travel along nerve fibers, occurs in 5% of SCCs.[28,58] Discontinuous skip lesions are characteristic of perineural invasion, and the risk of metastasis approaches 50% despite aggressive surgical excision.[28,58,61]

**TABLE 23.3 Factors Predisposing to Recurrence and Metastasis of Cutaneous Squamous Cell Carcinoma (SCC)**

| Risk Factor | RR of Recurrence | RR of Metastasis |
|---|---|---|
| Rapid growth | — | — |
| Size >2 cm | 2 | 3 |
| Site: lip | 2 | 3 |
| Site: ear | 2 | 3 |
| Immunosuppression | 2 | — |
| Radiation | — | — |
| Previous recurrence | 3 | 4 |
| Depth >4 mm or Clark IV/V | 2 | 5 |
| Poor differentiation | 2 | 3 |
| Perineural invasion | 5 | 5 |
| Infiltrative margins | — | — |
| Spindle cell histology | — | — |
| Acantholytic histology | — | — |

Relative risk (RR) for small primary squamous cell carcinoma (SCC) is defined as 1.

For patients with metastatic disease, the long-term prognosis is poor. In patients with regional lymph node involvement, 10-year survival rates are <20%. In patients with distant metastases from SCC, 10-year survival rates are <10%. Eighty-five percent of cases with metastasis involve regional lymph nodes, whereas the remaining 15% of cases involve the lungs, the liver, the brain, and bone.[28,57,62–64] Primary SCC of the head and neck also metastasizes to the parotid gland and the neck, not uncommonly. In this subset of high-risk patients, approximately 50% develop local recurrence within 1 year of surgical excision. Not surprisingly, positive surgical margins at the time of excision were associated with a greater risk of recurrence. Postoperative radiotherapy was not associated with improved outcomes or prolonged survival.[65]

# STAGING

Staging for primary nonmelanoma cutaneous malignancies is outlined in Table 23.4. Size and invasion of extradermal structures determines T stage, whereas presence of nodal metastasis results in a stage III classification and presence of distant metastases results in stage IV classification. Eyelid tumors are staged differently, and that system is provided in Table 23.5. Note that no stage groupings are currently recommended for eyelid tumors.[66]

# DIAGNOSTIC IMAGING

Most NMSCs are localized to the site of presentation and do not require any type of diagnostic imaging. However, locally advanced tumors as well as tumors located in the medial canthus or fixed to bone should be imaged to determine the extent of disease and to evaluate for invasion. Most commonly, computed

tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate these tumors. For SCC, CT with contrast should be done to evaluate the primary echelon of nodes to determine if the disease has spread regionally. Positron emission tomographic (PET) scan may also play a role for patients with high-risk SCC. Cho et al. showed PET correlation with both local and distant disease extent for all nine patients with high-risk features.[67] Another modality is the use of high-frequency ultrasonography to determine the depth of the lesion. A study by Lassau et al. examined 32 patients with BCC and was able to identify each as hypoechoic on ultrasonography.[68] Perhaps of more importance, 29% of BCC lesions were found to be larger than that predicted by clinical examination. This may represent an important tool in the pretreatment setting.

## TREATMENT

The rationale for treatment of NMSC is twofold. First, local control is important to limit the extent of immediate tumor destruction and preserve vital functional and cosmetic structures (particularly on the face). Second, complete eradication (either surgical or radiotherapeutic) is crucial for eliminating the risk of metastatic spread. Because the risk of locoregional recurrence and metastasis increases with increasing tumor size, there is particular incentive to treat tumors when they are small.[60]

## PATIENT EVALUATION AND RISK STRATIFICATION

Work-up of a patient with possible NMSC begins with thorough history-taking, physical examination, and possible skin biopsy. The history should focus on the duration, growth rate, and previous therapy for a suspected lesion. In addition, history of previous radiation or ultraviolet light therapy and personal or family history of previous skin cancers should be elicited. Standard medical history, including current medical problems, medications, and allergies should be reviewed, with particular attention to possible sources of immunosuppression, such as organ transplantation, HIV, immunosuppressive medications, and hematologic malignancy.

Physical examination of the lesion in question should be performed. It should first be assessed for location, size, whether the borders are well defined or poorly defined, and the presence of associated scars to indicate previous therapy. The site should be palpated to evaluate the depth of the lesion, as well

(c) 2014 Wolters Kluwer. All Rights Reserved.

as connections to underlying structures. Regional lymph node evaluation is indicated for all SCCs, and thorough full-body skin examination is essential to identify any additional primary skin cancers.

Lesions suspicious for cutaneous malignancy should be biopsied. Shave biopsy is sufficient in instances where a more superficial process is clinically evident such as superficial BCC or SCC *in situ*. When a deeper tumor is suspected, punch biopsy is the preferred method to obtain a diagnosis. If the biopsy is consistent with NMSC, the report should identify the subtype of BCC or SCC. In addition, the presence of any high-risk histologic features should be noted, including the degree of differentiation for SCCs and the presence of vascular or perineural invasion.

On the basis of this assessment, it should be possible to assign tumors to either high-risk or low-risk categories for recurrence and metastasis (Tables 23.2 and 23.3). This designation is essential in selecting the appropriate treatment regimen for an individual patient.

# TREATMENT MODALITIES

There are numerous proven treatment options for NMSC including cryosurgery, electrodessication and curettage, standard excision, Mohs micrographic surgery, and radiation therapy. In addition, there are several novel therapies, including laser surgery, photodynamic therapy, topical chemotherapy, and the biological response modifiers. These individual approaches, as well as an overall algorithm for the management of NMSC, are now discussed.

## Curettage and Electrodesiccation

Curettage and electrodesiccation is a simple and cost-effective treatment for low-risk NMSCs.[69] In this technique, a sharp curette is used to scrape away tumor that provides less resistance than normal healthy tissue. Gentle, deliberate pressure is utilized such that the relatively soft tissue of the tumor is removed without disturbing adjacent uninvolved skin. Following curettage, the area is treated with electrodesiccation to achieve hemostasis, as well as to delineate the borders of the tumor. By convention, this cycle of curettage and electrodesiccation is repeated for a total of three treatment cycles. One disadvantage of this procedure is that no pathologic specimen is sent for margin evaluation. This technique is not indicated in hair-bearing skin because of the risk that tumor extending down the hair follicles will not be adequately treated.[70] In addition, curettage and electrodesiccation is not appropriate when there is tumor extension into the subcutaneous layer, because it is more difficult to distinguish friable tumor from the surrounding fat.[70] When employed for the treatment of small, primary tumors, with nonaggressive growth patterns in low-risk areas, 5-year cure rates for NMSCs as high as 96% are reported.[53,71–74] Cure rates for tumors with high-risk features are much lower; however, controlled studies have not been performed,[75] and this technique is not recommended for aggressive NMSCs.

## Superficial Therapies

There are multiple superficial therapies that are available for treatment of NMSCs, including vigorous cryotherapy, photodynamic therapy, topical 5-fluorouracil (5FU), and topical imiquimod. Although they are minimally invasive and well tolerated, these therapies are associated with lower cure rates and should be reserved for patients in whom surgery or radiation are contraindicated or impractical.[76,77]

## Cryosurgery

Modern cryosurgery involves the use of liquid nitrogen in a closed system that enables continuous and rapid extraction of heat from tissue. The most commonly employed techniques include the hand-held canister with a spray-tip accessory and the cotton-tipped applicator. Freezing tissue results in vascular stasis, disruption of cell membranes, intracellular pH changes, loss of homeostasis, ice crystal formation, and thermal shock. Rapid cooling with slow thawing and repeated freeze–thaw cycles are ideal for producing maximal tumor destruction. Extensive tissue necrosis is required for eradication of malignant lesions. BCC cells have been demonstrated to be histologically absent at 3 days following treatment with cryosurgery. Specifically, temperatures of −50 to −60°C are required to produce sufficient tissue freezing for treatment of basal cell and SCCs.[78,79]

Cryosurgery is considered to be an effective therapy for the treatment of premalignant lesions and *in situ* malignancies, including actinic keratoses, actinic cheilitis, lentigo maligna, Bowen disease, and erythroplasia of Queyrat. Cryosurgery may be used to treat NMSCs, but is usually appropriate only for select circumstances. Tumors that may be considered include those with less aggressive histologic growth patterns, such as nodular and superficial BCC, and well-differentiated lesions for SCC, lesions with well-defined borders, small primary lesions (<1 cm), and those on low-risk locations.[80] Multiple authors have reported a >97% 5-year cure rates for treatment of these selected low-risk tumors.[78,81–84] NMSCs with aggressive growth patterns such as morpheaform and infiltrative BCC, and moderately/poorly differentiated SCC, those with ill-defined borders, recurrent tumors, or deeply penetrating lesions are not good candidates for cryosurgery. Although it is not considered first-line therapy for these more aggressive tumors, cryosurgery can be considered as an alternative treatment option for patients who are poor operative candidates or as palliative therapy to relieve pain and debulk large tumors.[80]

## Topical Medications

5FU is a pyrimidine analog that inhibits RNA processing and thymidylate synthesis and is used topically for treatment of actinic keratoses and actinic cheilitis. Topical 5FU is available in 0.5%, 2%, and 5% preparations, and treatment involves once-daily or twice-daily applications to affected areas for 2 to 4 weeks. Significant erythema and discomfort at the site of application is common, and residual erythema following treatment may persist for several months. Diclofenac sodium gel is an alternative topical therapy approved for the treatment of actinic keratoses. Twice-daily application for 60 to 90 days is the recommended treatment regimen. Although these topical therapies are not considered effective treatment for SCCs, they may be used to clear the field in severely actinically damaged patients so that new or transforming lesions may be detected earlier.

Imiquimod cream is a topical immune response modifier. Although the imiquimod strength used is generally 5%, a 3.75% formulation was recently approved to treat actinic keratoses on the face and balding scalp. Although the precise mechanism of action is unknown, imiquimod binds to toll-like receptor 7 to stimulate both innate and adaptive immune functions through the production of local cytokines, including interferon-α (IFN-α), interleukin-6, and tumor necrosis factor-α.[85] For actinic keratoses, imiquimod 5% was shown to have an 87.5% clearance rate following three times weekly treatment for 2 weeks, followed by twice-weekly treatment for 12 weeks in a randomized, double-blind, vehicle-controlled study.[86] For Bowen disease, once-daily application of imiquimod 5% for 16 weeks resulted in >93% clearance rates; however, only 66% of patients were able to

(c) 2014 Wolters Kluwer. All Rights Reserved.

complete the treatment protocol secondary to local skin reactions.[87] For superficial BCC, once-daily application of imiquimod 5% cream for 6 weeks has been shown to produce 77% to 93% histologic clearance at 12 weeks. Interim data from an open-label study to assess the 5-year recurrence rates among patients treated with imiquimod 5% for superficial BCC demonstrated that 79% of patients who were clinically free of disease at 12 weeks remained clear at 24 months.[88–90] The histologic clearance rate for nodular BCC appears to be significantly lower and ranges from 42% to 76%.[91,92] Imiquimod is not recommended for treatment of invasive SCC or BCC that are recurrent, occur in high-risk locations, or have a morpheaform, infiltrative, or nodular growth pattern.

## Photodynamic Therapy

Photodynamic therapy is a treatment modality that involves the delivery of a photosensitizing agent, which localizes to the site of a tumor and induces selective destruction upon activation with visible light.[93] The wavelength of light utilized for treatment determines the maximum therapeutic depth. Topical, oral, intralesional, and intravenous routes have all been explored for administration of photosensitizing agents such as 5-(δ)-aminolevulinic acid (ALA) and methyl-esterified ALA that are precursors of protoporphyrin IX in the porphyrin pathway.[94] These low-molecular-weight hydrophilic molecules are translocated to individual cells in both the targeted tumor and normal surrounding tissue, where they are converted to protoporphyrin IX, a potent photosensitizer. Exposure to a visible light source in the presence of oxygen results in the generation of highly reactive oxygen intermediates and free radial molecules and ultimately causes cellular death. Maximal selective necrosis of tumor versus surrounding normal tissue is achieved by delaying the timing of light delivery because the relative absence of lymphatic channels results in photosensitizer accumulation in malignant tissues.[94] Topical photosensitizers are advantageous in that they are easy to apply and photosensitivity is confined to the site, but they may be limited by the depth of tumor perfusion that can be obtained.

Photodynamic therapy has been demonstrated to be an effective treatment for actinic keratoses.[95,96] Numerous trials have been conducted that suggest a response rate of 71% to 100% for actinic keratoses on the face after a single treatment session.[97–100] Nonfacial and hyperkeratotic actinic keratoses respond less favorably, and studies demonstrate more modest cure rates of approximately 45%.[101] Response rates of ALA photodynamic therapy for treatment of actinic keratoses appear to be comparable to those obtained using topical 5FU and cryotherapy.[93,102] Case reports also suggest the effectiveness of topical photodynamic therapy for the treatment of actinic cheilitis, including one that demonstrated 100% clearance in three patients with excellent cosmetic results noted at 12-month follow-up.[103]

Bowen disease has also been shown to have excellent responses to photodynamic therapy. Studies of systemically administered photosensitizers demonstrate 89% to 100% clearance rates, even with larger tumors (>2.0 cm) and multiple tumors requiring increased numbers of treatment sessions.[104–106] In a comparison of cryotherapy versus 20% ALA photodynamic therapy for SCC *in situ*, Morton et al. demonstrated that photodynamic therapy had a higher clearance rate (75%) than cryosurgery (50%) after a single treatment session, although all lesions eventually cleared with multiple treatments.[102] Topical photodynamic therapy may be used for Bowen disease, but it should be coupled with more deeply penetrating red light to obtain adequate depth of treatment. Photodynamic treatment of invasive SCC has been attempted with unreliable results, and it is not a recommended modality at this time.[97,107,108]

Numerous investigations have been conducted to evaluate the efficacy of photodynamic therapy for treatment of BCC. Systemic photodynamic therapy provides cure rates of 51% to 95% depending on the intensity of the light source used.[109–112] Lesions on the nose and those with infiltrative growth patterns are most likely to recur. Topical photodynamic therapy with ALA is an effective treatment for superficial BCC with complete response rates ranging from 79% to 100%.[113] Methylation enhances the lipophilic properties of the ALA and results in increased tissue penetration.[94] Topical photodynamic therapy with methyl ALA has been shown to produce 89% complete tumor clearance for BCC of mixed histology and 91% for nodular BCC, but was ineffective in treating morpheaform lesions.[114,115] A more recent study of 194 BCCs treated with MAL-PDT found a better response for superficial BCC (82% tumor clearance) than nodular BCC (33% tumor clearance), with truncal lesions showing the best response to treatment.[116] In general, the use of photodynamic therapy for BCC is limited by unreliable cure rates, and treatment should be reserved for low-risk lesions with superficial histology.

## Excision with Postoperative Margin Assessment

Standard excision with postoperative margin assessment is a commonly utilized treatment modality for low-risk NMSCs. In contrast to curettage and electrodesiccation, surgical excision offers the advantages of histologic margin confirmation, rapid healing, and potentially improved cosmesis, although the 5-year cure rates do not differ significantly between the two techniques.[21] Zitelli et al. have demonstrated that for NMSCs that are well-circumscribed and <2 cm in diameter, excision with 4 mm of normal adjacent tissue results in tumor clearance with 95% confidence.[59,116] The authors note that for SCC, peripheral erythema must be included in the clinical margin of the tumor. For SCC, recurrence rates after excision for low-risk tumors range from 5% to 8%.[53] Tumors with high-risk features are associated with higher recurrence rates following excision, with lesions >2 cm recurring at a rate of 15.7% and poorly differentiated lesion recurring at a rate of 25%.[53] Accordingly, 6-mm margins are recommended for these high-risk lesions.[59] For BCC, surgical excision of primary lesions occurring on the neck, the trunk, arms, and legs is associated with a 99% 5-year cure rate.[69] Surgical excision of BCC occurring on the head demonstrate decreasing cure rates with increasing tumor size, with 97% cure rates for lesions <6 mm and 92% cure rates for lesions >6 mm.[69] According to the 2007 National Comprehensive Cancer Network (NCCN) guidelines, 4- to 6-mm margins are recommended for treatment of SCC because of concerns about achieving complete tumor removal. In addition, standard excision is reliably utilized for treatment of NMSCs occurring in low-risk locations that are considered to be high risk, either because of positive margins on initial excision or size >2 cm. For these lesions, however, the NCCN recommends that 1-cm margins be taken.[70] The NCCN guidelines also state that following excision of the tumor, wound closure utilizing side-to-side closure, skin grafting, or secondary intention healing are all appropriate. Closure involving tissue rearrangement (i.e., cutaneous flaps) that might alter the location of residual tumor must be avoided unless intraoperative margin evaluation is performed.[70]

## Mohs Micrographic Surgery

Mohs surgery is a highly specialized excisional technique used for the treatment of high-risk cutaneous neoplasms that permits examination of the complete peripheral and deep margins of the specimen. This procedure is named after Dr. Frederick Mohs, a general surgeon at the University of Wisconsin, who first described the technique in the 1930s.[117] Mohs surgery is performed under local anesthesia and involves removal of a narrow margin

(c) 2014 Wolters Kluwer. All Rights Reserved.

of clinically normal skin around a given tumor. The orientation of this specimen relative to the patient is carefully mapped using a series of tissue hatches before removing the specimen. Once the tissue is excised, it is further marked using colored inks, and a map is drawn such that a given color corresponds to a specific area of the patient's defect. The specimen is then processed using fresh frozen sections in such a way that the surgeon is able to visualize 100% of the peripheral and deep margin in a single section. In contrast, the traditional "bread-loafing" style that is commonly used for standard pathological specimens allows visualization of <1% of the complete margin of the surgical specimen, and residual tumor may unknowingly exist in between examined sections.[118] If residual tumor is seen at one of the margins of a Mohs layer, its location is mapped, and an additional layer is excised from the area of the patient's defect, which was positive. This process is repeated until a Mohs layer is obtained with no residual tumor, and the excision is then complete.

Mohs surgery offers two main advantages over traditional excision for NMSC. The first is that by processing specimens to examine 100% of the surgical margin, Mohs surgery offers the highest cure rates for all NMSC. For primary BCCs, the 5-year cure rate is 99% with Mohs surgery versus 90% to 93% using standard techniques.[119] For recurrent BCCs, the 5-year cure rate was 94.4% with Mohs versus 80.1% for standard treatments.[120] For SCCs, Mohs surgery for primary tumors offers a 5-year cure rate of 96.9% versus 89.1% for non-Mohs treatments. Mohs surgery for recurrent SCCs results in a 90% cure rate versus 76.7% for non-Mohs treatments.[53] The second advantage is that by obtaining a series of narrow excisional margins for a given tumor as opposed to one standardized margin, the Mohs technique removes the smallest amount of normal tissue possible to achieve histologic clearance. These advantages are particularly important for high-risk tumors such as those occurring on the face, where standardized margins might unnecessarily compromise functionally or cosmetically critical structures. The most significant disadvantages of Mohs surgery are that it is more time-consuming and expensive than standard excision, and therefore it is commonly reserved for high-risk tumors.

Once histologic clearance has been obtained, the Mohs surgeon must determine the optimal method for repair of the surgical defect. Whenever possible, wounds are closed primarily. Layered closures, flaps, and grafts are often utilized when sufficient tissue reservoirs exist immediately adjacent to the wound. In certain specific locations, wounds may be left to heal by secondary intention with excellent results. Commensurate with the degree of difficulty of the closure and the level of reconstructive training of the Mohs surgeon, referral to other surgical specialties such a plastic surgery, otolaryngology, and oculoplastic surgery may be indicated (Figs. 23-7 to 23-10).

## Radiation Therapy

Radiation therapy has been used successfully in the management of NMSC, with cure rates similar to those with surgical techniques. Radiation therapy is used for both definitive treatment and in the adjuvant setting. Although the goal of radiation therapy is to maintain or exceed cure rates achieved with other modalities, an emphasis on maintaining form and function is also critical.

There are several advantages to using radiation therapy in the treatment of NMSC. Primarily, radiation therapy is noninvasive and therefore requires no anesthesia, which is important in this patient population where median age is in the 70s. In addition, there is no removal of normal tissue. This is especially important for cosmetically sensitive areas and for larger tumors adjacent to critical structures. There may also be an advantage for patients receiving anticoagulants, which would have to be discontinued for surgery. The major disadvantage to the use of radiation therapy is the inability to histologically determine margins. This allows for the potential of "geographic miss," where the entire extent of tumor is not adequately included in the treatment field. However, the noninvasive nature of radiation allows for generous margins to be used without significant toxicity. Also, patients are typically given multiple radiation treatments, spread over 2 to 6 weeks, which may be difficult for patients who do not have adequate means of transportation or who do not live in close proximity to a radiation center. The treatment-related effects of radiation therapy are limited to the area treated. With proper technique, <3% of patients should have significant toxicity.

Most patients with head and neck NMSC are candidates for treatment with radiation therapy. Absolute contraindications include patients with Gorlin syndrome and other genodermatoses because ionizing radiation may result in significant adverse effects, as well as induce more skin cancers. An exception to this is xeroderma pigmentosum, where the defect is in nucleotide excision repair, and there does not seem to be an enhanced reaction to ionizing radiation. In addition, patients with active autoimmune disease such as scleroderma and systemic lupus erythromatosus may have increased morbidity from radiation therapy.

There are several techniques used to deliver radiation therapy in the management of NMSC. Brachytherapy involves the direct placement of radioactive sources into the tumor to treat the cancer with surrounding margin. This technique is less often used currently for skin cancers because it requires an invasive procedure and hospitalization to minimize radiation exposure to others. Superficial x-rays have long been used in the management of cutaneous malignancies because of the dose distribution peaking at the surface and rapidly decreasing with depth.

(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 23-9.** **A:** Squamous cell carcinoma of the left medial canthus. **B:** Surgical defect extending to muscularis after one stage of Mohs micrographic surgery. **C:** Repair of the defect using a laterally based advancement flap. **D:** Surgical site appearance 2 months postoperatively.

This spares deep tissues and maximizes dose to the surface of the tumor. Superficial x-rays are still used, although the application of these machines is limited to treatment of superficial tumors. Therefore, many centers no longer have these machines. Also, superficial x-rays are limited in the depth of tumor that can be treated. To treat tumors of >5 mm depth, there is a substantial dose gradient between the surface and the deepest extent of the tumor. Electrons have been used more in recent years. Electrons are produced from the same linear accelerators used to treat most other patients with external beam radiation therapy. In addition, electrons are available in different energies so that differences in tumor depth can be taken into account. The major drawback of using electrons is the wider penumbra (the distance between the area receiving 80% of the prescribed dose and the area receiving 50% of the prescribed dose), and the uncertainty in dose distributions when very small field sizes are used. As a result, margins should be 1.5 to 2 cm for treatment with electrons compared with 1 cm for superficial x-rays. Recurrence rates with superficial x-rays or electrons are similar. Initial reports of electron use showed higher recurrence rates. Lovett et al. reported on 339 patients and showed a local control rate of 98% for superficial x-rays and 88% with electrons.[52] However, a report by Locke et al. from the same institution showed that with more recently treated patients, there was no longer a difference between superficial x-rays and electron treatments.[121] The initial difference may have been secondary to treatment technique and margins. Griep et al. looked at 389 patients with BCCs and SCCs and noted a 2.2% local recurrence rate with both superficial x-ray treatment and electrons. In addition, the cosmetic outcome was better for patients treated with electrons.[122]

The optimal time, dose, and fractionation scheme for treatment of cutaneous SCC and BCC have not been determined. Several studies have shown that a higher biologically effective dose is required for adequate tumor control.[123,124] This can be achieved in several ways: by increasing the dose per treatment (fraction size) or increasing the total number of treatments delivered (total dose). Fraction size can be increased, and several regimens have been used with excellent local control rates, including 2,600 cGy in 2 fractions, 3,500 cGy in 5 fractions, 4,500 in 10 to 12 fractions, and 5,100 cGy in 17 fractions. The latter is commonly used by the authors. Although effective, several studies have shown increased morbidity and worse cosmesis with fraction size >5 Gy.[122–124] Large fraction size is only suggested for small tumors <2 cm, where critical structures will not be in the treatment field and for patients unable to come for a more protracted sequence. Schedules using 3 Gy × 17 fractions (5,100 cGy) or 2.5 Gy × 20 fractions (5,000 cGy) are associated with similar recurrence rates and better toxicity and cosmetic

profiles. For very large tumors, or when bone or cartilage are in the treatment field, 2-Gy fractions are recommended to a total dose of 6,500 cGy to 7,500 cGy.[125] Fraction size of <2 Gy is associated with increased local recurrence and should not be used.[121]

Treatment of BCC should include the primary lesion with an adequate margin taking into account beam profile and microscopic extension of tumor. The incidence of nodal involvement is <0.5%, and routine treatment of the primary echelon of nodes is not indicated. Treatment of SCC should also be directed to the primary tumor site. However, for tumors with high-risk features (Table 23.3), treatment should be extended to include the first echelon of nodes, typically the periparotid nodes with or without upper cervical nodes.

Results with radiation therapy in the management of BCCs and SCCs of the skin are excellent. Factors associated with recurrence after radiation therapy include, larger tumor size, recurrent tumors, invasion of adjacent structures, inadequate dose, and squamous cell histology. Table 23.6 shows outcomes with several large trials of radiation therapy. Petrovich et al. showed the influence of tumor size. Out of 646 patients, the local recurrence rate was significantly higher for tumors 2 to 5 cm and >5 cm compared with those <2 cm.[125] Lim et al. showed the importance of adequate effective dose to achieve cure of these tumors.[123]

The decision to use radiation therapy in the management of these patients is often due to the location of the primary tumor. Although flat surfaces of the forehead and neck are often treated surgically, the pinna, the nasal skin, and the periorbital regions are often treated with radiation therapy, as well as lip cancers, which are discussed with oral cavity tumors. As mentioned previously, H-Zone lesions are well suited to radiation therapy due to cosmetic outcomes. Surgical resection in these areas can result in tissue defects that may require significant reconstruction or result in functional impairment. Each of these sites has significant cosmetic importance and, in the case of periorbital tumors, significant functional importance. Radiation therapy has been used successfully in all the three sites.

***Pinna.*** Radiation therapy can be used to treat the pinna with either brachytherapy or external beam radiation therapy. Mazeron reported on 70 patients treated with low-dose rate iridium-192 ($^{192}$Ir) and had a 99% local control rate. These procedures were completed under local anesthetic using $^{192}$Ir wires with the most common dose 60 Gy delivered at 0.3 to 0.9 Gy/hour. Thirty-nine of these patients had SCC, whereas 31 had BCC. For patients with tumors <4 cm, 78% had good cosmesis. However, cosmesis was good in only 1 of 9 patients with tumor size >4 cm.

[a]Meta-analysis.

Ten percent of the patients with SCC developed regional nodal metastases in this population.[127] Silva et al. reported experience with 334 skin cancers of the pinna treated with superficial x-rays or electrons and noted local control rates of 86.6% at 2 years and 79.2% at 5 years. Grade IV toxicity was reported in 7.3% of patients, each of whom received fraction size >4 Gy. Of the failures, all but two patients underwent successful salvage therapy.[124]

***Nasal Skin.*** Radiation therapy has often been used for skin cancers of the nasal skin because this area is in a critical location for cosmesis and function (Figs. 23-11 to 23-13). Several studies have shown low recurrence rates with radiation therapy of approximately 5% (Table 23.7).[124,128,129] The largest study was a European multicenter retrospective review by Mazeron et al. with 1,676 patients with cancers of the nasal skin or nasal vestibule. Local control rates were 93% at 2 years and the necrosis rate was 2%. Patients with tumors <2 cm had a 96% control rate, and tumors of the external nasal skin fared better than those with vestibule tumors (94% vs. 75%).[130] Caccialanza[131] reported a large retrospective series of 671 patients with basal and squamous cell cancers of the nasal skin, treated with kilovoltage radiotherapy between 1972 and 2007. For the entire group, with mean follow-up of 38 months (range 1–351 months) local control was 88% with good cosmetic outcomes in 97%. No major complications were observed.

***Periocular Tumors.*** Treatment of periocular skin cancers results in higher recurrence rates than other sites. This is likely due to hesitancy in treating larger margins with critical adjacent structures. Radiation therapy is very effective for these lesions resulting in excellent form and function, unless the tumor has already destroyed much of the adjacent tissue (Fig. 23-14).

Fitzpatrick[132] reviewed 1,062 patients with BCC or SCC of the eyelids and found local control rates of 95% and 93%, respectively (Table 23.8). Technique must take into account the lens that is typically shielded, as well as the lacrimal gland to avoid dry eye after treatment. Most tumors arise in the lower lid or medial canthus.[133] Tumors are treated with 1 to 1.5 cm margins using fraction size of 3 Gy or less.

## TREATMENT ALGORITHM

### T1 and Small T2 Tumors

Most patients with T1 and small T2 basal or SCCs of the skin can be treated with any of the aforementioned treatments and expect recurrence rates of <10%, usually with good or excellent cosmetic and functional outcome. High-risk tumor factors should be taken into account and should be treated with Mohs surgery or radiation therapy (Tables 23.2 and 23.3). In addition, crucial to the decision regarding treatment modality is the anatomic area of the lesion and the specific treatment-related morbidity with respect to the individual patient. Few studies have compared different treatment modalities in a randomized prospective manner. A pivotal trial from the Institut Gustave-Roussy compared surgery and radiation therapy.[126] Because this study used techniques which are not used today, the results are of questionable value in the current era. This trial prospectively enrolled 347 patients with <4 cm BCC of the face and randomized them to surgery versus radiation therapy. The primary endpoint was the failure rate (persistent or recurrent disease) after 4 years of follow-up. The secondary endpoint was the cosmetic result assessed by the patient, the dermatologist, and three persons not involved in the trial. Of the 174 patients in the surgery group, 71% had local anesthesia and 91% frozen section examination. Of the 173 patients in the radiotherapy group, 55% were treated with interstitial brachytherapy, 33% with contact therapy, and 12% with conventional radiotherapy. The 4-year actuarial failure rate (95% confidence interval [CI]) was 0.7% (0.1%–3.9%) in the surgery group compared with 7.5% (4.2%–13.1%) in the radiotherapy group (log-rank $p = 0.003$). The cosmetic results assessed by four of the five judges were significantly better after surgery than after radiotherapy. Eighty-seven percent of the surgery-treated patients and 69% of the radiation-treated patients considered the cosmetic result as good ($p < 0.01$). A follow-up study compared the cosmetic outcomes of these patients as noted by five different evaluators, as well as photographic evaluation. This also showed a better cosmetic outcome for the patients treated with surgery. Proponents of radiation therapy note that patients treated with radiation in this trial were treated with suboptimal techniques compared with what is typically done currently. One of the key advantages to radiation therapy for NMSC is the noninvasive aspect of the therapy. Fifty-five percent of patients in the radiation arm of this trial were treated with brachytherapy, an invasive form of delivering radiation therapy yielding poorer cosmesis. In addition, many patients were treated with large fraction size. As discussed previously, large fraction size is associated with greater late morbidity and suboptimal cosmetic outcomes. Although the

**TABLE 23.7 Radiation Therapy Outcomes for Basal Cell Carcinoma (BCC) and Squamous Cell Carcinoma (SCC) of Nasal Skin**

| Author | Histology | Follow-up (Years) | No. of Patients | Local Control (%) | Cosmesis (Good/ Excellent) (%) | Grade 4 Toxicity (%) |
|---|---|---|---|---|---|---|
| Tsao et al. (1997)[128] | SCC | 5.0 | 100 | 85 | — | 0 |
| Petrovich et al. (1987)[125] | BCC and SCC | 5.0 | 350 | 95 | — | — |
| Childers et al. (1986)[129] | BCC | 9.3 | 26 | 96 | 81 | 0 |

recurrence rate with radiation therapy was higher than surgery in this trial, salvage rates for patients who have recurrences after radiation therapy are excellent with more radical surgical approaches. This trial showed that outcomes with either surgery or radiation provide excellent outcomes, and the practitioner must therefore individualize the optimal treatment strategy for each patient. Surgical techniques involve removal of tissue, and when in critical areas of function and cosmesis, reconstruction must be done to achieve adequate outcomes. Radiation therapy results in destruction of the tumor, but functional and cosmetic result is limited by the amount of destruction already done by the primary tumor. The tissue deficit after destruction of the tumor may be unacceptable. Therefore, the best approach is often a multidisciplinary one including medical, surgical, and radiation techniques. For most small lesions of the head and neck, either surgery or radiation provides excellent outcomes, cosmesis, and function. Surgery has the advantage of limited office visits and should be considered for most patients. Patients who undergo resection with positive margins should undergo additional resection or adjuvant radiation therapy. Again, the advantage of Mohs surgery is that residual tumor is identified and further excision can be completed on the same day. Pathology showing extensive perineural involvement or large nerve involvement should also be treated with adjuvant radiation therapy. Elderly patients, especially those who are unable to undergo resection and reconstruction, or who are at risk for poor wound healing, may benefit from radiation therapy. In addition, larger lesions involving the tip of the nose, the eyelids, and the pinna may sometimes be treated preferentially with radiation therapy because reconstruction in these areas may be less likely to provide adequate cosmetic and functional outcome. When surgical techniques are concerned, Mohs micrographic surgery allows control of margins and results in minimal tissue removal. The goal with standard surgical resection is to achieve margins of 4 mm or more with BCC and 1 cm with SCC, but it is important to note that normal tissue may be significant when taking margins, resulting in a large deficit. This may be required for complete removal. When radiation therapy is used, treatment with fraction size <4 Gy results in optimal cosmesis. In cases where bone or cartilage is likely to be included in the treatment field, one should consider fraction sizes of <3 Gy. Regardless of chosen modality, the recurrence rate should be <10% and 90% of patients should have good or excellent cosmetic outcomes with minimal morbidity. A treatment algorithm based on NCCN recommendations is provided for low-risk BCC and SCC in Figure 23-15 and for high-risk BCC and SCC in Figure 23-16.

## Recurrent Tumors

Recurrent tumors should be treated similar to primary lesions, although recurrence rates are generally 5% to 10% higher. Before initiating treatment, the tumor should be thoroughly reevaluated, particularly for extent of invasion. Treatment with a margin evaluating modality (Mohs) or wide-margin treatment (radiation therapy) results in lower recurrence rates. Rowe et al. reviewed outcomes for patients with recurrent BCC.[120] The 5-year recurrence rate was 5.6% for Mohs micrographic surgery and 9.8% for radiation therapy. Recurrence rates with other modalities were >17%, with the highest recurrence rate for curettage and electrodesiccation at 40%. Figures 23-17 and 23-18 show two clinical examples of recurrent disease.

## Locally Advanced and Metastatic Disease

Large T2 and T3 tumors can also be treated with either surgical resection or radiation therapy. Mohs micrographic surgery is the preferable surgical technique for these tumors to achieve negative margins. Radiation therapy allows for normal tissue sparing, and local control rates of >80% can be achieved when including those salvaged with surgery.[134] While most BCCs are adequately controlled with these interventions, patients with inoperable tumors or innumerable BCCs not amenable to surgery have had fewer treatment options. As a result, the development of targeted molecular therapy for BCC has been met with considerable excitement.[135] Targeted molecular therapy for BCC has focused mainly on the Hedgehog signaling pathway. Patched (PTCH) and

smoothened (SMO) are two key genes involved. PTCH, a member of the patched gene family, is a receptor important for its inhibition of SMO, a protein that results in downstream target gene transcription. Mutations in PTCH that result in continuous SMO activation are the most common genetic alterations found in BCC. GDC-0449 or vismodegib (Genentech, San Francisco, CA) is a small molecule inhibitor of the SMO protein. In a recently reported phase I study, 18 of 33 patients with BCCs that could not be treated with surgery, radiation, or other systemic therapy had an objective response to the drug on a basis of imaging, physical examination, or both. There were two complete responders and 16 partial responders, defined as a 50% reduction in visible or palpable tumor.[136] In another open-label, multicenter two cohort phase II study, 43% of patients with locally advanced BCC and 30% of patients with metastatic BCC showed improvement from baseline. Side effects included muscle spasms, hair loss, altered taste sensation, weight loss, fatigue, nausea, decreased appetite, and diarrhea.[137]

The presence of perineural invasion has been shown to be a significant factor in determining outcome. A clear distinction has been made between perineural invasion that is clinically obvious (cPNI) versus perineural invasion which is not clinically apparent, but is pathologically evident (pPNI). Postoperative RT has been used in both of these situations, with the general consensus that it improves the outcome. Jackson[138] reviewed 118 patients with PNI (97 with pPNI and 21 with cPNI) who received RT. With medial follow-up of 84 months (range 4–201), local control was 90% and 57% ($p < 0.001$) for pPNI and cPNI, respectively. This translated into worse relapse-free survival, disease-specific survival, and overall survival (76% vs. 46%, $p = 0.003$; 90% vs. 76%, $p = 0.002$; 69% vs. 57%, $p = 0.03$, respectively). Basal cell cancers with pPNI had better local control than squamous cell cancers with pPNI (97% vs. 84%, $p = 0.02$).

For patients presenting with nodal disease, neck dissection, radiation therapy, or a combination is effective, although there are limited data in the literature. Combination therapy for regional disease is associated with a 5-year cure rate of 30% to 40%.[53] NCCN recommends consideration of adjuvant radiation therapy for patients with multiple nodes positive, extracapsular extension, and nodes >3 cm after neck dissection.[70] Radical neck dissection and modified neck dissections may be helpful for debulking metastatic cervical disease.[139] Taylor et al. reviewed 60 patients with NMSC metastatic to regional nodes. Fifty-seven of these patients had SCC. At a follow-up of 2 years, local control was 63% with surgery alone, 46% with radiation alone, and 89% with a combination. Of the 60 patients, 30 (60%) underwent combined modality therapy.[140] Moore[141] reported 193 patients with squamous cell skin cancer of the head and neck. Twenty-one percent had nodal metastases. Interestingly, the nodal disease was not clinically apparent in 42% of cases. Recurrent cancers, lymphovascular invasion, perineural invasion, and inflammatory changes were factors predisposing patients to nodal disease. Regional control with surgery and postoperative RT was 95%.

Treatment of metastatic SCC may include systemic chemotherapy or treatment with biologic response modifiers, but the efficacy of these therapies has not been well established.[142–144] Epidermal growth factor receptor (EGFR) inhibitors are a new class of medicines which are proving effective in the treatment of locally advanced and metastatic cutaneous SCC.[145] A recent study of 8 patients with unresectable or metastatic cutaneous SCC showed that treatment with cetuximab alone or with concomitant radiotherapy can be effective, with 6/8 responses, including three complete responses, and a median overall survival of 22.5 months.[146]

Metastatic BCC is a rare occurrence with an estimated incidence of 0.03%.[147] Until recently, with the exception of isolated

case reports, radiation, surgery, and chemotherapy for metastatic BCC yielded only disappointing results.[148,149] However, the advent of targeted molecular inhibitors has given new hope to this small subset of BCC patients. Further studies will provide a better understanding of the full potential of vismodegib, cetuximab, and other targeted molecular therapies in the treatment of advanced NMSC.

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

The role of imaging for the patient with skin cancer, similar to any other head and neck cancer, is to determine the full extent of the primary tumor, with special attention to bone invasion, perineural spread, and lymphatic spread. Initial inspection of the primary site involves evaluation of the subcutaneous fat, and deep to that, the superficial musculoaponeurotic system (SMAS) (Fig. 23-19). Evaluation of the SMAS and the fat plane deep to it is critical as this is where branches of the facial nerve and trigeminal nerve innervate the muscles of facial expression. Once the SMAS is involved by tumor, the more proximal course of the facial and trigeminal nerves need to be examined to look for more extensive perineural spread (Fig. 23-20).

Imaging helps to determine the extent of cosmetic reconstruction that may be required. It is critical to evaluate bone invasion in this regard. CT is more sensitive than MRI for the detection of cortical bone invasion (Fig. 23-21), but MRI may be better for showing bone marrow extension. Critical areas for cosmesis include the orbits and also the eyelids where basal cell cancer is common[1] (Figs. 23-22 and 23-23). When skin cancer invades the calvarium, MRI should be obtained to evaluate the extent of dural or brain involvement (Fig. 23-24).

Perineural spread of skin cancer can occur with squamous cell cancer and basal cell cancer.[2] Central perineural spread is more common in basal cell or basaloid squamous lesions,[3] and skip lesions are possible. Therefore, the more proximal cranial nerves 5 and 7 should be evaluated with imaging. CT can show perineural spread, but MRI is definitely preferred (Figs. 23-25 and 23-26).[4–6] A recent study was performed to

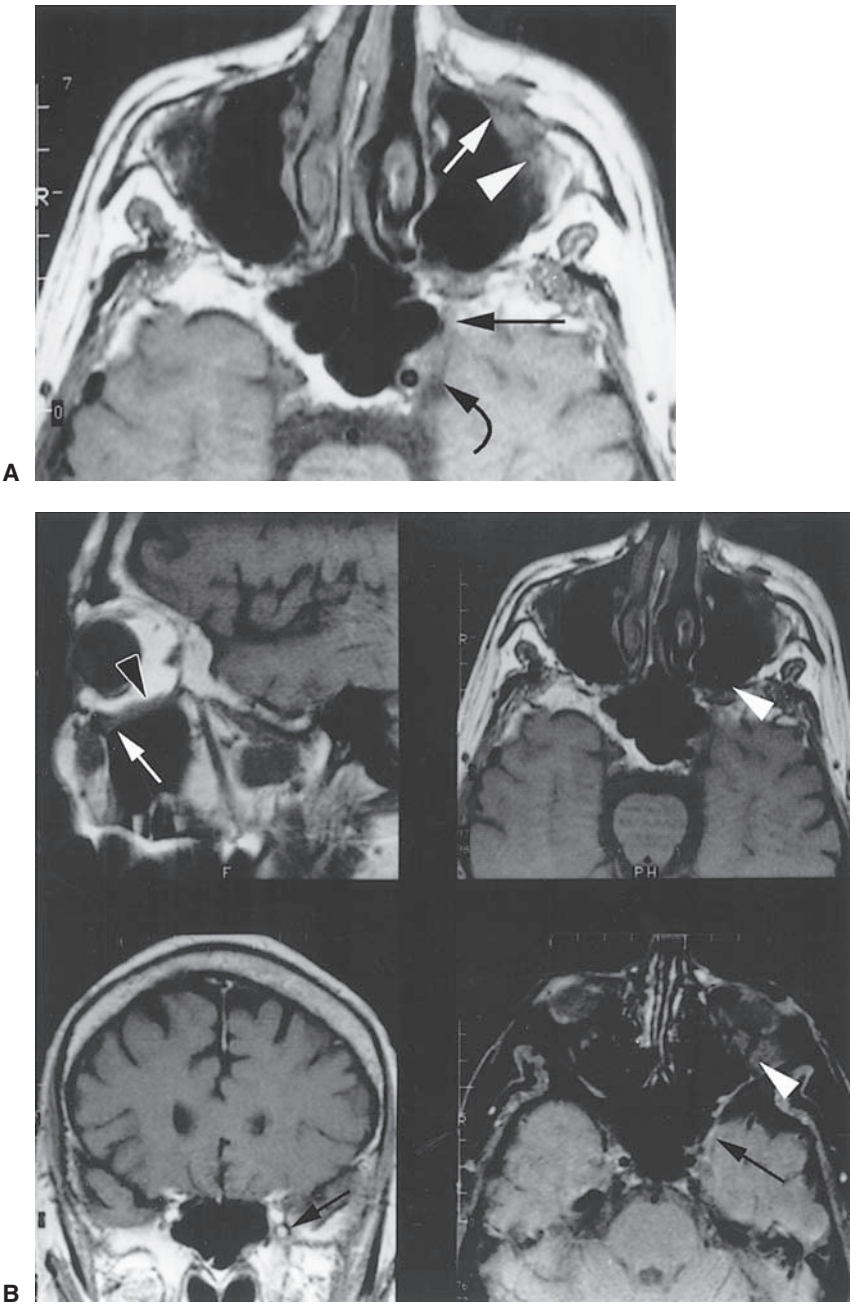

**FIGURE 23-25.** Neurotropic basal squamous cancer. Axial T1 magnetic resonance imaging **(A)** and fat-suppressed contrast axial T1 **(B)** views showing proximal neurotropic involvement entering the infraorbital foramen (*arrow*), extending along the inferior orbital groove (*arrowheads*), through the expanded foramen rotundum (*long arrow*), and into the cavernous sinus (*curved arrow*), producing anesthesia of the second division of the fifth nerve, despite healed primary nasolabial site.

determine the accuracy of well-protocoled MRI for the detection of perineural spread of malignancy.[7] This study not only found a 100% detection rate, but also showed that MRI underestimates microscopic spread proximal to the Gasserian ganglion.

Lymphatic spread is usually a late finding. Common sites of spread are to intraparotid nodes, as well as occipital and level 5 nodes (Fig. 23-27). Facial nodes are also at risk (Fig. 23-28).

Recurrent skin cancer should be imaged as spread may be deeper than appreciated on physical exam, and perineural extension is quite common. Image-guided biopsies are usually an option when disease recurrence is suspected in deep locations such as the pterygopalatine fossa or in lymph nodes. FDG-PET may be useful for recurrent squamous cell cancer or Merkel cell cancer. Distant metastasis from basal cell cancer is rare. Suggested protocols are given in Figures 23-29 to 23-31.

# PART C:
# Radiation Therapy Technique

Louis B. Harrison, Rudolph Woode, James E. Dolan, and Waleed Mourad

Electron beam radiation therapy is the mainstay of treatment for skin cancers of the head and neck. It is important to carefully map out the extent of the lesion on the patient and add at least 1-cm margin. A larger margin up to 1.5 to 2.0 cm can be used if this does not encroach upon vital structures or if there is uncertainty about the edge of the lesion. Our practice is to place wires around the final margins, which correspond to the electron field edge. We also construct custom wax bolus of 0.5 to 1.0 cm to fit perfectly over the involved skin, to provide optimal dose distribution. This approach will satisfactorily deal with the majority of early or intermediate-sized lesions. Figures 23-32 and 23-33 show a clinical example.

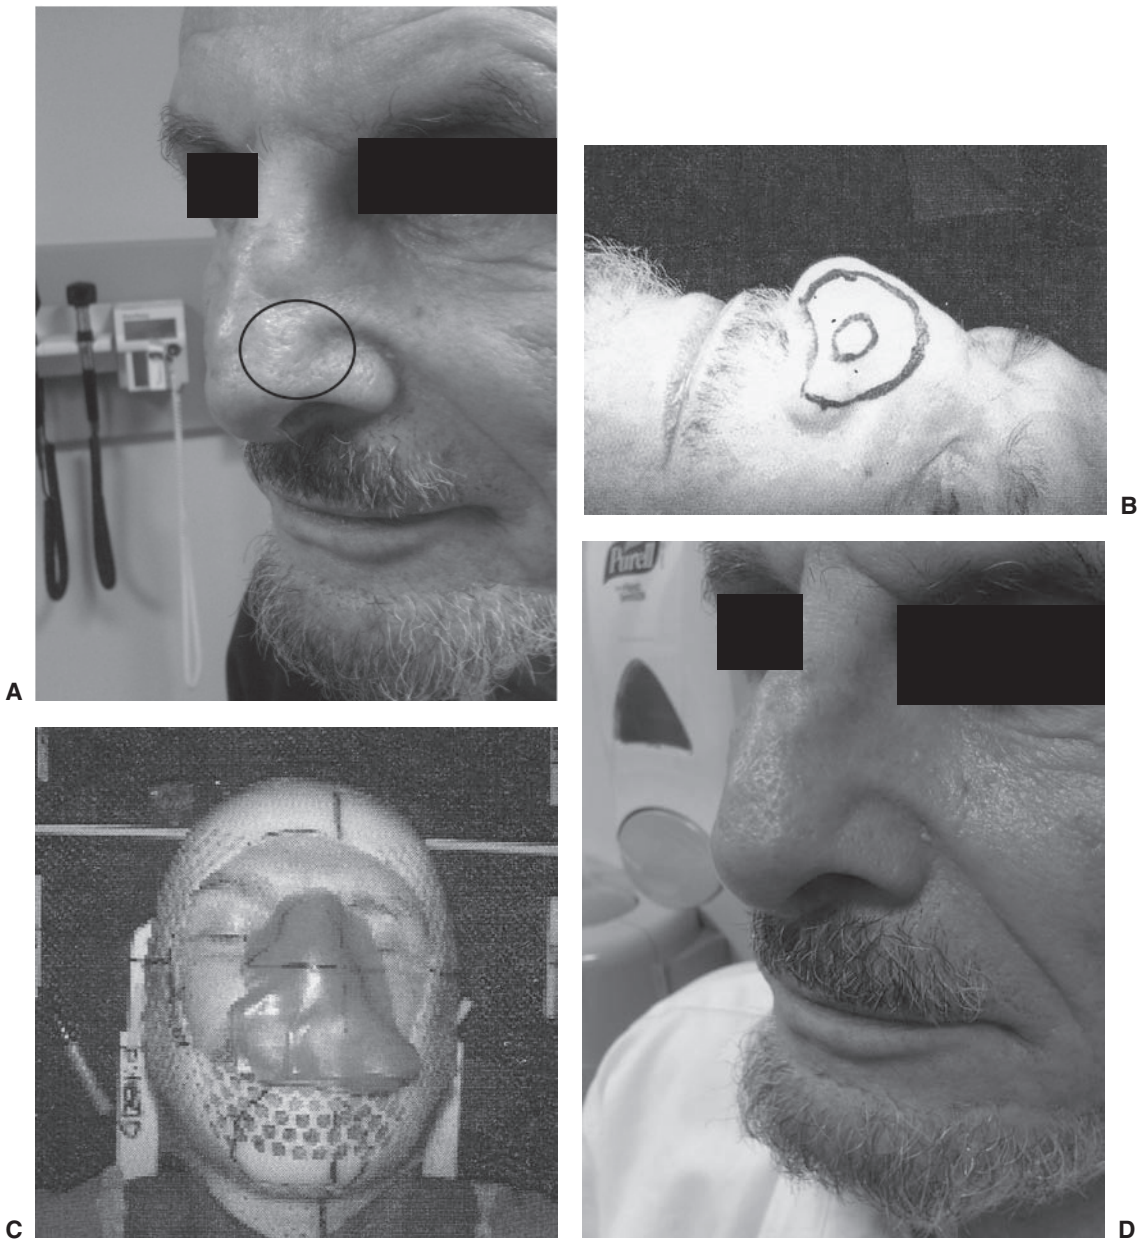

**FIGURE 23-32.** Basal cell carcinoma involving the skin of the left nasal ala. **A:** Before radiation therapy. **B:** Lesion mapped in inner circle and about 1.5 cm margin placed around lesion for electron field size. **C:** Custom was bolus placed over the nasal area, 1 cm thick. **D:** Patient received 5,100 cGy in 17 fractions using 6 MeV electrons with custom bolus. (See color insert.)

For more extensive lesions, more extensive planning is required. This will require CT-based planning and will often require combined photons and electrons. It is essential for the radiation oncologist to carefully assess the skin margins clinically and translate these into margins on the CT scan, as the radiologic assessment of the margins is impossible. Figure 23-34 shows a clinical example of an advanced basal cell cancer treated with definitive RT. Figure 23-35 shows a complicated recurrent squamous cell cancer of the forehead treated with combined photons and electrons to the forehead and ipsilateral neck.

# PART D:
# Surgical Technique

Marc S. Zimbler

When analyzing facial soft tissue skin defects certain considerations are important, even before examining the defect itself. First and foremost, the reconstructive surgeon must be comfortable with the tumor extirpation itself. This is essential in cases where the reconstruction will involve the rearrangement of local tissue. Otherwise, concealing residual tumor can have devastating consequences. For many basal and squamous skin cancers of the face this means removing the lesion with Mohs micrographic surgery. In cases of melanoma, reconstruction should be delayed until permanent section analysis of surgical margins are completed. Other considerations prior to examining the defect include the patients' skin thickness, skin color and texture, and surrounding solar damage. Age and resultant skin laxity are also important when determining how much tissue advancement can be achieved and how long incisions should be made. Many skin cancer patients have had prior malignancies or recurrences, and scar tissue in the immediate or adjacent regions can influence reconstructive choices. Also, prior elective operations such as rhinoplasty or rhytidectomy can influence the surgeon's decision making. Consideration of comorbidities is also important. Many elderly skin cancer patients are on anticoagulants, have a history of diabetes, may not tolerate general anesthesia, or lack the ability to care for complex postoperative wounds. Cancer monitoring is always a major concern with more invasive tumors or recurrences. In many specific cases, a simple reconstruction is chosen initially, and then a more complex staged procedure can be performed once sufficient cancer monitoring has been obtained. The patient's own expectations are also essential to the surgeon's planning. For instance, does the patient require a complex staged surgery if his/her own aesthetic satisfaction is achieved with a simpler option. Many times the surgeon's level of aesthetic may not correlate with that of the patient. This is often a subtle distinction.

After considering these issues, it is now time to examine the defect. When examining the defect, several factors are determined initially before a reconstructive is designed. Relative to the defect three factors are essential—defect location, size, and depth. Ideally, each layer of absent tissue should be replaced by like tissue. When possible, the cutaneous defect should be closed with skin of similar thickness, color, and texture to that missing. Missing cartilage should be replaced by appropriately

(c) 2014 Wolters Kluwer. All Rights Reserved.

positioned, contoured, and sculpted cartilage. Facial location is critical because defects of the nose may be treated differently than others in which adjacent lax skin is abundant. Defect size is particularly important in determining whether a flap or skin graft is preferable. Depth of the defect is also considered because some are very superficial and can be treated by allowing secondary intention healing. On the other hand, deeper defects with exposed cartilage or bone may require flap coverage.

The location of the defect in relation to relaxed skin tension lines (RSTLs) and facial aesthetic subunits (Fig. 23-36A,B) is also an essential consideration in planning reconstruction. Scar orientation parallel to RSTLs or those camouflaged within facial aesthetic subunits create an optimal environment for wound healing and eventual scar formation. The importance of reconstructions utilizing these two key factors cannot be over emphasized.

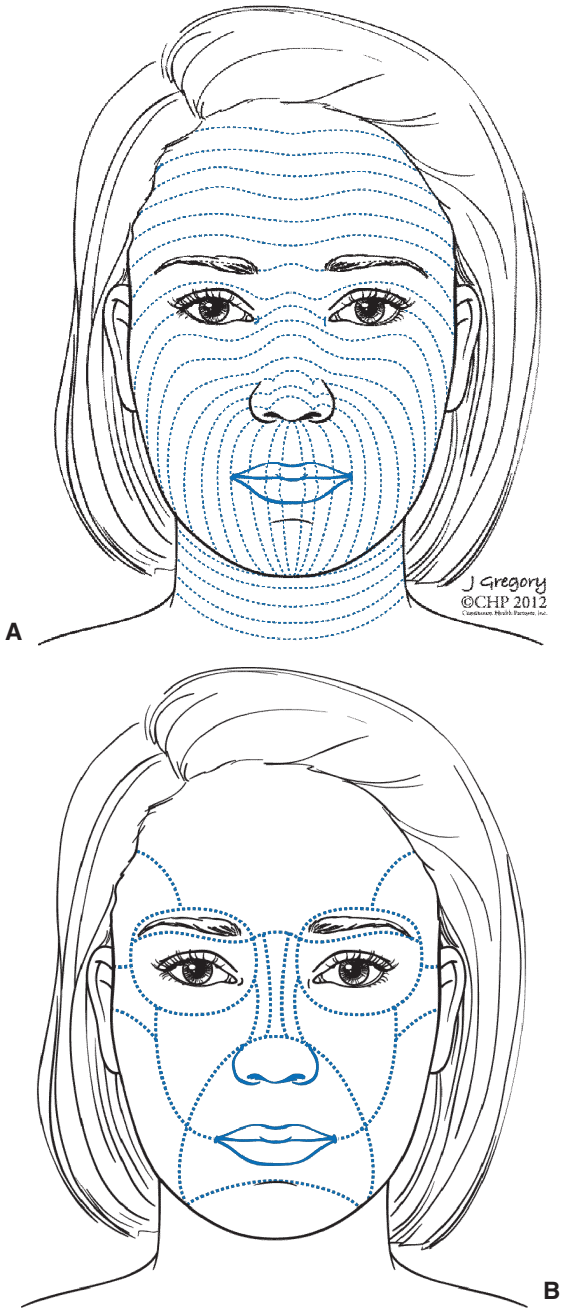

**FIGURE 23-36.** **A:** Relaxed skin tension lines (RSTLs) of the face. Incisions are designed parallel to RSTLs whenever possible. **B:** Facial aesthetic subunits. Incisions are designed at borders of facial aesthetic subunits whenever possible in order to camouflage scarring.

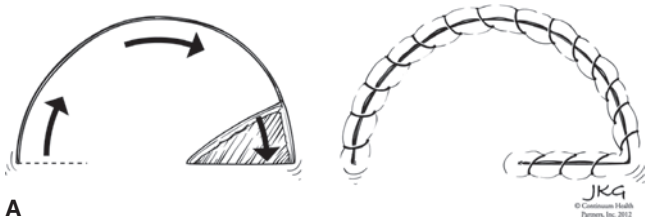
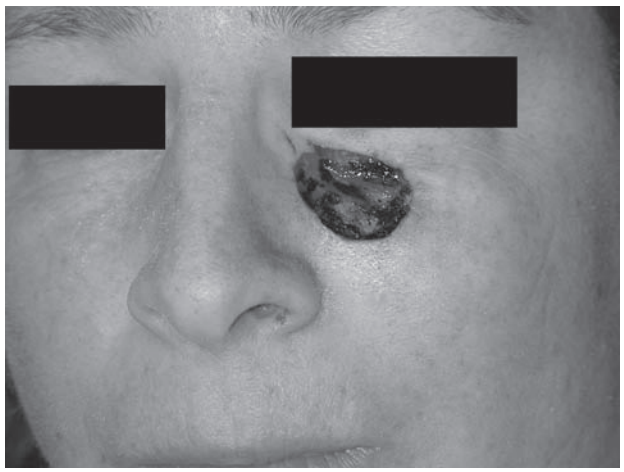


Generically speaking, options for repair include healing by second intention, primary closure, skin graft, and skin flaps—local, regional, or distal. Although most publications on reconstructive surgery concentrate on flap design, one should not underestimate primary closure as a viable source in the appropriately chosen regions. Key considerations to this method are wide subcutaneous undermining, defect size, and location. Primary closure should be the first consideration for reconstruction of a surgical defect, and especially in those patients in whom there is an abundance of adjacent lax tissue, it is often the method of choice. Many cheek and forehead defects can be closed primarily as long as they do not cause distortion of adjacent structures such as the lower eyelid and eyebrow. Key to this determination is defect size, proximity to the structure of concern, as well as laxity of the skin. Primary closure should be oriented parallel to relaxed skin tension lines or hidden within facial aesthetic subunits whenever possible. Except for small midline defects, primary closure is seldom possible on the distal nose. The size and midline location is critical to the outcome so as not to cause unilateral nasal distortion.

Skin grafts are also insufficiently discussed in the literature, even though they can play an essential role. Skin grafts on the face should be full thickness when possible. Compared with split thickness grafts, they have the advantage of creating a better color and texture match. They also create less contour irregularities, resist contraction, do not require special equipment to harvest, and are associated with less donor site morbidity. Typical donor sites for full thickness skin include postauricular, preauricular, and supraclavicular areas. Less commonly used sites are the upper forehead, upper eyelid, and nasolabial fold. When determining which site would be most appropriate to reconstruct, the surgeon must examine the defect for size, skin thickness, skin texture, and depth. Postauricular skin, which is often a first choice, is limited by amount of skin for harvest and thin nature, and often it is light colored. Preauricular skin is an excellent choice for thickness and color match, but is also limited by defect size. For larger defects, the supraclavicular region is excellent; however, skin match for the face may be suboptimal. When harvesting skin graft donor sites around the ear, prior facelift scarring can limit tissue availability. Adequate fat trimming from the skin undersurface and postoperative bolster placement are important in helping to maintain graft survivability after placement.



Flaps can be classified as local, regional, and distant. Local flaps are the most commonly used in facial cutaneous reconstruction and can be further divided into rotational, transposition, advancement, and island. Regional flaps include interpolated melolabial flaps, Abbe lip-switch flap, and paramedian forehead flaps. Distant flaps are usually microvascular free tissue transfer. Typically, a number of different flap designs can be considered for any given cutaneous defect. Surgical judgment is critical in the decision-making process. However, in the majority of cases, one or two flap designs are usually obviously preferable. Location and size of the defect are the two most critical factors in selecting facial flaps.

Rotational flaps are pivotal with a curvilinear configuration. They are designed immediately adjacent to the defect and are best used to close triangular defects. The "triangle" is covered by a portion of the standing cutaneous deformity, thus facilitating the pivotal movement of the flap (Fig. 23-37A). Typical examples include pivotal scalp flaps, dorsal glabellar flaps on the nose, and cervicofacial flaps (see Fig. 23-37B,C).

C

**FIGURE 23-37.** **A:** Rotation flap. **B:** 2.5 × 2.5 cm medial cheek Mohs defect. **C:** Closure of the Mohs defect with a rotation-advancement flap. Suture lines and standing cone deformities are designed at borders of facial aesthetic subunits.

Transposition flaps by definition cross over or transpose intervening tissue to reach their target location. Like rotational flaps, they are designed in such a way that one of the borders of the flap is also the border of the defect. Both rotational and transposition flaps develop standing cutaneous deformities at their base and have a pivotal point as movement (Fig. 23-38A). Typical examples of transposition flaps include nasolabial, rhombic, and bilobed (see Fig. 23-38B–D). For numerous reasons, this author does not perform the rhombus flap or its variations often.

Advancement flaps are the most common utilized for facial reconstruction. Advancement flaps have a linear configuration and move by sliding toward the defect (Fig. 23-39A). Stretching of the flap is the norm, and therefore they work best in areas of greater skin elasticity. Typical examples include uni -or bipedicle advancement, V-Y closure, and O-T plasty (see Fig. 23-39B,C).

(c) 2014 Wolters Kluwer. All Rights Reserved.

An island flap is incised on all borders so that there are no cutaneous attachments between the skin of the flap and the adjacent skin of the donor site. The pedicle of the flap consists only of subcutaneous tissue with its underlying vascular supply. Island flaps may be transferred by pivoting or stretching (Fig. 23-40A). Flap advancement length is limited with this type of flap; however, the deep vascular supply can be used to cover exposed bone or cartilage. Typical shapes for such island flaps include V-Y designs (see Fig. 23-40B–D).

Interpolated flaps, like the transposition flap is transferred by pivotal movement and has a linear configuration. However, it differs from transposition flaps in that its base is not contiguous with the defect. Thus, the pedicle must cross over intervening tissue and requires a second surgical procedure to divide and inset the flap (Fig. 23-41A). Typical interpolated flaps used on the face include the paramedian forehead flap, Abbe lip-switch flap, and melolabial flap. Melolabial flaps are excellent for reconstructing nasal alar defects and in certain situations may save the patient from having to undergo forehead flap reconstruction (see Fig. 23-41B–D). In the authors experience, forehead flaps are best utilized for complex nasal defects requiring more than just skin coverage. Both forehead flaps and melolabial flaps are excellent choices in combination with cartilage grafts to restore nasal form and function.

CHAPTER 24

# Melanoma of the Head and Neck

## PART A:
## General Principles and Management

Michael E. Kupferman and Michael A. Davies

### INTRODUCTION

More than 3.5 million new skin cancers are diagnosed every year. Although melanoma represents <5% of the cases, it is responsible for >75% of skin cancer–related deaths.[1] Thus, melanoma is the most aggressive form of skin cancer, and it is likely to be an increasingly prevalent problem in the future. An estimated 70,230 patients will be diagnosed with melanoma, and 8,790 will die from this disease, in the United States in 2012.[2] Currently, the lifetime risk of being diagnosed with melanoma is 1 in 37 for men and 1 in 55 for women. Concerningly, the incidence of melanoma has increased dramatically over the last several decades, with an increase of >200% in the age-adjusted incidence from 1975 to 2008.[3–8] The rise in incidence has been detected across all age groups and primary tumor thicknesses. The mortality rate has also increased approximately 60% over time, primarily due to increased mortality in patients ≥65 years of age, particularly among men.[3,7,8] However, many patients who die from melanoma are otherwise young and healthy, leading to melanoma being among the cancers with the highest life-years lost per fatality.[9,10]

Although melanoma is a highly aggressive cancer, patients can be cured of this disease if they are diagnosed early and managed appropriately. Carefully conducted studies over the last 20 years have defined the clinical and pathological criteria that define patient prognosis and guide current patient management.[11–13] Historically, melanomas have been grouped based on clinical and pathological features. However, recent discoveries about the molecular biology of melanoma have provided key insights into the molecular heterogeneity of this disease and are rapidly leading to new therapeutic approaches and improved clinical outcomes.[14] This chapter will review the existing standards for melanoma diagnosis and treatment and will discuss the recent advances in research and their implications for future patient management.

### ANATOMY

Melanomas of the head and neck most commonly present on the face, which corresponds to the area that has received the highest lifetime cumulative dosages of ultraviolet light. The scalp and ears are the next most common sites of presentation, followed by the skin of the neck. Due to the substantial cosmetic considerations associated with facial surgery, it is imperative that the operating surgeon has an understanding of the anatomic subunits of the facial structures and of lines of normal skin tension. On the nasal cavity, these include the dorsum, the nasal sidewalls, the nasal ala, the columella, and the tip. On the ears, these include the helix, the conchal bowl, the antihelix, and the lobule. On the eyes, these include the superior orbital rim, the inferior orbital rim, the medial canthal region, and the lateral canthal region. Placement of surgical incisions within the lines of normal skin tension will allow surgical reconstruction to proceed in a cosmetically appealing manner.

Of utmost importance in the management of head and neck melanoma is a concrete understanding of the surgical anatomy of the lymphatics, as the status of the regional nodes has the most impact on survival. For sentinel lymph node biopsy (SLNB), the identification of lymph nodes in the head and neck may be challenging due to their relationship to the cranial nerves. In particular, the lymphatics of the parotid gland may be superficial to the gland or may be embedded deep within the substance of the soft tissue, and surgical exploration for sentinel lymph nodes in this basin may place the facial nerve at risk for injury. Lymphatic drainage of regions such as the nasal skin, the lip, and the midface frequently drain to more than one nodal basin and may also drain in bilateral or contralateral directions.[15] Commonly, the facial lymph nodes that traverse the facial artery and vein are sites of SLN, and removal of these places the marginal mandibular branch of the facial nerve at risk.

Lesions of the scalp that are anterior to a line drawn along the coronal plane through the tragus oftentimes will drain to the

(c) 2014 Wolters Kluwer. All Rights Reserved.

parotid, the submental, or the anterior cervical lymph nodes.[16] Alternatively, melanomas that are posterior to this line will most often drain to either the suboccipital, the retroauricular, or the posterior triangle cervical lymphatics.[17] The removal of nodes that map to the posterior triangle places the spinal accessory nerve at risk for injury during the surgical excision. Thus, a precise understanding of the anatomy of the cervical lymphatics and of the cranial nerves is of critical necessity for surgeons managing patients with melanoma of the head and neck. Further elaboration of the anatomy of the cervical lymphatics may be found in other chapters in this text.

## RISK FACTORS

Improved awareness and screening are likely partially responsible for the marked increase in the incidence of melanoma over the last few decades. However, there is strong evidence that increased exposure to ultraviolet radiation (UVR) also plays a role.[18] Multiple studies support a causative role for UVR in cutaneous melanoma, including migration and epidemiologic studies.[3] A history of sunburns from natural UVR and the use of tanning beds (artificial UVR) are risk factors for melanoma, and public surveys have reported increasing prevalence of both behaviors among US adults.[19] Interestingly, while intermittent sun damage/exposure has consistently been identified as a positive risk factor, some studies suggest that chronic sun exposure is associated with a decrease in the risk of melanoma.[20] Other risk factors for cutaneous melanoma include a positive family history, multiple nevi, dysplastic nevi, freckled or fair skin, blue or green eye color, and red hair color.[21,22] The phenotype of fair skin, freckling, and red hair has been linked to polymorphisms in the *MC1R* gene, which encodes the melanocortin-1 receptor.[23] The polymorphisms in *MC1R* cause decreased signaling through the receptor, which ultimately results in decreased melanin production. The primary function of melanin is to absorb UVR, thus protecting cellular DNA from its damaging effects. Germline polymorphisms in other genes involved in melanin synthesis (*TYR*, *TYRP1*) have also been linked to an increased melanoma risk and further implicate the role of UVR in this disease.[23]

Approximately 10% of melanomas are familial (≥3 affected individuals). Familial melanomas are associated with a very early age of onset, frequently in areas without UVR exposure. The most common genetic feature in these families is germline deletion or inactivating mutation of the *CDKN2A* gene on chromosome 9.[23] Due to alternative splicing, *CDKN2A* is transcribed into two different proteins ($p16^{INK4A}$ and $p14^{ARF}$) which regulate cell cycle progression and cause cell cycle arrest in response to DNA damage. Inactivation of *CDKN2A* is detected in approximately 40% of melanoma-prone families. The critical role of DNA damage is also implicated by the identification of melanoma-prone families with germline mutations in the *CDK4* gene.[23] The detected genetic alterations result in a mutant CDK4 protein that is resistant to inhibition by $p16^{INK4A}$ and thus recapitulate loss of *CDKN2A*. Polymorphisms in a number of other genes involved in DNA repair have also been associated with increased risk of melanoma.[24]

## PATHOLOGY

Developmentally, melanocytes arise from the neural crest. The cells migrate most commonly to the epidermis of the skin, but they can also be found in the meninges lining the brain, the uveal tract of the eye, and the ectodermal mucosa. Melanomas can arise from each of these sites and are thereby clinically classified as cutaneous, primary meningeal, uveal, and mucosal melanomas. Cutaneous melanomas, which are by far the most common subtype, have been further subdivided into categories defined by a combination of pathological and clinical features. The majority of cutaneous melanomas fall into one of the following subtypes: superficial spreading melanoma (SSM), nodular melanoma (NM), lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM). A rarer but clinically relevant subtype in the head and neck is desmoplastic melanoma (DM).

Superficial spreading melanomas, the most common subtype (~70%) of cutaneous melanomas, generally arise on any skin with intermittent sun exposure. Nodular melanomas (~15%) are characterized by vertical growth without a prior radial growth phase. Nodular melanomas are often highly aggressive and clinically appear as raised nodules. Lentigo maligna melanomas (~10%) appear as flat brown macules, often with hypopigmented areas. Lentigo maligna melanomas are associated with chronic sun exposure and are typically located on the head, neck, and arms. Acral lentiginous melanoma (~5%) is the least common subtype among Caucasians, but represents 30% to 70% of the melanomas diagnosed in African Americans and Hispanics. Acral lentiginous melanomas occur on the palms or soles, or underneath the nail plate, where exposure to UVR is relatively limited. DMs occur in areas with chronic sun exposure, particularly of the head and neck. DM are usually detected in elderly patients and are highly invasive, often presenting as lesions with significant (>5 mm) thickness. DMs often invade along neural tracks, which can result in significant symptomatology.

## MOLECULAR BIOLOGY

A variety of studies have demonstrated that there are significant molecular differences between the melanoma subtypes. Whole-genome copy number analyses have demonstrated that cutaneous, acral, and mucosal melanomas are characterized by distinct patterns of chromosomal gain and loss.[25] Furthermore, cutaneous melanomas with and without evidence of chronic sun damage (CSD) show distinct patterns of DNA copy number changes; tumors with evidence of CSD appear relatively similar to acral and mucosal melanomas. Uveal melanomas show a pattern of chromosomal aberrations that are distinct from the cutaneous and mucosal melanomas and are characterized by a high prevalence of isosomy of chromosome 3, which is associated with poor clinical outcomes.[26,27]

In addition to differences in the pattern of chromosomal changes, melanoma subtypes are characterized by differences in the prevalence of somatic mutations, a number of which are emerging as both prognostic markers and therapeutic targets (Table 24.1).[14,28,29] The most common somatic event in melanoma is alteration of the *BRAF* gene.[30] *BRAF* encodes serine-threonine kinase that is a key component of the RAS-RAF-MEK-ERK signaling pathway (Fig. 24-1). More than 90% of the alterations in *BRAF* that are detected in melanoma are missense mutations that affects the valine residue at position 600.[31,32] The most common mutation (~75% of *BRAF* mutations) results in substitution of a glutamic acid (V600E), which increases the catalytic activity of the BRAF protein >100-fold.[33] Melanoma cell lines with activating *BRAF* mutations demonstrate constitutive activation of MEK and ERK signaling and functionally depend on this pathway for growth and survival.[34] Mutation of *NRAS*, which also results in hyperactivation of MEK and ERK, is the second most common somatic event in melanoma and thus reinforces the critical role of the RAS-RAF-MEK-ERK pathway in this disease.[32]

Studies of the clinical correlates of *BRAF* mutations have found positive associations with both younger age and a lack of CSD.[35–37] Although activating *BRAF* mutations are detected in 45% to 50% of cutaneous melanomas without CSD, the

rate is lower (10%–30%) in tumors with histologic evidence of sun damage (i.e., solar elastosis).[25,38] *BRAF* mutations are also relatively rare in acral (10%–15%), mucosal (5%), and uveal melanomas (<1%).[25,32,39] *NRAS* mutations are associated with thicker primary tumors and shorter relapse-free survival (RFS) from initial melanoma diagnosis.[35,40] *NRAS* mutations appear to have a similar prevalence of approximately 20% in cutaneous melanomas with and without CSD, but a lower prevalence in acral (15%), mucosal (10%), and uveal (<1%) melanomas.[25,32]

The relative paucity of activating *BRAF* mutations in CSD-cutaneous, acral, and mucosal melanomas led to interrogations of regions of DNA copy number gain for additional oncogenic drivers in these subtypes. These studies resulted in the identification of frequent abnormalities in the *KIT* gene in these subtypes.[41] The *KIT* gene encodes a receptor tyrosine kinase that is also frequently activated genetically in gastrointestinal stromal tumors (GIST), testicular seminomas, and certain types of leukemia.[42] In addition to amplifications, initial studies identified somatic mutations in the *KIT* gene in melanomas. Overall, *KIT* mutation or amplification were identified in 36% of acral and 39% of mucosal melanomas. *KIT* alterations in cutaneous melanomas without CSD have consistently been reported to be quite rare (≤1%), but variable results (2%–28%) have been reported for cutaneous melanomas with CSD.[38,41]

A variety of other somatic alterations have been identified in melanoma (Fig. 24-1).[14,29] Inactivating mutations and deletions of *PTEN*, a negative regulator of the PI3K-AKT signaling pathway, have been identified in 10% to 30% of melanomas.[43] Loss of PTEN expression in the absence of detectable abnormalities in the *PTEN* gene has also been reported, consistent with epigenetic regulation of the gene.[44,45] Genetic inactivation of *PTEN* is mutually exclusive with the presence of activating *NRAS* mutations in melanoma, but frequently occurs in tumors and cell lines that have activating *BRAF* mutations.[46,47] Although *BRAF*, *NRAS*, and *KIT* mutations are very rare in uveal melanomas, these tumors frequently have activating mutations in *GNAq* (45%) or *GNA11* (35%).[48–50] Both *GNAq* and *GNA11* encode regulatory subunits of G-protein coupled receptors, which may activate many of the same pathways affected by the mutations that are common in other melanoma subtypes. Uveal melanomas also frequently have inactivating somatic mutations of the *BAP1* gene, which is located on chromosome 3, and may function as a tumor suppressor in this melanoma subtype.[51]

## PATTERNS OF SPREAD

The clinical course of cutaneous melanoma is highly variable. Cutaneous melanomas can spread locally through dermal lymphatic channels to form cutaneous satellite lesions (within 2 cm of the primary lesion), as well as in-transit lesions along the course of the draining lymphatics. More commonly, initial tumor progression presents as metastasis to draining regional lymph nodes. Distant metastases generally are diagnosed after the development of regional involvement, although some patients have their first relapse at distant sites. In addition, approximately 5% of melanoma patients present with metastasis(es) with no detectable primary tumor.[52] Melanoma can metastasize to virtually any distant organ, including skin, lymph node, lung, liver, GI tract, and bone, among others. One of the most common sites of distant metastasis is the brain. Approximately 60% of patients with distant metastases will develop brain involvement at some time during the course of their disease, and up to 80% of metastatic melanoma patients have evidence of brain involvement in autopsy series.[53,54]

Similar to cutaneous melanoma, mucosal melanomas tend to spread initially to regional lymph nodes and then subsequently to distant sites. In contrast to cutaneous and mucosal melanomas, uveal melanomas spread almost uniquely hematogenously, and thus lymph node involvement is quite rare. However, almost all uveal melanoma patients with distant disease have liver involvement (95%). Some patients also develop metastases to the lungs (25%), bone (15%), and skin (10%), but uveal melanomas almost never metastasize to the brain.[55]

## CLINICAL PRESENTATION

The majority of patients with cutaneous melanoma of the head and neck present in an early stage of disease, as it is uncommon for nodal metastasis to be present at the time of diagnosis. A pigmented lesion may have been present for many years, but it is not until one has undergone substantial change in its clinical appearance that prompts an evaluation with a biopsy. The classic mnemonic of "ABCDE" of pigmented lesions represents an important reminder in public awareness of the warning signs of melanomas, as the vast majority of melanomas (>70%) arise in a preexisting mole. These signs include ***A***symmetry, ***B***order irregularity, ***C***olor variegation, ***D***iameter >6 mm, and ***E***volution. These lesions may also present as areas that bleed after minor trauma, such as hair brushing or shaving, and patients may complain of itching at the site. Other clinical features associated with cutaneous melanomas include ulceration, regression, and nonpigmented lesions. It is important that the clinician evaluate the surrounding skin for the presence of satellitosis, which represents stage IIIB or IIIC disease, even when nodal metastases are absent (Fig. 24-2).

Nodal metastasis is often subclinical in early-staged patients yet is present in 20% to 30% of patients with T2 lesions, and the incidence of occult nodal metastasis increases substantially in thicker tumors. One of the more challenging areas of the management of melanoma of head and neck involves patients with a regionally metastatic melanoma with an unknown primary tumor. It is important that the treating team perform a careful and detailed clinical history to elicit a history of a regressed lesion or a previously biopsied "benign" nevus. DMs have a propensity for neurotropism, and eliciting signs and symptoms of this aggressive subtype is important in the evaluation of patients with head and neck melanoma.

### Diagnostic Staging and Evaluation

The evaluation of a suspected head and neck melanoma entails surgical biopsy, which may be performed as either an excisional biopsy or incisional biopsy, depending on the anatomical location and size of the lesion. Ideally, an excisional biopsy with 1 to 2 mm margins is preferred, which will allow adequate pathological analysis of the entire specimen for staging, without disrupting the lymphatics should an SLNB be necessary. It must be stated that an excisional biopsy does not suffice for surgical management of a melanoma; appropriate surgical margins should be taken at a separate procedure. An incisional or punch biopsy may be performed for large lesions and for those in cosmetically critical areas, such as the nose, eyelid, or ear. In these situations, a complete excision may require significant reconstruction and rotational flaps, which is best performed after definitive resection has been completed. The general principles for the biopsy for a suspected melanoma include representative lesion sampling, adequate depth, and proper specimen orientation. Shave biopsies are often performed for cutaneous lesions, but may not provide adequate representation of the depth of the lesion when performed for a pigmented lesion. This is primarily due to transection of the base of the melanoma, which will impact appropriate tumor staging of the patient. It is also

difficult for pathologists to provide a complete histopathological staging of a shave biopsy and thus an incisional biopsy or punch biopsy may be necessary for suspicious pigmented lesion of the head and neck that cannot be assessed with an excisional biopsy.

The appropriate histopathological staging criteria of a biopsied pigmented lesion are outlined in Table 24.2. The pathological reporting of these discrete criteria provides the treatment in the appropriate staging criteria and determines the need for any further evaluation and/or any diagnostic workup or treatment. Use of a pathology template for melanoma has been shown to improve proper staging of patients, particularly when performed as part of an established multidisciplinary group.[56]

***Updates to AJCC Staging.*** The staging evaluation for melanoma of the head and neck are based on the seventh edition of the TNM staging system of the American Joint Committee on Cancer (AJCC), which was published in 2009 and is provided in Tables 24.3 and 24.4.[12] Thin melanomas are defined as ≤1 mm in thickness, intermediate are 1.01 to 4 mm in thickness, and thick melanomas are >4 mm. Stage III patients are defined as those with any nodal metastasis or in-transit metastasis, and stage IV represents distant metastatic disease.

The updated staging system had several differences from previous editions. Substantively, the increasing recognition that mitoses are an adverse prognostic features has been incorporated in the definition of T1b lesions, which broadens the indications

| Satellitosis | — |
| Margin status | Peripheral, deep |

for SLNB in early-staged patients and changes the prognosis for previously staged T1a patients. Clark levels are no longer used in the staging system with some exceptions (i.e., T1 lesions without information about mitotic rate), although pathologists continue to utilize it in pathology reports. Immunohistochemical analysis of sentinel lymph nodes with a melanoma marker (HMB-45, Tyrosinase, MART1, MelanA) is now considered standard of care in pathologically negative nodes, and immunohistochemically positive nodes are categorized as micrometastatic disease. The staging system also added serum lactate dehydrogenase (LDH) levels to the evaluation of patients with stage IV disease.

***Evaluation of Stages 0 to II Melanoma.*** The diagnostic evaluation of melanomas of the head and neck outlined in Figure 24-3 is based on the current National Comprehensive Cancer Network (NCCN) guidelines.[57] In patients with stages 0 to II melanoma, histological analysis of the primary tumor is the major diagnostic study, and for patients with thin melanomas without high-risk features, a thorough history and physical examination may suffice. For patients with ulcerated lesions, imaging of the head and neck may be beneficial, as this subset of patients are at a higher risk of harboring lymph node metastasis. This may be either with computed tomography (CT) of the head and neck or

**TABLE 24.3 2009 AJCC TNM Staging Categories for Cutaneous Melanomas**

Clinical staging includes microscopic evaluation of the primary tumor, and clinical and radiologic evaluation for metastases. Pathologic staging includes microscopic evaluation of the primary tumor, and microscopic evaluation of the regional lymph nodes after partial (SLNB) or complete lymphadenectomy. Pathologic stage 0 and stage IA do not require microscopic evaluation of regional lymph nodes for classification.

*Source:* From Edge SB, Byrd DR, Compton, CC, et al. *AJCC Cancer Staging Manual.* 7th ed. New York, NY: Springer-Verlag; 2010:326, with permission.

with an ultrasound (US) of the head and neck. The advantage of the US is the potential opportunity to perform a fine-needle aspiration of a suspicious lymph node, but it does not provide the same anatomic detail that actual imaging of the head and neck provides. However, staging can be personalized based on patient factors and physician preference. At our institution, the majority of patients with intermediate-thickness or thick melanomas will undergo imaging of the regional lymphatic basins with either a US or a CT, particularly if ulceration is present. Routine chest x-rays may optionally be performed for patients with IIB to IIC disease to evaluate for lung metastases. Chest x-ray, CT scans, or other imaging should also be performed if signs or symptoms are present that suggest the presence of distant metastases (i.e., pain, dyspnea, neurologic symptoms). Surgical staging of the lymph nodes will be discussed in forthcoming sections.

***Evaluation of Stages III to IV.*** Patients who are identified as harboring nodal metastasis, whether occult or clinical, should undergo baseline staging studies to exclude the presence of distant metastasis. These may include CT of the chest, abdomen, and pelvis; an MRI of the brain; and determination of serum LDH. More recently, the role of PET-CT for the evaluation of stage III melanoma has been explored and does provide effective baseline staging in this group of patients. The caveat to the use of PET for staging is the resolution for the detection of small metastases, as lesions smaller than 1 cm may be better appreciated on axial imaging. In similar manner, patients with in-transit metastasis require a formal metastatic workup. The timing of these studies should be at the discretion of the multidisciplinary team, but is often performed after local-regional treatment has been completed. Due to emerging therapeutic options, molecular testing for activating mutations in the *BRAF*, *NRAS*, and *KIT* genes should be strongly considered in patients with unresectable regional and distant metastases.[29]

***Role of SLNB.*** As the status of the lymph nodes remains the most powerful prognostic factor for patients with head and neck melanoma, proper staging of the lymphatics is one of the major diagnostic criteria for patients with melanoma of the head and neck.[58] Patients who are node negative generally do not require any adjuvant therapy. Conversely, those with nodal metastasis, even when present at microscopic levels, should be considered for adjuvant systemic therapy (discussed separately). Controversy regarding the management of regional lymphatics in melanoma has persisted for decades, and elective nodal dissection was frequently recommended for patients with melanoma in the past. However, as only approximately 20% of patients harbor occult metastasis, a substantial number of patients were subjected to unnecessary nodal dissections, which can result in significant morbidity.[59] Alternatively, observation alone is associated with adverse outcomes, compared with elective nodal dissection for certain groups of patients. With the increased recognition that most patients with intermediate-thickness melanomas do not benefit from elective nodal dissection, the staging philosophy for melanoma has changed substantially in the past decade.

Elective regional dissection has been supplanted by SLNB as the standard of care in the initial evaluation of the majority of patients with cutaneous melanoma. SLNB was first proposed as an effective staging tool by Cabanas in 1977 for the management of penile squamous cell carcinomas.[60] The technique was subsequently championed by Morton et al. for the diagnostic evaluation of metastatic melanoma, based upon the principle that melanoma metastasizes in an orderly fashion to the first-echelon draining lymphatic basin.[61] In the evaluation and staging of patient with melanoma, SLNB offers the following advantages: (a) increased sensitivity to detect regional metastases, (b) limited morbidity compared with elective nodal dissection, (c) identification of patients who may benefit from further therapies such as a neck dissection or systemic adjuvant therapy, and (d) potentially halting the regional progression of disease.

Although initially met with skepticism, SLNB is now the established approach for defining the presence of occult metastasis.[62] The rich and complex organization of the lymphatics of the head and neck make localization of the immediately draining nodes potentially more challenging, as compared with other sites. Moreover, initial published reports validating the role of this staging technique focused primarily on truncal and limb melanomas, with few studies having enrolled patients with lesions located in the head and neck.[63] One study has suggested that head and neck sites were associated with higher regional failure rates after a negative SLNB.[64] More recent studies with long-term follow-up of patients with head and neck melanoma suggest a regional failure rate of 4% to 8% after a negative SLNB, which is comparable to that for other anatomic sites.[65–67] Numerous studies

have now validated SLNB for cutaneous melanomas of the head and neck, with a negative predictive value close to 98% and a false-negative rate of 5%.[68,69]

The benefits from SLNB have been established in both retrospective studies and in prospective multicenter trials.[70,71] It is clear that patients with intermediate-thickness melanomas, measuring between 1 and 4 mm in depth, have a 15% to 45% risk of harboring occult nodal metastasis. For most patients with lesions <1 mm, and thus less than a 5% risk of metastasis, an SLNB may not provide any further prognostic information. This risk increases with increasing thickness of the lesion, and those with melanomas measuring 2 to 4 mm have a risk of approximately 30% to 40% nodal positivity and nearly 50% for patients with lesions >4 mm. Multiple studies have demonstrated that patients who are sentinel lymph node negative had a substantial survival benefit compared with those who were sentinel lymph node positive, even when only micrometastases are present.[12] Moreover, the number of positive sentinel nodes and the size of the metastatic foci are factors that directly correlate with the risk of non–sentinel node metastases.[11–13] Thus, the status of the sentinel lymph nodes plays an important role in establishing the role of adjuvant therapy for patients with malignant melanoma. In 2006, Morton et al. established the prognostic role of SLNB in terms of impacting local-regional control and the importance of establishing the prognostic benefit of this staging procedure.[59]

One area of substantial controversy is the role of SLNB for patients with thin melanomas. Studies support that those with melanomas <1 mm thickness with the following risk factors may benefit from SLNB: mitotic figures >1/mm$^2$, the presence of ulceration, or tumors >0.7 mm in thickness.[72] The likelihood of identifying a positive sentinel node for all anatomic sites is in the range of 5% to 7%, although this rate is unclear in the head and neck. Consideration of performing an SLNB in this group must be placed in the context of the potential morbidity of cranial nerve injury and the cosmetic issues associated with surgical incisions in the face and neck region. Therefore, the decision to perform an SLNB for patients with thin melanomas should be made on an individualized basis.

***Radiographical, Surgical, and Pathological Considerations of SLNB.*** Preoperative lymphoscintigraphy utilizing technitium-99m sulfur colloid provides accurate identification of the sentinel nodes and correlates with the intraoperative findings in the vast majority of case. One of the limitations remains the planar aspect of the images, and distinguishing the depth of some of the nodes within the neck is challenging. For example, external jugular nodes, which are a common site for SLN, may be difficult to distinguish from the internal jugular nodes. Other anatomic areas that remain challenging to assess with planar imaging are the suboccipital nodes and those nodes located at the junction of level IIB and level V, which are in the vicinity of the spinal accessory nerve. A recent addition to the surgeon's armamentarium is the single photon emission CT with CT (SPECT-CT), which provides anatomic imaging in conjunction with the functional nuclear imaging (Fig. 24-4).[73] When performed together with planar lymphoscintigraphy, this technique provides greater presurgical detail for the intraoperative identification of SLN. Moreover, precise localization of the lymph nodes within the neck can facilitate placement of incisions and may decrease operative times.[74] At out institution, preoperative static lymphoscintigraphy and SPECT-CT are performed for all patients undergoing SLNB for melnomas of the head and neck.

(c) 2014 Wolters Kluwer. All Rights Reserved.

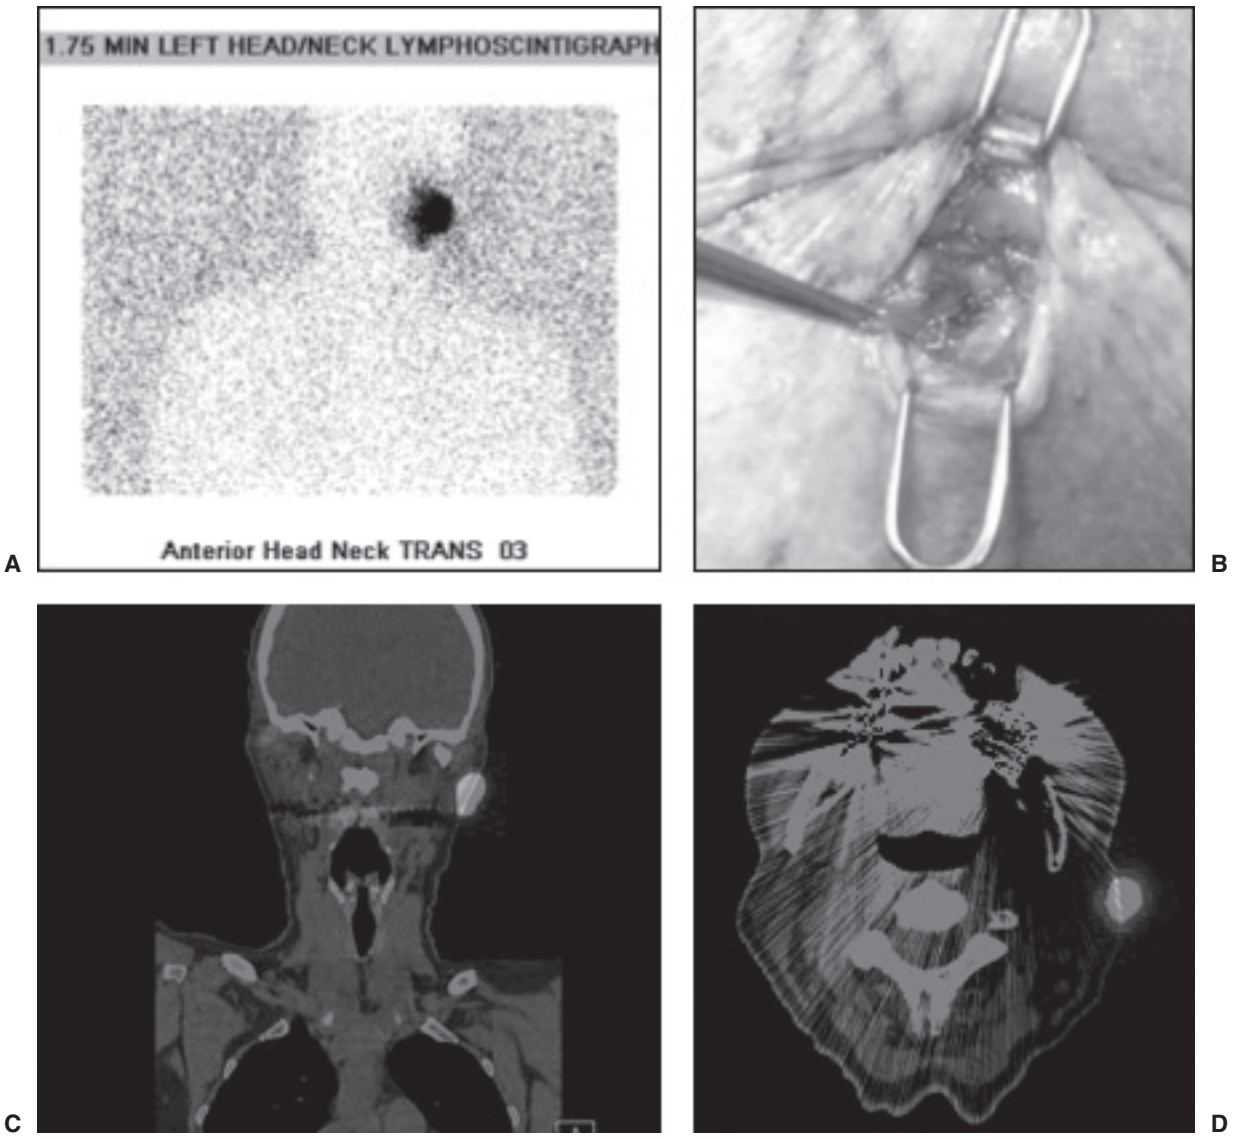

**FIGURE 24-4.** SPECT-CT in SLNB. **A:** Static lymphoscintigraphy demonstrates a lymph node inferior to the main lesion. It is difficult to discern the depth of the node and its precise level. **B:** Intraoperative findings reveal the SLN along the external jugular vein. Coronal **(C)** and axial **(D)** SPECT-CT images reveal the SLN to be located along the external jugular node, rather than in the deeper level II region.

A number of factors warrant discussion regarding the operative management of the sentinel nodes. The identification of the SLN with a gamma probe can be facilitated with the intraoperative injection of isosulfan blue 15 minutes prior to surgery. However, this injection must be placed intradermally, similar to the radioactive isotope, whereby improper placement of the injection can account for failed SLNB procedures. After measuring background counts, all radioactive nodes with counts within 10% of the highest recorded node should be excised. The addition of the isosulfan blue improves the detection with a visual cue, and all blue nodes should be removed as well.[75,76] It is not uncommon for melanoma to map to nonadjacent cervical basins, and multiple SLN are commonly identified. Reported nodal yields in the head and neck range are between 2 and 5 SLN per patient,[65,77] and discordance between the preoperative lymphoscintigraphy and the intraoperative SLN locations are not uncommon.[15]

Sentinel nodes are often found in proximity to the facial nerve and the spinal accessory nerve, and an iatrogenic injury is a surgical complication to be avoided. For melanomas in face and temporal scalp region, drainage to the parotid region is common, requiring dissection in proximity to the facial nerve. Thus, an understanding of the anatomy of this cranial nerve is of utmost importance. Initial concerns for removal of SLN from the parotid gland are unfounded, and careful dissection within the gland by an experienced surgeon can be safely performed without injury to the facial nerve.[68,78] This technique can obviate the need for removal of the parotid gland when this nodal basin is the site of SLN, although in some patients with deep nodes a formal parotidectomy with facial nerve dissection may be necessary. The aforementioned factors contribute to the complexity of surgical evaluation of occult disease.

The use of immunohistochemistry and step-sectioning of the SLN specimens increases the sensitivity of the SLNB technique

(c) 2014 Wolters Kluwer. All Rights Reserved.

for the detection of nodal disease. The role of frozen section analysis of SLN specimens remains controversial, and some institutions rely upon this approach for decision making vis-à-vis the complete nodal dissection.[69,79] However, there is a reported false-negative rate of 5% to 8% associated with frozen section of SLNs[80–82] due to the technical issues related to freezing artifact, tissue distortion, and tissue loss. Thus, in our practice, SLNs are not inspected with frozen sectioning, but rather are evaluated after formalin-fixation and paraffin-embedding of the entire block. Serial sectioning and immunohistochemical studies for HMB-45, Tyrosinase, MART1/MelanA increases the sensitivity for the detection of occult metastasis by approximately 20%.[83]

## CLINICAL MANAGEMENT

Surgery is the principle treatment for the management of malignant melanoma of the head and neck, with local excision of the primary tumor and operative resection of the involved lymphatic basins. Radiation therapy is offered to selected patients, and systemic therapies are indicated for selected stage II patients, most stage III patients, and for the majority of stage IV patients. This section will highlight some of the unique treatment principles that relate to the head and neck. General treatment algorithms are outlined in Figure 24-5.

### Stages 0 to II

***Surgery.*** Although debate has persisted regarding the extent of surgical resection for malignant melanoma, numerous randomized trials have demonstrated that for thin (<1 mm Breslow thickness) melanomas, margins of 1 cm are sufficient for local control.[84] For intermediate-thickness lesions, margins of 1 to 2 cm are adequate to prevent local recurrences, whereas margins of 0.5 cm are sufficient for melanoma *in situ* lesions.[85] These surgical principles have been validated in randomized trials both in the United States and internationally.[84,86,87] The current NCCN guidelines are outlined in Table 24.5 and serve as the standard approach for margin control in cutaneous melanoma. In the head and neck region, however, the recommended margins are not always feasible due to functional and cosmetic constraints. For example, resections near the eyelids may be limited due to ophthalmological morbidity, or nasal resections may result in substantial tissue loss and cosmetic deformities, and thus the extent of surgical resection is at the discretion of the operating surgeon. The excision should include the subcutaneous fat and underlying fascia of the neck, scalp, or face. The routine resection of sensory nerves and facial nerve branches is excessive. On the scalp, the pericranium can be left intact, whereas on the ear and nose, resections should include the perichondrium due to the thinness of the skin in these regions.

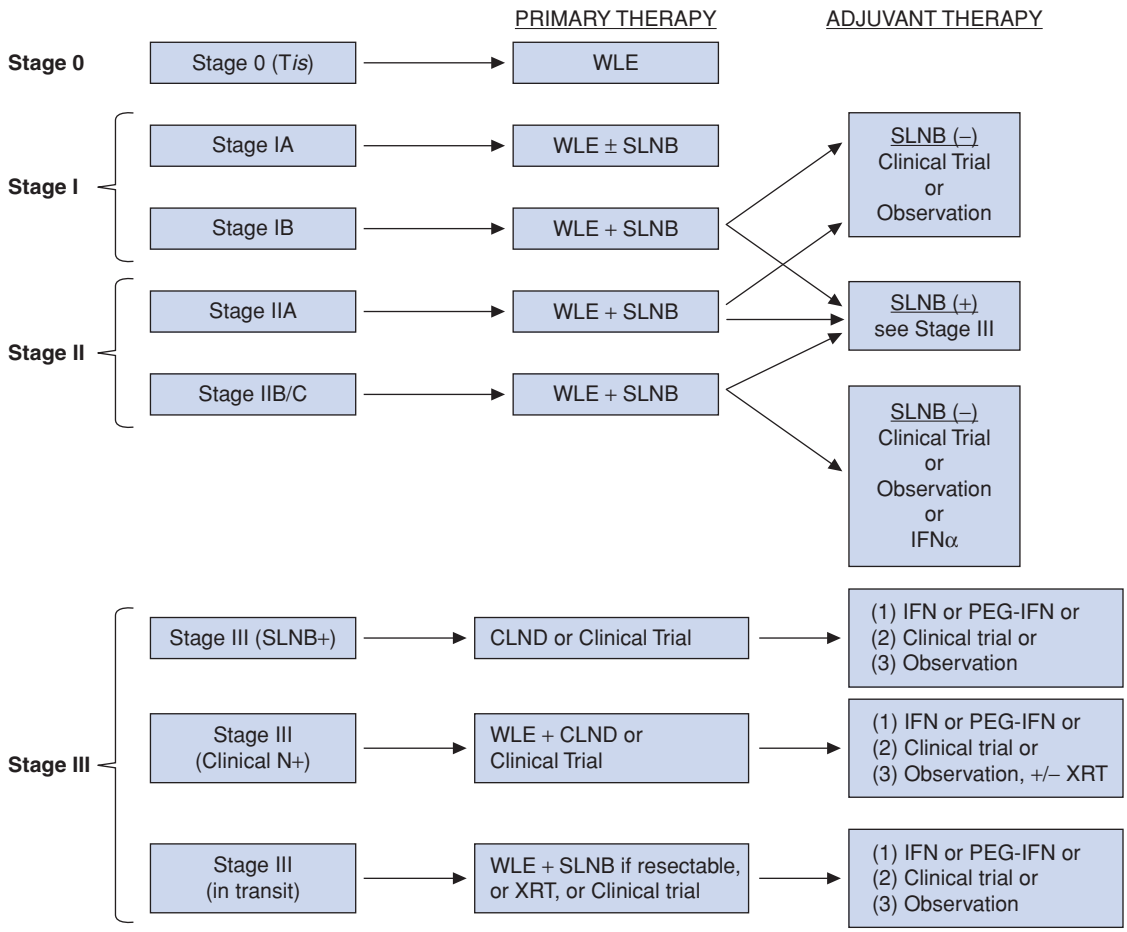

**FIGURE 24-5.** Management of stages 0 to III cutaneous melanoma. WLE, wide local excision; SLNB, sentinel lymph node biopsy; CLND, completion lymph node dissection; IFN, high-dose interferon α2b; PEG-IFN, pegylated interferon; XRT, radiation therapy.

**TABLE 24.5 Recommended Primary Tumor Surgical Margins**

| Depth of Invasion | Recommended Surgical Margins |
|---|---|
| *In situ* | 0.5 cm |
| ≤2 mm | 1 cm |
| ≥2.01 mm | 2 cm |

Reconstruction of facial, nasal, otologic, and scalp defects are beyond the scope of this chapter, but the surgeon should obey certain principles. Unlike the truck and limb, facial and scalp defects can rarely be closed in a simple straight-line manner and often require complex grafting or local flap reconstructive techniques, which in our practice are often performed in a staged fashion once the pathological status of the margins are confirmed. The vast majority of dermatopathologists do not rely upon frozen section analysis of skin margins for patients with melanoma due to the risk of false-negative results from the tissue-fixation techniques. This is in contrast to the proponents of Mohs micrographic surgery for melanoma, who advocate immediate analysis of the resected margins at the time of excision. In our practice, pathological analysis of the entire paraffin block is performed to determine the margin status. Moreover, the need for regional dissection is dependent on the results of the SLNB, which may require 3 to 4 days for assessment, as detailed above in the prior section. Resection of the parotid gland and cervical lymphatics in the SLNB-positive patient may have a significant impact on the types of flaps available to the reconstructive surgeon. Therefore, most patients with stages 0 to II melanomas of the head and neck undergo surgical resection and SLNB as indicated, with reconstruction performed at a later date. As discussed above, elective nodal dissection is no longer performed for malignant melanoma, and for patients with thick lesions with a negative SLNB, observation of the neck is a sound management strategy.

***Radiation.*** In general, adjuvant radiation therapy is not indicated for stages 0 to II melanomas, although it may be used selectively in specific clinical scenarios. For example, DMs have a high propensity for perineural spread and thus have a high risk of local recurrence at the primary tumor site that can be reduced with postoperative radiation therapy (PORT).[88] Primary tumors that exhibit extensive lymphovascular invasion are also at high risk for local and in-transit recurrence and also are candidates for adjuvant radiation. Postoperative radiation therapy may also be used in the setting of close or positive margins in areas that are not amenable to more extensive or repeat resection. For patients with extensive areas of melanoma *in situ* or lentigo maligna, where surgical resection would lead to profound functional or cosmetic sequelae, local radiation is a reasonable treatment option.[89] Primary irradiation may be considered under exceptional circumstances, but is not the standard of care.

***Systemic Therapy.*** As described above, systemic therapies are generally not used as the primary therapeutic modality in early-stage melanomas, where surgery is highly effective. However, for patients that have primary tumors that are not amenable or are refractory to surgery and/or radiation, topical treatment with imiquimod may be considered.[90–92] Imiquimod is an immunotherapy that stimulates a local antitumor immune response by activating toll-like receptors on lymphocytes. Its use remains investigational at this time.

There is an established but somewhat controversial role for postoperative systemic therapies in patients with thick primary melanomas. Adjuvant treatment with interferon alpha 2b (IFN) was approved by the US FDA for high-risk melanoma patients in 1995 based on the results of the Intergroup E1684 study.[93] This study included patients with primary tumors >4 mm deep without lymph node involvement (T4 N0) and patients with microscopic or macroscopic lymph node (Tx N1–3). All patients underwent complete lymph node dissection and then were randomized to receive interferon or observation only. All patients were randomized within 56 days of their initial biopsy or 42 days of lymphadenectomy. The IFN treatment consisted of an induction phase of 20 MU/m$^2$/d given intravenously (IV) 5 days per week for 4 weeks, followed by 10 MU/m$^2$/d subcutaneously (SQ) 3 times per week for 48 weeks. A total of 287 patients were enrolled, randomized, and treated (IFN, $n = 143$; observation, $n = 137$). After a median follow-up of 6.9 years, the patients treated with IFN showed significant improvements in RFS (median 1.72 years for IFN, 0.98 year for observation, $p = 0.0023$), and overall survival (OS) ($p = 0.0237$). The IFN dosing regimen used in this trial, which is now commonly referred to as "high-dose IFN" (HDI), was subsequently approved by the FDA for use in patients with stage IIB to stage III melanoma.

Despite these initial positive results, subsequent analyses of E1684 and other adjuvant IFN trials have raised questions about the survival benefit of this therapy. Analysis of the patients in the E1684 trial after a median follow-up of 12.6 years continued to demonstrate a significant improvement in RFS with IFN treatment (hazard ratio [HR] 1.38 for observation vs. IFN, $p = 0.02$), but the difference in OS between the groups was no longer significant (HR 1.22, $p = 0.18$).[94] In addition, the E1690 study tested the efficacy of the HDI regimen versus a lower-dose regimen (LDI) (3 MU/m$^2$/d subcutaneously 3 times per week for 2 years) and observation in the adjuvant setting. The eligibility criteria in this trial were the same as the E1684 except that T4 N0 patients were not required to undergo lymphadenectomy (24% underwent elective lymph node dissection, and 5% underwent SLNB). In the initial analysis (median follow-up 4.3 years), HDI achieved a significant improvement in RFS versus observation (HR 1.28 for observation vs. HDI, $p = 0.05$), but there was no improvement in OS (5-year OS 52% vs. 55%).[95] A subsequent analysis performed at a median follow-up of 6.6 years found that IFN still showed a strong but nonsignificant trend for improved RFS (HR 1.24 for observation, $p = 0.09$), but there was no difference in OS (HR 1.0, $p = 0.98$).[94] A pooled analysis of the results for HDI from these two studies showed a significant improvement in RFS (HR 1.30 for observation, $p = 0.006$), but not in OS (HR 1.08, $p = 0.42$).[94]

The clinical benefit of adjuvant IFN must be weighed against the toxicity of the regimen. In the E1684, approximately 50% of patients experienced grade 3 or worse constitutional symptoms (98% any grade), which included fever, chills, and flu-like symptoms (fatigue, malaise, diaphoresis). Almost 30% of patients had neurologic toxicity of grade ≥3, including mood changes such as depression, and 15% had hepatotoxicity.[93] The administration and toxicity of the treatment is also made challenging by the 12-month duration of therapy.

## Stage III Melanoma

***Surgery.*** Surgery is the mainstay of treatment for patients with regionally metastatic melanoma of the head and neck. Wide excision of the primary tumor to negative margins should be performed, as described above, with the reconstruction dictated by the size and location of the defect. Clinically apparent nodal disease mandates a complete lymphadenectomy of the involved stations. For tumors involving the face, neck, and anterior scalp (as defined by the sagittal plane through the eternal auditory canals), a modified radical neck dissection to remove levels I to V, with preservation of the spinal accessory nerve,

(c) 2014 Wolters Kluwer. All Rights Reserved.

sternocleidomastoid muscle, and internal jugular vein, should be performed. The details regarding the technical aspects of the neck dissection are found elsewhere in this text. The decision to perform a superficial parotidectomy, with preservation of the facial nerve, should be based on the anatomic location of the tumor and the SLNB findings. In general, patients with disease in the parotid bed should undergo parotidectomy and neck dissection. For patients with regional metastasis and a lesion with first-echelon drainage to the parotid gland should be considered for parotidectomy (e.g., anterior lateral scalp melanoma, lateral cheek melanoma), even if the parotid gland is not the site of the metastatic disease. For patients with metastasis from a posterior scalp or posterior neck melanoma, a postero-lateral neck dissection, with removal of levels II to V suboccipital and retroauricular nodes, is necessary.

In the era of SLNB, controversy has arisen regarding the potential role of serial observation of the neck for patients with micrometastatic disease identified on SLNB (N1a, N2a). Approximately 20% of patients with a single positive SLN will harbor additional metastasis in the regional nodes at the time of completion lymphadenectomy, and thus 80% of patients will undergo regional dissection and not have other foci of metastasis in the specimen.[59] Certain risk factors are associated with non-SLN metastasis in melanoma, including age, ulceration, and tumor thickness, but the significance of these factors has not been completely elucidated in the head and neck region.[96,97] Specifically in the head, the incidence of nonsentinel metastatic nodes is observed in approximately 20% of patients.[68,98] Among patients who are not candidates for further surgery, elective nodal irradiation may be considered. The results of the MSLT-II trial, which randomized SNLB-positive patients to either immediate completion lymphadenectomy or observation with serial US and salvage neck dissection, will help address this uncertain clinical scenario. However, based on the current existing data, it is recommended that patients with stage III melanoma undergo completion lymphadenectomy.

For patients with satellitosis or in-transit metastasis, surgical resection should be performed when feasible, and sentinel node biopsy should be considered to stage the regional nodal basin. However, in situations where extensive dermal involvement is present and surgical extirpation would lead to substantial morbidity, systemic therapy or radiation should be considered as the primary treatment modality. The high risk of distant metastasis in such patients provides a strong rationale for the use of systemic therapy to try to achieve concurrent distant control.

***Radiotherapy.*** The indications for adjuvant radiotherapy in stage III disease are based primarily on the risk of regional recurrences after complete nodal dissection. Patients with bulky nodal metastases are at particularly high risk of failure, and, in contrast to the trunk and extremities, smaller volume neck/parotid disease warrants radiotherapy. For regionally metastatic melanoma of the head and neck, adjuvant radiation should be considered for patients with (a) extracapsular extension of disease (b) nodal stage at least N2 (>2 lymph nodes) (c) nodes larger than 2 cm, and (d) extensive dermal metastasis or satellitosis. The indications for radiotherapy vis-à-vis the primary tumor remain those as described above for stages I to II patients. Adjuvant irradiation in these settings offers durable control in the regional basin, although effects on distant metastasis and OS are less clear.[99–102]

***Systemic Therapy.*** As described above, HDI was approved for the adjuvant treatment of resected stage III melanoma in 1995 and should be considered in all patients with stage III disease. More recently, a pegylated form of interferon alpha 2b (PEG-IFN) was approved by the US FDA for the adjuvant treatment of patients with stage III disease (but not stage II). The approval was based on the EORTC 18991 phase III trial.[103] This trial, which included 1,256 patients who had undergone complete lymphadenectomy for positive lymph node involvement, randomized patients to observation or PEG-IFN, which was given for 8 weeks at a dose 6 $\mu$g/kg weekly subcutaneously, followed by 5-year administration of 3 $\mu$g/kg weekly. Similar to HDI, treatment with PEG-IFN resulted in a significant improvement in recurrence-free survival (HR 0.84, $p = 0.02$). However, it did not produce a significant improvement in distant metastasis–free survival (HR 0.90, $p = 0.20$) or OS (HR 1.00, $p = 0.98$). Preplanned subgroup analyses suggested that patients with microscopic N1 disease may have the most benefit from this therapy, but future randomized trials in this specific group of patients will be necessary for definitive conclusions and recommendations. Thus, both HDI and PEG-IFN are FDA-approved options for patients with stage III melanoma, but the relative risks and benefits of these therapies must be considered, and enrollment in clinical trials should be considered as an alternative.

## Stage IV Melanoma

***Surgery and Radiation.*** Surgery generally has a limited role for patients with stage IV disease. The potential benefits for surgical extirpation of local or regional disease in the face of distant metastases are primarily palliative and include (a) limiting the morbidity of continued tumor growth into local structures, (b) reducing nodal burden to lessen great vessel and muscular invasion, and (c) potentially decreasing the source of future metastatic foci. In the head and neck, uncontrolled tumor growth can lead to a substantial decrement in quality of life, and thus local-regional control of clinical disease should be offered when appropriate. The therapeutic role of distant metastectomy is controversial. It is clear that certain sites of metastasis harbor more favorable prognosis, such as the lungs, and video-assisted thoracic surgery to excise a limited number of metastatic sites can be performed in the setting of low burden of disease and/or slow-growing lesions.[104,105] Lesions in the brain should also be considered for locally directed therapies, due to both the general lack of efficacy of systemic therapies for these patients and the significant risks associated with mass effects and intracranial hemorrhage.[106] However, other than for palliative relief of symptomatic lesions, surgical resection of brain metastases is generally only appropriate when three or less lesions are present.[107] The decision to operate on distant metastases remains complex and may evolve in the near future due to the availability of increasingly effective systemic therapies. Ultimately, decision making regarding the role of surgery in this setting should take into account the patient's estimated survival, surgical morbidity, and the potential success with other available therapeutic modalities.

Similar to surgery, radiation may offer palliative benefit in patients with stage IV disease, but is generally not used with curative intent. Radiation therapy plays a prominent role in the management of brain metastases. Stereotactic radiosurgery (SRS) can be offered as an alternative to surgical resection for brain metastases, most effectively in tumors ≤2 cm in diameter. Traditionally whole brain radiation therapy (WBXRT) has been used for patients with >3 lesions, but there is growing data that stereotactic radiosurgery is a reasonable alternative in patients with multiple metastases and may be associated with less cognitive decline.[108]

***Systemic Therapy.*** Systemic therapies are the primary therapeutic modality for patients with stage IV disease. Although chemotherapy has been used for many years in melanoma, other modalities (immunotherapy, targeted therapy) also play a prominent role in the management of these patients.

(c) 2014 Wolters Kluwer. All Rights Reserved.

***Chemotherapy.*** The first agent approved by the FDA for the treatment of metastatic melanoma was dacarbazine (DTIC). The active metabolite of DTIC methylates guanine nucleotides, resulting in errors in DNA replication and ultimately strand breakage and cell death. Dacarbazine achieves clinical responses in only 10% to 15% of patients, and the overwhelming majority of clinical responses are transient. Temozolomide (TMZ) is an oral agent that spontaneously hydrolyzes to the same active metabolite as DTIC. Clinical testing demonstrated that TMZ was noninferior compared to DTIC, but not superior.[109] In addition to the convenience of oral dosing, TMZ, unlike DTIC, is able to cross the blood–brain barrier. Despite this pharmacologic advantage, treatment with TMZ achieves clinical responses in only 6% of patients with brain metastases.[110] A number of other chemotherapies have been tested as single agents in melanoma, but none have demonstrated significant improvements in outcomes versus dacarbazine.[111] Similarly, a variety of combination chemotherapy regimens have been tested in melanoma. The most widely used combinations initially were cisplatin, vinblastine, and dacarbazine (CVD), and the Dartmouth regimen of cisplatin, dacarbazine, carmustine, and tamoxifen. Although impressive clinical response rates were observed in nonrandomized trials of each combination, neither regimen significantly improved OS in comparison to DTIC in randomized trials and were characterized by increased toxicity.[111,112]

***Immunotherapy.*** The regulation of melanoma by the immune system was initially suggested by a number of different observations, including rare spontaneous regression of metastatic lesions, and the occurrence of disease relapses many years (i.e., >10) after initial melanoma diagnosis and resection. These observations led to efforts to treat and control metastatic melanoma through stimulation of the immune system, as opposed to the use of agents that act directly on the tumor cells.

Interleukin-2 is a cytokine normally produced by the body in response to infections. Treatment with high-dose bolus IL-2 (HD IL-2) achieves clinical responses in approximately 15% of patients.[113,114] Although this response rate overall does not appear very different from that achieved by dacarbazine, the majority of the patients who achieve a complete clinical response (~6%) have very durable responses, with disease-free intervals of >10 years.[115] Although HD IL-2 was never shown to improve OS in a randomized trial, it was approved by the FDA in 1998 due to its ability to cure some patients with stage IV disease. Unfortunately, HD IL-2 treatment is extremely toxic, with critical side effects resembling the physiology of sepsis. Virtually every organ system is affected, with prominent toxicities including hypotension, renal insufficiency, dyspnea, confusion, and liver dysfunction; early trials reported a treatment-related mortality rate of approximately 2%. A number of efforts have been undertaken to identify patients most likely to benefit from HD IL-2. The highest response rates are observed in patients with skin and subcutaneous involvement only; conversely, patients with brain metastases have very low response rates, and their treatment is complicated by the risk of cerebral edema that could ensue from the aggressive fluid resuscitation required by this treatment.[114]

Biochemotherapy regimens were designed with the goal of increasing the response rate of IL-2 by combining it with chemotherapy.[116] A variety of biochemotherapy regimens exist and have been tested, most with the backbone of the cisplatin, vinblastine, and dacarbazine chemotherapy, along with IL-2 and IFN. IL-2 is generally given as a continuous infusion instead of as boluses, which reduces the severity of many of the hemodynamic side effects of this agent. However, the combined effects of the agents still results in significant toxicities. Nonrandomized trials with various biochemotherapy regimens have reported clinical response rates of 30% to 50%, but in randomized trials no significant improvement in OS has been demonstrated compared with chemotherapy alone.[111,117,118] However, similar to HD IL-2 therapy, patients who achieve complete tumor responses with biochemotherapy frequently experience very durable disease-free survival.[118]

An improved understanding of the factors that regulate the antitumor immune response has recently led to new immunotherapeutic approaches. CTLA-4 is an immunoglobulin that is expressed on the surface of regulatory and effector T cells. After activation of the T cells induced by the binding of antigens presented to antigen presenting cells (APCs) to T-cell receptors (TCRs), CTLA-4 becomes concentrated on the cell membrane and competes with the co-stimulatory CD28 receptor to bind to B7. Engagement of CTLA-4 inhibits signaling from the TCR and thereby attenuates the function of the T cell. In order to overcome this inhibitory signal, antibodies were designed to recognize CTLA-4. The most well-characterized CTLA-4 blocking antibody is ipilimumab. After promising preclinical and early-phase studies, the efficacy of ipilimumab has now been demonstrated in two independent phase III studies. The first study tested the efficacy of ipilimumab alone and in combination with the gp100 peptide vaccine in previously treated metastatic melanoma patients, with results compared to the effects of gp100 alone.[119] Treatment with ipilimumab alone resulted in a modest clinical response rate of 10.9%, but it was significantly improved compared with the gp100 arm (1.5%, $p = 0.001$). Interestingly, many of the responses were delayed, and some responses were observed with continued treatment after initial evidence of disease progression. More importantly, treatment with ipilimumab resulted in a significant improvement in OS (median OS 10.1 vs. 6.4 months, $p = 0.003$), making it the first agent to ever demonstrate a significant improvement in this outcome in a phase III trial in melanoma. Another phase III trial in treatment-naive metastatic melanoma patients showed that the combination of ipilimumab and dacarbazine resulted in significantly improved OS compared with dacarbazine alone (11.2 vs. 9.1 months, HR 0.72, $p < 0.001$).[120] Based on these results, ipilimumab was approved by the FDA for the treatment of metastatic melanoma in 2011. In both the first- and second-line trials, approximately 20% to 25% of the ipilimumab patients were alive 3 years after starting treatment, compared with approximately 10% in the control treatment arms, suggesting that the survival benefit of ipilimumab may be durable, although additional follow-up will be needed to compare to the durability of HD IL-2 complete responses. While ipilimumab is similar to HD IL-2 in its basic mechanism of antitumor activity, it differs significantly in its toxicities. Unlike HD IL-2, ipilimumab is not associated with significant acute effects on hemodynamics or other organ systems. However, a variety of toxicities are observed with this treatment over time, generally reflecting manifestations of autoimmune attack of organs. Notably, autoimmune colitis leading to intestinal perforation can be a lethal event and must be recognized and treated early in patients. Common toxicities of ipilimumab include diarrhea (~35%), rash (30%), liver dysfunction (2%–30%), fevers (20%–35%), and endocrine insufficiencies (hypothyroidism, hypopituitarism, hypophysitis, adrenal insufficiency; total <5%).[119,120] Multiple studies are ongoing to identify biomarkers to identify patients who are most likely to benefit from ipilimumab.[121]

In addition to ipilimumab, a number of other experimental immunotherapies have shown promise in early-phase testing. PD-1 is another inhibitory receptor on the surface of T cells, similar to CTLA-4. Treatment with MDX-1106, an antibody against PD-1, in phase I testing achieved several clinical responses, including in melanoma patients.[122,123] Interestingly, the toxicity of the agent was very mild, with the most common toxicities being hematologic (~25% lymphopenia) and fatigue/musculoskeletal (15%); the incidence of autoimmune colitis (2.5%) and

(c) 2014 Wolters Kluwer. All Rights Reserved.

endocrinopathies (2.5%) were both very low. Another promising approach is the use of adoptive cell transfer of tumor-infiltrating T cells (called TIL).[124–126] In this modality, tumors are harvested from patients, and then lymphocytes are isolated from the resected tumors (the TIL). If the TIL can be grown to sufficient numbers, patients then undergo lymphodepleting treatments (high-dose chemotherapy or total-body irradiation), followed by infusion of their TIL. Patients are then treated with HD IL-2 to promote the activity and viability of the TIL. Although no randomized studies have been performed, single-arm studies have reported clinical response rates approaching 50%, and many of the responses are durable.[126,127] While the results are promising, the regimen is quite toxic, and it is only possible to administer for patients from whom the TIL are able to expand. In addition, the expansion of T cells to sufficient numbers for treatment requires 1 to 2 months, and thus it is not an appropriate first-line therapy for patients needing immediate treatment. However, TIL can be stored safely after their harvest for treatment later, and thus TIL harvest may become a consideration in the management of stage III melanoma in the future.[128]

***Targeted Therapy.*** The identification of frequent activating mutations in melanoma has led to the aggressive testing of targeted therapies in this disease. The first target to be addressed was *BRAF*, which was an attractive candidate due to both its high prevalence (~45% of melanomas) and the presence of a single activating hotspot (*V600E*), which facilitates both clinical testing and drug development. Initial clinical trials targeting BRAF in melanoma were performed with sorafenib (also known as BAY43-9006). Sorafenib is a small molecular inhibitor of many kinases, including BRAF, although it binds to several other targets with greater affinity.[129] While it showed activity against melanoma cell lines in preclinical models, sorafenib achieved clinical responses in <3% of patients in single-agent clinical trials.[130,131] More promising results were observed in a phase I trial in which sorafenib was combined with paclitaxel and carboplatin, as 40% of the melanoma patients achieved clinical responses, although clinical benefit did not correlate with *BRAF* mutation status.[132] However, a phase III, randomized, placebo-controlled trial of paclitaxel and carboplatin with or without sorafenib showed that the addition of sorafenib did not improve the response rate (12% with sorafenib, 11% with placebo) or progression-free survival (median 17.4 weeks with sorafenib vs. 17.9 with placebo).[133]

While these results were very disappointing, much more impressive results have been achieved with V600-mutant-selective BRAF inhibitors. Vemurafenib (also known as PLX4032 or RG7204) was the first such agent to enter clinical testing. Vemurafenib was selected for development based on the fact that it not only was a selective inhibitor of BRAF compared with other kinases, but also has approximately 10-fold greater affinity for BRAF proteins with the V600E substitution mutation compared with the wild-type sequence.[134] The potent ability of vemurafenib to inhibit the growth of melanoma cell lines with *BRAF V600* mutations was demonstrated in preclinical models both *in vitro* and *in vivo*.[135] Unexpectedly, additional studies demonstrated that vemurafenib treatment of melanoma cell lines without *BRAF* mutation resulted in increased tumor cell growth.[136–138] In phase I clinical testing, no responses were observed in metastatic melanoma patients with a wild-type *BRAF* gene, but 83% of patients with a *BRAF V600E* mutation achieved (unconfirmed) clinical responses.[139] Clinical responses were only observed when serum levels of the vemurafenib exceeded doses that correlated with tumor shrinkage in preclinical models, and pharmacodynamic testing showed a dose-dependent effect on MAPK pathway inhibition that correlated with the magnitude of clinical response.[139,140] The efficacy of vemurafenib was shown definitively in the BRIM-3 phase III trial. In this trial comparing the efficacy of vemurafenib against dacarbazine in previously untreated metastatic melanoma patients with a *BRAF V600E* mutation, treatment with vemurafenib significantly improved the overall response rate (48.6% vs. 5.5%, $p < 0.001$), progression-free survival (median 5.3 vs. 1.6 months, $p < 0.001$), and the risk of death from melanoma (HR 0.37, $p = 0.001$). The trial was stopped at its first interim analysis, when the median follow-up for all patients was <4 months, so the effects on OS were quite preliminary and will need to be followed over time. Consistent with earlier studies, the most common toxicities of vemurafenib are cutaneous, including the development of cutaneous squamous cell carcinomas or keratoacanthomas in approximately 20% of patients.[139,141] Such lesions must be removed, but to date there are no reports of metastasis from them, and treatment with vemurafenib may be continued safely after they are treated. Other toxicities include rash, arthralgias, fatigue, and fevers. Vemurafenib was approved for the treatment of metastatic melanoma patients with *BRAF V600* mutations in 2011. Significant antitumor activity has also been observed with GSK2118436, which is a structurally unrelated, selective inhibitor of V600-mutant BRAF proteins. GSK2118436 achieved confirmed clinical responses in approximately 60% of metastatic melanoma patients with *BRAF V600E* mutations in phase I and II clinical trials, with a preliminary median progression-free survival of 6.7 months, although final results of these trials are pending at this time.[142] A variety of other inhibitors against the RAS-RAF-MEK-ERK pathway are currently in various stages of testing and development.

Although the high clinical response rate of the selective BRAF inhibitors is impressive, the benefit derived from these agents is relatively short lived. The median duration of clinical responses with vemurafenib in its phase I and II clinical trials was approximately 7 months, which is very similar to the initial results with GSK2118436.[139,142] Many studies have been conducted using both resistant cell lines and clinical specimens to determine the mechanisms of resistance to BRAF inhibitors.[143] Surprisingly, to date all samples have shown the continued presence of the *BRAF V600E* mutation at the time of resistance and have failed to identify any secondary mutations in the *BRAF* gene.[144] However, a number of other changes have been identified that result in reactivation of signaling downstream of BRAF despite the continued presence of the inhibitor. The mechanisms include alternative splicing of the *BRAF* gene, mutations in *NRAS* and *MEK1*, and utilization of other RAF isoforms (CRAF, ARAF). However, resistance has also been observed despite continued inhibition of signaling by BRAF due to activation of other signaling pathways. Research is ongoing to determine the efficacy of combinatorial approaches to prevent and/or overcome resistance to BRAF inhibitors.

In addition to *BRAF*, genetic alterations in *KIT* present a therapeutic opportunity. Small molecule inhibitors of KIT are the FDA-approved standard of care in gastrointestinal stromal tumors, a disease in which approximately 80% of patients have activating mutations in the *KIT* gene. Based on this previous experience, a number of melanoma patients with *KIT* mutations have been treated with various KIT inhibitors, many of whom have achieved dramatic clinical responses and benefit.[145–147] These responses contrast to the results of phase II trials of the KIT inhibitor imatinib in unselected melanoma patients. These trials, which overwhelmingly consisted of patients with cutaneous melanomas, which are unlikely to harbor *KIT* mutations, overall reported a response rate of approximately 1%.[42] Similar to the experience with selective BRAF inhibitors, trials with KIT inhibitors are now ongoing that are restricted to melanoma patients with *KIT* mutations and/or amplifications. Initial results from two such trials with imatinib reported clinical response rates of 15% to 25% in these patients.[148,149] Although these results appear to be superior to those achieved in unselected melanoma patients, research is ongoing to

(c) 2014 Wolters Kluwer. All Rights Reserved.

determine why the response rate is lower than what is observed in gastrointestinal stromal tumor patients (>50%).[150] Additional investigations are being undertaken to identify factors that correlate with response to single-agent KIT inhibitors in melanoma.[148]

## OUTCOMES AND RESULTS

In addition to providing data regarding new staging criteria (mitotic rate, serum LDH), the 2009 AJCC cutaneous melanoma staging and classification system provided important information about outcomes in a contemporary cohort of >38,000 patients.[12] Perhaps most critically, the outcomes reflect the current era in which SLNB has become a standard part of the management of local disease and can result in upstaging of patients without clinically apparent lymph node involvement. The survival outcomes by TNM categories and clinical stage groupings are shown in Figure 24-6. Importantly, the findings validated the previously established prognostic markers (i.e., Breslow thickness) and validated new markers incorporated into the staging system (mitotic rate, serum LDH). For patients with primary tumors only (stages I–II), 5-year OS varied from 97% for patients with T1aN0M0 disease to 53% with T4bN0M0. The 5-year survival for patients with regional metastases ranged from 70% (T1–4N1aM0) to 39% (T1–4N3M0). As to date no systemic therapies have been proven to significantly improve OS in randomized trials in patients with stages I to III melanoma, these rates likely remain highly relevant at this time. For patients with distant metastases, the reported 1-year survival rates were 62% with M1a, 53% for M1c, and 33% for M1c. However, the recent development of two different systemic therapies (ipilimumab, vemurafenib) that result in significant improvements in the OS of patients with stage IV disease provides a strong impetus to reevaluate the outcomes in the near future.[119,120,141] Furthermore, as vemurafenib is only effective in patients with activating *BRAF* mutations, and based on emerging data about prognostic significance of activating mutations, it is likely that future estimates of survival will need to incorporate information about molecular markers as well.[35,36,40]

### Complications

***Surgery.*** Complications related to surgery can be divided into systemic and local complications. A discussion of systemic complications is beyond the scope of this chapter and can be found in numerous texts of perioperative management. Specifically for melanoma surgery of the head and neck, treatment sequelae may be functional or cosmetic. Injury to the cranial nerves during surgical resection and reconstruction can be devastating and may result in facial (VII) or tongue paralysis (XII), shoulder dysfunction (XI), or facial parasthesias (V). Injuries to other cranial nerves are uncommon, but transection of cervical rootlets during a neck dissection can result in injury to the phrenic nerve and sensory nerves of the skin, and injury to the thoracic duct during neck dissection can lead to a chyle leak. Poor cosmetic outcomes are usually the sequelae of inappropriately designed facial incisions or suboptimal local flap reconstruction. Management of ear and eye defects requires reconstructive expertise, and complications in these regions include ectropion, telecanthus, "cup ear" deformity, and external auditory canal stenosis. The removal of nasal lesions can result in nasal stenosis when reconstruction is suboptimal. Medical comorbidities such as diabetes mellitus, vasculopathy, and cigarette smoking are associated with an increased risk of wound infections and failed reconstructive efforts, such as rotational flap or skin-graft necrosis.

***Radiation.*** Complications from radiotherapy can be divided into acute and chronic complications. Hypofractionation strategies generally lead to minimal morbidity in the acute setting, although skin sloughing and mucositis can occur, particularly for lesions in proximity to mucosal surfaces. Unlike irradiation to mucosal tumors of the head and neck, radiotherapy for cutaneous melanoma in this area does not result in substantial trismus, pharyngeal stenosis, chronic dysphagia, or dysgeusia, particularly when laryngeal blocks are used. Irradiation of lesions that are located near the mandible or maxilla can lead to osteoradionecrosis, and thus a thorough dental evaluation is necessary before treatment. Other long-term morbidities may include carotid artery stenosis, xerostomia, hearing loss, or cranial neuropathies. Osteoradionecrosis of the parietal or frontal scalp may occur after surgery and radiotherapy for melanomas located in this region. This often occurs when a nonvascularized skin graft is utilized in the reconstruction of a scalp defect, and thus a vascularized rotation flap is recommended when a full-thickness scalp resection is performed. Bilateral neck irradiation is associated with substantial morbidity, and due to the poor survival of patients with bilateral nodal metastasis, should be avoided in patients who have indications for postoperative radiotherapy.[151]

***Systemic Therapies.*** A number of the new therapies that have demonstrated efficacy in melanoma have relatively unique sequelae and complications than are traditionally observed with chemotherapy. Immunotherapies, such as ipilimumab, may induce the immune system to attack not only tumors, but also normal organs and tissues. Thus, patients receiving these therapies must be monitored for organ dysfunction due to autoimmunity.[152] The most commonly observed autoimmune side effects include endocrinopathies (thyroiditis, hypophysitis), dermatitis, hepatitis, and colitis; rarer manifestations include uveitis, nephritis, and myositis. The recognition of the autoimmune etiology in symptoms related to these manifestations is important clinically in order to provide appropriate therapy (immunosuppression) and to avoid fulminant toxicities (i.e., gastrointestinal perforations).[119]

Although they are cytotoxic to tumor cells, the mutant-selective BRAF inhibitors (vemurafenib, GSK2118436) generally do not induce the broad toxicity that is observed with cytotoxic chemotherapies. However, approximately 10% to 20% of patients treated with these agents develop hyperproliferative cutaneous lesions, including keratoacanthomas and squamous cell carcinomas. Emerging data suggests that many of these lesions harbor activating *RAS* mutations.[153,154] Preclinical models support that the selective BRAF inhibitors induce the proliferation of these cells, but they do not actually induce those oncogenic events, thus defining the BRAF inhibitors as promoters but not initiators of these lesions.[153] Treatment with the selective BRAF inhibitors may be continued safely after the removal of these hyperproliferative lesions, and to date there are no reports of metastases arising from them.

### Management of Recurrence

***Local Recurrence.*** Melanoma will recur at the site of the primary excision in approximately 1% to 8% of patients with stage I or II melanoma and is associated with adverse prognosis.[86,87,155,156] The head and neck has one of the highest sites of local recurrence, and risk factors associated with primary site recurrence include age >60, >4 mm thickness, and ulceration.[86,157] It is important to distinguish a local recurrence from an in-transit metastasis or a new second primary tumor, and therefore a biopsy of any suspicious lesion near the surgical bed should be undertaken. Resectable lesions should be managed operatively, but it is important to evaluate the patient for regional and distant disease with appropriate radiographic and laboratory studies. These will often include a CT or US of the head and neck. The value of a

*Source:* From Edge SB, Byrd DR, Compton CC, et al. *AJCC Cancer Staging Manual.* 7th ed. New York, NY: Springer-Verlag; 2010:329, 332–334, with permission.

sentinel node biopsy in the recurrent patient remains of questionable value, but if a patient has not had staging of the neck performed during prior treatment, the recurrent setting may be the appropriate time. However, the lymphatic drainage will likely be altered in this setting, and thus SLNB in this setting may lead to a false-negative result. For unresectable lesions, irradiation is a reasonable option to control local tumor growth, as progressive disease can lead to substantial cosmetic, functional, and neurological sequelae in the head and neck.

***Regional Recurrence.*** The incidence of regional recurrences in patients with malignant melanoma depends on numerous factors

(c) 2014 Wolters Kluwer. All Rights Reserved.

including age, tumor thickness, mitotic rate, ulceration, and LVI.[156,158,159] For stages I to II patients with negative SLNB, the reported regional recurrence rate is 2% to 7%,[64,69,155] which is distinguished from those with a false-negative SLNB. The risk of nodal recurrence among stage III patients is 10% to 15%. Clearly, the major concern in this population is the development of distant metastasis, and thus restaging studies should be performed. In the previously undissected neck, salvage lymphadenectomy is indicated as long as distant disease has not been identified. Regional control in the neck remains a high priority in this patient population due to the aforementioned issues surrounding morbidity. Whether to deliver adjuvant radiation in this situation is debatable and should be individualized and systemic therapy is indicated. Alternatively, the patient may be considered for a clinical trial.

## Special Issues/Future Directions

***Mucosal Melanoma.*** Melanoma of mucosal surfaces of the head and neck represents an aggressive form of the disease with a high propensity for regional spread and distant metastasis. At the molecular level, mucosal melanomas show a distinct pattern of chromosomal copy number gain and loss from the common cutaneous melanomas that lack evidence of CSD.[25] They also have a low prevalence of activating *BRAF* mutations (~5%), although the availability of effective therapies for those patients supports the rationale for testing for this abnormality (Table 24.1).[29] As discussed previously, mutations in the *c-KIT* gene are detected overall in 26% of mucosal melanomas, with specific studies in mucosal melanomas of the head and neck reporting mutation rates of 8% to 27%.[41,42] Clinical trials are ongoing to determine the overall efficacy of KIT inhibitors in melanoma patients with KIT mutations, but several case reports have described significant clinical responses to these agents.

Mucosal melanomas of the head and neck most commonly involve the oral cavity and sino-nasal tract. The lesions present as pigmented areas of the oral mucosa or as a polypoid mass of the nasal cavity that may be indistinct from a benign polyp. The general treatment paradigm entails surgical resection and adjuvant radiotherapy, although sentinel node biopsy is generally not utilized for the tumors. Margin control in these patients is difficult due to the proximity of the tumors to critical neurovascular and bony structures and is associated with adverse outcomes.[160] The addition of adjuvant irradiation improves local-regional control, but not OS.[161,162] In the paranasal sinuses, extension into the skull base is not uncommon. The outcomes for patients with paranasal sinus tumors are generally poor, with median 2-year survival of 65% for T1–T2 tumors and 20% to 30% for T3–T4 tumors.[163] For all mucosal sites in the head and neck, 5-year survival is approximately 25%.[164] A role for biochemotherapy is emerging for patients with unresectable disease or for those with distant metastasis.[165]

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

Imaging of the head and neck for melanoma is usually performed as part of staging for metastatic lymph nodes and intracranial metastases. If the primary site is the skin of the scalp, face, or neck, imaging can be performed to determine depth of invasion. This topic is dealt with in detail in the chapter on skin cancers. The lymphatic drainage of primary melanoma of the skin tends to follow the expected pattern associated with squamous cell cancer, that is, parotid and facial nodes, as well as occipital and level 1 nodes, followed by cervical chain nodes. However, there are reports of more variability of lymphatic drainage with melanoma.[1–3] Therefore, bilateral nodes at all levels must be examined carefully on the scans. The sentinel node is typically mapped with nuclear medicine lymphoscintigraphy (Fig. 24-7) and has prognostic value.[4] An FDG-PET scan is usually performed for initial staging to determine distant spread of disease. FDG-PET typically shows marked radiotracer uptake,[5] but there is variability of uptake perhaps related to the histologic type of melanoma[6] (Figs. 24-7 and 24-8). FDG-PET is commonly used in surveillance scanning following treatment.

Melanoma lymph node metastases tend to be quite aggressive in appearance. There is often a solid enhancing portion with areas of necrosis (Fig. 24-9). Extracapsular spread is common. Early necrosis is often present, and, occasionally, almost purely necrotic nodes will be encountered (Fig. 24-10).

Extranodal sites of melanoma in the head and neck are rare, but can occur in the thyroid gland (Fig. 24-11) and mucosal surfaces of the head and neck. The sinonasal region and oral cavity are the most common sites of involvement along the

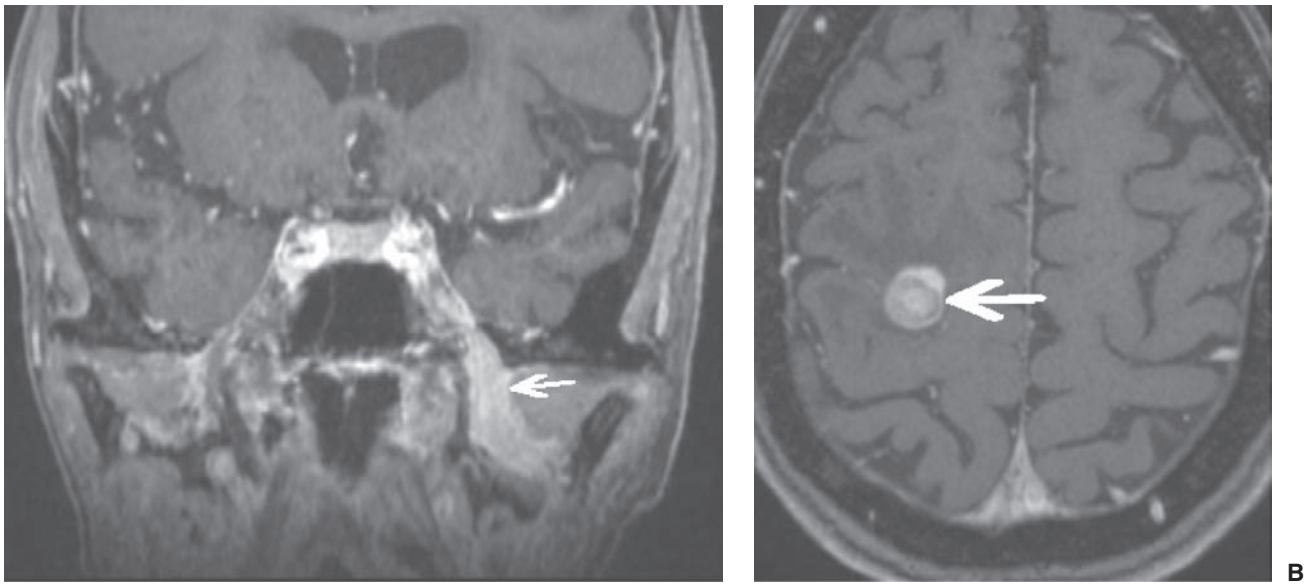

**FIGURE 24-14.** Perineural and hematogenous spread of melanoma. **A:** Coronal postcontrast T1-weighted MRI shows failure of treated melanoma along V3 (*arrow*). **B:** Also seen in the same patient on postcontrast T1-weighted MRI is a brain metastasis.

aerodigestive tract (see Fig. 24-8). Outcome remains poor, perhaps because of the dual lymphatic and hematogenous metastasis pattern, and the frequency of distant failure despite local/regional control.[7–9] Orbital melanoma is discussed separately in the chapter on cancer of the orbit.

Perineural spread of tumor is particularly common with desmoplastic melanoma,[10] and this finding should be anticipated and looked for on CT and MRI studies as this can affect the surgical extent of resection. Spread along the trigeminal nerve can be seen in facial melanomas (Fig. 24-12). A rare case of perineural spread along the brachial plexus is shown in Figure 24-13. Perineural spread of melanoma is often a site of failure in the head and neck following treatment (Fig. 24-14).

# PART C:
# Radiation Therapy Technique

William M. Mendenhall

The technique employed depends on the site and extent of the melanoma. The most common indication for radiotherapy (RT) in head and neck melanoma is for postoperative RT after resection of a lesion associated with a positive regional lymph node(s).[1] A common site of lymph node metastasis is the parotid gland alone or combined with cervical lymph nodes. The parotid may be treated with an appositional electron field; the energy will depend on the depth-dose desired and is often 12-MeV electrons. If it is necessary to treat to 4 to 5 cm depth, higher-energy electrons may be "mixed" with 6 MV x-rays to reduce the skin dose. In this instance, the electron field is 1 cm larger than the x-ray field, except where it matches the low neck field, due to

(c) 2014 Wolters Kluwer. All Rights Reserved.

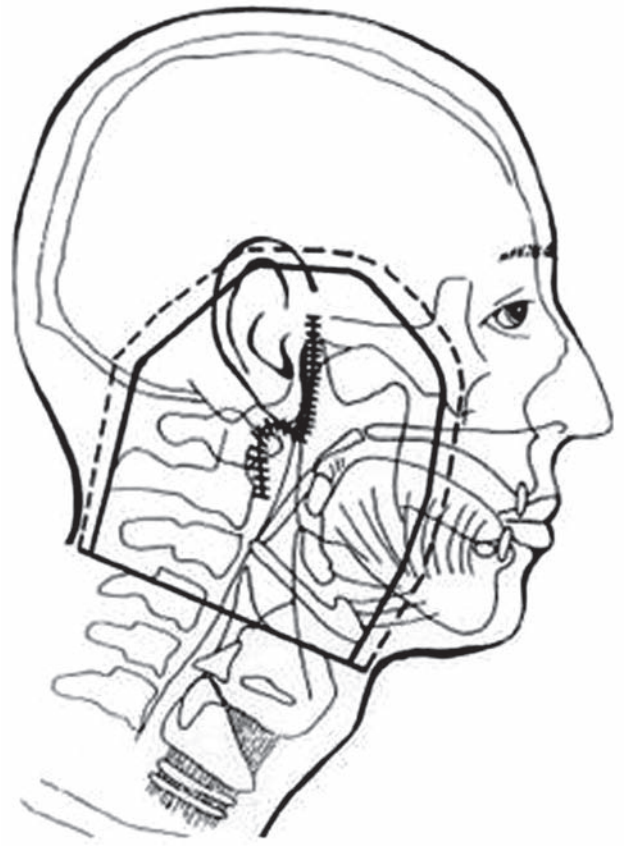

**FIGURE 24-15.** Appositional electron beam (*dashed line*) combined with 6-MV x-rays (*solid line*) to treat the parotid postoperatively.

beam constriction (Fig. 24-15). The anterior 6-MV x-ray field is matched with the parotid field(s) at the level of the thyroid notch. Alternatively, the parotid may be treated with intensity-modulated RT (IMRT).

Posterior cervical lymph nodes may be treated with opposed photon fields and reduced off the spinal cord once cord tolerance has been reached and the anterior aspect of the neck over the spine treated with 10-MeV electrons to the desired dose.

The primary site may be treated with orthovoltage RT or electron beam. The former is preferred (if available), unless the lesion is located in the scalp. Orthovoltage RT has several advantages compared with electrons: (a) there is less beam constriction; (b) it is easier to shield the eye; (c) the maximum dose is at the surface and bolus is not required; and (d) the dose distribution is not impacted as much by an irregular contour.[2] The orthovoltage beam energy is usually 250 Kvp. The field should be collimated on the skin surface with a customized lead mask for both orthovoltage RT and electrons.[2]

Lesions of the scalp associated with intransit metastases may require total scalp RT using a mixed pair of opposed 6-MV photon fields to treat the "rind" matched with lateral 6-MeV electron fields, a technique described to irradiate cutaneous angiosarcomas of the scalp.[3,4]

The dose-fractionation schedule is 30 Gy/5 fractions over 2.5 weeks with a reduction off the spinal cord and/or brain at 24 Gy.[1] Depending on the site treated, conventional fractionation may be employed if it is thought that a suboptimal cosmetic and/or functional outcome might be obtained with hypofractionation.[5]

CHAPTER 25

# Management of Salivary Gland Tumors

## PART A:
## General Principles and Management

Daniel G. Deschler, Kevin S. Emerick, Lori J. Wirth, and Paul M. Busse

## ANATOMY

### Parotid

The exocrine salivary gland system of the upper aerodigestive tract is composed of two distinct classes of salivary glands. The major salivary glands consist of paired structures in the head and neck region with consistent anatomic drainage patterns within the oral cavity. The largest of these is the parotid gland followed by the submandibular gland and finally the sublingual glands. The minor salivary gland system consists of between 500 to 1,000 small glands located throughout the upper aerodigestive tract. Great density is noted in the region of the lips and the anterior oral cavity but extension of these glands into the oropharynx, tongue, larynx, sinonasal passages as well as the trachea is also demonstrated.

The primary function of the salivary gland system is the production of saliva which is a complex fluid composed of electrolytes, mucopolysaccharides, mucoproteins, immunoglobulins, and lysozymes. The primary digestive enzymes of the salivary gland system are amylase and lipase. The quality of saliva produced by specific glands can be quite variable from the relatively serous saliva produced by the parotid glands to the thicker more mucoid secretion of the minor salivary glands. Saliva plays numerous critical functions within the oral cavity with primary focus on those affecting digestion. Saliva is critical for bolus formation and subsequent lubrication of the bolus to allow the various critically timed stages of deglutition. Enzymatic digestion of food begins with the interaction of the digestive enzymes contained within saliva. Adequate hydration from saliva allows successful speech and articulation. Similarly, saliva plays critical roles in the immune system as well as in the maintenance of dental hygiene. Treatment modalities, whether they be surgical, radiation therapy based, or chemotherapeutic, can have significant impact on salivary production and saliva quality and therefore significantly and negatively impact these critical functions.

The parotid glands are the largest of the major salivary glands weighing between 15 to 30 g each. The parotid gland is a lobulated gland that has its location based in the lateral aspect of the face, anterior and inferior to the auricle. The lateral aspect of the gland is covered by the facial skin. The posterior aspect of the gland rests against the ramus of the mandible. The superior extent of the gland is the zygomatic arch as it continues inferiorly to overlie the posterior belly of the digastric muscle. Laterally, a dense fascia will cover the parotid gland and this fascia will extend all the way from the zygomatic arch inferiorly toward the sternocleidomastoid muscle. Anteriorly, this fascia is contiguous with the fascia overlying the masseter muscle and is referred to as the parotidomasseteric fascia. At the superior and posterior aspect of the gland are several fascial attachments which are critical in the subsequent surgical intervention in and around the gland.[1] Superiorly, thick fibrous attachments connect the gland to the zygoma. The fascia becomes thinner as the gland extends inferiorly in the pretragal region but then becomes quite dense again in the region of the tympanic bone and mastoid. This layer must meticulously be divided to allow access to the stylomastoid foramen and the identification of main trunk of the facial nerve. The most inferior aspect of the parotid gland is referred to as the tail of the parotid and overlies the angle of the ramus, extending down to the sternocleidomastoid muscle. This is the region in which the majority of benign tumors of the parotid gland are located. Final component of the parotid gland extends deeply behind the ramus of the mandible through the stylomandibular tunnel to enter the prestyloid component of the parapharyngeal space.

The primary arterial blood supply of the parotid gland is provided through branches of the extension of the external carotid artery as it continues under the digastric and stylohyoid muscles after giving off the facial artery branch which will course through the submandibular gland. The external carotid artery will then course through the deep parotid tissue to give off the superficial temporal artery. Further continuation of this vessel will give off the internal maxillary artery as it exits the gland. Of note is a

(c) 2014 Wolters Kluwer. All Rights Reserved.

consistent arterial branch, the posterior auricular artery, which will be located approximately 2 mm lateral to the main trunk of the facial nerve and can be a useful landmark during facial nerve identification and subsequent dissection.

The venous system for the gland begins with the superficial temporal and the deep maxillary veins which combine within the gland to form the retromandibular vein. The retromandibular vein will exit the inferior-posterior aspect of the gland and usually be contiguous with the external jugular vein as it drains into the lower neck. If there is no external jugular vein of significance, the retromandibular vein will usually drain into a deep facial vein at the lower aspect of the gland and continue into the internal jugular vein. A critical anatomic relationship provided by the venous anatomy of the gland is that the facial nerve branches will standardly run in a plane just superficial to the retromandibular vein. Therefore, with axial imaging assessment of masses of the parotid gland, the orientation and displacement of the retromandibular vein can give useful information in potential facial nerve branch location.

The primary drainage pathway for the parotid gland is via the parotid duct. This structure is approximately 4 to 7 cm long and exits from the anterior aspect of the gland in the plane along the line from the oral commissure to the lobule of the ear. Upon leaving the gland, the parotid duct will course over the masseter muscle and then make a sharp turn medially as it pierces the buccinator muscle to exit in the oral cavity as the Stensen duct. The Stensen duct is visible as a small papule located in the buccal mucosa opposite the upper second molar. Accessory parotid glands are noted in between 21% and 56% of patients and will be situated anterior to the gland along the course of the Stensen duct. In most cases, the accessory gland will have ancillary drainage into the parotid duct, but may also have independent drainage.

Critical to the management of any lesion within the parotid gland is a clear understanding of the motor neural supply to the face which is intimately related to the anatomy of the gland. The facial nerve (cranial nerve VII) provides the primary motor neural function to the muscles of facial expression. A thorough understanding of its anatomic course is critical to any surgical management of parotid gland lesions. Originating from the brain stem, the facial nerve has five distinct segments prior to exiting the temporal bone. These include the intracranial pontine segment, the meatal segment through the internal auditory canal, the labyrinthine segment, the tympanic segment, and finally the mastoid segment. The extratemporal component of the facial nerve begins upon its exit from the mastoid bone at the stylomastoid foramen. Familiarity with the intratemporal components of the facial nerve is critical as perineural involvement by tumor may extend proximally requiring resection of a nerve within these regions as well as grafting from the intratemporal nerve to its muscular branches.

The extratemporal facial nerve is directly addressed in most surgeries of the parotid gland, and a clear understanding of its anatomy is critical to successful treatment in this delicate anatomic region. The main trunk of the facial nerve will exit via the stylomastoid foramen which is located laterally and inferiorly to the styloid process at the intersection of the mastoid and the tympanic bones. The nerve will usually give off small branches just upon exiting the stylomastoid foramen to the stylohyoid muscle and the posterior belly of the digastric. At this point, the nerve will then enter the parotid gland and extend for a short course before beginning its branching pattern. The nerve is standardly identified in this region at the main trunk and then dissected in an antegrade fashion to expose its orientation to masses within the gland.

There are numerous critical landmarks which facilitate the location of the main trunk of the facial nerve as it exits the temporal bone (Table 25.1). The most consistent anatomic landmark is the tympanomastoid suture line. The main trunk of the facial nerve will standardly rest between 2 and 4 mm deep to this.[2,3] The tragal pointer, the apex of the triangle forming the deepest part of the tragal cartilage, is another useful landmark and is defined as the triangular component of the deepest aspect of the tragal cartilage. This will rest approximately 1 cm superior and superficial to the nerve but is a less consistent landmark than the bony landmark of the tympanomastoid suture line.

**TABLE 25.1 Anatomic Landmarks for Identification of the Facial Nerve during Parotid Surgery**

| | |
|---|---|
| Tragal pointer | Nerve ~1 cm medial and inferior to tip of pointer |
| Tympanomastoid suture line (TMS) | Nerve ~2–4 mm deep to TMS |
| Superior portion of posterior belly of digastric muscle (PBD) | Nerve 5–14 mm superior to PBD |
| Posterior auricular artery | Nerve 2–4 deep to this artery |
| Styloid process | Nerve will run superficial and inferior to the palpated styloid process |
| Mastoid bone | Nerve can be identified through otologic drill out |

In the dissection of the facial nerve, it is critical that a wide and broad exposure is achieved. This involves freeing the fascial attachments in the pretragal and pretympanic components of the gland as well as broad inferior dissection which allows mobilization of the gland off the digastric muscle. Dissection is then done superiorly toward the digastric ridge where the muscle will enter the mastoid bone, and this similarly gives a good indication of the level at which the facial nerve will rest. With this broad superior and inferior dissection, meticulous dissection can then be done in the region of the tympanomastoid suture line to expose the stylomastoid foramen and the main trunk of the facial nerve. Once in the gland, the main trunk of the facial nerve will demonstrate one of numerous variations in branching pattern to innervate the various muscles of facial expression. The first major split in the nerve is at the pes anserinus. Here the nerve will usually break into two major branches, an upper temporofacial branch and a lower cervicofacial branch. Through various branching patterns described in Figure 25-1, five major branches will be given off. These include the frontotemporal branch, the orbitozygomatic branch, the buccal branch, the marginal mandibular branch, and the cervical branch.

As noted, clear identification of the facial nerve and its branches is critical to the surgical management of parotid masses, both benign and malignant. If there is an inability to adequately identify the main trunk of the facial nerve and proceed with a standard antegrade dissection, then alternative approaches can be undertaken. A retrograde means of dissection identifies specific branches of the facial nerve distally, once they leave the parotid gland, and then proceeds with dissection in a retrograde fashion as these branches coalesce to form the main branches and the main trunk of the facial nerve. The marginal mandibular branch can be identified inferiorly along the superior and posterior aspect of the submandibular gland and its fascia. The buccal branch will have a consistent location in the midface

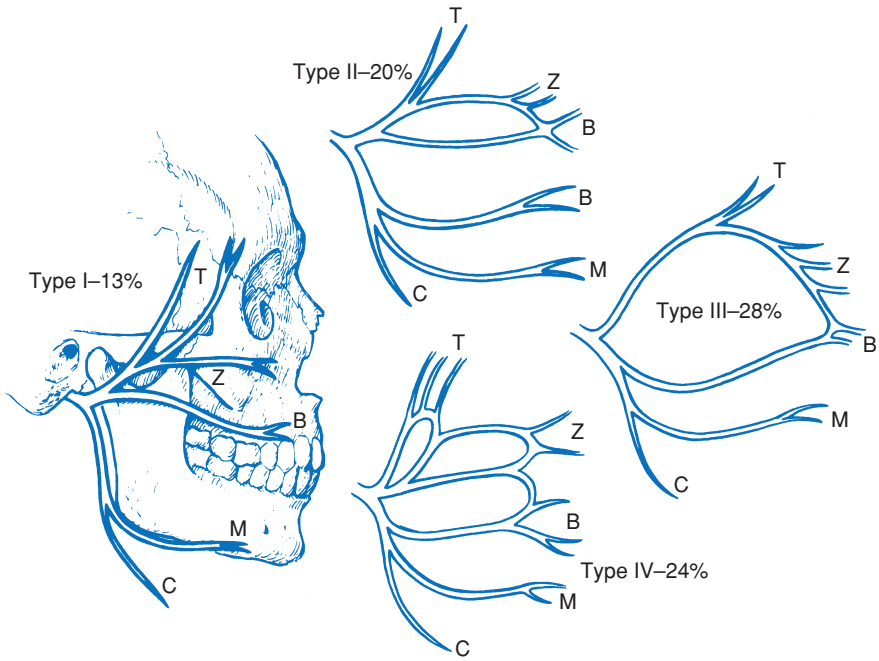

**FIGURE 25-1.** Anatomic variations of facial nerve branching. B, buccal; C, cervical; M, marginal mandibular; T, temporal; Z, zygomatic.

*Source:* From Johns ME, Kapan MJ. Malignant neoplasms. In: Cummings CW, Frederickson JM, Harker LA, et al., eds. *Otolaryngology—Head and Neck Surgery.* 2nd ed. St. Louis, MO: Mosby-Year Book; 1993:1048, with permission.

as it crosses the masseter in close relation to the parotid duct. Similarly, the orbitozygomatic branch is in a consistent position located on the line between the tragus and the lateral canthus of the orbit. Whichever means of dissection is utilized, be it antegrade or retrograde or some combination, clear identification of the nerve and its anatomy is critical to surgical success.

The sensory supply to the face and auricle surrounding the parotid gland is provided by the great auricular nerve which is formed from the cervical sensory plexus from rootlets C2 and C3. This nerve will course over the sternocleidomastoid muscle and then enter the parotid gland at a point that is usually 8 to 10 mm cephalad to the external jugular vein. The anterior branch of the great auricular nerve will course through the gland and supply the anterior facial skin whereas the posterior branch of the nerve will extend posterior to the lobule to innervate the ear. Preservation of the posterior branch of the great auricular nerve can be achieved with meticulous dissection of this branch through the posterolateral parotid parenchyma and maintenance of its course behind the lobule toward the ear, and studies have demonstrated potential benefit from the preservation of this nerve.

The secretomotor function of the parotid gland is controlled by the parasympathetic autoimmune system via the glossopharyngeal nerve (cranial nerve IX). Preganglionic parasympathetic fiber from the inferior salivary nucleus travel via cranial nerve IX through the jugular foramen where the tympanic branch will then turn back into the skull base via Jacobson nerve to enter the middle ear. These fibers will course along the roof of the middle ear becoming the lesser petrosal nerve which will then exit the skull base at the foramen ovale. The fibers then synapse at the otic ganglion located under the mandibular branch of cranial nerve V3. Postganglionic fibers exit the otic ganglion to join the auricular temporal branch of the trigeminal nerve in the inferotemporal fossa. These parasympathetic fibers supply the innervation for parotid salivary secretory function. Sympathetic innervation is modulated via the superior cervical ganglion sympathetic fibers, which travel along the external carotid system to innervate the gland.

The parotid gland is unique in its lymphatic anatomy. Through embryologic development, lymph nodes in the region of the parotid gland are incorporated into the gland itself and contained within the fascial borders. This is in distinction to the submandibular gland which contains no intraparenchymal lymph nodes. Ninety percent of the lymph nodes within the parotid gland will be located in the superficial lobe. The lymph nodes within the gland provide drainage from the scalp, face, ear, and orbit and primary tumors within these regions can lead to metastases within the parotid gland presenting as parotid masses. Similarly, lymphoma may occur within a lymph node in the parotid gland, presenting as a parotid mass.

## Parapharyngeal Space

The parapharyngeal space is the deep-neck compartment oriented as an inverted pyramid in the parasagittal plane bilaterally. The base of this pyramid is situated at the skull base abutting the petrosal bone. The apex of the pyramid is the hyoid bone. The lateral borders are formed by the medial pterygoid muscle and the ramus of the mandible, whereas the medial border is constituted by the lateral pharyngeal wall with its associated fascia and musculature. The anterior limit is the pterygomandibular raphe whereas the posterior limit is the spine.

The parapharyngeal space is divided into two distinct compartments by the styloid process and the stylomandibular fascia. The poststyloid compartment of the parapharyngeal space contains the neurovascular structures of the carotid sheath whereas the primary components of the prestyloid compartment are elements of the deep lobe of the parotid gland. Parotid masses may involve the parapharyngeal spaces in two distinct fashions. Tumors can arise within the deep lobe of the parotid gland and then extend into the parapharyngeal space through the stylomandibular tunnel. These masses will have a dumbbell shape constituted by a component within the deep lobe of the gland as well as in the parapharyngeal space. Alternatively, tumors may arise from salivary gland tissue distinctly within the parapharyngeal space and therefore present as an isolated mass within the prestyloid parapharyngeal space. Masses of the parapharyngeal space are often incidentally noted on imaging of the head and neck region obtained for other reasons. Similarly, they may be asymptomatic but physical exam of the oral cavity can demonstrate a distinct

(c) 2014 Wolters Kluwer. All Rights Reserved.

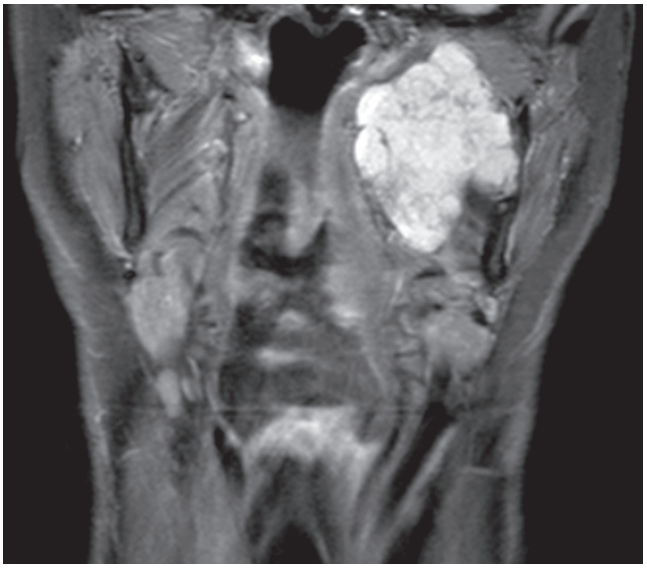

**FIGURE 25-2.** T2-weighted MRI demonstrated extension pleomorphic adenoma of the left parapharyngeal space.

fullness of the lateral pharyngeal region with displacement of the soft palate, tonsil, and lateral pharyngeal wall. Physical exam can also demonstrate a diffuse fullness in the region of the parotid gland secondary to the lateral displacement of the gland by the deeply situated mass (Fig. 25-2).

## Submandibular Gland

The second largest of the major salivary glands are the submandibular glands weighing 7 to 16 g each. These glands are located within the submandibular triangle that is bordered inferiorly by the anterior and posterior belly of the digastric muscle and superiorly by the lower border of the mandible. The majority of the submandibular gland is located below and posterior to the mylohyoid muscle with a smaller component anteriorly and superiorly, which extends deep to the mylohyoid muscle to abut the sublingual glands. This gives the gland a distinct horseshoe shape as it rests within the submandibular triangle. The submandibular gland is surrounded by the middle layer of the deep cervical fascia. This has importance as the marginal mandibular branch of the facial nerve runs in the plane immediately superficial to this fascia along the lateral and superior aspect of the submandibular gland. This becomes an important landmark in submandibular gland surgery designed to preserve the function of the lower branches of the facial nerve. As previously noted, there are no lymph nodes within the gland itself.[4] The majority of lymph nodes associated with the submandibular gland rest superiorly along the facial vasculature as it exits the gland and crosses the mandible. These perifacial nodes deserve a distinct consideration in the setting of cutaneous malignancies as well as oral cavity cancers. Lymph nodes can also rest along the posterior component of the gland where it abuts level IIA.

The arterial supply to the submandibular gland is from the facial branch of the external carotid artery. The facial artery will branch from the ECA and course medially under the digastric and stylohyoid muscle to enter the posterior aspect of the gland. The facial artery will then give off two to four branches to supply the gland and then exit superiorly from the gland over the border of the mandible. Often a small notch can be palpable in the lower border of the mandible where this artery will cross.

The venous supply to the submandibular gland can be quite variable but primarily consist of the anterior facial vein, which travels over the mandible with the artery and then courses on the anterior surface of the gland lateral to its fascia. It then will join the common facial vein and empty into the internal jugular system. On rare occasions, the anterior facial vein may empty into a prominent anterior jugular vein or the external jugular system. The facial vein does have anatomic importance as the marginal mandibular branch of the facial nerve will run in the plane just superior to the nerve and therefore this relationship can be utilized in nerve-preserving maneuvers during submandibular gland surgery. If the vein is located in the lower to mid portion of the gland and then elevated superiorly, this will allow the nerve to be rotated superiorly and provide a protective effect. The posterior venous system of the submandibular gland drains via the posterior facial vein which can be quite prominent. Specific situations that lead to this increased size are if the posterior facial vein provides drainage of the retromandibular vein in the setting of an underdeveloped external jugular system.

The ductal drainage system of the submandibular gland coalesces to form the submandibular duct, which exits the gland and then travels deep to the lingual nerve and medial to the sublingual gland. The duct then enters the floor of the mouth as Wharton duct, which exits at either side of the lingual frenulum in the anterior floor of mouth. The submandibular gland maintains an intimate relationship with the lingual nerve because of its anatomic proximity as well as the attachment of the nerve to the gland via the submandibular ganglion. The lingual nerve enters the submandibular triangle from posteriorly and superiorly as an extension of the mandibular branch of cranial nerve V3. The lingual nerve will then give off a small branch to the mylohyoid muscle which is standardly sacrificed in the majority of submandibular gland surgeries. Parasympathetic secretory fibers from the facial nerve and chorda tympani travel along the lingual nerve to synapse in the submandibular ganglion. From here, the sensory fibers of the lingual nerve will continue anteriorly into the floor of mouth to supply the somatosensory and taste functions of the anterior two-thirds of the tongue. The lingual nerve and submandibular ganglion are readily exposed during surgical exploration with inferior retraction of the gland and superior retraction of the mylohyoid muscle. This allows the gland to be severed from the nerve while maintaining sensory function. This maneuver likewise allows assessment of potential direct neural involvement.

During the same maneuver, the hypoglossal nerve will be evident running in a separate plane deep into the gland. Surrounded by the venae comitantes, the nerve will continue anteromedially to supply motor function to the tongue. The hypoglossal nerve will originate from the skull base exiting at the hypoglossal canal and then travel medially to the internal jugular vein and superficially to the external carotid system as it turns medially to enter the submandibular triangle. The hypoglossal nerve will enter the submandibular triangle inferior and posterior to the junction of the anterior and posterior belly of the digastric muscle at the lesser cornu of the hyoid bone. The submandibular tumors do not routinely directly involve the 12th cranial nerve. Care must still be taken to avoid injury during gland resection with resultant hypoglossal paralysis.

## Sublingual and Minor Salivary Glands

The smallest of the major salivary glands are the sublingual glands weighing between 2 and 4 g. The sublingual glands rest in the anterior floor of mouth superior to the mylohyoid muscle. Resting just lateral to the lingual frenulum and covered loosely by the oral cavity mucosa, the sublingual glands have a unique draining system via many small ductules (Rivinus ducts) which exit directly into the floor of mouth. Drainage may also occur via

(c) 2014 Wolters Kluwer. All Rights Reserved.

connections to the submandibular ductal system. The sublingual glands are innervated by the parasympathetic fibers from the seventh cranial nerve.

The minor salivary gland system consists of between 500 and 1,000 variably sized small glands located throughout the upper digestive tract. Ranging in size from 1 to 5 mm, these glands are found throughout the lips, tongue, soft and hard palate, buccal mucosa, pharynx, larynx, upper trachea, nasopharynx, and paranasal sinuses. The majority of the minor salivary glands are concentrated in the region of the lips, tongue, soft and hard palate as well as the buccal mucosa. Postganglionic parasympathetic secretomotor innervation to the minor salivary glands depends on the anatomic region that primarily is via the lingual nerve and branches from the sphenopalatine ganglion.

## EPIDEMIOLOGY

Salivary gland malignancies are not common. Considering that head and neck malignancies comprise only 5% to 6% of malignancies in the United States, the proportion of salivary malignancies overall is very small. They account for only 1% to 6% of head and neck cancer and only 0.3% of all cancers. The relatively small number of patients with salivary gland malignancy has made it difficult to thoroughly describe the epidemiology and prevalence of these malignancies. Additionally, with >20 histologic subtypes, which have undergone an evolution of classifications and limited data on the etiology and risk factors for these tumors, accurately defining the true epidemiology of these tumors has been very difficult. Large population-based data from SEER provides some insight. An early study from SEER shows a mean incidence of 0.89 per 100,000 per year.[5] A more recent SEER study using updated WHO histology classification found the incident rate to be 1.2 per 100,000 per year.[6] Smaller series from institutional databases and national tumor registries in Europe have reported a similar incidence.[7–9] The incidence appears to be very stable when compared over the last few decades.

There is a question of possible male predominance. The SEER data show a male predominance, with as much as a 51% increase in incidence rate compared with females.[9] However, other series have shown a much smaller difference in incidence rate which are effectively equal. Interestingly the SEER data identified a significant difference in the distribution of tumor histologies between men and women. For example, there are twice as many males with salivary ductal carcinoma, but there is no difference for adenoid cystic carcinoma (ACC). Depending on the makeup of tumor histology within a database, this could influence reported differences between males and females. There also appears to be a higher incidence rate among females <50; however, there is a higher rate among males >50.

Salivary glands malignancies typically present in the sixth decade of life. However, this too is likely impacted by histological subtype. Acinic cell carcinoma (AC), for example, has a mean age at diagnosis of 51 years, whereas squamous cell carcinoma has a mean age of >72 years of age. Some data have also suggested that more aggressive tumors tend to present at an older age, usually in the seventh decade.[7] Describing differences in race among such a small population has been difficult. Early SEER data also found a 1.4 times greater incidence in white patients than in black patients.[7,10] More recent data suggest this also may be histology driven.[9] The incidence rates are equivalent among all races for the two most common histologies, mucoepidermoid and ACC. However, most other subtypes have a higher rate in white patients.

Another consideration is the distribution of malignant tumors among the different salivary glands. More than half occur in the parotid gland. Thirty percent arise in the submandibular gland and the remaining 10% to 15% arise in the sublingual and minor salivary glands. These overall numbers are important to consider when assessing a neoplasm in each of these different sites. However, the parotid gland is also the most common site for benign salivary gland tumors as well. Benign neoplasm predominates in the parotid gland with only 15% being malignant. On the other hand, 50% submandibular neoplasms are malignant and 70% to 80% of sublingual gland and minor salivary glands are malignant.[11]

There is limited knowledge available regarding the etiology of these tumors. There are data demonstrating variable expression and mutations related to epidermal growth factor receptor (EGFR), c-kit, Ki-67, MUC1, antiapoptotic proteins (BIM, BAX, Bcl 2), and her-2 to name a few, but these findings are far from universal. Viral etiologies including cytomegalo virus has recently been reported as a possible etiology.[12] Altered p27/skp-2 expression has been reported as a key factor in differentiation and aggressiveness.[13] However, it is unclear what induces these changes. The embryology and ultrastructure of the salivary gland can provide a framework for understanding how the different histologies of tumors develop (Fig. 25-3). Major salivary glands have

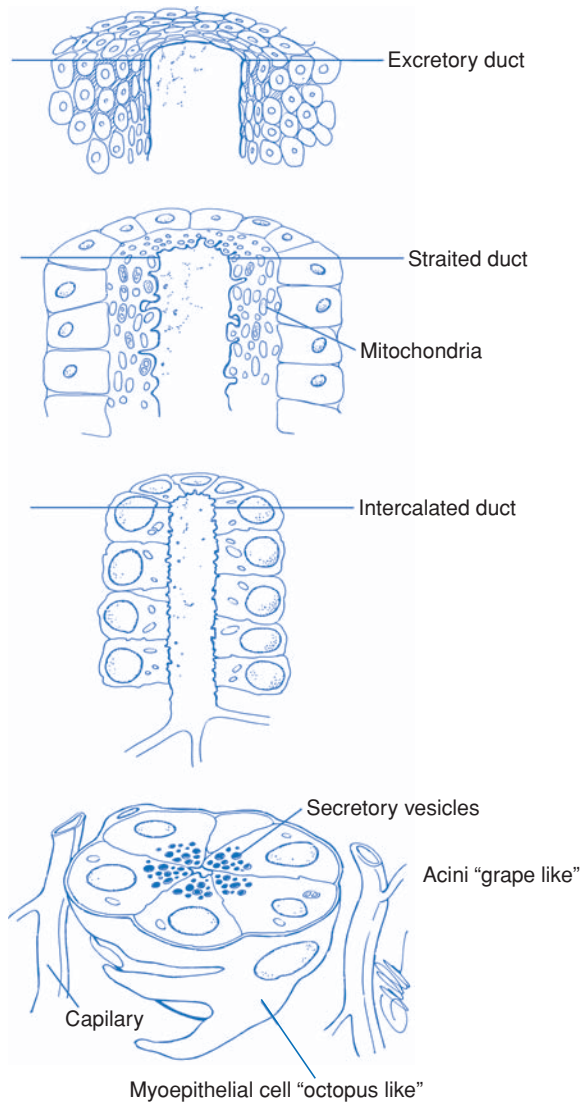

**FIGURE 25-3.** Histologic structure of salivary gland tissue.

(c) 2014 Wolters Kluwer. All Rights Reserved.

a ductal system through which both serous and mucinous cells drain. These are arranged into clusters called acini. The ducts are arranged in a series beginning with the acini, which drain into an intercalated duct which in turn drains into a striated duct and ultimately into the excretory duct.[14] These ducts are lined with an epithelium, and a layer of myoepithelial cells are present deep into the epithelium. From this histologic framework, there are two theories on how malignant neoplasm arise.[15] The multicellular theory suggests each type of neoplasm originates from a different cell type within the glandular unit, whereas the bi-cellular reserve cell theory suggests that all salivary neoplasm originate from either an excretory or intercalated duct cell which functions as a reserve cell with the ability to differentiate into different epithelial or epidermoid cells.

## PATHOLOGY

Although our understanding of histogenesis remains limited, there is a good descriptive knowledge of the different types of tumors classified as salivary gland malignancies. Additionally, this classification allows for tumors to be further subdivided into high grade and low grade (Table 25.2). The most common type overall is mucoepidermoid carcinoma (MEC) followed by adenoid cystic, acinic cell, adenocarcinoma, and carcinoma ex. However, the prevalence does vary based on age, gender, and anatomic location. The following is description of the key histologic subtypes.

### Mucoepidermoid Carcinoma

MEC is the most common salivary gland malignancy overall, yet only accounts for 15% of all salivary tumors. However, MEC alone accounts for nearly a third of parotid malignancies. Greater than 80% of MEC occur in the parotid gland, 10% in the submandibular gland, and <5% in minor salivary glands.[16] Palate is the most common minor salivary gland site for MEC, with rare occurrences on the retromolar trigone, floor of mouth, buccal mucosa, lip, and tongue. MEC is notably the most common malignant salivary gland tumor to arise in patients <20 years of age.

There is a variable composition of different cells in MEC: mucin-secreting, epidermoid, and intermediate. This variability has led to three distinct histological subtypes with different clinical courses.[17] The initial descriptions of these tumors came from Stewart et al. in 1945. Shortly thereafter, Foote and Frazell established a two-tier grading system, one grade thought to be benign and the other malignant.[16] However, it became clear to the authors that in fact all of these tumors were malignant, but in varying degrees of low, intermediate, and high grades. However, there has been a debate of the best way to consistently grade these tumors.

The two main grading systems were developed by Healey and modified by Batsakis[17] and the system developed by Goode et al. at the AFIP.[16] Each system grades tumors based on tumor architecture, pattern of invasion, cell type composition, histocytologic pleomorphism, and frequency of mitotic figures. Based on several studies using these grading systems, it has become clear there is a significant difference in the clinical behavior of these tumors depending on their grade. In addition to this focus on grade, there is also evidence for improved 5-year survival in stage I/II patients, 90%, compared with stage III/IV patients.[18] Ultimately, specific genetic changes may be identified that better define these and help predict clinical outcome and guide treatment.[14]

Low-grade MEC (Fig. 25-4) has an excellent prognosis ranging from a reported 92% to 100% 5-year survival. Batsakis reported these tumors are found in a young population with a strong female predominance and present at an early stage.[18,19] Surgical excision with negative margins yields an excellent local control rate, nearing 100%.[16,18,19] These tumors rarely metastasize to regional lymph nodes or to distant sites. A recent report showed that surgery even with positive or close margins had an excellent control rate when adjuvant radiation was given.[20]

High-grade MEC behave very differently than their low-grade counterparts.[21] Survival is very poor in this group, 22% to 43% 5-year survival. These tumors usually present in older patients, with a male predominance and present at stage III or IV[16–19,22] with up to 85% of these tumors having regional metastasis. Of patients with MEC who present or develop distant metastasis, they are nearly all high grade. Histologically, these tumors frequently have poorly differentiated epidermoid cells and rare mucin-positive cells. They can be confused with other high-grade carcinomas such as squamous cell carcinoma, salivary ductal carcinoma, adenocarcinoma, and malignant mixed tumors.

Intermediate-grade tumors have an intermediate clinical course, both in terms of presentation and outcome. Patients present with smaller tumors than high-grade MEC, but neck metastasis is relatively common, occurring in almost 20% of patients.[18]

**TABLE 25.2 Common Parotid Malignancies by Histologic Grade**

| Low Grade | High Grade |
|---|---|
| Low-grade mucoepidermoid carcinoma | High-grade mucoepidermoid carcinoma |
| Adenocarcinoma not otherwise specified (NOS), low grade | Adenocarcinoma NOS, high grade |
| Acinic cell carcinoma | Adenoid cystic carcinoma |
| Polymorphous low-grade adenocarcinoma | Salivary duct carcinoma |
| | Carcinoma ex-pleomorphic carcinoma |
| | Mixed malignant tumor |

(c) 2014 Wolters Kluwer. All Rights Reserved.

The local and regional/distant recurrence rates are 22% to 30% and 39%, respectively, which fall in between the incidence reported for high-grade and low-grade tumors. Five-year survival is approximately, 70% for the group as a whole.[18,19] There appears to be a population of intermediate-grade MEC which does well, much like low-grade MEC, and a population which does quite poorly, behaving more like a high-grade MEC. Further studies into biochemical markers may help distinguish these tumors in the future. Not surprisingly, the variable clinical course has led to variable treatment among institutions. However, many favor an approach based on stage. Small, localized tumors with a benign clinical picture can be treated with wide local excision. However, large size, regional spread, and aggressive pathologic features should direct a more aggressive treatment course similar to a high-grade tumor.

## Adenoid Cystic Carcinoma

ACC is the second most common salivary gland malignancy. It was first recognized in 1854, but the term ACC was not used until 1953 by Foote and Frazell.[23] They tend to present in the fifth and sixth decades of life without a clear sex predilection. It occurs most commonly in the minor salivary glands, with a predilection for the oral cavity and hard palate in particular. However, it is well known to occur in any salivary gland as well as other unexpected sites such as the lacrimal gland, esophagus, and tracheobronchial tree. Overall, these tumors are characterized by slow local growth with rare spread to regional lymphatics. However, they are well known for their propensity for perineural invasion (PNI) and distant metastasis.[24–26] These tumors are also unique in that distant metastasis can also present in a very delayed fashion, years or decades later; therefore, long-term follow-up is important.[27]

The grading of ACC is much less controversial than other salivary gland malignancies. It is characterized by three histological subtypes: solid, tubular, and cribriform (Fig. 25-5). Most tumors possess components of two or three subtypes. The solid type demonstrates solid sheets and nests of atypical basaloid cells with an undifferentiated appearance and many mitoses.[28] Several large series have demonstrated that the solid type histology imparts a worse prognosis with 5-year survival as low as 17% in some studies.[24–26] Tubular histology has the best survival. The cribriform pattern is considered the classic ACC with a "Swiss-cheese" appearance and accounts for up to 64% of reported cases of ACC. It is considered an intermediate grade when comparing survival among all three of these subtypes.

Overall survival (OS) varies widely from different series and subsite. ACC is notable for its atypical survival curve. Unlike most head and neck malignancies, the survival for ACC does not plateau at 5 years. This is attributable to late local recurrences, late development of distant metastasis, and the slow growth of distant metastasis when they do occur. Clinical stage, solid histological subtype, and increased *p53* expression are independent significant prognostic factors for poor survival.[24] Age >45, paresthesias, pain, PNI and margin status also correlate with survival.[25]

ACC is usually treated with surgical resection followed by radiation therapy. Negative margins along nerves are a challenge to obtain because of extensive perineural spread and the presence of skip lesions along nerves. Despite the overall high-grade nature of this tumor, there is a low incidence of regional spread and elective neck dissection is not mandatory for the N0 patient. However, more recent data have reported rates as high as 23% for occult regional metastasis including a 17% rate for early-stage tumors.[29] Therefore, dissecting the first echelon of at-risk nodes may be considered. Given the margin issue discussed above, postoperative radiation is important for improving both local control and OS.[24] Because of the slow-growing nature of this tumor, neutron beam therapy has been investigated.[30] However, its overall benefit has yet to be determined in the postoperative setting and it is only available in a few sites worldwide.

## Adenocarcinoma

Adenocarcinoma previously referred to a very heterogeneous group of tumors. However, today there are several well-described classifications of adenocarcinomas. These include tumors such as salivary duct carcinoma, polymorphous low-grade adenocarcinoma, and epithelial-myoepithelial carcinoma. These tumors are classified based on the different salivary subglandular units such as the different cells within the acini or different salivary ducts cells from which they arise. Those tumors that do not fall into recently described classifications are still collectively referred to as *adenocarcinoma, not otherwise specified*.

As more tumors are classified, the number of adenocarcinomas becomes much fewer, such that adenocarcinoma, not otherwise specified now represents the least common salivary gland tumor. This remaining group is still heterogenous with variable cytoarchitecture ranging from low grade to high grade in differentiation, solid or cystic, and papillary and nonpapillary features. They occur in older patients in their seventh decade of

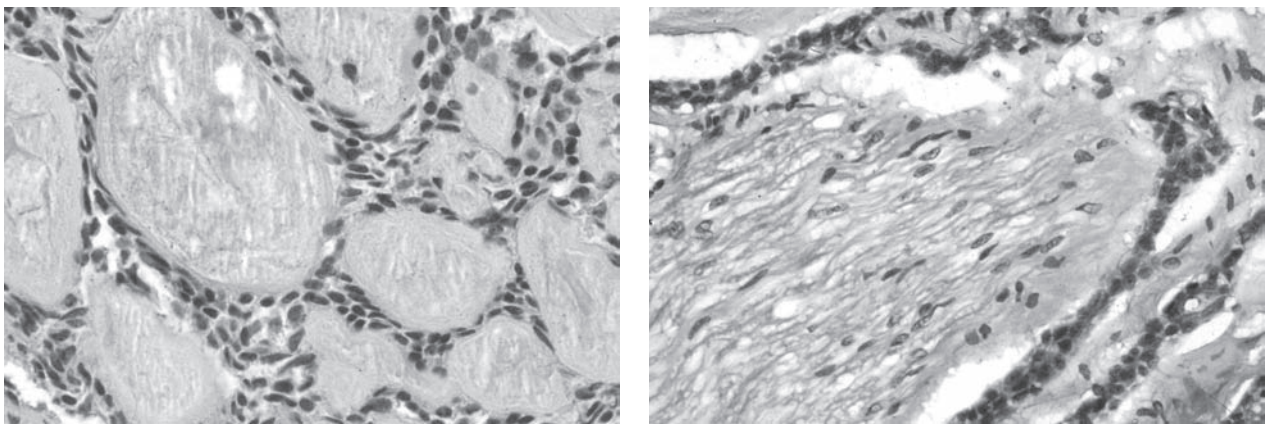

**FIGURE 25-5.** **A:** Cribriform type of adenoid cystic carcinoma with basaloid cells surrounding a myxoid matrix. **B:** Adenoid cystic carcinoma with extensive perineural spread. (See color insert.)

(c) 2014 Wolters Kluwer. All Rights Reserved.

life, with a 4:1 male predominance, and predominantly in major salivary glands.[31] Poor prognostic features have previously been described and include advanced stage, high histological grade, infiltrative growth factor, and tumor DNA content.[32]

Unfortunately, most of these tumors are high grade with a propensity for regional 23%, distant metastasis, 37%, and OS 10% to 60%.[31,33] Treatment is correspondingly aggressive with wide local excision, elective neck dissection, and postoperative radiation therapy.

## Acinic Cell Carcinoma

ACs account for up 17% of all salivary malignancies. However, it appears to have a higher incidence among children, where it is second only to MEC in incidence. These tumors are thought to arise from progenitor reserve cells of the terminal tubules and intercalated ducts of salivary tissue.[34] These tumors generally take the clinical course of a low-grade tumor. Batsakis did describe low- and high-grade histologic variants, with >90% of tumors considered histologically low grade.[34]

A recent National Cancer Data Base review of 1,353 cases has helped characterized this tumor.[35] It arises at a younger age than other salivary gland malignancies based on a median age of 52. This study also found a female predilection. It has been reported to occur in all salivary glands but is predominantly a tumor of the parotid gland, 86% of cases. This is likely attributable to the predominance of serous-type acini in the parotid compared with other salivary glands. It is notable for an incidence of bilateral tumors in up to 3% of cases, making it the second most common salivary neoplasm to occur bilaterally. Regional metastasis is not common. Studies report varying incidence from 0% to 17%, with most series reporting <10% and the National Cancer Data Base review identifying a 9.9% incidence.[35–37]

AC has an excellent 5-year disease-specific survival of >90%.[35] Clinicopathologic factors that predict a poorer outcome include high-grade histology, regional or distant metastasis at presentation, primary tumor in the submandibular gland, and age >30 years.[35] These patients likely have a 5-year survival around 30% to 40%. Interestingly, the overall recurrence rate from the Armed Forces Institute of Pathology series was 35%, yet within this group of recurrent disease only 16% died of this disease.[38] Other reports have also highlighted that prolonged survival is possible despite persistent disease. This has led many surgeons to consider palliative surgery for patients with incurable disease.

First-line treatment is surgical excision. Because the incidence of regional metastasis is <10%, routine elective neck dissection is not recommended. Adjunctive radiation therapy is reserved for high-grade tumors, recurrent tumors, positive margins, and stage III or IV tumors.[35–37]

## Salivary Duct Carcinoma

Salivary duct carcinoma is best known histologically for its resemblance to ductal carcinoma of the breast, from which it is indistinct.[39] Histologically, there are varying forms of cribriform, papillary, and solid growth patterns embedded in a sclerotic stroma. Comedonecrosis, PNI, and periglandular infiltration are common.

The clinical presentation is typical of a high-grade malignant tumor. It occurs most commonly in the parotid and is characterized by rapid onset, rapid progression, pain, and cranial nerve involvement. Advanced T and N stage are common as approximately half of patients present with stage IV disease, including up to 60% with regional metastasis.[39,40] Regional metastasis is common even in small T1 tumors. The presence of regional metastasis is a particularly poor prognostic indicator as up to 50% of patients with neck disease also had distant disease. Current treatment strategies provide good local regional control, unfortunately distant metastasis are not uncommon and make OS poor for these patients, 40% by 2 years and 20% by 5 years.[39,40]

All salivary duct tumors are treated as aggressive high-grade tumors. Aggressive surgical excision with facial nerve sacrifice, if clinically involved, and routine neck dissection are the standard first modality of treatment even for early T-stage tumors. Radiation to the primary and ipsilateral neck is also considered standard. Because of the poor survival and high incidence of distant metastasis, chemotherapy should also be considered. However, there is limited data on its efficacy, but a trial using cisplatin and 5-fluorouracil (5FU) is underway to investigate its use.[40]

## Mixed Malignant Tumor and Carcinoma Ex-pleomorphic Adenoma

There is a pathological distinction between these two tumors. The first is a true mixed malignant carcinoma arising *de novo* and consists of a malignant epithelial component and a malignant mesenchymal component. The second is an epithelial malignancy which arises from a benign pleomorphic adenoma. True mixed malignant tumors are very rare and are therefore difficult to characterize clinically.

Carcinoma ex-pleomorphic adenoma is an aggressive tumor with variable histology. Typically, pleomorphic adenoma can still be identified within the mass, but >50% of the mass shows malignant cells. This malignant component is most commonly adenocarcinoma (40%–44%), salivary duct carcinoma (25%–33%), adenoid cystic (14%), or adenosquamous cell carcinoma (7%).[41,42] Unfortunately, the exact pathogenesis of these tumors remains unknown, but there are DNA studies which show increasing anaploidy over time, which indicates the potential for malignant transformation.[43]

These tumors usually arise in a long-standing mass. When a change in the long-standing mass occurs, patients usually present with rapid growth, pain, skin changes, and cranial nerve involvement. However, an asymptomatic neck mass is also a common presentation. Neck metastasis occurs in 20% to 30% of patients and distant spread eventually occurring in more than 40% of patients.[40,41] As a group, survival is poor with 39% alive at 3 years and 30% at 5 years. There appears to be a subset which is particularly aggressive and progresses rapidly in the first year. These patients have approximately a 25% survival at 1 year.[41] This group has a high T stage and N stage, >50% of the mass is carcinoma, and invasion into surrounding structures.[41] Metastasis alone is a very poor prognostic factor. Spiro et al. reported only 1 of 31 patients with neck metastasis were alive at 10 years.[44]

## Polymorphous Low-grade Adenocarcinoma

Polymorphous low-grade adenocarcinoma is an appropriate name as it has a very low-grade clinical course and is an accurate histologic description. Grossly, they are well circumscribed but not encapsulated. Microscopically, a mixture of growth patterns can be seen: solid islands, glandular profiles, tubules, trabeculae, cribriform nests, and single file lines of infiltration. They have a characteristic perineural targetoid pattern of growth. When the diagnosis is not clear, immunohistochemistry (IHC) can be helpful. Glial fibrillary acidic protein, S100, and SMA are nonspecific but can assist in the diagnosis.[45]

This subtype is notable for its propensity to arise in minor salivary glands, specifically those in the oral cavity.[45] Within the oral cavity, the palate is the most common site, followed by the lip and the buccal mucosa. These tumors have a slow growth and

(c) 2014 Wolters Kluwer. All Rights Reserved.

indolent biology, such that the typical presentation is that of an asymptomatic mass in the oral cavity, which has often been present for years. Metastasis is uncommon. In a series of 164 patients from the AFIP, there was no cervical or distant metastasis.[45] Other series have reported up to a 12% neck metastasis incidence and 6% distant metastasis. The presence of a papillary component in these tumors may also be important. Some studies have shown a correlation with increased neck incidence of cervical metastasis when there is a prominent papillary component.[46] This all leads to an excellent prognosis with a >90% survival.

### Primary Lymphoma

Primary lymphoma of the salivary glands is uncommon, comprising only 1.7% to 3.1% of salivary neoplasm and only 10% of head and neck lymphomas.[47] Nearly all of them occur in the parotid gland. Greater than 85% are non-Hodgkin B-cell lymphomas, either nodular or diffuse. The remainder is nearly all Hodgkin disease. Parotid lymphomas can arise from intraglandular lymph nodes or can arise from the parenchyma itself. The latter is referred to as mucosa-associated lymphoid tissue and makes up the majority of cases. A previous history of underlying coexistent autoimmune disorder such as Sjogren syndrome or rheumatoid arthritis has been reported in up to 44% of patients. Approximately 5% of all Sjogrens patients will develop lymphoma. A mass occurring in a patient with a previous diagnosis of benign lymphoepithelial lesion, multiple masses in a unilateral parotid gland or bilateral parotid masses, or a mass associated with multiple, enlarged unilateral or bilateral cervical lymph nodes should all raise the suspicion of lymphoma.[48] The surgeon's role in this disease is to assist with diagnosis by providing adequate tissue in a safe manner. This can be accomplished with incisional or excisional biopsy, including parotidectomy, depending on the location and size.

## NATURAL HISTORY

Because of the varied locations for salivary glands, the presentation and natural history of salivary gland malignancies can vary. However, size, pain, nerve symptoms, symptoms related to invasion of nearby structures and evidence of metastasis are the common points of the natural history regardless of location.

The major salivary glands are relatively superficial in their location and therefore masses are often recognized on self-palpation by the patient and this is the most common initial presentation. These tumors will enlarge; however, the rate at which they grow is extremely variable based on histological subtype. Low-grade tumors as well as ACC tend to grow very slowly, similar to that observed for a benign pleomorphic adenoma. Patients may be aware of the mass for years before they seek medical attention because of this slow growth. However, high-grade tumors tend to rapidly grow. In the case of a carcinoma ex-pleomorphic, there may a long-standing slow-growing tumor that begins to rapidly change. However, a high-grade mucoepidermoid tumor may present initially with rapid growth.

Pain is an important component of the natural history. Up to a third of patients have pain on presentation. As the tumor grows into adjacent structures, other symptoms will develop such as trismus, fixation of mass, and overlying skin changes. Since all of the major salivary glands are adjacent to cranial nerves, tumors over time will ultimately involve these nerves either by direct invasion or perineural spread. In the parotid, this involves the facial nerve predominantly. The sublingual and submandibular glands are most likely to impact on the lingual and hypoglossal nerves. Trigeminal nerve involvement can be seen with tumors in any of these locations.

**TABLE 25.3 Incidence of Cervical Lymph Node Metastasis by Histologic Tumor Type**

| Tumor Type | Reported Incidence of Lymph Node Metastasis |
|---|---|
| Low-grade mucoepidermoid carcinoma | <5% |
| Adenocarcinoma, NOS | 20%–25% |
| Acinic cell | 5%–10% |
| Polymorphous low-grade adenocarcinoma | 10%–15% |
| High-grade mucoepidermoid carcinoma | 50%–85% |
| Intermediate-grade mucoepidermoid carcinoma | 20% |
| Adenoid cystic carcinoma | 4%–23% |
| Salivary duct carcinoma | 60% |
| Carcinoma ex-pleomorphic adenoma | 30% |

The natural history of metastasis is also quite varied based on histology (Table 25.3). Low-grade malignancies have a low risk of regional lymph node metastasis or distant spread.[18] However, high-grade MEC, for example, has an 80% incidence of regional metastasis in some series.[22] ACC, which is considered a high-grade malignancy, does not follow this trend and actually has a very low risk of regional spread. However, it has a very high risk of distant metastasis and unresectable perineural spread along the trigeminal and facial nerves.[24,26] AC and intermediate-grade MEC have a variable rate of regional spread, 10% to 20%. This can make lymph node management more challenging. Other clinical features may predict a higher risk of metastasis such as size and invasion of surrounding structures.

OS for salivary gland malignancies vary. Survival ranges from nearly 100% for low-grade MEC to as poor as 25% 1-year survival for carcinoma ex-pleomorphic. Other clinicopathologic features are likely important in the natural history as well such as margin status at resection and extracapsular spread.[49]

## STAGING

Table 25.4 summarizes the American Joint Committee on Cancer 7th edition staging for salivary gland malignancies.[50] Although much of the literature and discussion about treatment and prognosis of salivary gland malignancies focuses on histological grading, TNM staging remains an important and useful tool. Table 25.5 provides a review of survival based purely on histologic substype and Figure 25-6 highlights the impact of stage on survival. There is a clear incremental decrease in survival for each stage, such that at 5 years observed survival is 70% for stage I compared with 30% survival for stage IV.[50] This further demonstrates that stage and histology are important predictors of survival.

In the most recent update to the AJCC staging, there were a few changes. The most notable change to the staging in 2010 was the addition of stages IVA, B, and C. T4a tumors are now classified as stage IVA, T4b and N3 tumors are stage IVB, and patients with distant metastasis are stage IVC (Table 25.6).

**TABLE 25.4 American Joint Committee on Cancer (AJCC) TNM Staging System: Salivary Gland Staging**

| | |
|---|---|
| **Primary tumor (T)** | |
| T1 | Tumor 2 cm or less in greatest dimension, without extraparenchymal extension[a] |
| T2 | Tumor >2 cm but <4 cm in greatest dimension, without extraparenchymal extension[a] |
| T3 | Tumor >4 cm and/or extraparenchymal extension[a] |
| T4a | Moderately advanced (tumor invades skin, mandible, ear canal, and/or facial nerve) |
| T4b | Very advanced (tumor invades skull base and/or pterygoid plates and/or encases carotid artery) |
| **Regional lymph nodes (N)** | |
| N0 | No regional lymph node metastasis |
| N1 | Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension |
| N2a | Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension |
| N2b | Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension |
| N2c | Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension |
| N3 | Metastasis in a lymph node >6 cm in greatest dimension |
| **Distant metastasis (M)** | |
| Mx | Distant metastasis cannot be assessed |
| M0 | No distant metastasis |
| M1 | Distant metastasis |

[a] *Note:* Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.

**TABLE 25.5 Estimate of 5-year Survival Based on Histologic Subtype**

| Histology | 5-yr Survival |
|---|---|
| Polymorphous low-grade carcinoma | >90% |
| Low-grade mucoepidermoid carcinoma | 92%–100% |
| Acinic cell carcinoma | 85%–90% |
| Intermediate-grade mucoepidermoid carcinoma | 70%–95% |
| Adenoid cystic carcinoma | 80%–92% (60% at 10 yr, 40% at 20 yr) |
| Adenocarcinoma | 10%–60% |
| High-grade mucoepidermoid carcinoma | 22%–51% |
| Salivary duct carcinoma | 20% |
| Carcinoma ex-pleomorphic carcinoma | 30% |

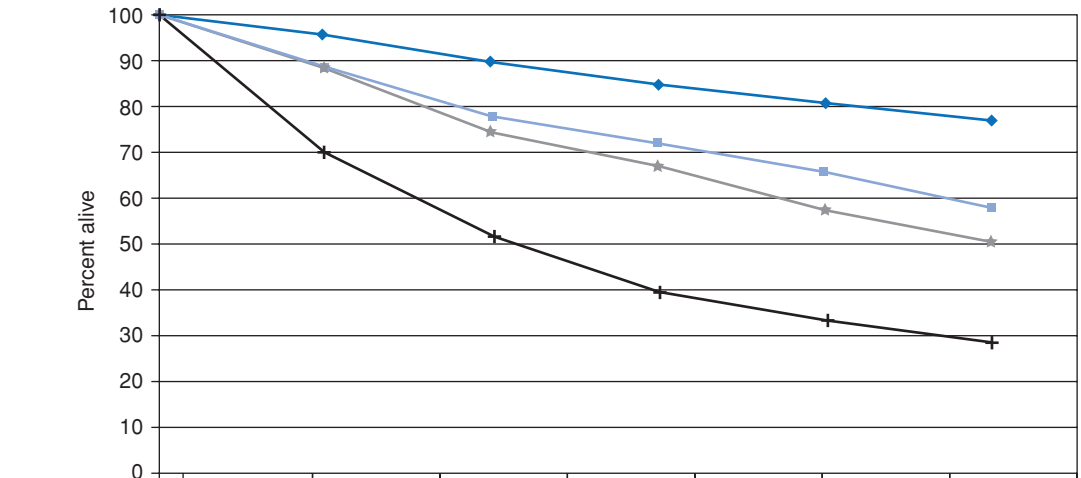
# EVALUATION

There are three key elements in the evaluation of a suspected salivary gland malignancy. Each has an important role in diagnosing a malignancy and helping direct treatment. These elements are the history and physical, imaging, and biopsy.

## History and Physical

Because of the varied locations for salivary glands, the history and physical examination appropriate for each site can also be quite varied. The major salivary glands are relatively superficial in their location and therefore masses are often recognized on self-palpation by the patient. As with any neck mass, it is important to ascertain the key elements of the mass: size, nature of the progression, firmness, associated pain, overlying skin changes, and previous presence of masses. Because of the critical location of the cranial nerves with respect to the major salivary glands, it is important to ask about symptoms associated with the cranial nerves. Since minor salivary glands are distributed throughout the aerodigestive tract, these patients may have a completely different presentation. They are more likely to present with symptoms typical of classic squamous cell carcinoma of the head and neck such as throat discomfort, change in voice and speech, otalgia, and blood in the saliva. The history should also ascertain information about potential systemic manifestations such as unintentional weight loss, fatigue, pulmonary symptoms, bone pain, and focal neurological deficits.

The physical exam such as the history should characterize the mass based on location, size, mobility, and involvement of surrounding structures. Evaluation should assess for facial twitching or facial asymmetry, dysarthria, limited tongue mobility, dysphagia, facial dysesthesia or hypoesthesia, and changes in the sensation of the tongue and floor of mouth. Cranial nerves II through XII should be fully assessed on examination in all patients with a suspected salivary gland neoplasm.



Although the most common presentation is an asymptomatic mass, other signs and symptoms will help alert the clinician of a possible malignancy. Up to one-third of malignancies have pain associated with the mass. Twenty percent have some cranial nerve symptoms and 10% have overlying skin involvement.[9]

## Imaging

Imaging studies are critical for evaluating and treatment planning for salivary gland malignancies in all sites. Computed tomography (CT) is most familiar to head and neck surgeons and is very useful for defining the presence of a mass as well as its relationship to boney structures such as the mandible and temporal bone. It is also an excellent modality for assessing lymph node statues. For minor salivary gland tumors or sublingual gland tumors, this remains an excellent first mode of imaging. However, in recent years MRI has become an important modality in salivary gland imaging.[51] Greater experience with MRI has helped define classic features of benign and malignant tumors, which makes this potentially a more specific test and sensitive imaging modality.

There are several important potentially diagnostic features on MR imaging that can be used in the preoperative assessment. Malignant lesions are hypointense on T2 imaging, which is helpful in distinguishing between benign tumors such as a pleomorphic adenoma. High-grade malignant tumors usually have an irregular border and can be seen infiltrating surrounding structures. Low-grade malignancies are usually well circumscribed but they are not encapsulated.[52,53] The hypointensity on T2 imaging and contrast enhancement should raise suspicion for

(c) 2014 Wolters Kluwer. All Rights Reserved.

| Observed survival | 1 | 2 | 3 | 4 | 5 | 95% CIs | Cases |
|---|---|---|---|---|---|---|---|
| 1 | 95.5 | 89.7 | 84.7 | 80.8 | 76.9 | 74.9–78.9 | 2,345 |
| 2 | 88.9 | 78.4 | 72.0 | 65.8 | 58.4 | 53.7–63.0 | 568 |
| 3 | 88.5 | 74.7 | 67.7 | 57.7 | 50.6 | 44.4–56.8 | 338 |
| 4 | 70.6 | 52.2 | 40.3 | 34.0 | 29.5 | 26.9–32.1 | 1,460 |

**FIGURE 25-6.** Observed survival by year based on stage.

a malignancy. Additional findings can be indicative of specific histological subtypes. Mucoepidermoid tumors may demonstrate a significant cystic component that has high intensity on both T1 and T2 imaging due to the mucin content.[53] Adenoid cystic tumors, which are predominantly solid type histology, have low signal intensity on T2 imaging whereas cribriform and tubular types have a higher intensity on T2 because of their lack of cellularity.[53] Primary salivary lymphoma can be distinguished when it arises in a periparotid lymph node. There is typically a distinct plane separating the mass from the gland. This is more difficult to assess when the node is intraparotid; however, it is usually low signal intensity on both T1 and T2 imaging with limited enhancement with contrast.[51,52]

In order to distinguish malignant from benign tumors, there are several characteristic features indicative of a likely benign lesion. Pleomorphic adenomas characteristically have a bright intensity on T2-weighted images with inhomogeneity and a well-defined capsule and margin. They also have a typical lobulated or bosselated contour, which occurs from the variable growth rate within the tumor. Vascular lesions such as hemangiopericytoma and hemangioma may also have this high signal intensity on T2. Benign cystic lesions generally have an enhancing peripheral rim with a smooth and well-defined border and may have intracystic fluid bright on T2.

Because of the importance of assessing perineural spread, a combination of MRI and CT may be helpful. MRI is considered more sensitive for this assessment, as the involved nerve may show a characteristic enhancement. However, CT may also be helpful by for detecting perineural spread by identifying a widened stylomastoid foramen, foramen ovale, or foramen rotundum. The assessment of fat in the foramina is also a key factor. Loss of this fat is very suspicious for nerve involvement. Lastly, one should assess the facial muscles and muscles of mastication. Loss of volume and asymmetry from one side to the other may be indicative of loss of neural input due to nerve involvement by tumor.

A last modality of consideration is PET/CT imaging. To date, there are limited data comparing its usefulness to MRI; however, there are several potential useful aspects. A primary benefit is the ability to detect distant metastasis. Salivary tumors appear to have a higher rate of nonlung distant metastasis such as bone and liver that could be missed with a standard chest CT assessment for distant metastasis. Similarly, PET may add information to CT imaging about more extensive local extension, which may show the tumor to be unresectable. However, there are limitations. PET/CT has been shown to be only 74% sensitivity, as there appears to be variability in PET avidity for different salivary gland tumors.[54] Additionally, its ability to accurately detect nerve involvement and the extent of involvement is unclear.

**TABLE 25.6 American Joint Committee on Cancer (AJCC) Staging for Salivary Gland Tumors by TNM Status**

| | N0 | N1 | N2 | N3 |
|---|---|---|---|---|
| T1 | Stage I | Stage III | Stage IVa | Stage IVb |
| T2 | Stage II | Stage III | Stage IVa | Stage IVb |
| T3 | Stage III | Stage III | Stage IVa | Stage IVb |
| T4a | Stage IVa | Stage IVa | Stage IVa | Stage IVb |
| T4b | Stage IVb | Stage IVa | Stage IVa | Stage IVb |

*Note:* Stage IVc is an T, any N and M1.

## Biopsy

Tissue acquisition is a key element of the evaluation. First, it is needed to confirm the diagnosis of malignancy. Second, it will help determine the histological subtype as this will likely impact on the management. Lesions suspicious for minor salivary gland tumors in the oral cavity, oropharynx, hypopharynx, or larynx can be biopsied in a traditional fashion in the office using injectable anesthetic and biopsy forceps or dermal punches, or in the operating room with direct laryngoscopy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Tumors in the submandibular and parotid regions are not quite as accessible. For these tumors, fine-needle aspiration (FNA) is the preferred method of biopsy. Several studies have now demonstrated FNA is a reliable technique achieving a diagnostic result in 88% to 98% of biopsies.[55–57] It has also been shown to be a safe and cost-effective diagnostic tool.

Additional work has shown these diagnostic specimens to have a consistent sensitivity, specificity, and accuracy. A summary of reported series shows a mean sensitivity of 81%, specificity of 95%, accuracy of 91%, and positive predictive value of 86%. For malignant tumors, specifically, there is a reported positive predictive value of 95%. Exact type-specific concordance with the histology was 81%. A last consideration involves lymphoma. FNA may provide this diagnosis or at least be suggestive of the diagnosis, which would likely change the management strategy.

There are a few additional considerations when evaluating the usefulness of FNA. Several studies show that the presence of a cytopathologist can decrease the number of nondiagnostic specimens, by providing immediate feedback while the patient is still present. There are a few diagnostic pitfalls that clinicians should be aware of with respect to FNA. Cystic lesions appear to be more difficult to accurately assess. AC and MEC in particular may have a cystic component which may appear benign on FNA. An ACC can be mistaken for pleomorphic adenoma because of their common basaloid appearance. Similarly, a lymphoma may be interpreted on FNA as a Warthin tumor due to the lymphoid component of these tumors.[58]

There are reported complications with FNA, which include hemorrhage, facial nerve injury, cellulitis, and parotitis, but all are considered rare.[59] When an experienced cytopathologist is available, FNA should be included in the evaluation. Accurate results from FNA of parotid tumors can allow for appropriate preoperative preparation, such as other services including reconstructive or otologic surgery, and operative intervention. This could range from a limited biopsy in the setting of a lymphoma to limited parotidectomy in the setting of a low-grade malignancy to potential radical parotidectomy with neck dissection and appropriate facial nerve reconstruction.

## SURGICAL TREATMENT OF SALIVARY GLAND MALIGNANCIES

The treatment of salivary gland malignancies has historically been surgically based. The bulk of treatment recommendations are driven by experience and reports focusing on parotid gland malignancies with extrapolation of this to the less common remaining salivary gland systems. Although most treatment plans begin with appropriate surgical intervention, studies have revealed the efficacy of adjuvant radiation therapy for advanced-stage disease and high-grade malignancies. Driven by experience with successful combined modality treatment for squamous cell carcinoma, experience in recent decades has demonstrated the increased utilization of radiosensitizing chemotherapeutic agents in the treatment of advanced salivary gland diseases. Initial experience was first recognized for the treatment of unresectable disease, but this principle has been gradually expanded to incorporate combined modality treatment for advanced-stage and high-grade malignancies, specifically those with poor prognostic features. There has likewise been interest in the utilization of biologic targeted agents to afford greater disease control.

Therefore, although surgical treatment remains the mainstay of any treatment algorithm for salivary gland malignancies, early multidisciplinary consideration is warranted and useful. This is specifically beneficial for patient education and perspective as well as formation of a multidisciplinary team to fully maximize adjuvant treatments. The National Comprehensive Cancer Network guidelines[60] for the management of salivary gland malignancies are outlined in Figures 25-6 and 25-7. Broken down by tumor size (T status) and tumor site, respectively, Figures 25-6 and 25-7 provide a useful framework for evaluation and treatment planning as well as the ultimate management of salivary gland malignancies. Yet, broken down into the most basic form, the management algorithm for the treatment of salivary gland malignancies is straightforward. Appropriate surgical resection with attempt for complete resection and functional preservation should be attempted. The addition of adjuvant radiation therapy based on the presence of high-grade histology, stage, and poor prognostic features such as positive margins, PNI, and nodal metastasis should be considered. Patients with unresectable disease or who are not surgical candidates may undergo nonsurgical treatment with radiation therapy or combination of chemotherapy and radiation therapy. Specific surgical intervention is based on the salivary gland site of origin of the malignancy with the primary goals being complete resection and functional preservation with inclusion of appropriate reconstructive efforts.

### Parotid Gland

Although the majority of parotid tumors are benign, 15% to 20% of these masses will have a malignant pathology. Malignancy may be suspected preoperatively based on the history, physical exam, preoperative imaging, or histology obtained with the FNA. Some parotid malignancies will only be diagnosed upon a frozen section or final pathology obtained upon parotidectomy or other surgical intervention for a parotid mass.

The management of parotid masses must adhere to the dictum of a complete resection with appropriate inclusion of adjoining parotid tissue and facial nerve preservation. The most efficient means of achieving these ends is the traditional approach of superficial parotidectomy with facial nerve identification, dissection, and preservation. Procedures such as enucleation or simple mass excision with nerve avoidance may only lead to unwanted and unwarranted findings of positive margins that could have been avoided and a potential higher risk of nerve dysfunction. Traditional descriptions of surgical procedures such as superficial and total parotidectomy can afford a simple framework to describe the degree of resection required in a parotidectomy. The most critical factor is that sufficient tissue surrounding the tumor be included with the resection. In the scenario of advanced disease, appropriate surgical extensions of the basic procedure may be warranted. These include facial nerve resection, resection of involved overlying skin, resection of the masseter muscle, resection of a portion of the mandible including the condyle, resection of major vessels such as the external carotid artery, resection of parapharyngeal space fat and dissection of adjoining structures, resection of the external auditory canal and possible inclusion of the auricle, and temporal bone resection. Yet, any extension of surgery must be consistent throughout the procedure avoiding morbid additional procedures when close or potentially microscopically positive margins are tolerated elsewhere, as with dissection and preservation of a functioning facial nerve. The planned extent of resection should be based on all available preoperative information from imaging, examination, and histology. The risks, benefits, and complications of the basic procedure should be discussed in detail as well as the necessity of potential surgical extensions to include total parotidectomy, neck dissection, mastoidectomy, mandibulectomy, skin resection, facial nerve sacrifice, and appropriate reconstruction.

The surgical approach in the setting of a defined mass with a functioning facial nerve begins with the creation of a cosmetically acceptable incision beginning in the pretragal skin crease. The incision extends around the lobule, over the mastoid, and

(c) 2014 Wolters Kluwer. All Rights Reserved.

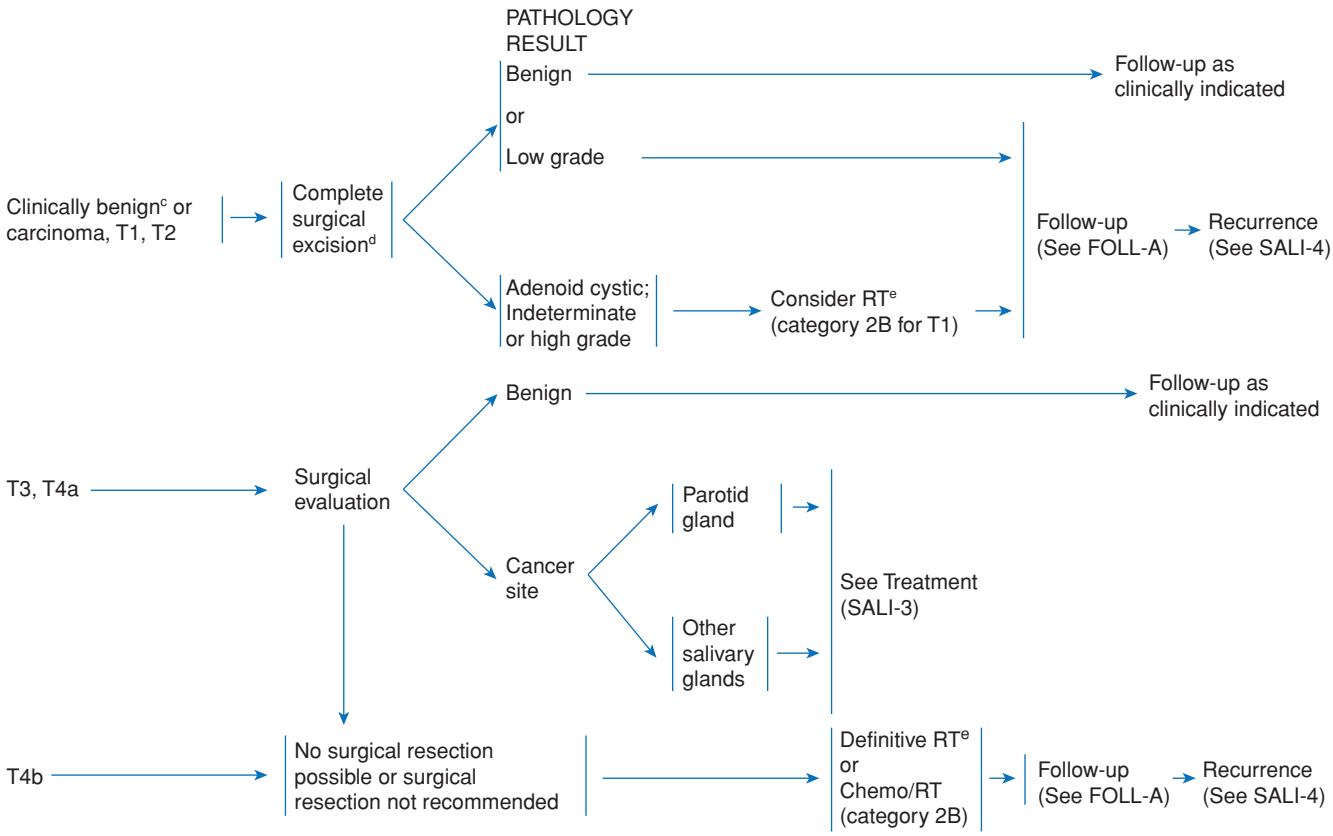


**FIGURE 25-7.** 2010 National Comprehensive Cancer Network guidelines for management of salivary gland malignancies based on tumor stage and histologic grade.

then inferiorly into a skin crease in the mid neck approximately 2 to 2½ fingerbreadths below the angle of the mandible. This incision can be extended forward in a skin crease to the submentum to facilitate extensions of the procedure such as neck dissection. Should a more complete neck dissection be required with dissections of levels IV and V, then the incision may be carried inferiorly into an Apron incision or a lower limb could be dropped to facilitate the exposure (Fig. 25-8). If a cervical advancement flap may be necessary for skin reconstruction, consideration of this should be given with initial incision planning. Facelift incisions have been advocated by many for the treatment of benign parotid tumors, but their use should be carefully considered in the setting of malignancy as limitations of exposure could be detrimental to ultimate resection.

The facial flap is then elevated forward in the deep plane just superficial to the parotidomasseteric fascia, unless contraindicated by tumor extension. During this maneuver, the great auricular nerve is identified as it crosses the sternocleidomastoid muscle and enters the parotid gland. At this point, it is usually taken and marked for a later use as a potential nerve graft. Preservation of the great auricular nerve in the setting of malignancy is not standard as this does require a dissection into the parotid parenchyma and may inadvertently cause a tumor disruption. The gland is now mobilized anteriorly by separating the fascial attachments at the digastric muscle and the mastoid tip. This facilitates exposure of the inferior aspect of the main trunk of the facial nerve. Gland mobilization is likewise completed anterior to the tragus and the external auditory canal exposing the tympanomastoid suture line. The main trunk of the facial nerve is now identified as it exits the stylomastoid foramen and enters the parotid gland. The key anatomic relationships previously discussed are critical in the identification of the main trunk at this level, and these are listed in Table 25.1.

Once the main trunk of the facial nerve is identified, dissection is carried forward in the plane directly overlying the nerve to identify the pes anserinus and the major branches of the facial nerve. Palpation of the mass during this component of the dissection is critical as it will indicate the position of the tumor relative to the branches of the facial nerve. The component of the parotid gland resting superficial to the facial nerve is now elevated by dividing the parotid parenchyma overlying the nerve while keeping the nerve under direct visualization. Dissection is usually completed through a combination of a superior to inferior as well as an inferior to superior dissection of the gland parenchyma. This allows superficial lobe of the gland to be elevated with the mass undisturbed. The approach likewise prevents filleting of the gland directly forward over the nerve during the dissection, which can lead to inadvertent disruption of the tumor. Should there be difficulty in identifying the main trunk of the facial nerve or if further identification of specific distal branches be necessary, retrograde dissection can be performed as described earlier (Fig. 25-9).

Division of the gland parenchyma can be completed with various techniques, each having specific advantages and disadvantages relative to hemostasis, cost, time, availability, and associated trauma. Whether utilizing sharp dissection, electrocautery, or devices such as the Hemostatix scalpel and Harmonic scalpel, the technique chosen is based on surgeon preference and experience.

(c) 2014 Wolters Kluwer. All Rights Reserved.

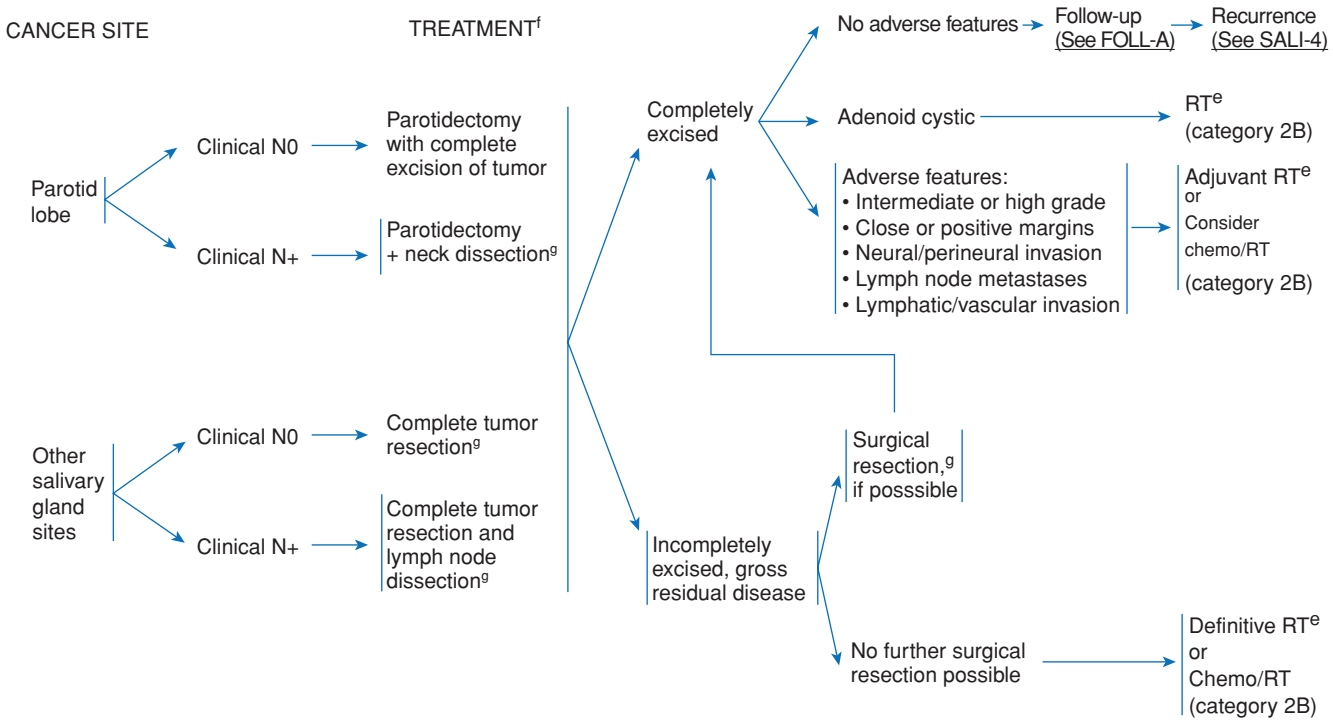

**FIGURE 25-8.** 2010 National Comprehensive Cancer Network guidelines for management of salivary gland malignancies based on tumor site.

Critical to any technique is the ability to minimize a neural trauma. This superficial parotidectomy approach should be sufficient for excision of a discrete mass without neural involvement.

Should superficial parotidectomy reveal a deep-lobe mass, complete mobilization of the superficial lobe should be undertaken to reveal the extent of the deep-lobe mass. Position of the tumor relative to the facial nerve branches as well as deep-lobe structures such as retromandibular vein, superficial temporal artery, deep temporal artery, and external carotid artery should be assessed. Dissection and delivery of the mass can then be undertaken if there is no discrete involvement of the nerve noted.

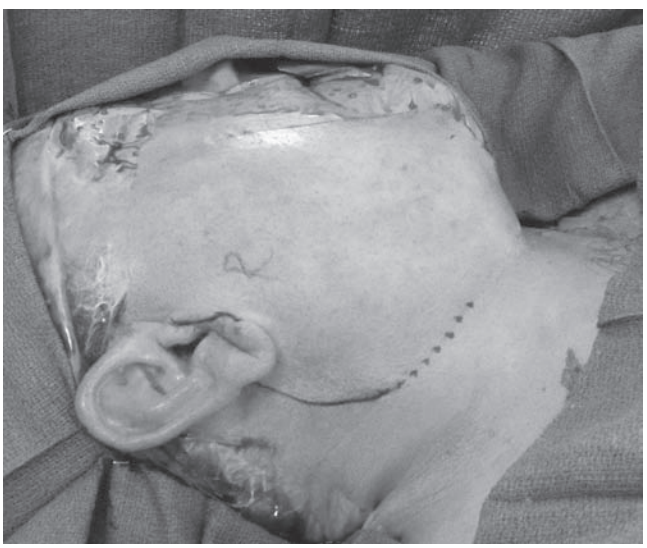

**FIGURE 25-9.** Pre-op incision planning for right parotidectomy, with dotted extension should selective neck dissection be warranted.

Once resected, the parotid tumor should be sent for frozen section analysis. Should a tumor previously noted to be suspicious for malignancy by FNA or imaging be found to be benign, closure can be undertaken as with standard parotidectomy for benign disease. If a low-grade malignancy is suspected, the closure may be undertaken, whereas if a high-grade lesion is noted, then consideration for selective neck dissection in the setting of an originally N0 neck can likewise be made.

During frozen section analysis, the wound is inspected and hemostasis is verified. Nerve integrity and function are verified and documented. A nerve stimulator, if used during any component of the procedure, facilitates this maneuver. The parotid bed is palpated for concerning lesions and associated lymph nodes, although the majority of parotid lymph nodes will be removed with the superficial parotidectomy. The level II lymphatic basin can likewise be palpated for any suspicious lymph nodes. Closure is then completed in a cosmetically acceptable fashion of surgeon choice over a closed suction drain.

## Management of the Facial Nerve

Intraoperative decision making relative to the facial nerve begins with thorough preoperative assessment of facial nerve function. Patients with paresis or paralysis of all or selective branches of the facial nerve system will require nerve sacrifice and appropriate reconstruction. Operative dissection should define distal nerve branches clear of tumor utilizing retrograde dissection. Similarly, the proximal nerve should likewise be cleared of tumor even if this should require mastoidectomy and clearance in the temporal bone. If nerve involvement by tumor is isolated to a discrete branch or system of branches such as the upper division or trunk, then preservation of the remaining facial nerve system can be undertaken with improved maintenance of function.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Much more challenging is the scenario of normal facial nerve function with a mass suggestive for malignancy on preoperative evaluation. The critical factor determining the applicability and feasibility with the facial nerve preservation will be the direct relationship of the tumor to the nerve. Tumor should not be transected to attempt preservation of a normally functioning facial nerve or specific facial nerve branches. This only leads to tumor spillage, decreased control, and temporary, if not permanent, dysfunction of the dissected nerve. Distal and proximal branches should be dissected to reveal normal appearing nerve and the tumor appropriately resected with nerve sacrifice. Yet, prior to nerve sacrifice, confirmation of a malignant diagnosis by frozen section is recommended. This can be done by identifying a portion of the tumor away from the major nerve branches and creating a small window through the fascia overlying the tumor. This will expose the mass where biopsy can be obtained with either a scalpel or a dermatologic punch. The fascia overlying the biopsy site can then be reapproximated with a figure-of-eight stitch to limit any potential tumor spillage. With diagnostic confirmation of malignancy, the tumor dissection and nerve sacrifice can be undertaken.

In the somewhat rare scenario, that a malignant diagnosis cannot be confirmed, the surgeon may elect to close and delay ultimate resection until a definitive diagnosis of malignancy is confirmed. Utilization of tissue barriers such as cadaveric dermis or fascia that can be placed overlying the dissection bed will isolate the tumor until later resection is undertaken. This maneuver can prevent unnecessary nerve sacrifice for rare processes mimicking parotid malignancies such as infarcting or infected Warthin tumors, lymphomas, and atypical inflammatory processes, which may affect nerve function preoperatively, but ultimately be benign processes.

Although, facial nerve preservation is not advised if the nerve is grossly abnormal or dissection attempts to preserve the nerve leads to tumor spillage and grossly positive margins, nerve preservation can be attempted for tumors abutting the main trunk of the nerve and its branches. Meticulous dissection aided by loupe magnification can allow for oncologically safe separation of associated nerve branches from the tumor without direct tumor disruption. Even if final pathology indicates microscopically positive margins in the region of such dissection, final disease control with the addition of adjuvant radiation therapy is not adversely affected.

Ultimately, the surgical resection of parotid salivary gland malignancies should achieve wide local excision with negative margins and may include multiple extensions of the procedure in this anatomic region dense with critical structures. Yet, each extension of the basic surgical resection must be considered carefully under the basic tenant "the closest surgical margin will remain the closest surgical margin" regardless of how wide a resection margin may be achieved in another area. As an example, it may not be advisable to extend a resection to involve a mandibulectomy to avoid a close surgical margin in this region while tolerating a potentially microscopic-positive margin during the dissection and preservation of a functioning facial nerve. Likewise, if the morbidity of facial nerve resection has been accepted, appropriate extension of the procedure should be considered to achieve widely clear margins throughout the resection basin.

The use of facial nerve monitoring during parotid surgery deserves discussion. First, one must differentiate between the use of the facial nerve stimulation to facilitate dissection and real-time continuous electrical nerve monitoring as an injury-avoidance maneuver during surgery. Nerve stimulation should be considered in all cases and is relatively inexpensive irrespective of whether a reusable or disposable device is used. With nerve stimulation, current is directly applied to the structure in question and specific facial nerve muscle movements can be directly assessed. Nerve stimulation aids in the identification of the main trunk of the facial nerve, specific branch identification during tumor resection, and verification of nerve integrity upon completion of the surgery.

Continuous nerve monitoring devices assess select muscles of facial expression such as orbicularis oculi, orbiculari os, depressor anguli, and so forth with real-time interpretation of motor stimulation as noted on the monitoring device. Such real-time constant interpretation may be provided by a specified individual or by the surgeon. As both mechanical and electrical stimulation can be noted on the monitor, nerve stimulation related to potential dissection trauma can be noted as well as nerve identification by the use of electrical stimulation during surgery. Real-time nerve monitoring is used by many surgeons in standard practice but studies have yet to demonstrate significant improvement in ultimate outcome.[61] Considered as an adjunct parotid surgery, the nerve monitor does not supplant clear knowledge of the relevant anatomy, sound surgical technique, and thoughtful decision making. Consideration of continuous nerve monitoring use may be given for revision cases or in those in which a transmastoid approach is warranted and the use of a nerve monitor is part of standard otologic practice.

## Reconstruction

Reconstructive efforts associated with parotidectomy and facial nerve dissection should focus both on function and cosmesis and address each extension of the basic ablative procedure that is required. When facial nerve resection is required, primary nerve reconstruction can be considered. For limited nerve resection, primary anastomosis can be achieved if adequate mobilization of the remaining facial nerve branches is attainable such that a tension-free anastomosis can be completed. The neurorrhaphy is usually completed with interrupted sutures placed in an epineural fashion using 8-0, 9-0, or 10-0 monofilament sutures. Loupe magnification or an operating microscope is usually necessary to achieve optimal coaptation. Although, primary anastomosis is optimal, this is usually not achievable in most ablative cases. In this setting, a nerve graft will be required to fill the gap between the remnant facial nerve branches. Better function will be achieved in a small single-branch reconstruction as this will allow reinnervation with minimal synkinesis (Fig. 25-10A,B).

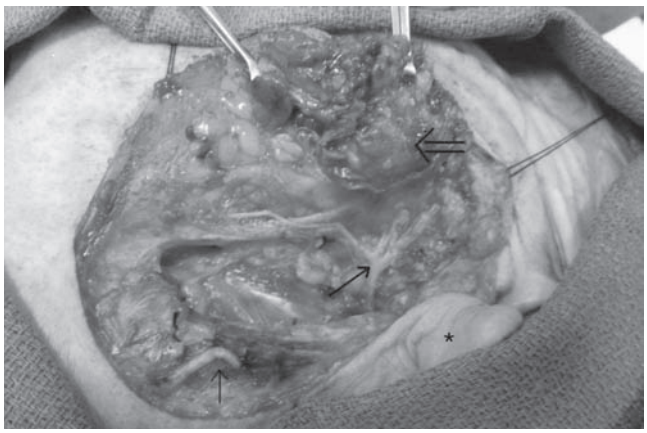

**FIGURE 25-10.** Dissected and preserved facial nerve system after during left superficial parotidectomy. Large single arrow at pes anserinus. Double arrow at Tumor. Small arrow at great auricular nerve dissected for potential nerve graft. Asterisk at earlobe.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Nerve defects involving the main trunk and the pes anserinus will require nerve grafts with acceptable branching patterns and length to achieve a tension-free reconstruction of available branches. Although, success with synthetic nerve conduit has been reported,[62] autogenous nerve grafts remain the favored option for nerve reconstruction. Common graft donor sites include the great auricular nerve system, the ansa cervicalis, the sural nerve, the medial antebrachial cutaneous nerve, and nerves associated with free-flap reconstruction such as the motor nerves to the latissimus dorsi or vastus lateralis muscles (Table 25.7). Although, synkinesis is unavoidable with most nerve reconstruction, optimal function can be achieved by carefully selecting the distal branches with the greatest motor input to the desired facial nerve musculature. This can be easily assessed with the use of a facial nerve stimulator. Nerve margins should be histologically cleared of disease prior to reconstruction. Nevertheless, small series have reported functionally successful nerve grafts in the setting of microscopically positive nerve margins.[63]

Should nerve grafting not be achievable in the primary ablative setting, attention is focused on rehabilitation of the deficits created by the loss of the facial nerve function. Rehabilitative procedures such as eyelid weight placement (gold and platinum), lateral tarsal strip procedures for ectropion, browlifts, and static slings to the oral commissure and midface as well as dynamic slings using the temporalis or masseter muscles can be considered with the primary ablative procedure.[64] Often these procedures are completed in the secondary setting once postoperative or radiation therapy effects have stabilized the exact deficit. Likewise, procedures can be considered if primary nerve grafting fails to achieve exceptional functional outcome. Excellent functional restoration to the oral commissure can be achieved with microvascular muscle transfer utilizing the gracilis, latissimus dorsi, or serratus free-flap systems.[65]

Free tissue transfer techniques also provide excellent reconstruction options for large defects. The fibula, radius, and iliac osteocutaneous flaps are excellent options for necessitated mandibular reconstructions.[66] The anterolateral thigh flap, rectus abdominus flap, and radial forearm flap are versatile and dependable option for large cutaneous and auricular defects.[67] Smaller cutaneous defects may be reconstructed with local regional flaps such as a cervical facial advancement flap, the submental flap, and the supraclavicular flap.[68] In certain clinical scenarios, the pectoralis major flap also affords a dependable reconstructive option.[69]

Free-flap reconstructive techniques such as the lateral arm flap and the anterolateral thigh flap are also quite useful for addressing large contour defects created with total and subtotal parotidectomies and neck dissection.[70] Smaller contour defects can be addressed with sternocleidomastoid flaps, dermal graft, and free-fat grafts,[71] although care should be taken not to delay the initiation of radiation therapy or significantly alter the wound bed for subsequent treatment and follow-up.

Specific reconstructive efforts may also be undertaken to limit or control the effects of Frey syndrome at the time of the primary procedure. A thick-flap elevation technique, barrier methods such as cadaveric dermis, autogenous fascia, or vascularized fascial flaps have been shown to successfully limit Frey syndrome, but not completely prevent it.[72] Again, such efforts must be balanced with the ultimate adjuvant treatment plan.

## Treatment of Submandibular Gland Tumors

Tumors of the submandibular gland demonstrate a far greater likelihood of malignancy with up to 50% being malignant and therefore require caution in diagnostic workup and therapeutic intervention. Preoperative evaluation including history and physical exam findings suspicious for malignancy such as pain, cranial nerve impairment (V, VII, and XII), fixation to adjoining structures and prominent lymphadenopathy must all be taken into consideration. Imaging with CT or MRI and FNA are also critical aspects of the preoperative evaluation.

Treatment of submandibular gland tumors begin with appropriate resection similar to the management of parotid tumors with the goals of complete excision—after achieving clear margins—and with maximal achievement of function and cosmesis. The single greatest law in submandibular surgery is the attempt to achieve these goals through an inadequate incision without effective exposure to the gland, the tumor, and the adjoining structures. As demonstrated by Weber et al.,[73] submandibular malignancies are significantly better managed when approached as a formal level I neck dissection rather than through a simple "shelling out" of the gland which is utilized by many for benign inflammatory processes involving the gland.

Surgical resection begins with a curvilinear incision planned roughly two fingerbreadths below the angle of the mandible. This will create the initial incision in a plane inferior to the course of the marginal mandibular nerve branch of the facial nerve system. The incision should extend from the anterior border of the sternocleidomastoid muscle into the submental region overlying the anterior border of the digastric muscle. The superior flap is elevated in a subplatysmal fashion to the level of the mandible with the attention to the marginal mandibular nerve. This branch of the facial nerve system will be located just superficial to the fascia overlying the submandibular gland. A nerve stimulator can be an effective aid to this part of the surgery and nerve identification.

Dissection deep to the gland fascia as a means of nerve preservation is not advised as tumors may abut the fascia and such dissection may lead to tumor disruption. The facial vein can be ligated inferiorly as it crosses over the gland. As mentioned previously, elevating the superior stump will then elevate the marginal mandibular nerve system as it runs superficial to this vein. This maneuver can provide further nerve protection during dissection. All efforts should be made to preserve the function of lower facial nerve branches, which may be related to submandibular gland tumors. However, if these branches are directly involved by tumor, they should be resected and reconstructed in a similar manner to nerves involved in the treatment of parotid tumors.

Once the nerve has been mobilized, the gland is meticulously freed from the attachments to the lower border of the mandible. This is facilitated by ligation of the facial vessels as they exit the gland superiorly at the facial notch of the mandible. Any associated perifacial lymph nodes are also mobilized at this time and included in the dissection. The anterior aspect of the gland is mobilized off the anterior belly of the digastric muscle and the mylohyoid muscle. Smaller arterial and venous branches will pierce the mylohyoid muscle during this dissection and that will

(c) 2014 Wolters Kluwer. All Rights Reserved.

require attention. The mylohyoid muscle is retracted superiorly exposing the deep submandibular triangle and the course of the lingual nerve with its attachment to the gland at the submandibular ganglion.

The hypoglossal nerve and the prominent veins that accompany it will run in the plane just deep to the gland and the lingual nerve as the hypoglossal nerve enters the submandibular triangle from deep to the posterior belly of the digastric muscle. Care is taken to preserve these structures during dissection. The submandibular duct is now identified as it crosses under the lingual nerve and ligated as are the connections of the lingual nerve to the gland at the submandibular ganglion.

The posterior fascial attachments of the gland are released at the angle of the mandible exposing the posterior submandibular space and the proximal lingual nerve. The facial artery is identified as it travels under the posterior belly of the digastric muscle to enter the posterior aspect of the submandibular gland. With ligation of the facial artery, the submandibular gland can be fully mobilized off the further fascial attachments to the posterior belly of the digastric muscle completing the dissection of the gland and its associated lymphatics. Closure is completed in a similar manner to parotid surgery over a closed suction drain.

Extensions of the basic submandibular gland resection procedure may include a resection of involved nerve and reconstruction with applicable nerve grafting of motor nerves. All nerve margins should be histologically cleared with frozen section analysis prior to reconstruction. If the lingual nerve is sacrificed, a surgical clip may be placed on its proximal stump to aid with later adjuvant radiation therapy. More advanced disease with significant local involvement of the floor of mouth, tongue, mandible, and skin will necessitate resection of these structures as appropriate. Effective tissue flap reconstruction can likewise be completed in this primary setting. As with the parotid surgery, critical appraisal of potentially close surgical margins throughout the field must be taken into consideration prior to significant extensions of the operation.

As with parotid malignancies, salivary gland cancer of the submandibular gland should be considered for adjuvant radiation therapy based on the same criteria relative to stage and histology. Advanced-stage tumors, high-grade tumors, and tumors with poor prognostic pathologic features such as positive margins, perineural, perivascular and perilymphatic spread, parenchymal extension, and nodal metastases should receive adjuvant XRT.

## Treatment of Sublingual Gland, Minor Salivary Gland, and Parapharyngeal Space Tumors

Sublingual tumors present as submucosal masses in the floor of mouth. Because of the high propensity of malignancy in these glands, all noncystic sublingual masses should be considered malignant until resected and proven otherwise by histology. As ACC is the most common malignant tumor of the sublingual glands, particular care in the clearance of margins is warranted, but can be quite challenging. The diagnosis of sublingual tumors is facilitated by imaging and transoral FNA if achievable. Transoral open biopsy is acceptable as the ultimate treatment of these masses will involve resection that can easily include a carefully planned oral biopsy site.

Small tumors may be approached intraorally but every effort should be made to optimally clear margins and achieve nerve preservation. Because of the tight and dense anatomy of the region and proximity of other structures, a transcervical approach with ipsilateral submandibular gland resection may be required to provide adequate exposure for resection and nerve preservation. As sublingual gland resection adversely affects the submandibular ductal drainage system, submandibular gland resection may be mandatory for this reason.

The lingual nerve may also be involved by sublingual gland tumors mandating nerve resection with frozen section clearance. Because the mucosal defect involved in the resection can be significant, reconstruction may be required. Options include skin grafts, local regional flaps such as a submental island flap or free tissue transfer techniques such as the radial forearm flap. Tumors of the sublingual gland can be quite aggressive with significant tongue and mandibular involvement necessitating large resection and therefore appropriate soft tissue and bony tissue reconstructive efforts should be considered with appropriate preoperative discussion and preparation.[74]

Minor salivary gland cancers are among the most challenging in the upper digestive tract. These tumors can present with advanced-stage disease and be quite locally extensive. Minor salivary gland tumors will often present with infiltrating borders as well as perivascular and PNI that can make the clearance of margins challenging. Regardless, surgery remains the primary treatment modality for minor salivary gland tumors and should be considered initial treatment for all resectable disease regardless of the subsite. Resection techniques are determined by the standard techniques of the specific subsite involved: oral cavity, base of tongue, oropharynx, sinonasal, or larynx. Again the goals of clear surgical margins with optimal functional preservation are desired. As with resection planning, the optimal reconstructive methods which pertain to each subsite form the goal standard for reconstruction after the surgical ablation of minor salivary gland tumors (Figs. 25-11A,B and 25-12A,B).

The majority of parapharyngeal space salivary gland tumors are benign with the pleomorphic adenoma being the most common. The transcervical approach with submandibular gland resection and/or parotidectomy for increased exposure provides excellent access for the safe resection of well-circumscribed parapharyngeal space lesions. Utilization of mandibulectomy for increased exposure is well described but rarely needed. Complex and infiltrative masses of the parapharyngeal space require more careful consideration prior to attempted resection. Tissue diagnosis with FNA obtained in a transcervical or transoral manner can be beneficial. Because of the intimate relationship of the parapharyngeal space to critical surrounding structures such as cranial nerves IX, X, XI, and XII as well as the carotid artery and cranial base, careful and critical assessment of the true resectability must be undertaken. If the surgical resection is untenable, then nonsurgical treatments should be considered. As with the other subsites, adjuvant radiation should be recommended based on advanced-stage, high-grade histology and poor prognostic features on final pathology. Widely clear margins can be particularly challenging with the anatomic complexity of malignancies in sublingual, minor salivary gland, and parapharyngeal space tumors.

# MANAGEMENT OF THE NECK

Without debate, patients with clinically positive neck disease at the time of presentation should undergo neck dissection in conjunction with initial surgical therapy of the primary site. With the accordant increase in stage related to neck metastasis and the subsequent negative effect on survival, adjuvant radiation therapy should be strongly recommended to patients with positive neck disease. Yet, the neck dissection must remain a critical part of treatment in patients with N-positive disease for the somewhat radioresistant tumors. Extent of neck dissection is based on the extent of the disease, but should become sufficiently comprehensive to address all nodal basins at risk.

More challenging is the scenario of the clinically N0 patient. The bulk of data related to this question center on parotid

(c) 2014 Wolters Kluwer. All Rights Reserved.

salivary gland cancers, but principles extractable from this experience are useful when approaching disease in other subsites. Historic series generally estimate the risk of cervical nodal metastasis in the clinically N0 parotid cancer patient to be 14% to 16%.[75] Although some series report higher rates of lymph node metastasis, these include intraparotid lymph nodes in their analysis, somewhat skewing the incidence.[76]

Factors associated with cervical metastatic disease include higher tumor grade, extraparotid extension, tumor size >4 cm (T3 and T4), pain, facial nerve involvement, and the presence of positive intraparotid lymph nodes.[77] The higher-grade histological subtypes for which elective neck dissection is generally recommended include high-grade MEC, malignant mixed tumor, salivary ductal carcinoma, squamous cell carcinoma, undifferentiated carcinoma, and adenocarcinoma not otherwise specified.[78] Interestingly, some recent reports note significantly higher rates of cervical metastasis for all salivary gland malignancies regardless of specific histologic subtype.[79] Histologically, low-grade

lesions which are advanced in size or demonstrate aggressive features such as facial nerve involvement should likewise be considered for treatment of the neck, which may include elective neck dissection at the time of a primary surgical therapy.

The extent of elective neck dissection warranted in the N0 patients is also an issue of continued debate. Although, the modified radical neck dissection was traditionally advocated, selective neck dissections of the nodal basins at highest risk have been increasingly used, largely based on the favorable experience in the treatment of squamous cell carcinoma. With the concomitant use of radiation therapy for identified occult positive disease, excellent control rates have been demonstrated. Therefore, treatment of the neck nodal basins most at risk for each subsite should be considered for all tumors with advanced T stage and for tumors with aggressive local features regardless of histologic grade. Similarly, all high-grade carcinomas should be considered for neck treatment regardless of size. Elective neck dissection can be incorporated with initial surgical management in such cases, if information from pathologic assessment of the sampled lymph nodes affects therapeutic radiation planning.[80] A case can also be made that control may be improved, with the combination of neck dissection and XRT in these less radiosensitive malignancies. Elective dissections of levels 2 and 3 for early T-stage parotid malignancies can usually be completed through the same incision and with minimal morbidity. In the setting of low-grade histologic disease <4 cm, pathologic information demonstrating lack of occult metastatic disease and favorable histology can allow single modality treatment to be undertaken with more assurance. If elective neck dissection is not undertaken, for whatever reason, and final pathology of the primary site reveals evidence of high-grade histology or aggressive local features, therapeutic radiation to the neck should be advocated. As control rates with radiation therapy in the N0 neck are acceptable, neck dissection is not recommended as a secondary procedure.[80]

## Radiation Therapy for Salivary Gland Malignancies

***Major Salivary Gland Tumors.*** The most common setting for radiation therapy in the management of major salivary gland carcinomas is a surgical adjuvant following gross total resection. This is true for all histologies. Because of the location of the major salivary glands, there are limits to the extent of a surgical resection before morbidity overshadows additional gain and for this reason average local control rates have historically hovered around 60% following surgery alone. Risk factors for local recurrence following a complete resection include stage, a close (<5 mm) or microscopically positive resection margin, bone invasion, the presence of lymphovascular invasion (LVI), PNI, multifocal disease, adherence to a nerve or perineural involvement, and extracapsular extension (ECE).[81–88] A detailed analysis of risk factors associated with local and regional recurrence for all histologies following definitive surgery was reported by Chen et al.[89] Patients with T3–4 disease, positive surgical margins, high-grade histology, or lymphatic spread had 10-year actuarial recurrence rates of 37% to 63%. Another group looked at a large cohort of patients with parotid tumors of all histologies with the endpoint being disease-specific survival. The most important factors in this series were age, stage, tumor size, neural involvement, and degree of differentiation.[90] In most series, histology did not emerge as an independent risk factor for local recurrence when subjected to multivariate analysis.

Radiation in doses >56 Gy to the postoperative clinical target volume (CTV) following gross total resection in patients with risk factors for recurrence has routinely been demonstrated to reduce the rates of local and regional failure. Data from single institutions report long-term actuarial local control rates of 80% to 90% with acceptable morbidity.[26,81,90–95] Larger and more thorough studies from the Dutch Head and Neck Oncology Cooperative Group indicate that postoperative radiation is associated with a risk reduction of 9.7 for local regional failure.[88] More detailed data from this group demonstrate the 10-year local control rate between surgery plus postoperative radiation and surgery alone is 84% versus 18% for T3–4 tumors, 95% versus 55% for close margins, 82% versus 44% for incomplete resections, 86% versus 54% for bone invasion, and 88% versus 60% for PNI. An improvement was also seen in the postoperative neck for patients with N1–3 disease.[96] The greatest benefit of adjuvant therapy seen by the Dutch group and others is for more advanced disease and higher-grade tumors, as well as following resections that left an incomplete or positive margin.[94,96,97]

There may also be a survival benefit for a subset of patients with more aggressive tumors.[98] A study of SEER data restricted to 2,170 patients with high-grade and/or locally advanced malignant major salivary gland tumors did demonstrate adjuvant radiation was associated with a significant improvement in survival when subjected to multivariate analysis.[99] This improvement in survival has not been seen in many smaller series, possibly due to their inclusion of all histologies and stages.

Once a decision has been made to treat with adjuvant radiation, three-dimensional treatment planning is used to define a CTV that completely encompasses the original anatomic boundaries of the resected gland including a centimeter expansion to account for radial tumor spread and surgical manipulation. For tumors arising in the parotid gland, it is important to locate and include the deep lobe which can sometimes be underestimated with respect to its medial extension. Once a CTV has been defined, either a three-dimensional or intensity-modulated radiation therapy (IMRT) approach is used to conformally irradiate the CTV with limits placed on the spinal cord, contralateral parotid, esophageal constrictor muscles, oral cavity, and mandible. For most clinical situations where the margin is not microscopically positive, a dose of 56 to 60 Gray (Gy) is considered sufficient when delivered in 1.8 or 2.0 Gy fraction sizes.[81,83] A resected tumor with a positive margin or a situation with incompletely resected gross disease requires a higher dose, 66 Gy in the first situation and 66 to 72 Gy in the latter. Ideally, one would like to treat the entire resected tumor bed as an initial CTV to 60 Gy and then identify a secondary volume at higher risk and treat this smaller CTV to the target dose of 66 to 72 Gy. Occasionally, when an area of concern is appreciated during surgery, clips can be placed to help define a volume for higher dose. More commonly, however, a positive or close margin is discovered when the permanent sections are being reviewed, and it is impossible to retrospectively define the area where there is greatest risk. In this situation, the entire initial CTV has to be defined as high risk and irradiated to 66 Gy to assure adequate coverage. The question of the viability of a facial nerve graft following postoperative radiation is sometimes raised; however, this has not been an issue and should not affect the decision making regarding the advisability of adjuvant treatment.[100] An example of an IMRT treatment plan for a resected parotid tumor is seen in Figure 25-13. The dose is highly conformal and localized to the ipsilateral tumor bed minimizing unnecessary dose to uninvolved normal structures.

Histology can have a major impact on the design of an appropriate CTV. As described, the CTV for the resected primary site is essentially the same for all settings; however, the pattern of spread varies greatly and knowledge of the natural history of disease can avoid unnecessary treatment failures. Low-grade malignant tumors such as AC and low-grade MEC have minimal risk of lymphatic or perineural spread and the CTV is restricted to the salivary gland itself. A common clinical occurrence is a low-grade parotid tumor initially treated with a superficial parotidectomy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

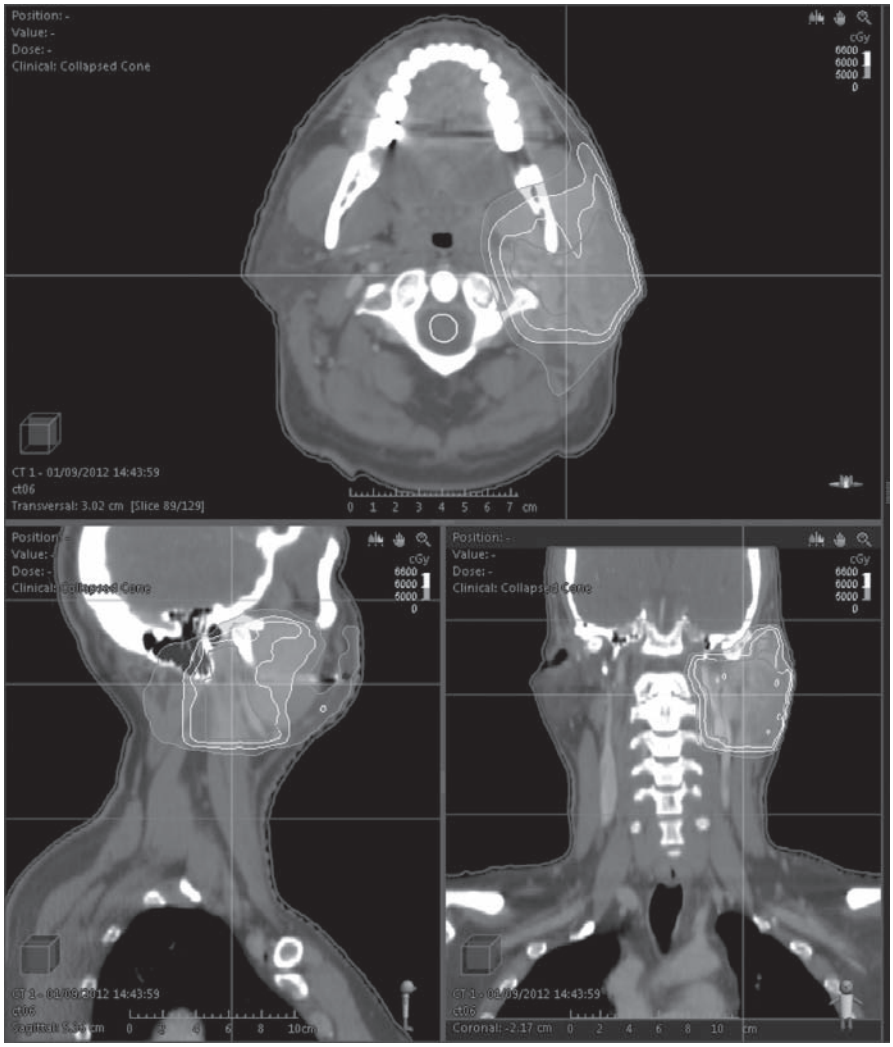

**FIGURE 25-13.** Postoperative IMRT plan for a parotid gland carcinoma. The CTV is the entire initial volume of the parotid gland including both superficial and deep lobes (magenta) and the 66-Gy, 60-Gy, and 50-Gy isodose volumes are shown.

These tumors can be well circumscribed and superficial enough so that no further therapy is needed; however, they can also be situated deeper into the gland where the facial nerve becomes a limiting factor in obtaining a comfortable resection margin. The risk of recurrence may still be relatively low, between 10% and 20%, however, should this occur; the consequences are high as salvage surgery would require sacrifice of at least part of the facial nerve. Postoperative radiation, 60 Gy to the primary CTV, should be considered in this setting.[101]

Higher grade tumors, most notably intermediate- or high-grade MECs, adenocarcinomas, and salivary gland duct carcinomas carry a substantial risk of involvement of the ipsilateral lymphatics, and this is a negative prognostic factor.[74,102,103] For N0 but high-risk disease, the CTV includes not only the resected salivary gland but lymphatic levels as well. For tumors that arise in the parotid gland, levels II, III, IV, and V are covered;[74] submandibular gland tumors should include level IB in addition to the above. The dose of radiation to the lymphatic CTV should reflect the risk of involvement; that is, the more proximal the lymphatic chain is to the salivary gland primary, the greater the risk and therefore, the higher the dose. Levels IB, II and III should receive 56 to 60 Gy whereas levels IV and V can be treated to 50 to 54 Gy. Almost always, irradiation of the neck is ipsilateral for N0 disease. Elective neck irradiation in this setting has proven to be very effective in preventing subsequent relapse in the neck;[103] however, it is very difficult to determine the true level of efficacy.[104] The role of radiation therapy in the management of an N1–3 neck is much the same as for squamous cell carcinoma of the upper aerodigestive tract.

Since the primary management of salivary gland tumors is surgery, a neck dissection is often performed at the time of primary resection and there is little emphasis on radiation as a single modality for gross disease as opposed to squamous cell carcinomas of the head and neck. Indications for postoperative radiation include the presence of gross or microscopic extracapsular extension, multiple lymph nodes, or N3 disease. The lymphatic CTV is similar to what is described above for the N0 neck; however, in the presence of level II disease, the CTV includes level Ib for parotid tumors.[105] The radiation dose is higher to account for the higher probability and/or extent of subclinical disease. The ipsilateral lymphatic levels of an involved neck are treated to a dose of 56 to 60 Gy and the area in the neck where extracapsular extension is noted can be treated for an additional 6 Gy to increase the likelihood of controlling minimal residual disease in the soft tissue or adjacent structures in the neck. Even with N2 disease, the contralateral neck is rarely treated[84] unless imaging demonstrates borderline contralateral adenopathy or if there is massive adenopathy in the ipsilateral low neck raising a concern for retrograde flow and collateral involvement.

ACC is a special case in all salivary gland sites as PNI and tracking along proximal cranial nerves is a significant pattern of spread. This has been associated with an increased risk for local

(c) 2014 Wolters Kluwer. All Rights Reserved.

failure and as a negative prognostic factor for survival especially if a named nerve is involved.[83] For tumors arising in the parotid gland, this is the facial nerve (cranial nerve VII); tumors arising in the submandibular gland can involve the lingual nerve (cranial nerve $V_3$) in addition to the hypoglossal nerve (cranial nerve XII) and facial nerve (cranial nerve VII). Whether or not perineural involvement is identified pathologically, its presence must be suspected and appropriate imaging needs be obtained prior to treatment planning. MRI is the preferred imaging and thin cuts should be obtained through the entire skull base and the brain stem as skip areas along an affected nerve are possible. In addition to the primary site CTV definition and doses previously described, an additional element to treatment planning for ACC is the course of the potentially involved cranial nerves to their respective foramina.

For potential subclinical perineural extension, 54 Gy is used. In the event of a completely resected primary tumor and radiographic findings of gross involvement of a proximal segment of a cranial nerve, the dose for treating subclinical disease along the path of the nerve should be higher, 56 to 60 Gy, and the gross disease needs to receive a dose of at least 66 to 70 Gy. The extension of the CTV does not always end at the neural foramina but may extend proximally to include the ganglion and even the afferent branch up to the anterior brain stem. Only advanced methods of radiation treatment planning and delivery such as IMRT can treat a complex CTV such as this and achieve the target doses while not excessively treating important normal structures. Concurrent chemotherapy may be considered in patients with multiple adverse or high-risk features.[106]

***Minor Salivary Gland Tumors.*** Any type of salivary tumor, benign or malignant, can arise from a minor salivary gland, and, like major salivary gland tumors, complete resection is the preferred treatment in many cases, followed by adjuvant radiation therapy.[107–109] The natural history and pattern of spread is determined by the histology rather than site of origin and the risk factors for recurrence share some overlap with those of the major salivary glands. As the anatomy is more complex for these tumors, so is the design of postoperative CTVs, which can range from the immediate tumor bed to the primary site and lymphatics and/or areas of potential perineural spread.

As with major salivary gland tumors, high-grade MEC and adenocarcinomas warrant additional attention to the lymphatic drainage; however, unlike major salivary gland tumors, the region at risk is not always ipsilateral. Centrally located primary sites such as the hard and soft palate, base of tongue, and larynx have the potential for bilateral lymph node involvement, and in these settings radiation is delivered to the bilateral neck as well as primary CTV. The same dose specifications elaborated in major salivary glands apply. Three-D planning and the use of IMRT are encouraged to develop an optimal treatment plan that avoids unnecessary irradiation to the parotid glands and other normal structures.

ACC of the minor salivary glands represents an even more complex challenge to the design of an appropriate CTV due to the nature of the innervations of the primary site and need to account for these along their proximate course. By the time each nerve is identified and traced back to its respective foramina, a CTV can become large and complex. For example, postoperative treatment of an ACC in the hard palate requires a CTV that not only includes the palate but also the course of $V_2$ and the parasympathetic chain to the pterygopalatine fossa and more proximally to the neural foramina of the skull base.

***Benign and Low-grade Tumors.*** Benign and low-grade tumors such as pleomorphic adenoma, grade 1 MEC, and low-grade pleomorphic adenocarcinoma often do not require additional therapy other than complete resection. For pleomorphic adenomas, the typical natural history is primary resection followed by a long disease-free interval and another resection. Each surgical iteration has a shorter interval[110] and adjuvant radiation is given after the second or third surgery, a decision governed by the degree of morbidity thought to be associated with the next round of surgery. A dose of 50 to 60 Gy has been shown to effectively prevent further recurrences with minimal morbidity or risk of malignant transformation or a second primary.[111] Pleomorphic adenoma can also arise in a minor salivary gland and even present as a submucosal parapharyngeal mass. In these settings, surgical resection is often incomplete and there is concern about a microscopic margin or even residual gross disease. Another concern is when there is tumor spillage during the course of the resection. Rather than wait until a recurrence manifests itself, radiation is offered after the initial resection since there will be little or no opportunity for surgical salvage. If given immediately after the initial resection, postoperative radiation is very effective in preventing the recurrence of this benign disease; however, if there is a delay and radiation is given after a second recurrence, often with incomplete resection the local recurrence rate goes from a negligible number (<1%) to 12.5%.[112]

Ideally, all margins are carefully documented and if part of the margin is positive or 1 mm or less and amenable to additional resection, it is preferable to undergo another course of surgery than use radiation at this step as the morbidity is often less. If the area of concern cannot be identified or if further surgery will lead to much higher morbidity, then postoperative radiation is advised. The CTV is the initial site of disease plus a centimeter if possible or the entire anatomic site to account for subclinical extension; a dose of 56 to 60 Gray (Gy) is considered sufficient; however, a positive margin requires a higher dose, 66 Gy. As mentioned, minor salivary gland tumors can arise in a myriad of anatomic sites, and not just the hard palate, and represent a more challenging problem in postoperative treatment planning. There is no one-size-fits-all approach to defining a CTV other than for radiographic and clinical documentation of the primary site and thoughtful consideration of potential patterns of subclinical spread.

***Unresectable Salivary Gland Tumors.*** Some salivary gland tumors are unresectable at presentation because of extensive involvement of adjacent structures such as the skull base, pterygoid muscles, or gross involvement of cranial nerves proximal to the neural foramina. It is more common to find a minor salivary unresectable than a major salivary gland. One reason for this is the submucosal nature of the malignant growth in a minor salivary gland, which can be asymptomatic and undetected unlike the presence of a mass in a major salivary gland. The initial clinical symptom is frequently numbness with a classic distribution pattern due to gross involvement of a branch of the trigeminal nerve.

Patients can also have disease that is technically resectable but have a high operative risk due to medical comorbidities, and in these cases, radiation becomes the primary modality,[108,113] often combined with concurrent chemotherapy.[114,115] Even though surgery and radiation therapy is the preferred approach, if surgery is not feasible, these cases are by no means simply palliative. If a sufficiently high dose is given, between 70 and 76 Gy, to gross disease, there is a reasonable chance of long-term control with 5-year actuarial local rates that range from 50% to 70%.[96,97,116,117] An experience using BID radiation was reported by Wang and Goodman with a local control rate of 85% but with relatively short follow-up.[118] It should be noted that these series contained some patients with T1 and T2 disease, a factor that could have contributed to the favorable outcome. The degree of the clinical response 3 to 6 weeks after the completion of

(c) 2014 Wolters Kluwer. All Rights Reserved.

radiation can have predictive value as to the ultimate outcome.[96] These cases are often complex and should be treated by IMRT with both CT and MRI imaging at the time of planning to assess the full extent of disease that includes bone involvement and perineural/soft tissue extension. As with any treatment plan involving the base of skull, dose constraints need to be placed on the optic nerves, optic chiasm, cochlea, brain stem, and temporal lobe in order to limit the likelihood of collateral damage to these structures. It is unclear whether resection of gross disease at the primary site in the setting of unresectable extension into the skull base is beneficial; it is most likely not, as the additional morbidity of debulking does not lead to a reduction in dose or translate into a higher likelihood for tumor control.

## Particle Therapy

Because of the complexity of cases with gross disease extending into the skull base and the need to deliver a dose in excess of 70 Gy, other radiation modalities have been studied in an attempt to achieve higher control rates than have historically been achievable with photons and to do so with an acceptable level of morbidity. Three different particle beams have been clinically examined, protons, fast neutrons, and carbon ions and a clinical experience exists for each.

Proton radiation for large-field radiation therapy has been studied at Massachusetts General Hospital since 1973, first with a fixed horizontal beam at the Harvard Cyclotron Laboratory and starting in 2001, with a fully rotational, gantry-based delivery system on the Massachusetts General Hospital campus. Unresectable salivary gland tumors were among the first disease sites to be studied and because of the favorable dose distributions attainable with protons and the sharpness of the penumbra, doses of 72 to 76 Gy have safely been delivered to gross disease close to the optic structures and the brain stem.[119] Currently, the practice is to treat complex cases such as these with once-daily proton radiation using conventional fraction sizes of 1.8 to 2.0 Gray Equivalent (an adjustment for an RBE of 1.1) to doses of 72 to 79 GyE. A review of an experience of 23 patients with unresected, incompletely resected ACC treated with this approach showed the actuarial local control rate at 5 years to be 93%, with minimal morbidity.[120] An example of one such case, a patient with ACC of the hard palate and gross involvement of V2, is presented in Figure 25-14.

Fast neutron radiation has been studied at several institutions in the US and Europe; the most extensive experience is at the University of Washington. The advantage of neutrons over photons is an RBE of 3, and according to investigators at University of Washington this can be as high as 8 for ACCs. A randomized trial conducted by the RTOG and MRC was conducted comparing neutron irradiation with conventional photon radiation for unresected salivary gland tumors. As reported by Laramore et al.,[121] there was a significant improvement in local control for the neutron arm of the study, 56% versus 17%. Additional single-institution studies were subsequently conducted at the University of Washington and primarily focused on patients with gross disease, either initially unresectable or with gross residual disease following primary resection. For all histologies, an actuarial 5-year local control rate of 59% was reported, 80% for patients with tumors <4 cm. A large cohort of patients with ACC experienced a similar, 57% local control rate.[122,123] Huber[124] reported a nonrandomized series of 75 patients with ACC treated with either neutrons, photons, or mixed beams where the 5-year actuarial local control rate was 75% for neutrons and 32% for all others. There are disadvantages to neutrons, however. The first is difficulty in collimation due to the lack of positive or negative charge. The second is poor tissue penetration leading to regions of underdosing for deep-seated sites of gross disease, such as the skull base. The third is the RBE of 3; although this can be advantageous to delivering more biologically effective radiation to a tumor, it also produces the same increased effectiveness in the irradiation normal tissue; for example, patients in the Huber study experienced more grade 3 and 4 late complications with neutrons alone (19%) than with mixed (10%) or with photons (4%).

An additional approach, still experimental and available only in a few centers in Europe and Japan is carbon-ion radiation. This particle has the dual properties of carrying a charge, like protons, so they can be effectively steered and collimated. They also have the advantage of a larger RBE than do protons. Preliminary results from a nonrandomized group of patients treated at the University of Heidelberg comparing either photon radiation to mixed photon–carbon-ion radiation showed 2- and 5-year actuarial local control rates of 72% and 25% for photons while the patients treated with mixed beam were 78% and 78%.[125] This regimen, 50 Gy with IMRT followed by a 24 Gy carbon-ion boost, is an ongoing phase II trial.[126] A companion study by the same group is evaluating cetuximab added to this regimen because of the high levels of EGFR seen in ACC and the opportunity for synergy.[127]

## Systemic Treatment of Salivary Gland Cancers

The rarity of salivary gland cancers, plus the fact that the majority of patients will be cured with initial treatment, makes the study of systemic therapy for salivary gland cancers challenging. Most salivary gland cancers are resectable at presentation. Thus, a major question in the field is the role for adjuvant therapy. As detailed above, the outcomes with surgery and adjuvant radiotherapy alone are generally quite favorable. Whether there is any additional benefit from the addition of chemotherapy to radiation has been studied in unresectable salivary gland cancers. Several small retrospective series are available, the largest of which reports on salivary gland cancers arising in the nasopharynx.[114,128–130] These series include patients with multiple primary sites and histologies and report upon various chemoradiotherapy regimens, though platinum-based approaches are most common. One additional series describes outcomes of salivary gland cancer patients receiving adjuvant IMRT with or without chemotherapy.[106] Adverse features in this series included histology, positive margins, neural or PNI, lymphovascular invasion, lymph node involvement, and extracapsular nodal extension. Overall, the reported toxicities of chemoradiotherapy are consistent with that expected, and the rates of locoregional control and OS are encouraging. A cautionary note should, however, be raised when considering chemoradiotherapy as a substitute for surgery, given the experience reported by Katori and Tsukuda on 17 salivary gland cancer patients treated with chemoradiotherapy followed by resection in the case of residual disease.[131] Although most patients experienced some tumor shrinkage, only 4 patients (24%) had a complete response. Definitive statements regarding the role of concurrent chemoradiotherapy in salivary gland cancers cannot be made without more prospective data; however, the data that are available indicate that concurrent chemoradiotherapy for salivary gland cancers is feasible and may be appropriate in select high-risk postoperative or unresectable SGC patients.

## Treatment of Recurrent or Metastatic Disease

Although the majority of patients with salivary gland cancer will have potentially curable disease at presentation, a significant percentage of patients will experience recurrence, particularly those with stage III or IV disease.[5,132,133] Distant metastasis is more common than locoregional recurrence, with lung, bone, and liver being the most frequent sites of disease. Metastases in low-grade tumors are rare, whereas metastases from ACC, salivary duct

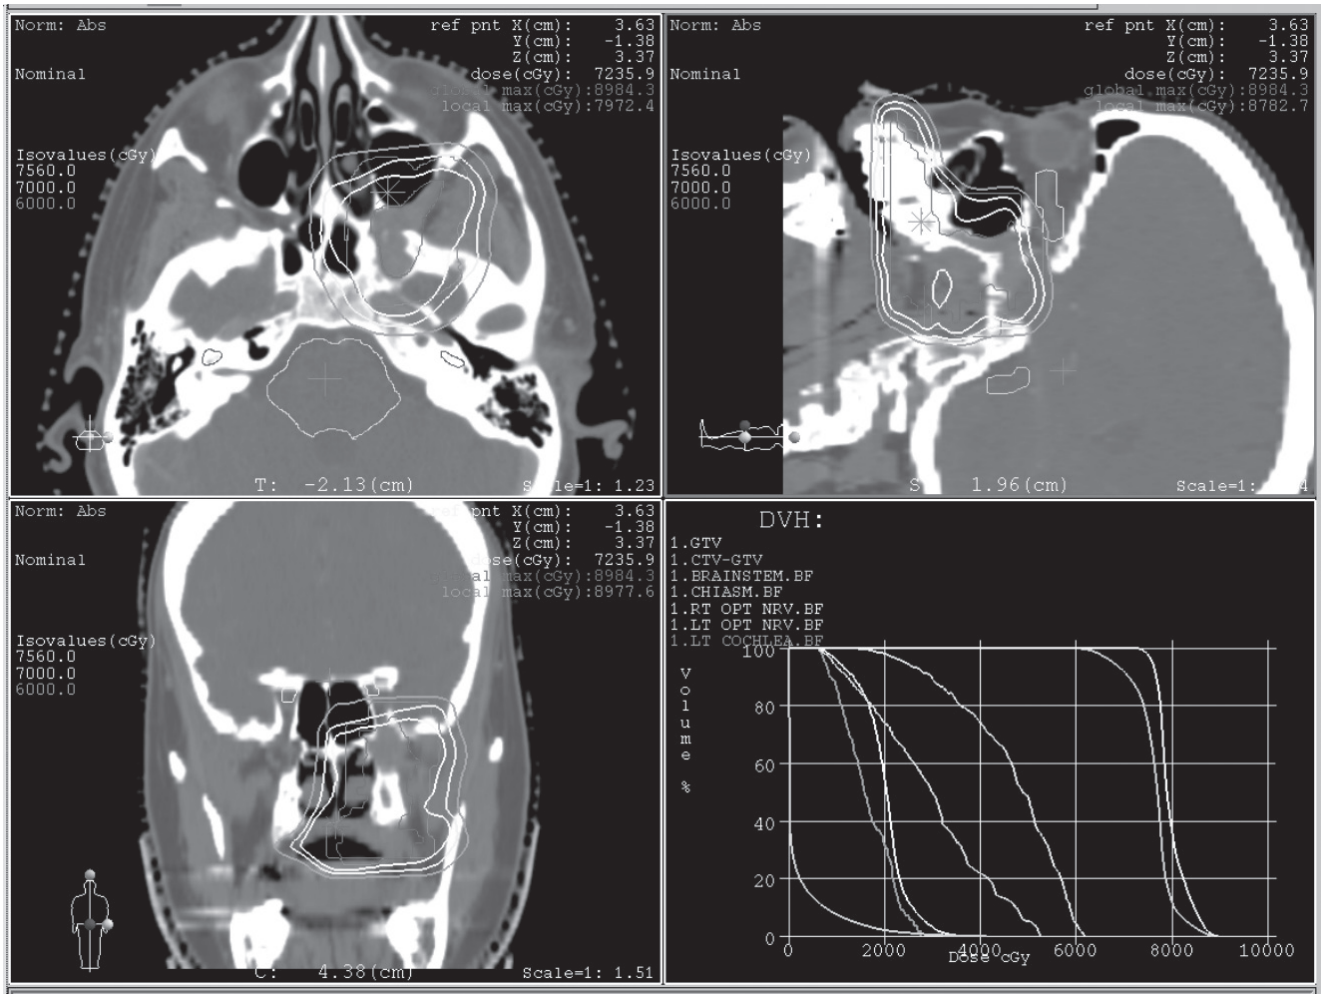

**FIGURE 25-14.** Definitive proton therapy for an unresectable adenoid cystic carcinoma of the hard palate with gross involvement of V2. Note the restriction of the irradiated volume to the defined CTV and relative sparing of the optic structures and the brain stem. There is no fall off or compromise of dose in the deepest part of the skull base. This patient is NED 6 years after 75.6 GyE to the GTV. (See color insert.)

carcinoma, high- or intermediate-grade MECs, ACs, and carcinoma ex-pleomorphic adenomas are more common.[85,134–138] Within ACCs, solid-type tumors are more likely to metastasize. Other risk factors include advanced stage, close or involved margins, vascular invasion, and histologic grade.[5–7,132–137] Fortunately, metastases from ACC tend to be asymptomatic and grow slowly over many years. The prognosis for other metastatic salivary gland cancers is less favorable.

A number of clinical trials investigating systemic therapies in recurrent/metastatic salivary gland cancer have been conducted over the last three decades; however, there are limitations to this body of work. The studies are generally small, noncomparator studies, and most have enrolled patients with varying baseline characteristics, including histologic subtype and lines of prior therapies. This heterogeneity makes comparison between studies impossible. In addition, the methodologies used, particularly in the older studies, have not been uniformly consistent with current standards.

One regimen for recurrent/metastatic salivary gland cancer that has been investigated in the largest number of patients is cyclophosphamide, doxorubicin, and cisplatin (CAP).[139–145] Overall response rates (ORRs) range from 27% to 100%, though the data must be interpreted with caution as most are from older studies with few patients. The largest series by Licitra et al. included 27 patients with various histologies, including ACC, salivary duct carcinoma, and adenocarcinoma.[144] Six patients (27%) achieved a partial response, with a median duration of 7 months. Responses were seen in multiple histologies, including ACC. The median OS was 21 months. Other combination chemotherapy regimens from older series include cisplatin; 5FU plus an anthracycline; cyclophosphamide plus doxorubicinr; and cisplatin, 5FU, cyclophosphamide, and doxorubicin.[146–149] The overall response and survival rates were similar to those of CAP; however, more toxicity was generally encountered with the more intensive regimens.

Single-agent chemotherapy has also been of interest. As combination chemotherapy is not necessarily superior to monotherapy, the toxicity of combination chemotherapy will be greater. Cisplatin has been studied in the phase II setting, showing an ORR of 16% and OS of 14 months.[150] More recently, single-agent vinorelbine has been compared with combined vinorelbine plus cisplatin in a randomized phase II study.[151] Thirty-six patients with recurrent/metastatic salivary gland cancer were enrolled. Responses were seen in patients with ACC and adenocarcinoma. ORRs were, respectively, 20% and 44%. The survival curves showed a trend of improved survival with the combination, but

(c) 2014 Wolters Kluwer. All Rights Reserved.

this was not statistically significant. The two most recent trials investigating cytotoxic chemotherapy in salivary gland cancer were phase II trials of paclitaxel run by the Eastern Cooperative Oncology Group (ECOG) and gemcitabine plus cisplatin run by the National Cancer Institute of Canada (NCIC).[152,153] The ECOG study showed an ORR of 26% in patients with mucopepidermoid or adenocarcinoma, but no responses were seen in 14 patients with ACC. Median OS was 13 months. The NCIC study showed an ORR of 24% to gemcitabine plus cisplatin, and responses occurred in all histologic subtypes. OS was 14 months. Taken together, these data indicate that several cytotoxic chemotherapies, including single-agent and doublet regimens, have modest activity in recurrent/metastatic salivary gland cancer, though there is no one clear best regimen.

Several phase II investigations of cytotoxic chemotherapy have limited enrollment to ACC. Given the unique, typically protracted course of ACC, it makes sense to study ACC as a separate entity.[154–157] Mitoxantrone, epirubicin, and gemcitabine have been studied as single agents. Mitoxantrone showed an ORR of 6% and 12%, respectively, in two phase II studies, the larger of which included 32 patients.[154,155] In this study, median OS was 18 months. Epirubicin showed similar activity, whereas gemcitabine yielded no objective response.[156,157] Combination regimens that have been studied in ACC include 5FU, cyclophosphamide plus vincristine; cisplatin plus 5FU; and epirubicin, cisplatin plus 5FU.[158–160] 5FU, cyclophosphamide plus vincristine yielded two responses in eight patients with recurrent/metastatic disease.[158] Cisplatin plus 5FU yielded no responses in 11 patients.[159] The most recent study investigating epirubicin, cisplatin plus 5FU was small, enrolling only eight patients, one of which experienced a partial response to treatment. In this group, OS was 27 months.[160] Thus, data on cytotoxic chemotherapy for ACC are sparse and activity is modest at best. For this reason, enrollment on a clinical trial for patients with ACC in need of treatment is currently preferred over the administration of cytotoxic chemotherapy, when available.[60,161]

## Molecular Targeting of Salivary Gland Malignancies

The diversity of salivary gland cancers is now an even more critical factor in treatment decisions, as molecularly targeted therapies are becoming available for the treatment of recurrent/metastatic disease. To date, evidence of overexpression of EGFR, human epidermal growth factor receptor 2 (HER2), c-kit, and vascular endothelial growth factor receptor (VEGFR) in various salivary gland cancers has led to the study of newer targeted agents in recurrent/metastatic disease.

EGFR has been found to have intermediate to high expression in the majority of salivary gland cancers, across all subtypes.[162] Three EGFR targeted therapies have made it to phase II study: gefitinib, an EGFR tyrosine kinase inhibitor; cetuximab, a monoclonal antibody directed against EGFR; and lapatinib, a dual EGFR, and HER2 tyrosine kinase inhibitor.[163–165] All three studies enrolled ACC and non-ACC patients. There were no responses seen.

HER2 overexpression by immunohistochemistry has been described in several salivary gland cancer subtypes, most commonly in salivary duct carcinoma.[164] When examined by fluorescence *in situ* hybridization, gene amplification was found in 10 of 10 salivary duct carcinomas, 2 of 3 adenocarcinomas, and 1 of 4 poorly differentiated carcinomas.[164] Trastuzumab, the monoclonal antibody directed against HER2, has been investigated in a phase II study of salivary gland cancers overexpressing HER2 by IHC.[166] The study closed early after the majority of tumors screened did not overexpress HER2; however, 14 patients were enrolled and treated. Of these, only one patient with an MEC experienced a response. There have since been several case reports since detailing results of trastuzumab plus cytotoxic chemotherapy in various subtypes with HER2 overexpression, some of whom did experience durable responses to treatment.[167–171] Thus, trastuzumab as a single agent does not appear as promising as the drug in combination with chemotherapy, though more definitive trials are needed.

Identification of c-kit expression in a single adnexal ACC, as well as the success of targeting this proto-oncogene in leukemias and gastrointestinal stromal tumors with the c-kit inhibitor, imantinib, led to larger studies of c-kit expression in ACCs. KIT protein expression was found in 90% of ACCs.[172] KIT expression has been found in several other salivary gland cancers subtypes, as well.[173] Six small phase II trials of imantinib in ACC have been conducted, two of which limited treatment to ACCs expressing KIT.[174–179] Of the 64 patients enrolled across these studies, only 2 responses were reported. An additional study investigated imantinib as a single agent first, then added cisplatin after 2 months of imantinib alone.[180] In the 28 patients enrolled, there were no responses to imantinib alone; however, 2 responses were seen after cisplatin was added. The lackluster activity of imantinib most likely reflects the fact that KIT is not an oncologic driver in ACCs, consistent with the absence of c-kit mutations in this disease.[181]

Lastly, efforts targeting angiogenesis have been studied in ACCs, in part due to high expression of VEGF and other angiogenesis factors found in ACCs.[182] Sunitinib, an oral multikinase inhibitor of VEFGR and c-kit, has been investigated in a phase II study of ACC.[183] Fourteen patients were enrolled, but no responses were seen. The proteosome inhibitor, bortezomib, has also been studied in ACC, given the idea that inhibiting proteosome degradation of key regulatory proteins involved in regulating the cell cycle and angiogenesis may have anticancer efficacy.[184] Twenty-five patients were enrolled in a phase II study. There were no responses to single-agent bortezomib; however, one patient out of 10 given bortezomib plus doxorubicin experienced a partial response.

## Ongoing Trials/Future Efforts

Although clinical trials of targeted therapies in salivary gland cancers have not yet led to major progress in the treatment of recurrent/metastatic disease, several clinical trials of new drugs are underway. Current studies are primarily enrolling patients with ACC and include phase II studies of the histone deacetylase inhibitor, vorinostat, the c-kit inhibitor, dasatinib, and the fibroblast growth factor receptor and VEGFR inhibitor, dovitnib.

Moreover, recent findings regarding the molecular underpinnings of salivary gland cancers offer new opportunities for more specific targeted therapies.[162,185] One example is the recent identification of the *MYB-NFIB* translocation common in ACCs, which leads to overexpression of Myb, as well as downstream mediators of apoptosis, cell cycle control, and growth. This provides new targets for rationale drug development for the management of ACC.[186–188] Beyond ACCs, salivary duct carcinomas are another histologic subtype in which recent advances are expected to translate into more effective therapies. Salivary duct carcinomas harbor frequent molecular abnormalities, including mutations in PIK3CA and BRAF as well as the overexpression of HER2 and androgen receptor, all potentially targetable with drugs that are currently available or in development.[162,189–191] More discoveries identifying critical oncogenic pathways that drive specific salivary gland cancers are expected. As the future unfolds, the new challenges will emerge. It is most likely that molecularly driven therapies will offer the greatest benefit, but demonstrating this in these uncommon, histologically and molecularly diverse cancers will require new approaches in clinical trial design.

(c) 2014 Wolters Kluwer. All Rights Reserved.

In conclusion, the study of systemic therapy for salivary gland cancers has been primarily confined to recurrent/metastatic disease. In addition to the small number of patients that develop recurrent/metastatic disease, investigations of systemic therapy are further limited by the heterogeneity in histology and trial design. Cytotoxic chemotherapies have modest activity in recurrent/metastatic salivary gland cancers. Recent advances in the understanding of the biology of various salivary gland cancers has, however, brought us closer to developing effective systemic therapies. If these advances can be coupled with broad cooperation across multiple institutions to study new agents in well-designed clinical trials, real progress in the systemic treatment of salivary gland cancers will be within reach.

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

MRI is generally preferred over CT for the imaging of salivary gland neoplasms. This is because of its ability to better characterize the internal morphology of the tumor, its boundaries, and to determine perineural spread. For example, benign mixed tumors often appear very bright on T2-weighted images with variable enhancement (Fig. 25-15). However, imaging cannot confidently predict whether the lesion is benign or malignant.[1] Features that suggest a benign mass are sharp margins of the lesion and no lymphadenopathy or signs of perineural spread. A malignant lesion is suggested by indistinct margins, enhancement, and edema of the facial nerve suggesting perineural invasion, and lymphadenopathy (Fig. 25-16). Nevertheless, many benign and malignant salivary gland tumors will appear to be well circumscribed both on CT and MRI.[2] Suggested protocols are given in Figures 25-17 and 25-18.

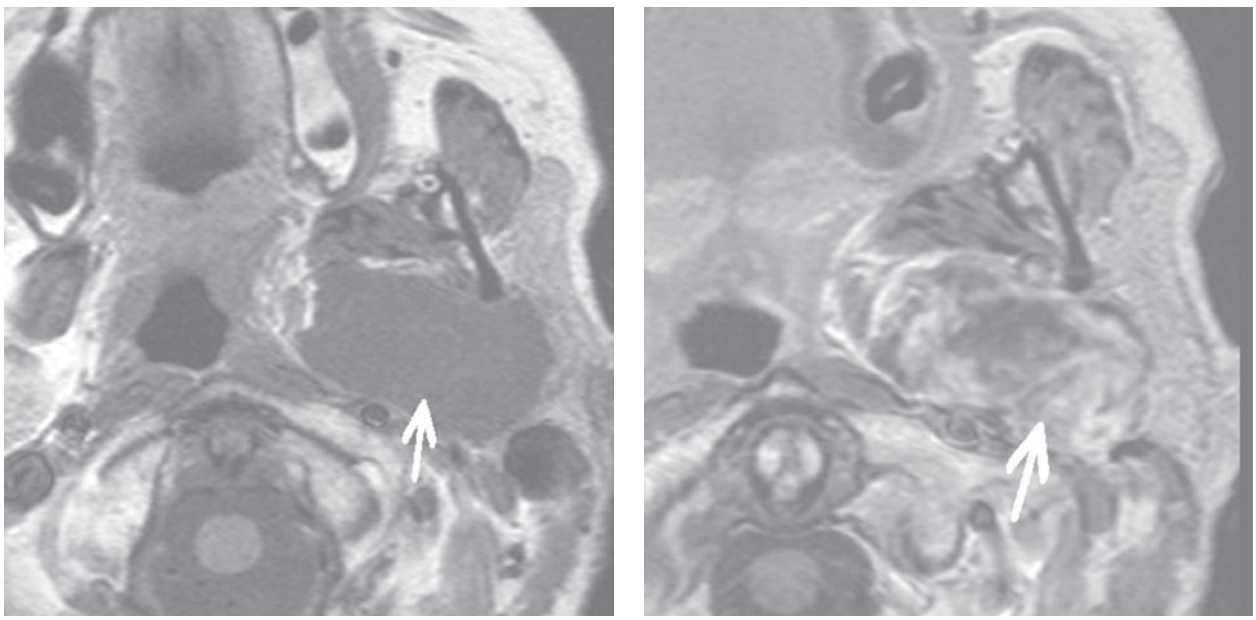
Imaging is often performed to plan an approach for biopsy, as therapy is different depending on whether the mass is a primary salivary gland tumor, or lymphoma, or other metastasis such as squamous cell cancer from a skin primary site. Fine-needle aspiration has proven to have reliable sensitivity and specificity for salivary gland neoplasms.[3] Ultrasound guidance is usually excellent for more superficial parotid and submandibular gland lesions. CT is often better for biopsy of lesions in the deep lobe of the parotid, as a transfacial approach (Fig. 25-19) can often be used to avoid crossing the facial nerve. In most cases, a core biopsy can be safely obtained when FNA is not diagnostic and is often helpful in the workup of lymphomas or sarcomas. Core-needle biopsies can be obtained either with ultrasound guidance or CT guidance.[4]

MRI is particularly useful for evaluating the presence of perineural spread. This is very common in certain types of neoplasm such as adenoid cystic carcinoma. Intravenous contrast is essential for making this diagnosis, and the use of fat suppression often makes perineural spread more apparent. The axial plane is excellent for demonstrating perineural spread of cancer along the auriculotemporal nerve, which is a connection between the facial nerve and mandibular nerve (Fig. 25-20). The coronal plane is better for demonstrating tumor spread along the descending facial nerve canal (Fig. 25-21).

In the recent past, surface coils were very useful to obtain high-resolution MR images of the superficial parotid gland. The prevalence of multichannel head coils and 3T magnets has made surface coils unnecessary.

It has been found that dynamic contrast-enhanced MRI may be useful in the identification of Warthin tumor as this tumor demonstrates rapid enhancement and rapid attenuation.[5] Presumably, this enhancement pattern could be detected with dynamic contrast-enhanced CT as well. Other investigators have found the detection of low-signal areas in a parotid tumor on short tau inversion recovery and T2-weighted sequences, as well as low apparent diffusion coefficient values on diffusion-weighted imaging suggested Warthin tumor.[6,7]

Posttreatment imaging for tumor recurrence is challenging because of the difficulty in differentiating scar from recurrent tumor.



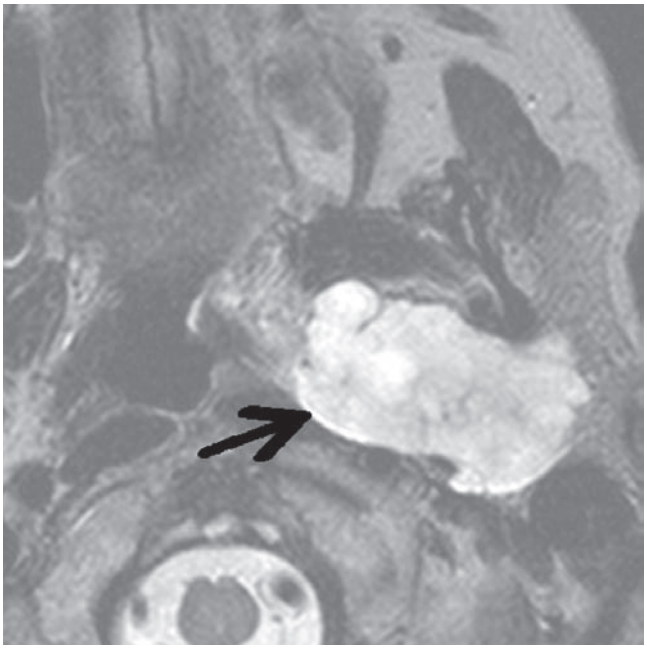


**FIGURE 25-15.** Axial noncontrast T1-weighted MRI **(A)**, axial postcontrast T1-weighted MRI **(B)**, and axial T2-weighted MRI **(C)** show a large mass (*arrows*) in the deep lobe of the left parotid gland. The mass demonstrates homogeneous low signal on T1-weighted images, is very bright on T2-weighted images, and shows irregular patchy enhancement. This tumor was determined on pathology to be a benign mixed tumor.

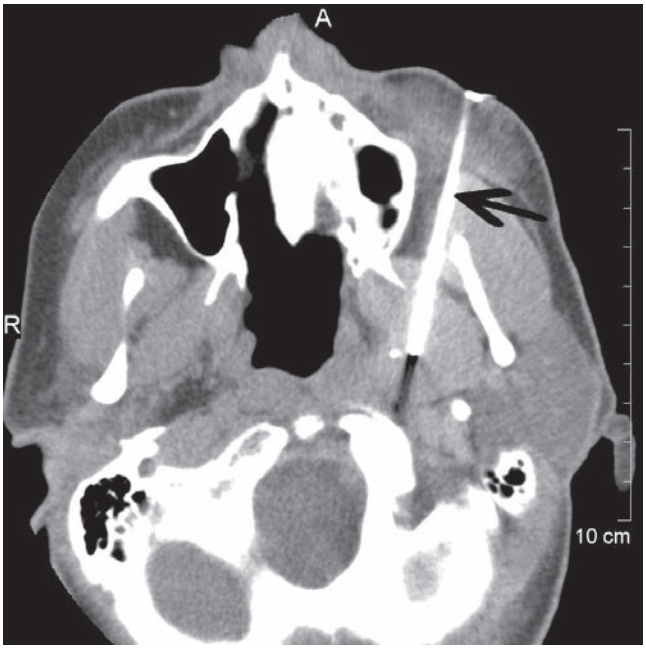

**FIGURE 25-19.** Axial CT scan shows a transfacial approach for biopsy of a deep-lobe parotid mass. The needle in this case is a 16G guide needle (*arrow*) through which fine-needle aspirates or core biopsy can be performed using a coaxial technique. The transfacial approach is a useful safe approach to deep-lobe parotid lesions, which avoids potential damage to the facial nerve.

T2-weighted images are useful in those cases where tumor, such as benign mixed tumor, is high signal, differentiating it from scar which is dark (Fig. 25-22). FDG-PET normally shows uptake in the salivary glands. Nevertheless, increased FDG uptake has been demonstrated in both benign and malignant salivary gland neoplasms and thus may be helpful in cases of recurrent cancer (Fig. 25-23).[8–11] Image-guided biopsy is often necessary when recurrent tumor is suspected.

Submandibular gland lesions are infrequently imaged, as they usually present early and are easily palpated. Large parotid tail lesions can sometimes be mistaken for submandibular lesions because they can extend down into the submandibular space (Fig. 25-24). Lesions of the sublingual gland are often imaged to see if there is involvement of the lingual neurovascular bundle (Fig. 25-25).

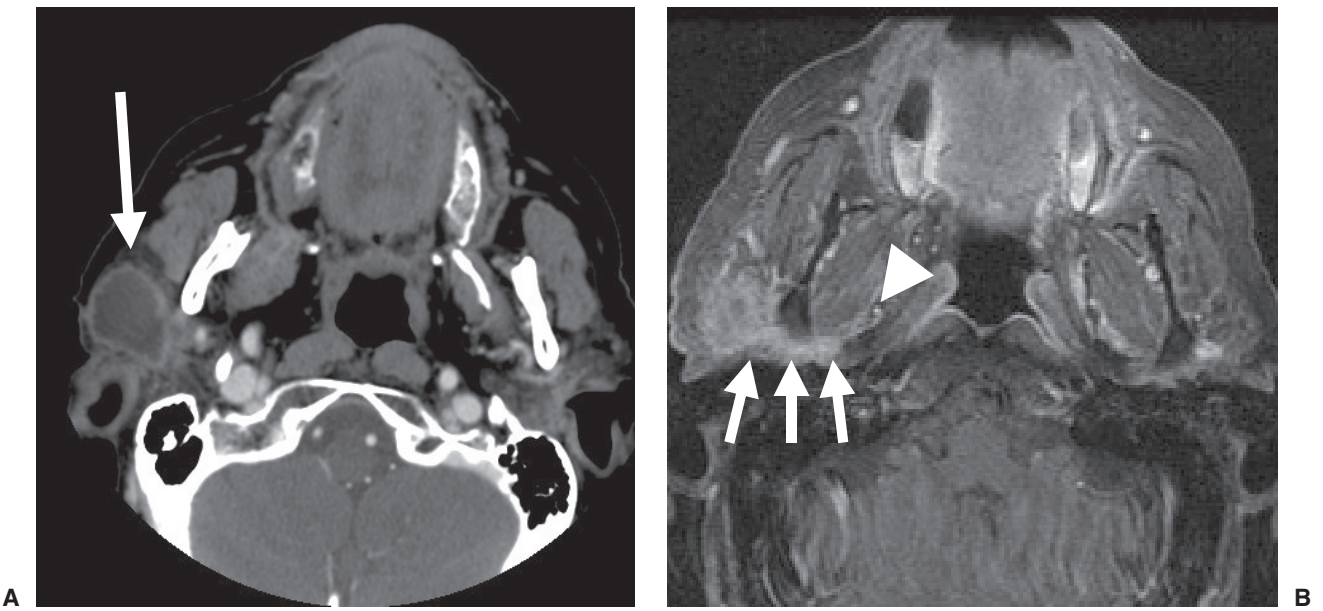

**FIGURE 25-20.** Perineural spread of parotid metastases along the auriculotemporal nerve. **A:** Contrast-enhanced computed tomography (CT) shows a necrotic tumor involving the right parotid gland. **B:** Contrast-enhanced T1-weighted (T1 W) sequence with fat suppression shows the enhancing tumor extending posteriomedially behind the posterior portion of the mandible (*small arrows*) toward V3 (*arrowhead*).

# PART C:
# Radiation Therapy Technique

William M. Mendenhall

The irradiation techniques employed for salivary gland tumors varies with the primary site, histology, and whether the patient is being treated with postoperative irradiation or definitive radiotherapy (RT). Surgery is the preferred initial step in essentially all patients, unless the tumor is incompletely resectable, resection that would be associated with an unacceptable cosmetic or functional deficit, the patient is medically inoperable, and/or the patient refuses surgery.

Patients with pleomorphic adenoma are treated with surgery alone, unless the margins are positive, and/or the tumor is recurrent, and is multifocal. Postoperative RT is unemployed in the latter circumstances; the dose-fractionation schedules are the same as those employed for carcinomas.[1] Low-grade carcinomas, such as low-grade mucoepidermoid carcinomas, are usually treated with surgery alone. Postoperative RT is indicated for positive or close (<1–2 mm) margins. High-grade carcinomas are treated with surgery and postoperative RT. High-grade carcinomas include high-grade mucoepidermoid carcinomas, poorly differentiated adenocarcinomas, salivary duct carcinomas, carcinoma ex-pleomorphic adenomas, and lymphoepitheliomas.[2] Patients with adenoid cystic carcinomas usually are treated with surgery and postoperative RT.[3] An exception would be the patient with a grade I $T_1N_0$ lesion with widely negative margins. Patients with adenoid cystic carcinomas undergo magnetic resonance imaging

**Figure 25-26.** The patient underwent a left parotidectomy and neck dissection for a $T_3N_{2B}$ high-grade mucoepidermoid carcinoma of the left parotid gland. Although a gross total dissection was achieved, margins were microscopically positive. Postoperative IMRT was used to treat the left parotid bed and neck to 74.4 Gy in 62 twice-daily fractions. **A:** Axial dose distribution. **B:** Coronal dose distribution. (See color insert.)

prior to surgery to detect gross perineural invasion. The regional lymph nodes are electively irradiated in patients with high-grade lesions and a clinically negative neck. The ipsilateral neck is irradiated for lateralized primary sites, such as the parotid. Both sides of the neck are treated if the lesion arises in a middle structure, such as the base of tongue.[4]

Parotid carcinomas are treated with a wedge-pair technique; an anterior low neck field is matched to the parotid fields at the level of the thyroid notch if the neck is to be irradiated. Alternatively, intensity-modulated radiation therapy (IMRT) may be employed to reduce the dose to the ipsilateral temporal lobe and cerebellum (Fig. 25-26). Submandibular gland neoplasms may be treated with an ipsilateral mixed beam composed of photons and high-energy electrons. Intensity-modulated radiation therapy may be employed, particularly if there is perineural invasion and it is necessary to irradiate the "at risk" nerves to the skull base. Patients with skull base involvement due to perineural invasion may benefit from treatment with proton beam RT to reduce the dose to adjacent structures, such as the optic nerves and the brainstem.[5,6] The techniques used to irradiate minor salivary gland tumors varies with the site and is similar to those described for squamous cell carcinomas, depending on the risk of regional node involvement and perineural invasion.

Patients are treated at 2 Gy per once-daily fraction to 50 Gy for electively undissected nodal basins, 60 Gy for negative margins, 66 Gy for positive margins, and 70 Gy for gross disease. Alternatively, patients with positive margins or gross disease are treated to 74.4 Gy in 62 twice-daily fractions.

CHAPTER 26

# Primary and Recurrent Disease of the Lateral Skull Base

## PART A:
## General Principles and Management

Esther X. Vivas, Andrew A. McCall, Paul A. Gardner, and Carl H. Snyderman

### INTRODUCTION, NATURAL HISTORY, PATHOLOGY, AND PATHOGENESIS

Lateral skull base malignancy is rare. The lateral skull base is an ambiguous term that denotes the area lateral to the central skull base and is generally congruous with the middle cranial fossa and its adjacent areas. It includes the infratemporal skull base and extends from the lateral cavernous sinus to the temporal bone. It encompasses the temporal bone, petrous segment of the internal carotid artery (ICA), the Eustachian tube, and branches of the trigeminal nerve. The lateral skull base can be approached from multiple directions, each approach requiring a different understanding of complex anatomical relationships.

Carcinoma of the temporal bone, including the external auditory canal (EAC), middle ear, and mastoid, is thought to affect approximately one to six people per million in the United States.[1–3] The true incidence of disease, however, is unknown and varies depending on the publication cited. This problem is compounded by absence of a centralized data-collecting system for temporal bone carcinoma, which is available for other malignancies such as through the Surveillance Epidemiology and Surveillance Results (SEER) database. The SEER database, maintained by the National Cancer Institute, collects information on incidence, prevalence, and survival from specific geographic areas of the US population and reports cancer mortality. Unfortunately, it does not support a category for lateral skull base or temporal bone carcinoma. In addition, there is no standardized staging system for temporal bone cancer. Neither the American Joint Committee on Cancer (AJCC) nor the International Union Against Cancer (IUAC) have published staging guidelines. Currently, the modified University of Pittsburgh staging system (2000) is the most accepted and validated system in use.[3–6]

To date, there is no large prospective study on the treatment and outcomes of lateral skull base malignancies. The bulk of peer-reviewed literature consists of retrospective analyses. As a result, information on incidence and prevalence is dominated by reports of independent institutional experiences. Due to these limitations and the inherent rarity of the disease, some larger studies have reported their experience using pooled data from various tumor histology subtypes.[5]

Overall, primary cancer of the temporal bone is thought to account for <0.2% of all tumors in the head and neck.[7] Squamous cell carcinoma (SCCA) is the most common primary tumor type to affect the temporal bone. In following with the overall incidence of SCCA of the upper aerodigestive tract, temporal bone malignancies affect more men than women. Certain reports, however, have shown an approximate even gender distribution.[8] Caucasians are much more affected than are Blacks and Hispanics. Primary temporal bone cancer typically arises during the fifth and sixth decades of life.

Primary neoplasms of the lateral skull base include cancers that arise from the bone and cartilaginous tissues of the skull base. The lateral skull base is secondarily involved by neoplasms that arise in skin appendages, the parotid glands, the paranasal sinuses, and the nasopharynx and spread along natural corridor tissue planes. SCCA is by far the most common malignancy to affect the temporal bone, though basal cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, and melanoma have all been reported as possible tumor types in adults.[5] Etiology of the disease is not entirely known. For SCCA, correlations with exposure to ultraviolet radiation, frostbite, prior radiation therapy, and even chronic infection have been reported in the literature.[3] Aside from SCCA, reports vary on the next most frequent tumor type, with adenoid cystic carcinoma, adenocarcinoma, or basal cell carcinoma coming in as second depending on the particular study.[3,9–11] In the pediatric population, rhabdomyosarcoma is a rare, but aggressive malignancy that can be encountered in the temporal bone. Basal cell carcinoma is the most common cancer of the pinna and as such is often misleadingly included in reports of primary lateral skull base malignancies. Much more common than primary malignancies of the temporal bone are secondary malignancies from locoregional spread. Upper aerodigestive tract,

(c) 2014 Wolters Kluwer. All Rights Reserved.

parotid gland, and cutaneous cancers comprise the bulk of locoregional disease.

Primary bone and mesenchymal tumors can also affect the lateral skull base. Chordomas are malignant tumors that are thought to arise from embryologic remnants of the notochord. Outside the spine, the clivus is the most common site. These tumors typically present as midline tumors, but can extend laterally to involve the temporal bone and occipital condyles. Chondrosarcomas of the skull base typically arise in the region of the petroclival synchondrosis and have a more parasagittal location than do chordomas. Patterns of growth are similar with concentric destruction of bone and lateral extension to the temporal bone, occipital condyles, and craniocervical junction.

Metastatic disease can involve the temporal bone and lateral skull base. Spread to the temporal bone can occur hematogenously or through meningeal carcinomatosis, which pathognomonically presents with multiple cranial neuropathies. Primary tumor sites that metastasize to the temporal bone can be from the breast, lungs, kidney, stomach, and prostate.[12] When metastatic disease involves the temporal bone, widespread hematogenous metastases to other body sites are often present, and prognosis is poor.

## RELEVANT ANATOMY AND PATTERNS OF SPREAD

The lateral skull base is a complex anatomic structure that houses important neurovascular structures. The temporal bone articulates with the sphenoid, parietal, occipital, and zygomatic bones. It has four main anatomic components: the squamous, mastoid, petrous, and tympanic parts. It has a pyramidal shape and contributes to the lateral skull base. The squamous part forms the lateral wall of the middle cranial fossa. The mastoid portion houses the mastoid air cell system and vertical segment of the facial nerve to its exit point from the skull base at the stylomastoid foramen. The petrous temporal bone contains the petrous portion of the carotid artery, the otic capsule, petrosal nerves, and the internal auditory canal. The tympanic part houses the bony component of the EAC and at its anterior edge forms the tympanosquamous suture line. The posterior edge of the tympanic ring terminates at the tympanomastoid suture line. The medial two-thirds of the EAC is composed of bone and the lateral third is cartilaginous. The bony-cartilaginous junction is the narrowest segment of the EAC. This junction is an important structure as it serves as a potential pathway for spread of malignant disease. Other potential sites of tumor spread beyond the confines of the temporal bone, including the foramen of Huschke and the fissures of Santorini. The foramen of Huschke refers to a defect in the anterior inferior tympanic ring that usually closes by 5 years of age, but persists in 7% of adults.[13] It is a structure that opens into the infratemporal fossa due to incomplete ossification of the anterior bony canal and can allow for tumor extension into the deep lobe of the parotid. The fissures of Santorini are found within the cartilaginous canal and can also allow tumor spread into the parotid gland and periparotid tissues. Nasopharyngeal cancer may spread along the Eustachian tube to gain access to the temporal bone and floor of the middle cranial fossa. Figure 26-1 provides a more comprehensive review of potential avenues for tumor spread. Neoplasms that have a predilection for perineural growth such as adenoid cystic carcinoma and SCCA may track along branches of the facial nerve along its course and extend intratemporally or intracranially. Similarly, perineural invasion by tumor can track along branches of the trigeminal nerve for long distances to reach the middle cranial fossa through Meckel cave or by connections with the facial nerve.

The course of the ICA is a key landmark that defines different surgical approaches to the lateral skull base. The parapharyngeal ICA enters the carotid canal medial to the glenoid

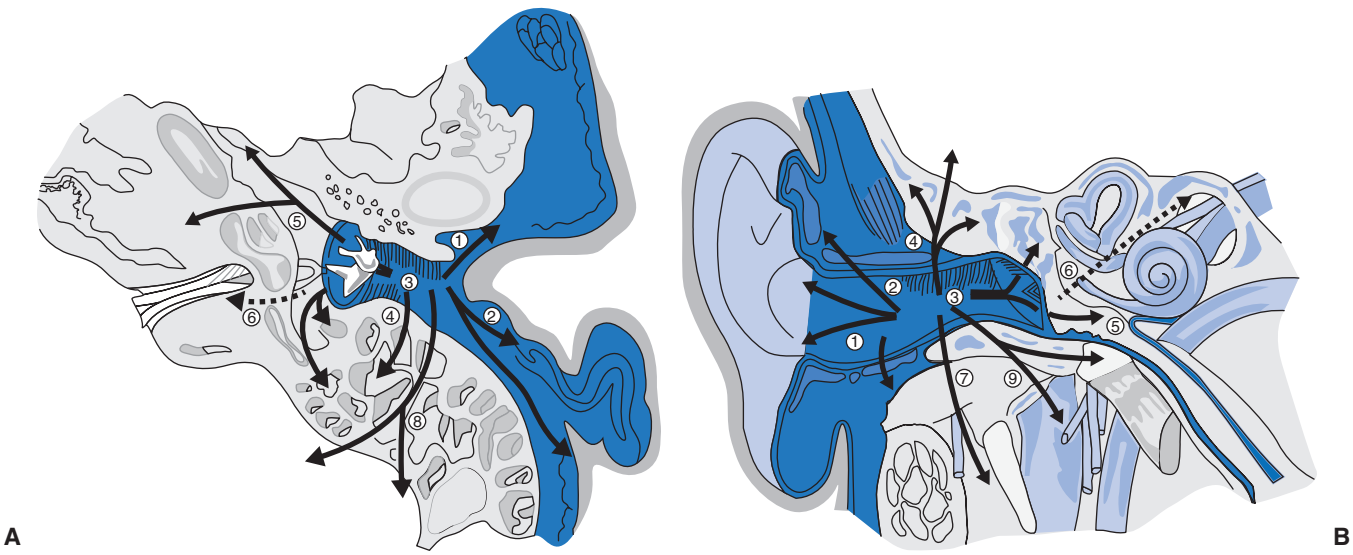

**FIGURE 26-1.** Axial **(A)** and coronal **(B)** temporal bone anatomy, identifying pathways of the spread of cancer. Cancer can spread (1) anteriorly through the cartilaginous ear canal into the parotid gland; (2) through the concha into the postauricular sulcus; (3) through the tympanic membrane into the middle ear; (4) posteriorly into the mastoid; (5) into the anterior mesotympanum to the carotid artery and the Eustachian tube; (6) into the inner ear through the round window or otic capsule; (7) along the facial nerve into the infratemporal fossa; (8) through the mastoid, posterior fossa dura, and sigmoid sinus; and (9) beneath the skull base to the jugular fossa, carotid artery, and lower cranial nerves.

(c) 2014 Wolters Kluwer. All Rights Reserved.

fossa and courses horizontally (in an anteromedial direction) as the petrous segment. The petrous segment of the ICA is situated deep to the Eustachian tube, which runs obliquely across the ICA. Thin bone separates the ICA from the Eustachian tube, measuring about 2 mm at the level of the foramen ovale.[14] The lateral pterygoid plate, foramen ovale, foramen spinosum, and spine of the sphenoid are oriented in a line that is superficial to the Eustachian tube. These are useful landmarks for lateral skull base approaches to the petrous ICA. Medially, the petrous segment continues as the paraclival (vertical) segment at foramen lacerum. The pterygoid canal transmitting the Vidian nerve and sometimes artery is a useful landmark for identifying this second genu of the ICA. The Vidian artery is present in a minority of patients, but the Vidian nerve reliably courses superolaterally over the petrous ICA to join the greater superficial petrosal nerve (GSPN) and deep petrosal nerve. Meckel cave and the trigeminal ganglion are bounded by the petrous and paraclival segments of the ICA, the temporal lobe, and the lateral cavernous sinus (Fig. 26-2). The sixth cranial nerve courses superolaterally behind the midportion of the vertical paraclival ICA to Dorello

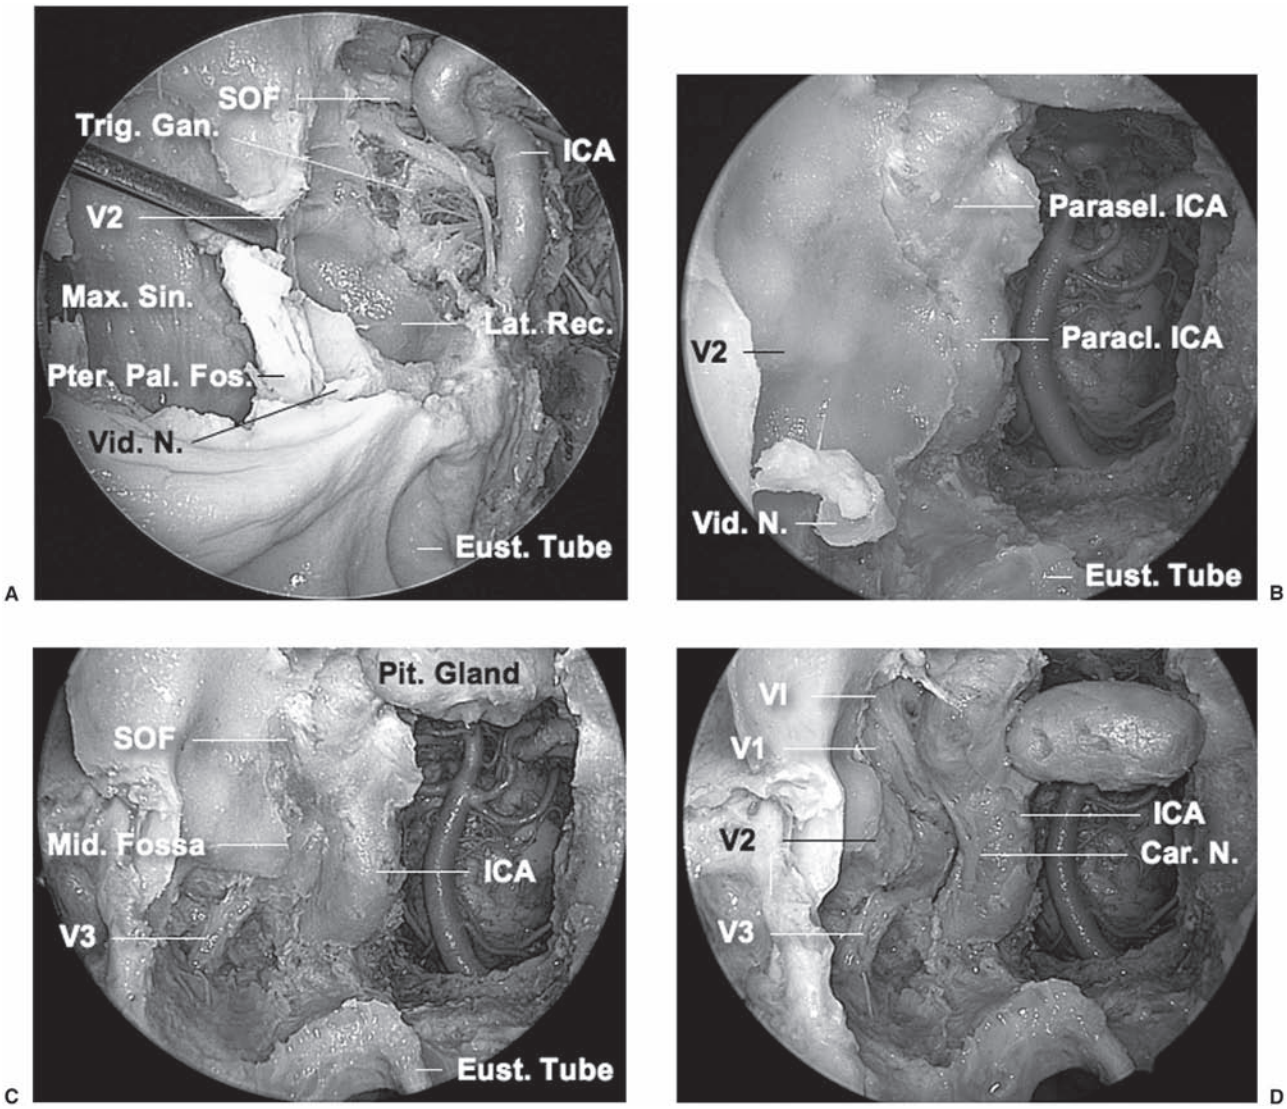

**FIGURE 26-2.** A right-sided Meckel cave approach. **A:** A general overview of the endonasal approach to Meckel cave. **B:** Stepwise approach. **C:** Drilling now continues lateral to the paraclival carotid artery, exposing the dura of the middle fossa. **D:** The dura of the middle fossa has been opened to expose the three branches of the trigeminal nerve. The abducens nerve runs medial to the ophthalmic nerve (V1) from the cavernous sinus to the superior orbital fissure. **E:** Further drilling has been performed at the anterolateral triangle of the middle fossa (between V2 and V3), whereas the osseus covering of the anteromedial triangle has not been removed. **F:** Close-up view of Meckel cave. **FIGURE 26-2.** *Continued*

canal on the superior surface of the temporal bone. It traverses the lateral cavernous sinus just superior to Meckel cave.

The cavernous sinus surrounds the sella and encompasses the cavernous segment of the ICA, the nerves to the extraocular muscles, and the first division of the trigeminal nerve. The nerves are all lateral to the ICA and run in the lateral wall of the cavernous sinus before entering the superior orbital fissure. From superior to inferior, the order of the cranial nerves within the lateral wall of the cavernous sinus is III, IV, and V1. The sixth cranial nerve lies medial to the first division of the trigeminal nerve (V1) and runs obliquely through the cavernous sinus lateral to the ICA after exiting Dorello canal. The cavernous sinus can be divided into four compartments based on the course of the ICA: medial, lateral, postero-superior, and antero-inferior. Tumors of the lateral skull base are more likely to involve the lateral (perineural invasion of head and neck malignancy) and antero-inferior (chordomas, chondrosarcomas) compartments.

## CLINICAL PRESENTATION

The clinical presentation of incident lateral skull base malignancies can be elusive. It can masquerade as a chronic otitis externa or suppurative otitis media. As a result, the diagnosis of temporal bone malignancies is often delayed until the disease is at an advanced stage. An average 6-month delay in diagnosis has been reported.[15] Gidley et al.[5] reported a series of 124 patients with SCCA of the temporal bone, of which 71 had incident disease. Within this group, 62% of the patients presented with otorrhea, followed by otalgia (52%), hearing loss (43%), and facial nerve dysfunction (15.5%). Additionally, a mass can be frequently seen in the EAC on examination.[3] The presence of persistent, deep-seated, unrelenting pain despite adequate treatment for chronic otitis media is an ominous sign and should raise a care provider index of suspicion. This type of pain must be discriminated from other nonmalignant causes; deep otalgia, along with coexistent otorrhea, and abducens nerve palsy is seen with petrous apicitis (Gradenigo syndrome) and deep ear pain that is exacerbated with swallowing or face pain can be seen with Eagle syndrome or geniculate neuralgia, respectively. Spontaneous bloody otorrhea is an unusual presentation of infectious ear disease and as such raises concern for the presence of a more threatening cause. Trismus and pain are ominous signs and indicate tumor extension into the pterygoids and masticator space. Temporal bone carcinoma initially presenting as malignant otitis externa (MOE) has been reported, thus underscoring the importance of early biopsy in suspicious cases.[16] Temporal bone involvement by malignancies of salivary gland origin can present with tumors developing insidiously and relatively asymptomatically, with 75% manifesting with a painless mass and only 6% to 13% manifesting with facial nerve palsy.[17] Chondromatous skull base lesions, chordoma, and chondrosarcoma commonly present with headache and diplopia secondary to abducens nerve palsy. Inferolateral extension can result in dysarthria, hoarseness, dysphagia, and aspiration from involvement of the lower cranial nerves.

Metastatic disease to the temporal bone commonly occurs in the setting of more widespread metastatic disease. Temporal bone metastatic lesions can remain clinically silent when tumor is located within the petrous temporal bone because the otic capsule is relatively resistant to neoplastic invasion. If tumor involves the internal auditory canal, or if the otic capsule is breached, symptoms of hearing loss, dizziness, or facial paralysis may ensue.

Perineural extension to the lateral skull base typically involves branches of the trigeminal nerve and may be associated with facial hypesthesia, or pain, or weakness of mastication (Fig. 26-3). If tumor gains access to the lateral cavernous sinus, diplopia secondary to loss of function of extraocular muscles may develop. Most commonly, decreased abduction from a sixth nerve palsy is observed, but ptosis, pupillary dilation, and restriction of gaze in other directions may result from a third nerve palsy.

## DIAGNOSTIC EVALUATION AND CLINICAL STAGING

As with any malignancy, a thorough physical examination should be the initial phase in the diagnosis and staging algorithm. A complete head and neck examination is performed with microscopy, assessment of cranial nerve function, and palpation of the parotid gland and cervical lymph nodes. The examiner should also look and test for any temporal lobe or cerebellar signs,

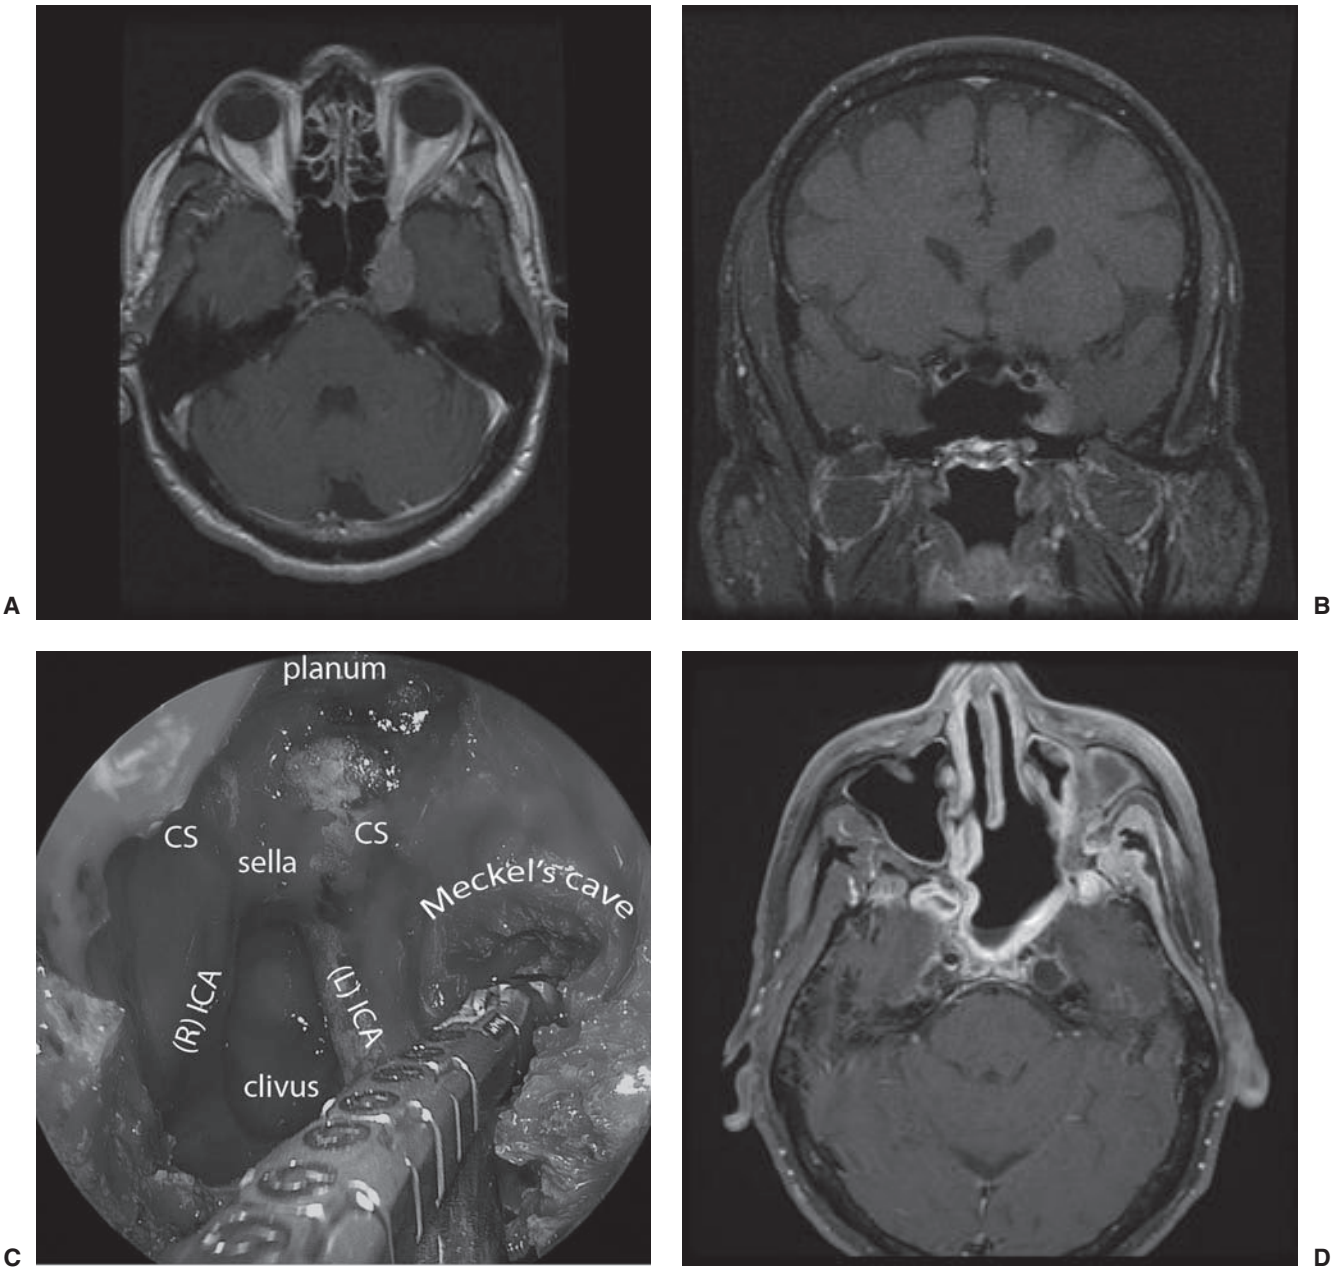

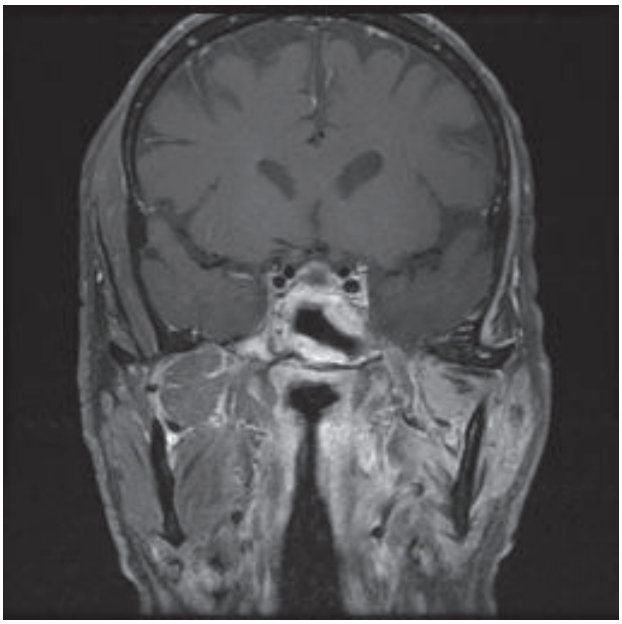

**FIGURE 26-3.** A 59-year-old man with new onset paresthesias in a left V1 and V2 distribution. Preoperative imaging revealed extensive perineural spread of neoplasm along the course of V2 and proximal V3 with tumor extending along the greater palatine nerve, within the pterygopalatine in fossa, and extending along the foramen rotundum and infraorbital nerve and within the Vidian canal. **A:** Preoperative T1 axial scan with gadolinium. **B:** Preoperative T1 coronal scan with gadolinium. Superiorly, tumor extended to the level of the inferior orbital fissure and inferiorly to the level of the foramen ovale. Extensive bulky tumor was noted along the lateral margin of the left cavernous sinus and filling the Meckel cave, with tumor bulging into the prepontine cistern. Endonasal biopsy revealed adenoid cystic carcinoma. The patient underwent a left Caldwell-Luc approach for excision of the infraorbital nerve and a left endoscopic transpterygoid approach to the middle cranial fossa for excision of the carcinoma. Reconstruction consisted of an abdominal fat graft in the Meckel cave and a septal mucosal flap. **C:** Intraoperative image during endoscopic endonasal transpytergoid surgery for resection of adenoid cystic carcinoma with trigeminal nerve involvement in the left Meckel cave. The bone overlying the Meckel cave has been removed, the dura has been incised, and the tumor has been identified and partially resected. Identification of the anatomical landmarks, as specified in the image, is important to proceed with safe tumor resection. **D:** Postoperative T1 axial scan with gadolinium. **E:** Postoperative T1 coronal scan with gadolinium. The postoperative changes reflect debulking of tumor with postsurgical expansion of the left Meckel cave. There is extensive abnormal enhancement within the muscles of mastication on the left most compatible with denervation atrophy. CS, cavernous sinus; ICA, internal carotid artery.

which can be indicative of very advanced disease. New onset seizures likely represent intracranial spread of cancer. A complete audiometric evaluation is required. This provides an objective assessment of the functional status of the middle and inner ear, which is useful during surgical planning and preoperative patient counseling. Conductive losses can be seen with lesions in the external or middle ear, whereas anacusis, tinnitus, and vertigo suggest inner ear involvement.

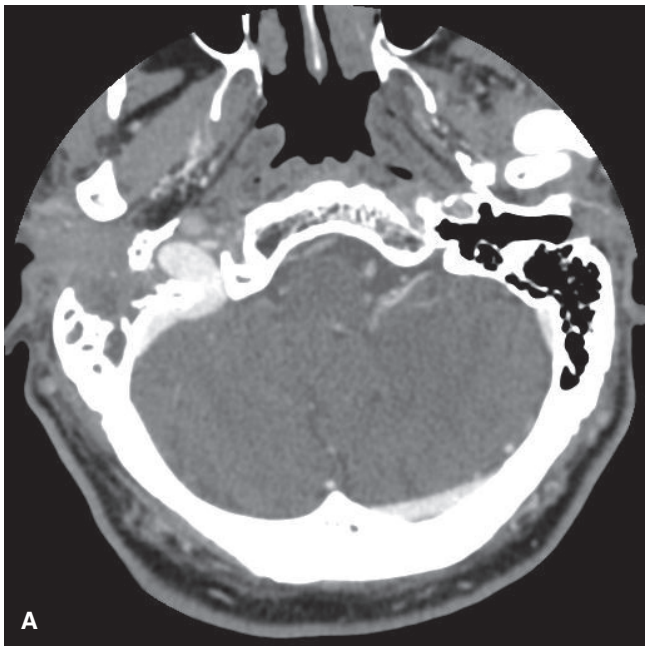
Preoperative histologic confirmation of cancer should be obtained whenever possible. However, aside from lesions found in the EAC, access to tissue for biopsy and diagnosis is limited by the anatomic constraints and relative inaccessibility of the lateral skull base. As a result, radiographic imaging has become an integral part of the diagnosis and staging of these malignancies. CT and MRI provide complementary information for most skull base neoplasms. Arriaga et al. determined that preoperative CT can accurately diagnose the pathologic extent of tumor, but not without limitations.[18] Some limitations include differentiating fluid and inflamed mucosa from tumor in the middle ear or mastoid, as well as distinguishing inflammation from tumor in the absence of adjacent bony erosion.

Fine-cut CT images are used to evaluate the presence and extent of bone erosion, whereas MRI is more apt for evaluation of the soft tissues. CT images should be obtained in axial and coronal cuts with and without contrast. Iodinated contrast is used to evaluate tumor extent, nodal metastasis, carotid involvement, patency of the sigmoid, transverse, petrosal, and cavernous sinuses and to assess for intracranial extension. It is important to evaluate all lymph nodes in the drainage echelon of the lateral skull base, which include the facial, parotid, and jugulodigastric chains. Noncontrast bone window cuts demonstrate the presence of bony erosion or remodeling, two findings reflective of tumor invasion. MRI is optimal for the evaluation of soft tissue invasion, particularly perineural spread. High-resolution T1 and T2 images in axial and coronal planes are essential. T1 sequences should be obtained with and without gadolinium. T1 images are used for spatial relationships and bone marrow involvement, whereas T2 images can help to define differential diagnosis, especially of hyperintense, heterogeneous tumors such as chordomas or chondrosarcomas. Postgadolinium T1-weighted images with fat saturation can help to delineate tumors that enhance brightly and are used for evaluation of perineural involvement, which can manifest as foraminal widening or enhancement, replacement of fat density, or increased signal intensity.[17]

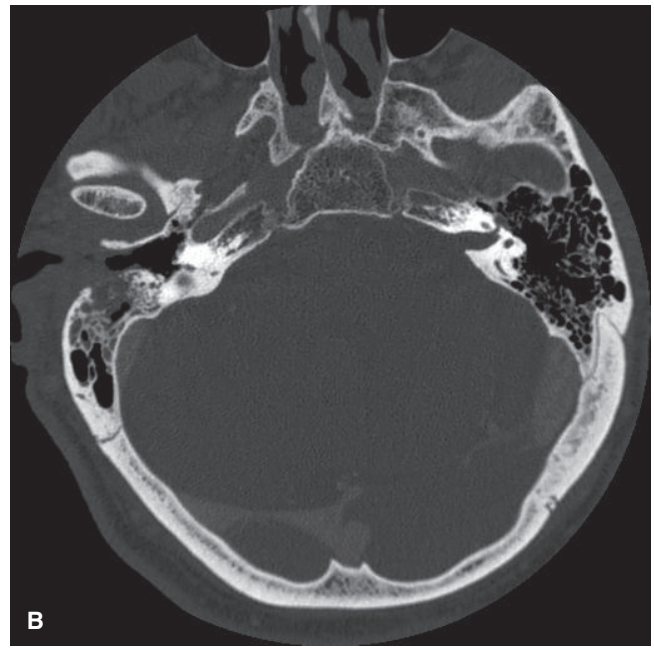
It is important to carefully evaluate known pathways for tumor spread on pretreatment imaging as overlooked tumor spread can result in treatment failure. For example, when assessing the medial extent of disease, special attention is paid to the course of the facial nerve. Proximal invasion can lead to involvement of the geniculate ganglion and greater superficial petrosal nerve, whereas distal spread toward the stylomastoid foramen can involve the digastric and sternocleidomastoid musculature, parotid, or the adjacent skull base. Perineural spread can also occur via cranial nerves V and VIII. As described earlier, the fissures of Santorini and foramen of Huschke are routes to the parotid gland and infratemporal fossa, respectively. Extension via the petrotympanic fissure can reach the carotid canal, carotid artery, and Eustachian tube.

Posterior involvement can affect the sigmoid sinus or jugular bulb and can be seen as sinus or venous compression, occlusion, or thrombosis. CT and MRI are used in conjunction to evaluate for intracranial extension via perineural spread, transdural invasion, and bone marrow invasion. Metastasis from a primary lateral skull base malignancy is rare, but if suspected, a metastatic evaluation consisting of chest radiography and liver function testing is adequate. Positron emission tomography (PET)/CT scanning has made identification of metastasis more accurate. Positron emission tomography imaging can be used as part of an initial metastatic work up and can also be used in posttreatment surveillance for recurrent or persistent disease. It is limited, however, in its ability to differentiate inflammatory and malignant disease. When diagnostic imaging suggests involvement of the carotid artery, preoperative angiography with a balloon test occlusion (BTO) should be considered in preparation for possible ligation during tumor extirpation.[17] Consideration should also be given to embolization when intraoperative hemorrhage is a concern.

Chondromatous neoplasms such as chordoma and chondrosarcoma can be difficult to differentiate radiographically. Both demonstrate bone destruction on CT with varying amounts of calcification. They are heterogeneous on MRI and are characteristically bright on T2-weighted images due to increased water content. The apparent origin, sagittal versus parasagittal, can provide helpful clues as to the suspected origin of the tumor.



Although there have been multiple templates proposed and used over the years to stage primary temporal bone malignancies, the University of Pittsburgh Staging System is the most widely used and accepted. It was proposed initially by Arriaga et al. in 1990[17] and then modified by Moody et al. in 2000.[6] In the modified version, facial palsy was recognized to be a poor prognostic factor and as such placed the patient in T4 status as opposed to T3. Multiple studies have validated the original and modified staging system.[4,5,10] In 2010, Higgins and Moody-Antonio performed a pooled data survival analysis where they demonstrated that preoperative facial palsy carried a significantly worse survival prognosis and therefore validated classification into a T4 status that was reflected in the modified 2000 staging system.[4]



The staging system relies on preoperative CT radiography and uses bone erosion, location of the tumor, soft tissue extension, and facial paralysis as the major factors in determining T status and survival prognosis as outlined in Table 26.1. T1 tumors are those limited to the EAC without bony erosion or soft tissue extension. T2 tumors are also limited to the EAC, but with some bony erosion or for radiographic evidence of soft tissue extension (<0.5 cm). T3 tumors are those with full-thickness bony canal erosion and limited (<0.5 cm) soft tissue extension or if the tumor involves the middle ear and/or mastoid (Fig. 26-4). T4 status is allocated to anyone presenting with facial paralysis.

**TABLE 26.1 University of Pittsburgh Staging System for Squamous Cell Carcinoma of the Temporal Bone**

| Status | Description |
|---|---|
| T status | |
| T1 | Tumor limited to the external auditory canal without bony erosion or evidence of soft tissue extension |
| T2 | Tumor with limited external auditory canal bony erosion (not full thickness) or radiographic finding consistent with limited (<0.5 cm) soft tissue involvement |
| T3 | Tumor eroding the osseous external auditory canal (full thickness) with limited (<0.5 cm) soft tissue involvement, or tumor involving middle ear and/or mastoid |
| T4 | Tumor eroding the cochlear, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen or dura, or with extensive (>0.5 cm) soft tissue involvement; patients presenting with facial paralysis |
| N status | Lymph node involvement is a poor prognostic sign and places the patient in an advanced stage (i.e., T1 N1 [stage III] and T2, 3, 4, N1 [stage IV]) |
| M status | M1 disease is stage IV and is considered a very poor prognostic sign |

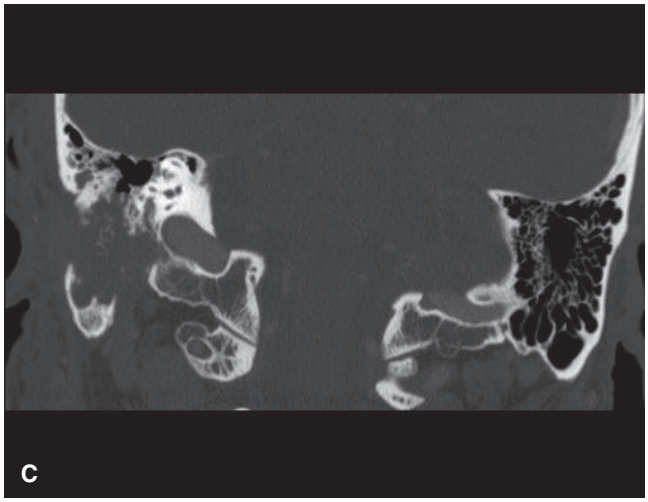

**FIGURE 26-4. A–C:** Axial and coronal CT images in bone and soft tissue windows from a patient with squamous cell carcinoma of the external auditory canal with bony canal erosion on the right. This represents a T3 lesion under the Pittsburgh staging system.

T4 tumors can alternatively involve the cochlea, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen, or dura, or if there was extensive extratemporal soft tissue involvement (>0.5 cm). Lymph node involvement is a very poor prognostic sign and places the patient in an advanced stage as does metastatic disease.

Chondrosarcomas are staged by their histologic appearance and presence of metastases. The histologic grade (scale from 1 to 3) is one of the most important predictors of biological behavior and prognosis and is based on factors such as mitotic rate, cellularity, nuclear size, and staining pattern.[19–21] Low-grade tumors can be very indolent and often have a favorable prognosis.

Assessment of tumor involvement of the cavernous sinus is best done with an MRI scan. This can differentiate displacement of the wall of the sinus from true invasion as well as assess encasement or involvement of the ICA. MRI is also superior for demonstration of perineural extension.

## MANAGEMENT STRATEGIES AND TREATMENT PLANNING GUIDELINES

Surgical resection is the gold standard for primary temporal bone malignancies and is obtained with a lateral temporal bone resection (LTBR), subtotal temporal bone resection, or a total or radical temporal bone resection (Fig. 26-5). Total temporal bone resection is rarely performed because of the high level of morbidity and a lack of well-documented survival benefit, except with specific histology such as verrucous squamous carcinoma, an entirely local and indolent disease.[17] A negative tumor margin at the initial intervention is of paramount importance. Positive margins are associated with a very poor prognosis. An *en bloc* resection is advocated for LTBR. For subtotal and total temporal bones resections, there is still ongoing debate on whether piecemeal as opposed to *en bloc* resection compromises survival. It has been reported that *en bloc* resection of the EAC with surrounding soft tissue structures followed by piecemeal resection of tumor and structures medial to the middle ear provides better operative control and probably does not negatively influence the cure rate.[22,23]

Treatment modality is dictated by the extent of disease, with medial extension indicative of aggressive pathology, and therefore requiring aggressive intervention. Radiation as a single modality is not adequate for the treatment of temporal bone cancer, but is readily used as adjuvant therapy, particularly for advanced tumors. In general, the use of adjuvant radiation should be anticipated whenever the middle ear is involved with disease. The University of Pittsburgh group routinely recommends postoperative radiation of 50 to 60 Gy delivered to the primary site, parotid region, infratemporal fossa, and ipsilateral neck.[23] An exception would be small lesions in the EAC with very limited or no bone erosion and complete surgical resection. As with radiotherapy, chemotherapy is not effective as single modality treatment for these cancers. In general, chemotherapy is usually reserved for palliation in patients with distant metastases or recurrences. The role of chemotherapy is evolving, however. A group of patients treated by preoperative chemoradiation therapy and temporal bone resection had better survival than did patients treated by surgery or radiation therapy alone.[24] A group out of Japan recently reported their experience with superselective intra-arterial cisplatin and radiotherapy for patients with T3 and T4 SCCA of the temporal bone.[25] For those patients who are not surgical candidates because of poor state of health, chemoradiation is offered as a palliative alternative.

Concomitant parotidectomy with selective neck dissection has been increasingly advocated and has become common practice for T1 and T2 lesions, whereas a total parotidectomy is performed for more advanced disease with facial nerve invasion.[6,26] Ideally the parotid is removed *en bloc* with the temporal bone specimen. In regard to the neck, it is well known that lymph node metastasis carries a very poor prognosis. Moffat et al. reported on 39 patients with SCCA of the temporal bone, 9 (23%) had positive nodes in the neck and all died of the disease within 27 months.[27] A supraomohyoid neck dissection is recommended, although the survival benefit is unclear.[23] In the clinical N0 neck, this practice allows for assessment of the first echelon of drainage and assists with staging and determining adjuvant therapy. An additional benefit is to have cervical access and control of the great vessels, should the intraoperative need for control arise.

### T1 and T2 Disease

T1 and selected T2 lesions of the temporal bone should always be treated surgically by an LTBR. A true LTBR is now accepted

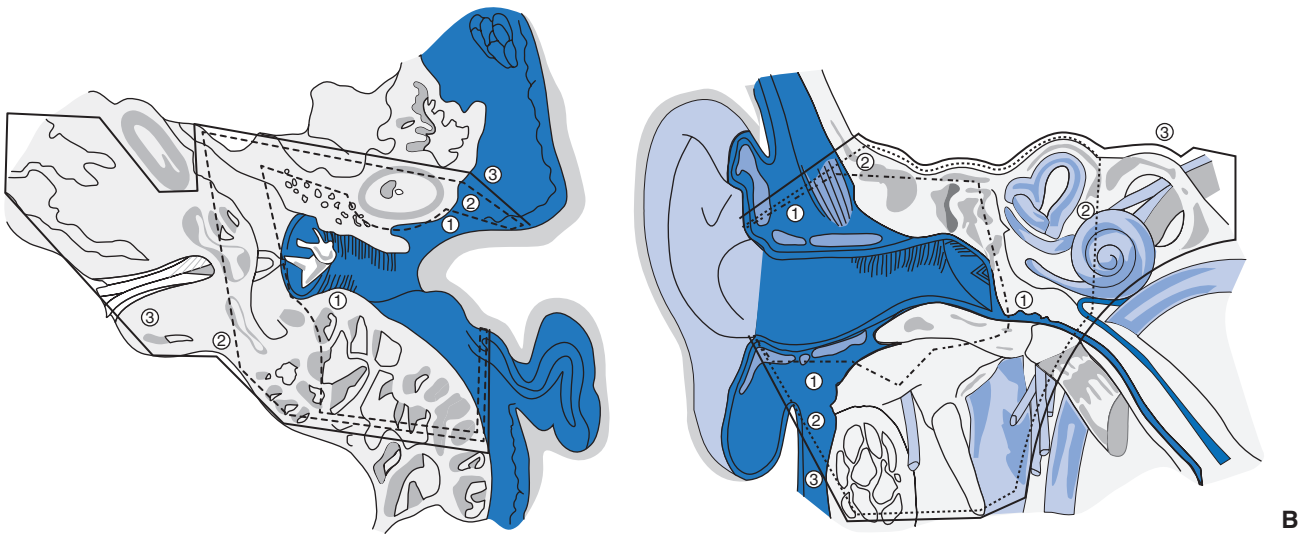

**FIGURE 26-5.** Axial **(A)** and coronal **(B)** illustrations demonstrating (1) lateral resection of the temporal bone, (2) subtotal resection of the temporal bone, and (3) total resection of the temporal bone. The carotid artery is preserved in this illustration.

as the standard of care. In the past, so-called sleeve resections were employed. Sleeve resections became an umbrella term for procedures that ranged from simple transcanal circumferential excisions of canal skin with attached tumor to more extensive resections resembling a modified LTBR. Because of such variability, reports provided a wide range of disease-specific surgical outcomes, complications, morbidity, and mortality. As previously discussed, a superficial parotidectomy with selective neck dissection should be performed in conjunction with an LTBR.

## T3 and T4 Lesions

For lesions that extend to the middle ear or mastoid cavity (T3 or T4), a subtotal temporal bone resection is required. A total or radical temporal bone resection is indicated when disease extends to the petrous apex. A superficial parotidectomy with selective neck dissection should be performed unless the facial nerve is to be resected, when a total parotidectomy is then warranted. Postoperative radiation is advocated, and the results of the lymph node dissection can help guide its use.[6] Zanoletti and Danesi felt that nodal disease can be considered a marker of the aggressiveness of the tumor, and as such a prophylactic selective neck dissection played a role.[26] Adjuvant chemoradiotherapy has been driven by surgeon and institutional experience, and a consensus on its effect on disease-free survival has not been reached.

There is a limited role for surgery for the treatment of high-grade neoplasms with extensive secondary involvement of the lateral skull base. Extension of epithelial cancers to the cavernous sinus, carotid canal, and brain generally makes them unresectable, and primary treatment with radiochemotherapy is preferred with possible surgical salvage. Surgery does play a role, however, in the diagnosis and palliation of these neoplasms. Resectable tumors with perineural extension can be followed to Meckel cave in an attempt to achieve a clear margin. This may provide immediate relief from neuropathic pain and improve the response to radiotherapy.

On rare occasions, sacrifice of the ICA may be considered in order to obtain a clear margin or for palliation of symptoms. Tumors that are in close proximity to the ICA may increase the risk of intraoperative injury and subsequent stroke. Preoperative evaluation of collateral cerebral flow is helpful in determining the best strategy for management of the ICA in such situations.[28,29] If 4-vessel cerebral angiography demonstrates good collateral cross-fill through the communicating vessels, it is likely that the patient, especially if young, would tolerate sacrifice of the ICA without risk of a stroke. Approximately 15% of patients, however, are at risk for a delayed stroke due to watershed areas of ischemia in the distribution of the middle cerebral artery. Preoperative balloon occlusion testing prior to ICA sacrifice can be performed to better stratify patients into high-, intermediate-, and low-risk groups. Cerebral perfusion is assessed using clinical monitoring of neurological function during balloon occlusion and is followed by measurement of cerebral perfusion with CT perfusion or nuclear imaging (single-photon emission computed tomography [SPECT]). Clinical changes in the neurological examination or significant drops in cerebral perfusion on the side of occlusion would generally preclude sacrifice of the ICA without a vascular bypass operation.

# SURGICAL TECHNIQUE

The selection of the optimal surgical approach depends on multiple factors including the diagnosis, extent of disease, age, and comorbidities of the patient, surgical morbidity, prior therapy, and the training and experience of the surgeon. The introduction of endoscopic endonasal approaches to the skull base has added another option (especially for midline tumors with lateral extension), and multiple corridors may be utilized to provide optimal exposure with the least morbidity for the patient. Intraoperative frozen sections are essential and will guide the extent of resection for advanced disease. The following descriptions of surgical techniques have been predominantly adapted from the second edition of Myers' *Operative Otolaryngology: Head and Neck Surgery* book where the details of the dissection are available.[23]

## Temporal Bone Resection

***Lateral Temporal Bone Resection.*** A LTBR removes the conchal meatus, cartilaginous, and bony portion of the EAC and intact tympanic membrane with an attached malleus. Boundaries of resection include the middle ear cavity medially, the TMJ capsule anteriorly, the zygomatic root superiorly, the mastoid cavity posteriorly, and the infra temporal fossa (ITF) inferiorly. Laterally, the resection can include the concha, as well as portions or entire pinna, depending on the extent of the disease. Briefly, a postauricular incision is made 3 cm behind the postauricular sulcus and extended superiorly toward the temporal area, and inferiorly past the mastoid tip, and into the neck to allow for a neck dissection. The skin is raised briefly and dissection is then directed medially through the fibro-periosteal layer, followed by development of a soft tissue flap over the mastoid cortex. This allows for a tight three-layer closure should CSF be encountered. The lateral part of the EAC is sutured closed to prevent tumor spillage. The skin flap is dissected superficially to the deep temporalis fascia, the sternocleidomastoid fascia, and the parotid fascia, until the masseter muscle is identified and the entire parotid gland bed is exposed. At this point, a complete mastoidectomy is performed. The sinodural angle, tegmen mastoideum, posterior bony ear canal wall, and the digastric ridge all need to be well exposed. The lateral semicircular canal is identified and used for orientation. The zygomatic root is drilled to expose the epitympanum and tegmen tympani up to the capsule of the TMJ. The vertical portion of the facial nerve is exposed and followed to the second genu and stylomastoid foramen. The facial recess is then opened and the middle ear inspected for cancer that has penetrated the tympanic membrane. The incudostapedial joint is disarticulated, incus removed, and tensor tympani tendon transected. The facial recess is then extended inferiorly through the chorda tympani nerve to expose the posterior hypotympanum, and the inferior portion of the tympanic ring is drilled toward the anterior wall of the EAC. The limit of this dissection is the periosteum between the temporal bone, the ITF, and the capsule of the TMJ. Once the bony dissection has been completed, the EAC is attached anteriorly by anteromedial section of bone just lateral to the Eustachian tube. An osteotome is inserted through the extended facial recess lateral to the Eustachian tube orifice and with gentle taps, the EAC is dissected from the TMJ capsule. It is important to avoid injury to the ICA with the osteotome. The ICA lies just medial to the Eustachian tube. At this point, the specimen is attached only to the parotid gland, the superficial lobe of which can be removed in continuity with the specimen and the facial nerve preserved. The Eustachian tube should be plugged with the incus and/or a soft tissue plug. If the surgical defect is large and deep, the posterior half of the temporalis muscle can be rotated into the surgical defect and secured with sutures. An abdominal fat graft can also be used to fill part of the cavity. Hemovac drains are recommended.

Further reconstruction options will be discussed later in this chapter.

## Subtotal Temporal Bone Resection

A subtotal temporal bone resection (STBR) is undertaken when cancer has extended medial to the tympanic membrane into the middle ear or mastoid. This procedure can be performed in an

(c) 2014 Wolters Kluwer. All Rights Reserved.

*en bloc* or discontinuous fashion, as previously described. The procedure begins in the same manner as an LTBR. If facial nerve function is normal preoperatively and intraoperative assessment is without evidence of tumor invasion, the surgeon has to decide, based on the extent of the disease, whether the nerve is to be preserved. If the nerve is to be preserved, piecemeal resection of tumor is undertaken, and the facial nerve skeletonized along the labyrinthine, geniculate, horizontal, and vertical segments down to the stylomastoid foramen. The tegmen and posterior fossa plates of bone are thinned and resected piecemeal after dural elevation and sent for permanent section, avoiding dural and superior petrosal sinus injury. Translabyrinthine dissection exposes the IAC and jugular bulb, and if cancer is not present at the jugular bulb, the dissection stops over the bulb. If the facial nerve is to be preserved, the dura of the IAC is opened to allow mobilization of the facial nerve at the porus acusticus. The greater superficial petrosal nerve is transected from the geniculate ganglion, and the facial nerve is gingerly dissected out of the bony canal and mobilized posteriorly. If the facial nerve is to be sacrificed, the IAC dura is still opened and the facial and vestibulocochlear nerves transected. The remaining tympanic ring inferiorly is then drilled to the periosteum of the skull base, which should not be resected unless it is invaded by tumor because it protects vascular and neural structures in the ITF. The mandibular condyle need not be taken if the cancer has not infiltrated into the protympanum. The bone lateral and posterior to the vertical portion of the ICA above the jugular bulb is drilled until the artery from the otic capsule is exposed, at which point the remainder of the otic capsule is drilled. The vaginal process between the jugular bulb and the ICA is also drilled out. At this time, only the petrous apex is left. If cancer involves the lateral wall of the sigmoid sinus and jugular bulb, residual tumor resection can be achieved with an ITF approach similar to the Fisch type A. The subtotal temporal bone resection is completed once dissection and isolation of the internal jugular vein (IJV) and cranial nerves IX, X, XI, and XII in the neck is accomplished.

## Total Temporal Bone Resections

A subtotal temporal bone dissection needs to be completed, followed by proximal control of the ICA at either the skull base or neck, and distal control achieved in the floor of the middle cranial fossa via middle fossa craniotomy. The carotid artery posterior to V3 is exposed so that a clip can be placed for distal control if necessary. The bone lateral to the ICA at the genu is removed, and the ICA is dissected free from its canal from the skull base to the foramen ovale. The petrous apex is drilled to complete the total resection of the temporal bone. The Eustachian tube can be resected anteriorly to the level of the foramen ovale. If cancer is found anterior to this area, nasopharyngeal resection and possibly cavernous sinus dissection may be necessary. In order to prevent CSF rhinorrhea, the transected end of the Eustachian tube should be sutured closed. Should disease involve dura, it needs to be resected and repaired in conjunction with a neurosurgeon, and additional exposure may be necessary via craniotomy. The reader is encouraged to review the classic description by Sataloff and Myers published in 1987 as it offers much more details than what is relayed above.[30] Only minor modifications have been implemented since its publication date.

In terms of reconstruction, consideration should be given to the probable need for postoperative radiation. Small defects of the pinna can be repaired with a split-thickness skin graft. Skin grafts can also be used to line the mastoid and middle ear and sutured to the remaining soft tissue of the meatus. The surgical defect can be partially filled with a vascularized flap such as with temporalis muscle or fat as previously mentioned. A posterior scalp or cervicofacial advancement flap can be used for resections involving the pinna, and this would close the external canal. Alternatives include a lower island trapezius or pectoralis major myocutaneous flap. A free flap with microvascular anastomosis, with rectus abdominis muscle or anterolateral thigh, may be necessary for more extensive defects. A head and neck reconstruction team should aid in this part of the procedure. Facial nerve reconstruction via cable graft should be performed when the facial nerve is sacrificed. The greater auricular nerve, cervical cutaneous nerve, accessory nerve, or sural nerve can be used. Gold weights for corneal protection should be used when the facial nerve has been sacrificed. Should excessive lid edema preclude placement at time of the oncologic resection, a temporary tarsorrophy is performed and the gold weight placed at a later date. Hearing rehabilitation should also be considered in time.

***Infratemporal Skull Base Approach.*** An infratemporal skull base approach provides wide access to the lateral skull base and may be combined with other transtemporal and transfacial approaches. A hemicoronal scalp incision with extension to the preauricular skin crease is made and the scalp is elevated superficial to the cranium and deep temporal fascia. The temporal branches of the facial nerve are preserved by incising the superficial layer of the deep temporal fascia above the zygomatic arch and elevating the fat pad that is superficial to the temporalis muscle with the scalp. Periosteum is elevated from the zygomatic arch and lateral orbit, and the masseter muscle is detached from the inferior margin of the zygomatic arch. The temporalis muscle is elevated from the underlying cranial bone and reflected inferiorly. A frontotemporal craniotomy is performed to provide access to the floor of the middle cranial fossa and facilitate orbitozygomatic osteotomies. The dura is elevated from the orbital roof and a reciprocating saw is used to transect the orbital rim and roof at the margin of the craniotomy. The zygomatic arch is transected at its posterior attachment and a cut is made across the zygomatic bone from the lateral limit of the inferior orbital fissure. The orbital contents are protected while remaining bone is drilled across the orbital walls to connect the bone cuts. The orbitozygomatic bone segment is removed in one piece and saved for reattachment with titanium microplates at the end of the case. If exposure of the petrous ICA is necessary, the bone of the glenoid fossa is included. This requires dissection of the temporomandibular joint capsule. The bone cuts must be placed carefully to avoid injury to the ICA deep to the glenoid fossa and the cochlea posteriorly. A subtemporal craniectomy is then performed with removal of bone up to foramen ovale and foramen spinosum. This provides access to the floor of the middle cranial fossa. If necessary, the mandibular nerve and the middle meningeal artery are sacrificed to gain access to the petrous ICA and the Eustachian tube. The petrous ICA runs deep to the Eustachian tube. The lateral recess of the sphenoid sinus can be accessed between the second and the third divisions of the trigeminal nerve.

***Endoscopic Endonasal Approach.*** Meckel cave can be approached using an endonasal suprapetrous approach (Figs. 26-2 and 26-3). A transpterygoid approach is first performed with exposure of the contents of the pterygopalatine space. The sphenopalatine and palatosphenoidal branches of the sphenopalatine artery are sacrificed and the posterior wall of the maxillary sinus is removed. A wide sphenoidotomy is performed and the landmarks of the lateral sphenoid wall are identified. In a well-pneumatized sinus, the paraclival ICA is visible lateral to the clival recess. The lateral recess is bounded by the foramen rotundum superolaterally and the Vidian canal inferolaterally. The contents of the pterygopalatine space are dissected from the base of pterygoid bone to gain full access to the lateral sphenoid recess. The Vidian nerve is followed to the plane of the petrous ICA, but must be sacrificed to fully access Meckel cave. The Vidian nerve and maxillary nerve

(c) 2014 Wolters Kluwer. All Rights Reserved.

converge on Meckel cave. The bone lateral to the paraclival ICA is carefully drilled to expose the dura. The dura is incised to expose the trigeminal nerve. Foramen ovale with the mandibular nerve is located inferior to the second division and lateral to the paraclival ICA. Meckel cave is bounded superiorly by the lateral cavernous sinus and the cranial nerves V1 (ophthalmic branch of trigeminal) and VI.

## OUTCOMES AND RESULTS

Reports vary a great deal on survival outcomes for temporal bone malignancies. As previously discussed, this is in part due to the lack of a standardized staging system, variable surgical interventions, and the inherent rarity of the disease, thus making it impossible to carry large prospective trials. Most reports are from institutional experiences and consist of relatively small series. In addition, some reports include patients with histology other than SCCA or with cancer that has secondarily involved the temporal bone. Attempts have been made to analyze data that only includes primary SCCA of the temporal bone. Pooled data from various studies has been analyzed by several groups and findings reported in the literature. Brackmann et al.'s analysis noted that T1 lesions successfully treated with surgery alone had a 95% 5-year survival, with no benefit from the addition of radiation. Some T2 and T3 lesions treated with radiation after complete surgical removal showed an 85% 5-year survival. The 5-year survival of patients with more advanced lesions decreased to <50%. Cancer requiring a total temporal bone resection carried a dismal prognosis, with a 50% 1-year survival and reports of 0% 2-year survival.[17] Moody et al. reported a 2-year survival of 100% for T1 lesions, 80% for T2 lesions, 50% for T3 lesions, and 7% for T4 lesions. Survival for T3 tumors was 75% with postoperative radiotherapy, compared with 0% with surgery alone in a series of 32 patients with SCCA. Positive margins decreased survival from 75% to 32%.[7] Chi et al. studied 72 patients with SCCA of the temporal bone. All patients were treated surgically. The 5-year survival for patients with T1 disease was 100%, 67% for T2 disease, 21% for T3 disease, and 14% for T4 disease. In their series, patients with histopathology of poorly differentiated SCCA had significantly worse survival than those with well or moderately differentiated SCCA (0%, 37.5%, and 35.3%, respectively).[10]

In summary, several factors are clearly associated with decreased survival, and they include facial nerve paralysis, positive margins, dural involvement, and lymph node involvement. Goodwin and Jesse felt incomplete resection was the primary cause of failure and that postoperative radiation was of no benefit if the cancer could not be resected completely.[31] Arriaga et al. found that patients with negative pathologic margins had a 63% survival rate compared with 25% in those with positive margins.[32,33] Morris et al. reported on 31 patients with squamous cell cancers of the EAC seen between 1994 and 2010.[6] They felt the strongest negative prognostic factors in the study were neck metastasis, positive surgical margins, and extratemporal spread of disease, especially to the mandible, parotid gland, or brain/dura. The 5-year overall survival was 63.2%, disease-specific survival was 67.7%, and recurrence-free survival was 53.5%. Their 5-year rate of local failure was 33.5%, regional failure 0%, and distant failure 6.3%. The 5-year disease-specific survival was 80.8% in node negative patients, and 18.8% in node-positive patients ($p < 0.0001$). The 5-year survival in node-negative patients was 90.5% versus 29.4% in those with nodal disease. Zanoletti and Danesi reported on 51 patients with SCCA of the temporal bone treated between 1983 and 2004. There was an overall survival of 47% and a disease-specific survival rate of 60% at 5 years of follow-up. The disease-free rate in the positive neck cases was 25% and in the negative neck cases was 70%. All the failures in their study were local recurrences at the primary tumor site.[26]

## COMPLICATIONS

Vascular complications represent the most common risk in temporal bone resection. Hemorrhage from venous structures is not uncommon and can occur from injury to the sigmoid sinus, superior petrosal sinus, inferior petrosal sinus, jugular bulb, or internal jugular vein. Significant bleeding most commonly occurs at the inferior petrosal sinus. The excessive use of packing at the jugular foramen can result in injury to CN IX, X, and XI, so this should be done with caution.[17] The vein of Labbé is an important route of venous outflow from the temporal lobe and, if damaged, can lead to temporal lobe infarction with aphasia, if it occurs on the dominant side. It can be injured where it inserts into the transverse sinus. Seizures can also develop with venous infarct or temporal lobe retraction. Arterial bleeding can occur from injury to the middle meningeal or carotid artery. The middle meningeal can simply be controlled with coagulation, but carotid injury is much more challenging. This can be managed with direct pressure and placement of temporary clips, followed by primary repair. Intra-arterial and systemic heparin should be administered. If the artery cannot be repaired, the surgeon has to decide on the risk of ligating the vessel. Results of the preoperative balloon occlusion test will guide management. Consultation with vascular and neurosurgical services is encouraged.

Cerebrospinal fluid leaks can occur postoperatively and put the patient at risk of developing meningitis. They occur with inadequate closure of the dura, and an existing path for egress into the soft tissues and into the external environment. Typical sites are the Eustachian tube, incision site, and remnant of the EAC. Prevention is maximized with good dural repairs, adequate Eustachian tube plugging, and a water-tight wound closure. Leaks can be managed conservatively with bed rest, head of bed elevation, stool softeners, and a lumbar drain. Should these measures fail, surgical exploration is warranted. Postoperative paralysis of CN IX and X can occur with tumors that extend to the jugular foramen, and this carries high morbidity. These patients suffer dysphagia, vocal cord paralysis, and inability to protect the airway with subsequent aspiration. A tracheotomy may be needed as well as a gastrostomy tube. Aspiration pneumonia carries a high morbidity. Wound infections do not occur more frequently than with other head and neck procedures and are typically managed with local care and antibiotics as needed.

Less common complications include stroke from an emboli on ICA manipulation or repair or from intentional sacrifice. Intracranial bleeding can occur when resection or repair of dura takes place, and this in turn can lead to intracranial hypertension. Management should be immediate and in conjunction with a neurosurgeon.

## MANAGEMENT OF RECURRENCE

Recurrent disease carries a grave prognosis. Local and locoregional recurrences can be addressed on a case-by-case basis. These are typically managed with chemoradiation. Prasad and Janecka reported the site of recurrence in 54 patients to be local in 45, local and regional in 5, regional in 3, and local and metastatic in 1. Salvage surgery is not typically offered for recurrent temporal bone cancers as an attempt to improve survival, but can play a role in palliation. Surgery does have a role in management of recurrent chondromatous neoplasms. Recurrences usually occur in the first 2 to 3 years postoperatively.[3,26]

## SPECIAL ISSUES AND FUTURE DIRECTIONS

As mentioned earlier, primary cancer of the lateral skull base is rare. With lack of a standardized staging system, reporting surgical and survival outcomes is challenging. Transpharyngeal approaches to the parapharyngeal space and infratemporal skull base are being explored in the context of robotic surgery and may provide another corridor for surgical therapy.

# PART B:
# Radiation Therapy Technique

William M. Mendenhall

Malignancies involving the lateral skull base are treated with techniques similar to those described for parotid neoplasms. A wedge-pair technique may be employed; the low neck is irradiated with an anterior field matched at the level of the thyroid notch for those with high-grade malignancies.

Alternatively, intensity-modulated radiation therapy (IMRT) may be used to reduce the dose to the adjacent brain. Proton beam RT may be used to further reduce the RT dose to critical adjacent normal tissues without compromising target volume coverage.

Patients are treated at 2 Gy once-daily to 50 Gy for undissected subclinical disease, 60 Gy for negative margins, 66 Gy for positive margins, and 70 Gy for gross disease. Alternatively, patients with positive margins or gross disease are treated to 74.4 Gy in 62 twice-daily fractions.

CHAPTER 27

# Paragangliomas of the Head and Neck

## PART A:
## General Principles and Management

Spiros Manolidis, Kenneth S. Hu, and Mark S. Persky

### INTRODUCTION

Paragangliomas represent highly vascular neoplasms that embryologically arise from the paraganglia of neural crest origin and most commonly occur in the head and neck region. These tumors are closely associated with either blood vessels (carotid artery, jugular bulb) or nerves (vagus, tympanic plexus), and their clinical presentation may involve a wide spectrum of signs and symptoms. A slowly enlarging neck mass and/or findings consistent with cranial nerve dysfunction are the hallmarks of presentation. A familial history of these tumors may be present, and there is a significant incidence of multicentric tumors, both in familial and sporadic cases. Malignant paragangliomas are uncommon and their diagnosis can only be confirmed by the presence of metastatic disease, usually within regional lymph nodes. There are no strict histologic criteria within the primary tumor that can differentiate between benign and malignant paragangliomas.

Computed tomography (CT) and magnetic resonance imaging (MRI) usually establish the diagnosis. $^{111}$Indium pentetreotide imaging can also be used to evaluate paragangliomas, define multiple tumors, and detect the possible presence of metastatic disease.[1] Angiography defines the vascular supply and may visualize vessel involvement (invasion) and paves the way for preoperative embolization, if surgery is contemplated.

Paragangliomas are highly vascular, and they characteristically have early blood vessel and neural involvement, in addition to skull base and potential intracranial extension. These factors all contribute to the challenging nature of effectively treating these tumors. Traditionally, surgery has been the preferred method of treatment, especially with the evolution of more sophisticated skull base approaches, safer embolization protocols, and advanced vascular bypass procedures.[2,3] Postoperative cranial nerve dysfunction is anticipated in patients with tumors characterized by early neural involvement, larger tumors, and skull base involvement, therefore, a focus on rehabilitation efforts is necessary.

Radiation therapy was traditionally relied upon for treating unresectable paragangliomas or tumors in elderly or debilitated patients. However, advances in radiation oncology and long-term experience have demonstrated high tumor control with low rates of chronic complications, such that primary radiation treatment of paragangliomas has assumed a prominent role in treatment algorithms.

### ANATOMY AND PHYSIOLOGY OF PARAGANGLIA

Paraganglia are part of a system of cell clusters that facilitate the baroreceptive and chemoreceptive reflexes of the cardiovascular system. They are diffusely distributed throughout the upper body. They contain cells that are capable of secreting neuropeptides that have the capability to influence vascular reflexes.

These structures are part of the diffuse neuroendocrine system (DNES) and are either neural crest origin cells or neuroectodermally derived. The former, neural crest derivatives, produce the C cell of the thyroid gland, the melanocyte, and the paraganglia. Paraganglia are found in the adrenal medulla or diffusely distributed as the extra-adrenal paraganglia.[4,5] The diffusely distributed extra-adrenal paraganglia are divided into branchiomeric paraganglia and vagal paraganglia. The branchiomeric are distributed along arteries and cranial nerves in the head and neck. The jugulotympanic paraganglia arise from the second branchial arch, whereas the carotid paraganglia arise from the third branchial arch. The intravagal paraganglia do not follow this embryologic pharyngeal pouch distribution and are thus classified separately. Even so, unusual paraganglioma locations have been recorded that do not fit this classification: larynx, orbit, thyroid, nasal cavity, and sinuses, as well as intracranial (Fig. 27-1).[6]

The carotid body is a chemoreceptor that senses changes in arterial oxygen pressure, pH, and carbon dioxide. Along with the cardiac and aortic bodies, these are the only chemoreceptors in

(c) 2014 Wolters Kluwer. All Rights Reserved.

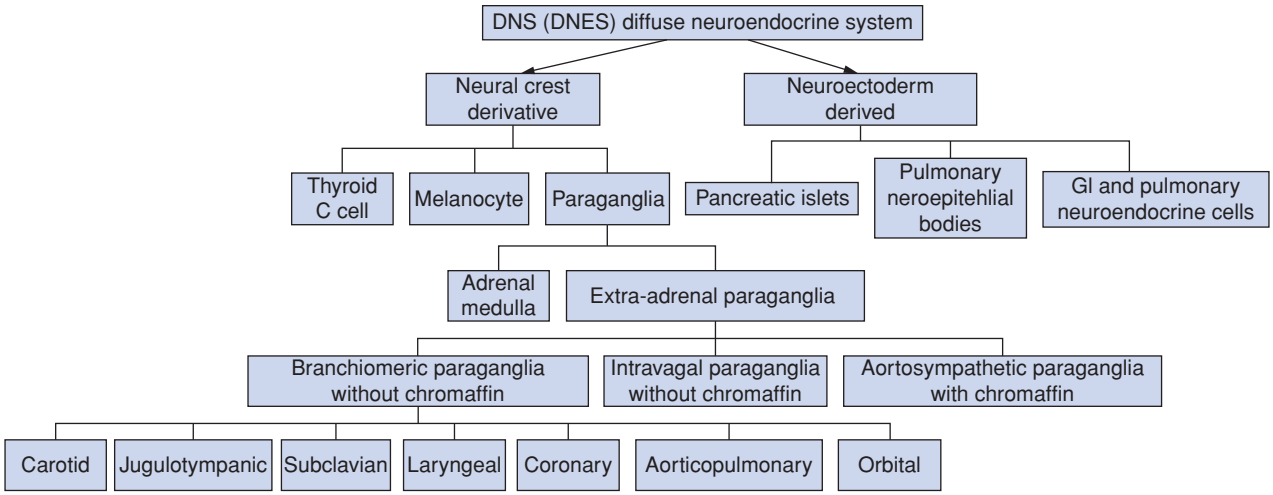

**FIGURE 27-1.** Classification of the diffuse neuroendocrine system. GI, gastrointestinal.

the paraganglia. The carotid body is a discrete oval structure situated behind the carotid bifurcation and receives blood supply directly from the carotid bifurcation via the glomic arteries. The afferent reflex is mediated by a branch of the glossopharyngeal nerve (nerve of Hering) (Fig. 27-2).[7]

The jugulotympanic paraganglia are distributed within the temporal bone in close association with the tympanic branch of the glossopharyngeal nerve (Jacobson nerve) and the auricular branch of the vagus nerve (Arnold's nerve). The majority of the temporal bone paraganglia are located in the jugular fossa and the rest are located in the bony canal that transmits Jacobson's nerve or in the submucosa of the tympanic cavity. There is a marked difference in the clinical behavior of tumors arising from the jugular paraganglia versus the tympanic paraganglia, a fact that has significant therapeutic implications (Fig. 27-3).[8]

The vagal paraganglia are distinctly different from the jugulotympanic paraganglia. They do not form discrete bodies and are incorporated within the vagus nerve underneath the perineurium or interspersed within the vagal nerve fibers in the pars nervosa of the jugular foramen (which transmits the lower cranial nerves IX, X, and XI). The superior vagal ganglion is found at the level of the jugular foramen. The nodose vagal ganglion lies just below the jugular foramen. Both ganglia are in close proximity to cranial nerves IX through XII, the pars venosa of the jugular foramen, as well as the ascending portion of the petrous internal carotid artery (ICA).[9] Thus, vagal paragangliomas have distinct therapeutic implications based on their close association with the superior portion of the vagal nerve and their adjacent neurovascular structures.

The microanatomy of normal paraganglia is that of clusters that contain chief cells (type I cells) surrounded by sustentacular cells (type II). These clusters are interspersed by a web of blood vessels. The equivalent structures seen in paragangliomas are termed Zellballen cells, and they retain part of this structural arrangement. The sustentacular cells do not secrete catecholamines and are similar in nature to the Schwann cells enveloping autonomic ganglia. The chief cells have abundant secretory granules—typical of secreting cells. The biochemistry of paraganglia chief cells is characterized by catecholamine production.[10] This sequence is characterized by enzymatic conversion of tyrosine to dopamine, norepinephrine, and epinephrine. Extra-adrenal paraganglia lack the methyltransferase required for the conversion of norepinephrine to epinephrine. The metabolic breakdown of catecholamines to metanephrine (from epinephrine) and normetanephrine (from norepinephrine), as well as vanillylmandelic acid (VMA), each can be detected in the urine. Actively secreting paragangiomas can, therefore, be detected with appropriate urine and serum analysis (Fig. 27-4).

## PARAGANGLIOMA EPIDEMIOLOGY AND PATHOPHYSIOLOGY

### Incidence

Paragangliomas are neoplasms of the paraganglia. Paragangliomas of the head and neck are rare tumors, comprising about one in 10,000 of all tumors in the head and neck area excluding intracranial tumors. A review by the surgical pathology department at Memorial Sloan-Kettering Cancer Center showed an incidence of head and neck paragangliomas accounting for 0.012% of all head and neck tumors.[11] The annual incidence of extra-adrenal paragangliomas is estimated at 1 in 300,000.[12] The carotid body is the most common site for paraganglioma. Carotid body tumors and jugulotympanic tumors account for approximately 80% of these, and vagal paragangliomas add another 5%. Nasal, orbital, laryngeal, and other head and neck sites are much more rare.[13] Significant referral pattern distortions make these numbers less reliable. Multiple paragangliomas are present in up to 22% of all patients with a paraganglioma, and these are frequently hereditary in nature with a family history of such tumors.

### Multicentricity

Approximately 10% of sporadic cases will have a concurrent second paraganglioma.[14–16] Multicentricity may be present in up to 22% of those with a genetic predisposition. The most common pattern of a synchronous secondary paraganglioma is a second carotid body tumor, and occurrence is present in 20% of carotid body tumors. Bilateral carotid body tumors, as well as an additional paraganglioma ipsilaterally or contralaterally present significant and challenging treatment problems due to the potential for cranial nerve deficits and loss in baroreceptor function, which results in labile hypertension.[17–19] Multiple tumors may be metachronous, and this has implication for surveillance for

patients with a paraganglioma. Since multicentric tumors may be metachronous, routine follow-up MRI, $^{111}$indium pentetreotide (Octreoscan$^{R}$) or (18)F-DOPA positron emission tomography imaging is indicated.

## High Altitude

Other than genetics, the only known predisposition for a paraganglioma is high-altitude living associated with chronic hypoxemia. Several studies show that there is an increased incidence of these tumors with high-altitude living, a 9-fold increase for those living between 2 and 3 km and 12-fold increase for those living between 3 and 4.5 km above sea level. Patients forming these tumors at higher altitude show a lower rate of bilaterality and a lesser degree of familial history of paragangliomas.[20–22] Rodriguez-Cuevas et al. reported a retrospective analysis of 120 cases of carotid body tumors occurring in inhabitants living at a high altitude (>2,200 m above sea level). As compared with cases occurring in populations living below 1,500 m above sea level, they noted a higher female predominance (8.3:1 vs. 2:1), a lower rate of bilaterality (5% vs. 10%–20%), and a less frequent familial history (1% vs. 7%–25%).[23] High-altitude paraganglioma has a prevalence of up to 1 in 10 in humans and 1 in 2 in bovines compared with an estimated 1 in 500,000 prevalence in humans at low altitudes.[24,25] A higher incidence of carotid body hypertrophy and carotid body tumors has also been noted in patients with chronic obstructive pulmonary disease, perhaps related to chronically low $pO_2$ levels.[26]

## Functioning Paragangliomas

Approximately 1% to 3% of paragangliomas secrete catecholamines. A five-fold increase in catecholamines is sufficient to produce symptoms. Symptoms consistent with a functioning tumor are tachycardia, excessive sweating, weight loss, and hypertension. Secreting paragangliomas account for approximately 2% of all instances of secondary hypertension. Twenty-four hour urine collection in these patients will show elevated levels of the catecholamine metabolites, metanephrine, and VMA. Serum catecholamines will show elevated levels of norepinephrine in functioning extra-adrenal paragangliomas. Elevated serum epinephrine is indicative of a concurrent pheochromocytoma.[6,27] Paraganglioma familial syndrome subtypes 1 and 4 (PGL1 and PGL4) are associated with a higher incidence of concurrent pheochromocytoma. Conversely, multiple endocrine neoplasia type IIA (pheochromocytoma, medullary thyroid carcinoma, and parathyroid hyperplasia) and type IIB (pheochromocytoma, medullary thyroid carcinoma, parathyroid hyperplasia, and mucosal neuromas) are associated with head and neck paragangliomas.[28]

## Malignant Variant

Malignant paragangliomas represent a small subset of extra-adrenal paragangliomas that have a propensity for regional lymph nodes and distant metastatic disease, primarily to the lungs, liver, and bones. Sporadic paragangliomas have a higher rate of malignancy than familial type paragangliomas, except for PGL4 syndrome that is associated with a rate of malignancy as high as 54%, and importantly, the likelihood is site specific. Orbital and laryngeal paragangliomas have the highest rate of malignancy, approximately 25%. With vagal paragangliomas, the rate is up to 10%, followed by jugulotympanic paragangliomas with a malignancy rate of 5%, and carotid body tumors being last at 3% to 6%. Unfortunately, there are no histologic criteria by which primary tumor malignancy can be diagnosed, and that determination depends on tumor present in lymph nodes or distant metastatic sites. The presence of malignancy has profound implications in the treatment of these tumors.[29–31] In a review of 43 cases of malignant carotid body tumors, the best locoregional control was achieved by primary resection combined with neck dissection, and followed by adjuvant radiation therapy. The interval to recurrence is long, ranging from 20 months to 20 years.[32]

## Genetics

Overall, germline mutations can be identified in approximately 30% of patients with head and neck paragangliomas.[33,34] Familial glomus tumors constitute approximately 20% of affected patients, for which the genetic defects are known. One subgroup (10% of all glomus tumors) appears to be caused by sporadic mutations in SDHB and SDHD.

Hereditary susceptibility to paragangliomas, mainly of the head and neck region, was recognized at least two decades ago, and led to the identification through linkage analysis of three loci on chromosomes 11 and 1, named PGL1 on 11q23, PGL2 on 11q11.3, and PGL3 on 1q21–23. Following the discovery of succinate dehydrogenase (SDH) subunit D gene (*SDHD*) as the gene responsible for PGL1 in familial head and neck paragangliomas, it was thereafter recognized that two other subunits of this mitochondrial enzyme, SDHC (PGL3) and SDHB (PGL4, 1p36) were associated with heritable pheochromocytoma and/or paraganglioma. To date, the gene for PGL2 has not been identified.[20,35–38]

At present, causative gene mutations are identified in about 32% of paragangliomas-pheochromocytomas.[39] In the hereditary tumor syndromes: MEN2A, MEN2B, Von Hippel-Lindau and NF-1, in which a pheochromocytoma or paraganglioma presents, a causative gene mutation is seen in 17% of cases. Within the mitochondrial SDH complex, paragangliomas account for 15% of mutations.

The molecular basis for tumorigenesis in paragangliomas resides in mutations, germ line, and somatic for the most part in the genes that control SDH. The product of these multiple genes is a 4-dimer protein that catalyzes succinate to fumarate in mitochondria as the first step of oxygen-dependent glucose breakdown via the respiratory pathway. The enzyme is composed of 4 dimers, namely, SDHA, SDHB, SDHC, and SDHD, and is anchored in the internal bilipid membranes of the mitochondria. SDHA and SDHB are the proteomic components that anchor the enzyme in the membrane, while SDHC and SDHD are the proteomic components that catalyze the reaction from succinate to fumarate. This reaction is crucial to entering glucose breakdown from anaerobic to aerobic metabolism.[34] SDH or succinate-ubiquinone reductase is the complex II of the mitochondrial respiratory chain located in the mitochondrial matrix. SDH couples the oxidation of succinate to fumarate in the Krebs cycle with electron transfer to the terminal acceptor ubiquinone, thus leading to the generation of ATP.[40]

SDH is an enzyme complex composed by four subunits encoded by four nuclear genes (*SDHA*, *SDHB*, *SDHC*, and *SDHD*). *SDHC* (cybL, 15 kDA, 169 amino acids) and *SDHD* (cybS, 12 kDa, 159 amino acids) subunits are hydrophobic and provide membrane anchor and the binding site for ubiquinone. *SDHA* (flavoprotein, 70 kDa, 664 amino acids) and *SDHB* (iron–sulfur protein, 27 kDa, 280 amino acids) are hydrophilic, with the former involved in substrate binding and oxidation and the latter in electron transfer. Both *SDHB* (35.4 kb, 8 exons) and *SDHC* (50.3 kb, 6 exons) genes are located on chromosome 1, in the short and long arm, respectively. *SDHD*, located on 11q23.1, spans 8.9 kb and contains four exons whereas *SDHA* lies on the short arm of chromosome 5 (5p15) and is composed of 15 exons spread in a genomic region of 38.4 kb. Whereas homozygote germline mutations affecting *SDHA* cause Leigh syndrome, a subacute necrotizing encephalomyelopathy during infancy, *SDHD*, *SDHB*, and *SDHC* heterozygous mutations cause a genetic

(c) 2014 Wolters Kluwer. All Rights Reserved.

predisposition to head and neck paragangliomas and adrenal/extra-adrenal pheochromocytomas.[41] This inherited tumorigenic predisposition is transmitted in an autosomal dominant fashion with age-dependent and incomplete penetrance. However, for *SDHD* located on chromosome 11q, a parent-of-origin effect is revealed as the disease is manifest almost exclusively when the mutation is transmitted from the father. A maternal imprinting has therefore been postulated, but despite the pattern of inheritance, *SDHD* shows bi-allelic expression in normal tissues and neural crest-derived tissues.[20,31]

All of these genes are tumor-suppressor genes showing loss of heterozygosity (LOH): the loss of the normal allele in the tumor, in conjunction with germline mutation. This results in loss of a protein subunit that destabilizes the SDH complex and alters or abolishes its enzymatic activity.[42]

Inactivation of the SDH complex leads to a hypoxic state with accumulation of succinate resulting in the stabilization of HIF1a (hypoxia-induced factor 1a). Oxygen normally facilitates the degradation of HIF1a through prolyl hydroxylases. As oxygen levels decline HIF1a enters the nucleus and initiates the transcription of a host of genes known to be involved in tumorigenesis, including Vascular endothelial growth factor (VEGF).[43] VEGF and platelet-derived endothelial growth factor (PD-ECGF), as well as endothelin-1, has been found in the majority of specimens examined. It has been postulated that this was consistent with a paracrine mechanism for tumor development.[44,45]

Recent hypotheses for the mechanism of a tumorigenesis link a decrease in apoptosis and the activation of a pseudohypoxic pathway via these mechanisms.[46] This peudohypoxia is known as the Warburg effect and is the basis for tumor imaging by F-16 PET/FDG.[47]

***Paraganglioma Syndrome 1: SDH Subunit D.*** SDH Subunit D (SDHD) is the second anchoring peptide for mitochondrial complex II in the inner mitochondrial membrane. The gene resides at 11q23 and was the first mitochondrial gene to be linked to tumorigenesis.[20] The proportion of mutation carriers at *SDHD* gene that will develop a tumor is 87% to 100% (very high penetrance).[48] *SDHD* is responsible for PGL1 syndrome. Patients with PGL1 commonly have multifocal tumors and very rarely malignant ones. Maternal imprinting (absence of disease transmitted by the mother) suggesting sex-specific epigenetic modifications.[34] Higher altitudes in SDHD/PGL1 patients show increased phenotypic severity as well as increased likelihood of developing a pheochromocytoma.[49] In a similar manner, nonsense/splicing mutations show earlier presentation of head and neck paragangliomas as well as increased incidence of pheochromocytomas.[48] It has been proposed that *SDHD* is a critical component of a cellular oxygen-sensing system. Mutations in *SDHD* may incapacitate the oxygen-sensing mechanism, leading to an apparent or real hypoxic state accompanied by chronic hypoxic stimulation and cell proliferation. Support for hypoxia-induced hyperplasia comes from evidence obtained in high-altitude physiological studies. Cows, guinea pigs, rabbits, and dogs experience carotid body hyperplasia when living at high altitudes, which exposes them to a hypoxic condition, and this has also been described in humans. Another clinical observation lending support to these theories is the finding that patients suffering from conditions resulting in hypoxemia, such as cystic fibrosis, cyanotic heart disease, and chronic obstructive pulmonary disease, experience carotid body hyperplasia, and those suffering from chronic obstructive pulmonary disease have a higher rate of carotid body tumors.[20,21,35–38]

***Paraganglioma Syndrome 2: SDH Assembly Factor 2.*** SDH Assembly Factor 2 (SDHAF2) is essential for the correct flavination of *SDHA* and thus the function of the SDH complex.[40] This is referred to as the PGL2 locus. Mutations in SDHAF2 have been described to produce only head and neck paragangliomas, and these make a small contribution to the genetic burden of this condition.[50] *SDHAF2* gene maps to chromosome 11q13 and as with the *SDHD* mutations there are parent-of-origin effects on expression, such that tumor development only occurs after paternal inheritance. A striking aspect of mutations on *SDHAF2* is the very high level of penetrance and the development of tumors at an early age.[40]

***Paraganglioma Syndrome 3: SDH Subunit C.*** SDH Subunit C (SDHC) is one of two peptides anchoring mitochondrial complex II in the inner mitochondrial membrane. The gene resides at 1q23.3. Only 10 index cases of families with head and neck paragangliomas have been identified worldwide.[51] It accounts for <1% of all head and neck paragangliomas and is responsible for PGL3 syndrome.[39]

***Paraganglioma Syndrome 4: SDH Subunit B.*** SDH Subunit B (SDHB4) is the iron sulfur protein catalytic subunit of complex II. The gene resides at 1p36.1-p35.[52] It has been identified as the susceptibility gene for PGL4 (paraganglioma syndrome 4—OMIM: #115310). Patients with head and neck paragangliomas due to mutations of *SDHB* gene show a high rate of malignancy at 20% to 54%. These mutations have a low level of penetrance of 25% to 40%.[21,40,53] Only 37% of *SDHB* mutation–positive index cases report a family history at presentation.[34] *SDHB* is known to be a significant cause of adrenal pheochromocytomas.

## Succinate Dehydrogenase Subunit A

SDHA is a flavoprotein and the main catalytic subunit of SDH. Head and neck paragangliomas had not been associated with mutations in the gene for SDHA. However, recently a patient with an SDHA mutation and a catecholamine-secreting abdominal paraganglioma was described.[54] Congenital deficiency due to homozygous recessive mutations of *SDHA* gene have been described, and these patients are severely affected with early cardiomyopathy, but no development of paragangliomas.[52,55,56] Other *SDHA* mutations produce Leigh syndrome, a mitochondrial encephalopathy.[55] These mutations are generally missense.[52] It has been postulated that complete loss of *SDHA* function as would occur with a truncating mutation would not be compatible with life.

Neurofibromatosis type 1 is also associated with both pheochromocytomas and jugulotympanic paragangliomas. Pheochromocytomas are also associated with multiple endocrine neoplasia type II with *RET* gene mutations, and with Von Hippel-Lindau syndrome and mutations in *VHL* gene.

In patients with successive generations of a family harboring the mutations, tumors develop at progressively younger ages. This finding is a good example of genetic anticipation, in which the mutation appears to be more severe with succeeding generations.

***Succinate Dehydrogenase Complex Assembly Factor 2 (SDHAF2).*** This protein is responsible for the addition of the flavin–adenine dinucleotide (FAD) prosthetic group to form the SDHA flavoprotein. Studied mutations in the gene that codes for SDHAF2 show that this is related to high penetrance for head and neck paragangliomas.[20]

In summary the genetic associations in these paraganglioma syndromes are as follows:

- Patients with paraganglioma develop tumors at a younger age than sporadic cases
- In PGL1, PGL2, and PGL3, the genetic transmission is autosomal dominant, with highly variable expressivity and reduced penetrance. Genomic imprinting is seen in PGL1: the

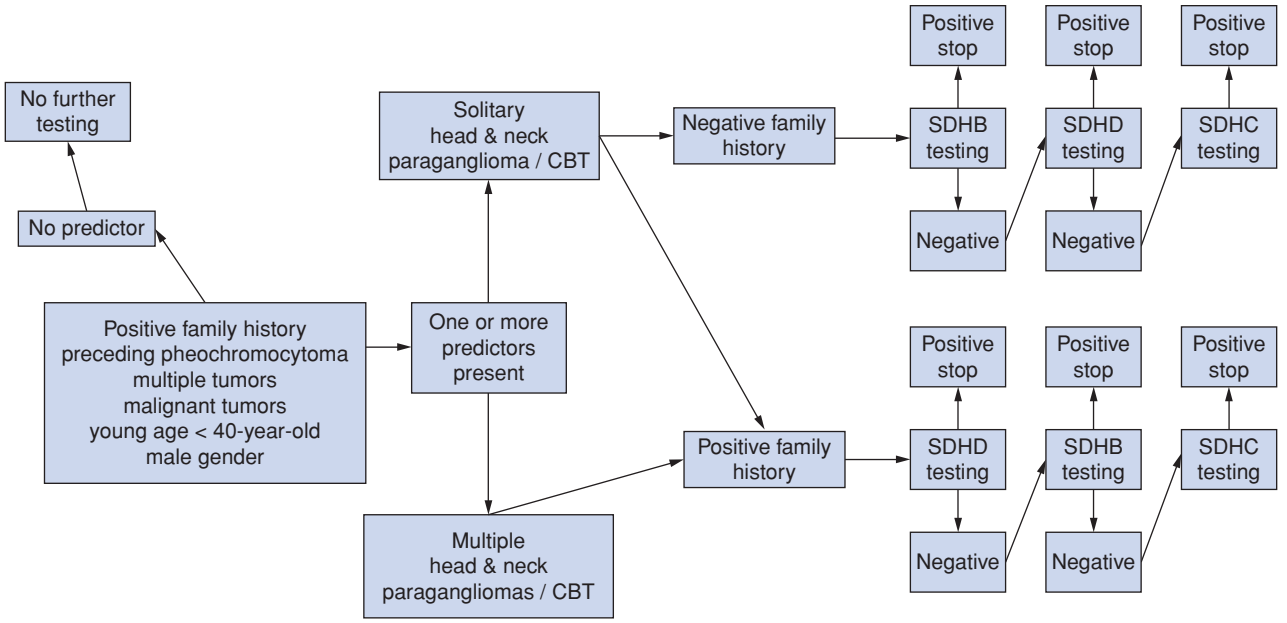

**FIGURE 27-5.** Algorithm for genetic testing for patients with head and neck paraganglioma. CBT, carotid body tumor.

paternally transmitted genes lead to tumor development and the maternally transmitted gene gives carrier status without developing tumors

- PGL1 and PGL4 show multicentricity and pheochromocytomas
- PGL1 has a high degree of penetrance whereas PGL4 shows moderate penetrance
- PGL4 shows a marked increase in malignant paragangliomas
- PGL3 present exclusively as benign paragangliomas with no multifocality and has no association with pheochromocytomas
- Other tumor syndromes: Neurofibromatosis type 1, MEN type 2, and Von Hippel-Lindau predispose to paragangliomas

## Genetic Testing

Head and neck paragangliomas are associated primarily with PGL1, PGL3, and PGL4 syndromes which correspond to the SDH genes: *SDHD*, *SDHC*, and *SDHB*. Multiple endocrine neoplasia and Von Hippel-Lindau that can be associated with head and neck paragangliomas correspond to the *RET* and *VHL* genes, respectively. In one study, these five genes produce 25 at-risk exons and the cost of testing all five was estimated at US$4,100/patient.[57] The same study developed an algorithm on the basis of clinical/history predictors for efficient genetic testing in head and neck paragangliomas (Fig. 27-5) (Table 27.1).

**TABLE 27.1 Genetics of Paraganglioma: SDH- and SDH-related Genes**

| Gene | Locus | Protein | Mechanism | Syndrome | Anatomic Location |
|---|---|---|---|---|---|
| SDHD | 11q23 | Membrane anchoring Protein of complex II | Autosomal dominant | Paraganglioma Pheochromocytoma | Head and neck |
| SDHB | 1p36.1–p35 | Iron sulfur catalytic Subunit of complex II | Autosomal dominant | Paraganglioma Pheochromocytoma | Abdominal thoracic paraganglia adrenal |
| SDHC | 1q23.3 | Membrane anchoring Protein of complex II | Autosomal dominant | Paraganglioma Pheochromocytoma | Head and neck |
| SDHA | 5p15 | Flavoprotein catalytic subunit of complex II | Autosomal recessive | Mitochondrial encephalopathy Leigh syndrome | Systemic |
| SDHAF2 | 11q12.2 | Assembly factor 2 for SDHA | Autosomal dominant | Paraganglioma Pheochromocytoma | Head and neck |
| SDHAF1 | 19q11.12 | Assembly factor 1 for SDHB | Autosomal recessive | Infantile leukoencephalopathy | Systemic |

## CLINICAL PRESENTATION AND CLASSIFICATION

The clinical presentation(s) of paragangliomas is (are) location specific. As these tumors enlarge, they tend to produce cranial neuropathies. Additionally, secreting tumors can produce hypertension, tachycardia, sweating and nervousness, secondary to catecholamine release.

### Carotid Body Tumors

Carotid body tumors typically present as a slowly enlarging asymptomatic deep neck mass at the level of the carotid artery bifurcation. In a small minority of patients, pain is present around the tumor. Because of the association with the carotid artery, the tumors are laterally mobile, but are cephalic-caudally fixed on examination. As the tumor enlarges, a bruit may be detectable and parapharyngeal extension can result in the lateral displacement of the soft palate. Cranial nerve paralysis symptoms are unusual and present in very large tumors with superior extension toward the jugular foramen. Shamblin's classification is commonly used to stage carotid body tumors and though this is based on intraoperative findings, it can be applied to radiologic findings prior to treatment (Table 27.2) (Fig. 27-6).

**TABLE 27.2 Shamblin's Surgical Classification of Carotid Body Tumors**

| | |
|---|---|
| Type 1 | Relatively small tumor with minimal attachment to the carotid vessels |
| Type 2 | Larger tumor with moderate attachment to carotid vessels, but resectable with preservation of the carotid vessels |
| Type 3 | Tumor encases the carotid vessel requiring arterial sacrifice with reconstruction |

### Jugulotympanic Paragangliomas

Jugular and tympanic paragangliomas occur predominantly in the fifth and sixth decades of life with an overwhelming female predominance. They are slow growing and their pattern follows pathways of least resistance in the temporal bone and surrounding skull base structures. Although tympanic and jugular paragangliomas differ in presentation in the early stages, both types produce similar symptoms related to consistent cranial nerve deficits in their later stages. Tympanic paragangliomas present early with pulsatile tinnitus and conductive hearing loss. Tympanic membrane exam suggests a red-blue middle ear mass that blanches with positive pressure on pneumatic otoscopy (Brown's sign). With subsequent growth, there is expansion in the middle ear cleft and ossicular erosion. Extension through the tympanic membrane produces an ear canal polypoid mass that can spontaneously produce bloody otorrhea. Extension to the mastoid can occur through a number of pathways. Involvement of the facial nerve (usually in the mastoid) can produce paralysis as a presenting sign. Anterior growth toward the pericarotid air cells can involve the petrous carotid artery and occupy the Eustachian tube. Medial growth into the infralabyrinthine air cells can reach the petrous apex and petroclival area, as well as cavernous sinus. Intracranial extension is possible with extension through the jugular foramen and/or petrous apex. More infrequently, there is involvement of the otic capsule and the inner ear with attendant sensorineural hearing loss and vertigo at presentation.

Because of their site of origin within the jugular bulb, jugular paragangliomas have the capacity for early and extensive skull base invasion with involvement of cranial nerves IX through XII.

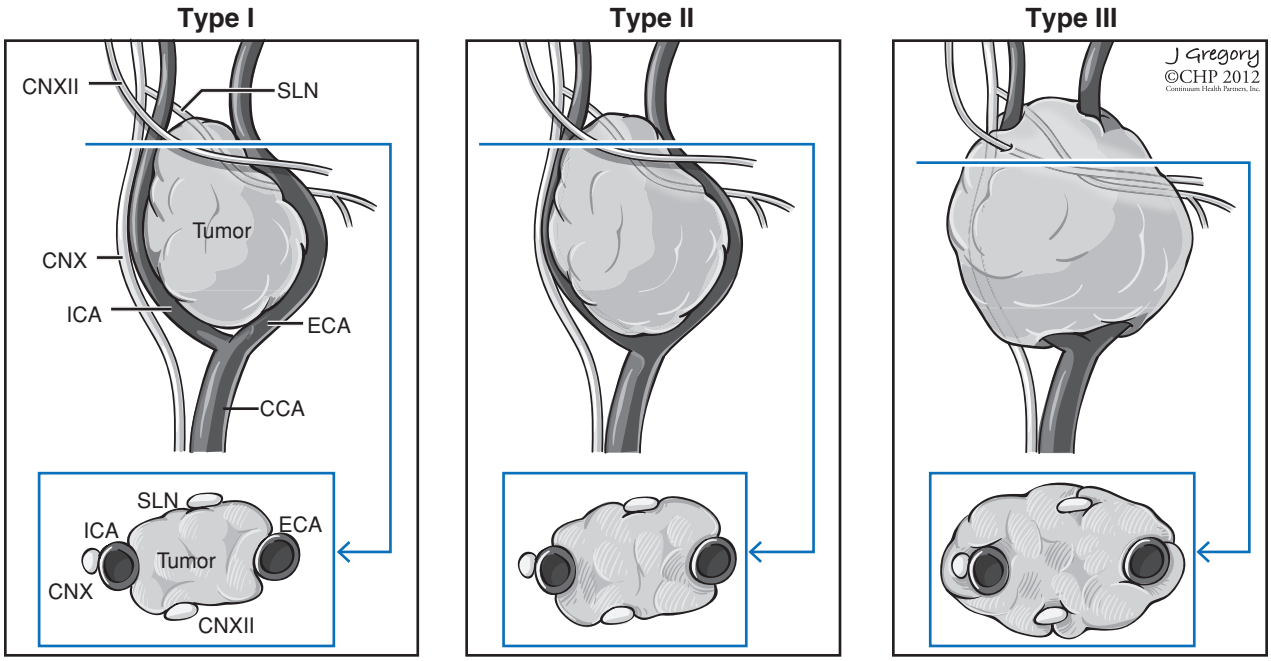

**FIGURE 27-6.** Shamblin's classification of carotid body tumors. CCA, common carotid artery; CN, cranial nerve; ECA, external carotid artery; ICA, internal carotid artery; SLN, sentinel lymph node.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Growth through Jacobson nerve canal and the hypotympanic air cells leads to involvement of the middle ear and mastoid bone leading to conductive hearing loss, tinnitus, and facial paralysis. Intracranial involvement through the jugular foramen is frequent. Erosion of the jugulocarotid spine leads to involvement of the vertical petrous carotid artery, and further anterior extension leads to involvement of its horizontal portion. More medial extension to the infralabyrinthine air cells lead to involvement of the petrous apex. Further medial extension along this pathway leads to involvement of the clivus and cavernous sinus. Occasionally, jugular paragangliomas will escape the confines of the temporal bone and involve the infratemporal fossa and parapharyngeal space. Lower cranial nerve involvement is frequent and ranges from 38% to 58%.[58,59] Multiple cranial nerves are frequently involved in Vernet syndrome (paralysis of CNs IX, X, and XI) or Collet–Sicard syndrome (paralysis of CNs IX, X, XI, and XII). In at least 10% of jugular paragangliomas, one of these sequences is present (Fig. 27-7). The attendant symptomatology is hoarseness, swallowing difficulty, hemipalatal dysfunction with nasal air escape, shoulder motion restriction, and dysarthria due to tongue hemiparalysis. Two surgical classification systems are in wide use today. Both can be used preoperatively based on radiographic findings. The Fisch classification system makes no distinction between tympanic and jugular paragangliomas and is predicated on detailed patterns of progressive disease extension, whereas the Glasscock-Jackson system treats tympanic and jugular paragangliomas differently[27,58] (Tables 27.3 and 27.4).

Vagal paragangliomas account for 5% of all head and neck paragangliomas and originate in that nerve where the paraganglia are diffusely distributed in the superior, middle, and inferior vagal ganglia. There is a female preponderance of 3:1. Tumors originating superiorly will often present with a dumbbell appearance, with an intracranial component in the posterior cranial fossa. Tumors originating inferiorly will extend into the poststyloid compartment of the parapharyngeal space. Vagal paragangliomas are frequently associated with multiple cranial neuropathies at presentation in up to 50% of patients. The vagus nerve is affected most commonly, followed by the hypoglossal and the spinal accessory nerves (Fig. 27-8).[60]

## WORKUP FOR PARAGANGLIOMAS

Patients presenting with signs and symptoms of a paraganglioma should undergo a thorough history and physical examination to evaluate cranial nerve dysfunction, evidence of signs and symptoms related to catecholamine secretion, and signs of malignant

transformation. Attention should be focused on a familial history of paragangliomas, MEN type 2, and Von Hippel-Linday syndromes. Genetic testing for PGL gene should be done if there is a positive family history, and other members of the family should be screened for paragangliomas.

Twenty-four-hour urine screening as well as serum catecholamine screening for norepinephrine, epinephrine, and their metabolites should be performed to exclude a functioning tumor. A fine-needle biopsy is not indicated in most tumors because the radiographic studies are virtually diagnostic.[17,18,27,61]

## DIAGNOSTIC IMAGING STUDIES

### Computed Tomography

CT with contrast is an excellent imaging choice for the diagnosis and delineation of paragangliomas. Since these tumors are highly vascular, early and intense contrast enhancement is seen. The relation of the tumor to the external and internal carotid arteries, as well as the jugular vein makes this modality essentially diagnostic.[62] The delineation of the pattern of invasion of the temporal bone and skull base is indispensable in treatment, especially preoperative planning. Carotid body tumors display the characteristic splaying of the internal and external carotid arteries by a circumscribed mass occupying the carotid bifurcation. These tumors displace the ICA posterior and laterally. Vagal lesions typically displace the ICA anteriorly and occupy the high parapharyngeal space, with or without involvement of the skull base. Jugulotympanic paragangliomas can be distinguished in their early phases, especially when a tympanic paraganglioma is confined to the tympanic cavity. Characteristic patterns of bone destruction occur with jugulotympanic paragangliomas. These include erosion of the jugulotympanic spine, enlargement of the jugular foramen with bone destruction, and involvement of the middle ear and mastoid.[62,63] Multiplain reconstruction of high-resolution CT scans—axial, sagittal, and coronal—is of great assistance in the planning of operative management of these tumors. Middle ear and/or Eustachian tube involvement will create obstructive fluid accumulation in the aerated spaces of the temporal bone, including the mastoid (Fig. 27-9).

### Magnetic Resonance Imaging

MRI is a complementary and equally important imaging modality in the evaluation and treatment of head and neck paragangliomas. MR with gadolinium contrast serves three purposes: delineation of the tumor in question, surveillance and detection of concurrent paragangliomas of the head and neck, and confirmation of the diagnosis of paraganglioma. The classic, "salt and pepper" appearance of paragangliomas on T2-weighted images is due to the high-flow vascular voids that are essentially pathognomonic. Paragangliomas show intense signal enhancement with gadolinium contrast.[64] Fat-suppressed sequences are exceptionally useful in delineating the extent of the tumor. Patterns of carotid artery displacement can be accurately determined distinguishing carotid body tumors from vagal paragangliomas.[64] More importantly in tumors with intracranial extension, intradural versus extradural involvement can be appreciated, and the relationship of the tumor to important intracranial structures can be delineated. Specialized techniques such as MR angiography and contrast time-of-flight three-dimensional angiography increase the sensitivity of the diagnosis of concurrent tumors, but do not supplant selective angiography in the preoperative planning setting (Figs. 27-10 and 27-11).[65,66]

## Angiography

With the evolution of detailed MR and CT techniques, angiography plays a much more limited role in the diagnosis of head and neck paragangliomas, but is still very important in preoperative planning of these tumors. Angiography provides a detailed map of tumor blood supply and venous drainage, demonstrates the tumor-flow dynamics, and details the general vascular anatomy of the head and neck and intracranial space. Importantly, four-vessel cerebral angiography provides qualitative and quantitative flow studies of the cerebral circulation. This angiographic information creates the ability and access for the preoperative preparation provided by superselective embolization of the feeding arterial supply to the tumor. Bleeding is thus decreased intraoperatively.

Arterial supply of carotid body tumors is derived directly from the feeding vessels to the carotid body that is typically hypertrophied in the presence of a tumor.[27,58,67] Arterial supply of jugulotympanic tumors is well defined when these tumors are early in their development and invariably involves the ascending pharyngeal artery. As these tumors grow, they recruit additional blood supply that comes from the internal carotid circulation via the caroticotympanic arteries. With invasion of the posterior fossa and medial extension of the tumor toward the cavernous sinus, additional vascular recruitment is possible through the posterior circulation by means of the vertebral arteries through the clival anastomoses, as well as the cavernous sinus microcirculation. This is especially important in the preoperative embolization of these tumors. Assessing tolerance to interruption of the ICA is of paramount importance for extensive paragangliomas

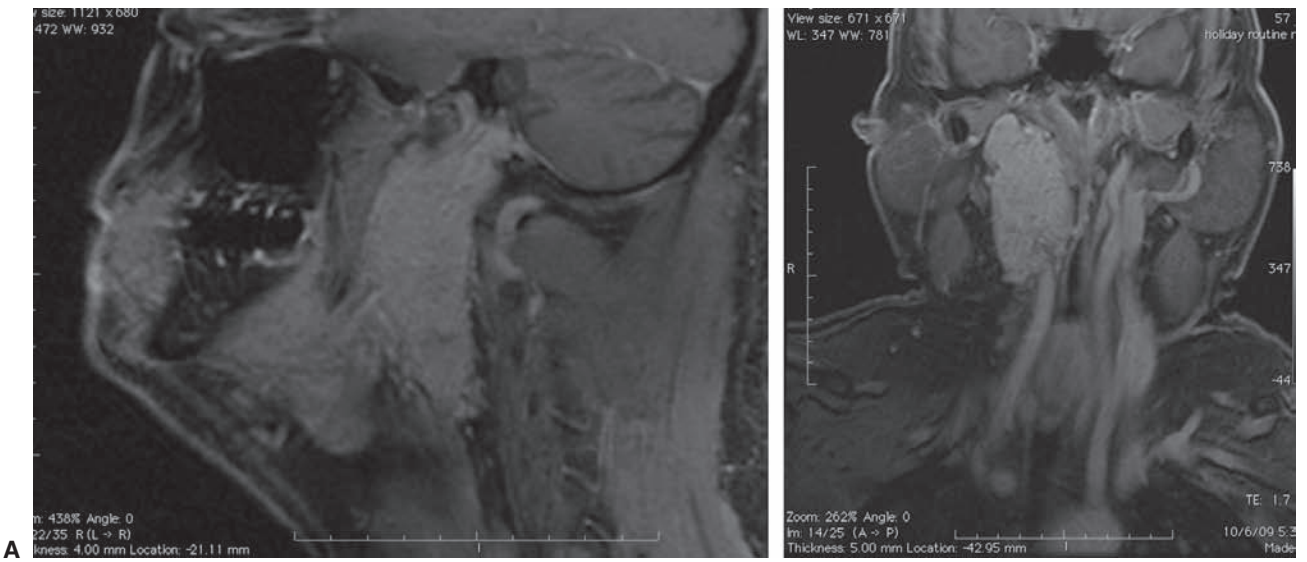

**FIGURE 27-11.** Vagal paraganglioma. Sagittal **(A)** and coronal **(B)** enhanced fat-suppressed T1-weighted images demonstrate typical rostrocaudal growth. The internal carotid artery is displaced anteriorly.

that involve the ICA because of its vulnerability to injury during surgery, or where a planned internal carotid resection is contemplated. An angiographic balloon occlusion test involves the use of a femoral-artery-introduced catheter guided ultimately into the internal carotid, which is temporarily occluded usually at the carotid siphon within the cavernous sinus. This helps to determine whether there will be neurologic deficit.[17,19] During occlusion, several methods of neurologic monitoring testing can be utilized. In order of decreasing sensitivity, they are clinical neurologic examination, electroencephalography (EEG), and quantitative blood-flow examination through xenon CT concurrent examination. Xenon CT angiography is a precise quantitative study with the best sensitivity, but is rarely available and cumbersome (Fig. 27-12).[68,69]

## Radionuclide Imaging

Radionuclide imaging of paragangliomas targets the biochemical pathways of catecholamine synthesis, storage, and secretion by chromaffin tumor cells. A variety of different imaging techniques exist: $^{123}$I-metaiodobenzylguanidine (MIBG), $^{18}$F-3,4 dihydroxyphenylalanine ($^{18}$F-DOPA-PET), $^{18}$F-fluorodopamine ($^{18}$F-FDA-PET), $^{18}$F-fluoro-2-deoxyglucose ($^{18}$F-FDG-PET), and Indium octreotide scanning ($^{111}$In-octreoscan).[70,71]

Different functional imaging agents target paraganglioma tumor cells through different mechanisms. $^{123}$I- and $^{131}$I-labeled MIBG and $^{18}$F-FDA are actively transported into neurosecretory granules of catecholamine-producing cells via the vesicular monoamine transporters after uptake into cells by the norepinephrine transporter. In contrast, $^{18}$F-DOPA enters the cell via the amino acid transporter, a biochemical phenomenon based on the capability of paraganglioma and other neuroendocrine tumors to take up, decarboxylate, and store amino acids along with their biogenic amines. Instead of targeting catecholamine pathways, $^{18}$F-FDG enters the cell as the glucose transporter, and its accumulation is an index of increased glucose metabolism. While $^{111}$In octreoscan images indicate somatostatin type 2 receptors that are expressed in paragangliomas.[17,18]

$^{111}$Inoctreoscan specificity and sensitivity is approximately 90% in head and neck paragangliomas, a fact that makes it a very effective screener for secondary tumors as well as a postoperatively screen for recurrent disease when structural studies like CT and MRI may be compromised. $^{123}$I-MIBG shows similar sensitivities and specificities. Malignant and metastatic paragangliomas are best imaged with $^{18}$F-FDG-PET, which shows sensitivities of 74% to 88%.[17,18]

It is increasingly understood that there is a link between genotype-specific tumor biology and imaging. For example $^{18}$F-FDG-PET has an excellent sensitivity for paragangliomas due to *SDHB*-associated mutation. The *SDHB* gene encodes for subunit B of the mitochondrial SDH complex II that catalyzes the oxidation of succinate to fumarate in the Krebs cycle and feeds electrons to the respiratory chain, which ultimately leads to the generation of ATP (oxidative phosphorylation). Higher glucose requirements for anaerobic metabolism explains the increased $^{18}$F-FDG uptake by malignant *SDHB*-related paragangliomas.[71]

# TREATMENT

Surgical resection has been the traditional treatment for paragangliomas of the head and neck. Microsurgical skull base techniques such as the Fisch infratemporal fossa approaches were developed to specifically resect temporal bone paragangliomas (Fig. 27-13). The refinement of these elegant surgical techniques, especially when aided by preoperative embolization, have significantly reduced morbidity and have minimized mortality associated with surgery. However, with complete tumor extirpation, lower cranial nerve resection or inadvertent injury to the lower cranial nerves can result in significant morbidity affecting phonation and deglutition, along with the risk for aspiration.

Radiation therapy—initially used only for the treatment of unresectable tumors or for surgical treatment failures—has become an established treatment modality in untreated lesions and has been incorporated into the treatment algorithms for head and neck paragangliomas. External beam radiation, intensity-modulated radiation therapy, and, more recently, stereotactic radiation, all have been used with excellent results.

In deciding what modality of treatment to select, the following factors should be taken into account: the patient's age and

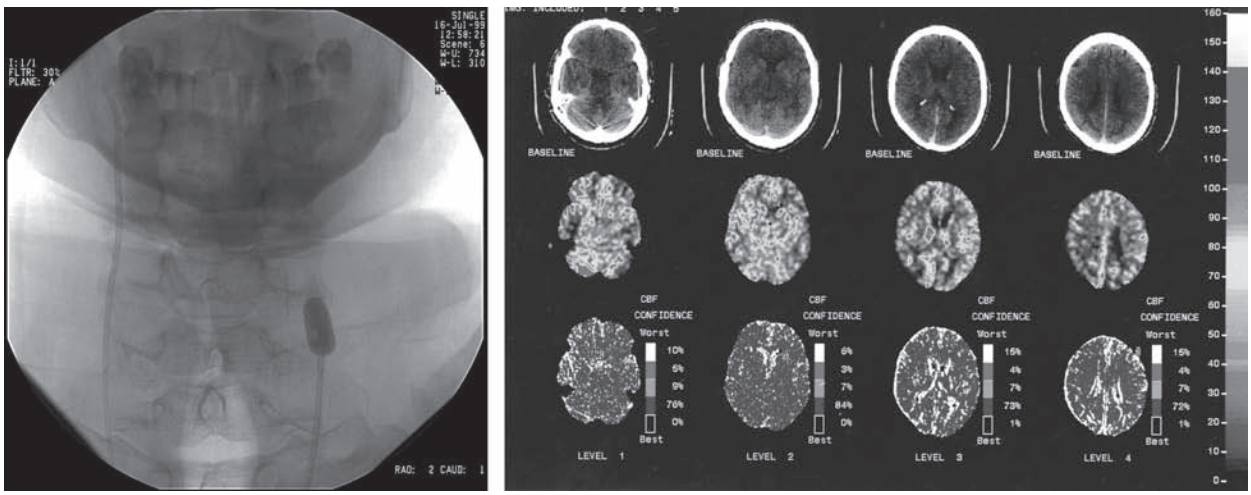

**FIGURE 27-12.** Balloon occlusion testing. **A:** Frontal angiographic image shows the inflated radiodense balloon in the proximal left internal carotid artery, occluding flow. **B:** Quantitative cerebral blood flow images created by inhaling xenon gas during dynamic CT. medical comorbidities, the type of paraganglioma in question (vagal, tympanic, jugular, carotid body), the presence of concurrent paragangliomas, the extent of the tumor, as well as any preoperative cranial nerve deficits, whether partial or complete. When surgery is contemplated, the availability of a surgical team with experience in lateral skull base methods, as well as an experienced interventional neuroradiology team, is sought.

## SURGERY

Preparation for surgery requires angiographic evaluation for most paragangliomas. Anesthesia requirements should take into consideration tumors that may be actively secreting catecholamines, which will require alpha and beta adrenergic blockade. Continuous arterial pressure monitoring is required, and transfusions may be necessary. Central venous pressure monitoring may be required depending on the underlying comorbidities.

### Angiographic Evaluation

Superselective angiography is invaluable in surgical planning for paragangliomas. This sophisticated technology provides an arterial map that not only identifies the feeding blood vessels, but also provides the flow dynamics of the tumor. This is especially useful with larger tumors in which multiple feeding vessels from both the internal and external circulation may be present with anastomoses between the external and internal carotid systems.[72] Similarly, the ICA can be evaluated for structural integrity and areas of constriction or irregularity that might suggest vessel involvement and the potential need for its sacrifice. The venous phase of angiography is equally important in identifying the draining vessels and especially in jugulotympanic paragangliomas, the degree of occlusion of the jugular bulb, sigmoid sinus, and jugular vein.

Equally important is the angiographic evaluation of adequate cerebral circulation in the event of ICA disruption or sacrifice. There are many methods for assessing for adequate contralateral cerebral circulation. Xenon CT scanning with concurrent balloon occlusion is a quantitative analysis of cerebral flow and is the most precise method of cerebral circulation evaluation though it is cumbersome and not readily available.[68,69] Temporary balloon occlusion of the carotid with monitoring of the clinical neurologic examination in the presence of a patent circle of Willis is easier to perform and also very reliable. EEG monitoring can be performed during balloon occlusion, as well as hypotensive challenge during the period of balloon occlusion. Approximately 93% of patients can tolerate sacrifice of the carotid artery based on the appropriate angiographic evaluation. It should be noted that intraoperative conditions may be different in terms of cerebral delivery of oxygen than those in the angiographic suite.[19] Tolerance with temporary internal carotid occlusion does not predictably avoid the possibility of a delayed postoperative cerebrovascular ischemic event. The venous outflow of the ipsilateral and contralateral sigmoid and jugular systems should be noted, especially in jugulotympanic paragangliomas. Because of the possibility of a postoperative venous stroke, a contralateral hypoplastic or absent jugular system constitutes a contraindication (Fig. 27-14).[73–75]

### Embolization

Embolization is a very useful adjunct to surgery of large paragangliomas, and when done by an experienced endovascular team, carries a very low morbidity rate. The obvious risk of embolization

(c) 2014 Wolters Kluwer. All Rights Reserved.

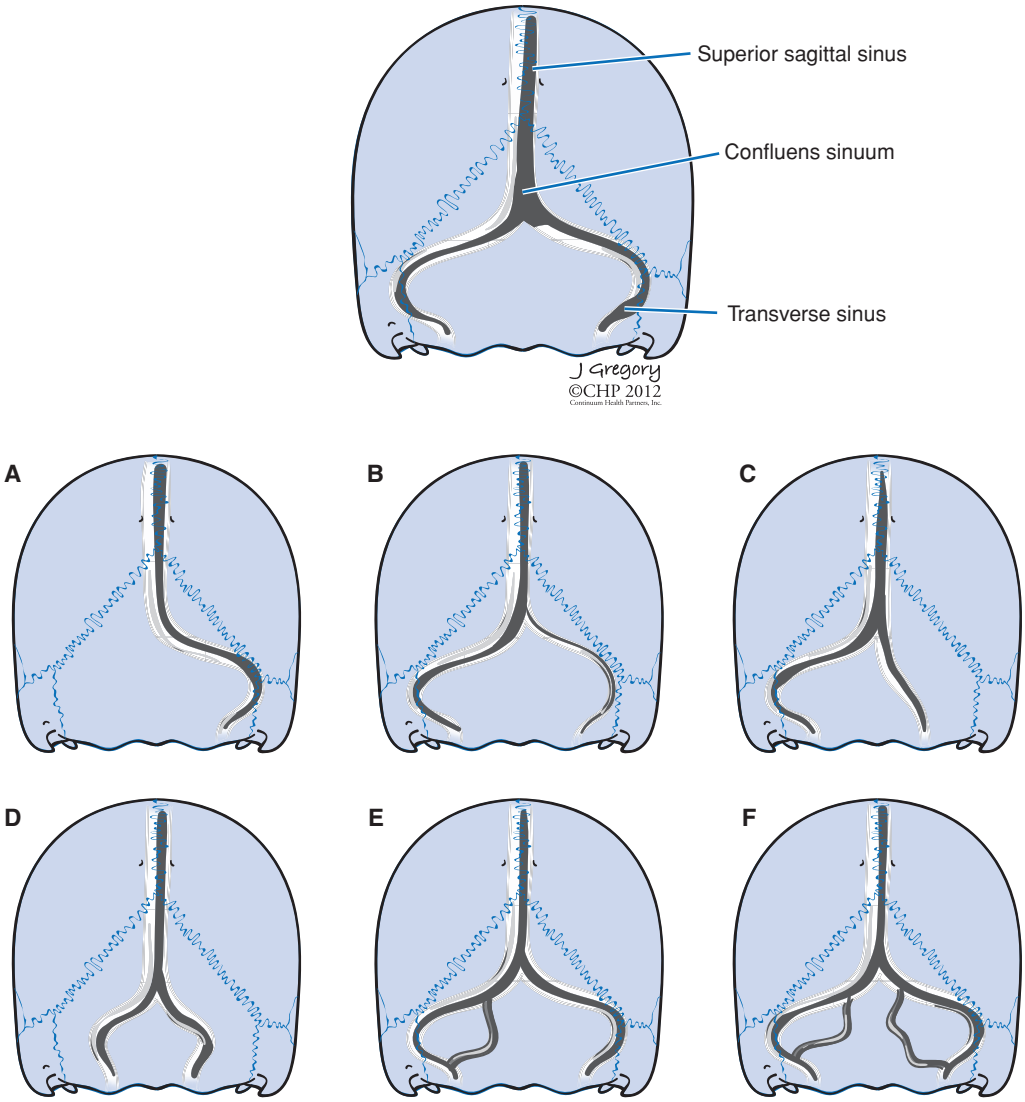

**FIGURE 27-14.** Variations of the intracranial posterior venous outflow system at the level of the transverse sinus, sigmoid sinus, and jugular bulb. Variations A and B would have a high surgical significance if a lesion were to involve the dominant side.

is the escape of embolizing particles into the cerebral circulation with all risk of stroke. This can occur through external–internal carotid circulation anastomoses or flow reversal from the arterial supply of the tumor. The advantages of embolization are tumor shrinkage and decreased blood flow that in large tumors have profound benefits. Less intraoperative bleeding is generally associated with a much easier dissection—more obvious tissue planes and less risk to normal anatomic structures, especially cranial nerves. Importantly, such a circumstance lessens the likelihood of requiring transfusion. Larger paragangliomas have multiple arterial feeding vessels that require superselective angiography. Using these methods, each successive embolization devascularizes additional compartments of the tumor until an absence of a tumor "blush" is achieved. It is essential that surgery be performed within 48 hours of embolization to avoid recruitment of collateral circulation. The inflammatory tumor reaction that has been reported following embolization is countered somewhat by the administration of steroids (Fig. 27-15).[72,76]

## Surgery

***Carotid Body Tumors.*** Smaller carotid body tumors can be approached through a transverse neck incision, but the removal of larger ones is facilitated by an oblique/vertical incision along the anterior border of the sternocleidomastoid muscle. Proximal and distal tumor dissection identifies the common, internal and external carotid arteries and jugular vein. Vessel loop control is achieved on the appropriate vessels. Carotid bypass precautions should be readily available. The cephalic extent of the large tumors can make control at the skull base substantially more difficult. The entire course of the ICA is then exposed, and usually it is noted to be displaced posterolaterally. A subadventitial plane of dissection must be done with extreme care. The tumor may require splitting in configurations in which it encases the ICA. In a similar fashion, the external carotid artery is then addressed. Encasement and infiltration of the external carotid artery may necessitate vessel sacrifice, although this should be avoided when possible. Ligation of this artery for control of blood flow to the tumor is ineffective since it usually does not alter the main supply, and, additionally, the collateral circulation is not infrequent (Figs. 27-16 and 27-17).

The dissection of the tumor at the bifurcation of the carotid is done as a last step since this site is the most vulnerable breaching the artery. As the site of origin (carotid body) of these tumors, the association with the arterial wall is its most intimate. The surrounding cranial nerves associated with carotid body

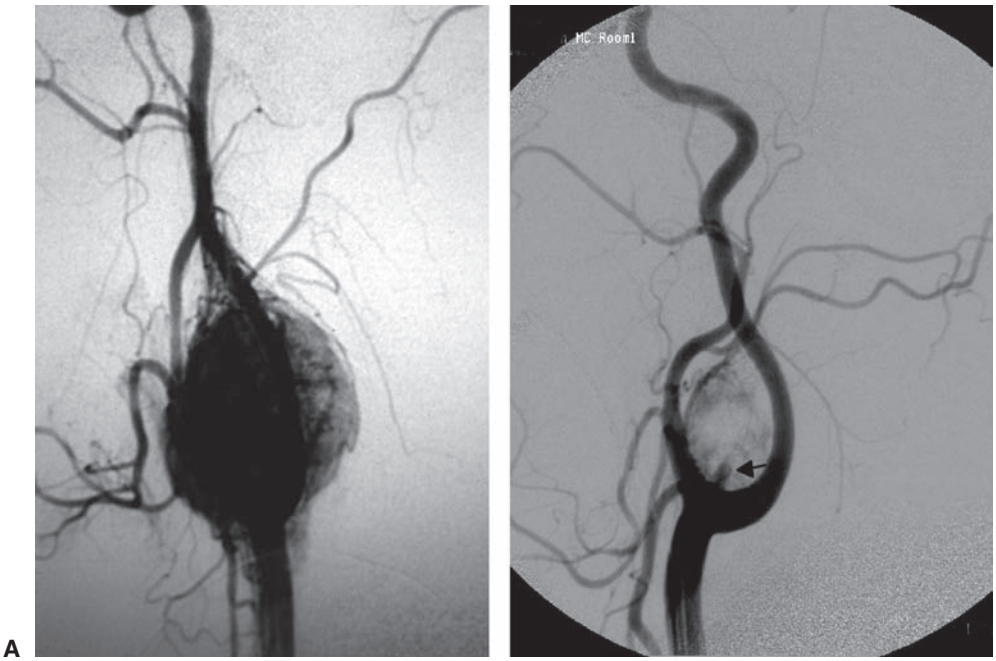

**FIGURE 27-15.** Preoperative embolization of a carotid body tumor. **A:** Preembolization lateral angiogram shows early, intense blush reflecting high vascular flow with multiple collateral feeding vessels. **B:** Postembolization frontal angiogram shows marked reduction in vascularity. The primary feeding vessel (*arrow*) terminates abruptly.

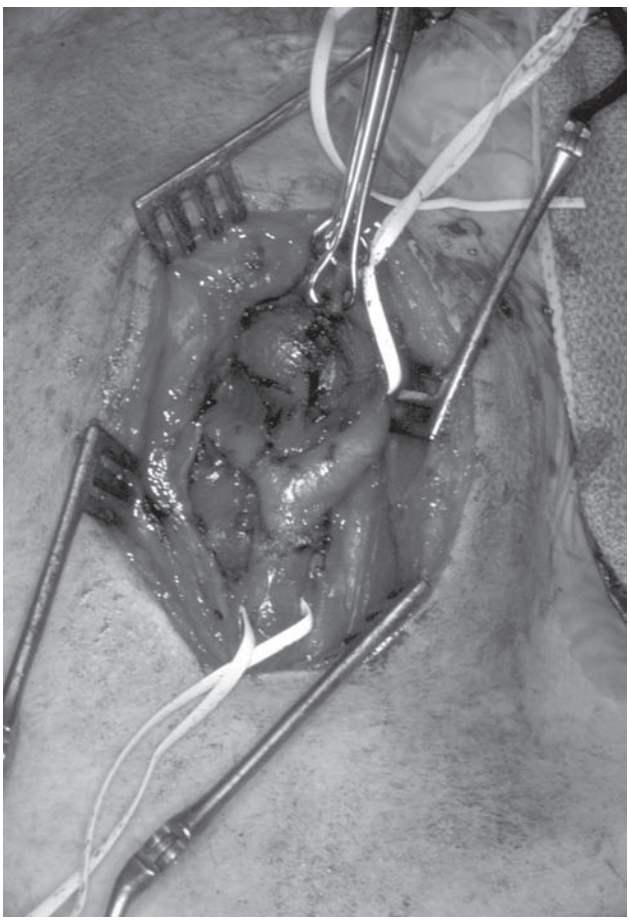

**FIGURE 27-16.** Intraoperative picture of a carotid body tumor. Tenaculum is on the lateral tumor surface. Vessel loops are around the common carotid artery (inferiorly) and internal carotid artery (superiorly).

tumors usually show marked hyperemia of the vasa nervosum of the sheath. In larger tumors, these nerves—vagus, hypoglossal, and glossopharyngeal—may be intimately involved and their dissection can cause dysfunction.

***Jugulotympanic Paragangliomas.*** Small tympanic paragangliomas (Glascock–Jackson type I, Fisch Class A) can be approached through a transcanal/inferiorly based tympanomeatal flap. Embolization of these tumors is not required. Bipolar electrocautery microforceps can be used to shrink the tumor and resect it. Larger tympanic paragangliomas confined to the middle ear and/or mastoid, but that do not breach the bone overlying the jugular bulb or the jugulocarotid spine, can be exposed through a combined postauricular/endaural approach with a canal-wall-up mastoidectomy and extended facial recess approach inferiorly that sacrifices the chorda tympani and removes the vaginal process of the tympanic bone to expose the hypotympanum.

When the jugular bulb is involved, a combined temporal/cervical approach is required. An extended mastoidectomy and extended facial recess approach is performed with skeletonization of the sigmoid sinus and exposure of the jugular bulb through the retrofacial air cells. The ICA is dissected superiorly and controlled. Cranial nerves IX, X, and XI are identified and traced proximally and distally. The internal jugular vein is then ligated superiorly and dissected toward the jugular bulb in the neck. The sigmoid sinus is occluded and ligated above the tumor extension. Contralateral venous outflow should be verified through preoperative studies. When occlusion of the sigmoid sinus is performed, this should be done in a manner that avoids interfering with the outflow from the anastomotic vein of Labbe, which drains the temporoparietal cortex and thereby avoids the risk of a venous stroke.[77] Once the sigmoid sinus is opened and the jugular vein is ligated inferiorly, hemostatic agents can be injected to gently occlude the inferior petrosal veins. This provides blood-free visualization of the jugular bulb and improves the microsurgical dissection at the pars nervosa of the jugular bulb, the site most likely to sustains cranial nerve injury. Dissection of the tumor should proceed with irrigating bipolar electrocautery. At the level of the jugular bulb, the dissection should be undertaken with extreme

(c) 2014 Wolters Kluwer. All Rights Reserved.

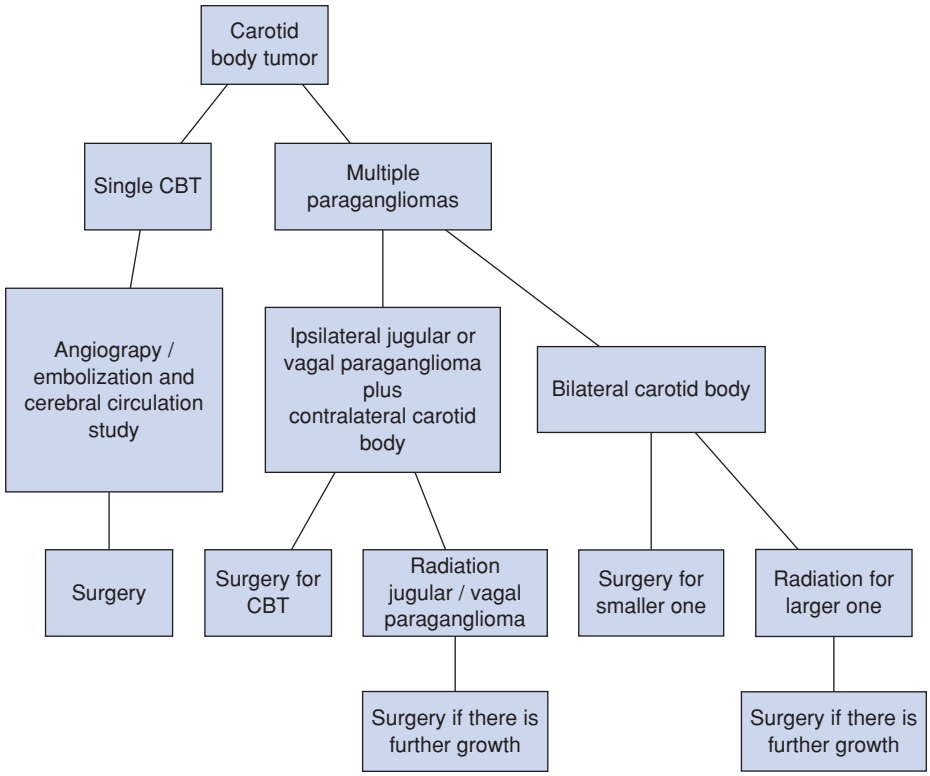

**FIGURE 27-17.** Decision analysis tree for the treatment of carotid body tumors (CBTs).

caution since the cranial nerve rootlets of the glossopharyngeal and the vagus are at their most vulnerable. In jugulotympanic paragangliomas, these rootlets are displaced medially and are thus in a favorable position. If the tumor does not extend into the pars nervosa/medial jugular bulb compartment, preservation of the cranial nerves is desirable.[78]

Those more advanced tumors that involve the vertical and/or horizontal petrous carotid artery and possible intracranial extension require a postauricular infratemporal fossa approach. These approaches begin with an extended mastoidotomy, removal of the external auditory canal, tympanic membrane, malleus, and incus. The external canal is permanently closed, which condemns the patient to a profound ipsilateral conductive hearing loss. The peritubal and pericarotid air cells are removed and the intrapetrous carotid artery is skeletonized proximal to the tumor extent. This may involve sacrifice of the middle meningeal artery and removal of the foramen spinosum as well as the foramen ovale if the tumor has extended toward the cavernous sinus. Tumor is removed from the carotid, middle ear, and sigmoid/jugular bulb/jugular vein (Fig. 27-18). Tumor extension to the medial jugular bulb compartment and/or intracranially places the nerve rootlets of cranial nerves IX, X, and XI in a vulnerable position, and more frequently than not, it is necessary to sacrifice them. If there is no such extension, an effort is made to gently dissect the tumor away from the nerves. The Eustachian tube should be permanently occluded to avoid postoperative cerebrospinal fluid rhinorrhea. Intracranial extension is addressed by opening the dura in the presigmoid area down to the tumor extension at the level of the jugular bulb. Tumor extension toward the petrous apex and clivus may necessitate a translabyrinthine/transcochlear approach. In these approaches, the facial nerve is mobilized out of the fallopian canal in its vertical and horizontal portion to the geniculate ganglion. This will result in temporary facial paralysis due to interruption of the blood supply to the nerve as well as the retraction anterosuperiorly.[27,58,79] Incomplete recovery of facial nerve function is a possible outcome. Reconstruction with temporoparietal fascia flap or temporalis muscle alone is done at the conclusion to assist healing and prevent a cerebrospinal fluid leak. Lumbar drainage for a limited period of time in the immediate postoperative recovery may be indicated for the prevention of a cerebrospinal fluid leak. When cranial nerves have been sacrificed, immediate surgical amelioration with a concurrent vocal cord medialization and a pharyngoplasty with cricoesophageal myotomy at the same sitting have been recommended.

Technical refinements include the juxtacondylar approach as well as the transjugular craniotomy.[78] These modifications both shift the surgical angle of approach posteriorly. The advantages are that they obviate the need for facial nerve transposition and improve the control and preservation of the lower cranial nerves in the jugular foramen. The limitation is that they cannot address tumor involvement in the petrous carotid artery area.

***Vagal Paragangliomas.*** Most vagal paragangliomas originate in the nodose (inferior) ganglion that is situated 2 cm below the jugular foramen. Their bidirectional growth along the vagus results in involvement of the jugular bulb superiorly and postyloid parapharyngeal space inferiorly. The ICA is displaced anteriorly.[60] Vagal paragangliomas originating in the superior and middle ganglia that are situated within the jugular foramen cause early skull base invasion with intracranial extension. The surgical techniques to approach these tumors are identical to those for jugulotympanic paragangliomas when the skull base is involved. The inferior extent of vagal paragangliomas requires detaching the digastric muscle from its origin and removing the styloid process to access the parapharyngeal space extension. Sacrifice of the vagus nerve in these tumors is inevitable. With involvement of the jugular foramen and skull base, additional cranial

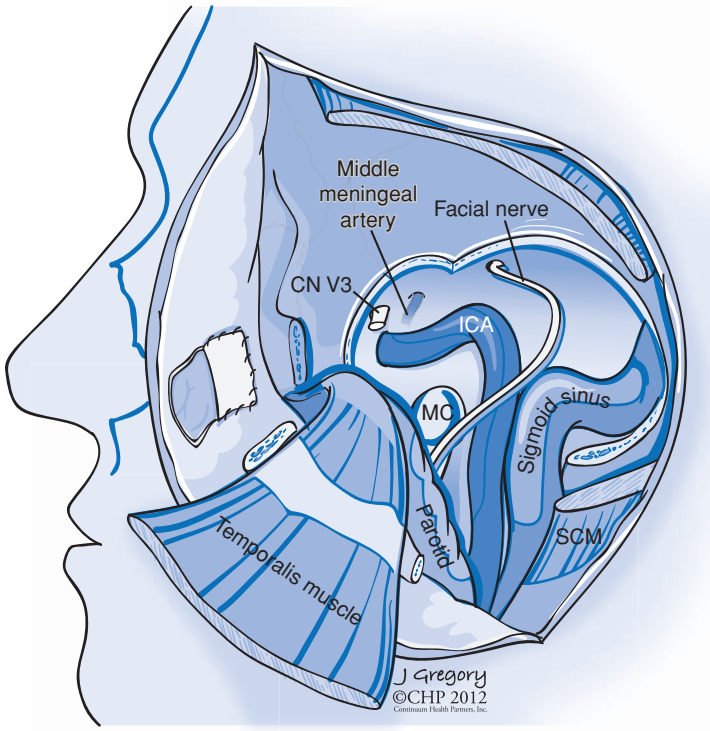

**FIGURE 27-18.** Schematic representation of a type B infratemporal fossa approach. Lateral temporal bone has been removed exposing the petrous carotid artery, jugular vein, jugular bulb and sigmoid sinus. Facial nerve has been mobilized in its horizontal and vertical portions. The third division of the trigeminal nerve (V3) has been divided as well as the middle meningeal artery right behind it. CN, cranial nerve; MC, mandibular condyle; SCM, sternocleidomastoid muscle; ICA, internal carotid artery.

nerve deficits are to be expected as these tumors extend medial to the cranial nerve rootlets, within the pars nervosa of the jugular foramen.

## POTENTIAL COMPLICATIONS

### Vascular Injury

Early series of paraganglioma surgery reported a stroke rate of 10% to 20%; recent series report rates of 0% to 2%. Because of contemporary diagnostic methods, preoperative planning, and microsurgical techniques, the risk of injury or need for internal carotid sacrifice is minimal. For carotid body tumors, the risk of injury and need for vessel sacrifice is size specific with tumors larger than 5 cm likely requiring carotid reconstruction. In addition, preoperative findings of stenosis and irregularity on angiography and/or circumferential involvement on MRI with loss of the pericarotid adventia make preoperative preparation for carotid resection and reconstruction critically important.[80–83]

Vagal paragangliomas differ from carotid body tumors and jugulotympanic tumors because they are not intimately associated with the carotid artery. In advanced vagal and jugulotympanic lesions, however, the ICA can be completely encased by tumor within the petrous portion. With adequate surgical exposure and microsurgical technique, injury should be infrequent in experienced hands. Internal carotid sacrifice in this location is fraught with problems; therefore, if sacrifice is contemplated, consideration for alternate treatment in these instances is important. If the vessel is at high risk for injury within the petrous carotid portion, and the patient has safely passed balloon occlusion testing, permanent preoperative occlusion of the carotid distal to the tumor should be considered.

Reported more recently, a novel approach to the artery that is particularly at risk for injury is to place a vascular endoprosthesis and then perform the surgery several weeks later. Fibrosis around the self-expanding stent creates a leak-proof artery. This has the advantage of reducing blood flow to the tumor, as well as preventing vascular injury.[84]

### Baroreflex Failure

Surgery for removal of bilateral carotid body tumors results in loss of the baroreceptor reflex with bilateral denervation of the carotid sinus. In the immediate postoperative period, this results in labile refractory hypertension, tachycardia, diaphoresis, and headache that is treated with sodium nitroprusside. Long-term treatment is control with clonidine.[85] This complication is more than theoretical, and in this bilateral circumstance, alternative therapy should be considered for one of the tumors.

### Cranial Nerve Injury

The risk to the lower cranial nerves in surgery for paragangliomas is location and tumor size specific. In decreasing order of risk these tumors pose to injury: vagal, jugulotympanic, and carotid body paragangliomas. Size of lesion is especially important in vagal and jugulotympanic paragangliomas. Tumors with extensive skull base involvement, intracranial and/or infratemporal fossa extension are likely to have extensive involvement of the lower cranial nerves with at least one nerve involved, and oftentimes, multiple nerve deficits preoperatively. Involvement of the facial nerve with preoperative paralysis is a sign of such extensive involvement.[27,58,59,86,87]

Single cranial nerve deficit most commonly results postoperatively in temporary deglutition, dysphonia, tongue motion abnormalities, and/or aspiration problem. Because of the complex interactive physiology of swallowing, and speaking, multiple cranial nerve deficits have additive effects and are poorly tolerated in older patients. In this population, recovery is often very difficult, and permanent aspiration requiring management with a gastrostomy and tracheostomy is a real possibility, especially in

(c) 2014 Wolters Kluwer. All Rights Reserved.

high vagal nerve injuries. Bilateral lower cranial nerve paralysis, especially of the vagus nerve, as a result of therapy or progression of tumor in bilateral disease is a devastating injury that can results in significant dysphagia and dysphonia.

The clinical manifestations of vagal nerve injuries reflect the level of the insult, whether from tumor or from surgical trauma. Injuries distal to the origin of the superior laryngeal nerve will result in vocal cord paralysis that is generally easily managed. Higher vagal injuries, such as those at the nodose ganglion or at the level of the jugular foramen, result in vocal cord paralysis, anesthesia of the ipsilateral supraglottic and hemilarynx, and paralysis of the ipsilateral soft palate. These deficits result in aspiration and dysphagia. In addition, air and food escape into the nasopharynx because of the paralysis of the soft palate. Vagal nerve injuries at the jugular foramen are often associated with glossopharyngeal nerve injuries that add ipsilateral pharyngeal anesthesia, an occurrence that further compromises swallowing function. Superior vagal injuries require prompt and intensive swallowing therapy in addition to surgical management of the vocal cord paralysis (Fig. 27-19). Most injuries at the level of the jugular foramen are permanent, and early surgical management helps mitigate the over effects of the deficits. Vocal cord medialization with a thyroplasty combined with cricopharyngeal myotomy will improve phonation and deglutition, as well as minimize the risk of aspiration. An ipsilateral palatal adhesion procedure can mitigate the hypernasality in speech and nasality during deglutition. Additional lower cranial nerve injuries are seen in 30% to 50% of patients with a vagal nerve injury. When this occurs, overall recovery is significantly more complicated.[88–91]

Accessory nerve injury results in loss of trapezius and/or sternocleidomastoid muscle function. Physical therapy is required for this to avoid pain secondary to shoulder "drop" as well as limitation of motion. If the nerve is injured below the jugular foramen, it may be amenable to primary repair by a nerve graft.[90]

Injury to the hypoglossal nerve results in ipsilateral tongue paralysis and long-term hemi-atrophy of that structure. When this is combined with additional cranial nerve injuries, swallowing becomes even more difficult and physical therapy becomes essential in preventing aspiration. Swallowing therapy is directed at teaching the patient to move the bolus to the functioning side.[90]

Injury to the sympathetic chain is seen in approximately 25% of patients postoperatively as a result of interruption of the sympathetic ganglia. This results in partial or complete Horner syndrome. The resultant ptosis can be easily rectified through a Müller muscle eyelid tightening procedure. "First bite syndrome," which is intense pain with the first bite, can develop as a result of denervation hypersensitivity of the myoepithelial cells of the parotid gland. This problem improves gradually and spontaneously in most patients.

Following the manipulation of removal, up to 40% of patients with carotid body tumors demonstrate cranial nerve deficits, the majority of which are transitory. Vagal nerve injury is the most common of those so affected. More specifically, in jugulotympanic paragangliomas the most common nerve deficit is also vagal (27%), followed by the glossopharyngeal (18%), the accessory and the hypoglossal (8%) on account of older surgical series.[17–19,59,90]

## Results of Recent Surgical Experience

The oncological outcomes from surgical management of advanced-stage jugulotympanic and vagal skull base paragangliomas have significantly improved in the last two decades. Surgical control ranges from 72% to 98%, results that are associated with a very low perioperative mortality and morbidity.[92] Tumors that were previously considered inoperable such as lesions that completely engulf the carotid artery, and those with extensive intracranial extension are now technically resectable.[93,94] A review

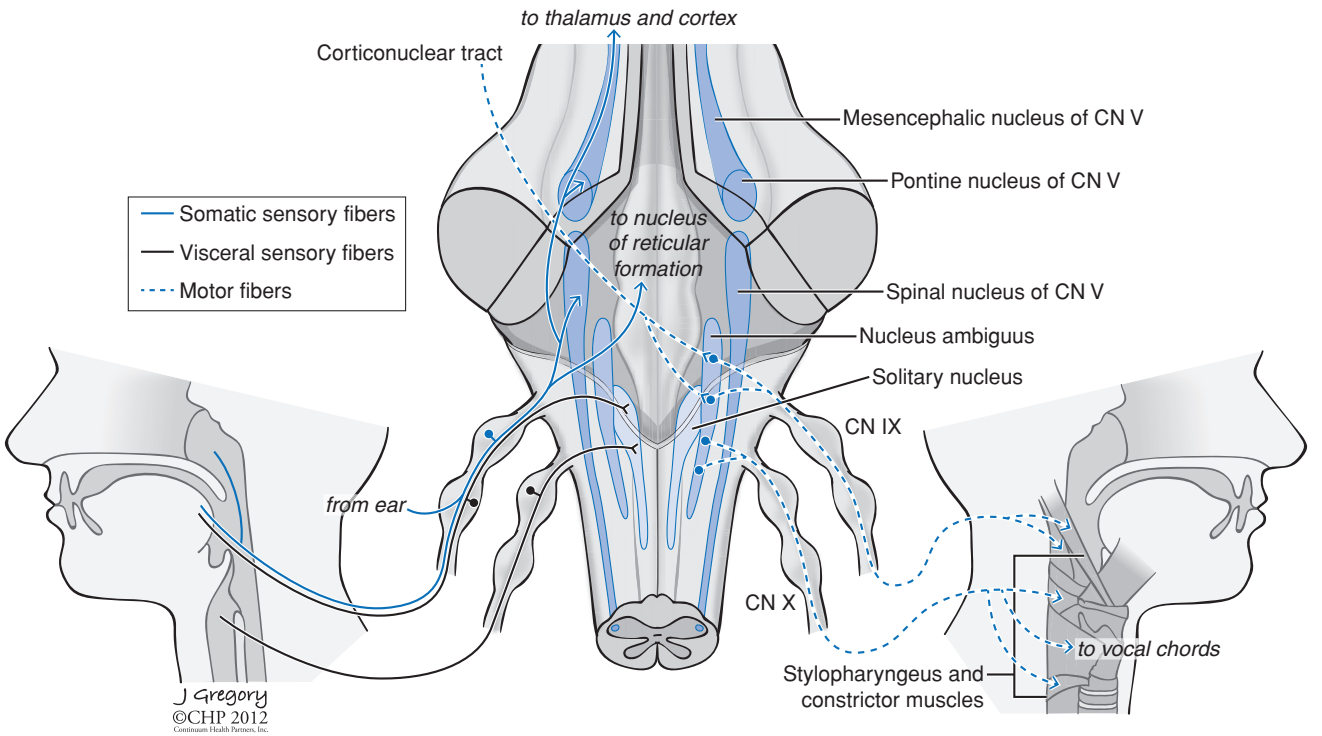

**FIGURE 27-19.** Schematic representation of the afferent and efferent swallowing reflex. CN, cranial nerve.

(c) 2014 Wolters Kluwer. All Rights Reserved.

of 9 publications of surgically managed temporal bone paragangliomas of advanced stage (Fisch C and D), with a substantial proportion of these patients having intracranial extension of their tumors showed tumor control in 84% to 100%, with a mortality of 1.7%, and morbidity from cerebrospinal fluid leaks ranging from 1.6% to 14.9%. In these largest series, new cranial nerve deficits were 15.9% to 17.6%.[92,95–102]

Sanna et al. reported on 121 cases surgically managed, with extensive tumors including 55.4% of which demonstrated intracranial extension. There were no deaths in the series, but morbidity was as follows: cerebrospinal fluid leak was 1.6%; cranial nerve dysfunction for CN IX was from 29.8% preoperatively to 54.5% postoperatively (24.7% additional); CN X dysfunction was from 47.1% preoperatively to 47.1% postoperatively (15.0% additional); CN VII dysfunction similarly was an additional 19%, with most of these being transient due to the nerve transposition. The same study reports that all but 4 patients (3.3%) required a secondary intervention for aspiration or dysphagia at 6 months.[92] Similar results are presented in a series of advanced tumors reported by Al-Mefty; 91.6% tumor control and a 7.1% new cranial nerve deficit as a result of treatment.[97] Moe and Tra Ba Huy also report recent series with similar patient profiles and outcomes.[95,97]

The keys to these encouraging results are the preoperative management of the ICA either by stenting or by preoperative occlusion when necessary, as well as the evolution of surgical techniques toward a safer tumor dissection; hence, a lesser mobilization of the facial nerve as well as proper management of the lower cranial nerves in their exit from the jugular foramen and the hypoglossal canal.

The common denominator for such outcomes in the surgical management of temporal bone paragangliomas is the interaction of a multidisciplinary team that includes expert preoperative interventional radiology and wide-ranging experienced surgeons.

## RADIATION THERAPY

Historically, radiotherapy has been considered for treatment of subtotally resected, technically unresectable paragangliomas (e.g., extensive skull base involvement or intracranial extension) or those considered inoperable because of age or medical comorbidities. However, with long-term experience reporting the efficacy of CT-based planning and modern radiation therapy delivery techniques, definitive radiotherapy has become recognized to be a highly effective treatment for paragangliomas. The most commonly treated site has been jugulotympanic paragangliomas followed by carotid body or vagal paragangliomas. Both conventionally fractionated radiotherapy and stereotactic radiosurgery have been utilized. Successful treatment of paragangliomas with radiotherapy must be defined since there is rarely total resolution of the tumor after treatment. Thus, "local control" usually means stability (or regression) of tumor size and nonprogression (or improvement) in neurologic symptoms.

### Radiation Effects

***Histopathologic Changes.*** The basis by which radiation prevents tumor growth and reduces symptoms is not completely understood. Essentially, the chief cells can be present long after radiation.[103–106] Few studies have reported the actual radiobiologic effect of radiation on paragangliomas.[103–105] Gardner studied 6 irradiated tumor specimens resected 4 to 6 weeks postradiation.[106] The distinctive finding was of vascular endarteritis with mural thrombi when compared with nonirradiated specimens. One of six specimens showed a necrotic infarct, whereas two cases showed changes in tumor cells consistent with pyknotic cellular death. No significant difference in fibrosis was noted between the irradiated and nonirradiated specimens. However, Rosenwasser and others have noted a 6-month postradiation dramatic increase in stromal fibrous connective tissue with wide separation of tumor nests and diminished vascularity.[103,107–109] Chief cells are present, but may develop nuclear pleomorphism with coarse chromatin clumping and irregular nuclear outlines. Others have described similar histopathologic findings in irradiated specimens.[106–108]

***Radiographic Changes.*** On postradiotherapy radiographic evaluation, the majority of lesions demonstrate unchanged size or modest tumor regression.[110–112] Mukherji reported the University of Florida experience of 17 patients with 18 paragangliomas that were treated with definitive radiation. These patients had been studied with pretreatment CT or MRI, and following radiation, were restudied with the same imaging.[113] Sixty-one percent showed a decrease in tumor size with an average reduction of 23% (range 8%–45%) at a median follow-up of 2½ years. All tumors persisted, but none showed an increase in size. Postradiation MRI findings included reduction in flow voids, decreased heterogeneous enhancement, and reduced T2 signal. CT detected improvement in skull base erosion in rare cases (1/8 patients).[110,111] Other smaller studies demonstrate regression in 57% to 73% of patients followed by CT.[114,115] Angiographic follow-up after radiation might not show significant change in patients, even in those in whom there has been no evidence of clinical tumor progression. Maruyama reported the results of three paragangliomas followed by serial angiography over several years and though tumors were clinically controlled, only minimal reductions in vascularity was detected angiographically.[116] In summary, paragangliomas show modest radiographic change or stable tumor in the majority of cases.

Based on these findings, it seems that radiation induces an obliterative endarteritis with resultant fibrosis that probably prevents regrowth in addition to promoting partial tumor involution.[103,117] Even though radiation exerts a primary effect on chief cells, it is difficult to determine whether morphologically persistent cells have lost reproductive capability.[118]

### Local Control with External Beam Radiation Therapy

The first major review demonstrating the efficacy of radiation was reported by Alford and Guildford (1962), on 106 cases of paragangliomas.[119] Although more advanced lesions were treated with radiotherapy, local control was comparable to surgery, 72% versus 78%, respectively. Unfortunately, follow-up was relatively short for a disease with a long natural history. Since then, numerous reports with follow-up as much as 35 years have demonstrated the effectiveness of radiation in control of head and neck paragangliomas (Tables 27.5 and 27.6). The accumulated data represent a wide variety of dose levels (30–70 Gy), radiation techniques (electrons, photons, radium implant) and beam energies (superficial, cobalt, 4–6 megavolts). Overall, local control rates range from 65% to 100% with an average of 90% based on >1,000 tumors from 37 series (985/1,094) (see Table 27.5).[103,110,111,114–116,120–151]

No obvious difference in local control is detectable between those primarily involving the temporal bone (jugular and tympanicum) versus the carotid body tumors and vagal paragangliomas (local control 97%—61/63) (see Table 27.6).[121,126,138,152–154] Mean or median follow-up was at least 10 years[110,115,121,123–125,129,137,139,145,148] in multiple series with a maximum follow-up of >30 years in some.[121,125,126,130,137,148] Kim reported a local control of 90% on

RMH, Royal Marsden Hospital; UF, University of Florida.

225 temporal bone tumors from 11 radiotherapy series published from 1965 to 1980.[111] Schild updated the analysis by including studies published from 1965 to 1992.[114] Local control was obtained in 91% (337/370) after radiotherapy. In his report, Kim demonstrated a dose–response relation between local control and total radiotherapy delivered.[111] The optimal dose appeared to be >40 Gy. Local failure was 1% versus 25% if patients received >40 Gy ($n$ = 142) versus <40 Gy ($n$ = 83), respectively.

In general, a dose of 45 Gy/5 weeks is recommended; however, a Canadian schedule of 35 Gy/3 weeks has also shown to be effective.[139] The high rates of local control after radiotherapy led Rosenwasser to conclude that "radiation failures occur, but perhaps they are not so much failures in the sense that irradiation is not effective, but that irradiation may not have reached the tumor in its entirety."[155] Paralleling such high rates of control are disease-specific survivals ranging from 65% to 100% with the majority of series reporting rates between 90% and 100%, as well as high rates of overall survival of 65% to 100% (see Table 27.5).

## Toxicity of Fractionated Radiotherapy

Severe complications after radiotherapy have been reported in 30 series involving 795 patients, and are summarized in Table 27.7.[110,114,115,120–128,130,131,133,134,136–149] This review involves 37 years of literature (1964–2001) with a wide variation in techniques and doses. The incidence of severe complications is 6% (49/795), and treatment-related mortality is 0.6% (5/795). Four of the five reported deaths resulted from brain complications including necrosis and abscess. Several of these deaths resulted from overdosage of radiation with external beam radiation (66–70 Gy), obsolescent brachytherapy techniques using radium implant, or large-volume brain irradiation. Severe morbidity consisted primarily of osteoradionecrosis ($n$ = 12 [1.5%]), chronic otitis ($n$ = 8 [1%]), brain necrosis ($n$ = 6 [0.8%]), radiation-related cranial neuropathy ($n$ = 4 [0.5%]), radiation-induced sarcoma ($n$ = 3 [0.4%]), external auditory canal stenosis ($n$ = 2 [0.3%]), and trismus ($n$ = 2 [0.3%]). The majority of such complications were related to treatment using excessive doses, outdated treatment techniques (orthovoltage, which is preferentially absorbed in the bone or radium implant), or reirradiation. For example, of the four cranial neuropathies related to radiotherapy, three occurred after 64 to 66 Gy. Cole and Beiler[124] reported that all severe complications in their series occurred in the orthovoltage-treated patients and none in those treated with megavoltage. Of importance is the low incidence (0.4% [3/795]) of radiation-induced secondary malignancy, including two fibrosarcomas occurring 15 and 25 years posttreatment, and one osteosarcoma occurring 5 years later. One fibrosarcoma developed after a radium implant; the other two malignancies occurred after treatment with 50 and 62 Gy (see Table 27.7). Common complications that can occur include epilation, skin dryness, fibrosis, and cerumen buildup in the external auditory canal.

With modern treatment planning and appropriate dosing, definitive radiotherapy for paragangliomas should be well tolerated. In the acute setting, patients may experience dermatitis, alopecia, mucositis, epilation, and alterations in taste and saliva, along with either otitis externa or media. The potential complications vary according to the radiation technique and treatment site. At standard doses, most of these side effects are transient, and treatment-related mortality is exceedingly rare. Care must be taken to minimize dose inhomogeneity and volume of treated normal tissues, especially brain (Fig. 27-20).

## Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) has been explored in the primary treatment of paragangliomas and salvage of surgical failures. The first published report for SRS was in 1995, and numerous reports have subsequently followed. SRS offers the possibility of a single, highly focused small-field treatment with a steep dose gradient to maximally spare surrounding normal tissue. The radiobiologic rationale of delivering one large dose is to effectively treat tumors that may be radioresistant while minimizing the amount of normal tissue in the treatment field. Two methods of delivering stereotactic radiation involve (a) the use of radioactive cobalt sources (gamma-knife) or (b) the generation of radiation from a linear accelerator (LINAC). Typically, all imaging (e.g., CT scan or MRI), planning, and treatment are completed in a one-time treatment session, and the radiation is delivered with the highest precision of all current radiation-delivery techniques.

Multiple series have reported success using this approach to treat primarily jugular paragangliomas with high local control (Table 27.8).[112,156–160] A wide range of median doses have been reported delivering from 15 to 32 Gy with 15 Gy being the most common dose prescribed. Tumor regression is noted in 36%.[161] Treatments appear to be well tolerated, with no reported iatrogenic lower cranial neuropathies, and low incidence of transient facial neuropathy, hearing impairment, and vertigo. Limitations of SRS include eligibility restrictions, lesion size, and location, as well as a greater risk for geographic miss due to the sharp dose gradient.[156] Tumors may be no >4 cm to achieve tight dose conformality.

A population-based meta-analysis of 19 studies comprising 335 glomus jugulare patients treated with radiosurgery was reported by Guss et al.[162] For all studies, tumor control was 97%, while among the 8 studies with median follow-up of >36 months,

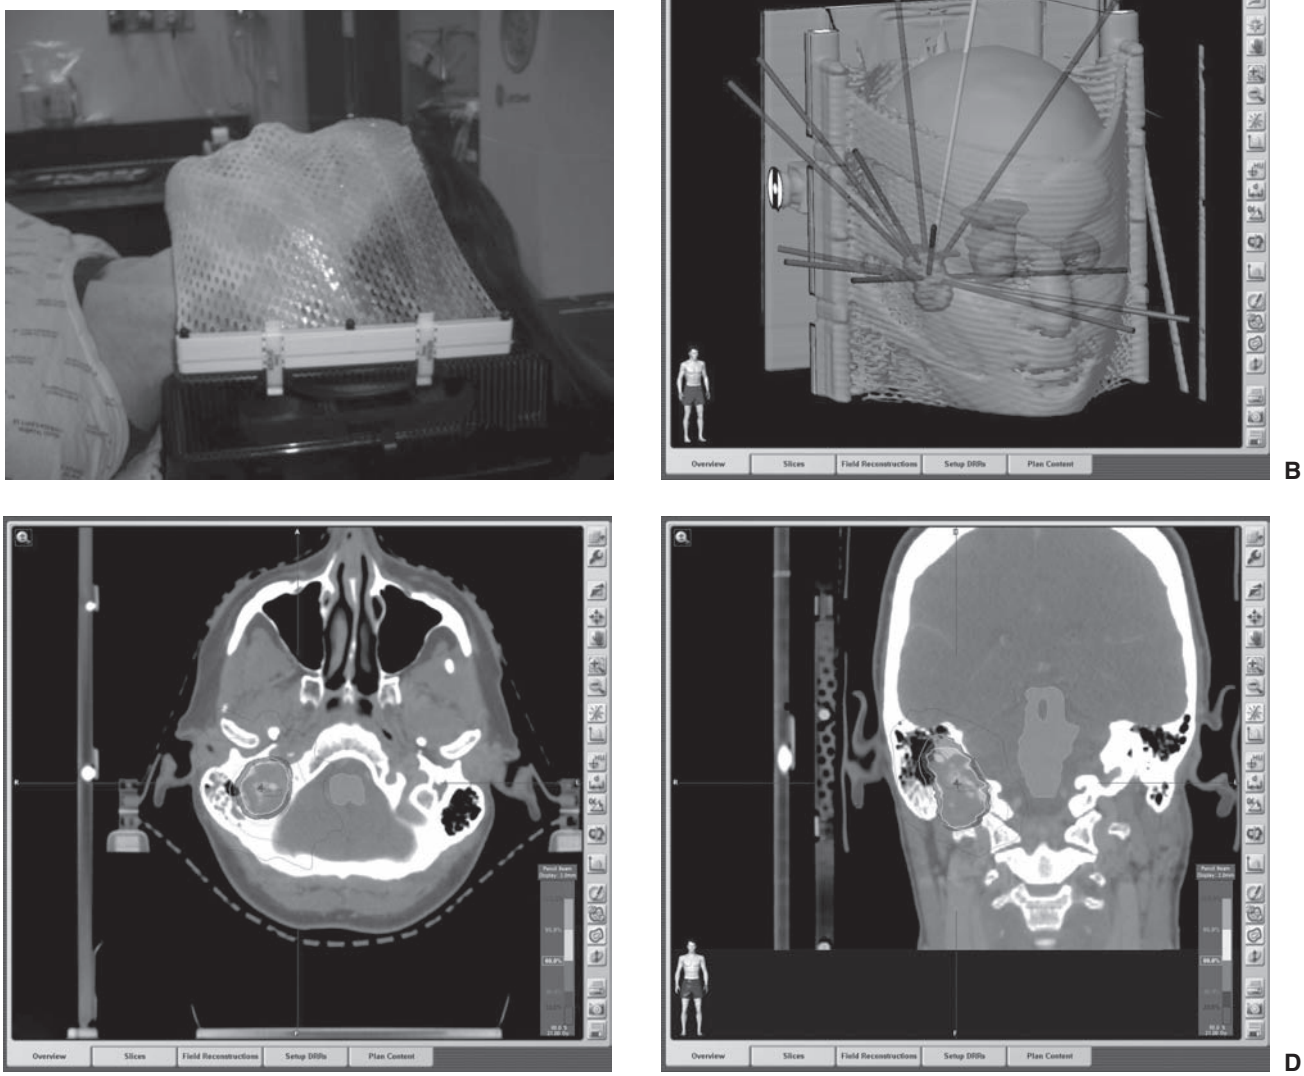

**FIGURE 27-20.** Fifty-year-old female with an incapacitating jugulotympanic paraganglioma causing tinnitus and dizziness causing gait instability and nausea. Due to the size of the lesion and proximity to the seventh and eighth cranial nerve, a stereotactic fractionated radiation therapy approach was recommended to minimize risk of iatrogenic neuropathy. **A:** The patient was immobilized with a frameless stereotactic mask. **B:** Multiple noncoplanar beams were used to deliver 21 Gy in 3 fractions. Dosimetry is seen in axial **(C)** and coronal views **(D)**. (See color insert for Parts **C** and **D**)

95% achieved control. No difference in outcome was reported by SRS technique whether by LINAC, gamma-knife, or cyber-knife approaches.

### Toxicity of Stereotactic Radiosurgery

Toxicity after stereotactic radiosurgery is detailed in Table 27.8. Based on a weighted series of 6 studies of radiosurgery for 133 jugular paragangliomas, the neurologic deterioration related to SRS was 4%, whereas there was improvement or stability in 96%. Reported complications included radiation-induced transient cranial neuropathy, impaired hearing, and chronic vertigo.[163] Others report a worsening of neurologic deficit after SRS in 8%, with 6% transient and 2% permanent. No patients experience new cranial nerve deficits.[161]

## IMPACT OF RADIATION THERAPY ON NEUROLOGIC FUNCTION

The most frequent symptoms associated with temporal bone paragangliomas are hearing loss and tinnitus, which are noted in 55% to 58% and 56% to 66% of patients, respecti vely.[110,123,126,128,136,139] After radiotherapy, tinnitus commonly improves or resolves in up to 88% of cases.[126,139] Among temporal bone tumors treated with radiation with a median follow-up of 10 years, Cummings demonstrated complete subsidence in 79% of 38 reported cases and stable or partial decrease in 21%.[139] Of the 40 patients with initial hearing impairment, 5% reported a return to normal hearing, 30% reported some improvement and 62% were unchanged. Christie Hospital reported

their outcomes using external beam radiotherapy (EBRT) in 49 patients with jugular or tympanicum tumors.[164] The median age was 55 years. Twenty-seven patients presented with deafness, 25 with tinnitus, 10 with facial nerve palsy, 14 with otalgia, 8 with bleeding, and 6 with other cranial nerve palsies. Patients were treated with a median dose of 45 Gy. At a median follow-up of 7.4 years, complete clinical response was noted in 78% (39/49) and the 5- or 10-year local control was 92%. Others have also reported an 8% to 85% incidence of hearing impairment as a presenting symptom,[110,123,126,128] but do not detail a follow-up response to radiotherapy as measured by audiologic testing.

The incidence of other lower cranial neuropathy at presentation is usually about 40% for temporal bone tumors, but may range from 8% to 60%.[110,114,115,123,125,126,136] Often, the presenting cranial nerve symptoms are long-standing with only a modest possibility of improving after radiotherapy. The probability of improvement is most likely inversely related to the duration of cranial neuropathy.[126,138] The reported rates of improvement vary from 0% to 83% with an average of 35% for all series that document response (Table 27.9).[110,114,123,126,128,131,134,136,138,139,141] Complete restoration of cranial nerve function can occur in about 10% (range 8%–20%); however, no change is noted in the majority. Importantly, only about 1% of cranial neuropathies worsen after radiotherapy. Radiation-induced cranial neuropathy is rare, and those reported have been associated with doses above what is currently recommended. Four such cases have been reported; two cases of CN VII palsy, one CN VIII dysfunction occurring after high dose of radiotherapy (64–66 Gy),[126,138] and one case of CN VI palsy, which the authors stated had an "unclear etiology."[134]

[a]Cranial neuropathy stable or improved, excluded from total analysis of those improved.

## Fractionated Radiotherapy Compared with Surgery

Extraction of meaningful data from retrospective studies is inherently fraught with difficulty. Single-institution retrospective series often report conflicting results based on small patient numbers and selection bias. For example, Ogura et al.[165] reported a cure rate of 80% (39/49) after surgery alone for jugular paragangliomas versus 25% (3/12) after radiotherapy alone, and 64% (7/11) with combined surgery and radiation. In this series, and those from Glasscock et al.,[166] surgery was recommended as the treatment of choice for resectable tumors, and radiotherapy was proposed for large, inoperable tumors. Moore et al.[167] reported successful control in 88% (7/8) of tympanic paragangliomas treated with surgery alone, and 25% (1/4) of petrosal/extrapetrosal tumors treated by surgery alone versus 100% (5/5) of similar tumors treated with radiotherapy alone, and 88% of tumors treated with surgery followed by radiotherapy. Other series have demonstrated no obvious differences between surgery and radiotherapy.[117] Carrasco and Rosenman[168] reported a large series showing similar local recurrence rates after surgery versus radiotherapy occurring in 7% versus 8% (19/283 vs. 24/299), respectively. The mortality rate from progressive disease was low after treatment with either modality, 2.5% (7/283) with surgery versus 6% (18/299) with radiation. Due to the retrospective nature of the data, the impact of selection bias on such an analysis cannot be determined.

In an effort to extract meaningful data, one may compare outcomes based on a common staging system. Few studies report their results based on a staging system that can be used for cross-modality and interinstitutional comparison. However, several series report results based on the McCabe/Fletcher staging system, which categorizes temporal bone paragangliomas into the tympanic, tympanomastoid, and petrosal/extrapetrosal categories (Table 27.10).[110,111,121,125,130] Although this staging system is based on the use of outdated radiographic examinations, such as plain x-ray films and retrograde jugulography, it is similar in principle to the Fisch and Glasscock/Jackson systems, which are currently preferred. A combined analysis of five studies reporting the results of surgical or radiotherapeutic treatment of temporal bone tumors staged according to the McCabe/Fletcher system is presented in Table 27.10.[110,111,121,125,130] Patients were treated with radiotherapy alone ($n$ = 94), surgery alone ($n$ = 45), or surgery and radiation ($n$ = 39). Patients in the last cohort received radiation, usually in the postoperative setting, for gross residual disease. Median follow-up ranged from 11 to 16 years. The average local control was 93%, 78%, and 85% for patients treated with radiotherapy, surgery, or combined surgery and radiation, respectively. Despite a selection bias against the radiotherapy group (65% were group III paragangliomas) compared with the surgery alone (13% were group III), or combined surgery and radiation (51% were group III), local control appeared at least as good after radiotherapy alone compared with the other two treatment groups. Local control

**TABLE 27.10 Local Control after Primary Radiation Therapy versus Surgery versus Surgery and Postoperative Radiation in Temporal Bone Paragangliomas**

| McCabe-Fletcher Stage | RT[a] | Sx[a] | Sx + RT[b] | All Patients |
|---|---|---|---|---|
| I | 93% (14/15) | 87% (27/31) | 78% (7/9) | 87% (48/55) |
| II | 100% (18/18) | 88% (7/8) | 70% (7/10) | 89% (32/36) |
| III | 92% (56/61) | 17% (1/6) | 95% (19/20) | 87% (76/87) |
| Total | 93% (88/94) | 78% (35/45) | 85% (33/39) | 87% (156/178) |

[a]RT, radiation therapy; Sx, surgery. Based on pooled analysis of five series that reported results by a common staging system (Wang, Larner, Pryzant, Kim, Hinerman).

[b]Note the majority received radiation therapy in conjunction with surgery as upfront definite treatment rather than as salvage.

for group III tumors was better after definitive radiotherapy (92%) or combined modality treatment (95%) versus surgery alone (17%). Patients with early or intermediate group tumors did well regardless of treatment approach. Although McCabe and Fletcher recommended surgery alone for tympanic tumors, combined treatment for tympanomastoid tumors, and radiotherapy alone for petrosal or extrapetrosal tumors,[137] the combined analysis suggests that surgery or radiotherapy are equally effective alternatives for group I and II tumors of temporal bone paragangliomas (local control 87% and 88% vs. 93% and 100% after surgery and radiation therapy for group I and II tumors, respectively), and radiotherapy is the preferred treatment option for advanced tumors (local control 92% for group III tumors) (see Table 27.10). Moreover, a combined approach does not appear to improve local control compared with radiotherapy alone. Kim et al.[111] also emphasized that there is no obvious benefit of a debulking subtotal resection in conjunction with definitive radiotherapy. The pooled analysis is based on retrospective data on 174 patients and is subject to selection/reporting bias; nevertheless, it represents a comparison based on a common staging system with reasonably long-term follow-up. Unfortunately, the respective morbidities of the different treatment groups were not detailed in these studies.

## Surgery Compared with Stereotactic Radiosurgery

A meta-analysis of tumor control rates and treatment-related morbidity was performed for glomus jugulare patients.[169] One hundred nine studies with 869 patients were collected for the analysis. Four groups of patients were compared—(a) those undergoing gross total resection (GTR), (b) subtotal resection (STR), (c) subtotal resection combined with stereotactic radiosurgery (STR + SRS), and (d) stereotactic radiosurgery alone (SRS). The median follow-up and tumor control were as follows: (a) GTR 88 months, 86%; (b) STR 72 months, 69%; (c) STR + SRS 96 months, 71%; and (d) SRS 71 months, 95%. The patients undergoing SRS alone had the best tumor control rates ($p < 0.001$). Regarding morbidity, those undergoing GTR had worse cranial IX to XI deficits compared with the SRS group although CN XII deficits were comparable.

A comprehensive literature review comparing stereotactic radiosurgery versus conventional surgery for the treatment of jugular paraganglioma in 576 patients was reported by Gottfried.[161] Eight radiosurgery series reporting outcomes on 142 patients and seven conventional surgical series detailing outcomes on 374 patients were reported. The mean patient age undergoing surgery was about 10 years younger (47 vs. 57 years, respectively) than those treated with stereotactic radiosurgery. Five of the eight series on radiosurgery had used gamma-knife whereas three were LINAC based. Patients were treated between 1990 and 2001 with 48% receiving radiosurgery as primary treatment and 52% undergoing salvage or adjuvant radiosurgery. Shrinkage of tumor was reported in 36% treated with radiosurgery, whereas 61% remained unchanged. With regard to neurological symptoms, 39% showed improvement, 58% showed no change, and 3% showed worsening. Most patients experiencing neurologic improvement did so within the first 12 months. The neurological complication rate was 8.5% with 6.4% transient and 2.1% permanent. Transient complications include exacerbation of preexisting cranial nerve deficits, tinnitus, or vertigo. The permanent complication rate was worsening facial nerve function in three patients, worsening vertigo in one patient, and progressive hearing loss to deafness in one patient. No patients experienced new lower cranial nerve deficit. No treatment-related deaths were reported. With regard to the surgically treated cohort, gross total resection was obtained in 83% to 86% of complex tumors; that is to say, those with tumors having catecholamine secretion, malignancy, multiple paragangliomas, and those with previous treatment with adverse events such as sacrifice of the ICA and 88% of 288 noncomplex tumors. The major surgical morbidities were cerebrospinal fluid (CSF) leak in 8.3%, aspiration 5.5%, wound infection/ischemia 5.5%, pneumonia 2.3%, and meningitis 2.1%. New cranial nerve deficits reported in several surgical series were noted in the seventh cranial nerve in 4% to 11%, in the ninth 26% to 42%, tenth 13% to 28%, eleventh 25% to 26%, and twelfth 5% to 21%[161,170–172] and occurs in 22% to 83%% of all surgical patients.[161,172–176] Surgical mortality was 1.3%. Additional surgical procedures included vocal cord injection (10%–25%), thyroplasty (8%–10%), eyelid weights, cricopharyngeal myotomy (4%), tracheostomy (0%–5%), tarsorrhaphy (20%), and nasogastric tube feeding (8%–20%). At a follow-up of 49 and 39 months (20–86.4 months) for the surgical and radiosurgical groups, respectively, the surgical local control was 92% and radiosurgical control was 98%.

## Stereotactic Radiotherapy

To minimize treatment morbidity, an alternative is stereotactic radiotherapy. Wegner reports an early experience of 18 glomus jugulare patients treated with LINAC-based stereotactic radiation therapy (SRT). Eight of the patients had persistent tumor after previous surgery, and one recurred after external beam radiation, whereas two were treated with combined extracranial stereotactic radiation therapy with intracranial gamma-knife radiotherapy. The median prescribed dose was 21 Gy in 3 fractions (16–25 Gy/1–5 fractions) to the 80% isodose line. At a median follow-up of 22 months, the local control rate was 100%. No patients experienced any new or worsening neurologic deficits. No patients experienced iatrogenic cranial neuropathy.

## Salvage Therapy

Late recurrences have been reported up to 19 years after radiotherapy[121] with the majority recurring within 10 years after radiotherapy (see Table 27.5), highlighting the need for continued long-term surveillance. If local failure occurs after definitive

(c) 2014 Wolters Kluwer. All Rights Reserved.

radiotherapy or surgery, Carrasco concluded that salvage rates are high based on a review of 24 series from 1964 to 1987 comprising 582 patients treated with surgery and/or radiation.[168] Four percent (25/582) died of disease (2.5% [7/283] of surgery patients and 6% of radiation patients [18/299]), and salvage was obtained in 88% in patients failing initial treatment with either surgery or radiotherapy. Of 62 patients recurring after initial resection, 95% (56/59) were salvaged with definitive radiation and 100% (3/3) with additional surgery with an overall salvage rate of 95% (59/62). Salvage of radiotherapy failures with surgery or additional radiotherapy was successful in 95% (19/20) and 71% (25/35), respectively, for an overall rate of 80% (44/55). Thus, the use of either surgery or radiotherapy as initial treatment does not preclude the success of salvage surgery or radiation for tumor recurrence.

For jugulotympanic tumors recurring after previous resection, radiation therapy represents the preferred option. Elshaikh reported the Cleveland Clinic experience comparing surgery versus radiation therapy to salvage 29 recurrent paragangliomas having undergone previous resection.[177] Median time to recurrence from initial surgery was 36 months. Sixteen were jugular, 7 carotid body, 5 tympanic, and 1 thyroid. Radiation was used in 12 patients deemed unresectable or who refused surgery (9 jugular, 2 tympanicum, and 1 thyroid), whereas surgery was used in 17 patients (7 jugular, 7 carotid body, and 3 tympanicum). Radiation consisted of SRS in 7 patients and 5 with external beam radiation. Surgery was effective in controlling all carotid body recurrences. However, in patients with jugular or tympanicum paragangliomas, radiation was more effective with local control of 100% versus 62% ($p = 0.0124$), respectively, at a median follow-up of 55 months. No significant side effects were reported from radiation while postsurgical complications occurred in 47% including lower cranial nerve palsy, CSF leak, and meningitis.

## Malignant and Catecholamine-secreting Paraganglioma

Metastatic disease is often indolent and asymptomatic. The standard treatment of malignant paragangliomas is resection of the primary and regional node dissection followed by postoperative radiation. These tumors may demonstrate more aggressive local behavior and surgery, especially of paragangliomas involving the temporal bone, may have an increased rate of complications.[113] Data regarding outcome of malignant paraganglioma after definitive radiation is rare. Hinerman reported on 3 patients with malignant carotid body tumors and neck metastases who underwent definitive radiation (64.8–70 Gy) who were without evidence of disease at 15 months, 4 years, and 6 years.[121] Catecholamine-secreting tumors should be treated with resection as case reports indicate poor functional control in patients treated with radiation therapy despite lack of tumor progression.[178]

## Treatment Strategies

Ideal treatment for a patient with paraganglioma is one that offers a high chance of cure with single-modality treatment without debilitating morbidity and with preservation of cranial nerve function. The concept of "cure" must be defined and accepted by the treating physician and, of course, the patient. Certainly, the surgical definition of "cure" is total tumor resection and long-term confirmation of tumor absence. The radiation therapy literature defines "cure," in the paraganglioma patient, as nonprogression of tumor as documented by appropriate long-term imaging follow-up. Only infrequently is there appreciable tumor regression as is often seen in the successful treatment of malignant neoplasms of the head and neck.[105,124] Therefore, the concept of "cure" in a paraganglioma patient should be modified to include stabilization or nonprogression of tumor growth.

Based on such definitions, surgery and radiation therapy demonstrate equal cure rates[121] for nonmalignant paragangliomas. Thus, in selecting a treatment modality, the focus should center on the treatment morbidity, the potential to improve symptoms, and the likelihood to preserve existing cranial nerve function. Refinements in surgery, interventional radiology, and medical care have resulted in significantly lower rates of surgical morbidity/mortality and cranial nerve dysfunction. Primary surgery should be considered for patients with small to moderate-size carotid body tumors and tympanic paragangliomas without cranial nerve dysfunction. These tumors can usually be totally excised without significant morbidity.[179] Bilateral carotid body tumor surgery should be avoided since the resulting baroreflex failure syndrome would require long-term and occasionally difficult-to-control symptoms.[180] Patients undergoing surgery for vagal paragangliomas almost always require sacrifice of the vagus nerve and, often, additional adjacent cranial nerves.[181] Primary surgery may be considered for patients with jugular or vagal paragangliomas in the presence of lower cranial nerve dysfunction (CNs VII, IX–XII), whereby resection of the tumor would not result in additional significant functional deficits, especially in younger and middle-aged patients without coexisting medical problems. For patients with catecholamine-secreting or malignant tumors, upfront surgery is recommended. In patients with an associated PGL4 mutation, surgery should be considered as the first line of treatment because of the marked increase in incidence of malignant paragangliomas.

Primary radiation therapy should be considered in jugular and vagal paragangliomas, which have a natural history for skull base or cranial nerve involvement, especially those with minimal symptoms as such tumor may be controlled with high rates of cranial nerve function preservation. For jugulotympanic tumors presenting with tinnitus, radiation therapy offers a high likelihood for improvement/resolution of such symptoms. Improvement of cranial nerve dysfunction is less likely, especially in those with a long history of deficit. Primary radiation therapy should also be

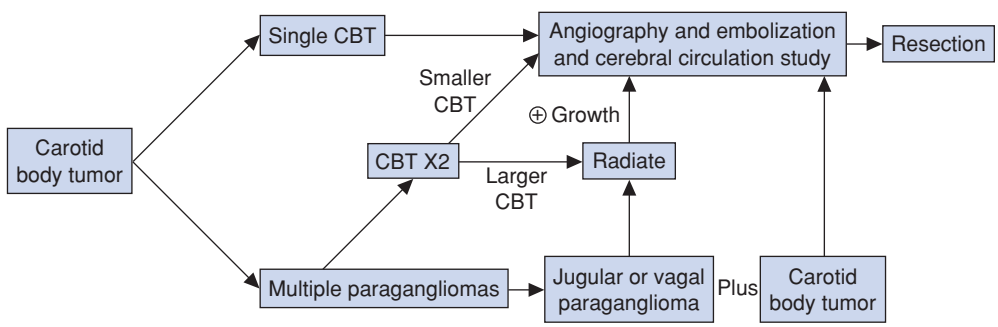

**FIGURE 27-21.** Decision analysis tree for the treatment of carotid body tumors (CBTs).

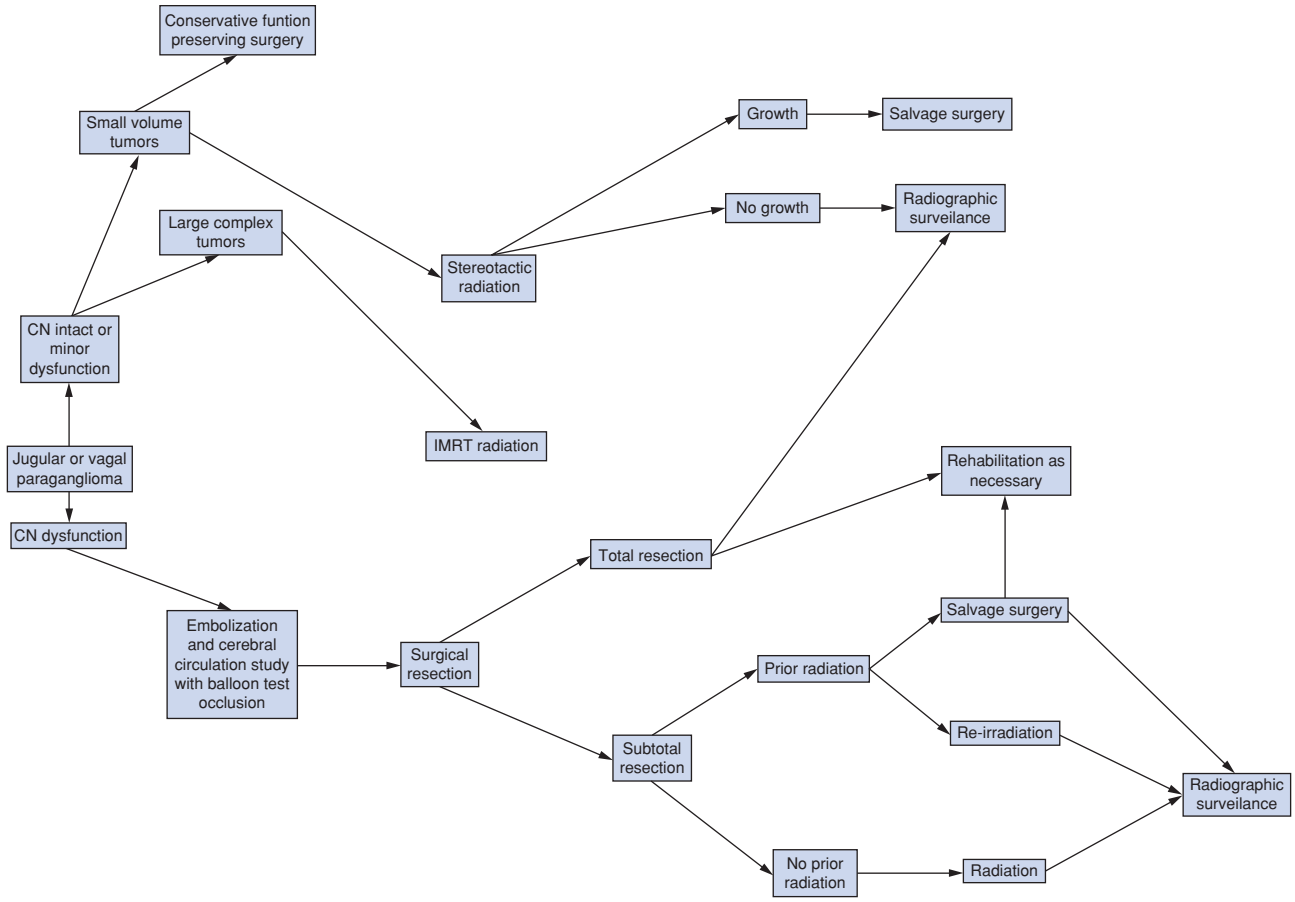

**FIGURE 27-22.** Decision analysis tree for the treatment of vagal and/or jugular paragangliomas. CN, cranial nerve.

considered in the treatment of the elderly, patients with multiple or severe medical conditions, and patients with extensive skull base or intracranial involvement.[12,76,106,107,158,176,182,183] In patients with bilateral carotid body tumors, primary radiation therapy to the larger tumor should be considered. Adjuvant radiation therapy is recommended in patients with malignant tumors and subtotal resection.

Primary radiation therapy may be delivered with conventional fractionation or with ablative stereotactic radiation doses. Typically, a dose of 45 Gy in 5 weeks is given with conventional fractionation and 15 Gy with stereotactic dosing. Excellent outcomes have been attained with both approaches, with a modestly increased risk of worsening of cranial nerve dysfunction and additional cranial nerve morbidity from stereotactic radiosurgery. Fractionated stereotactic radiation therapy may represent the optimal approach, but the experience to date is limited with shorter follow-up. In general, smaller tumors are better suited for stereotactic approaches where dose in homogeneity is lessened and volume of normal tissue at risk is smaller.

Observation without treatment is also an option for older patients and patients with a high operative risk due to medical comorbidities who can be closely followed in the setting of these slowly growing tumors.[108,109]

The appropriate treatment algorithms are shown in Figures 27-21 and 27-22 with emphasis based on multiple factors, including the patient's age, type and extent of paraganglioma, status of pretreatment neural dysfunction, comorbidities, and support network for possible treatment morbidity in determining the appropriate mode of treatment. Despite advances in surgical treatment and radiation techniques, these tumors have the potential for significant morbidity. Overriding factors such as the patient's wishes, the patient's lifestyle, and family support structure may alter the treatment choices. Regardless of the modality of treatment, long-term follow-up with serial scanning is indicated.

# PART B:
# Radiation Therapy Technique

William M. Mendenhall

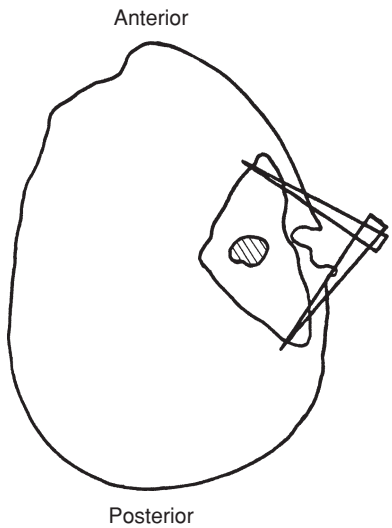
The treatment technique depends on the location of the tumor, the number of lesions (1 or ≥2), and whether the tumor is malignant. The vast majority of tumors are single and benign.

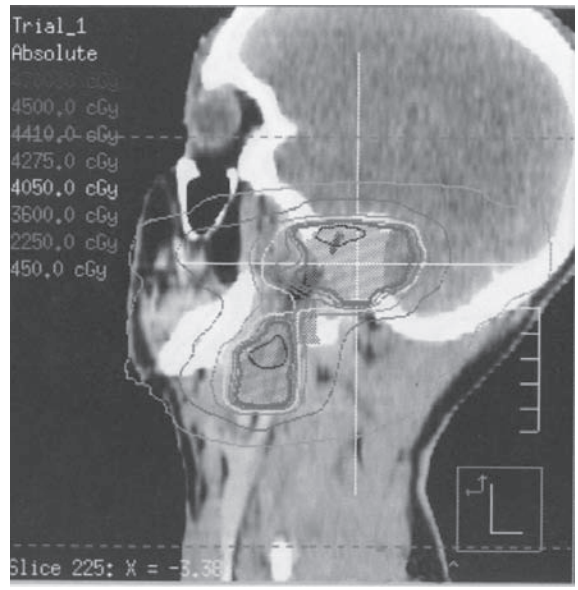
Temporal bone tumors may be treated with stereotactic radiosurgery or fractionated radiation therapy. Stereotactic radiosurgery is performed with either a linear accelerator-based system or a gamma knife; the results with either technique are equivalent.[1]

Fractionated radiation therapy may be delivered with stereotactic radiation therapy, intensity-modulated radiation therapy (IMRT), or a wedge pair technique using three-dimensional (3D) conformal treatment planning (Figs. 27-23 and 27-24).[2] The lesion is treated with a 1-cm margin of normal tissue to a dose of 45 Gy in 25 fractions over 5 weeks. The disadvantage of the wedge pair technique is that a larger volume of normal tissue is treated. However, even very large tumors can be treated with an ipsilateral technique that will result in a very low dose to the contralateral parotid gland and minimize the risk of xerostomia.

Glomus vagale and carotid tumors are not suitable for stereotactic radiosurgery and are better treated with IMRT or three-dimensional treatment planning using a wedge pair technique.

The technique used for patients with multiple tumors is variable and depends on the location and extent of the lesions. Very large bilateral tumors may require parallel-opposed fields. Alternatively, resection of one lesion and irradiation of the contralateral





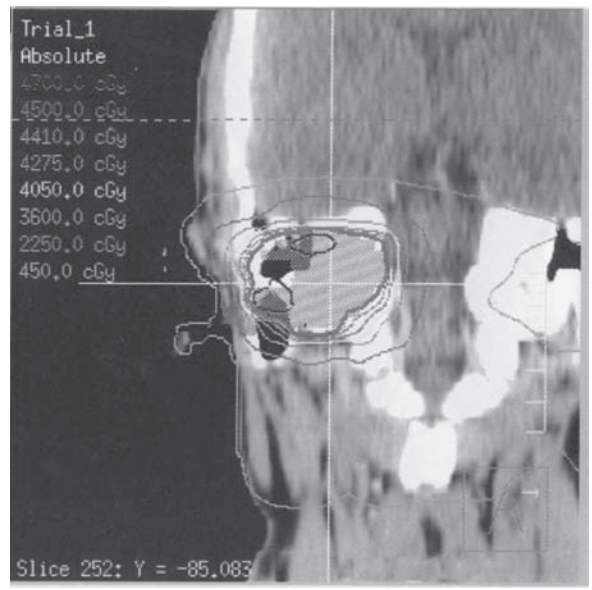


**FIGURE 27-23.** Axial contour of skull through the temporal bone depicting the dose distribution for the wedge pair technique. This consists of oblique 6-mV x-ray fields with wedge compensating filters. The fields enter anteroinferiorly and posterosuperiorly so that the beams enter and exit below the eyes. The 93% isodose line encompasses the temporal bone chemodectoma (hatched area).

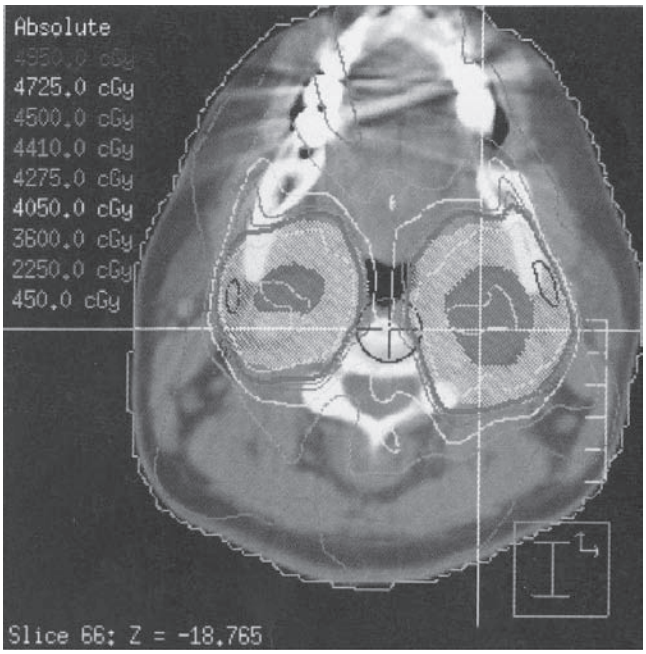

**FIGURE 27-25.** The patient is a 33-year-old woman with bilateral glomus vagale paragangliomas. She received 45 Gy in 25 fractions with 6-mV x-rays using intensity-modulated radiation therapy (IMRT). The mean parotid doses were 18.4 Gy and 20.2 Gy, respectively. Follow-up computed tomography (CT) at 1 year revealed no evidence of progression. (See color insert.)

*Source:* From Mendenhall WM, Million RR, Parsons JT, et al. Chemodectoma of the carotid body and ganglion nodosum treated with radiation therapy. *Int J Radiat Oncol Biol Phys*. 1986;12(12):2175–2178, with permission.

tumor may minimize the long-term morbidity of treatment if one of the lesions can be resected with acceptable morbidity. Relatively small bilateral paragangliomas may be treated with IMRT with adequate sparing of one or both parotid glands (Fig. 27-25).

There is little information pertaining to radiation therapy for malignant paragangliomas. The diagnosis of malignancy is based on the presence of metastatic disease. The author's philosophy has been to resect lesions that can be resected with acceptable morbidity and to add postoperative irradiation depending on the pathologic findings. In practice, most patients who are operated on for malignant paragangliomas receive adjuvant postoperative irradiation at the author's institution. The dose fractionation schedules are similar to those employed for other malignancies. Because (by definition) the regional lymph nodes are involved, the ipsilateral lymph nodes must be included in the target volume.

CHAPTER 28

# Cancer of the Thyroid and the Parathyroid

## PART A: General Principles and Management

Bruce J. Davidson, Kenneth A. Newkirk, and Kenneth D. Burman

## THYROID CANCER

### Introduction

***Epidemiology—Increasing Incidence of Thyroid Cancer.*** According to cancer statistics, there has been a substantial rise in thyroid carcinoma in the United States in recent years. Cancer statistics for 2012 estimate 56,460 new cases of thyroid cancer will occur. This is more than three times the number of thyroid cases reported 15 years earlier (Fig. 28-1).[1] The mortality is increasing at a slower rate, with 1,780 deaths expected due to thyroid cancer in 2012.[1] Were thyroid cancer outcomes more ominous, the public awareness of this significant trend would be widespread. In fact, the rise in incidence is of uncertain significance. Although this increased incidence may represent a true increase in disease, there are other possible explanations including reporting variability, increased diagnostic effort, and improved technology.

Although the reported incidence of thyroid cancer is alarming, these figures must be assessed in the context of data implying a much larger prevalence of these tumors. Several autopsy series around the world have suggested that the prevalence of occult papillary cancer (typically defined as tumors <1 cm in diameter) in patients dying of other causes ranges from 6% to 28%.[2] In the United States, studies have shown the incidence of occult papillary cancer to be 6% to 13% in patients dying of other causes.[2–4] If one were to make a very conservative estimate of occult thyroid cancer in the United States at 1% of adults, it could be estimated that there are currently >3 million undiagnosed thyroid cancers. The Surveillance, Epidemiology, and End Results (SEER) database estimated a prevalence of thyroid cancer of 458,403 in 2010; therefore, it would appear that what is seen is only a minority of the total number of thyroid cancers in cancer statistical data.[5]

There are several suspected reasons for the increased incidence of thyroid cancer. These reasons include (a) an increased reporting of occult tumors, (b) an increased diagnostic suspicion due to increased awareness by clinicians, (c) an improvement in diagnostic skills through increased ultrasound surveillance, (d) an increased use of fine-needle aspiration (FNA), and (e) the growing use of ultrasound-guided FNA to evaluate small lesions of the thyroid. If any or all of these reasons were the cause of the increase in thyroid cancer incidence, one might expect that there would be an increase in the proportion of cancers diagnosed at lower stage.

Using SEER data from 1975 to 2002 and historical staging, there has been no change in the proportion of thyroid cancer that is confined to the thyroid, so it would not appear that increases are of low-stage tumors only.[6] However, improvements to the SEER database beginning in 1988 lend further insight. First, it has been shown that the entire increase in incidence of thyroid cancer consists of papillary carcinomas. Secondly, as primary size has been better reported by SEER since 1988, 49% of the increased incidence between 1988 and 2002 consists of tumors <1 cm diameter, and 87% of the increase consists of tumors <2 cm.[6] Therefore, a significant portion of this "epidemic" of thyroid cancer would appear to be a reflection of increased investigation and assessment of small thyroid lesions. The controversy about this is not resolved as more recent analysis of SEER data shows that although the majority of the increase in thyroid cancer is among low-stage tumors, a measurable increased incidence can be shown for higher stage tumors as well.[7]

Although the diagnosis of small papillary cancers appears to be responsible for the majority of increase in thyroid cancer incidence, it is difficult to predict the natural history of even small papillary thyroid cancers and clinical judgment is important in the monitoring of such patients.[8] Mazzaferri has cautioned that even patients with micropapillary cancer have a cancer-related mortality of approximately 1%, a risk of distant recurrence of approximately 2.5%, and a risk of local node recurrences of approximately 5.0%. These figures are why clinicians are uneasy as they try to address this epidemic.

***Worldwide Epidemiology.*** The worldwide incidence of thyroid cancer varies as shown in Figure 28-2, with the highest reported incidence in Polynesia, followed by North America. In general, the

incidence in more developed countries is higher than that in less developed countries.[9] Worldwide incidence varies considerably, and even within Europe (Fig. 28-3), wide variations are seen.[10]

With such a wide variation in incidence of thyroid cancer, the impact of environmental exposures may be considered. For the countries surrounding the Chernobyl nuclear facility, an increase in thyroid cancer incidence has been shown and more will be written on this later in the chapter.[11] However, similar to the U.S. experience, multiple studies have demonstrated an increase in thyroid cancer incidence throughout the world. A relationship to the Chernobyl incident or to other radiation or environmental exposures has not been suspected in this increase.[12] Instead, the increase in thyroid cancers has been explained by a changing management strategy in thyroid disease. A French multi-institutional study demonstrates a relationship to both the increased use of diagnostic ultrasound and to rigorous cytologic evaluations. The result has been an increase in the proportion of surgical cases that result in malignant pathology.[13]

Lithuania introduced ultrasound-guided FNA in 1997 and a recent retrospective evaluation shows a significant increase in the incidence of thyroid cancer beginning in 2000. Before this, the annual increase in thyroid cancer incidence was approximately 5% per year. Since 2000, the annual increase in thyroid cancer is 28% per year. The increased incidence is seen in both papillary and follicular cancers, but is confined to stage I disease only.[12]

***Changes in Histology.*** Over the last 50 years, there has been an increase in the frequency of papillary cancers primarily, with a decrease in follicular cancers and anaplastic cancers and essentially no change in medullary cancers.[14] It has been proposed that the difference in the proportion of tumors of each histology is partly explained by variations in environmental iodine exposure. Iodine-deficient areas are associated with an increased risk of goiter and an increased proportion of follicular cancer and anaplastic cancer. Iodine-sufficient areas are associated with increased autoimmune thyroid disease and an increased proportion of papillary thyroid cancers with a decrease in follicular and anaplastic cancers. A dose–response relationship is indicated with the proportion of papillary to follicular cancers changing from approximately 5:1 in high iodine-intake areas, to 2.5:1 in moderate iodine areas to 1:1 in iodine-deficient areas.[15]

Changes in pathologic interpretation of thyroid cancers over time may confound our ability to make generalizations about the proportion of cancer histology over time and about the relationship between iodine and thyroid cancer histology. A review of previous thyroid cancer cases entered in the Geneva Cancer Registry over a 30-year period demonstrated that 45% of follicular cancers diagnosed between 1970 and 1979 were reclassified as papillary cancers. Cases entered more recently, 1990 to 1998, were less likely to be reclassified, but the rate of reclassification was still 25%. The possible explanation for this high rate of reclassification is not known but could relate to the development of stricter guidelines for microscopic characterization.[16]

***Etiology.*** A relationship between ionizing radiation and thyroid cancer was first described in 1950 by Duffy and Fitzgerald.[17] A dose–response relationship has been established for lower doses of radiotherapy, particularly in individuals exposed in childhood.[18] Between approximately 1920 and 1960, the use of low-dose irradiation was practiced for benign diseases of childhood

(c) 2014 Wolters Kluwer. All Rights Reserved.

including acne, tinea capitis, impetigo, sinusitis, adenoid hypertrophy, thymic enlargement, and keloids. The practice has now been discontinued since the recognition that this practice contributed to an increased risk papillary thyroid cancer development. However, the risk of developing thyroid cancer in patients treated with low-dose radiotherapy is increased, even for doses as small as 0.1 Gy, and although the risk begins to decline at 30 years, it remains elevated far longer. The risk is greatest for those irradiated at younger than 15 years of age with an estimated relative risk of 7.7 per Gy.[18] The risk of nodules in patients irradiated for benign disease has been reported at 38%[19] and approximately a third of these nodules will be malignant.[20–22] While the risk is significant for those patients irradiated, the numbers of irradiated patients is not felt to be large enough to explain the increase in cancer incidence across populations discussed earlier.

While childhood radiation for benign conditions is no longer used, there remains a cohort of patients who are treated in childhood for malignancy with radiation therapy. This is a population that has been shown to be at increased risk of thyroid cancer. Estimates of increased risk ratio (RR) of 4.6 to 14.6 have been reported.[23,24] The risk increases with increasing thyroid radiation dose up to about 20 Gy and then tapers off.[24] The risk is greater with younger age of treatment and in females. Subsequent thyroid cancer risk is most often associated with Hodgkin and non-Hodgkin Lymphoma[23] and neuroblastoma.[24] For lymphomas, the field of radiation includes the thyroid bed whereas for the latter tumor the early age of treatment is a major factor influencing thyroid cancer risk. The relative risk of developing thyroid cancer peaks at 20 years after treatment,[23,24] but lifelong monitoring is recommended.[23]

There has been evidence of increased rates of differentiated thyroid cancer (DTC) in areas downwind from nuclear test sites.[24] Following atomic testing in the United States between 1950 and 1958, the estimated average cumulative dose of radiation from environmental iodine-131 ($^{131}$I) has been estimated to range from 1 to 4 rads per individual across the United States. Some areas are estimated to have had exposures up to 16 rads. In contrast, the average annual background radiation is 0.1 rad.[26] A careful evaluation of thyroid cancer rates attributable to atmospheric nuclear testing found that the risk of thyroid cancer was only suggested for individuals exposed before the age of 1. Older children and adults did not demonstrate an increased risk.[26]

The risk of environmental exposure from radiation has been clearly documented following the Chernobyl nuclear disaster in the Ukraine in 1986.[27–29] The pattern of development, however, is quite different from that seen in childhood therapeutic radiation exposure. In childhood low-dose therapeutic radiation exposure, the risk of thyroid cancer rises after a latency of approximately 10 years and peaks at 25 to 30 years as shown in Figure 28-4.[30] Following Chernobyl, the increase in thyroid cancers was seen as early as 1989, only 3 years after the accident.[27–29] The impact of the Chernobyl disaster may not be yet fully known. Data from Belarus (whose border is <20 miles from Chernobyl) indicate a significantly higher incidence of thyroid cancer in high-exposure areas when compared with low-exposure areas. The rate of thyroid cancers continues to increase in individuals who were between 0 and 15 years of age at the time of the disaster.[11]

Other environmental factors that might lead to an increase in thyroid cancer development are not clear. In a thorough case-control study using the Swedish Cancer Registry and an extensive review of lifetime diagnostic radiograph exposures, there was no evidence of an increased exposure to diagnostic radiographs in patients with DTC.[31] Similarly, there is no strong indication that irradiation from the use of therapeutic $^{131}$I leads to an increased risk of thyroid cancer.[32–35] One exception is work by Franklyn et al. which evaluated patients with hyperthyroidism given $^{131}$I and found a higher incidence and mortality rate of thyroid cancers as well as a higher incidence of small bowel tumors, although the absolute incidence rates were low.[36]

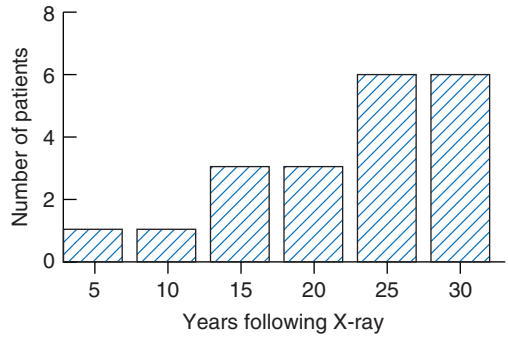

**FIGURE 28-4.** Incidence and timing of papillary thyroid carcinoma in patients exposed to ionizing radiation during childhood.

*Source:* Adapted from DeGroot M, Sternberg T. *The Thyroid and Its Diseases*. 5th ed. New York, NY: Churchill Livingstone; 1984, with permission.

Associations between thyroid cancer and other exposures have been investigated. Owing to the fact that thyroid cancer is a relatively common disease in young women and the increased incidence of thyroid cancer is greatest in women, multiple studies have investigated the relationship between thyroid cancer and reproductive history and exogenous hormone use. The data are mixed but describe an increased risk of thyroid cancer with early menarche,[37] early first pregnancy,[38] late first pregnancy,[39] and late last pregnancy.[39,40] Other studies show no relationship to reproductive history.[41,42] The relationship between oral contraceptive use and thyroid cancer has been positive, negative, or unrelated depending on the study,[37,43,44] although there is a suggestion from pooled data that oral contraceptives can act as a promoter of thyroid cancer.[43] The risk of oral contraceptive use appears to be eliminated after the hormone is discontinued.[43]

Genetic causes of thyroid malignancy are well known for medullary cancer, and this will be discussed in detail later in the chapter. For papillary cancer, there are a handful of syndromes that manifest this cancer. These include Gardner syndrome, Cowden disease, and Carney complex, all autosomal dominantly inherited.[45,46]

## Relevant Anatomy

***Embryology.*** The thyroid gland develops from the endodermal tissues of the primitive gastrointestinal tract. The site of origin ultimately is the foramen cecum at the tongue base and descent of the thyroid occurs by the seventh gestational week to lie anterior to the cricoid and cervical trachea. The thyroid is able to concentrate iodine and form thyroid hormone by the 11th gestational week. It reaches its full size of 15 to 25 g in adulthood.

The descent of the thyroid through the anterior midline neck explains several anomalies that relate to thyroid pathology. These include ectopic thyroid located at the tongue base, termed a *lingual thyroid*. Lingual thyroid tissue has been reported in up to 10% of children.[47,48] When noted, this may represent the only thyroid tissue in patients and evaluation of the neck for additional thyroid tissue is important. Along the pathway of thyroid descent, a cyst of ciliated pseudostratified epithelium and variable amounts of thyroid tissue may remain. These thyroglossal duct cysts are usually closely related to the central portion of the hyoid bone, and it is generally accepted that this bone must be resected to successfully remove the cyst. The cyst, or similarly located ectopic thyroid tissue, may give rise to thyroid neoplasia

(c) 2014 Wolters Kluwer. All Rights Reserved.

on occasion. The most inferior point on the pathway of normal thyroid descent would be represented by the pyramidal lobe, thyroid tissue located just cephalad to the thyroid isthmus.

Other ectopic locations of thyroid tissue have been noted including mediastinum, heart, liver, esophagus, larynx and trachea, and ovary.[49–54] These structures are obviously beyond the range of the typical descent of thyroid tissue and represent true ectopic locations. Thyroid rests in cervical lymph nodes deserve special mention. Although these have been described previously in cervical lymph nodes,[55] the concern when thyroid tissue is identified in these nodes is that this represents well-DTC metastatic to that node. As a general rule, thyroid rests in nodes along the jugular chain (i.e., lateral neck nodes) are considered diagnostic for thyroid malignancy. On the other hand, thyroid rests in central compartment lymph nodes are felt to represent benign thyroid rests if no suspicion of malignancy is noted in the thyroid itself. These guidelines may not apply to all patients and each patient's context should be reviewed to determine when additional testing for the presence of malignancy must proceed.

While the thyroid follicular tissue develops from the embryologic foregut, the calcitonin producing (C or parafollicular) cells of the thyroid develop from neural crest ectoderm related to the fourth and fifth branchial pouches. These tissues, known as the *ultimobranchial body*, migrate anteriorly and merge with the descending follicular thyroid tissues, thus explaining their designation as parafollicular cells. Analysis of thyroid tissues has shown that these C cells lie in greater concentration in the superior and posterior aspect of the thyroid, a location similar to the superior parathyroid, which also arises from the fourth brachial pouch.

The parathyroid glands develop as two paired structures from the third and fourth branchial pouches. The third pouch gives rise to the inferior parathyroid and the more inferior thymus gland. This relationship explains the fact that ectopic parathyroid tissues may be located within the thymus. As stated, the superior parathyroid develops from the fourth branchial pouch along with the ultimobranchial body, which gives rise to the C cells.

## Anatomy

The thyroid consists of two lobes, each approximately 8 to 10 mL in size connected by a thin isthmus lying over the trachea. A pyramidal lobe of any significant size is present in a minority of cases. The average gland weighs 15 to 25 g. The thyroid isthmus is often easily palpated, just below the cricoid cartilage. The thyroid lobes are palpable lateral to this, with the examination made easier when the patient swallows. The left and right lobes of the thyroid lie just deep to the sternothyroid muscles. The gland is encased by a thin layer of fascia, but the posterior attachment of the gland to the trachea is quite dense and lies just medial to the area where the recurrent laryngeal nerve enters the cricothyroid membrane. It has been estimated that up to two-thirds of thyroid glands may have a tubercle of Zuckerkandl, a posterior, lateral extension of the thyroid lobe that may be an important landmark in identifying the recurrent laryngeal nerve and the superior parathyroid gland.[56–58]

***Vascular and Lymphatic Anatomy.*** The vascular anatomy of the thyroid is described as two paired arteries and three paired veins. These include superior and inferior thyroid arteries and superior, middle, and inferior thyroid veins. Although this is true, the practical application of this information is significantly limited by the surgical anatomy of the thyroid. The superior thyroid vein, and to a lesser extent the artery, anastomose with the thyroid through several small branches. The superior laryngeal nerve may be intertwined with these branches, so meticulous dissection of individual branches of the superior thyroid artery and vein is required when dissecting the superior pole of the thyroid. Likewise, the inferior vein is always divided into multiple branches at the margin of the thyroid gland. Individual ligation of these branches is required due to the fact that the inferior parathyroid is often located on the thyroid capsule in this area. Finally, the inferior thyroid artery has been shown to contribute the major blood supply to both the inferior and superior parathyroid glands. Preservation of the vascularity of these glands is felt to be important in order to preserve their function after thyroidectomy. Therefore, dissection and ligation of only the distal branches of this artery as they enter the thyroid has been felt to be most judicious. Regarding the last point, however, there may be some debate as two randomized studies looking at subtotal thyroidectomy found no difference in postoperative hypocalcemia whether or not the inferior arteries were ligated at the main trunk.[59,60] Whether these studies apply to the performance of total thyroidectomy is unclear.

The superior thyroid artery arises as the first branch of the external carotid artery in the vast majority of individuals. From this point, it descends to the upper thyroid pole by passing deep to the omohyoid muscle and superficial to the superior constrictor muscle and cricothyroid muscle. The superior laryngeal nerve arises from the vagus nerve high in the neck and passes deep to the carotid artery to reach the larynx. The internal branch of the superior laryngeal nerve enters the thyrohyoid membrane just inferior to the hyoid whereas the external branch travels parallel and deep to the superior thyroid artery and then passes medially to the cricothyroid muscle.

The relationship between the superior thyroid artery and nerve is variable. This variability was emphasized in a recent anatomic study that included review of previous data. In this, the nerve was shown to cross the plane of the superior thyroid artery over 1 cm above the superior thyroid pole in 18% to 68% of cases. The nerve crossed within 1 cm of the superior thyroid pole in 11% to 60%. However, the more important, and most consistent, anatomic relationship for surgical dissection was the finding that the nerve crosses the artery below the upper pole of the thyroid in 14% to 20% of patients.[61] In addition to this study, recent work has shown that in almost half of all thyroidectomies the superior laryngeal nerve may be located below the superior pole of the thyroid gland and be at risk for injury,[62] with oversized glands having a higher risk.[63]

The inferior thyroid artery is a branch of the thyrocervical trunk and passes deep to the common carotid artery to reach the thyroid. In this orientation, it is roughly perpendicular to the recurrent laryngeal nerve. The relationship between the inferior thyroid artery and this nerve is variable, but is stated to demonstrate the nerve as deep to the artery in 70% of cases. A distinction has been suggested between the two sides of the larynx with the right nerve most often passing between branches of the inferior thyroid artery and the left nerve most often passing behind the artery.[64]

Lymphatics of the thyroid consist of a rich intraglandular network as well as extraglandular drainage. The intraglandular network has been thought to explain the high rate of multifocality in papillary thyroid cancers by allowing tumor emboli to travel through the thyroid and metastasize to other intrathyroidal sites. The extraglandular network passes through the medial compartment of the neck and also follows the arterial supply in a retrograde manner as it exits this medial compartment. The medial or central compartment of the neck, shown in Figure 28-5, represents the primary echelon nodal drainage from the thyroid gland. Surgical dissection of the central compartment in the treatment of thyroid papillary carcinoma has been shown to yield an average of eight nodes per patient.[65]

Secondary echelon nodal drainage is to the lateral neck compartment and posterior triangle lymph nodes. The retrograde lymphatic drainage following the arterial supply to the thyroid

(c) 2014 Wolters Kluwer. All Rights Reserved.

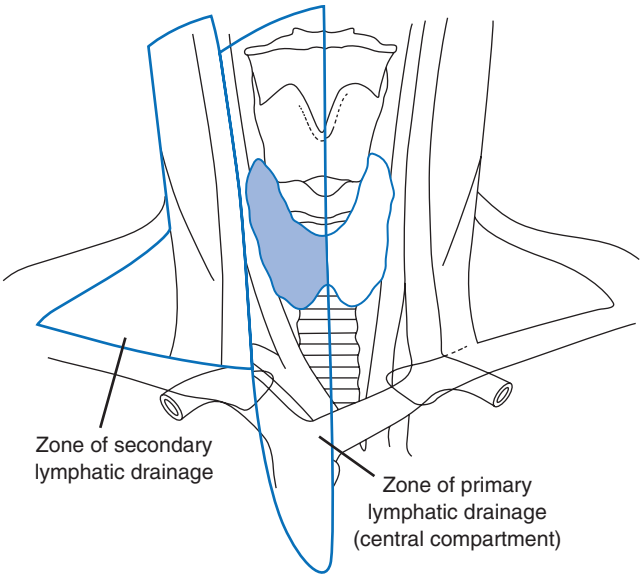

**FIGURE 28-5.** Primary and secondary echelon lymphatic drainage from the thyroid gland.

is demonstrated by work on subcentimeter papillary thyroid cancers. Small tumors of the upper portion of the thyroid are as likely to spread to level II in the upper jugular chain (presumably through lymphatics along the superior thyroid artery) as to lower neck nodes.[66]

***Neuroanatomy.*** The nerves important in thyroid anatomy and thyroid surgery are those of the larynx. The superior laryngeal nerve and recurrent laryngeal nerve are branches of the vagus nerve. This nerve exits the skull base at the jugular foramen, and just below this point, the superior laryngeal nerve branches off to pass deep to the carotid artery and medially toward the larynx. The internal branch of this nerve enters the thyrohyoid membrane to supply sensory innervation to the supraglottic larynx. The superior location of this branch means that is it not at risk in thyroid surgery unless a large cephalad extension of the thyroid is present. The external branch of the nerve is of greater concern in thyroid surgery. This branch innervates the cricothyroid muscle, a nerve important in vocal fold stretch and in vocalizing at high pitch. The nerve travels to this muscle along the superior thyroid artery, to which it lies deep. Near the upper pole of the thyroid and occasionally between branches of the superior thyroid artery, the nerve travels medially to the cricothyroid muscle. *En route*, the nerve may penetrate the inferior constrictor muscle and, in fact, has been shown to travel deep to this muscle throughout its course in 10% of patients.[61] The nerve is quite small and even with significant effort can prove difficult to identify. In fact, one study reported an effort to identify the nerve in 50 cases using a nerve stimulator and was only able to identify the nerve in 20% of cases.[67] Other surgeons have been more successful and have reported success in identifying the nerve in >90% of cases.[68]

The recurrent laryngeal nerve branches from the vagus nerve in the thoracic cavity. On the left side, the nerve passes around the aortic arch and then superiorly up along the tracheoesophageal groove to the Berry ligament. On the right side, the nerve passes around the subclavian artery and then passes in a more oblique direction toward the larynx. The nerve passes deep to the inferior thyroid artery in most cases (Fig. 28-6). As the nerve proceeds cephalad, small branches may be seen that enter the

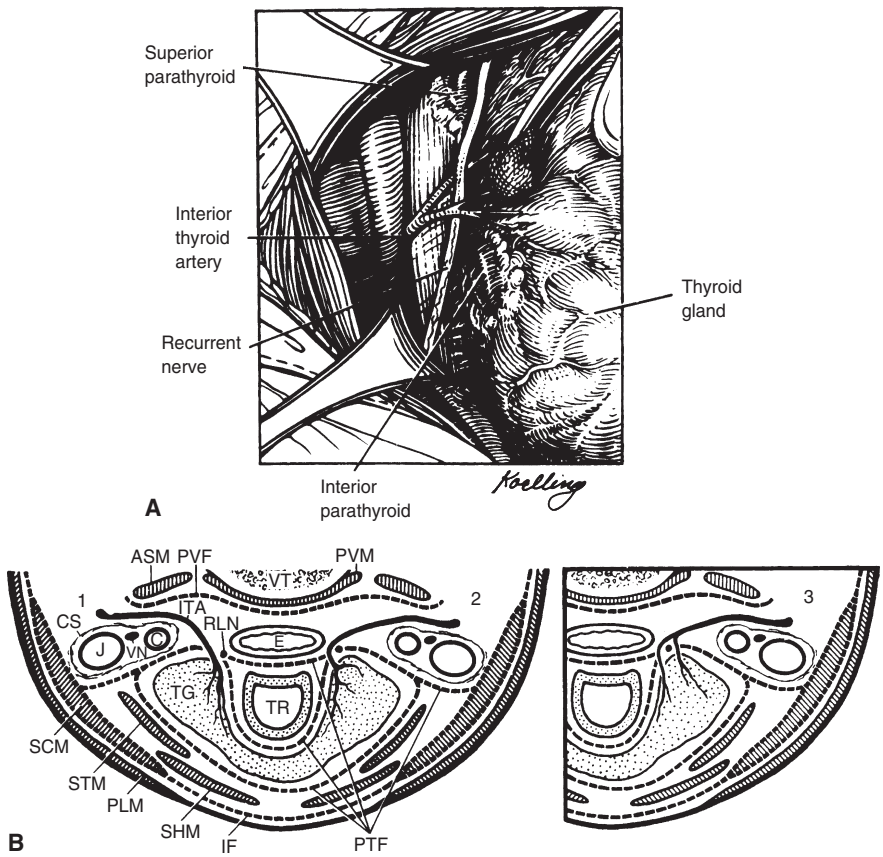

**FIGURE 28-6.** The various relationships of the inferior thyroid artery to the recurrent laryngeal nerve. **A:** View of the right neck with the inferior artery dividing to straddle the recurrent laryngeal nerve. **B:** Cross-sectional diagram of the neck showing the various relationships between the inferior thyroid artery and the recurrent laryngeal nerve (*1*, artery superficial to nerve; *2*, artery deep to nerve; *3*, artery dividing around nerve). trachea and esophagus. These include sensory branches to the upper trachea and subglottic larynx. The motor component of the recurrent laryngeal nerve may divide into a posterior and anterior division below the level of the Berry ligament. Katz describes branching of the nerve over 5 mm below the lower border of the cricoid cartilage in 63% of >1,100 thyroidectomies.[69] In addition, recent work suggests that in 1% of cases the recurrent nerve or its branches may enter the larynx in a higher-than-expected location making the nerve more prone to injury.[70] It is important to recognize this branching of the nerve during thyroid surgery. Failure to recognize this anatomy may result in injury to a branch of the nerve. The function of the motor branches of the recurrent laryngeal nerve is to supply all of the muscles of the larynx except the cricothyroid. These include both the abductors and the adductors of the larynx. Injury to the nerve can result in significant laryngeal incompetence. When disruption of those sensory fibers from the recurrent laryngeal nerve to the upper trachea and subglottic larynx occurs in conjunction with motor injury to the recurrent nerve, the combination of vocal cord incompetence and hemitracheal anesthesia can make the postoperative course of such a patient much more problematic.

The anatomy of the recurrent laryngeal nerve results in some specific risks during thyroid surgery. The nerve can be placed under significant stress during the surgery as dissection proceeds along the lateral aspect of the thyroid and the gland is retracted medially to expose the path of the nerve. During this medial retraction of the gland, the nerve may become compressed by a distal branch of the inferior thyroid artery or by a fascial band stretched across the nerve. At the ligament of Berry, the nerve courses posteriorly to enter the larynx behind the cricothyroid joint. This fixed relationship between the nerve and the cricothyroid joint and the medial traction of the gland described earlier can also contribute to stretch on the recurrent laryngeal nerve during the dissection. Inadvertent transection of the recurrent laryngeal nerve is not a significant risk for an experienced thyroid surgeon. However, stretch injuries of the nerve may still occur. Almost all of these are temporary. The use of intraoperative recurrent nerve monitoring has been suggested to decrease the risk of injury. However, in recent review of the literature, Dralle et al.[71] found that in six studies comparing intraoperative recurrent nerve monitoring with postoperative laryngoscopic findings, nerve monitoring had a high negative predictive value (NPV; 92%–100%), but relatively low and variable positive predictive values (PPVs; 10%–90%), potentially limiting the role of nerve monitoring. International study guidelines have recently been published on the role of intraoperative nerve monitoring.[72]

A special anatomic relationship should be mentioned in the case of the right recurrent laryngeal nerve. This nerve may be nonrecurrent in a small number of patients, typically estimated at well below 1%. This occurs when there is an aberrant takeoff of the right subclavian artery. This anomaly represents an anomaly of the fourth branchial arch resulting in the right subclavian to arise from the aorta and pass deep to the esophagus. The recurrent laryngeal nerve will then pass deep to the carotid and directly toward the larynx. The authors have seen nonrecurrent nerves that travel parallel (and deep) to the superior thyroid artery and others that resemble a recurrent nerve except that they travel behind the carotid at the level of the inferior thyroid artery.

***Parathyroid Anatomy.*** Normal parathyroid glands are each approximately 40 to 70 mg in weight, meaning a size of approximately 4 × 6 mm at surgery. The location of these glands is variable. The typical location of the superior parathyroid gland is behind the thyroid at the cricoid level, lateral to the recurrent laryngeal nerve. The inferior glands are located on or adjacent to the lower pole of the thyroid in 50% of cases. The inferior glands may lie within thymic tissue in up to 40% of cases.

In the treatment of primary hyperparathyroidism, the surgeon must be familiar with various ectopic locations of parathyroid tissue in order to identify and resect adenomas or hyperplastic glands in these locations. The treatment of malignant diseases of the thyroid does not typically require direct application of this knowledge. However, the surgeon should be aware that 4% of parathyroid glands are found embedded within the thyroid gland.[73] Figure 28-7 shows such a case where both inferior parathyroid glands were identified within the thyroid on pathologic study. This case emphasizes both the possibility of intrathyroidal parathyroid gland and the symmetry often seen when searching for parathyroid glands at surgery. Beyond identification and preservation of parathyroid glands while dissecting the thyroid gland, the treatment of thyroid malignancy will often require a medial compartment neck dissection. Here, the parathyroid glands are at significantly greater risk of devascularization or inadvertent removal during the dissection process and surgeons must be facile at parathyroid gland identification, dissection, and preservation of the parathyroid vascular pedicle, and when necessary, perform parathyroid autotransplantation, usually into an adjacent muscle.

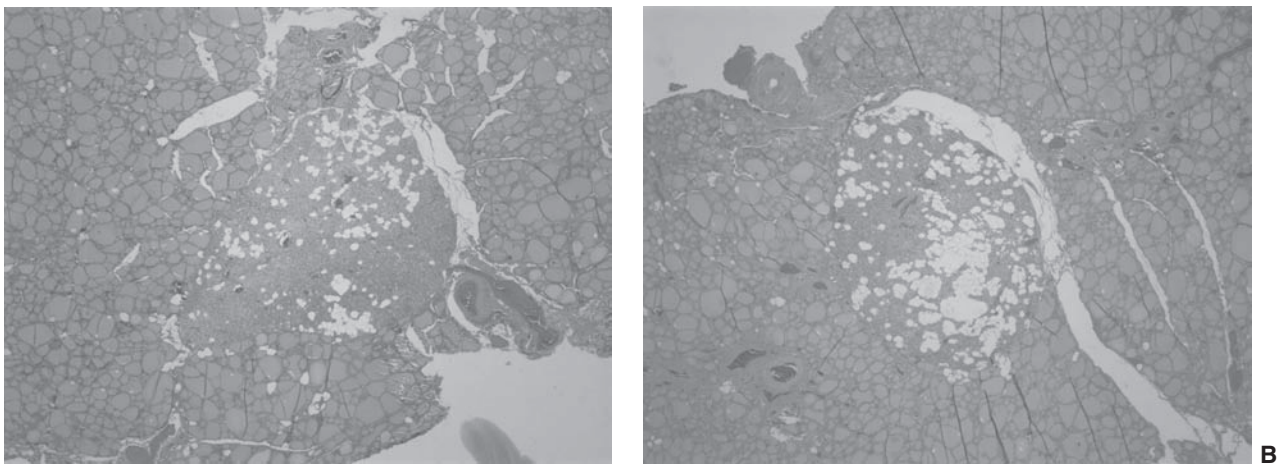

**FIGURE 28-7.** Pathologic evaluation following thyroidectomy revealed that this patient's left **(A)** and right **(B)** inferior parathyroid glands were both located within the thyroid parenchyma. This example demonstrates the relative symmetry that may be seen in parathyroid anatomy.

## Physiology

The application of thyroid physiology in the treatment of patients with thyroid cancer is one of the basic tools of the clinician. These applications include the possible use of exogenous thyroid hormone to suppress stimulation of benign and malignant thyroid tissue, withdrawal of thyroid hormone to allow intrinsic stimulation to be maximized in anticipation of radioactive iodine, and, more recently, the use of exogenous thyroid stimulation to prepare patients for radioactive iodine without the need for exogenous thyroid hormone withdrawal.

The basic functional unit of the thyroid is the thyroid follicle, which consists of a space filled with colloid and lined by thyroid follicular cells. These cells avidly trap iodide molecules through sodium iodide symporter channels and transport this iodide to the follicular lumen. Meanwhile, follicular cells also synthesize thyroglobulin (Tg), a glycoprotein that serves as the backbone and storage molecule for thyroid hormone. On the luminal side of the follicular cell plasma membrane, iodide molecules are oxidized and attached to tyrosyl peptides of the Tg molecule. Subsequent coupling of iodinated tyrosyl residues leads to the formation of the functional thyroid hormones, still embedded within the Tg glycoprotein through these tyrosyl residues.[74] The two active thyroid hormones, thyroxine (T4) (3,5,3',5'-tetraiodothyronine) and 3,5,3'-triiodothyronine (T3), are stored in this manner within the thyroid colloid until released into circulation. Release of active hormone occurs by reverse pinocytosis from the intrafollicular space back through the follicular cell where the Tg molecule is cleaved to release the T3 and T4 hormones into the plasma.

Tg itself may leak out or be released from follicular cells into the circulation, and the serum measurement of Tg has become an important tumor marker. The molecule is present in serum in normal and pathologic conditions. Increased serum Tg concentrations may be seen in the hyperthyroid phase of silent or subacute thyroiditis; multinodular thyroid disease; and in papillary, follicular, and anaplastic thyroid cancers. The use of serum Tg measures in previously untreated patients (with intact thyroid glands) is limited by its lack of specificity to distinguish benign from malignant conditions. However, in patients previously treated for DTC, in whom there is little or no residual normal thyroid tissue, Tg has become an essential indicator of residual or recurrent DTC (i.e., papillary or follicular thyroid cancer).

In plasma, T3 and T4 are bound to thyroxine-binding globulin (TBG) as well as prealbumin and albumin. Thyroxine-binding globulin is a protein made in the liver and is the dominant thyroid hormone–binding protein. T4 mainly acts as a prohormone and is metabolized to the active form of thyroid hormone, T3, in the liver and kidney primarily. Actions of thyroid hormones influence growth, development, and metabolism. In adulthood, the major effects of thyroid hormone are in the regulation of metabolism, including changes in oxygen consumption and protein, carbohydrate, lipid, and vitamin metabolism.[75]

Iodine and thyroid-stimulating hormone (TSH) are the major influences on thyroid hormone secretion and thyroid stimulation. TSH is excreted from the anterior pituitary and is in turn regulated by thyrotropin-releasing hormone (TRH) from the hypothalamus. Both TSH and thyrotropin-releasing hormone excretion are influenced by feedback from serum levels of thyroid hormones (Fig. 28-8). TSH has been shown to increase thyroid hormone production through multiple mechanisms, from increasing iodine uptake by the sodium–iodine symporter to expediting Tg reuptake by thyrocytes as well as multiple steps in thyroid hormone production.[74]

TSH also stimulates thyrocyte proliferation. It is this effect that has led to the use of TSH suppression as an adjunct in the treatment of thyroid malignancy. Consistent TSH suppression therapy, interrupted only for short periods of TSH stimulation, in order to perform diagnostic studies or ablative treatment with radioactive iodine has long been the mainstay of papillary and follicular thyroid cancer treatment. TSH stimulation has traditionally required withdrawal of exogenous thyroid hormone for several weeks. More recently, however, this stimulation can be obtained through the use of recombinant human TSH (rhTSH) injections without the need for thyroid hormone withdrawal.

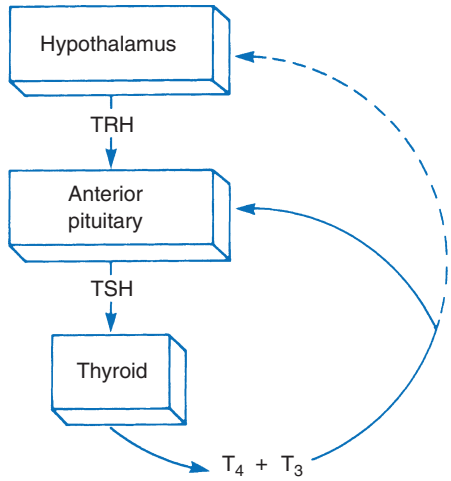

**FIGURE 28-8.** Autoregulatory feedback system for thyroid activity. TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

## NATURAL HISTORY, PATHOLOGY, PATHOGENESIS, AND PATTERNS OF SPREAD

Papillary thyroid cancer, and to a lesser extent follicular thyroid cancer, generally grows as an intraglandular mass before developing lymphatic and distant disease. For this reason, most patients will be alerted to the possibility of the presence of cancer by the discovery of a thyroid mass. Most thyroid masses are, in fact, benign, so the level of clinical suspicion may impact upon the discovery of a malignancy.

A myriad of pathologic processes might present with a mass in the thyroid. Among the benign thyroid masses are adenomatoid nodules, follicular adenomas, and thyroiditis. Adenomatoid nodules are the most common finding to present as a thyroid mass. These may occur as individual masses, but are commonly seen in multinodular glands. Follicular adenomas are benign, but due to the limitations of cytologic evaluation cannot reliably be distinguished from follicular carcinomas. Patients with autoimmune thyroiditis are at risk of developing thyroid lymphomas.

Malignant thyroid masses include papillary and follicular cancer, medullary and anaplastic cancer, lymphoma, squamous cell carcinoma, metastatic tumors to the thyroid, and other rare malignancies. Most of these tumors arise from follicular epithelium. The exceptions are medullary cancer, which arises from parafollicular cells and lymphomas, which arise from intrathyroidal lymphoid cells.

Papillary cancer is the most common thyroid malignancy and makes up approximately 80% of all thyroid cancers.[76,77] Follicular cancer makes up approximately 10% of thyroid cancers and the remaining 10% of tumors are medullary, anaplastic, and other tumors. The distribution of these cancers changes with age. Papillary cancer is more common in patients younger than 40 years of age,

(c) 2014 Wolters Kluwer. All Rights Reserved.

and follicular cancers more common in older patients. Anaplastic cancers are almost exclusively seen in older patients.

## Papillary Cancer

Papillary architecture is the histopathologic feature that is characteristic of papillary cancer. However, there are multiple additional features that may be seen. The tumors consist grossly of a firm mass within the thyroid gland. Papillary fronds and areas with laminated calcified structures known as *psammoma bodies* may be present. Crowded follicular epithelial cells with cleaved nuclei, nuclear clearing, prominent nucleoli, and mitotic figures define this cancer.[78] Many of these nuclear features can be identified easily in cytologic specimens, making the diagnosis of this tumor by FNA quite accurate.

Earlier in this chapter, the authors reviewed the frequency of occult thyroid cancer and estimated that a large proportion of occult cancers of the thyroid are currently undiscovered. These occult tumors are papillary cancers and are defined by a diameter of <1 cm. The term *papillary microcarcinoma* has been used to describe these tumors. Their natural history is statistically inconsequential, given that most will go undiscovered and never cause any clinical disease. However, whether these occult tumors are biologically distinct from clinically apparent papillary cancers is unknown. There is recent retrospective data from Hong Kong that suggests that only clinically apparent microcarcinomas are of clinical importance due to the fact that, when compared with occult microcarcinomas, only the overt tumors demonstrated a risk of extrathyroidal or lymphovascular invasion, nodal metastases, and postoperative recurrence.[79]

The natural history of clinically apparent thyroid tumors consists of progressive enlargement, intraglandular metastases, involvement of adjacent structures, regional lymphatic disease, and distant metastatic disease. This series of events is not thought to necessarily occur in a stepwise manner; intraglandular metastasis and regional nodal involvement are the most common clinical findings for this tumor type.

A common pathologic feature in papillary thyroid cancers is for multiple foci of tumor to occur within the gland.[80] It has not been clear whether these are intraglandular metastases or true multifocal tumors. Previous literature suggested that this was more commonly a feature seen in irradiated glands.[81] Others found support for a mechanism of intraglandular metastatic spread.[82] However, recent investigations have found genotypic distinctions between multifocal tumors in 40% to 50% of patients with papillary cancer.[83,84] These data indicate that a significant portion of multifocal tumors arise independently in a gland at risk as opposed to intraglandular spread of tumor.

Others, however, have shown evidence of clonal origin in >85% of these multifocal tumors.[85] The papers showing genotypic differences between tumor foci utilized single gene comparisons whereas the paper demonstrating clonality utilized multiple loci in a loss of heterozygosity investigation. Given that tumor development is a multistep process, with multiple genetic events, additional genetic events may occur after intraglandular dissemination. The prognostic impact of multifocality seems to predict an increased risk of recurrence without an impact on survival.[86]

Regional lymphatic metastases are the second most common pathologic feature of papillary thyroid cancer. These occur in >35% of adults with papillary cancer[87] and an even higher proportion, 40% to 75%, in patients older than 40 years of age at diagnosis.[88–90] The risk of regional lymph node metastasis has been shown to be higher in patients with multifocal disease and in those with intratumoral lymphatic vessels.[91,92] The risk of nodal disease is not confined to those with macroscopic primary tumors as some series of microcarcinomas have shown metastatic nodal disease in approximately 50% of patients.[93]

The prognostic impact of nodal disease is unclear. Although there is a high rate of nodal disease in young patients, these patients have an excellent prognosis. The impact of age on prognosis is so dominant that the overall significance of nodal disease has been debated. However, in multivariable analyses and in age-matched case-control studies, a worse prognosis emerges for patients with nodal disease.[91,94] This is shown for both cancer recurrence and disease-specific survival.[86] The greatest impact of nodal disease on survival may be seen in patients older than 60 years of age, a cutoff significantly older than is reflected in the current staging system (where age 45 is thought to be determinant).[95]

Between 10% and 20% of papillary thyroid cancers will show evidence of local invasion. When this extends beyond perithyroidal fat, adjacent structures may be invaded. Most commonly, extension to strap muscles anterior to the gland may be seen. The clinical significance of this is minimal as these muscles may be resected without significant postoperative sequelae. Tumor or medial compartment nodes may also invade the recurrent laryngeal nerves, the hypopharynx, the esophagus, the larynx, or the trachea. Invasion may range from microscopic to gross invasion of these structures. Preoperative indications of involvement include voice change, dysphagia, and respiratory compromise.

Distant metastatic disease from papillary thyroid cancer is most commonly seen in the lungs. Other distant sites include bone, brain, and, less commonly, other locations. Distant metastases are shown in 2% to 3% of papillary thyroid cancers at diagnosis.[96,97] Microcarcinomas have been suggested to have an equivalent likelihood of distant metastasis at the time of diagnosis.[98] In follow-up, another 3% developed lung metastases. The risk is greater when follicular variant papillary cancer is present and even higher for macroinvasive follicular carcinoma.[97] The prognostic impact of distant metastatic disease is significant with a worse survival when disease is macroscopic and does not concentrate radioiodine.[99,100] Adults with macrometastases have been reported to have a 50% survival at 1 year,[101] but this can depend significantly on the number and location of the distant metastases.

Distant metastases from DTC appear to be more common in children than in adults. The prognostic impact, however, is less. Children younger than 21 years of age will present with distant disease in approximately 25% of cases, but 10-year cause-specific survival approaches 100%. The need for ongoing management of these cases is indicated by a progression-free survival rate of 66% at 10 years.[102]

A growing body of evidence shows the high frequency of BRAF mutation in PTC. Next to melanoma, papillary thyroid cancer has the highest frequency of this mutation, ranging from 27% to 81%.[103] The result of these mutations is activation of the mitogen-activated protein kinase (MAPK) pathway leading to tumorogenesis. Other pathways leading to activation of this kinase include ras mutations (more common in follicular thyroid cancers). These pathways to MAPK activation appear to be mutually exclusive mechanisms within individual tumors. There are >40 different BRAF mutations reported, but >90% consist of a T to A transversion at nucleotide 1,799 and lead to an amino acid change at residue 600. This mutation is described as BRAFV600E and causes constitutive activation of the protein, thus driving the MAPK pathway.[104]

There may be geographic variability in BRAF mutations in PTC with the highest rates shown in Korea (63%–81%).[103] The lowest reported rates are in Southern Europe (27%–60%). Interestingly, data from University of California, San Francisco (UCSF) describes an increase in BRAF mutations in papillary cancers treated at that institution over time with a rate of 43% to 51% prior to 2001 and a rate of 88% since that time.[105] The prognostic impact of BRAF mutations is under study.[104]

## Follicular Variant of Papillary Thyroid Cancer

The World Health Organization reports 15 variants for papillary thyroid carcinoma.[106] The most common of these variants are the follicular, tall cell, and diffuse sclerosing variants (DSVs). In a series of >1,000 cases in 30 years, reviewed with present day diagnostic criteria, classic papillary cancer was seen in 46%, microcarcinoma in 28%, follicular variant in 18%, tall cell in 4%, and diffuse sclerosing in 2%. Other variants, including insular, oncocytic, and others were seen <1% of the time.[107]

While several variants of papillary thyroid cancer exist, the follicular variant of papillary thyroid cancer (FVPTC) is most common. According to Livolsi, this variant was first described in 1960, but was not widely recognized until approximately 20 years later.[78] The hallmarks of this tumor are a predominantly follicular pattern with the nuclear features of papillary cancer. The tumors may be encapsulated or unencapsulated, with the encapsulated version difficult to distinguish from follicular neoplasms.[78] Although the architecture may resemble a follicular neoplasm, the diagnosis is made on the nuclear features that the tumor presents, most commonly intranuclear inclusions, nuclear grooves, and ground glass nuclei. There is inconsistency seen among pathologists when evaluating thyroid specimens for the presence of FVPTC. In fact, in a series of >85 cases of FVPTC, there was complete agreement by 10 pathologists in <40% of cases.[108]

Although FVPTC is considered to be the most common subtype of papillary thyroid cancer, recent molecular investigations indicate that this tumor may be distinct from papillary cancer.[109] Ras mutations are more common in the FVPTC than in classic papillary cancer and are thought to be associated with the follicular differentiation of these tumors.[110] The peroxisome proliferator–activator receptor-γ alteration can also be seen in these tumors and in follicular neoplasms, but not in papillary thyroid cancers of the classic type.[109] In addition, BRAF mutations, which are very common in classic papillary cancer, are seen in as few as 12% of FVPTC cases.[111] Recent data indicate the FVPTC phenotype may vary with the molecular signature of the tumor.[112]

The clinical presentation of FVPTC is similar to other thyroid neoplasia. Grossly, the tumor differs from classic papillary thyroid cancer by the presence of a tumor capsule in most cases. The diagnosis is confirmed, however, by nuclear features as opposed to capsular invasion, thereby following a pattern for papillary cancer. Some series indicate that this tumor presents in a manner that is intermediate between papillary and follicular cancers with respect to extrathyroidal extension, lymph node metastases, and distant metastases. Extrathyroidal extension and nodal disease has been shown less commonly in these tumors than in papillary cancers, but still more commonly than in follicular tumors.[96] A greater prevalence of multifocality in FVPTC has been shown when compared with papillary cancer.[113] Depending on the study, distant disease can be found more commonly in FVPTC than in papillary cancer, but neither tumor has distant metastases as commonly as follicular cancer.[96,113] In the authors' own experience, it was found that although FVPTC tumors are larger at diagnosis, the behavior demonstrates less likelihood for local invasion and a lower recurrence rate.[114]

Owing to the fact that the diagnosis of FVPTC is made by the nuclear features of the tumor, it is suspected that previous cases have been overlooked. In an effort to evaluate the outcome of these cases, a series of FVPTC cases including those previously classified as follicular adenomas and carcinomas has been performed. This leads to the assessment that most (~80%) FVPTC are encapsulated tumors, some of which are invasive and some not invasive, but both groups show low incidence of lymph node metastasis and excellent outcomes. The 20% of FVPTC cases that are unencapsulated appear to represent those with a poorer prognosis, although their behavior was shown to be similar to papillary cancer, not worse. Therefore, even within this tumor type there appears to be subtypes that may have distinct behaviors.[115] Recent investigation of BRAF mutations in these tumors correlates genotypic findings with histologic appearance and clinical behavior (Fig. 28-9).[112]

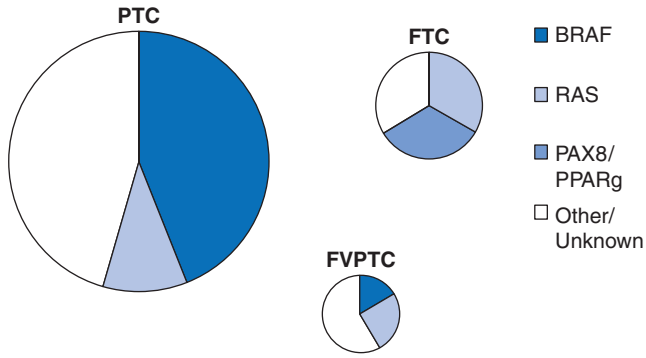

**FIGURE 28-9.** Proposed molecular relationship between phenotype and genotype in follicular variant of papillary cancer.

*Source:* From Rivera M, Ricarte-Filho J, Knauf J, et al. Molecular genotyping of papillary thyroid carcinoma follicular variant according to its histological subtypes (encapsulated vs. infiltrative) reveals distinct BRAF and RAS mutation patterns. *Mod Pathol.* 2010;23:1191–1200, with permission.

Given that the diagnosis of FVPTC is made by cellular and nuclear features, one might expect that diagnosis of this tumor may be afforded by FNA biopsy. Unfortunately, the sensitivity of cytology is low, estimated as low as 9% by researchers at the University of Pennsylvania. Intraoperative pathology is better, but still less than optimal at 36%.[116] Others have reported more favorable sensitivity with FNA, but still <50%.[117]

The pathogenesis and presentation of FVPTC may be distinct from classic papillary cancer. However, most reports reflect an overall survival that is similar to classic papillary thyroid cancer.

## Other Variants of Papillary Cancer

The third most common variant of papillary cancer, after the classic type and the follicular variant, is the tall cell variant (TCV). This is diagnosed based on the appearance of the follicular cells making up the tumor. Diagnosis is made when >70% of the follicular cells are found to be twice as tall as their basal width. These are often large, locally aggressive tumors and vascular and lymphatic invasion may be seen.[78] The diagnostic prevalence of TCV appears to vary between institutions. A review of cases in Sweden found that in a series of papillary cancers, the diagnosis was made in 2% of cases read by a local pathologist. However, further review by "expert" pathologists led to diagnosis in another 5% of cases.[118] The presentation of these tumors is more often in males and in older patients and show increased likelihood of extrathyroidal extension.[119] The authors have found that tall cell cancers were more likely to be smaller than 1.5 cm in diameter, but more likely to be extrathyroidal and of higher stage than typical papillary cancers.[120] One factor that might impact on this tendency for extrathyroidal extension is a higher rate of expression of c-MET, a tyrosine kinase that influences cellular invasiveness.[121]

Decreased disease-specific survival has been shown in most series with a mortality as high as 25%.[119,122] The authors' review of survival was more favorable with a mortality of 5% although the mean follow-up was <4 years.[120] A recent matched-pair analysis comparing tall cell to classic PTC was performed using the

(c) 2014 Wolters Kluwer. All Rights Reserved.

SEER database. Controlling for demographics, extent of disease, and treatment, this found worse disease-specific 5-year survival (82% vs. 91%) in tall cell cancer.[123]

The features of the DSV of papillary cancer include diffuse involvement, numerous micropapillary structures with lymphatic permeation, extensive squamous metaplasia, numerous psammoma bodies, marked lymphocytic infiltration, and prominent fibrosis. When compared with classic papillary cancer, the clinical features of these tumors reveal a similar predilection for women, a younger age at the time of diagnosis, a greater incidence of cervical metastases, increased incidence of lung metastases, and decreased disease-free survival on follow-up.[124] Others have confirmed that this variant is associated with increased lymph node involvement, increased regional recurrence, increased distant metastases, and decreased survival.[125]

Tall cell and DSVs of papillary thyroid cancer would appear to have a more aggressive behavior and worse prognosis than classic papillary thyroid cancer. Unfortunately, the surgeon is still limited by incomplete knowledge at the time of surgical treatment of thyroid cancers. This is due to overlapping cytologic features among the various papillary cancer subtypes. While some cytologists have retrospectively determined cytologic features that indicate tall cell cancers, the ability to distinguish these subtypes on biopsy or frozen section in practice is limited.[126,127] Surgeons, therefore, are usually required to make decisions about surgical treatment based on clinical features and intraoperative findings.

While subclassification can indicate prognostic differences between various patients with papillary carcinoma, tumor grading may be a more important prognostic factor in multivariable analysis. This may be due to the relative infrequency of each particular papillary variant. However, when taken together, patients presenting with high-grade tumors, represented by nuclear atypia, tumor necrosis, and vascular invasion, do demonstrate decreased survival.[128]

## Follicular Carcinoma

Follicular thyroid cancer represents the second most common thyroid cancer type. Approximately 10% to 15% of thyroid cancers are classified as follicular. These tumors are typically encapsulated, solid neoplasms with minimal colloid, microfollicle formation, and variable degrees of nuclear atypia. This histologic pattern is similar in benign and malignant follicular neoplasms; therefore, the distinction between the adenoma and carcinoma hinges on identification of vascular and/or capsular invasion by tumor.

The behavior of follicular cancer is thought to be somewhat worse than papillary carcinoma. However, this may be secondary to an older age and more advanced stage at diagnosis when compared with papillary cancer.[87,129] When controlled for age, gender, and stage, the prognosis of follicular and papillary cancer are similar.[129] Mazzaferri and Jhiang report similar 30-year survival and recurrence rates for these tumors types after eliminating those patients found to have distant metastatic disease at diagnosis.[87]

Tumor stage appears to be critically important in comparing these tumor types, and inherent biologic differences are probably indicated by the 11% to 18% rate of distant metastatic disease in follicular cancer at the time of diagnosis, more than twice that of papillary cancer.[130,131] However, this difference in distant metastatic disease may be partly explained by tumor size at diagnosis. The prevalence of distant disease appears to correlate with tumor size and when tumors of similar size are compared, no difference is seen between follicular and papillary cancer and the likelihood of distant disease.[131]

The pattern of capsular invasion merits further discussion. Limited invasion into (but not through) the fibrous capsule surrounding the tumor is termed *minimally invasive follicular carcinoma*. More complete extension through the capsule represents classic follicular carcinoma. The behavior of these two types of follicular cancer differs and some favor an approach to minimally invasive cancer that utilizes conservative surgical treatment only. With regard to vascular invasion, it is associated with a higher rate of distant metastasis.[132]

Pathologists attempted to define minimally invasive follicular carcinoma as follows: "an encapsulated follicular tumor (not papillary), with only small to medium vessel invasion within or immediately adjacent to the tumor capsule and/or up to full-thickness capsular transgression without accompanying extension into the thyroid parenchyma."[133,134] Unfortunately, there is significant discordance between pathologists as shown in a study from France where diagnostic interpretation was discordant in >50% of minimally invasive follicular carcinomas when reviewed by a group of experienced pathologists.[135] Although the excellent outcomes of patients with minimally invasive carcinoma are encouraging, the authors favor a similar approach to all follicular carcinomas given the limitations of pathology and the potential negative prognostic impact of vascular invasion.

While the pathology of papillary cancer is made in large part on the cellular and nuclear features of the tumor, follicular tumor diagnosis is determined by the tumor architecture, specifically capsular invasion. Cytologically, therefore, papillary cancers are typically diagnosed by FNA biopsy. This is not true for follicular cancers. The cytologic distinction between follicular carcinomas, follicular adenomas, and some cellular adenomatoid nodules is not possible and requires surgical resection to establish the precise tumor pathology. Recent efforts to define the immunohistochemical or genetic distinctions between these various entities hold promise, but are not yet sufficiently sensitive for clinical use.[136] Because it is not possible to establish a firm diagnosis of follicular carcinoma preoperatively, it would be helpful to be able to obtain this assessment by intraoperative frozen section. However, capsular invasion may only involve a small portion of the capsule, making the diagnosis of follicular cancer very difficult using standard frozen-section analysis. A diagnostic accuracy of 98% has been reported when the pathologist is able to process multiple[5–12] frozen sections.[137] However, this is a significant undertaking and pathologists in the United States have repeatedly emphasized the difficulty in establishing a diagnosis of these cancers on frozen section.[138,139] For this reason, most surgeons will try to avoid decision making based on a frozen section in follicular neoplasia.

Invasion of the tumor capsule in follicular carcinoma should be distinguished from extension beyond the thyroid parenchyma. This is an important difference that can confuse the student of thyroid neoplasia. Invasion of the tumor capsule defines the disease of follicular carcinoma but tumor may still remain entirely intrathyroidal. Extension beyond the thyroid parenchyma can occur in a tumor of any histology, and may result in invasion of adjacent structures such as the larynx, trachea, or esophagus. Invasion of these structures demonstrates a biologically aggressive tumor and portends a worse prognosis.[140–142]

The two most common sites of distant disease in follicular cancer are bone and lung. This tumor is more likely than papillary cancer to involve bone, and, not uncommonly, the first manifestation of a follicular cancer will be a bone metastasis. However, because of the greater overall incidence of papillary cancers, that tumor type is more common than follicular in series of metastatic thyroid cancer to bone. In a series from Memorial Sloan-Kettering Cancer Center (MSKCC) with bone metastases from thyroid cancer of various histology, the prognosis was generally poor with survival estimated at 29% after 5 years. Although survival was worst among those with anaplastic and medullary cancer with no 5-year survivors, other histologies revealed a 5-year survival approaching 40%. This rate did not vary between papillary, follicular, or other histologies nor by tumor differentiation.[143]

## Hurthle Cell Carcinoma

Hurthle cell carcinoma is considered to be a variant of follicular carcinoma. These tumors demonstrate large cells with granular cytoplasm and abundant mitochondria. The Hurthle cells themselves are felt to represent a metaplastic response of follicular cells and may be seen in inflammatory as well as neoplastic lesions.[78] Although distinguishable from follicular cancer, Hurthle cell carcinoma typically shows a similar histologic pattern and a similar behavior.

The finding of Hurthle cells in cytologic specimens can raise concern for a Hurthle cell neoplasm, but in fact these cells are seen with regularity in benign thyroid nodules. When these cells predominate, then concern for a Hurthle neoplasm is raised. Like other follicular lesions, cytologic diagnosis cannot distinguish malignancy and surgical resection is required. According to experience from the University of Michigan, the likelihood of malignancy in those Hurthle cell lesions undergoing surgical resection is approximately 30%, similar in their experience to that for follicular lesions.[144] Other experienced pathologists have indicated a rate of malignancy of 45% in nodules diagnosed as Hurthle cell lesions by FNA, a higher rate of malignancy than for follicular lesions.[145]

There has been previous concern that Hurthle cell cancers carry a worse prognosis than follicular cancers. Larger nodules are more likely to be cancer with Hurthle cell cancer in 55% of those over 4 cm versus 13% in smaller lesions.[146] A recent report has used a smaller cut point and integrated age as well. Using these criteria, a lesion >1.5 cm in a patient older than 45 was cancer in 63% versus 10% in younger patients with a smaller lesion.[147]

There has been previous concern that Hurthle cell cancers carry a worse prognosis than follicular cancers. An assessment of SEER data, however, does not show a statistical difference between the two. For a group of >900 patients, 20% were Hurthle cell and 80% were follicular cancer. Ten-year survival was 73% in Hurthle cell carcinoma and 83% in follicular cancer. Multivariate analysis revealed that a worse survival was associated with older age (50 years or older), male gender, larger tumor size (>5 cm), nodal metastases, and distant metastases. The histologic type (Hurthle vs. follicular), presence of local extension, extent of thyroidectomy, and radioactive iodine use did not impact the mortality rate.[148]

## Insular Carcinoma

Insular carcinoma is a form of thyroid cancer with aggressive behavior that is intermediate in behavior between the differentiated papillary and follicular cancers and anaplastic carcinoma. An insular pattern may be seen to a variable degree in papillary or follicular cancers, but the prognostic impact of this finding is not significant.[149] However, tumors of pure insular pattern are more aggressive than both papillary and follicular cancers. It has been pointed out that the current thyroid cancer staging system distinguishes between differentiated and anaplastic cancer; it does not allow for independent staging of these intermediate-grade tumors.[150] Insular cancer is associated with nodal disease in 50% of cases and with distant metastases in an even greater proportion of cases.[139] Disease-specific death rates range from 38% to 62% in recent series.[151,152]

## Medullary Carcinoma

Medullary thyroid carcinomas (MTCs) arise from the parafollicular or C cells of the thyroid. These cells, derived from neural crest and part of the diffuse neuroendocrine system, secrete calcitonin and the cancers that derive from these cells also secrete calcitonin. The cancers occur in a sporadic form in approximately 75% of cases. The other 25% occur in a familial form, most commonly associated with an autosomally dominant transmitted syndrome.

Medullary cancers present clinically as firm, encapsulated tumors, often with nodal metastases at presentation. In sporadic cases, the primary tumor is usually unilateral, whereas in familial cases it is typically bilateral. This is explained by the fact that familial susceptibility to medullary cancer leads first to C-cell hyperplasia, and the development of medullary cancer follows this. Multifocal tumors are common in familial medullary cancer.[153] The embryologic location of C cells in the upper two-thirds of the thyroid makes this the most common site of MTC.

The pathology of medullary cancers demonstrates a variety of growth patterns. Most often, tumors show a nested, trabecular, or solid growth pattern that invades adjacent thyroid tissue. Cells may be round or spindle shaped.[78] Amyloid has long been noted as a common feature in MTC, present in 60% to 80% of tumors.[154] Amyloid consists of the fully formed protein of calcitonin hormone.[155]

Calcitonin can be seen in MTC tumors using immunohistochemical staining. Calcitonin can also be measured in serum, and this is a reliable tumor marker with which to measure the presence or absence of disease. There are few other tissues in the body that secrete calcitonin, and none to any significant amount leaves calcitonin as an accurate serum tumor marker for this disease. Data in the U.S. and Europe suggest that routine screening of serum calcitonin is a cost-effective means of screening for MTC, with a basal serum calcitonin level of >20 pg/mL necessitating further work-up. Recommended preoperative tests for patients with known or suspected MTC include serum calcitonin, calcium, carcinoembryonic antigen (CEA), and RET analysis.[156]

The familial form of medullary cancer is inherited through autosomal dominant transmission. When it occurs without any other neuroendocrine feature, it is termed *familial medullary thyroid cancer* (FMTC). When other neuroendocrine tumors are associated, then these tumors form one of the multiple endocrine neoplasia (MEN) type II syndromes. These are listed in Table 28.1. MEN 2A is the most common syndrome and represents >75% of familial MTC. This syndrome presents with MTC in 90% of patients with a smaller proportion of carriers developing pheochromocytoma (50%) and parathyroid hyperplasia/adenoma formation (20%–30%). The inclusion of FMTC under the heading of MEN 2 is deliberate due to the fact that some kindred of MEN 2 may be incorrectly diagnosed as FMTC due to incomplete history and inadequate follow-up for additional neuroendocrine tumors.[157]

Familial MTC is associated with a germline mutation of the RET oncogene, located on chromosome 10. This oncogene encodes for a tyrosine kinase that has both intracellular and extracellular components. These germline mutations are usually point mutations in one of the exons 10 to 16 and cause tyrosine kinase activation.[157]

Extensive work has been done in recent years to characterize the most common mutations in order to predict the clinical behavior of patients with MEN 2.[157] This information correlates to the observed clinical behavior of hereditary MTC. It has been observed that MTC, arising as part of MEN 2B, is more aggressive than MTC in MEN 2A or FMTC. MEN 2B is associated with mutations at 918. Cancers with this mutation arise early in life, at a mean age of 3, according to data by Machens et al.[158] and may be associated with higher local recurrence and lower survival.[156] Mutations associated with MEN 2A (Fig. 28-10) will tend to manifest later in childhood or young adulthood. The most common of these mutations are at codons 618, 620, 634, 790, 791, and 804. The mutations at 768 and 804 appear to be associated with an onset of C-cell hyperplasia and progression to MTC that

occurs at a somewhat later age than many of the other mutations, and MTC with nodal disease is typically not seen before the age of 50.[158]

Although the age of onset of MTC is variable depending on the specific RET mutation, there may be differences in penetrance related to specific mutation as well. For instance, RET mutation C634Y, causing cysteine to be replaced by tyrosine at that codon, leads to a highly active transformation in the RET gene. This is associated with a high penetrance of MTC (79% by age 30).[159] Mutations at this codon are also associated with a 50% penetrance of pheochromocytoma and 10% penetrance of parathyroid hyperplasia.[146] In contrast, a mutation such as E768D, which causes glutamate to be replaced by aspartate, has a lower penetrance for MTC (36% at 45 years) and seldom leads to pheochromocytoma or parathyroid hyperplasia.[160]

Patients presenting as putative sporadic MTC may, in fact, harbor germline mutations. All patients diagnosed with sporadic MTC should be tested due to the fact that previously unrecognized kindreds may emerge or that these patients might harbor spontaneous germline mutations. In a large series of patients thought to be sporadic on clinical grounds, approximately 6% were found to harbor germline mutations.[161] Tumor tissue can also be assessed for RET mutations occurring within the thyroid tissue itself. More than 40% of tumors demonstrate these mutations, usually of codons 918 or 634. A worse outcome has been reported for these patients. Of course, only familial cases will have a germline defect in the RET oncogene (e.g., seen in white blood cells) whereas both familial and sporadic disease may harbor a RET oncogene mutation within the thyroid tissue.[162]

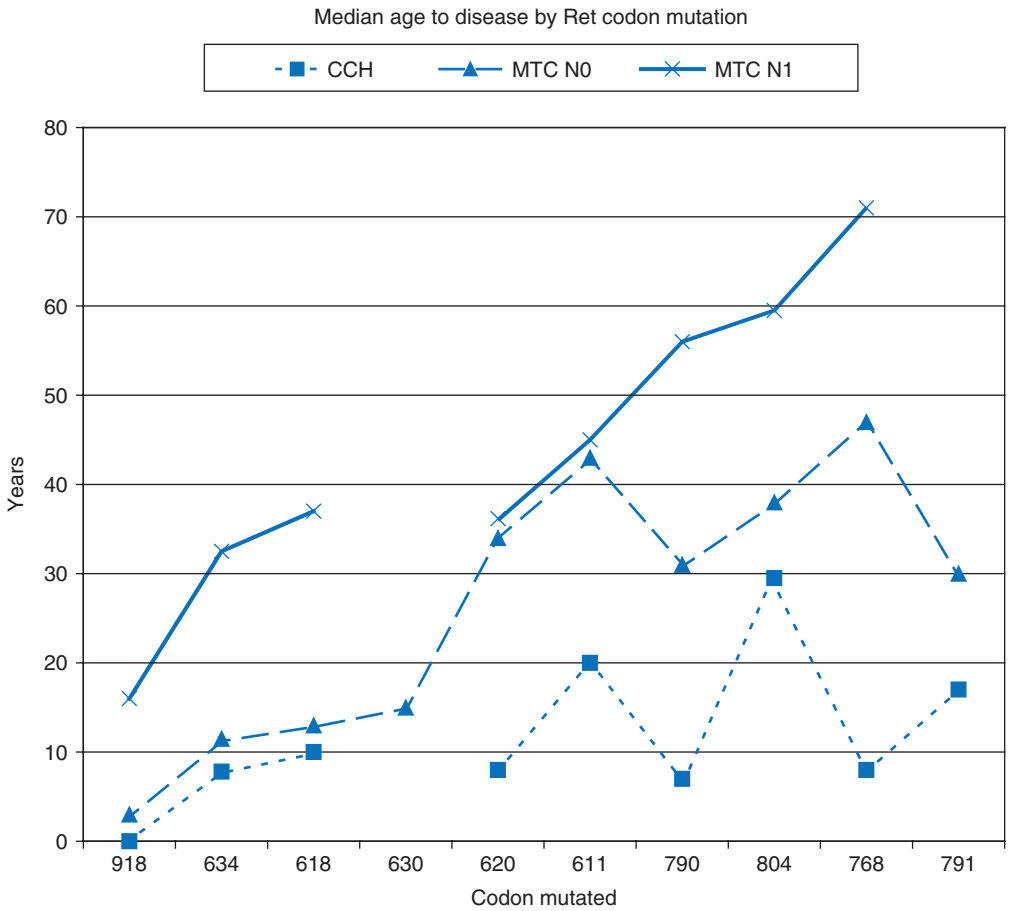

**FIGURE 28-10.** Age of onset of C-cell hyperplasia (CCH), and medullary cancer varies by the specific germline mutation of the RET oncogene. MTC, medullary thyroid carcinoma.

*Source:* Adapted from Machens A, Holzhausen H-J, Thanh PN, et al. Malignant progression from C-cell hyperplasia to medullary thyroid carcinoma in 167 carriers of RET germline mutations. *Surgery.* 2003;134:425–431, with permission.

Although the primary tumor in MTC is often well circumscribed and encapsulated, lymph node metastases are common. These nodal metastases tend to first occur in the central compartment, but lateral neck nodes are also common and may require treatment.[163] Mediastinal lymph nodes are less accessible for primary surgical sampling, but this area is also frequently involved in more advanced MTC. Data suggest that at the time of thyroidectomy, measurement on intraoperative serum calcium levels 30 minutes after thyroid removal may be a predictor of persistent or distant disease even in patients with no clinical or radiographic evidence of disease.[164] However, these data warrant further study. While lymphatic spread is more common, hematogenous spread may occur and result in distant metastases to the lung, liver, and other organs.

When MTC presents clinically, approximately 50% to 80% of the patients will have medial compartment lymph node metastases. A similar proportion will have ipsilateral nodal disease in the jugular nodes. Contralateral nodal metastases will be seen in approximately 20% to 40%.[163,165] These high rates of nodal disease have a significant impact on treatment recommendations in MTC and on the ability to normalize serum calcitonin levels after surgical therapy. Detection of lateral neck disease may present a challenge. Ultrasound imaging of the lateral neck has been controversial as up to one-third of scans of the neck may be falsely negative. Some data exist that biochemical marker analysis may be a more sensitive means of determining the need for lateral neck dissection, with serum calcitonin levels >200 pg/mL being suggestive of contralateral neck metastasis and >400 to 500 pg/mL suggestive of distant metastasis.[156]

In spite of the common feature of nodal disease in MTC and a reduced cure rate when significant nodal disease is present, the natural history of this disease typically manifests slow growth and metastatic spread. Patients with persistent hypercalcitoninemia after definitive treatment may live for many years with no appreciable worsening of their disease. There are exceptions to this rule, typically when more aggressive variants of MTC are seen, and a rapidly fatal course may be seen. These aggressive tumors may be recognized by necrosis, pleomorphism, and multiple mitoses on pathology analysis.

## Thyroid Lymphoma

The lymphoid tissues within the thyroid gland can be the tissue of origin for a primary lymphoma of the thyroid. These are unusual, constituting between 1% and 5% of all thyroid tumors. Less than 2% of all extranodal lymphomas will present in the thyroid.[166] Most of these will be either mucosa-associated lymphoid tumors, known as *MALT lymphomas,* or *diffuse large B-cell lymphomas*. Other lymphoid malignancies present in the thyroid more rarely and include Hodgkin lymphoma, T-cell and other lymphomas, and extramedullary plasmacytomas.

Primary thyroid lymphomas show a female predominance and typically present with painless thyroid enlargement in an elderly female. Approximately 50% will present with aerodigestive tract compressive symptoms.[167] Hoarseness is often present and appears to be related to laryngeal edema rather than vocal fold paralysis (Fig. 28-11).[168]

Preexisting autoimmune disease of the thyroid is commonly seen in thyroid lymphomas according to most series[169,170] but more rarely in others.[167] The preexistence of autoimmune thyroiditis in these cases not only has pathogenetic implications for lymphoma development, but also creates a dilemma in diagnosis (clinically, cytologically, and pathologically). The development of thyroid lymphoma occurs in most cases with thyroid enlargement over a few months. FNA will demonstrate lymphoid tissue in both Hashimoto thyroiditis and lymphoma, but determining monoclonality of lymphoid cells is critical in order to make the diagnosis of lymphoma. Obtaining adequate material for biopsy may require an open surgical procedure, and depending on the presentation, thyroidectomy may be appropriate, although most frequently chemotherapy without a thyroidectomy represents appropriate management. Jonak et al. have reported good chemotherapy responses with Rituximab plus dose-reduced mitoxantrone, cyclophosphamide, vincristine, and prednisolone.[171]

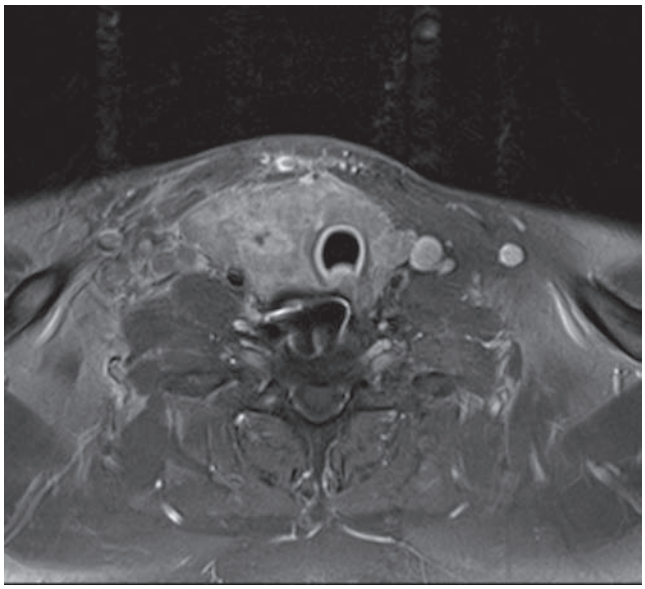

**FIGURE 28-11.** MRI demonstrating extensive thyroid lymphoma. Note displacement without invasion of the airway. Recurrent laryngeal nerve function was normal.

There is a female predominance in patients with thyroid lymphoma. Recent efforts to demonstrate monoclonality using polymerase chain reaction methods show promise to improve the diagnostic sensitivity of FNA biopsy for these lymphomas.[172]

MALT lymphomas are typically indolent, and when diagnosed while still contained within the thyroid parenchyma, stage IE, surgical resection alone may be curative. Diffuse large B-cell lymphoma is more aggressive than MALT lymphoma. It is reported to develop from a transformed MALT lymphoma approximately 40% of the time. At diagnosis, however, disseminated disease is seen in >50% of these cases. These tumors will most often require chemotherapy and radiation with the role of surgery limited to biopsy and airway palliation.[173]

While this section describes primary lymphoma of the thyroid, it should be recognized that systemic lymphoma may involve the thyroid tissues secondarily. In fact, autopsy series report thyroid gland involvement in 15% of systemic lymphomas[174]; thus, all patients with lymphoma in the thyroid merit a complete staging evaluation.

## Anaplastic Carcinoma

Among the most aggressive of human malignancies, anaplastic thyroid cancer typically presents in the elderly with a rapidly growing neck mass, and compression of the trachea and the esophagus.[175] Only 8% of cases present with intrathyroidal disease. Extrathyroidal extension is the rule, making surgical intervention difficult without sacrificing vital structures. Although >40% of patients present with distant metastatic disease, the disease process is so rapid in the locoregional area, that the natural history is one of progressive aerodigestive tract compromise.

(c) 2014 Wolters Kluwer. All Rights Reserved.

It is suspected that frequently anaplastic carcinoma develops from preexisting thyroid disease. In support of this, 80% of cases have a history of a preexisting goiter.[176] These cancers may develop from transformation of a DTC.[177–179] In fact, the vast majority of anaplastic tumors will show some component of papillary, follicular, or Hurthle cell carcinoma, indicating the likely original tumor.[168,180] Anaplastic cancer cells are distinct from DTCs in their lack of thyrotropin receptors and in their inability to transport iodine or produce Tg[181] and they do not seem to respond to radioactive iodine therapy. Among anaplastic cancers, it has been shown that a low serum thyroxine level is associated with a worse prognosis, but whether this indicates biologic differences between anaplastic tumors or simply reflects total thyroidal tumor burden is not clear.[182]

In an evaluation of the anaplastic thyroid cancers reported to the National Cancer Institute's SEER database between 1973 and 2000, 516 cases of anaplastic thyroid cancer were evaluated. Surgical resection was performed in 64% of these cases and radiation therapy was used in 63%. Patients younger than 60 years, patients with intrathyroidal tumors, and patients treated with surgery followed by radiation were independent predictors of increased survival in multivariate analysis. However, as a whole, the prognosis was poor with 81% of patients dead of disease at 1 year.[183] Even in studies demonstrating improved locoregional control, most patients died of distant metastasis.[184,185] There is some evidence that an aggressive treatment plan with surgery, chemotherapy, radiation sensitizers, and IMRT may be of benefit.[186,187]

Anaplastic tumors typically are composed of varying proportions of spindle, polygonal, and giant cells.[188] Papillary cancers may also contain areas with these same cellular features. Although not diagnostic of anaplastic cancer, these papillary cancers are more aggressive and show a lower survival than typical papillary thyroid cancers.[189,190] Of more concern, however, is the situation where, within a differentiated tumor, an area shows complete transformation to an anaplastic tumor. These tumors merit aggressive treatment due to a behavior that follows a typical anaplastic pattern. The pathologic diagnosis of even a small focus of poorly differentiated or anaplastic features in a thyroid sample should be considered seriously and treated appropriately. The American Thyroid Association (ATA) is formulating guidelines for the management of anaplastic thyroid cancer that will soon be published.

### Metastases to the Thyroid

Microscopic metastases to the thyroid are common when evaluated in autopsy specimens of patients dying with a disseminated cancer of any type. Up to 24% of these specimens reveal thyroid metastases.[191,192] The presentation of clinically apparent metastases in the thyroid is significantly less common than this. However, when a thyroid mass presents in a patient with a known malignancy, metastatic cancer should be considered. FNA should be used to evaluate such a lesion. Typically, diagnosis of such a metastasis will lead to an approach to treatment that is systemic, such as chemotherapy, rather than surgery directed at the thyroid gland. Exceptions may be seen in slow-growing tumors such as renal cell carcinoma that present with a resectable thyroid metastasis,[192] where surgical resection can be expected to promptly and effectively reduce the risk of future aerodigestive tract compromise. Renal carcinoma, pulmonary carcinoma, and malignant melanoma seem particularly prone to metastasize to the thyroid gland.

## CLINICAL PRESENTATION

The most common presenting sign of thyroid cancer is a thyroid nodule. Although the vast majority of thyroid nodules are benign, all nodules merit careful evaluation for malignancy. Elements of the history and specific clinical symptoms and signs can increase the suspicion of malignancy.

The age and gender of the patient should be considered. Children with nodules present a risk of malignancy that ranges from 15% to 60%.[193–195] Similarly, nodules in patients older than 60 years of age present an increased risk of malignancy.[196,197] The risk of malignancy in a nodule is between two and three times greater in a male than in a female patient.[197–199]

A history of a rapidly enlarging thyroid nodule usually indicates hemorrhage, and this can occur in both benign and malignant disease. These patients usually have thyroid tenderness, discomfort, or pain. Increasing thyroid-related pain should raise concern for malignancy. Hoarseness can be present due to tumor effects on the recurrent laryngeal nerve. This can be seen in benign disease on occasion, but is typically felt to indicate a malignant process. Dysphagia is a common symptom in large multinodular goiters and is gradual at onset in these cases. Dysphagia which increases over several weeks in the setting of a small- or moderate-sized thyroid mass should raise concern for a malignant process involving the inferior constrictor or cervical esophageal musculature. Airway compromise can result from tracheal involvement by tumor or by bilateral recurrent laryngeal nerve paralysis. Both would indicate a likely malignancy.

A personal history of low-dose irradiation is a major consideration when attempting to assess a thyroid nodule. This is associated with an increased risk of both benign and malignant thyroid nodules. The concern for malignancy is significant, and a high degree of suspicion for malignancy should be entertained in these cases.

A family history of thyroid malignancy should be integrated into the assessment of patients with thyroid nodules and trigger the exploration for both papillary thyroid carcinoma and familial medullary carcinoma. For papillary thyroid carcinoma, Cowden syndrome and Gardner syndrome should be considered. Cowden syndrome is associated with hamartomas, breast lesions, gastrointestinal polyps, ovarian cysts, uterine fibroids, and thyroid tumors. Gardner syndrome is associated with colonic polyps and other benign tumors, including osteomas of the facial skeleton. A personal or family history of these related diseases should lead to further evaluation.

The patient suspected of presenting with a familial medullary carcinoma might report chronic diarrhea, which is probably related to the hypercalcitoninemia (or related chemokines). Patients with MEN may report a personal or family history of hypercalcemia, hyperparathyroidism, renal stones, or pheochromocytoma. A history of severe hypertension or symptoms of sweats, flushing, palpitations, and headaches should raise concern for a pheochromocytoma. The fact that, in the past, pheochromocytoma was a major cause of mortality in patients with MEN 2B should be kept in mind while pursuing this history. The possibility of a pheochromocytoma should be excluded in patients with possible or definite MEN 2 before consideration of thyroid or parathyroid surgery.

Examination of the thyroid should focus on the number, size, and laterality of thyroid nodules. Firm nodules are the hallmark of malignant disease. Benign disease tends to be softer on examination, but these physical findings are not considered to be sufficiently accurate to determine management. Benign nodules with hemorrhage may be both firm and tender. Autoimmune thyroiditis may be associated with a diffusely enlarged, rubbery gland, but these glands can harbor DTC and can also give rise to thyroid lymphomas.

Cysts may be evident on examination. Cysts are typically thought to be low risk for malignancy, but cystic cancers do occur. The risk of malignancy in thyroid cysts is 2% to 9%.[200] However, the ultrasonographic characteristics of the cyst are important. A stepwise rise in malignancy has been shown between

(c) 2014 Wolters Kluwer. All Rights Reserved.

pure cysts (7%), complex cysts (12%), and solid nodules (21%).[201] This relationship emphasizes the importance of ultrasonographic evaluation in thyroid disease.

The distinction of solitary versus multinodular thyroid disease has been useful in assessing the likelihood of malignancy. As a general rule, solitary nodules are thought to present a greater risk of malignancy than the nodules in a multinodular goiter. However, in a recent, large, retrospective study, the risk of malignancy was found to be approximately 15% for glands with either solitary or multinodular glands when nodules of >10 mm diameter were present. For the individual solitary nodules, the risk of malignancy was greater than for the individual nodules in a multinodular goiter.[202] The multinodular glands revealed that the cancer occurred in the largest nodule approximately 70% of the time and that approximately 45% of the multinodular glands with cancer harbored multifocal cancer.[202] The number of nodules may be helpful in predicting malignancy. In patients selected for thyroidectomy at the University of Pennsylvania, the risk of malignancy was approximately 40% in glands with one or two thyroid nodules, but this risk was reduced by half when more than two nodules were present.[203]

Assessment of the mobility of the thyroid mass with respect to neck musculature and the laryngotracheal complex is critical and may trigger assessment for local tumor extension by imaging studies. A loss of tissue planes on examination, especially in a rapidly growing mass, should raise concern for anaplastic carcinoma.

Following assessment of the thyroid, the cervical nodes should be evaluated. A delphian node refers to midline adenopathy and may be seen in either thyroid carcinoma or advanced laryngeal cancer. Medial compartment lymph nodes can be difficult to appreciate on examination due to the overlying thyroid tissue and the proximity of the sternoclavicular joints inferiorly. These nodes, however, constitute the primary echelon nodal basin for thyroid cancers. The lateral cervical nodes include those along the jugular vein and in the posterior triangle. The jugular nodes are typically involved before the posterior triangle lymph nodes. High jugular nodes will typically be seen in aerodigestive infections and malignancies. However, thyroid metastases may occur in high jugular nodes, particularly with primary tumors of the upper thyroid pole. These nodes, therefore, should be assessed carefully in patients with thyroid cancer.

Examination of the larynx is critical in thyroid disease. Malignant lesions, and benign lesions less commonly, can result in laryngeal paralysis. Usually, the patient is aware of a recent voice change. Occasionally, however, this paralysis is gradual at onset, and the patient has spontaneously compensated for the paralysis without calling it to the attention of a physician. A preoperative examination on the awake patient is the most sensitive way to discover the paralysis. The authors feel strongly that it is important to document the preoperative laryngeal examination before any thyroid surgery. Preoperative paralysis will increase the concern for malignancy in the assessment of thyroid masses and may also influence intraoperative decisions during thyroid surgery.

The assessment for aerodigestive tract compromise on clinical examination may include indirect or flexible laryngoscopy, and palpation and auscultation of the laryngotracheal complex. If the tumor is compressing or invading the hypopharynx or cervical esophagus, distortion of the hypopharynx may be seen on office laryngoscopy. Pooling of saliva in the hypopharynx may indicate invasion of the pharyngoesophageal junction. Invasion of the laryngotracheal complex may be indicated by immobility of the tumor with respect to these organs, and significant airway compromise may result in stridor, sometimes best appreciated on auscultation of the midline neck.

The remainder of the physical examination in patients under evaluation for thyroid cancer can be directed by symptoms. The lungs are the most common site of involvement by metastatic disease in papillary thyroid cancer, but evidence of this on physical examination is exceedingly rare. New bone pain or discomfort should be fully investigated.

## DIAGNOSTIC EVALUATION AND CLINICAL STAGING

When patients present with thyroid nodules following a routine clinical and laboratory examination, the basic workup begins with thyroid function testing and FNA. Ultrasonography is the basic imaging test and provides information of nodule location and architecture as well as an objective measurement of the nodule size. For nodules that are difficult to palpate, ultrasonography is essential in obtaining an accurate FNA. Figure 28-12 describes an algorithm for assessment of thyroid nodules. In the multinodular gland, the largest of the nodules is most likely to reveal cancer, if present in the gland.

### Laboratory Testing

When evaluating thyroid nodules, thyroid function testing should include TSH with or without free T4. These tests are almost always normal in patients with thyroid malignancy, so confirmation of normal thyroid function does not reduce the need for cytologic evaluation of the thyroid nodule. One utility of thyroid function tests is in determining whether a patient is presenting with a toxic nodule. These nodules can cause suppression of TSH and typically have a very low rate of malignancy.[204,205] The discovery of a suppressed TSH therefore should reduce the clinician's suspicion of malignancy. In fact, although controversial, some reports suggest that toxic nodules may show cellular abnormalities that can confuse the cytologist; individual circumstances must be considered in the decision whether to perform an FNA on an apparent toxic nodule.

Thyroid antibodies are not routinely obtained in patients with thyroid nodules, but are recommended to a patient suspected of having Hashimoto thyroiditis; these laboratories may support the diagnosis. However, rapid thyroid growth in such a patient may indicate lymphoma, so this should be factored into the assessment.

Tg is normally present in serum at concentrations of approximately 20 to 40 ng/mL. Tg elevation in a previously untreated patient is nonspecific and may be seen in thyroiditis and in hyperthyroidism.[206] A markedly elevated Tg may be suggestive of carcinoma, but is not diagnostic.[207] This is in distinction to patients followed up for a previous history of differentiated thyroid carcinoma (who have had a thyroidectomy) in whom Tg is a useful tumor marker. When ordered, Tg testing should include simultaneous measurement of anti-Tg antibodies because the presence of antibodies limits the utility of Tg measurement. Tg antibodies commonly interfere in a chemiluminescent Tg assay causing an artifactual lowering of apparent serum Tg levels (frequently being interpreted as undetectable). Radioimmunoassays for serum Tg can report a falsely elevated serum Tg level in the presence of Tg antibodies. In summary, reported serum Tg levels in patients with Tg antibodies are extremely difficult to interpret.

Calcitonin serum measurement is essential when medullary carcinoma is suspected. Elevation indicates either C-cell hyperplasia or MTC. False-positive elevation has been reported in Hashimoto thyroiditis, hyperthyroidism, and goiter,[208] so the laboratory test itself is not considered diagnostic without further pathologic confirmation. However, in benign thyroid disease, these calcitonin elevations are usually mild.

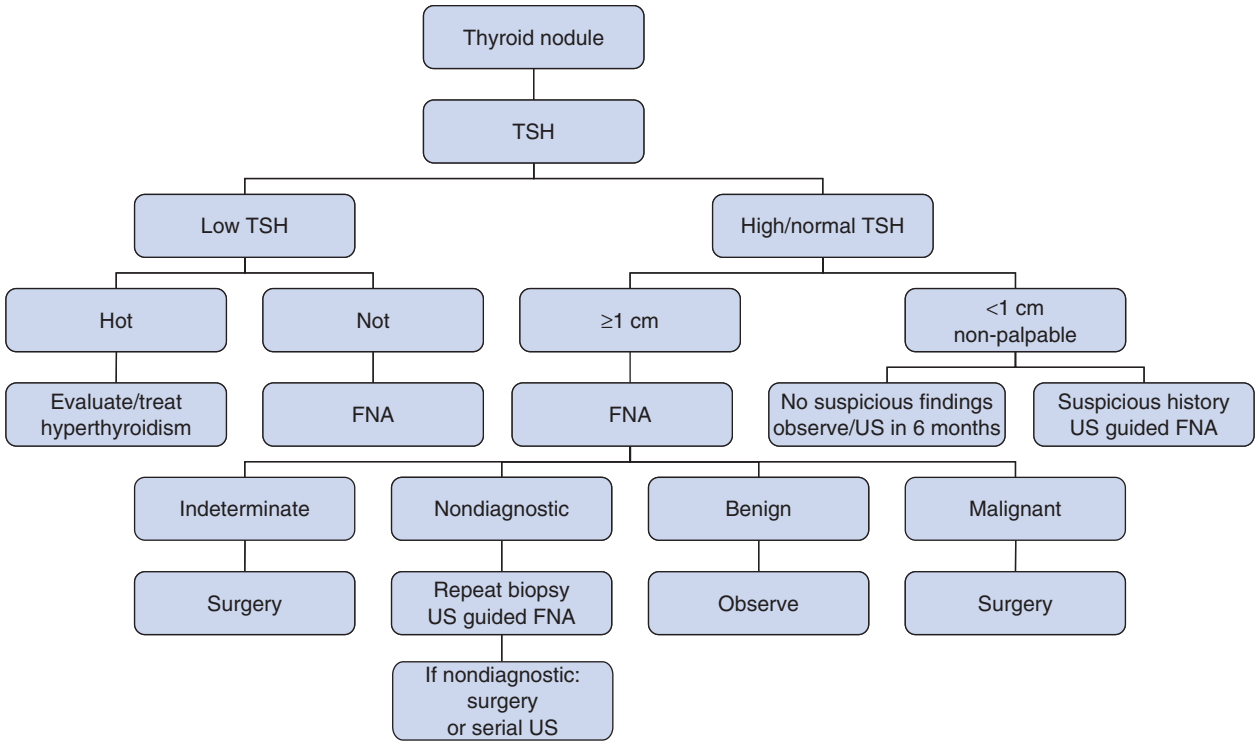

**FIGURE 28-12.** Algorithm for evaluation of thyroid nodules. FNA, fine-needle aspiration. US, ultrasound. FNA with onsite verification preferred. US guidance preferred for small nodules, nodules located in the posterior aspect of the thyroid and nodules >50% cystic. Indeterminate lesions such as "follicular lesions of undetermined significance" may be considered for repeat FNA with molecular testing for mutations of *raf* or *ras* and for PAX8/PPAR gamma rearrangements.

Over the last few years, different centers have begun to advocate routine calcitonin testing in patients with thyroid nodules. In a large study from Italy, >10,000 patients were evaluated with routine calcitonin screening. Calcitonin was elevated in 47 patients, 44 of whom were later shown to harbor MTC, resulting in an MTC prevalence of 0.4%.[209] This has not been widely used in screening in the United States,[210] and in 2006, the ATA Guidelines Taskforce could neither recommend for nor against routine calcitonin testing.[211]

When medullary carcinoma is suspected, there are other laboratory tests that must be considered (Fig. 28-13). Most importantly, MEN 2A and 2B are associated with pheochromocytoma, so urine (e.g., 24-hour urine vanillylmandelic acid [VMA], total metanephrines, catecholamines) and/or serum evaluation (e.g., catecholamines, free metanephrine, free normetanephrine) should be obtained before any surgical intervention. It is presently controversial whether urine or serum measurements are more sensitive in detecting a pheochromocytoma, but it is extremely important to perform as complete an evaluation as necessary to exclude the presence of a pheochromocytoma. Occasionally, an adrenal imaging study (e.g., computed tomography [CT] of adrenal glands or magnetic resonance imaging [MRI]) may be useful. Hyperparathyroidism should also be ruled out for MEN 2A, so that surgery can address both the thyroid and parathyroid disease as appropriate. All patients with MTC merit testing for RET oncogene mutations. This can be done after a verified diagnosis has been obtained and does not need to be obtained before surgery for the thyroid malignancy.

## Fine-needle Aspiration and Cytologic Evaluation

The single most useful study in the assessment of a thyroid nodule is an FNA biopsy. Cytologic assessment is highly accurate and can indicate whether surgical intervention is required. FNA has historically been used to assess solitary nodules and in the dominant nodule of multinodular goiters. With increased use of ultrasound (US), the ATA has defined an array of indications for FNA based on size, US appearance, and clinical suspicion.[212] While the need for thyroid surgery has long been determined by clinical information, ultrasonographic, and nuclear medicine studies, the introduction of FNA has led to a 35% to 75% decrease in the number of patients requiring surgery.[213–216] As a result, there has been a substantial increase in the proportion of malignant lesions in surgical cases.[217–219] Also, FNA has led to a reduction of approximately 25% in the overall cost of managing thyroid nodules.[220]

Results of FNA are typically categorized as benign, malignant, suspicious, or insufficient for diagnosis. In most studies, aspirates are interpreted as benign, typically adenomatoid nodule, Hashimoto thyroiditis, or cysts. The actual percentage of benign aspirates reported has varied from 45% to 82% in reported series.[221–223] For benign biopsies, a false-negative rate of <5% is reported. Traditionally, this has led to a recommendation that benign lesions should be reaspirated at some point in order to confirm the initial diagnosis. This recommendation is in evolution with multiple reports now showing an even smaller false negative and therefore less need for routine reaspiration.[224–227] These series demonstrate a false-negative

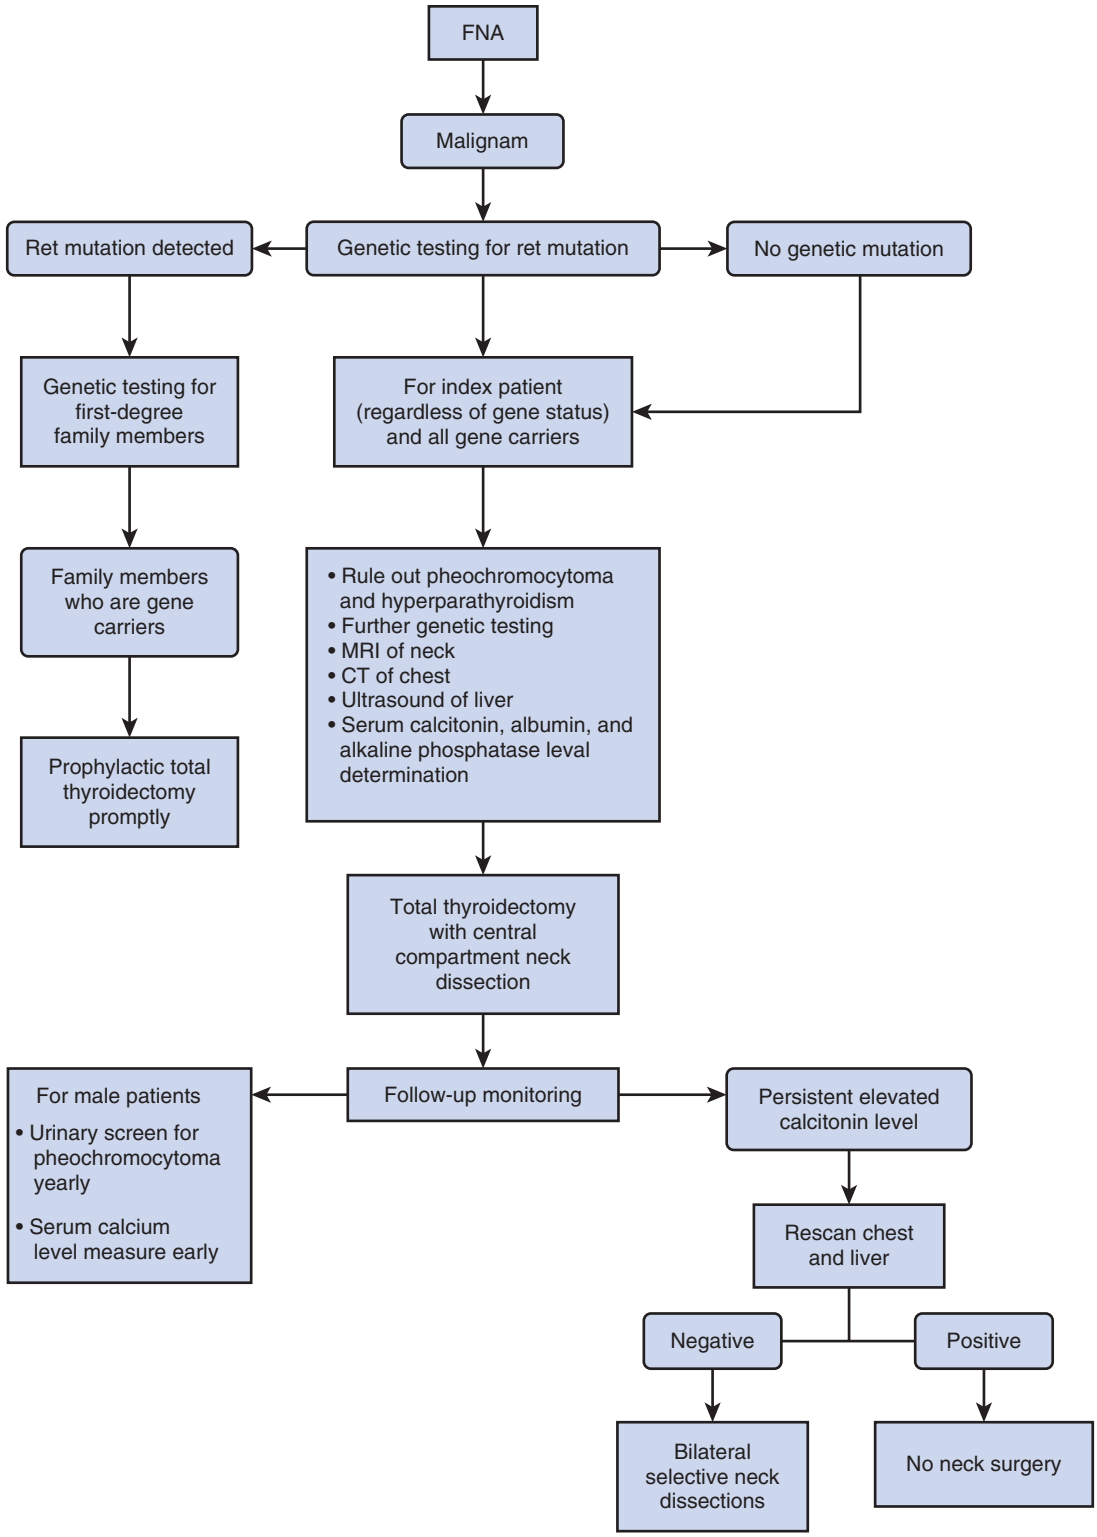

**FIGURE 28-13.** Fine-needle aspiration (FNA) suspicious for medullary carcinoma should trigger additional testing as outlined in this algorithm. MRI, magnetic resonance imaging; CT, computed tomography.

rate of 0% to 1.5% with papillary thyroid cancer diagnosed subsequently in most circumstances. These data are reassuring, but individual clinical circumstances, including physician and patient suspicion, imaging characteristics, and follow-up, will determine the role for reaspiration after an initial benign aspiration.

The primary reason to evaluate thyroid nodules is to determine whether they represent cancer. Malignant diagnoses are

(c) 2014 Wolters Kluwer. All Rights Reserved.

often obtained for papillary cancers with identification of papillary fronds, psammoma bodies, nuclear grooves, intranuclear inclusions, and other nuclear and cellular features. The false-positive rate in these cases approaches 0% in most reports, and the surgeon can proceed to address the surgical treatment without additional biopsies or frozen-section analyses. When a less common malignancy, such as medullary cancer, is present, cytology may be accurate, but calcitonin staining of the thyroid FNA specimen can aid in the diagnosis. Similarly, malignant diagnoses of anaplastic carcinoma or lymphoma may be made on cytologic criteria, but the need for immunohistochemistry, flow cytometry, and even open biopsy is common in these circumstances.

A "suspicious" cytologic diagnosis may represent a number of different circumstances. This terminology may be used to describe follicular lesions. These biopsies are typically highly cellular, with little colloid and with or without nuclear atypia. Microfollicles may be described. These lesions may represent simply cellular adenomatoid nodules, follicular adenomas, or follicular carcinomas. Hurthle cell lesions would also fall into this category. For both of these lesions, the ability to distinguish benign from malignant tumors requires surgical pathology in order to visualize vascular or capsular invasion. The likelihood of cancer in these suspicious lesions ranges between 15% and 22% in recent series.[221,228,229] The rate of malignancy in Hurthle cell lesions has been reported to be higher at 32%.[228]

Other suspicious lesions include those that have some nuclear features of papillary carcinoma, but insufficient in degree to make a malignant diagnosis. This raises the issue about variability between cytologists and the increased accuracy seen with increased experience by the cytologist. The University of Pennsylvania reports this group as a subset of their follicular lesions. These constitute approximately 25% of the total number of follicular lesions in their group.[229] At surgery, between 40% and 72% of these lesions will malignant, and more than half will be diagnosed as follicular variant of papillary cancer.[229,230] Unlike typical follicular lesions, these lesions may merit frozen-section assessment in order to determine the extent of surgery.[230]

Aspirates that are insufficient for diagnosis are reported 15% to 20% of the time.[221,231] In many cases, reaspiration will lead to a diagnostic specimen. The use of ultrasound guidance has been shown to reduce the rate of insufficient aspirates from 16% to 7%.[231] The authors encourage that aspiration be done with a cytologist on site to verify the adequacy of the sample obtained. This is true for both palpation-guided and ultrasound-guided biopsies.

When a cyst is encountered on aspiration, a dilemma arises. Most often, cysts represent degeneration of an adenomatoid nodule. Palpation-guided aspiration of the cyst may provide symptomatic relief, allow resolution of the "nodule" by removing the cystic fluid and allowing sclerosis to occur, and provide cytologic assessment. Although cysts are typically found to have a lower chance of harboring malignancy than a solid nodule, cystic changes may be seen in both papillary and follicular cancers, and an accurate cytologic interpretation requires cellular material to be seen. Accurate sampling of the cyst wall can be difficult, and this is a circumstance where ultrasound guidance can be helpful. Repeated reaccumulation and recurrence of a drained cyst should lead to the consideration of surgery.

## Imaging

The evaluation of the typical thyroid patients with thyroid cancer may differ from the patient undergoing workup for a thyroid nodule. In the case of a thyroid nodule, ultrasonography is typically the most revealing single-imaging study. In thyroid cancers, ultrasonography is also useful, but additional studies may include chest x-ray, CT, MRI, and positron emission tomography (PET) scans.

Ultrasound is able to determine whether the thyroid nodule is isolated or part of a multinodular goiter. Imaging characteristics of the nodule can provide information that can aid in the prediction of malignancy. Regarding the risk of cancer in a uninodular versus multinodular goiter, the overall risk of malignancy is similar—approximately 15%. However, the risk of cancer in each individual nodule in a multinodular goiter is less.[232] Nodule characteristics that increase the concern for malignancy are an irregular shape, a jagged border, the presence of internal echoes, and the absence of peripheral echoes.[233]

A major advantage in ultrasound imaging over palpation alone in thyroid evaluations is the improvement in objective measurements. These can be helpful in follow-up of nodules in that objective measures can be compared over time. An additional application of ultrasonography is in FNA. As compared with palpation-guided FNA, ultrasound-guided FNA has shown an increase in diagnostic yield on biopsy and also on cancer yield on final pathology when patients undergo subsequent surgery.[231]

Ultrasound in workup of thyroid malignancy has been extended beyond the thyroid bed to the cervical nodes. An ultrasound of the neck in cases of documented thyroid malignancy is a routine component of the preoperative workup in order to assess lymph nodes. This includes imaging of the central and lateral necks. Given that the initial ultrasound may focus primarily on the thyroid gland itself, the nodal assessment usually requires a separate study requisition. The goal of this study is to avoid overlooking identifiable nodal metastases at the initial thyroid surgery.

Routine radiography does not have a significant role in evaluation of thyroid nodules except in larger lesions where tracheal deviation, substernal extension, and tracheal compression may be seen. Occasionally, calcification of the thyroid or cervical lymph nodes may be seen of chest x-ray. Calcification in cervical nodes may suggest papillary thyroid carcinoma, but other causes include tuberculosis, previously treated lymphoma, adenocarcinoma, or squamous carcinoma.[234]

Calcification of the thyroid on ultrasonography or chest x-ray raises concern for thyroid malignancy. However, calcification is a nonspecific finding and degenerated adenomatoid nodules will frequently form calcifications. Degenerated nodules are more likely to form peripheral calcifications or large, so-called chunk, calcifications. Malignancies are more likely to be associated with smaller calcifications. Microcalcifications have the highest association with malignancy.[235] Calcifications may also be seen in MTCs, but have no diagnostic or prognostic value.

CT and MRI are helpful in defining the three-dimensional anatomy in thyroid disease. In benign thyroid disease, these are used in the evaluation of substernal goiters. In thyroid malignancy, these studies may indicate regional adenopathy or local extension. It is very important that the decision to use iodinated contrast be carefully considered in the workup of DTC when CT evaluation is required. The large iodine load can persist for several weeks after contrast is given. The result can be reduced radioactive iodine uptake and less effective radioactive iodine treatment after surgery. Delayed treatment with radioactive iodine is usually required in these cases. As an alternative, an MRI with gadolinium contrast can be used for preoperative imaging, as this compound does not contain iodine. CT and MRI are useful in thyroid cancer when invasion of the visceral structures is suspected. Laryngotracheal and esophageal invasion are better visualized on these studies than on ultrasonography.

PET scan has emerged as a useful tool in the management of patients with thyroid cancer. In follow-up, these studies may localize metastatic disease when $^{131}$I scans are negative, apparently due to dedifferentiation of these cancers. In the workup of preoperative patients with thyroid disease, the role for PET scan is less clear and it is not typically used. When all lesions are considered,

(c) 2014 Wolters Kluwer. All Rights Reserved.

PET scans may distinguish benign from malignant tumors and a standard uptake value (SUV) of 5.0 has been proposed as a cutoff value distinguishing malignancy.[236] For lesions with indeterminate cytology and for follicular lesions, studies differ on whether PET can distinguish benign from malignant lesions.[236–238] The authors have shown that digital merging of PET scan and MRI images is useful in identifying suspicious cervical lesions in patients being examined for recurrent thyroid cancer.[239]

It is quite common that patients undergoing evaluation for nonthyroid conditions will be found to have thyroid lesions in an imaging study. These incidental findings may be identified as thyroid calcifications on radiographs, or thyroid nodules on ultrasonography, CT, MRI, or PET scan. The incidence of malignancy in these incidental lesions is estimated to be between 8% and 17%.[240–241] When incidental lesions are found on routine radiographs, CT, or MRI, a follow-up ultrasonography is recommended due to improved detection of suspicious morphology and a greater sensitivity for multinodular disease. The true incidence of these small lesions may in fact be underestimated by routine radiology review. In a study of 200 consecutive CT scans and equal number of MRI scans, the initial reading identified incidental lesions in 6% of cases. However, rereview of these scans found incidental lesions in 16% of the patients.[242]

Incidental lesions found on PET scan may present a greater risk of malignant tumors. In large studies, such lesions are found in 2% to 4% of PET scans. Because these patients may undergo PET scan due to the presence of other malignancies, not all patients get further evaluation, but most patients do. Cancer is identified in approximately 40% of incidentally discovered discrete thyroid lesions on PET scans.[243,244]

Not all incidental lesions merit an extensive workup. If the incidental thyroid lesion was discovered on CT, MRI, or PET, then an ultrasonography should be ordered to evaluate the thyroid for single versus multinodular disease and to document the characteristics of the lesion. Biopsy should be strongly considered for incidental lesions >1 cm in diameter. For smaller lesions, workup should be considered if there is a history of radiation exposure, a family history of thyroid disease, or symptoms or physical findings worrisome for malignancy or if the sonographic characteristics of the lesion are worrisome. Otherwise, lesions <1 cm in diameter should be evaluated by thyroid function tests and followed with serial ultrasonographic examinations.

## MANAGEMENT STRATEGIES AND TREATMENT PLANNING GUIDELINES

The previous section described the approach and diagnostic evaluation of patients suspected of having thyroid cancer. Given the limitations of FNA and other diagnostic studies, a significant number of patients undergo thyroid surgery without a diagnosis of malignancy. This group includes those who have a lesion suspicious but not diagnostic of cancer on needle aspiration, patients with follicular lesions, and other patients operated upon for benign conditions who are found on surgical pathology to have a thyroid malignancy. Before proceeding with a stage-by-stage review of treatment for thyroid cancer, the physicians must therefore begin with a description of the surgical approach to the patient with an uncertain diagnosis of malignancy.

Much has been written about various surgical approaches to the thyroid in the past. These approaches range from the rarely appropriate excision of a thyroid nodule to total thyroidectomy. Between these lies a confusing array of possible procedures: lobectomy, lobectomy and isthmusectomy, subtotal thyroidectomy, and near-total thyroidectomy. This range can be extended as well to include various neck dissections that may be used in thyroid malignancy.

The minimal surgery in thyroid disease is typically considered to be a thyroid lobectomy. This removes all of the thyroid tissue from one side of the trachea, preserves the superior and recurrent laryngeal nerves and parathyroids, and includes an assessment for abnormal cervical lymph nodes in the ipsilateral central neck. Performing a lesser surgery such as excision of a thyroid nodule causes scarring around the thyroid lobe, which may increase the risk of complications from any subsequent surgery on that same lobe. In selected circumstances, excision of a small thyroid nodule may be appropriate, such as discovery of a small nodule in the thyroid at the time of parathyroidectomy, or resection of a small nodule in the thyroid isthmus. By performing a thyroid lobectomy as the minimal surgical intervention, the surgeon can be relatively certain that an adequate oncologic surgery was performed on that half of the thyroid. A subsequent completion thyroidectomy can be done safely because the contralateral lobe has not been dissected.

Most thyroid lobectomies extend to about the midline, so some refer to their basic surgery as thyroid lobectomy and isthmusectomy. Extension beyond that point into the contralateral thyroid lobe is described as a subtotal thyroidectomy. In this procedure, the surgeon preserves some portion of the opposite thyroid lobe. Some prefer to save a layer of thyroid tissue along with the posterior capsule of the gland. Others may save the contralateral superior pole. In the former group, the dissection is done with the intention of leaving the contralateral recurrent laryngeal nerve protected by a layer of thyroid tissue, but significant bleeding from the remnant of the thyroid gland can occur and obscure visualization. In the latter group, the upper lobe is preserved with the suggestion that this will avoid injury to the superior parathyroid gland and reduce the risk of hypocalcemia. For any patient undergoing thyroid surgery because of potential malignancy, neither of these operations is favored by the authors. In the former, the risk of contralateral recurrent laryngeal nerve injury remains, particularly where the nerve rises to pass close to the Berry ligament. In fact, the rate of nerve injury has been reported to be higher in subtotal than in total thyroidectomy.[245] In the latter surgery, the risk of superior parathyroid injury remains due to its unpredictable location ranging from the uppermost extent of the superior thyroid pole to a position adjacent to the recurrent laryngeal nerve. These surgeries may have a role in the surgical treatment of thyrotoxicosis in which the intention is to render the patient euthyroid without the need for medication after surgery.

Total and near-total thyroidectomy are the procedures typically recommended for the treatment of malignant disease. The authors prefer these surgical approaches in bilateral benign thyroid disease as well. The distinction between these two procedures is unclear, but "near-total" recognizes a reality confronted by thyroid surgeons. At the posterior thyroid ligament, variable amounts of tissue may extend over or under the recurrent laryngeal nerve. It is here that the surgeon will weigh the risks of leaving a small amount of normal thyroid tissue versus skeletonization of the recurrent laryngeal nerve. As long as there is no concern about tumor extension in this area, leaving this small amount of tissue is considered safe. It is usually this small amount of tissue that will be seen in radioactive iodine scans following total thyroidectomy. The difference in surgical dissection between total and near-total thyroidectomy is otherwise negligible. Both procedures should involve identification and preservation of the recurrent laryngeal nerve and preservation of any parathyroid glands. Except for tissues immediately surrounding the Berry ligament, the understanding that total and near-total thyroidectomy differ is erroneous and therefore, in this chapter, these two procedures will be described as total thyroidectomy.

The decision to perform a total thyroidectomy in a patient who is not yet diagnosed with a malignancy of the thyroid will

(c) 2014 Wolters Kluwer. All Rights Reserved.

depend on a number of factors, including the preference of the patient. Some surgeons favor total thyroidectomy in any patient undergoing thyroid surgery. Many patients favor a procedure that will allow them to go without thyroid replacement following surgery, so will choose thyroid lobectomy. For patients with multinodular disease, particularly if it is bilateral, the authors favor a total thyroidectomy. For patients with a single small nodule found to be a follicular lesion, a lobectomy will be performed. When follicular lesions are larger, the risk of invasion is greater, so a total thyroidectomy is favored.

Therefore, the array of thyroid procedures to be considered in a patients presenting with a potential thyroid malignancy is reduced to just two, thyroid lobectomy or total thyroidectomy. With these two interventions, the thyroid surgeon can be certain to perform an oncologically sound surgery for every patient encountered.

## Treatment by Stage

The staging system for papillary and follicular thyroid malignancy is unique in that patient age (younger than 45 years vs. older than 45 years) is the dominant factor in assigning stage. In younger patients, the stage for differentiated cancer is either stage I or stage II depending on the presence of distant metastatic disease. Although this overall staging definition can help in predicting survival, it is less helpful in defining the treatment required. For that distinction, the tumor, node, metastasis (TNM) definitions can be more useful. The fact that all patients (younger than age 45) without distant metastatic disease are defined as stage I emphasizes the excellent outcomes that can be expected in these patients. The 50-year-old patient with a small tumor isolated to the thyroid and a 30-year-old patient with multiple enlarged cervical metastases are both stage I tumors. However, the treatment of these two stage I tumors will differ markedly.

In 2002, the distinction between T1 and T2 thyroid cancers was revised. Previously, the distinction point between these two T stages was a primary tumor diameter of less than or greater than 1 cm. The revision in 2002 changed this to less than or greater than 2 cm. The previous T stage allowed for a clear distinction between occult or microcarcinomas as T1 tumors and the higher T-stage tumors. Now, T1 tumors will include both the occult cancers (T1a) and multiple other tumors up to 2 cm (T1b) in diameter. For older patients with differentiated carcinoma and for patients with medullary carcinoma, the staging system is more familiar with stages I through IV represented. In addition, the present 2010 staging system has been changed descriptors to subdivide the T-stage categories into solitary (s) and multifocal disease (m).[246] All anaplastic cancers are considered as stage IV (Table 28.2).

# DIFFERENTIATED THYROID CANCER (PAPILLARY, FOLLICULAR, AND HURTHLE CELL CARCINOMA)

## T1–3N0 (Stage I Younger than 45 Years, Stages I to III Older than 45 Years)

***Surgery.*** For tumors confined to the thyroid, the initial treatment of a thyroid cancer is surgery. If cancer is identified before surgery by FNA, the authors feel that a total thyroidectomy is indicated and evaluation and removal of abnormal medial compartment lymph nodes should be included. For tumors extending beyond the thyroid capsule into the perithyroidal soft tissues (T3), effort should be made to resect all gross disease. This may require resection of the strap muscles anteriorly or a shave of tracheal perichondrium or esophageal musculature posteriorly to obtain adequate margins.

Treatment guidelines by the ATA and the National Comprehensive Cancer Network (NCCN) agree that total thyroidectomy is appropriate for these differentiated thyroid cancers. However, both guidelines suggest that treatment by thyroid lobectomy is equally effective in certain circumstances. These "low-risk" patients are those with cancers confined to the thyroid, with no cervical metastases or distant disease, with no aggressive histologic variant, and with no previous radiation exposure and ages 15 to 45 years. A major difference between these two guidelines is the definition of "small." The ATA suggests that only tumors smaller than 1 to 1.5 cm would merit this approach whereas the NCCN guidelines include cases up to 4 cm in diameter. The NCCN guidelines acknowledge that most patients with these favorable characteristics do undergo total thyroidectomy and also suggest that a completion thyroidectomy is indicated if final pathology after lobectomy demonstrates more aggressive features than initially thought.[212,247]

The question of performing a completion thyroidectomy is most often encountered when lobectomy is performed for benign disease and a microscopic (<1 cm) papillary carcinoma is discovered by the pathologist. The NCCN guidelines provide a framework for the evaluation of these patients. These guidelines suggest that evaluation of the pathology for multifocal disease and that ultrasound imaging of the opposite lobe and the medial and lateral compartments compartment may indicate patients who require completion thyroidectomy. Most patients without any of the above poor prognostic findings require no additional surgical treatment and some can be followed up without suppressive therapy with thyroxine postoperatively, although many may need thyroxine replacement to maintain normal TSH. The longer such a patient is monitored, the more likely they will require L-thyroxine replacement, especially considering the newer interpretations of what is considered a "normal" serum TSH.

The role of medial compartment neck dissection in patients with DTC who are clinically N0 is unclear. A recent consensus statement on the terminology, classification, and indications for central compartment neck dissection has been published in the last few years.[212] For papillary thyroid cancer, the prevalence of nodal disease ranges from 20% to 90% of cases.[248,249] These nodes are often not clinically suspected on preoperative evaluation or imaging. However, preoperative ultrasound may identify suspicious nodes in 20% to 30% of cases and may potentially alter the surgical approach in 20% of cases.[250] Present ATA guidelines recommend central and lateral neck ultrasounds for all patients undergoing thyroidectomy for malignant cytologic findings on biopsy (Recommendation 20).[212] The discovery of enlarged lymph nodes at surgery merits medial compartment neck dissection. However, the authors find it quite common that metastatic nodes appear normal in size, but firm to palpation at surgery.

The extent of medial compartment neck dissection needed in DTC is also unclear. At its most extensive, this is an *en bloc* dissection that includes the nodes between the hyoid and innominate vein and from one carotid sheath to the other. It includes skeletonization of both recurrent laryngeal nerves with preservation of their fibers to the cervical esophagus if possible and preservation of all parathyroid glands *in situ*. Although this is technically safe, the rate of temporary hypoparathyroidism has been reported to be 21%.[251] Given the fact that prognostically favorable papillary thyroid cancers can be treated by lobectomy alone, it seems overly aggressive to treat these same cancers with routine medial compartment neck dissection. The authors prefer to evaluate the medial compartment nodes carefully, perform a limited dissection of the ipsilateral tracheoesophageal groove, and extend this to a complete medial compartment neck dissection

## TABLE 28.2 Thyroid Staging Table

**Definitions**

**Primary tumor**

Differentiated and Medullary tumors

TX: Tumor cannot be assessed

T0: No evidence of primary tumor

T1: Tumor <2 cm

T1a: 1 cm or less limited to the thyroid

T1b: 1–2 cm limited to the thyroid

T2: Tumor >2 cm and <4 cm

T3: Tumor >4 cm limited to the thyroid or any size with limited (sternothyroid muscle or perithyroidal soft tissue) extrathyroidal extension

T4A: Moderate Advanced Disease

Tumor extending beyond the thyroid to subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve

T4B: Very Advanced Disease

Tumor extending to prevertebral fascia, encasing carotid, or mediastinal vessels

Anaplastic Cancers

T4a: Intrathyroidal—surgically resectable

T4b: Extrathyroidal—unresectable

**Regional nodes**

NX: Nodes cannot be assessed

N0: No regional nodal metastases

N1a: Medial compartment nodal metastases

N1b: Unilateral, bilateral, retropharyngeal or mediastinal nodal metastases

**Distant metastases**

MX: Distant metastases cannot be assessed

M0: No distant metastases

M1: Distant metastases

**Staging**

**Papillary or follicular thyroid cancer**

**Age <45 years**

Stage I
Any T, any N, M0

Stage II
Any T, any N, M1

**Papillary or follicular thyroid cancer**

**Age >45 years**

if obvious metastatic disease is identified. This approach would appear to be validated by data from Toronto where a group of patients with microscopic disease in medial compartment lymph nodes who did not undergo medial compartment neck dissection showed a 7% risk of medial compartment nodal recurrence on follow-up. This risk of medial compartment recurrence was similar to those patients undergoing medial compartment neck dissection.[252]

Determining the need and utility for prophylactic medial neck dissection in papillary thyroid cancer has been a subject of debate in recent years. Studies typically demonstrate no survival advantage for patients undergoing limited neck dissection.[253] Exceptions to this are studies showing both a survival and locoregional control advantage for patients undergoing a compartment-oriented approach to papillary cancer[254] and studies showing a survival advantage only for older patients older than 60 years who undergo neck dissection.[90]

Recent work raises an additional issue beyond survival and locoregional control. A retrospective evaluation compared a large series of patients undergoing thyroidectomy and ipsilateral medial compartment neck dissection to those undergoing thyroidectomy alone. A significant difference in stimulated Tg was demonstrated with the rate of an undetectable stimulated Tg at 6 months at 72% in the dissected group versus 43% in those who had thyroidectomy alone.[255] These results will need to be confirmed in larger series with longer follow-up. However, if it is possible to reliably reduce the proportion of patients with detectable Tg after treatment, there should be a decrease in the downstream financial and emotional costs of continued evaluation and monitoring of patients. For some patients with clinically N0 necks, central compartment neck dissection may upstage patients to N1a and upstaging patients over the age or 45 from stage I or II to stage III.[256] Recent ATA consensus guidelines suggest that prophylactic central compartment neck dissection may be performed in the N0 neck for advanced primary tumors (T3 and T4), but it may be appropriate to forgo prophylactic dissections for small (T1 and T2) papillary tumors and most follicular tumors (Recommendation 27).[212]

***Radioactive Iodine.*** The use of radioactive iodine treatment in thyroid malignancies varies depending on the surgical pathology. Guidelines by both the ATA and the NCCN have recommended radioactive iodine treatment if an aggressive variant is identified. These include tall cell, columnar cell, insular, oxyphilic, or poorly differentiated carcinoma. According to the NCCN, the indications for radioactive iodine in cases where no nodal disease is present include macroscopic multifocal disease, extrathyroidal extension (T3 or T4), and positive margins. The ATA guidelines recommend radioactive iodine treatment in multifocal disease, except when all foci are <1 cm, and does not recommend it for unifocal or multifocal disease <1 cm in the absence of other high-risk features (Recommendation 32d).[212] Further adding to the cautions about the use of radioactive iodine in low-risk (T1N0) disease, recent data have shown an increasing incidence of second primary malignancies (including salivary gland malignancy and leukemia in particular).[257] Additionally, the guidelines recommend treatment for those with extrathyroidal extension or vascular invasion. Although Hurthle cell tumors are less radioistope avid than papillary and follicular cancers, the indications for radioactive iodine are similar.

To summarize, not all patients younger than 45 years of age with T1-2N0M0 tumors require radioactive iodine. T3 tumors will merit radioiodine. Patients older than 45 years of age require radioiodine except in those cases where the disease is of limited size. Also, while the ATA recommends ablation in all patients with a postsurgical indication except patients with nodules <1 cm (unifocal or microscopic multifocal), the NCCN guidelines allow for no radioactive iodine treatment if a stimulated Tg is <1 ng/mL and the postoperative radioactive iodine scan shows no residual uptake.

If a total thyroidectomy has not been performed, and radioactive iodine treatment is indicated, a completion thyroidectomy will simplify and expedite treatment, but ablation of the thyroid remnant may be considered if a small volume of thyroid tissue remains. Therapeutic radioactive iodine treatment will then be possible 6 to 12 months after ablation of the thyroid remnant.

To be most effective, patients treated with radioactive iodine should be prepared for the treatment with TSH stimulation. This may consist of thyroid hormone withdrawal, allowing the TSH to rise accordingly, or by administering rhTSH. During withdrawal, the serum TSH at the time radioiodine administration should be >30 $\mu$U/mL. Patients should also be instructed to adhere to a low-iodine diet in the 2 weeks before the radioactive iodine treatment. Excess iodine, either through dietary intake or as a result of a recent dose of iodinated contrast such as would be given for a diagnostic CT scan, will reduce the uptake of iodine and potentially reduce the effectiveness of radioactive iodine therapy, and therefore, should be avoided.

Recent ATA guidelines suggest that remnant ablation can be performed effectively after thyroxine withdrawal or rhTSH stimulation (ATA Recommendation 34).[212] Studies have shown that thyroxine withdrawal and rhTSH equally prepare patients for remnant $^{131}$I ablation, with rhTSH studies showing an improvement in the subjective quality of life[258] and similar short-term recurrence rates.[259]

Currently, it is controversial which patients should have $^{131}$I administered under levothyroxine withdrawal conditions or with rhTSH stimulation. The authors' view at present is that most patients can be administered radioactive iodine following rhTSH stimulation rather than during levothyroxine withdrawal. Withdrawal is associated with severe symptoms of hypothyroidism that can be avoided by using rhTSH. On the other hand, rarely rhTSH administration may result in rapid enlargement of some thyroid cancer lesions with particular attention to those in the brain or skull where such mass changes could have deleterious effects. Radioactive iodine therapy following rhTSH injections has not yet been demonstrated to have the same long-term benefit in all circumstances as has $^{131}$I therapy after levothyroxine withdrawal. Nevertheless, most comparative studies published thus far show these different methods to be of equivalent benefit in ablating residual thyroid tissue and possibly in treating metastatic lesions. Current approaches will be modified as more relevant studies are performed and reported.

The dose of iodine administered will vary depending on the indications and the desired goal of therapy. If iodine is being administered for ablation of the thyroid remnant only, then the dose of radioactive iodine is typically between 30 and 100 mCi. If there is concern about residual cancer, such as in cases where extrathyroidal extension is identified, or aggressive histology is documented, the dose will typically be 100 to 200 mCi. Some institutions favor the use of dosimetry in selected patients with aggressive or recurrent disease in order to help determine radioiodine retention in an individual patient, which then allows calculation of a more specific radioiodine dosage.[260,261]

***TSH Suppression.*** The use of thyroxine as a mechanism to provide TSH suppression is commonly used after thyroid cancer treatment. The concept is that TSH is a growth factor for thyroid cells and that decreasing its level may have a beneficial effect on thyroid cancer growth or recurrence. When an occult papillary cancer is discovered after lobectomy, this is typically not required. However, the TSH should be monitored in an effort to

(c) 2014 Wolters Kluwer. All Rights Reserved.

detect subclinical hypothyroidism, and, if identified, thyroxine replacement should be initiated.

For larger stage I tumors, and for microscopically invasive follicular cancers, TSH suppression is often utilized after surgical treatment. However, the goals of TSH suppression are typically modest and values in the low normal range are adequate. Stages II and III tumors merit greater TSH suppression although a recent study by Jonklaas failed to show significant benefit of aggressive suppression therapy even in stage II tumors.[262] Stage III tumors should be treated with a goal of keeping TSH 0.1 to 0.5 $\mu$U/mL for 5 to 10 years after treatment. Present ATA Guideline recommendations (Recommendation 40) suggest that TSH suppression below 0.1 mU/L is appropriate for intermediate-risk and high-risk tumors, whereas maintenance levels of 0.1 to 0.5 mU/L may be appropriate for low-risk patients, whether they have undergone remnant thyroid ablation or not.[212]

## T4N0M0 (Stage I Younger than 45 Years or Stage IV older than 45 Years)

***Surgery.*** For tumors with extension beyond the thyroid into trachea, esophagus, larynx, recurrent laryngeal nerve, prevertebral fascia, carotid, or mediastinal vessels, surgery remains the recommended first-line therapy in DTC. For tumors adherent to the larynx or trachea, a shave resection may be possible but if intraluminal extension is identified, tracheal resection or partial laryngectomy is indicated.[263–266] A total laryngectomy is rarely indicated in DTC and in the patients in whom this is considered, a subtotal resection and external bean radiotherapy would be an appropriate alternative. Esophageal invasion may be limited to the muscular layers of the esophagus, allowing a submucosal resection to be accomplished. The recurrent laryngeal nerve can often by dissected away from the tumor capsule, but encasement or invasion of the recurrent laryngeal nerve may require nerve sacrifice. This tumor involvement usually is suspected preoperatively because vocal fold motion is abnormal or absent.

***Radioactive Iodine.*** Tumors of such aggressiveness should be treated with radioactive iodine unless they are proved to be noniodine avid. Doses of radioactive iodine may be near 100 mCi if no uptake beyond the thyroid bed is detected, but usually higher doses will be administered.

***External Beam Radiotherapy.*** Not typically used for routine management of thyroid cancer, external beam radiotherapy is appropriate in T4 tumors. Radiotherapy doses will typically be administered in standard fractionation to doses of approximately 60 Gy. The fields chosen for treatment will typically include the thyroid bed, central compartment, and mediastinal nodes. Recent ATA Guidelines recommendations (Recommendation 41) suggest that external beam radiation (EBRT) should be considered in any patient above the age of 45 with gross visible extrathyroidal extension with a high likelihood of microscopic disease, in those patients with gross residual disease in whom RAI or further surgery would not be beneficial. NCCN Guidelines provide similar recommendations. EBRT has also been suggested for those patients with extensive pT4 disease above the age of 60 even in the absence of evident residual disease.[267] Recent data suggest that PET may play a role in evaluating the posttreatment response following EBRT and should be part of the management algorithm, especially in noniodine avid (RAI scan-negative) tumors (Recommendation 48d).[212]

The timing of EBRT and radioactive iodine needs some comment. It is preferred that radioactive iodine precedes external radiotherapy. This avoids the potential for reduced radioactive iodine uptake in tumor tissue previously subjected to external radiotherapy. In addition, if a radioiodine-avid tumor is shown by radioactive iodine treatment, then there is a theoretic advantage in waiting for some period of time (e.g., 3 months) before EBRT commences.

***Thyroid-stimulating Hormone Suppression.*** These high-risk tumors should be treated with thyroxine with a goal of maintaining TSH at or <0.1 $\mu$U/mL. Medical contraindications such as atrial fibrillation and osteoporosis will need to be considered with aggressive TSH suppression.

## T1–4N1M0 (Stage I Younger than 45 Years, Stage III or IV Older than 45 Years)

***Surgery.*** The treatment of patients with clinical neck disease starts with surgery. All patients merit total thyroidectomy and a neck dissection. Neck dissection is associated with better outcomes than management of clinical nodal disease by "berry picking." The extent of neck dissection should be determined by the extent of neck disease. In cases with medial compartment nodal disease, a complete medial compartment dissection is warranted. For patients with nodal disease along the jugular chain or in the posterior triangle, both a medial compartment neck dissection and a lateral neck dissection should be performed. To address the levels of neck disease at risk, levels II through V should be dissected in most cases. Preservation of the spinal accessory nerve, the sternocleidomastoid muscle, the jugular vein, and even the cervical sensory nerves is usually possible. Levels II to IV are the most common levels involved. Level I is rarely involved in thyroid disease and can be omitted. Levels I and V are never involved in isolation.[268]

The importance of level II in the management of neck disease in thyroid cancer merits further discussion. Whereas levels III and IV have the highest prevalence of nodal metastasis, the rate of level II disease has been reported at approximately 50% by Sivanandan and Soo.[268] Even in papillary microcarcinomas, when lateral neck dissections are performed routinely, level II involvement ranges from 15% to 30% depending on the location of the tumor within the thyroid gland. The finding that upper lobe and multifocal cancers metastasize to level II in 30% of the cases argues for careful attention to this level of the neck.[66] Level II can be reached by a low transverse incision in many cases although access to tissues posterior to the spinal accessory nerve (level IIb) can be difficult. Ridge et al. have reported a 21% incidence of nodal involvement of level IIb (above the spinal accessory nerve) in their series of neck dissections for thyroid cancer.[269]

***Radioactive Iodine.*** For patients with DTC identified as having lymph node metastases, treatment guidelines differ. ATA guidelines recommend postsurgical radioactive iodine in all patients with follicular cancer and all patients with papillary thyroid cancer larger than 1 cm. NCCN guidelines provide for options in therapy with no treatment when postoperative stimulated Tg is low and radioactive iodine scan is negative. The NCCN guidelines acknowledge the fact that a high number of papillary thyroid cancers will harbor occult nodal disease, but that the historical behavior of these tumors remains favorable.

***Thyroid-stimulating Hormone Suppression.*** Patients with nodal disease at diagnosis merit TSH suppression therapy following surgery. However, as noted by Jonklaas, young patients in this group are stage I tumors and the benefit of TSH suppression is not clear.[262] Typically all patients with nodal disease are treated, but more aggressive TSH suppression goals are used in older patients and in those with documented metastatic disease on post-therapy radioactive iodine scans. The clinical context must also be considered especially with regard to the possibility of aggravating or precipitating atrial fibrillation or bone loss.

### T1–4N1M1 (Stage II Younger than 45 Years, Stage IV Older than 45 Years)

***Surgery.*** Patients with distant metastatic disease at presentation merit thyroid surgery both to provide control of the primary site and to allow the use of radioactive iodine to treat the distant disease. In this circumstance, neck dissections may be limited to grossly positive nodal disease, again to reduce the tumor burden and allow effective treatment with radioactive iodine.

***Radioactive Iodine.*** For patients with M1 disease, radioactive iodine is given in most cases. Dosimetry may be used to maximize the tolerable dose; however, there is not clear evidence that this form of treatment is better than empiric radioactive iodine dose selection. Micronodular pulmonary metastases respond well to radioactive iodine and treatment should be repeated until there is no further tumor response. Macronodular lung disease is less responsive but treatment is appropriate as long as tumor nodules uptake radioactive iodine.

Other sites of metastatic disease merit radioactive iodine treatment as well. Possible exceptions include solitary brain metastases, or bone metastases that threaten spinal cord integrity, or involves weight-bearing bone. Instead, these metastases should be considered for resection or treated by local irradiation. The reader is referred to both the ATA and NCCN guidelines[212,247] for a description of treatment options for various metastatic situations.

***Thyroid-stimulating Hormone Suppression.*** Patients with metastatic disease merit aggressive TSH suppression therapy with a goal of maintaining TSH at <0.1 $\mu$U/mL. Again, the exception would be a young patient with minimal evidence of metastatic disease such as radioavid microscopic lung metastases. Ideally, these situations should be individualized.

## MEDULLARY THYROID CARCINOMA

### Sporadic or Inherited Presenting with Clinical Disease (Stages I–IV)

***Surgery.*** Surgery is essential in the treatment of MTC; however, a sporadic tumor may be the index tumor of a pedigree with MEN, and it is therefore important that an effort to evaluate for both pheochromocytoma and hyperparathyroidism be undertaken before surgery. If present, the former may require surgery before the thyroid surgery.[247]

For medullary cancer, a total thyroidectomy is recommended along with at least a medial compartment neck dissection. The threshold for performing lateral neck dissections is low, and some authors have recommended that all patients undergo bilateral neck dissections in addition to the thyroidectomy and medial compartment dissection. NCCN guidelines favor thyroidectomy and medial compartment neck dissections in all patients. Ipsilateral lateral neck dissection is recommended for clinical or radiologic evidence of nodal disease. In addition, prophylactic lateral neck dissection should be considered when there is significant central neck disease. Dissection of the contralateral neck is recommended when clinical or radiologic disease is identified there. The neck dissections done in medullary carcinoma should be as thorough as possible in the regions dissected because these tumors are not responsive to radioactive iodine and are considered less responsive to external beam radiotherapy as well.[247]

***Surgery with RET Germline Mutation.*** RET mutations may be seen in familial medullary carcinoma and in MEN 2A and 2B. Patients with these germline mutations require special consideration regarding the management of the thyroid. RET mutations of codons 883, 918, and 922 are associated with MEN 2B. This aggressive syndrome merits surgical intervention in the first year of life in order to prevent the emergence of clinical disease.[157,247] A central neck dissection should also be performed in these cases. If a tumor >5 mm is detected, the NCCN guidelines advise consideration of an ipsilateral neck dissection as well.[247]

RET mutations of codons 609, 611, 618, 620, 630, 634, 768, 790, 791, 804, or 891 are associated with MEN 2A and FMTC. Patients with these mutations merit surgery at age 5 or when the mutation is identified in older individuals.[247] Previous guidelines had distinguished patients with mutations at codons 611, 618, 620, and 634 from the other MEN 2A hotspots. These guidelines had advised surgery before age 5 in the former group with the possibility of later surgery (before age 10) in the latter group. These strategies are still undergoing modification and should be individualized.[157]

Surgical preparation should include measurement of parathyroid hormone level in order to be able to address parathyroid disease at the time of surgery, if hyperparathyroidism is present. Surgery should consist of total thyroidectomy with central compartment neck dissection in those patients with elevated calcitonin or CEA and in those with thyroid nodules identified by ultrasonography or at surgery. Lateral neck dissection should be considered for those with primary tumors >1 cm diameter[247] (NCCN guidelines).

If the preoperative parathyroid hormone level was elevated (or high normal in the context of hypercalcemia), then parathyroid disease should be managed at surgery. This will consist of excision of a parathyroid adenoma, if present, or subtotal parathyroidectomy and preservation of the equivalent of one parathyroid gland *in situ* or autotransplanted when hyperplasia is identified.[247]

***Radiation Therapy.*** There probably is no role for radioactive iodine in MTC. If radiotherapy is indicated, external beam radiotherapy is required. The role for radiation therapy as an adjunct in the treatment of medullary thyroid cancer is unclear. There are no randomized trials supporting its use, but institutional reports demonstrate activity against this tumor type when compared with historical controls. For disease that has been completely resected, with clear margins and minimal nodal disease, there does not appear to be any role for radiotherapy. The NCCN guidelines recommend that radiation be considered in T4 tumors (NCCN guidelines). The authors feel that those patients with close or positive surgical margins or multiple nodal metastases, especially if extracapsular extension is noted, should be considered for postoperative radiotherapy.[270]

## ANAPLASTIC CARCINOMA

### Surgery

Typically, anaplastic carcinoma presents so aggressively that surgery is not feasible because of extensive infiltration of surrounding structures. In these cases, surgical intervention is limited to biopsy and, if indicated by airway compromise, tracheotomy. Biopsies in this disease may be obtained by core needle biopsy although some cases required additional tissue by open biopsy to complete the pathologic assessment. Tracheotomy may require resection of the thyroid isthmus and adjacent tumor to provide unobstructed access to the airway.

Rare cases of anaplastic cancer may present early enough to allow surgery to be considered. However, even small anaplastic tumors may show extensive tumor infiltration, so the decision to pursue surgery should be made with care. Total thyroidectomy with resection of involved regional nodes and structures should be considered. The authors would not consider resection of

(c) 2014 Wolters Kluwer. All Rights Reserved.

aerodigestive tract structures due to the quality-of-life effects and no expectation of therapeutic benefit. For those patients selected for surgery, the therapeutic goal is to allow for locoregional control of disease and preservation of voice, airway, and swallowing with recognition that distant disease is highly likely to present. Occasionally, a diagnosis of anaplastic thyroid cancer emerges on final pathology. There is no role for completion thyroidectomy or neck surgery in these cases.

### Radiation Therapy

Anaplastic cancer does not concentrate radioiodine, so radioactive iodine treatment is not recommended. External beam radiotherapy to the thyroid bed and neck is commonly utilized in an effort to establish locoregional control of tumor. Standard fractionation and hyperfractionation regimens have been utilized. Radiation doses in the range of 60 Gy are more effective than lower doses. Toxicity is a major limiting factor in twice-daily fractionation schemes, but seems to show more responsiveness than once-daily regimens.[271]

### Chemotherapy

As part of the standard care for anaplastic cancer, chemotherapy is used in combination with radiotherapy. Doxorubicin is considered the single most effective agent.[184,272] This can be combined with cisplatin in a manner that yields relatively favorable responses.[181,272] Other agents, including paclitaxel, have also been utilized.[273]

## OUTCOMES AND RESULTS

### Differentiated Thyroid Cancer

Owing to the similar outcomes in papillary and follicular thyroid cancer, many series report these two cancer types together. Although differences may be seen in the presentation and behavior of these two tumor types, the outcomes of this group as a whole will first be discussed and distinctions will then be made between the two tumor types as required. It is generally accepted that the vast majority of patients with DTC do well, with overall survival in excess of 90% in multiple series. In the largest series of thyroid cancers reported, Hundahl utilized the National Cancer Data Base (NCDB) to evaluate outcomes of >53,000 patients treated between 1985 and 1995. This series shows the value of American Joint Committee for Cancer (AJCC) staging as a predictor of prognosis. Table 28.3 shows the outcome of papillary cancer by stage and Table 28.4 shows the same data for follicular cancer. What is most notable here is both the excellent outcome of low-stage tumors and also the low prevalence of high-stage tumors. These two factors have contributed to the general understanding that patients with differentiated cancer do well.[76]

**TABLE 28.3 Papillary Carcinoma Stage Distribution and Survival**

| Papillary Cancer Stage (16% Unknown Stage) | I | II | III | IV |
|---|---|---|---|---|
| 5-yr survival | 100% | 100% | 94% | 48% |
| Proportion of cases | 57% | 14% | 10% | 2% |

There is both an excellent outcome of low stage tumors, but also a low prevalence of high stage tumors.

*Source:* Adapted from Hundahl SA, Fleming ID, Fremgen AM, et al. A national cancer data base report on 53,856 cases of thyroid carcinoma treated in the United States, 1985–1995. *Cancer.* 1998;83:2638–2648, with permission.

**TABLE 28.4 Follicular Carcinoma Stage Distribution and Survival**

| Follicular Cancer Stage (18% Unknown Stage) | I | II | III | IV |
|---|---|---|---|---|
| 5-yr survival | 99% | 99% | 82% | 47% |
| Proportion of cases | 41% | 27% | 7% | 7% |

Similar to papillary cancer, there is both an excellent outcome of low stage tumors, but also a low prevalence of high stage tumors.

*Source:* Adapted from Hundahl SA, Fleming ID, Fremgen AM, et al. A national cancer data base report on 53,856 cases of thyroid carcinoma treated in the United States, 1985–1995. *Cancer.* 1998;83:2638–2648, with permission.

Tables 28.3 and 28.4 describe 5-year survival data. At 10 years, similar outcomes are seen for patients younger than 45 years. In contrast, older patients begin to show poorer survival. This is clearly demonstrated in the data from Hundahl represented in Figure 28-14. Increased age at the time of diagnosis corresponds to worse 5-year survival, but 10-year survival is markedly worse in older patients. These data also emphasize the need for long follow-up in thyroid cancer studies. It is generally felt that, when possible, 20-year survival figures should be compared in this disease to determine optimal therapy.

Although it is generally understood that patients with DTC will do well following treatment, there are cases that fail treatment and a small number of patients who die of disease. Determining which patients will do well and which patients will do poorly has been an area of debate in thyroid cancer study. Those patients with an excellent prognosis may be managed with less aggressive therapy than those with a more ominous prognosis. As an example, studies have shown that patients who die of DTC often have distant disease at presentation. In a study from Germany in which 38 of 484 patients with DTC died of thyroid cancer, 20 had distant disease at presentation.[274] Similar data are seen from Toronto, where 10 of 522 patients with DTC died of disease and 5 of these had distant metastases at presentation.[275]

Efforts to define prognosis in DTC have led to risk stratification criteria. Shaha describes an experience from Memorial Sloan-Kettering Cancer Center of >1,000 DTCs. In his analysis, using criteria echoing the age, metastases, extent, and size (AMES) risk criteria, he differentiates low-risk, intermediate-risk, and high-risk cancers. The definitions of these risk groups are shown in Table 28.5. Cancers are equally distributed between low-risk (39%) and intermediate-risk (39%) groups with high-risk cancers seen in only 22% of patients. Patients with high-risk cancers show a 57% 20-year survival with recurrences predominantly being distant in 34% and lesser risks of local in 18% and regional in 17%. Intermediate-risk tumors on the other hand show an 85% 20-year survival with almost equal distribution between local (10%) and regional (14%) and distant (12%) recurrences. Low-risk cancers show a 99% 20-year survival with low risk of local (5%), regional (10%), and distant (2%) recurrences. Because of the low risk of recurrence and negligible risk of death in the low-risk group, Shaha has recommended that thyroid lobectomy alone be considered, perhaps with suppression of TSH, in this group.[276]

(c) 2014 Wolters Kluwer. All Rights Reserved.

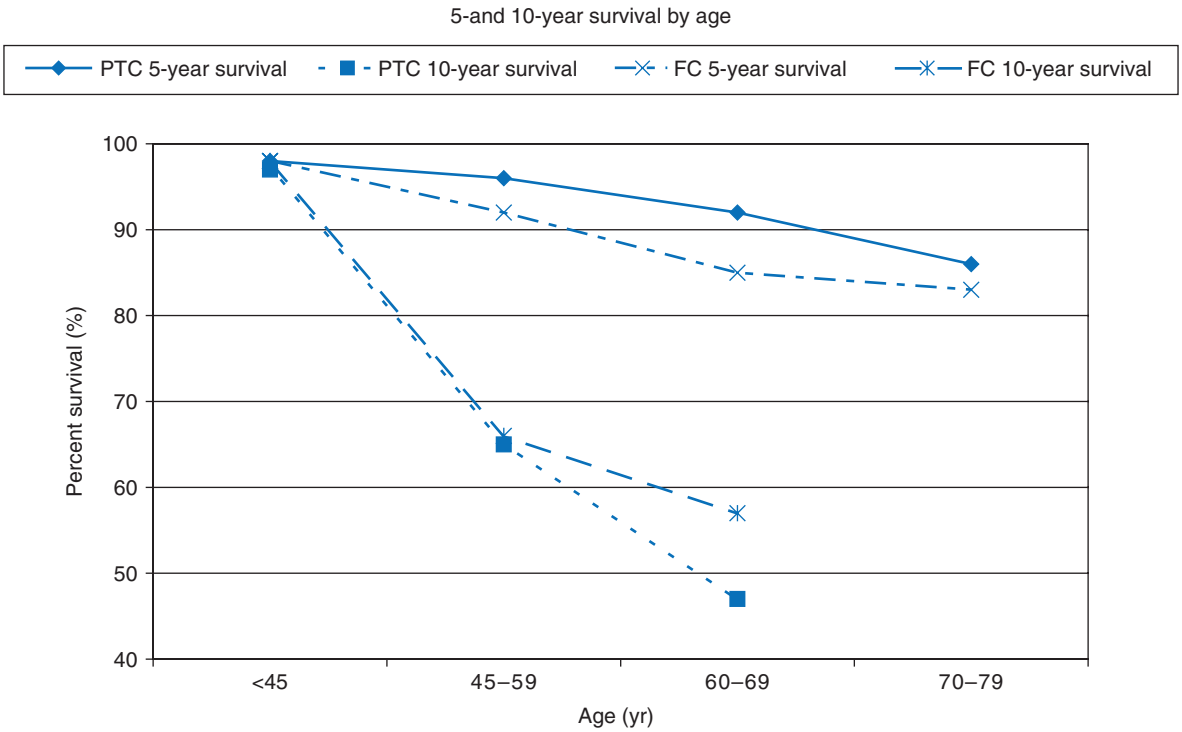

**FIGURE 28-14.** Five-year survival and 10-year relative survival for young patients are similar for both papillary and follicular cancer. However, a difference in survival is seen in older populations when comparing 5- to 10-year survival. PTC, papillary thyroid carcinoma; FC, follicular thyroid cancer.

By utilizing three risk groups instead of two, these data select out the very low-risk patients who may be appropriate for partial thyroidectomy. Not all clinicians agree with this approach, and if the previously reported NCDB data are a reflection of accepted practice, most T1 papillary thyroid cancers (63%) were treated by total or near-total thyroidectomy between 1985 and 1990. Two issues are worth noting here. One is that this era was one in which T1 was defined by tumors <1 cm in diameter, as opposed to the more recent staging cut-off point of 2 cm. Second, the Memorial Sloan Kettering and the NCBD data are derived from a period when neither serum Tg nor relevant radiologic studies such as cervical sonograms were used routinely in follow-up; therefore, residual or recurrent disease may have been underestimated.[76]

## Papillary Cancer

It is difficult to determine survival differences in treatment options for DTC because patients typically do well. Differences, however, do emerge relative to treatment and locoregional control. In an often quoted series of papillary thyroid cancers published by Mazaferri, 576 patients were followed for a median of >10 years. There was no difference in the risk of death from

**TABLE 28.5 Risk Group Stratification in Differentiated Thyroid Cancer**

**Differentiated Cancer of Thyroid: Risk Group Definitions**
**Risk Groups**

| | Low | Intermediate | Intermediate | High |
|---|---|---|---|---|
| Age (y) | <45 | >45 | <45 | >45 |
| Distant metastasis | M0 | M1 | M0 | M1 |
| Tumor size (cm) | T1/T2 (<4) | T3/T4 (>4) | T1/T2 (<4) | T3/T4 (>4) |
| Histology and grade | Papillary | Follicular and/or high grade | Papillary | Follicular and/or high grade |
| Frequency | 39% | 39% | | 22% |

*Source:* Adapted from Ashok R, Shaha MD. Implications of prognostic factors and risk groups in the management of differentiated thyroid cancer. *Laryngoscope.* 2004;114:393–402, with permission.

(c) 2014 Wolters Kluwer. All Rights Reserved.

disease whether a total (0.6%) or less than total (1.5%) thyroidectomy was performed. There was, however, a significantly lower risk of recurrence in the total thyroidectomy group (11% vs. 19%).[141] The Mayo Clinic has described a series of papillary cancers followed up for a median of 23 years and indicates no difference in cause-specific mortality or risk of distant metastases between patients treated by total thyroidectomy or lobectomy. There was a significant decrease in local recurrence (2% vs. 14%) and nodal recurrence (6% vs. 19%) when total thyroidectomy was performed versus lobectomy.[277] An analysis of the SEER database looking at patients who have undergone surgery for papillary thyroid cancer has confirmed the above findings. In this study of 22,724 patients, increased tumor size, extrathyroidal extension, positive nodal status and increased age were associated with worse disease-specific and overall survival. When controlling for tumor size in multivariate analysis, there is no survival difference between patients undergoing total thyroidectomy and lobectomy.[278]

For follicular variant of papillary thyroid carcinoma, the survival appears no worse, possibly even better, than classical papillary carcinoma with survival at 21 years reported as 86% and 80%, respectively, in one series.[279] Reports, including the authors' own, comparing papillary cancer and follicular variant of papillary cancer have indicated a higher chance for local invasion (10% vs. 0%)[104] and distant metastasis (4% vs. 0%) in papillary cancer[103] as well as a higher chance of local recurrence.[104] Recently, data have indicated that FVPTC may consist of both encapsulated and invasive forms and that the encapsulated form has essentially no risk of local recurrence or death, even when treatment is limited to hemithyroidectomy.[105] In the same SEER database review mentioned previously, follicular variant of papillary was not associated with worse DSS or OS. These results will need to be confirmed by others, and therefore at this time the authors recommend that this variant be treated using the same protocol that one would use to treat the classic form of papillary cancer.

One issue in determining the outcome in papillary thyroid cancer is the use of serum Tg as a tumor marker. This is a highly sensitive test, estimated at 80% to 100% sensitive, with a negative predictive value of 99% when measured under thyroid hormone withdrawal following previous thyroidectomy and radioiodine treatment.[280] The test does, however, lack specificity and false-positive readings can be seen. Furthermore, these comments only apply to patients who do not have Tg antibodies, which may interfere in the accurate measurement of serum Tg.

Although it is logical to assume that an elevated serum Tg following previous thyroidectomy and radioactive iodine would indicate residual gland or recurrent tumor, there are many situations in which tumor is suspected but cannot be verified clinically. Studies from France and Italy both indicate that patients with low-risk papillary cancer need to be evaluated judiciously for mild increases in Tg. When patients have been treated by thyroidectomy and radioactive iodine and undergo Tg determination under TSH stimulation, 30% to 67% of those with Tg elevations of 1 to 10 ng/mL will normalize without further treatment.[280,281]

Utilizing ultrasound, metastatic disease is often identified in the neck when recurrence has been indicated by elevated Tg. When Tg is 1 to 10 ng/mL, 19% of patients will be found to harbor cervical metastases. When Tg is >10 ng/mL, the likelihood of cervical lymph node metastases increases to >50%.[281]

Despite the caveat that false-positive Tg levels may be seen and lead to unnecessary testing, a consensus panel concluded that this form of evaluation was appropriate follow-up testing in low-risk papillary cancer patients and that radioactive iodine diagnostic scans were not required to search for recurrent disease. Specifically, this panel reviewed 784 patients with no clinical evidence of cancer and low serum Tg (<1 ng/mL) on thyroxine replacement. These patients were evaluated by both rhTSH stimulated Tg and rhTSH stimulated or withdrawal radioactive iodine whole body scans. Twenty-one percent of patients had Tg stimulated to >2 ng/mL after rhTSH and 36% of these were found to have metastases. Thyroid radioiodine scans found only 19% of these recurrences, and the consensus panel concluded that rhTSH stimulated Tg was adequate follow-up in low-risk patients.[282] Present ATA guidelines on low-risk patients who have remnant thyroid ablation recommend that in the setting of a negative cervical ultrasound and undetectable TSH stimulated may be followed with a thyroxine withdrawal or rTSH stimulated Tg at 12 months after ablation (Recommendation 45a) and thereafter may be followed with annual clinical exams and Tg measurements on hormone replacement (Recommendation 45b).[212]

Indications for PET scanning in well-differentiated cancers is expanding beyond previous recommendations of follicular histology with an elevated suppressed Tg and a negative diagnostic whole body RAI scan. Possible indications include use in the initial staging of poorly differentiated carcinomas, as a prognostic tool for predicting disease specific mortality risk in patients with metastatic disease and in the evaluation of posttreatment response of systemic or local treatment for metastatic or locally aggressive disease (Recommendation 48).[212]

A proportion of papillary thyroid cancers are poorly differentiated, and these tumors have a more ominous prognosis. Among the poorly differentiated papillary thyroid cancers, tumors with trabecular, insular, and solid (TIS) pattern predominate. Outcomes for these cancers have been described by a report from the University of Turin. Overall, 10-year survival was worse for these tumors (67%) than for either papillary thyroid cancer or follicular cancer (90%). The data allowed a scoring system to be developed which rated necrosis, mitoses, and patient age in order to subclassify these trabecular, insular, and solid tumors into three classes. Class I tumors showed a prognosis similar to papillary and follicular cancers. The 10-year survival for these three classes of trabecular, insular, and solid cancers was 83%, 74%, and 48%.[283] In addition, the previously mentioned TCV and the DSV of papillary have also been shown to have a worse prognosis compared to classic papillary type.[284] In a review of 43,738 patients from 1988 to 2008, the incidence of TCV and DSV increased by 126% compared with papillary cancer for the same time period. In addition, the DSV and TCV were associated with higher rates of extrathyroidal extension, multifocality, and nodal (more common with DSV) and distant (more common with TCV) disease. Overall survival was less for DSV (5-year OS 87.5%) and TCV (80.6%) compared with classic papillary (93.5%, $p < 0.001$).

## Follicular Cancer

Although the outcomes for minimally invasive follicular carcinoma are typically excellent, a worse prognosis can be seen in macroscopically invasive follicular cancer. Among 215 follicular thyroid cancers reported from Hong Kong in which total thyroidectomy was done in 80.5% and radioactive iodine was used in 81.4%, a 10-year cause-specific survival of 81% was seen with multivariate analysis showing significantly worse survival with extrathyroidal extension, gross residual disease after surgery, metastatic disease at presentation, or lack of radioactive iodine treatment. This series included minimally invasive follicular cancers as defined by complete encapsulation and invasion noted only on pathologic evaluation. For these minimally invasive cancers, the cause-specific survival was significantly better at 97.6% at 10 years. Most of the 52 patients with minimally invasive cancer underwent total thyroidectomy and radioactive iodine treatment. Although there were no locoregional recurrences among the minimally invasive cancers, three (5.8%) patients developed bone metastases, two of whom were treated with radioactive iodine previously, and one patient died of diffuse bone metastases.[285]

(c) 2014 Wolters Kluwer. All Rights Reserved.

In another series from Hong Kong, the excellent outcomes in minimally invasive follicular carcinoma are shown. This series of 156 patients with follicular cancer were followed up for an average of 14 years and included 49 (31%) classified as minimally invasive, 23 (15%) others showing angioinvasion, and 84 (54%) with widely invasive tumors. Seventeen (11%) presented with distant disease and half of these died of disease. In the entire series, a total of 17 (11%) died of disease, and death from disease was limited to those with widely invasive follicular cancer. No patients with minimally invasive cancer or angioinvasion alone died of disease.[130]

Although the first of these two series from Hong Kong tended to treat all follicular cancer with total thyroidectomy and radioactive iodine, regardless of the degree of invasion, the second recommended hemithyroidectomy alone for minimally invasive follicular cancers. Paradoxically, the first series resulted in subsequent distant metastatic disease in 6% whereas the second, more conservative, approach reported no risk of distant disease in follow-up.[130,285] A series from the AFIP also supports lobectomy as adequate treatment for minimally invasive follicular carcinoma. In this series of 95 cases of minimally invasive follicular carcinoma, all recurrences were local and only one patient died of disease.[134]

Comparing the outcome between those minimally invasive tumors with capsular invasion alone versus those with angioinvasion demonstrates a higher cause-specific mortality (28% at 10 years) among tumors with angioinvasion.[286] The terms *angioinvasive* or *moderately invasive* follicular cancer has been proposed to describe the worse outcome in angioinvasive tumors compared with tumors with capsular invasion alone.[130] A stepwise decrease in 5-year survival is seen between tumors with capsular invasion alone (98%), versus those with angioinvasion with or without capsular invasion (80%) versus those with macroscopic invasion (38%).[287] These results may be interpreted to suggest that treatment of minimally invasive follicular cancer by hemithyroidectomy alone may be best limited to those cases with capsular invasion alone and more comprehensive treatment advised in cases with angioinvasion.

## Hurthle Cell Cancer

Hurthle cell cancer is considered to be a variant of follicular cancer, with similar behavior. In a study from M.D. Anderson, evaluating outcomes in 127 Hurthle cell neoplasms (89 adenomas and 38 carcinomas), Hurthle cell carcinoma showed a 62% disease-specific survival at 20 years. In contrast, there was a 100% disease-specific survival in patients diagnosed with Hurthle cell adenoma, an area that had been controversial.[268] The NCDB data show a difference in outcome between follicular and Hurthle cell carcinomas with longer follow-up. In this series, there were >1,585 cases of Hurthle cell cancer reported versus 6,764 follicular cancers. At 5 years, survival was equivalent at 91%, but at 10 years, Hurthle cell cancer survival was 76% versus 85% for follicular cancer.[76]

## Medullary Thyroid Cancer

The NCDB data show 80% survival at 5 and 10 years despite the fact that only 38% of these patients were treated by total thyroidectomy and lateral neck dissection.[76] This same database has indicated that when medullary cancer occurs in a patient with a positive family history, 50% of cases are stage I whereas only 8% of those without a family history are stage I. In fact, in the absence of a family history, patients are most commonly stage II (40%). The prevalence of higher stage (III or IV) tumors is roughly similar between those cases with and without a family history, 39% and 44%, respectively. These data show that there is a significant incidence of higher stage tumors regardless of family history.[77]

Nodal disease has a critical impact on the ability to render patients with medullary cancer disease-free, at least as indicated by a normalized calcitonin. Following total thyroidectomy, medial compartment neck dissection, and bilateral neck dissection, calcitonin has been shown to normalize in 70% to 95% of those without pathologic nodes, but only 20% to 32% of those with nodal disease.[289] Similar relationships can be seen when numbers of nodes and numbers of involved compartments are evaluated. Compartments refer not to neck levels, but to the medial compartment, the two lateral compartments, and the mediastinal compartment. Biochemical cure is achieved in 32% of patients with one to nine nodal metastases, but in no patient with 10 or more positive nodes. Similarly, cure is achieved in 33% of those with one involved nodal compartment, 23% of those with two involved compartments, and 0% of those with more than two compartments.[290] Therefore, the role of mediastinal dissection is controversial. Typically, mediastinal dissection is limited to those patients with radiologic suspicion of mediastinal adenopathy.[247] Machens has demonstrated associations between both extrathyroidal extension and cervical adenopathy and positive mediastinal adenopathy.[291] However, although biochemical cure is rare, Machens has shown significant palliation of symptoms when recurrent MTC requires mediastinal dissection.[292]

For many years, there were conflicting data whether sporadic or hereditary forms of medullary thyroid cancer had a worse prognosis. Initially through intensive biochemical screening of kindred at risk and now with the advent of RET testing, the data have pointed toward worse outcomes in sporadic forms of medullary cancer.[293] Early intervention in hereditary forms of the disease can be assumed to account for this difference. For example, a 40-year experience at University of California, San Francisco described a 95% survival when patients with hereditary medullary were discovered by genetic or biochemical screening. Unfortunately, only one-third of these hereditary patients were discovered by screening. Overall, only 49% of patients (hereditary and sporadic) were cured with recurrence in 12% and persistent disease after treatment in 38%.[294] Survival in medullary cancer has been shown to be equivalent to that of a general population when one of the following is present: patients with a family history discovered by screening or patients with tumors <1 cm in diameter whose tumors are stage I or II.[295]

MEN 2B has a poorer prognosis than MEN 2A with a biochemical cure shown in 56% of those medullary cancer patients with MEN 2A and 0% of those presenting with cancer in the setting of MEN 2B.[293] This clinical experience, from the Mayo Clinic, reflects a series of cases before widespread genetic testing and supports the current recommendations for prophylactic thyroidectomy in carriers of RET germline mutations. A recent report describes an experience with 50 patients treated by prophylactic thyroidectomy due to demonstration of a RET gene mutation. At 5 and 10 years after treatment, no patient had evidence of clinical medullary cancer. Forty-four (88%) had undetectable basal and stimulated serum calcitonin levels; two patients had elevated basal and stimulated calcitonin levels and four had a rise in stimulated levels, but remained within the normal range for serum calcitonin.[296]

The persistence of hypercalcitonemia following thyroidectomy is a common occurrence in medullary thyroid cancer. Despite this finding indicating residual medullary cancer following treatment, often there is no clinically demonstrable tumor and patients can survive for many years with occult medullary cancer. In fact, a Mayo Clinic case series with hypercalcitoninemia after treatment for medullary cancer reports 5- and 10-year survival rates of 90% and 86%, respectively.[297]

(c) 2014 Wolters Kluwer. All Rights Reserved.

It has been reported that outcomes in patients with medullary thyroid cancer who are discovered by routine screening is better than that in an historical cohort who presented clinically. The detection of MTC was noted in 0.4% of the >10,000 patients screened. Screened cases were of lower stage and following treatment were more likely to be rendered biochemically free of disease by serum calcitonin measurement (59%) than those presenting clinically (2.7%). Survival was also significantly better in the screened group. Screening for medullary cancer remains controversial due to the low yield of cases identified, but this group estimated a cost per MTC discovered of US$12,500 assuming a calcitonin test cost of US$50/sample (probably low by U.S. standards).[209] This group, from Pisa, Italy, favors calcitonin screening in all patients with thyroid nodules.

The utility of calcitonin screening remains controversial. This is due to the low prevalence of medullary cancer in patients with nodular disease, 0.5% to 1.5%. However, the likelihood of finding an abnormally elevated serum calcitonin level in patients with nodular thyroid disease is 3.8% to 5.1%, with most patients having a nonspecific elevation of serum calcitonin not believed to be related to the presence of medullary thyroid cancer. The degree of elevation of serum calcitonin level can be predictive of medullary thyroid cancer with a level >100 pg/mL being relatively diagnostic. While measurements after pentagastrin stimulation may eliminate false-positive readings on baseline studies, pentagastrin is not available in the United States. Therefore, the issue of whether to recommend universal serum calcitonin screening universally must take into consideration the lack of availability of pentagastrin as well as the costs of serum calcitonin measurements and pentagastrin stimulation where available (including the expense of the medication and personnel time) versus the ability to detect medullary thyroid cancer in unsuspected patients with nodular disease. The measurement of serum calcitonin in a patient with an FNA suggestive of medullary thyroid cancer should, of course, be performed. Furthermore, a clinical history of palpitations, severe or chronic diarrhea, episodes of diaphoresis, headache, hypertension, or hypercalcemia may increase suspicion for the presence of an MTC. Marfanoid habitus, neural crest-derived mucosal skin or gastrointestinal lesions, and a family history of other neuroendocrine tumors or medullary thyroid cancer should also trigger the consideration of appropriate testing including a serum calcitonin level. The present controversial issue focuses solely on the diagnostic evaluation and cost-effectiveness of screening patients with thyroid nodular disease with a serum calcitonin level and not on the appropriateness of measurement when clinically suggestive.[210]

## Anaplastic Cancer

The survival of patients with anaplastic cancer is extremely poor. NCDB data describe a 10-year survival of 14% with the vast majority of these patients dying in the first year after diagnosis.[76] In fact, this survival rate is surprisingly high, particularly considering that this is an observational database. Others have reported lower survival, including a 10% to 21% 1-year survival,[192,193,298] a 6% to 11% 2-year survival,[298,299] and a 5% 5-year survival.[298] A recent report of 37 patients treated at Memorial Sloan-Kettering Cancer Center using doxorubicin and radiotherapy reveals locoregional control of 45% and overall survival of 28% at 1 year.[300]

The most favorable series reported in the literature utilized surgery, chemotherapy, and hyperfractionated radiotherapy and described a 27% 3-year survival. In this series of 30 anaplastic thyroid cancers treated over a 10-year period, 17 of the 24 patients without distant metastatic disease underwent surgical resection. Subsequent treatment included two cycles of doxorubicin and cisplatin followed by b.i.d. radiation therapy. Adjuvant chemotherapy was then followed for an additional 6 months. Three additional patients underwent surgery following chemotherapy and radiotherapy. With this protocol, 3-year actuarial survival was 27% overall and 35% among patients without distant metastases at diagnosis.[301]

# COMPLICATIONS

## Surgical

Surgical complications consist of infection, hematoma, laryngeal nerve injury, hypoparathyroidism, and other rare complications. Complications recorded from a prospective cohort study of >5,500 patients treated in the United States in 1996 and German prospective study of >5,800 patients in 1998 both showed that the most common complication was transient hypocalcemia, which occurred in 12% to 24% of patients undergoing total thyroidectomy.[77,302] In the U.S. study, significant voice change was interpreted to mean recurrent laryngeal nerve paralysis and was shown in approximately 1% of thyroid surgeries, slightly lower in lobectomies. However, this probably underestimated the incidence of nerve injury because routine laryngoscopy was not performed.[77] The German study reports a rate of 2.3% permanent vocal fold paralysis for total thyroidectomy.[303] Other complications reported are airway problems, bleeding, and infection, all below 1%.[77]

Complications have been correlated to the volume of thyroid surgery performed by the operating surgeon. In a report on 5,680 various thyroidectomies performed in the state of Maryland between 1991 and 1996, the complication rate for the 1,144 total thyroidectomies was volume dependent with surgeons performing >100 cases/year showing 75% fewer complications than those performing <10/year (4.3% vs. 16.1%). Although this difference is significant, the data included a wide variety of complications, ranging from recurrent nerve injury to drug reactions to cardiac events. The specific difference in the rate of recurrent laryngeal nerve injury in total thyroidectomy was not reported, but the rate between the highest and lowest volume surgeons was 0.4% versus 1.5% for all thyroid surgeries. No information was provided to assess transient versus permanent paralysis.[304] Others have reported on the safety of thyroid surgery in the setting of residency education.[305,306] In addition, the prospective German trial reported earlier showed a correlation between surgical volume and permanent recurrent laryngeal paralysis but failed to show any significant correlation with transient laryngeal paralysis or transient or permanent hypocalcemia.[302] In a review of 21,270 thyroid surgeries listed in the Maryland Health Service Cost Review Commission Database from 1990 to 2009, Gourin et al. concluded that high-volume surgeons had a lower incidence of recurrent nerve injury and hypocalcemia.[307]

## Laryngeal Nerve Paralysis

Among patients, one of the most feared complications is a loss of voice after thyroid surgery. Although the authors acknowledge that the rate of laryngeal nerve injury can be underreported depending on the extent of laryngeal examination postoperatively, the concern about the risk of voice loss after surgery is typically unfounded. The degree of voice alteration after laryngeal nerve injury is highly variable, as some patients detect no voice change when a postoperative paralysis is present and others are highly symptomatic. It is extremely rare to have a complete loss of voice, even with recurrent laryngeal nerve paralysis. Detailed preoperative discussions are warranted with all patients, especially those who use their voice professionally such as singers.

The nerves at risk in thyroid surgery include the superior laryngeal nerve and the recurrent laryngeal nerve. The incidence

(c) 2014 Wolters Kluwer. All Rights Reserved.

of superior laryngeal nerve paralysis is almost certainly underreported because this results in only a mild voice change, typically consisting of a loss of upper range vocalization and some voice fatigue. A large Italian study estimated the rate of superior laryngeal nerve paralysis after thyroid surgery at 3.7%.[308] Recurrent laryngeal nerve injury is the injury of more concern. The most significant problem regarding recurrent laryngeal nerve paralysis is the rare occurrence of bilateral paralysis, which results in airway compromise due to the inability to abduct the two vocal folds during inspiration. The incidence of bilateral paralysis has been noted to be 0.2% to 0.4%.[308,309] In spite of the airway issue, the postoperative voice can be quite good in these situations because the two vocal folds are in a paramedian position.

In an excellent review by Sulica, the incidence of recurrent laryngeal nerve injury was tabulated for recent series. Eighteen studies, each with at least 100 patients, published between 1991 and 2005 were included. The total number of patients reported was >28,000. In these series, the rate of vocal fold paralysis was 1% to 8.6% with 1% to 5.1% of cases being reported as temporary paralysis and 0% to 2.9% reported as permanent paralysis.[310]

Malignant pathology typically presents higher risk of nerve injury at surgery than benign pathology[311–313] and lower rates of injury have been shown when the nerve is identified at surgery.[311,314–316] Similarly, techniques that utilize subtotal thyroidectomy have been shown to have a higher rate of recurrent laryngeal nerve injury (3.6%) than cases that include complete removal of the thyroid lobe (0.9%).[245] Nerve monitoring during thyroid surgery has become more commonplace in the last several years, despite a lack of evidence that this practice reduces laryngeal paralysis.[317–320] The authors have typically used monitoring in patients who have undergone thyroidectomy or who they feel are at higher risk of nerve injury based on information available preoperatively (e.g., reoperations, preoperative nerve weakness, medial compartment nodal disease, history of radioactive iodine, history of Graves disease, and history of thyroiditis), but their experience suggests only a small (~1%), reduction in temporary paralysis.

As indicated earlier, most vocal fold paralyses after thyroidectomy will be temporary, caused by stretch or devascularization injury to the nerve. Over several weeks, these will typically resolve. Management of patients with these injuries may include laryngeal electromyography to demonstrate the nerve or nerves that have been injured (although this is typically indicated by the examination) and to help define the potential for recovery. Intervention typically includes speech therapy in an effort to maximize contact between the paralyzed vocal fold and the functional vocal fold. Medialization of the paralyzed vocal fold can be done either with absorbable material if a symptomatic paralysis is deemed to be temporary, or permanent medialization in the case of a permanent paralysis (e.g., sacrificed nerve or an unrecovered paralysis after a period of observation).

## Hypoparathyroidism

Less well understood by patients is the risk of hypocalcemia following thyroidectomy. This is the most common complication of thyroidectomy and is limited to those patients undergoing bilateral dissection. The NCDB series placed the risk of hypoparathyroidism at 12% to 14% of total thyroidectomy and 3% of near-total thyroidectomy.[77]

In a large prospective German study, hypocalcemia after total thyroidectomy was transient in 24% and permanent in 9%. Similarly, the rates for primary treatment of thyroid cancer were 19% and 5%, respectively, and 26% and 9% for treatment of recurrent thyroid cancer.[302] Lower rates were seen in benign thyroid disease, perhaps related to the fact that malignant disease was more likely to be treated by total thyroidectomy. Using multivariate analysis, total thyroidectomy (vs. surgery where a thyroid remnant of >4 mL remained) was the greatest risk factor for both transient and permanent hypocalcemia. Other significant factors in transient hypocalcemia were bilateral ligation of the inferior thyroid artery near the carotid sheath, female gender, and thyroid surgery for Graves disease. Additional significant factors for permanent hypocalcemia were bilateral ligation of the inferior thyroid artery at the carotid sheath and the visualization of less than two parathyroid glands.[302] Table 28.6 shows several studies reporting the rates of hypocalcemia after total thyroidectomy.[303,245,321–323]

Given that hypocalcemia is the most common complication of thyroid surgery and that this complication often determines whether patients can be managed in a short-stay postoperative unit, much effort has been made to try to predict or to avoid symptomatic hypocalcemia in patients undergoing thyroidectomy. Routine serum parathyroid hormone measurement is not typically required, but some have shown that a parathyroid hormone level >10 pg/mL at 4 hours after surgery predicts with 98% accuracy that the serum calcium will remain >2 mmol/L (8 mg/dL).[324] More typically, patients are followed by serum or ionized calcium levels and for symptoms of hypocalcemia. Rising calcium levels demonstrate that the risk of hypocalcemia is essentially zero. Nahas reports a 13% incidence of symptomatic hypocalcemia when calcium levels are not rising but calcium is >8 mg/dL. In contrast, the rate rises to 75% when nonrising calcium levels are seen along with calcium levels <8 mg/dL.[325]

In an effort to avoid symptomatic hypocalcemia and reduce hospitalization, the routine use of calcium and vitamin D in the perioperative period has been proposed. Randomized comparisons of calcium (3 g/day) and vitamin D (1 $\mu$g/day) therapy for 2 weeks versus no supplementation show that symptomatic hypocalcemia is reduced from 24% to 7% and overall rates of hypocalcemia are reduced from 36% to 13%.[326] Similar favorable results have been shown by others.[327,328] However, the optimal dosing and length of calcium and vitamin D replacement is not clearly defined and a higher dose of calcitriol (1 $\mu$g b.i.d.) has been indicated by some.[327] Studies that have included postoperative parathyroid hormone measurements do not appear to justify the concern that routine calcium supplementation will reduce the recovery of parathyroid gland function.[328]

**TABLE 28.6 Transient and Permanent Hypocalcemia after Total Thyroidectomy**

| Author (Ref) | Year | *N* | Transient Hypocalcemia | Permanent Hypocalcemia |
|---|---|---|---|---|
| Tartaglia et al. (287) | 2003 | 1,636 | 2% | 0.9% |
| Pisunu et al. (293) | 2003 | 310 | 11.9% | 0.9% |
| Bellantone et al. (294) | 2002 | 526 | NA | 3.4% |
| Thomusch et al. (275) | 2003 | 88 | NA | 12.5% |
| Rosato et al. (295) | 2002 | 9,599 | 14% | 2% |

## Completion Thyroidectomy

Reoperation in thyroid disease is associated with increased risks of complications. The risk will depend on whether the specific area that requires reoperation has been previously dissected. When lobectomy has been performed on one side, a completion thyroidectomy to remove the residual lobe is usually safe, although careful attention to parathyroid preservation is warranted due to concerns about the effects of the first surgery on parathyroid tissues.

Kupferman et al. describe a single-institution experience in which both the initial and compilation surgeries were done at the University of Pennsylvania. Completion thyroidectomies were associated with a 14% incidence of temporary hypoparathyroidism and no cases of permanent hypoparathyroidism. There were no recurrent laryngeal nerve injuries. One hematoma and one seroma were reported among the 36 cases described.[329] Similar favorable results for hypoparathyroidism and for permanent recurrent laryngeal nerve injury are reported by others,[330,331] although temporary recurrent laryngeal nerve injury rates of up to 4% are described.[331] Wu et al. showed a 4.4% incidence of overall complications in 204 patients undergoing completion thyroidectomy in 2,034 patients over a 10-year period. Transient, clinically symptomatic hypocalcemia was seen in 2% of the study population, whereas transient laboratory hypocalcemia was seen in 1.5%. No cases of vocal cord paralysis were reported, and there was no difference in the complication of patients before or after 4 hours of observation.[332]

## Neck Dissection

Complications following neck dissection for thyroid cancer vary depending on the extent of neck dissection. Medial compartment neck dissection places the patient at greatest risk of hypoparathyroidism whereas lateral neck dissection is more likely to be associated with temporary trapezius muscle weakness due to effects upon the spinal accessory nerve.

In an evaluation of complications after medial compartment neck dissection with or without lateral neck dissection for papillary cancer, Roh showed a significantly higher rate of hypocalcemia (31%) in these patients as compared with patients undergoing total thyroidectomy alone (10%). The rate of permanent hypoparathyroidism was 5% and 0%, respectively. Overall rates of complication were also higher in the neck dissection group (50% vs. 12%).[333]

Kupfermen et al. described a mixed group of thyroid cancer patients undergoing various neck dissections for thyroid cancer with or without simultaneous thyroidectomy. This series reported that complications were greatest when medial compartment dissection was included and demonstrated a 21% rate of temporary hypoparathyroidism, but no cases of permanent hypoparathyroidism. Of patients undergoing lateral neck dissection, 27% demonstrated postoperative shoulder weakness.[334]

# MANAGEMENT OF RECURRENCE

Thyroid cancer is one of the few malignancies in which recurrence may be noted simply from serologic results, elevated serum Tg levels in differentiated carcinoma, and serum calcitonin levels in medullary cancers. As an overall rate of recurrence, Mazaferri reports a 40-year recurrence rate of 35% for DTCs. Approximately two-thirds of recurrences occur in the first 2 years after treatment and approximately two-thirds of all recurrences are in the neck. For the most part, cervical recurrences are successfully managed as long as extensive soft tissue recurrence is not present. Distant metastatic disease is associated with a 30-year survival of 43%.[335]

In low-risk cancers, there is an association between the initial serum Tg levels at the time of remnant ablation and the risk of recurrence. Tg <2 ng/mL is associated with a recurrence rate in follow-up of <2%, whereas a level of 2 to 10 ng/mL is associated with an 8% rate of recurrence and a level >10 ng/mL with a 42% rate of recurrence.[336] Similarly, a single Tg measurement after rhTSH stimulation can predict recurrence rates with Tg levels of <0.5 ng/mL associated with a recurrence rate of 1.6%, Tg 0.6 to 2 ng/mL associated with a recurrence rate of 5.5%, and Tg levels >2 ng/mL associated with an 80% recurrence rate. This astounding rate of recurrence was derived from a small number of patients (16 of 20 patients in the last group recurred). However, the data were derived prospectively.[337]

The presentation of recurrent disease may occur in a number of ways. Clinical symptoms and signs of disease will depend on whether this is local, regional, or distant disease. Local or regional recurrence may present with a palpable mass or an abnormality on ultrasound. More aggressive disease may manifest vocal fold paralysis or tracheal or esophageal invasion with their attendant symptoms. Distant disease most often occurs in lung, bone, or central nervous system and may be discovered during routine imaging or due to symptoms.

In the past, the radioactive iodine scan was considered the single most effective tool in following up patients treated for DTCs. This has more recently been found to be less sensitive than rhTSH stimulated Tg levels. With most recurrences in the neck, imaging of the neck by ultrasound has gained a greater role in follow-up.

The discovery of an elevation in stimulated Tg will lead to further investigation in an effort to identify the site of recurrence. If there has been no recent neck ultrasonography, then this is a simple next step. If a radioactive iodine scan has not recently been done, then this will typically follow in an effort to identify a site of recurrent disease and potentially to treat that disease with further radioactive iodine treatment.

## Locoregional Recurrence

In many cases, it is difficult to tease out local recurrence from medial compartment nodal recurrence. The use of ultrasound may be able to distinguish the recurrence as nodal or thyroidal. Once a recurrence is imaged, if it is of any significant size and if surgery can be done, this will usually follow. This allows for both a resection of all known disease and allows for less volume of disease to be treated by subsequent radioactive iodine treatment.

Small-volume nodal disease may be nonpalpable and of insignificant size on ultrasonography, but still visualized on radioactive iodine diagnostic scans. In these circumstances, radioactive iodine has been used as the primary treatment with surgery held for salvage cases. Iodine uptake can be abolished in approximately two-thirds of cases in which nodal metastases <1 cm in diameter were treated by a single dose (100–150 mCi) of radioactive iodine.[338] When repeated doses of $^{131}$I are used for small-volume neck disease, surgical resection of residual nodal disease is needed in only 16% of cases.[339] Partial response is typically seen when nodes are >1 cm in diameter, so surgery is recommended in these cases.

The complexity of surgery in the neck for recurrence will depend in large part on the extent of previous surgery. Recurrence in the thyroid bed or in medial compartment lymph nodes will usually be managed by a medial compartment neck dissection. While bilateral medial compartment dissection is ideal, concerns about the risk of hypoparathyroidism and recurrent laryngeal nerve injury may cause the surgeon to limit dissection to one side of medial compartment neck only if oncologically possible. These surgical risks have been shown to be minimal in a series of >200 central neck dissections for recurrent disease recently

(c) 2014 Wolters Kluwer. All Rights Reserved.

reported by Clayman. This study includes a heterogeneous group of patients with a large proportion undergoing simultaneous lateral neck dissection and 2 of 3 receiving postoperative $^{131}$I. However, the series shows excellent disease control with undetectable Tg in 66% and central neck clinical control in 76% of patients. In fact, although some patient needed additional surgery for recurrent disease of the central neck, there was ultimately a 98% control rate.[340]

When disease recurs in the thyroid bed, there may be involvement of aerodigestive tract structures. These require a surgical approach similar to that described in the section describing primary surgery. However, more aggressive surgical techniques may need to be considered if there is evidence that the recurrent disease is not likely to take up radioactive iodine.

Lateral neck recurrence is much more straightforward because most patients will not have had a lateral neck dissection previously. In these cases, a neck dissection that includes levels II to V is recommended with sparing of the jugular vein, sternocleidomastoid muscle, and spinal accessory nerve. In addition, the cervical nerve roots can often be spared as well. Figure 28-15 shows a left lateral neck node confirmed to be metastatic cancer by FNA. In the recurrent setting, neck dissection is associated with clinical neck control in 95%.[341] Tg can become undetectable in these cases and two recent series employing central and/or lateral neck dissections and median follow up of at least 5 years have been reported. Clayman reports undetectable Tg in 66% and no evidence of clinical or biochemical disease in about half.[340] A group from Ohio State found that stimulated Tg was undetectable in 27% of their patients.[342]

The frequency of level II involvement in thyroid cancer merits some discussion. This has been shown to be associated with primary tumors of the upper thyroid pole, likely related to retrograde lymphatic drainage along the superior thyroid artery. The rate of level II metastasis has been shown to be 40% to 56% when there is lateral neck disease, thus arguing that all lateral neck dissections include level II. The need for inclusion of level IIb is controversial,[269,343,344] but is recommended if nodal disease at IIa is identified. Level Vb is involved in 20% to 40% of cases, but the incorporation of level Va is very rare and appears to be unnecessary.[341,343]

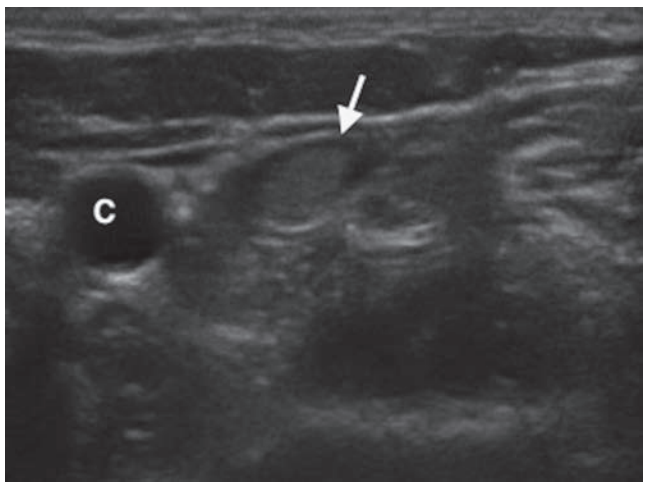

**FIGURE 28-15.** Ultrasound of the left lateral neck at level IV. Arrow indicates a lymph node showing loss of fatty hilum and heterogeneous density. Metastatic cancer was confirmed on FNA prior to neck dissection. C, Carotid artery.

The use of radioactive iodine in the treatment of locoregional recurrence will vary. All patients merit evaluation for further treatment. If a high-dose ablation has not previously been performed, an empiric dose may be given at this point in an effort to visualize (and treat) other foci of metastatic disease that may not be revealed on diagnostic scans. However, when after surgery there is no uptake in the surgical bed, the effectiveness of further radioactive iodine treatment is unknown. Oftentimes, patients will be treated empirically at that point, but the effectiveness of this treatment is debated.

One interesting approach to cervical nodal recurrence has been utilized at the Institute Gustave Roussy. This involves treating with 100-mCi radioactive iodine preoperatively and undergoing surgery 4 to 7 days later using a gamma probe intraoperatively to improve the detection of nodes that harbor metastatic disease. This is reported to have a 92% cure rate.[345] Follow-up radioactive iodine scans have demonstrated that most uptake after surgery was behind the sternoclavicular joint and this region probably merits close attention whenever surgery is performed for recurrent disease in the neck.[346]

The impact of locoregional recurrence upon survival is variable. Mazzaferri describes a mortality of 12% at 30 years whereas Rouxel et al. report a mortality of approximately 50% at 10 years.[335,347] In multivariate analysis, the following factors were associated with worse survival after locoregional recurrence: age older than 45 years at diagnosis of primary tumor, a follicular histology, extrathyroidal extension of the primary tumor, distant metastases before locoregional recurrence, absence of radioiodine ablation after initial surgery, recurrence in the thyroid bed, and the absence of radioiodine uptake of the recurrence.[347] Some of these factors would be associated with higher risk stratification at the time of initial treatment.

## Distant Recurrence

When distant metastatic disease is found, the site of disease will impact the management strategy. Brain metastases will often be managed with surgery due to the concern that radioactive iodine may cause edema and compromise neurologic function. External radiation therapy or focused radiation (e.g., GammaKnife, Cyberknife) may be used alone or following surgical resection. Bone metastases can be treated with radioactive iodine, but response is limited when the bone metastasis is large enough to be causing symptoms. Surgery may be required in weight-bearing bones. External beam radiation therapy may be used to control metastatic lesions in bone. Radiofrequency ablation and cryotherapy represent newer adjuvant techniques that have been used to address bone metastases. It is important to consider the entire clinical context in helping to decide whether a biopsy of a metastatic lesion is warranted to confirm the source of as thyroid cancer. In general, if a lesion (e.g., osseous) is the initial site of appearance (of the original tumor or the first metastases), then a biopsy may be indicated. However, if a new osseous lesion occurs in the setting of multiple of other sites of known metastatic thyroid cancer a biopsy may not be routinely required. Patients with osseous metastases should be considered for intravenous zolendronic acid therapy or subcutaneous Denosumab therapy. An international committee has recommended bisphosphonate therapy in patients with osseous metastases from solid tumors. The committee noted that there was more literature regarding the effectiveness of intravenous bisphosphonates regarding their ability to delay cancer-related skeletal events.[348] Preliminary studies suggest that in patients with thyroid cancer intravenous zolendronic acid may decrease osseous complications.[349] Possible complications of bisphosphonate therapy, especially when given intravenously, include hypocalcemia, an acute phase reaction, and in unusual circumstances osteonecrosis or atypical femoral

(c) 2014 Wolters Kluwer. All Rights Reserved.

fractures.[350] Recent studies have also indicated that Denosumab, an inhibitor of Receptor Activator of Nuclear Factor B Ligand (RANK Ligand), may also be effective in decreasing skeletal events in patients with osseous metastases.[351] Clinicians administering these agents should be familiar with their indications, contraindications, and possible adverse effects. The frequency and long-term duration of treatment of each of these treatments is controversial given the generally relatively prolonged survival of DTC patients and the potential adverse effects of these treatments to include jaw osteonecrosis and atypical hip fracture.

Overall, approximately one-third of cases with distant metastases will be controlled with radioactive iodine. This will typically involve $^{131}$I treatments every 6 months until uptake is abolished on posttreatment scans, although other centers will treat these patients only once or twice with radioactive iodine as many of these lesions do not trap or respond to radioactive well. The most success is seen when pulmonary metastases are visualized only on radioactive iodine scans. This will be controlled by radioactive iodine in 83%. Approximately half of the cases with pulmonary metastases <1 cm will be controlled whereas only 14% of patients with larger pulmonary metastases will be rendered disease free.[352] Survival after diagnosis of distant metastases in DTC is actually relatively favorable with one recent report describing overall survival of 88% and 77% at 5 and 10 years after the diagnosis of metastatic disease. There was no significant difference in survival between papillary and follicular cancers with distant metastases.[353]

## Radioactive Iodine As It Pertains to Distant Thyroid Carcinoma

When treating residual or recurrent distant thyroid carcinoma (DTC), there are often competing issues that impact the use of radioactive iodine. These include limits on cumulative radioactive iodine dose given to the patient previously and long-term risks of radioactive iodine exposure on the bone marrow. At the same time, disease that has persisted in spite of previous radioactive iodine can be suspected to be less iodine avid than untreated tumors. Decreased avidity of tumor tissue can theoretically be addressed by increasing the dose of radioactive iodine given. However, this effort to increase the total dose of iodine is associated with increased side effects of treatment, such as bone marrow suppression, xerostomia and epiphora, or increased tearing. These latter two complications can remarkably affect the quality of life and bone marrow suppression can have important clinical implications. There is also evidence that radioactive treatment is associated with a higher risk of certain malignancies, such as salivary gland tumors and leukemia.[354]

There are three ways to address metastatic disease with radioactive iodine. Empiric therapy is the most common method with historical experience used to guide dosing. Most metastatic disease would be treated with 150 to 200 mCi of $^{131}$I. However, this may underdose tumor tissue and a higher dose might be possible if one could measure the patient's potential for systemic complications. A more scientific approach uses quantitative tumor dosimetry in which the dose delivered to the tumor itself can be calculated and adjusted. The risk of systemic complications requires blood or whole-body dosimetry to determine the safe dose of iodine that can be given without exposing the bone marrow or lung tissue to excessive radioactivity. When large doses of radioactive iodine are given, there is a greater need for medical follow-up in the posttreatment period to evaluate for anemia and leucopenia.[335] Long-term follow-up studies assessing the benefit of dosimetry as compared with empiric dosing need to be performed, but at present the approach seems rational in patients with aggressive or metastatic disease. Empiric dose $^{131}$I therapy may exceed standard limits of radiation exposure to the patient or more commonly, may underestimate the appropriate dose.[355–357] A recent study compared empiric radioactive therapy versus a dosimetrically determined dose in patients with known metastatic thyroid cancer. Dosimetry was found to increase progression-free survival.[358]

## Management of Tg Positive, Scan Negative Patients

Often, patients in follow-up will be found to have an elevated serum Tg concentration without evidence of disease on whole-body radioactive iodine scanning (or physical examination). The management of these cases is a matter of debate. Even when diagnostic radioiodine scans are negative, a posttreatment scan can be positive and demonstrate the site of recurrent disease. This is especially true for microscopic pulmonary metastases. However, the yield of posttreatment diagnostic scans in this setting has been estimated to be as low as 5% to 6%.[359,360] On the other hand, others have found that 80% to 94% of diagnostic scan negative patients will show disease on a posttreatment scan.[335,361] This remains controversial with advocates on both sides. In a compilation of previously published studies, a rate of posttreatment scans being positive was placed at 62% and 63% of patients showed a drop in Tg following treatment. These writers advocate empiric dosing in these cases when the Tg is >10 ng/mL or in age, metastases, extent, and size high-risk cases.[362] This issue has become even more controversial with the use of cross-sectional imaging or PET scans, which can detect lesions that may or may not concentrate radioactive iodine.

## Recurrent Medullary Thyroid Cancer

Recurrent medullary cancer is a relatively common event, and most often this is manifest by an elevated serum calcitonin after completion of treatment. The serum half of human calcitonin is measured in minutes (estimates vary but the half-life is probably ~10 minutes). However, perhaps because of prolonged thyroid and extrathyroidal storage with slow release, because of thyroidal release at surgery, or possibly because some calcitonin assays may show interference with calcitonin precursors, serum calcitonin levels obtained within several days or even weeks after thyroidectomy may be elevated and falsely indicate residual disease. In most cases, at least 3 months should be given before evaluating posttreatment calcitonin levels. Management of this finding will include efforts to identify treatable residual or recurrent disease. In this effort, neck ultrasonography may be the single most useful test. Beyond this, multiple other imaging studies may be considered, including MRI of the neck, CT scans of the head, neck, chest abdomen, and pelvis, FDG-PET scans, and MDP bone scans. In selected circumstance, a brain MRI may be useful. However, the sensitivity of any particular test is limited and the yield of these investigations in asymptomatic patients is low.

PET sensitivity is 62% to 86% in patients with recurrent MTC. The higher sensitivities are shown for patients with calcitonin >1,000 pg/mL. The sensitivity is low with PET scanning when the calcitonin level is <500 pg/mL.[363,364]

One of the major problems in managing patients with residual or recurrent MTC is determining whether liver metastases are present. The rate of hepatic metastases in this population is approximately 25% and CT and MRI imaging studies are not sufficiently sensitive in the detection of these metastases. Laparoscopy and hepatic angiography have shown greater sensitivity for detection of these metastases.[365,366] A hepatic MRI may also be useful.

(c) 2014 Wolters Kluwer. All Rights Reserved.

When recurrent disease is discovered or suspected in the neck, then surgery may be considered. Reoperation in the neck has been evaluated and advocated by Tissell and others.[367] In a series by Moley from Washington University, 45 of 115 patients with recurrent MTC were treated with curative intent by medial compartment and lateral neck dissections as well as mediastinal dissections. Thirty-eight percent showed normalization of stimulated calcitonin.[368] The selection of patients is probably one of the most important determinants of success. Others have not shown such favorable results. The experience reported in a similar-sized group of patients at UCSF describes that only 4% showed normalization of even basal calcitonin.[369]

In addition to selection, the clinical presentation of these patients can determine the success of reoperation. Patients with normal imaging studies will obtain normal serum calcitonin levels in 29% whereas those with evidence of nodal disease on imaging studies show normalization in only 6%.[370] Similarly, in the primary treatment of MTC, the finding of disease in the neck contralateral to the tumor and/or disease in the mediastinum is correlated with the likelihood of calcitonin normalization and with the rate of distant metastases. When one of these compartments is involved, the rate of calcitonin normalization is 10%, but when two are involved the rate is zero. The rate of distant disease is 61% when both compartments are involved.[371]

Beyond surgery for cure of recurrent MTC, palliative surgery may be required in some cases of incurable disease. In a group of 16 patients treated for symptomatic recurrent disease with palliative procedures ranging from neck mass excision to liver resection, symptomatic improvement was demonstrated in all patients. The median time to recurrence of these symptoms was over 8 years, indicating significant palliation in the face of incurable disease.[372] In the face of recurrent medullary cancer, it is important to realize and to help patients understand that the survival is favorable with 5- and 10-year survival rates of 90% and 86%.[296]

When recurrent medullary cancer is not resectable, and if radiotherapy has not previously been given, this may be considered. The response rate to radiotherapy is difficult to quantify and verify. However, in retrospective series, an improvement in locoregional control has been suggested.[373]

Chemotherapy may be used for distant metastatic medullary cancer, however, with low response rates. The slow-growing nature of this tumor is reflected in a 10-year survival of 20% even with distant disease. Typical chemotherapeutic regimens may include cisplatin and doxorubicin. A recent report describes a prolonged, objective response without toxicity using capecitabine.[374] In a series of 20 patients given alternating cycles of doxorubicin-streptozocin and 5-fluourouacil (5FU)-dacarbazine, only 3 showed a response, although 10 had stability of their disease.[375]

Some medullary cancers will express CEA and efforts to target this with antibodies to CEA have shown some responses when used with doxorubicin.[376] More notable is a French trial that demonstrated improved survival in patients undergoing therapy with a bispecific monoclonal antibody able to attach $^{131}$I to anti-CEA targeted cells. With this trial, the median survival was 61 months in untreated patients and 110 months in patients given the radioimmunotherapy.[377] Recently, targeted specific therapy (i.e., multikinase inhibitors) has been used[378] and one agent, Vandetanib, has recently been approved for use for aggressive medullary thyroid cancer by the FDA (http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm250168.htm). However, multikinase inhibitors have potential adverse effects to include fatigue, leukopenia, nausea, hand-foot syndrome, hypertension, proteinuria, interaction with other concurrently administered medications (e.g., P450 inhibitors), and prolongation of the QT interval.[378] Prolongation of the QT interval seems particularly applicable to this agent and specific training is required for the health care personnel desirous of utilizing this agent. (http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm250168.htm). Close monitoring of these patients is required.

## SPECIAL ISSUES AND FUTURE DIRECTIONS

### Pregnancy

Thyroid nodules and thyroid cancer that occur during pregnancy deserve special consideration. With regard to thyroid nodules, thyroid sonography and FNA should be performed when appropriate in a pregnant patient with a thyroid nodule. If the FNA is benign, and there are no worrisome clinical parameters or a large suspicious thyroid nodule (>2–3 cm), then these patients usually can be monitored during pregnancy. If the nodule is growing and the clinician is concerned or if the FNA is diagnostic of papillary cancer, then a thyroidectomy can be performed, preferably during the second trimester of pregnancy. More controversial is the circumstance in which the FNA is suspicious but not diagnostic for papillary thyroid cancer or if the FNA shows follicular neoplasm. Individual considerations must be taken into account as to whether to recommend surgery and regarding its timing. As a general approach, the authors tend to recommend surgery during the second trimester if the FNA shows papillary thyroid cancer, and in most cases if the FNA is suspicious for papillary thyroid cancer or shows follicular neoplasm. The type of surgery may vary based on the clinical context and the experience of the surgeon, but the authors generally favor a lobectomy rather than a total thyroidectomy because of the possible risks of hypocalcemia and its treatment on the developing fetus. If further thyroid surgery is required it may be performed following delivery. There are no approaches to these issues that are evidence based and further studies are required. $^{131}$I must be avoided during pregnancy and during breast-feeding. Radioactive iodine in the breast may persist for several weeks or months following the discontinuation of breast-feeding. If a patient is taking exogenous levothyroxine for the treatment of hypothyroidism (surgically induced or due to primary hypothyroidism), it is recognized that the requirements for levothyroxine may increase during pregnancy, and close monitoring and dose modulation are required.

### Renal Failure

$^{131}$I is excreted mainly by the kidneys and its dose should be altered in patients with renal failure or more importantly in patients on chronic hemodialysis. The authors have reviewed this topic and concluded that it seems reasonable to perform dosimetry to estimate the retention of radioiodine and calculate a more rational $^{131}$I therapeutic dose. The $^{131}$I is also removed rapidly by hemodialysis and special radiation precautions need to be taken by dialysis personal. The physicians recommended giving tracer radioiodine doses and therapeutic doses immediately following hemodialysis. The radioiodine given would then be largely retained without removal (except for small nonsensible losses) until the next hemodialysis session in 1 to 2 days. Therefore, the radioactive exposure of the patient and the tumor are difficult to estimate empirically without dosimetry.[379]

### Targeted Chemotherapy

Major advances in the understanding of the development and progression of thyroid cancer have occurred mainly with recognition of relevant oncogenes. Specific agents have been developed to inhibit these oncogenes and some have already reached clinical trials. Tyrosine kinase inhibitors serve as the prototype for this type of therapy. Specific kinase inhibitors, such as sorafenib

(c) 2014 Wolters Kluwer. All Rights Reserved.

(an inhibitor of Raf kinase) or axitinib (an oral tyrosine kinase inhibitor which also inhibits vascular endothelial growth factor [VEGF] receptors 1, 2, and 3) are being utilized in trials of thyroid cancer.[380] Many different types of targeted therapy are being attempted and various clinical trials are available. A current listing is found on Clinicaltrials.gov.[381–384] As noted above, Vandetanib has been approved by the FDA for treatment of advanced medullary thyroid cancer (http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm250168.htm).

### Future Directions

Further studies assessing the utility of molecular thyroid cancer markers will be helpful in the preoperative differentiation of benign from malignant thyroid nodules. In addition, identification and characterization of oncogenes and other biochemical factors that are important in the development and progression of thyroid cancer of all types will help in the development of specific targeted therapy. Clinical studies in the areas of dosimetric analysis of $^{131}$I, attempts to prevent the possible adverse effects of $^{131}$I, and the proper algorithm to monitor patients with thyroid cancer will also be important. Identification of which patients would benefit from additional doses of $^{131}$I and attempts to identify the avidity of residual thyroid cancer for $^{131}$I should also be performed.

## PARATHYROID CANCER

### Introduction

Parathyroid cancer is a rare event. Among cases of primary hyperparathyroidism, <1% will be attributable to parathyroid cancer.[385] These statistics are similar worldwide except for Japan where a significantly higher proportion of patients with hyperparathyroidism are found to have parathyroid cancer.[386]

Within the last several years, two cancer registry reports of parathyroid cancer have been published. The largest of these describes 286 patients with parathyroid cancer registered in the NCDB between 1985 and 1995.[387] The second of these is a report from the SEER database, which includes 224 cases presenting between SEER 1988 and 2003. This report demonstrates an increase in the incidence of parathyroid cancer over time. The incidence in the first 3 years of this series was 3.58 cases/100,000 whereas the incidence for the last 3 years was 5.73 cases/100,000. A significant upward trend was shown. The increase has been attributed to the increased in frequency of surgeries done for primary hyperparathyroidism because routine calcium screening has become more common, and surgical guidelines for primary hyperparathyroidism were liberalized after 2002.[388]

The etiology of parathyroid cancer is unknown. One risk factor is previous radiation therapy that is associated with later development of parathyroid cancer in five cases in the literature.[385] Approximately 2% of parathyroid cancer cases have been reported to have a family history of primary hyperparathyroidism. This relationship appears to be more common than the relationship between parathyroid cancer and MEN type I, although this too is reported to be associated with an increased risk of parathyroid cancer.[389]

Hyperparathyroidism-jaw tumor (HPT-JT) syndrome is a rare disorder consisting most often of hyperparathyroidism and ossifying fibromas of the maxilla and mandible, and less commonly renal cysts, hamartomas, or Wilms tumors. Although benign primary hyperparathyroidism is the most common finding in this syndrome, there is a 15% incidence of parathyroid cancer.[389]

Secondary and tertiary parathyroid hyperplasia is thought to be a risk factor as well with 18 cases reported in the literature.[390] Parathyroid cancer in these patients has occurred approximately 6 years after the start of hemodialysis. Unfortunately, these cases of parathyroid cancer in end-stage renal disease do not appear to differ significantly in clinical presentation from patients with benign secondary hyperparathyroidism, so preoperative suspicion is usually limited.[391]

Whereas benign hyperparathyroidism is more common in women by approximately 3 to 1, parathyroid cancer occurs with equal frequency in men and women. The disease also appears to present at a mean age that is 10 years younger than patients with benign hyperparathyroidism.[385]

### Relevant Anatomy

Anatomy in parathyroid disease is essentially that reported in the section on thyroid disease. Koea reports on a large review of the world literature that the left inferior gland is the site of presentation of parathyroid cancer in about half of all reported cases. However, any gland, including those in ectopic positions, may develop carcinoma.[385] This can result in the rare presentation of parathyroid cancer beyond the thyroid bed to the carotid sheath, retropharyngeal tissues, or mediastinum.[385,392]

## NATURAL HISTORY, PATHOLOGY, PATHOGENESIS, AND PATTERNS OF SPREAD

### Pathology

The intraoperative findings that raise suspicion for parathyroid cancer include a gray-white, firm, spherical tumor with a thick capsule adherent to adjacent structures. Most of these cancers weigh between 2 and 10 g. The appearance of these lesions differs from the red-brown, soft characteristic of parathyroid adenomas.[393] Unfortunately, the intraoperative findings are often not suspicious for carcinoma and frozen sections are not particularly reliable for this disease either. In fact, frozen section is contraindicated due to the concern for tumor seeding. In some cases, the diagnosis of cancer may be made only after a recurrence of parathyroid disease.[390] In Koea's review of 358 cases from the literature, approximately half were suspected to be cancer at the time of surgery. Local invasion is the typical feature indicating cancer. The structures invaded are the thyroid (89%), the strap muscles (71%), the recurrent laryngeal nerve (26%), the esophagus (18%), and the trachea (17%).[385]

The pathologic criteria for the diagnosis of parathyroid cancer were established by Schantz and Castlemen. These include the presence of a fibrous capsule, a trabecular or rosette architecture, mitotic figures, and vascular or capsular invasion.[394]

### Pathogenesis

Parathyroid cancers have been associated with alterations in the *CDC73* (also known as *HRPT2*) tumor suppressor gene on chromosome 1 in addition to the alteration of the tumor suppressor genes *RB1* and *BRCA2*. The *CDC73* has been found to exist in hyperparathyroidism-jaw tumor syndrome, with 10% to 15% of these patients developing parathyroid cancer.[395] *HRPT2* is a tumor suppressor gene encoding for the protein parafibromin. This gene has also found to be mutated in cases of apparently sporadic parathyroid carcinoma, so a role in the pathogenesis of some case of parathyroid cancer is suspected. The role of parafibromin in normal and malignant tissues is not yet known. It has been suggested that patients with parathyroid cancer undergo testing for HRPT2 mutations and that familial screening may be considered, if mutations are discovered.[389]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Other genes thought to be significant in parathyroid cancer are the retinoblastoma (RB) gene, and the *BRCA2* gene, both on chromosome 13.[389] The role of the RB protein in parathyroid cancers may be further implicated by the frequency of PRAD1/cyclin D1 overexpression in 91% of parathyroid cancers. The cyclin D1 protein has been shown to inactivate the *RB* gene product.[396]

### Patterns of Spread

A small number of patients will be found to have nodal metastases or distant metastases at presentation, both estimated at 3% by Koea. When left untreated, patients typically succumb to their disease in approximately 14 months.[385]

The typical difficulty in managing parathyroid cancer is in obtaining local control. Koea shows that *en bloc* resection should be favored over parathyroid gland excision. This is in part due to the fact that the mortality after local recurrence is 90%.[385]

## CLINICAL PRESENTATION

The hallmark of parathyroid cancer is a markedly elevated serum calcium level. Most cases of primary hyperparathyroidism are discovered when routine screening shows mildly elevated serum calcium, and patients are often asymptomatic. In contrast, patients with parathyroid cancer will present with serum calcium in the range of 14 mg/dL or more and severe symptoms of hypercalcemia including nephrolithiasis, nephrocalcinosis and impaired renal function in 80% of patients and severe bone involvement in 90%.[397] This high level of calcium leads to symptoms of fatigue, weakness, nausea, anorexia, polydipsia, and polyuria.

Less than 5% of patients with parathyroid cancer will be asymptomatic. Also in contrast to benign hyperparathyroidism, the frequency of a palpable neck mass, renal disease, or bone disease are each estimated to be >35% to 40%.[385] Recurrent laryngeal nerve paralysis is also relatively common. Parathyroid hormone levels are higher in carcinoma than in hyperparathyroidism. Alkaline phosphatase levels are also elevated.[391]

Approximately 2% of all reported cases have been nonfunctional parathyroid cancers. Because these do not cause hypercalcemia, they tend to present later in their course, and this probably explains the worse survival seen in this subgroup.[385]

Because intraoperative suspicion usually is the most critical point in proper diagnosis and treatment of parathyroid cancer, familiarity with the intraoperative appearance of parathyroid cancer is essential. These cancers are firm to rock hard as compared with the typical softer consistency of parathyroid adenomas.[391] As stated previously, these are often gray-white, firm, spherical tumors with a thick capsule adherent to adjacent structures.

When cancer is recognized, the surgeon should proceed to a bilateral neck exploration with examination of all four parathyroid glands to exclude the presence of parathyroid hyperplasia. *En bloc* resection should include the ipsilateral thyroid and adjacent strap muscles. Formal lymphadenectomy is rarely indicated as lymph node involvement is present in <5%.[389]

## DIAGNOSTIC EVALUATION AND CLINICAL STAGING

There is no agreed-upon staging system for parathyroid cancer. This is due in part to the rarity of parathyroid cancer. Another reason why staging is typically not done is that tumor size and lymph node status do not correlate with survival. For these reasons and due to the fact that many cases are not diagnosed preoperatively or even intraoperatively, there is no specific staging workup.[388]

When there is preoperative suspicion, ultrasonographic scanning may be helpful in assessing parathyroid anatomy preoperatively. In addition to demonstrating larger benign parathyroid tissues, ultrasound can identify features that may be indicative of malignancy, such as lymphadenopathy or erosion into adjacent structures. Imaging using sestamibi scanning may demonstrate metastatic disease.[393] Data suggest that 4-D CT scanning may play an increasing role in the localization for benign parathyroid disease and potentially have a role in parathyroid carcinoma.[398] There is no utility in preoperative FNA due to the difficulty in establishing a histologic diagnosis. Another reason to avoid FNA is that this may weaken the parathyroid capsule and make capsule rupture more likely. This raises a risk of seeding into the soft tissues of the neck.

## MANAGEMENT STRATEGIES AND TREATMENT PLANNING GUIDELINES

The ability to predict parathyroid cancer based on preoperative findings is lacking. In a large Swiss series in which nine parathyroid cancers were discovered among 311 patients with primary hyperparathyroidism, the factors associated with parathyroid cancer were high serum calcium, high parathyroid hormone level, and gland weight, but the positive predictive value of any one of these indicators is <20%. This series does seem to support the negative predictive value of parathyroid hormone level less than four times the normal and gland weight <1.9 g. When these two factors are present, the likelihood of parathyroid cancer was zero.[399]

Surgery is the primary treatment modality for parathyroid cancer and suspicion of disease appears to be a major driver in assuring optimal care for these patients. The recommended treatment for parathyroid cancer is *en bloc* resection of the parathyroid gland, the ipsilateral thyroid lobe and strap muscles as well as recurrent laryngeal nerve, trachea, or esophagus if involved.[385] A bilateral exploration is recommended in order to evaluate for parathyroid hyperplasia.[389] Prophylactic lymphadenectomy is not recommended due to the low rate of nodal disease, estimated to be 6% in the SEER data.[388]

If disease is suspected, then *en bloc* surgery should proceed as noted earlier based on clinical appearance. A frozen section or partial resection to obtain a histological diagnosis only risks tumor seeding and is contraindicated.[393] Unfortunately, distinguishing parathyroid cancer from an atypical parathyroid adenoma is difficult at surgery. An atypical parathyroid adenoma may have fibrous bands, trabecular growth pattern, mitoses, and nuclear atypia, but has essentially no chance for recurrence after parathyroidectomy. Parathyroid cancer, on the other hand, has a chance of recurrence >50% even with *en bloc* resection according to one recent report.[400]

During the immediate postoperative period, there is a significant risk of hypocalcemia due to hungry bone syndrome from the hyperparathyroid bone disease, and serum calcium levels should be followed closely. When hungry bone syndrome with hypocalcemia does occur, the treatment with calcium and vitamin D usually needs to be vigorous.[393]

Some patients are found to have carcinoma only on final pathology after parathyroid gland excision. In these circumstances, a prompt return to the operating room for *en bloc* resection is controversial. Those in favor report that this will allow a complete resection of at-risk tissues before postsurgical inflammation affects the surgical bed.[385] Others feel that cancers not apparent at initial surgery do not require reoperation and can be followed clinically. Those with gross residual disease should be operated upon, whereas those with no demonstrable disease can be followed up.[389]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Radiotherapy for bulky disease has not shown effectiveness, although has been reported anecdotally to be effective in controlling microscopic disease in the adjuvant setting. Chemotherapy has been used for unresectable or recurrent disease with dacarbazine appearing to be the single most effective agent.[385]

When metastatic disease can be resected, it probably should be because this is associated with a 5-year survival approaching 25% as compared with no survival in the patients treated nonsurgically. This undoubtedly is a reflection of selection bias as well as extent of metastatic disease.[385]

## OUTCOMES AND RESULTS

In the literature reviewed by Koea, approximately 40% of patients were treated by *en bloc* resection and the remainder by parathyroid gland excision. The difference in outcomes is notable. When treated by parathyroid gland excision, local recurrence occurred in 51% of patients and the mortality in this group was 90%. The cause of death was equally divided between uncontrolled neck disease and distant metastatic disease. When *en bloc* resection was used, the recurrence rate was only 8%. The mortality in those few patients in this group who recurred locally was still 88%, and another 4% of patients died of distant disease. However, at 15 years, Kaplan-Meier survival is estimated at 70% for those undergoing *en bloc* resection and only 20% in those undergoing parathyroid excision. The key appears to be intraoperative suspicion because only those cases suspected to be cancer were subjected to *en bloc* resection.[385] By multivariate analysis, the treatment by simple parathyroid excision, the presence of metastatic lymph nodes, distant metastases, and nonfunctional cancers were all independent predictors of worse survival.[385]

This experience described in the previous literature is quite different from the recent SEER database experience. In that, most patients underwent simple parathyroidectomy (78.6%) with *en bloc* resection in a small minority of cases (12.8%). With this, the 10-year cause-specific survival is excellent at 87.6%. Multivariate analysis revealed that older age, male gender, and distant metastases at diagnosis were associated significantly with a worse overall survival rate. In addition to these factors, cases diagnosed in the early part of the series did worse. This could indicate that the earlier cases presented with more advanced disease, but there was no evidence that earlier cases presented with tumors of greater size.[388] Other data also appear to indicate a high rate of local recurrence in spite of *en bloc* resection. Rates as high as 69% have been reported.[401,402]

## COMPLICATIONS

Surgical complications are similar to the thyroid cancer portion of this chapter. As noted earlier, patients should be followed up for hungry bone syndrome after surgery. Most deaths in this disease are related to the complications of uncontrolled hypercalcemia, and this will be further reviewed in subsequent text.

## MANAGEMENT OF RECURRENCE

Following treatment, serum calcium levels are followed as a tumor marker. If these become elevated, then a search for tumor recurrence is indicated. Recurrence is most commonly a local problem. When tumor recurs at a distant site, the lungs are most commonly involved. Other distant sites are liver and bone.[393] Imaging of recurrent disease may utilize sestamibi scanning. One recent report was able to use an intraoperative gamma probe to successfully resect a tumor recurrence providing long-term palliation,[403] and PET scanning may have a role in the diagnosis of metastatic disease.[404]

When local recurrence or metastatic disease is identified, patients should be evaluated for surgical resection. This is indicated for four reasons: (a) these tumors are relatively slow growing, (b) these tumors rarely cause mortality due to the physical effects of the local or metastatic disease, (c) the tumors are not particularly responsive to radiotherapy or chemotherapy, and (d) the mortality of this cancer is most often related to the effects of severe hypercalcemia.[393] Prolonged survival rates of up to 70% have been shown despite disease recurrence.[389]

When resection is no longer feasible, then the treatment should be directed at lowering the serum calcium.[390] This may involve treatment with bisphosphonates to control both hypercalcemia and bone disease.[390]

Acute hypercalcemia is managed in the standard manner and includes IV hydration, loop diuretics, calcitonin, bisphosphonates, and even calcimimetic agents. The latter (e.g., Cinacalcet) act on calcium receptors on parathyroid cells and increases the sensitivity of these receptors to circulating calcium. This leads to a decrease in parathyroid hormone secretion.[389] Cinacalcet has been shown to be effective in the management of inoperable parathyroid carcinoma and intractable hypercalcemia.[405]

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

Thyroid nodules are detected frequently on physical examination and are found even more commonly on imaging studies of the neck, including computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound, performed for reasons other than evaluation of the thyroid gland. There remains controversy over how to manage these nodules as their initial workup and surveillance poses a considerable economic burden on society, and the vast majority of the lesions will never pose a threat to the patient's life. Ultrasound is the main imaging modality used to evaluate and triage lesions for biopsy and/or follow-up. Recommendations have been made concerning imaging features that suggest a nodule might be biopsied or followed, depending on the clinical scenario.[1–8] If a nodule is >75% cystic, it is probably benign. Nodules <1 cm in diameter are usually not biopsied. A dominant nodule that is >1 cm in diameter and is >25% solid is usually biopsied. Other ultrasound features that suggest malignancy are nodules with central rather than peripheral hypervascularity and nodules with irregular margins. Palpable nodules can be biopsied without image guidance. Ultrasound guided biopsies are performed when the nodule is not palpable (Fig. 28-16). Biopsy is almost always performed with fine-needle aspiration. A 25 or 27 gauge needle should be used as larger needles produce inferior samples with more blood.

New techniques in ultrasound are now being applied to the evaluation of thyroid nodules. Acoustic radiation force impulse imaging is being used to evaluate the elasticity of nodules. Two methods termed Virtual Touch tissue imaging and Virtual Touch tissue quantification (Siemens Medical Solutions, Mountain View, CA) have shown the elastic parameters of malignant nodules to be significantly higher than those of benign nodules.[9] It remains to be determined whether this type of imaging can reduce the need for fine-needle aspiration.

Nuclear medicine imaging studies with radioactive iodine rarely help in the workup of asymptomatic thyroid nodules. They can aid in the determination of which nodules should be biopsied

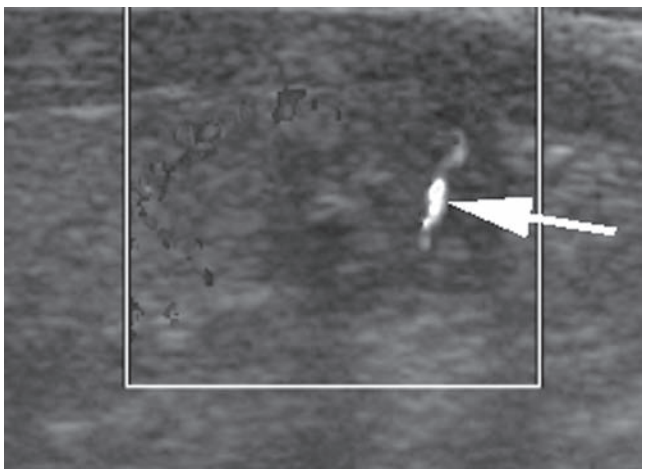

**FIGURE 28-16.** Ultrasound image of a thyroid nodule being biopsied with fine-needle aspiration. The needle is seen in the nodule as an echogenic line (*arrow*).

in the patient with multiple nodules, as cold nodules are three times more likely than other nodules to be cancer. Radioactive iodine studies are used often for follow-up of papillary and follicular cancer, but not all cell lines are or remain iodine avid. Thallium-201 has been used as a general tumor marker for thyroid cancer. Octriotide nuclear scanning is useful for detecting and staging medullary thyroid cancer. FDG-PET is also used for evaluation of recurrent thyroid cancer, usually in the scenario where despite a rising thyroglobulin level, iodine-131 scan does not show activity. These iodine negative metastases are better detected with FDG-PET.[10] FDG-PET is also useful for more aggressive biologically active tumors such as medullary and anaplastic cancers and remains useful for the detection of distant metastases.

Once the diagnosis of thyroid cancer is established, CT or MRI can be used for staging. CT is limited as intravenous iodinated contrast hinders subsequent postoperative tumor ablation or scanning with radioactive iodine for several weeks. MRI is therefore the study of choice. Both modalities can assess extension of tumor outside of the thyroid capsule (Fig. 28-17). The amount of extraglandular extension is important for surgical planning. MRI is best for imaging invasion of the trachea and esophagus. Axial T2-weighted images are especially useful for demonstrating invasion of the esophageal wall (Fig. 28-18). CT may be better at demonstrating invasion of the laryngeal cartilages (Fig. 28-19). Both CT and MRI can document encasement of the carotid artery (Fig. 28-20) or invasion of the jugular vein (Fig. 28-21), as well as involvement of the recurrent laryngeal nerve resulting in hoarseness.

Regional lymph node assessment can be made with CT or MRI, with positive nodes most commonly seen in the low neck. Positive neck nodes are often calcified. In general, if calcified low neck lymph nodes are encountered on CT scan, thyroid cancer should be considered, even if a lesion is not seen within the thyroid gland. Imaging is critical for lymph node staging as level VI, mediastinal, and retropharyngeal lymph nodes cannot be palpated. The presence of positive retropharyngeal lymph nodes is not uncommon (Fig. 28-22).

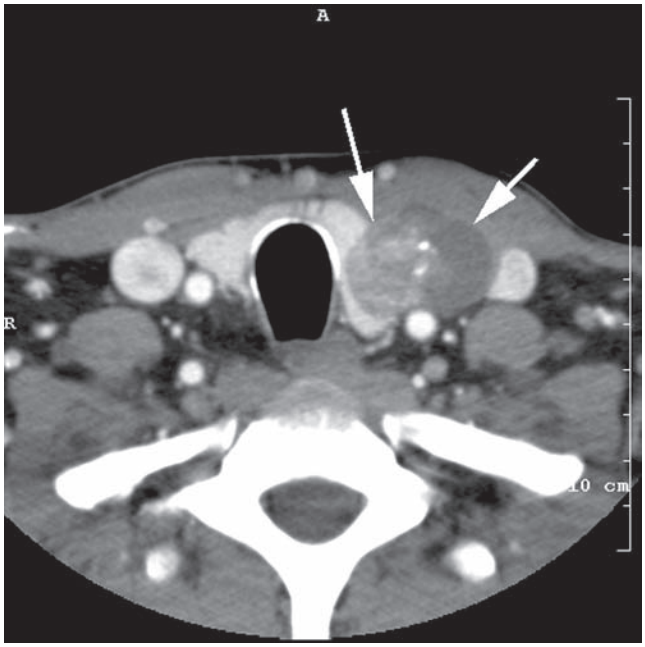

**FIGURE 28-17.** Axial contrast-enhanced CT scan shows a papillary thyroid cancer containing a solid enhancing portion, calcifications, and a more lateral cystic portion. The tumor (*arrows*) has clearly invaded through the thyroid capsule into the surrounding soft tissue.

Posttreatment surveillance imaging for local recurrence can be performed with CT or MRI, but MRI is preferred because it is superior for differentiating tumor from scar. Most follow-up imaging is performed with iodine-131 scans, thallium-201 scans, or

FDG-PET scans. Indium-111 octreotide scans are used to follow-up medullary thyroid cancer.

Parathyroid cancer (Fig. 28-23) is often suspected preoperatively by very high calcium or parathyroid hormone levels, a palpable neck mass, or relatively large or aggressive appearing lesions seen on ultrasound, CT, or MRI, usually in the region of the posterior thyroid. These lesions must be carefully staged with attention to tumor encroaching on the recurrent laryngeal nerve and tracheoesophageal margin.

Radiologists are frequently asked to localize abnormal parathyroid glands in patients with hyperparathyroidism. The recommended first test to locate a parathyroid adenoma is a Tc-99m Sestamibi nuclear medicine scan,[11] although ultrasound in experienced hands is a good alternative. Recent studies have investigated the use of dynamic contrast-enhanced CT scanning[12,13] utilizing the characteristic of early contrast enhancement of parathyroid adenomas for their identification. These studies are typically performed with a power injector

to inject contrast at 3 mL/s, and scans are obtained at 30, 60, and 90 seconds following the initiation of the IV contrast injection. The sensitivity and specificity of CT localization has been reported at 82% and 92%, respectively.[13] A recent study investigated the effectiveness of C-11 methionine PET/CT for parathyroid adenomas.[14] This study reported a sensitivity of 83% for single gland adenomas and 67% for multiglandular disease. However, this technique is more expensive and less available than the alternatives. Suggested protocols are given in Figures 28-24 to 28-27.

# PART C:
# Surgical Technique

James Kenneth Byrd, Samuel L. Oyer, and Eric J. Lentsch

Historically, little change has occurred in thyroid surgery since Theodore Kocher developed the classic techniques of thyroid surgery described below. However, in the last few decades there has been a period of innovation with the advent of "minimally invasive" surgical techniques. Over this time, multiple minimally invasive techniques (including $CO_2$ insufflation, endoscopic without $CO_2$, and video assisted) have been described, and for each technique multiple approaches (including cervical, axillary, postauricular, sublingual, and chest wall) have been followed. Of the many procedures, two techniques have become popular and well-studied—minimally invasive video-assisted thyroidectomy (MIVAT) and transaxillary endoscopic thyroidectomy, with or without robotic assistance.

MIVAT was developed for thyroid nodules, but soon the technique was expanded for use in early thyroid cancer and even central compartment dissections.[1] Multiple groups have reported on the safety and efficacy of the procedure for thyroid nodules,[1,2,3] and the data continue to be compelling for its use in early differentiated thyroid cancer.[4,5] However, the studies on the use of MIVAT for cancer have very short follow-up, and more time is necessary to fully evaluate its efficacy in the cancer setting.

Transaxillary endoscopic thyroidectomy, with or without robotic assistance, is the latest progression in the evolution of thyroid surgery and has taken the "minimally invasive" concept to its extreme by providing for "scarless" thyroid surgery. The best studied example of this is transaxillary endoscopic/robotic thyroidectomy. This technique can be done with standard endoscopic instruments or with the use of the daVinci robot; it has become popular in the past decade in Korea and Japan because it completely avoids a neck incision. When compared with open thyroidectomy, preliminary experiences have shown a comparable rate of complications and surgical completeness with superior cosmesis.[6] However, few studies are available to document the efficacy of this technique for thyroid cancer,[7] and as with MIVAT, they are limited in terms of follow-up.

Therefore, at this time "classical" open thyroid surgery, as described by Kocher, remains the "gold standard" for thyroid cancer. Thyroid lobectomy (or hemi-thyroidectomy) may be an option for early cancers, as has been well demonstrated in the literature. However, at this time most thyroid cancers are treated with total thyroidectomy. Recent evidence has shown that MIVAT appears to provide as complete a removal of diseased tissue as open techniques,[4] however, the follow-up data on patients undergoing this procedure are not mature, and definitive recommendations for its use are difficult to make with certainty. In our opinion, it is a reasonable technique for early-stage differentiated cancers, but the surgeon should be willing to convert to an open technique if complete tumor removal is in any way compromised. Transaxillary endoscopic/robotic thyroidectomy has not been well studied in cancer patients and no recommendations for its use can be made. The following technique descriptions represent the distillation of these techniques and represent the current mainstays in our surgical armamentarium of thyroid surgery.

## CLASSIC THYROIDECTOMY

The classic procedure for thyroidectomy has changed little since Kocher's time. Paramount to the surgery is identification of critical structures in the neck, including the superior and recurrent laryngeal nerves, common carotid artery, superior and inferior thyroid arteries, middle thyroid vein, and parathyroid glands.

The classic thyroidectomy begins with the patient under general anesthesia, positioned supine, with a shoulder roll in place. A horizontal skin incision, preferably placed in a skin crease, is made between the cricoid cartilage and sternal notch. Dissection is taken to the strap muscles, which are separated in the midline to expose the gland (Fig. 28-28A).

The middle thyroid vein is usually encountered first and ligated to provide better exposure (see Fig. 28-28B and C). Next the gland is dissected superiorly, remaining on the thyroid capsule, and the superior thyroid vessels are identified. When taking

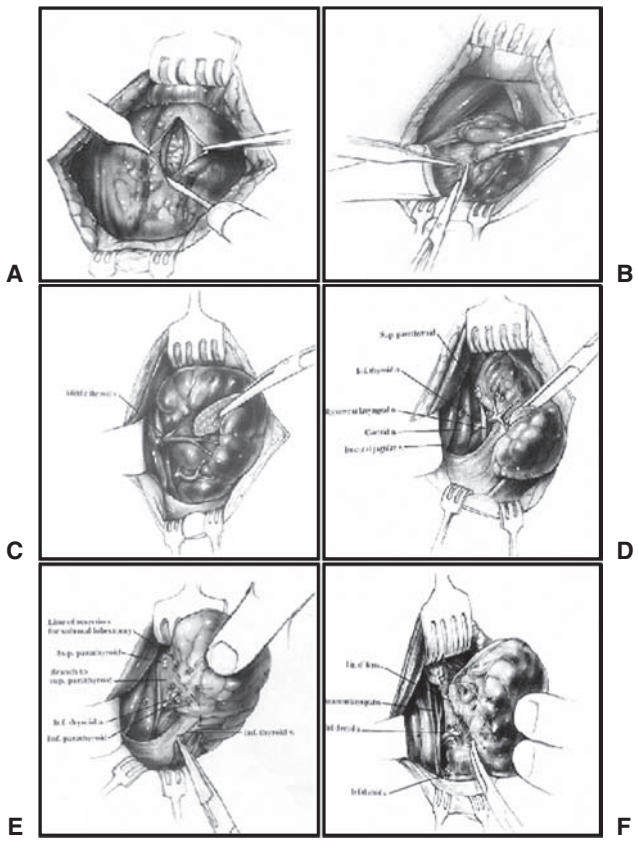

**FIGURE 28-28.** Classical thyroidectomy. **A:** Exposure via the midline raphe; **B:** Initial dissection; **C:** Middle thyroid vein ligation; **D:** Superior pedicle dissection; **E:** Inferior pedicle dissection; **F:** Dissection off of trachea.

(c) 2014 Wolters Kluwer. All Rights Reserved.

down the superior pedicle, individual branches of the artery should be divided on the gland with the superior laryngeal nerve visualized, as the nerve may cross the superior pole of the gland (see Fig. 28-28D). As the gland is dissected inferiorly, a careful observation should reveal the parathyroid glands and the recurrent laryngeal nerve. The inferior thyroid artery is a relatively reliable landmark for the recurrent laryngeal nerve, which crosses deep to the artery in most, but not all, cases. At this point, the inferior thyroid vessels are identified and ligated (see Fig. 28-28E). As the gland is further rotated medially, the gland is dissected free from the recurrent laryngeal nerve. By tracing the nerve to its point of entry into the larynx, the gland can be dissected off Berry ligament, and subsequently off the trachea (see Fig. 28-28F). The pyramidal lobe, if present, is removed at this time. If a lobectomy is to be performed, the isthmus is divided and the procedure ended. If a total thyroidectomy is to be performed, the identical procedure is performed on the opposite side. The wound is closed in multiple layers, with or without a drain.

## LARGE GOITER AND SUBSTERNAL GOITER

Large goiter can be a cause of concern for both the anesthesiologist and the surgeon. Goiter size and bilateral goiter appear to be predictors of difficult intubation[8]; therefore, careful preoperative planning with the anesthesiologist may be required in these cases.

In cases of substernal goiter, standard techniques and gentle upward traction on the gland is usually all that is needed to "deliver" the gland into the neck. Identification and tracing the RLN inferiorly is often necessary to free the gland from surrounding tissues and safely pull the substernal portion superiorly. The need for sternotomy or thoracotomy in substernal goiter is rare. A recent review of the literature, found that extracervical approach was required only 2% of the time.[9] To date, there are no clear-cut indications for sternotomy, and much of the time it is dependent on the surgeon's experience, skill, and comfort level.

## MINIMALLY INVASIVE TECHNIQUES

### Video-assisted Thyroidectomy

In this technique, the room is set up as shown in Figure 28-29. The surgeon may stand on either side of the neck based on preference, with one to two assistants standing on the opposite side. The patient is positioned as for a classical thyroidectomy, except the neck is only slightly extended without the use of a shoulder roll. A 15-to-25-mm horizontal cervical incision is placed in the midline conforming to a preexisting skin crease if possible (Fig. 28-30A). The incision is made and carried down through the skin, dermis, and subcutaneous tissues. Notably, the platysma muscle is typically not encountered because the location and short length of the incision results in a dissection plane between the medial heads of this muscle. The midline raphe is exposed and opened and the thyroid gland is identified (see Fig. 28-30B). The thyroid gland is then mobilized away from the strap muscles, and the middle thyroid vein branches are ligated with the ultrasonic shears. At this point, retractors are placed laterally around the strap muscles, and medially around the thyroid gland itself, to retract the gland up and over the trachea.

At this point, the endoscope is brought into the field. Usually a 5-mm 30-degree laparoscopic telescope is placed just inside the wound, and both the surgeon and the assistant work off the appropriately positioned monitors. The dissection is then carried out, as described above, for a classical thyroidectomy (see Fig. 28-30C–D) until the gland is mobilized and freed from all surrounding structures. The main difference in this portion of the operation is the use of special endoscopic instruments, and the ultrasonic shears are used throughout.

Once the gland has been mobilized, the final removal of the gland is achieved using an open approach. The thyroid isthmus is divided at this point, or alternately it can be done as a last step before retrieving the specimen. The thyroid gland is delivered through the wound and remains attached primarily by the ligament of Berry. At this point, the recurrent laryngeal nerve is traced to its entry in the region of the cricothyroid joint (see Fig. 28-30E). The connective tissue attachments between the gland and the trachea are divided and the specimen is removed (see Fig. 28-30F). If a total thyroidectomy is to be performed, the contralateral gland is removed in similar fashion.

### Transaxillary Endoscopic/Robotic Thyroidectomy

The differences in technique for robotic thyroidectomy are many and are beyond the scope of this chapter. However, of note, the surgeon sits at the robotic control console across the room, with an assistant next to the surgical field to use the suction and apply clips if necessary. Patient positioning is different since the approach is from the axilla and over the chest wall. In addition, the surgeon must get used to approaching the gland from

lateral to the strap muscles, rather than from the midline of the neck. As noted above, the procedure can be done with standard endoscopic instruments or the daVinci Surgical System.

## Surgery for Locally Invasive Disease

Extension of cancer beyond the thyroid gland is associated with a poorer prognosis, higher rates of recurrence, and distant metastases and necessitates extension of surgical resection beyond total thyroidectomy. When extrathyroidal extension occurs, the strap muscles are most commonly involved (53%), followed by the RLN (47%), trachea (37%), esophagus (21%), and larynx (12%).[10] Local invasion is the norm for anaplastic carcinoma, and the role of surgery in this disease is generally limited to confirming a diagnosis with biopsy or establishing a secure airway; therefore, the focus of this section will be on management of local invasion of differentiated and medullary carcinoma. Surgery remains the primary treatment modality for local invasion of these tumors with the goal of complete tumor removal with negative margins. Resection of many of these structures, however, is associated with significant morbidity, and there has been much debate regarding the appropriate extent of resection, particularly for patients with airway invasion.

***Strap Muscle Invasion.*** Local invasion of the strap muscles is the most commonly encountered pattern of invasion, and the surgical management is the most straightforward. The involved muscle including a cuff of normal muscle should be resected along with the primary tumor when possible. There is relatively little morbidity associated with strap muscle resection.

***Recurrent Laryngeal Nerve Invasion.*** Invasion of the RLN is often suspected preoperatively when a patient describes hoarseness or has an immobile vocal cord on exam. The most likely locations of RLN invasion include the entry point into the larynx at the cricothyroid joint and along the course of the inferior thyroid artery,[11] but any portion of the nerve can be involved. In general, RLN preservation should be the goal for any nerve that is functional preoperatively, as long as all grossly visible tumor can be removed. Even when tumor is found to encase or compress the RLN, if a plane of dissection can be established between the tumor and the epineurium, the nerve can be preserved without negatively impacting survival.[12] This is done by identifying the nerve both proximal and distal to the site of involvement and painstakingly dissecting parallel to the course of the nerve until the tumor is freed. RLN function can be affected by either compression or direct neural invasion. In patients with abnormal preoperative vocal cord movement without frank tumor invasion of the RLN, the nerve can be safely preserved with some patients demonstrating return of RLN function once the compression is relieved.[13]

Alternatively, if there is a known vocal cord paralysis with tumor clearly invading the nerve at the time of surgery, there is no benefit to attempting nerve preservation, and the involved segment should be resected. When resection is necessary, it is important to know the functional status of the contralateral RLN, and if the tumor is extensive, it may be wise to explore both nerves before sacrifice to determine if one RLN can be spared to prevent the patient the morbidity of bilateral vocal cord paralysis and tracheostomy-dependent airway. If RLN sacrifice is necessary, the nerve should be resected *en bloc* with the rest of the specimen, including proximal and distal margins to determine the completeness of resection. It is possible to perform vocal rehabilitation procedures at the time of nerve sacrifice, and authors have reported improved outcomes with simultaneous type I thyroplasty and arytenoid adduction procedures compared with delayed intervention.[14] Alternatively, others advocate for concomitant neurorrhaphy at the time of RLN sacrifice. Generally, there is not sufficient length of the remaining nerve to accomplish a tension-free primary neurorrhaphy, but return of neural function measured by voice analysis, laryngoscopy, and EMG has been demonstrated following RLN repair with nerve grafting in conjunction with nimodipine therapy.[15] Nerve grafting is accomplished first by harvesting an appropriate donor nerve (e.g., great auricular, sural, etc.) of adequate length to bridge the resulting defect without tension. Next, under loupe or microscopic magnification, neurroraphy is carried out on both ends of nerve graft with three to four interrupted 9-0 or 10-0 permanent sutures placed in the epineurium.

***Pharyngoesophageal Invasion.*** Fortunately, the mucosa of the pharynx and esophagus represents a relatively resistant barrier to cancer spread, and true intraluminal invasion is rare. When pharyngoesophageal involvement is evident, the invaded muscle should be resected along with the primary tumor. Often it is possible to separate the tumor from the pharyngeal submucosa without violation of the mucosa, and in such cases, no further repair is required. Small mucosal tears that occur during dissection should be repaired primarily. When mucosal invasion is present, the involved mucosa and surrounding muscular layers require resection, and repair should be carried out in a layered fashion with reinforcement from a vascularized muscular flap like a portion of the sternocleidomastoid. Larger defects that cannot be closed primarily may require reconstruction with larger regional flaps or free tissue transfer in a manner similar to management of pharyngeal defects created for squamous cell carcinoma of the pharynx.

***Laryngotracheal Invasion.*** Much debate surrounds the appropriate extent of resection for tumors that invade the airway, and this is largely related to varying definitions of tumor invasion and surgical technique. McCaffrey has developed a useful staging system for extent of thyroid cancer invasion where stage I disease represents an intrathyroidal tumor, stage II describes a tumor that invades the perichondrium without cartilage invasion, stage III represents a tumor that has invaded into cartilage without submucosal extension, stage IV is for submucosal involvement, and stage V describes transmucosal spread.[16] Stage I disease is treated with total thyroidectomy alone, whereas stages II and III require partial thickness resection of the involved airway segment, and stages IV and V necessitate complete through-and-through resection of the airway.

Partial thickness airway resection is commonly known as a "shave resection" in which all grossly visible tumor is removed without violating the luminal mucosal surface. Studies have demonstrated that both shave excisions and complete resection offer superior survival to incomplete resection, and the removal of all grossly apparent tumor is paramount.[17] For these cases, a thyroidectomy is carried out as described with mobilization of the gland off the airway, wherever there is a clear plane of dissection. The site and extent of airway invasion is identified and the depth of invasion determined. Bronchoscopy may be necessary to evaluate for intraluminal or submucosal involvement, and in cases where circumferential resection is planned, rigid bronchoscopy is required to delineate the superior and inferior margins of extent. If superficial invasion only is present, the perichondrium may be gently freed off the underlying cartilage. When the tumor has invaded beyond the perichondrium, however, at least a partial thickness resection of the underlying cartilage is necessary. For stages II and III disease, the involved portion of cartilage can gently be dissected off the underlying submucosal layer leaving the airway mucosa and submucosa intact. A defect of one or more tracheal rings involving <30% the airway circumference with intact mucosa is known as "window resection," and reconstruction can involve primary repair if sufficient laxity exists, or

(c) 2014 Wolters Kluwer. All Rights Reserved.

reinforcement with a rotational flap such as a myoperiostial sternocleidomastoid flap.[18] An anterior window defect can occasionally be used for a tracheostomy with eventual decannulation and spontaneous healing.

The most common location for tracheal invasion is along small perforating tracheal vessels that pass between tracheal rings providing a direct route for tumor spread into the airway.[19] Airway invasion can also occur through the cricothyroid membrane, thyroid, or cricoid cartilage, or posterolateral to the thyroid cartilage into the paraglottic space and pyriform sinus. Stages IV and V lesions or those that involve >30% to 50% of the circumference of the trachea or cricoid cartilage require circumferential airway resection. This is carried out in the standard fashion limiting circumferential dissection only to the portion of the airway that will be resected to avoid devascularizing surrounding segments of airway. At least one RLN should be preserved if possible, and primary anastomosis is generally achievable following adequate mobilization of the remaining airway segments. The importance of negative margins cannot be overemphasized as tumor recurrence can lead to anastomotic breakdown. Generally, patients remain intubated for a few days following the procedure with the tube cuff distal to the anastomosis, or a temporary tracheostomy may be required.

Direct laryngeal invasion through the thyroid cartilage or paraglottic space may require a partial laryngectomy, and a vertical hemilaryngectomy is generally sufficient. Rarely, a total laryngectomy may be needed for bilateral involvement with a dysfunctional larynx or extensive subglottic extension. This is most frequently encountered in recurrent disease or extension from metastatic paratracheal lymph nodes.

Symptoms such as hoarseness and hemoptysis are clues to advanced local invasion of thyroid cancer, and ideally the extent of tumor invasion is identified preoperatively so both the surgeon and patient can prepare for the appropriate aggressiveness of resection and related operative morbidities. Occasionally, local tumor invasion is only identified intraoperatively at which point the surgeon must be prepared to perform the necessary resection or abort the procedure. Adjuvant therapy such as radioactive iodine or external beam radiation may play a role in control of microscopic disease, but should not be expected to treat grossly residual tumor. Therefore, the surgeon undertaking an operation on advanced thyroid cancer should be knowledgeable and trained in various surgical techniques required to adequately resect and reconstruct invasion of the surrounding structures to provide optimal patient outcomes.

## Neck Dissection

Lymphatic metastases are common in thyroid cancer, particularly among the papillary and medullary subtypes. Although nodal spread has been shown to decrease survival in medullary carcinoma, the impact in papillary carcinoma is less clear cut, especially among younger patients. Therefore, indications for lymph node dissection in thyroid cancer are controversial with much debate in the literature. Current guidelines for differentiated thyroid cancer from the American Thyroid Association recommend therapeutic central-compartment lymph node dissection when clinically involved central or lateral neck nodes are present and consideration of a prophylactic central-compartment dissection for patients with advanced primary tumors.[20] However, a recent meta-analysis[21] including 16 studies and >3,500 patients found no difference in locoregional recurrence between patients treated with thyroidectomy plus central neck dissection versus thyroidectomy alone; this trend persisted even for the subgroup of patients who underwent a central neck dissection for therapeutic removal of positive nodes. A prophylactic central neck dissection is recommended for patients with medullary thyroid cancer, regardless of nodal involvement.[22]

The first echelon of lymphatic drainage for the thyroid gland is the central compartment or level VI. This consists of the lymphatic structures bounded by the carotid arteries laterally, the innominate artery inferiorly, and the hyoid bone superiorly. Generally, this accounts for 5 to 10 lymph nodes, including the prelaryngeal (Delphian) and pretracheal nodes, as well as paratracheal nodes bilaterally along the tracheoesophageal groove. When performing a thyroidectomy for cancer, the central compartment lymph nodes should be inspected intraoperatively, and a central neck dissection performed if the nodes appear involved. A unilateral central neck dissection consists of removing the prelaryngeal and pretracheal nodes along with the paratracheal nodes on the same side of the tumor, while a bilateral dissection involves removing all lymph nodes from the central compartment.

Dissection begins by skeletonizing the boundaries of the central compartment described above. If the nodes are matted with tumor and contiguous with the primary cancer, they should be removed along with the thyroid gland; otherwise, the neck dissection can be performed once the thyroid is removed to improve visualization. The pretracheal and prelaryngeal nodes with any intervening lymphatic vessels are dissected off the airway leaving the perichondrium intact, unless there is evidence of direct invasion. Next, the RLN is identified and isolated atraumatically throughout its course to allow for thorough dissection of the entire paratracheal gutter from the level of the cricoid cartilage to the plane of the innominate artery intersection with the trachea. Care should be taken to preserve the parathyroid glands along with their vascular supply by separating the feeding vessels as distally as possible and retracting the parathyroids laterally on their respective vascular pedicle. Often the inferior parathyroid glands are more difficult to dissect freely during a level VI dissection, and any glands that appear devascularized should be autotransplanted and marked with a clip to minimize potential hypocalcemia. Rates of hypocalcemia and RLN injury are higher following central neck dissection compared with standard thyroidectomy due to the more extensive dissection of the tracheoesophageal groove.

Occasionally, retropharyngeal nodes are a site of tumor metastasis or direction extension and require dissection. This is accomplished by following the visceral facial layer that invests the thyroid gland and airway posteriorly and reflecting the aerodigestive tract laterally. Dissection is continued bluntly around the posterior aspect of the pharynx until the retropharyngeal space is exposed between the buccopharyngeal fascia overlying the pharynx and the alar fascia. The involved lymph nodes are then removed. The prevertebral tissues should be inspected for involvement when retropharyngeal dissection is necessary, but fortunately prevertebral spread is rare in thyroid cancer.

Following spread to the central compartment, tumor metastases tend to reach the lateral neck in predictable patterns based on the course of the thyroid vasculature. Tumors of the superior lobe often metastasize to the upper jugular lymph nodes of levels II and III along the course of the superior thyroid artery. The inferior thyroid artery courses posterior to the carotid after it branches off the thyrocervical trunk and can be a route of spread to the inferior neck levels IV and V. Spread to level I is exceedingly rare, and level V involvement is uncommon in isolation, but skip metastases to the lateral neck can occur without obvious central neck involvement.[23] The type of neck dissection performed is dictated by the extent of disease as most are therapeutic dissections to eradicate clinically positive nodes. Generally, at least a selective dissection of all involved levels is preferred to a “berry plucking” procedure, but level I dissections are almost never required, and the jugular vein, sternocleidomastoid, and accessory nerve can usually be preserved. The dissection can be performed through an extension of the thryoidectomy incision using standard techniques described elsewhere in this

(c) 2014 Wolters Kluwer. All Rights Reserved.

text. If disease is present in the lower neck levels IV to Vb, it is important to evaluate for tumor located posterior to the carotid artery along the course of the inferior thyroid artery. Dissection in this area should proceed cautiously to avoid damage to the sympathetic chain, thoracic duct, and brachial plexus.

## Parathyroid Surgery

Unlike thyroid cancer, parathyroid cancer is often not suspected prior to definitive surgery. Therefore, surgery for parathyroid cancer is often done without preparation, when the diagnosis is made intraoperatively during a parathyroidectomy. A high level of suspicion, as well as good pathological analysis, is necessary to make the diagnosis. Intraoperatively, parathyroid cancers may be distinguished from adenomas by their firm, stony-hard consistency and lobulation. They also tend to be a grayish-white color and infiltrate adjacent tissues. Parathyroid adenomas, on the other hand, tend to be soft, round, or oval in shape, and of a reddish-brown color. Parathyroid cancers also tend to be larger, mostly >3 cm, whereas most benign adenomas are 1 to 2 cm in size. Histopathologically, capsular and vascular invasions appear to be the most significant markers of malignancy.[24]

Surgery is the only known curative therapy for parathyroid carcinoma. Due to the rarity of the disease, few data exist to guide our surgical decision making; however, it is clear that standard parathyroidectomy is not sufficient treatment for most parathyroid cancers, as local recurrences are approximately 50%.[25] Instead, definitive surgery involves *en bloc* resection of the tumor with all potential areas of invasion. This usually includes the strap muscles and the ipsilateral thyroid (sometimes total) and may involve resection of the recurrent laryngeal, thyroid cartilage, constrictor muscles, trachea, or esophagus. Cervical lymph node dissection should be reserved for those patients with enlarged or firm nodes, particularly those found in level VI and levels III and IV.

CHAPTER 29

# Soft Tissue and Bone Sarcomas of the Head and Neck

## PART A:
## General Principles and Management

Brian O'Sullivan, Abha Gupta, and Patrick Gullane

### INTRODUCTION

Sarcomas are rare malignancies of mesodermal origin. The annual incidence is <10,000 per year in North America. Fifteen percent of cases occur in the head and neck region comprising <1% of all head and neck cancers. Not only are they rare, but also an excess of 40 histopathologic subtypes may affect numerous anatomic sites within the head and neck. Unique challenges present themselves in the head and neck demanding special expertise in nutritional support, dental and voice rehabilitation, ophthalmology, and social support.[1] The rarity and complex nature of these tumors warrant referral to specialized centers for multidisciplinary evaluation, including expert imaging and pathology assessment.[2] All such consultations and evaluations should take place prior to therapy. A recent report evaluated outcome in 4,205 operative cases of soft tissue sarcomas (STS) and showed that high volume centers (those in the upper one-third of case volume in a geographic region) had better survival outcomes in numerous sites, including the head and neck, which comprised 12% of the cases studied.[3] Smaller centers may have more difficulty formulating a multidisciplinary team with all necessary components of care, including access to an effective multidisciplinary cancer conference that meets frequently and regularly. This is especially so for head and neck sarcoma management where the case volume is low. It may be preferable to have linkage with the main sarcoma team at the center so that treatment protocols and pathology expertise are maintained as consistently as possible. We have found the latter approach to be essential in our practice even though both the overall sarcoma referral and the head and neck program are of substantial size.

The management of head and neck sarcoma follows principles extrapolated from other anatomic sites where the disease is more common.[4,5] Although primary data about the head and neck would be desirable, evidence that the biologic behavior differs by anatomic site is not apparent. What sets these lesions apart from tumors elsewhere are the unique functional and cosmetic imperatives of the treatment.[1] Thus, both surgery and radiotherapy must be applied more precisely and with greater complexity than elsewhere in the body because of the presence of critical anatomy. In particular, juxtaposed neurologic tissues (especially optic apparatus, spinal cord, and brain stem), nonexpendable vascular anatomy, organs necessary for speech and swallowing, and cosmetically sensitive tissues provide substantial challenges.

The chapter provides general information for both soft tissue tumors and their osseous counterparts relying on individual center experience, outcome reports from several registries, and reports of meta-analyses and clinical trials where these are available. Management focuses on the principles of curative approach initially for the more common STS, followed by bone tumors. The discussion of adjuvant systemic treatments will rely for the most part on published meta-analyses for soft tissue sarcoma and the meta-analysis (overviews) that have been undertaken in head and neck osteosarcoma. Special features in the head and neck including treatment or behavior of unique histologic subtypes are also acknowledged. The general problem of salvage for recurrence and the treatment of metastases (soft tissue and bone) will conclude the discussion.

### PATHOLOGY AND GRADING

Soft tissue and bone sarcoma may present in a nondescript manner related to the presence of a mass, since the full range of histologic subtypes seen in other body sites can present in the head and neck. However, there are also several rare clinical entities that are disproportionately represented in the head and neck but space limitations prevents a comprehensive discussion. A summary of some of the main issues to be considered in evaluating and classifying these lesions is presented. A brief description of particular clinical features different histologic subtypes is also presented later.

(c) 2014 Wolters Kluwer. All Rights Reserved.

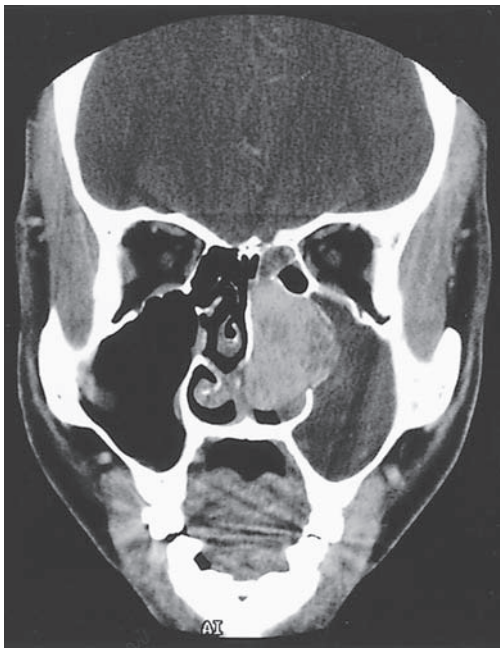
## Classification of STS Subtypes

The most common classification scheme for soft tissue sarcoma is based on histogenesis, as outlined in the World Health Organization (WHO) classification (Table 29.1).[6] The classification is reproducible for the better differentiated tumors. However, as the degree of histologic differentiation declines, the determination of cellular origin becomes increasingly difficult. In the head and neck, as elsewhere in the body, the prototypical STS has been the malignant fibrous histiocytoma (MFH) but additional unique predispositions include nonpleomorphic rhabdomyosarcoma, angiosarcoma of the scalp and facial regions, hemangiopericytoma of the sinonasal region (Fig. 29-1), and dermatofibrosarcoma protuberans of the dermal regions of the low neck and supraclavicular regions. Recently, advances in molecular genetic pathology are influencing the classification, diagnosis, and treatment of soft tissue tumors of the head and neck.[7–9] Molecular biologic techniques are becoming the preferred means of understanding the pathogenesis and behavior of sarcomas, and the specific chromosomal aberrations found in certain types of sarcoma can be exploited for diagnosis. Already a number of cytogenetic findings and corresponding genetic abnormalities characterize a number of the histologic subtypes (Table 29.2). For example, in synovial sarcoma, the t(X;18) translocation can almost invariably be detected with the demonstration of a fusion between the *SSX* and *SYT* genes providing a very useful diagnostic tool that is also associated with the two morphologic forms of this disease (the *SSX1* associated with monophasic histology and the *SSX2* gene with biphasic histology) (Fig. 29-2). The specific molecular subtypes of the SYT-SSX fusion transcripts have also been associated with prognostic discrimination,[10] although this evidence has recently been overshadowed by observations that morphologically determined tumor grade may override this.[11]

Nonpleomorphic rhabdomyosarcoma, most often of alveolar histology, can be defined by the presence of PAX3 or PAX7 translocation, partnered with FOXO1, which is much more sensitive at defining the biologic behavior than histology alone.

Since the late 1970s, MFH has borne the mantle of most common STS of middle and late adulthood and is therefore mentioned specifically though it has no particular predilection for head and neck and there is now doubt about its status as a specific entity. Originally described in the 1960s, the term MFH was used to describe a group of sarcomas considered to have a mixed histiocytic and fibroblastic lineage. However, it is now regarded as a heterogeneous group of tumors without a specific line of differentiation. Reclassification of many tumors in this group seems to afford better prognostication and the old term "MFH" is generally considered obsolete today.[12] Current nomenclature recognizes the entities undifferentiated high-grade pleomorphic sarcoma (previously storiform-pleomorphic "MFH") and myxofibrosarcoma (formerly myxoid "MFH").

**TABLE 29.1 Principal Histologic Types of Soft Tissue Sarcoma in the World Health Organization (WHO) Classification of Bone Tumors with International Classification of Diseases for Oncology (ICD-O) Morphology Rubrics Listed in Alphabetic Order**



| Histologic Type | ICD-O Morphology |
|---|---|
| Alveolar soft part sarcoma | 9,581/3 |
| Angiosarcoma | 9,120/3 |
| Clear cell sarcoma | 9,044/3 |
| Dermatofibrosarcoma protuberans | 8,832/3 |
| Epithelioid sarcoma | 8,804/3 |
| Extraskeletal chondrosarcoma | 9,220/3 |
| Extraskeletal osteosarcoma | 9,180/3 |
| Fibrosarcoma | 8,810/3 |
| Leiomyosarcoma | 8,890/3 |
| Liposarcoma | 8,850/3 |
| Malignant fibrous histiocytoma | 8,830/3 |
| Malignant hemangiopericytoma | 9,150/3 |
| Malignant mesenchymoma | 8,990/3 |
| Malignant peripheral nerve sheath tumor | 9,540/3 |
| Malignant Schwannoma, melanotic | 9,560/3 |
| Rhabdomyosarcoma | 8,900/3 |
| Synovial sarcoma | 9,040/3 |
| Sarcoma NOS (not otherwise specified) | 8,800/3 |

| Synovial sarcoma | t(X;18)(p11.2;q11.2) | *SYT/SSX1 or SSX2* |

## Grading STS

One of the most durable prognostic factors for the risk of distant metastasis and tumor-specific mortality in STS is histologic grade whose effect is so pronounced that it is included in the staging classification. Although a number of grading systems have been used in the management of soft tissue sarcoma, the three-tier system proposed by the French Federation of Cancer Centres is precisely defined, easy to use, and most widely employed. The French system relies on a relatively balanced evaluation of

**A** **B**

**FIGURE 29-2.** **A:** Coronal projection of computed tomography (CT) of an 18-year-old patient with synovial sarcoma arising from the left temporomandibular joint region. There is a large heterogeneously enhancing soft tissue mass causing distortion of the facial contour. Remodeling of bone is apparent as well as spiculated periosteal reaction and calcification. The diagnosis was established by the characteristic molecular gene fusion and translocation seen in synovial sarcoma (see text). **B:** T1 sequence postgadolinium magnetic resonance image (MRI) in coronal plane of the patient in **A**. The expansile mass is again apparent with heterogeneous features centered along the mandibular ramus and involving the temporalis muscle into the suprazygomatic masticator space.

(c) 2014 Wolters Kluwer. All Rights Reserved.

parameters (differentiation score, mitoses, necrosis), but its greatest limitation lies in the assignment of a differentiation score.[13] Roughly defined as the extent to which a lesion resembles normal tissue, differentiation score has little applicability for tumors which ostensibly have no normal tissue counterpart.

It is also recognized that no system performs perfectly in all sarcomas. In a recent review, Deyrup and Weiss highlighted problems including the fact that some STS do not lend themselves well to grading. These include (a) those in which grade provides no additional information (e.g., well-differentiated liposarcoma/atypical lipomatous neoplasm); (b) "ungradable" histologic subtypes (e.g., epithelioid sarcoma, clear cell sarcoma, angiosarcoma); and (c) sarcomas that have traditionally been graded but where this characteristic does not appear to differentiate these lesions prognostically (e.g., malignant peripheral nerve sheath tumor [MPNST]).[13]

## CLASSIFICATION OF SELECTED BONE SUBTYPES

In contrast to STS, primary malignant tumors of bone are predominantly confined to two histologic types: osteosarcoma and chondrosarcoma. Other histologies including primitive neuroectodermal tumor/Ewing sarcoma are much less frequent in the head and neck although a wide variety of histologic subtypes may be found[14] (Table 29.3).

### Osteosarcoma

Osteosarcoma is a primary malignancy of osteoblastic tissue and is discriminated from all other tumors, including chondrosarcoma, by the direct formation of bone or osteoid tissue by its tumor cells. It covers a wide spectrum of lesions with distinct clinical and pathologic features. The malignant component comprises an undifferentiated stroma characterized by dense cellularity, pleomorphism, and cytologically atypical osteoblasts. Although the tumor is derived from osteoblasts and the malignant cells can be shown to contain intracytoplasmic alkaline phosphatase, it usually exhibits a mixed picture containing fibroblastic, osteoblastic, and chondroblastic areas, based on the predominant characteristic of the stroma. Tumor osteoid may be seen copiously with numerous pleomorphic tumor osteoblasts.

Smith et al. reported the largest series, that of the National Cancer Data Base (NCDB), for patients diagnosed with osteosarcoma of the head and neck from 1985 to 1996.[15] Accounting for about 5% to 10% of all osteosarcomas, they most usually affect individuals in the fourth decade of life of equal gender. The mandible (40%) and maxilla are the most frequent bones involved, although other skull bones may be affected.[15] In general, it is perceived that they often comprise low-grade lesions, different from their high-grade counterparts found in the long bones, have a lower potential for metastatic spread compared with other sites, and thus patients with these tumor may not necessarily benefit from neoadjuvant or adjuvant chemotherapy.

### Chondrosarcoma

Chondrosarcoma constitutes approximately 10% of malignancies of bone and is the second most common sarcoma of bone after osteosarcoma. Like osteosarcoma, the largest series ($n = 400$) of chondrosarcoma of the head and neck was also reported from the National Cancer Data Base (NCDB) for the years 1985 to 1995.[16] This comprised 0.1% of head and neck cancers during the same period and makes up 1% to 12% of chondrosarcoma in various reports.[16] The hallmark of chondrosarcoma is its origin from tumor cells that form chondroid (cartilage) as opposed to osteoid. In addition, most (60%) arose from osseous tissue grouped as "head and neck bones" and "sinonasal," the latter including 8% originating in the mandible. Almost one-quarter

**TABLE 29.3 Principal Histologic Types of Bone Sarcoma Selected from the Second Edition (1993) World Health Organization (WHO) Classification of Bone Tumors**

| Histologic Type | ICD-O Morphology |
|---|---|
| **Bone-forming tumors** | |
| Conventional central osteosarcoma | 9,180/3 |
| Telangiectatic osteosarcoma | 9,183/3 |
| Intraosseous well-differentiated (low-grade) osteosarcoma | 9,180/31 |

arose from the laryngotracheal cartilages.[16] While a rare site for chondrosarcoma, the cricoid lamina of the larynx is a unique tumor of generally indolent behavior.

Mesenchymal chondrosarcoma is seen in the skull as well as the bones of the trunk. This highly malignant tumor is composed of primitive mesenchymal cells focally differentiating in cartilage. The lesion is usually osteolytic with poorly defined limits and permeates cortex into soft tissues. A biphasic appearance is usual with two histologic patterns comprising sheets of dense small round or oval undifferentiated cells resembling Ewing sarcoma or lymphoma, alternating with a second pattern of easily identified cartilaginous tissue. Chondroid islands may appear quite abruptly among the undifferentiated cells that mimic early chondrogenesis, although more gradual transitions are also seen. Mitoses are frequent.

## Ewing Sarcoma

Ewing sarcoma also amounts to about 10% of bone tumors but is exceptionally rare in the head and neck comprising 1% to 9% of all Ewing sarcoma.[17] A cooperative Ewing sarcoma study of 301 cases recruited only 6 lesions affecting skull bones (2%) and 3 (1%) in the clavicles.[18] The true cell of origin remains elusive, although it appears to arise from pluripotent mesenchymal tissue although a neuroectodermal origin is suspected.[19,20] The histologic features are characterized by a structureless array of small hyperchromatic cells as one of the group of "small round blue cell" tumors. The diagnosis is established by additional measures beyond conventional light microscopy. For example, the majority of Ewing sarcomas (at least 80%) exhibit the specific translocation t(11;22)(q24;q12) between the *EWS* gene on chromosome 22 and the *FLI1* gene on chromosome 11. Alternate partners within the E-twenty-six (ETS) family are also present. Regardless of site, the treatment of all Ewing sarcoma mandates multiagent chemotherapy, in addition to local therapy, to reduce the likelihood of distant recurrent disease.

## Grading Bone Sarcomas

As with STS, the grading of bone tumors provides an important prognostic measure and has been incorporated in the tumor, lymph node, metastasis (TNM) staging system discussed below.[21]

Osteosarcomas are graded according to the cell type and relative anaplasia of the stromal component of the tumor. Low-grade lesions (grade 1) may resemble parosteal osteosarcoma or fibrous dysplasia. Increasingly anaplastic tumors are given higher grades with the least well-differentiated tumors representing the highest grade. High-grade tumors (grade 3 or 4) generally comprise conventional (osteoblastic), telangiectatic, and dedifferentiated tumors. Chondroblastic and fibroblastic tumors are usually lower grade (grade 1 or 2).

The gross and microscopic appearance of chondrosarcoma varies according to the grade and anatomical site, which itself is often associated with grade. For chondrosarcoma, well-differentiated appearance (grade 1) is associated with longevity and favorable prognosis. For example, as mentioned earlier, tumors of the cricoid cartilage are invariably low grade as determined by cellularity, nuclear features, and mitotic activity. Metastasis is almost never seen and dedifferentiation to high-grade sarcoma is quite exceptional. In the NCDB report, progression to distant metastases was three times more likely to occur among higher-grade cases than the lower-grade cases. Overall, most cases in the NCDB series were grade 1 (50%) and grade 2 (37%) whereas only a minority were grades 3 and 4.[16] Low-grade (well-differentiated) chondrosarcomas may also be difficult to discriminate histologically from benign cartilaginous lesions because they have the consistency of hyaline cartilage. Although most chondrosarcomas have a clearly dominant grade, multiple foci of different grade may be present and there is controversy about whether grading should only consider the highest grade identified within a tumor or be the predominant grade.[16] Myxomatous changes with cystic degeneration in the tumor correlates well with a low or medium histologic grade though it is important not to confuse myxoid change in common chondrosarcoma with the myxoid chondrosarcoma variant.[16] An absence of cartilaginous lobulation and the presence of spindle cell forms is characteristic of high-grade (grade 3) malignancy and heralds an unfavorable prognosis.

Of importance, Ewing sarcoma is always classified as high grade (and grade IV in the AJCC TNM classification).

# ETIOLOGY AND SCREENING

## Etiology

Apart from the diagnostic dilemma in distinguishing additional neurofibromata from metastatic lesions in patients with neurofibromatosis, the precise etiology of an individual sarcoma is of little clinical significance because it does not affect therapeutic decision making beyond the obvious fact that patients who have sarcomas arising in a previously irradiated field usually cannot receive further external-beam radiotherapy (EBRT). In fact, most sarcomas of the head and neck or elsewhere are without obvious cause. Of known factors, an induced STS and osteosarcoma is a long-term hazard of either iatrogenic or accidental exposure to radiation. Frequently, such tumors arise in the low-dose areas at the edge of prior radiation target volumes. Sarcomas have also been reported after chemotherapy, especially for pediatric cancers, such as acute lymphatic leukemia. The relative risk appears to increase with cumulative exposure to alkylating agents. Chemical exposure (usually occupational) is also linked to sarcoma causation being most recognized with thorotrast (x-ray technicians), vinyl chloride gas (plastics industry), phenoxy acetic acids (agricultural and forestry workers), chlorophenols (sawmill workers), and arsenic (vineyard work).

Association of rhabdomyosarcoma with genitourinary or central nervous system anomalies have been noted, as well as links to a variety of genetic conditions.[22] Multiple factors are implicated in the etiology of angiosarcoma. Although the usual patient with a head and neck angiosarcoma will not manifest these, the disease is typically seen in the scalp and face of an elderly white male. In addition to prior radiation exposure, chronic infection or solar exposure have been implicated, as well as vinyl chloride, thorotrast, insecticides, and steroid exposure. There is up to a 10% cumulative lifetime risk of developing sarcoma (usually malignant peripheral nerve sheath tumor) in patients with type 1 neurofibromatosis, an autosomal dominant disease with dysfunction of the *NF1* gene on chromosome 17q11.2.[23] The *NF1* gene product (neurofibromin) appears to be a tumor suppressor gene acting through GTPase activity with mutations leading to dysfunction and uncontrolled signaling via *ras* pathways. This may facilitate the development of malignant peripheral nerve sheath tumor.

Osteosarcoma (OS) has a number of risk factors. Exposure to radiation was noted earlier, but trauma and thorotrast exposure have also been described. OS may develop secondarily to underlying Paget disease, fibrous dysplasia, multiple osteochondromatosis, chronic osteomyelitis, and myositis ossificans. Retinoblastoma survivors provide a specific example of a dysfunctional or deleted tumor suppressor genetic element (in this case, the product of the *Rb* gene on chromosome 13q14) rendering these patients and their families at risk of soft tissue sarcoma, osteosarcoma (with or without radiotherapy) and several other malignancies including breast cancer. Alterations in *p53* germlines are also associated with the high predisposition of families

(c) 2014 Wolters Kluwer. All Rights Reserved.

with Li-Fraumeni syndrome for the development of osteosarcoma, again with or without radiotherapy.[24]

The etiology of chondrosarcoma remains obscure although various physical and chemical agents may be implicated. Speculation concerning undetermined dietary or environmental factors was prompted by the observation of a disproportionate incidence in low-income patients, although the mesenchymal subtype was more common among higher income groups.[16] Chondrosarcoma (especially in the skull base) may complicate Maffucci syndrome, a congenital nonhereditary condition associating multiple cutaneous hemangiomas, dyschondroplasia, and often enchondromas (see Fig. 29-12B).[25]

## Screening for Sarcomas

Predisposing genetic tendencies and environmental exposures associated with sarcoma development should be borne in mind when assessing patients. Genetic counseling would be appropriate to discuss issues relating to the genetic predispositions. However, no general screening is indicated beyond routine health care surveillance because of the rarity of sarcoma, with the rare exception of families suspected of carrying germline *p53* abnormalities associated with Li-Fraumeni syndrome.[26] A more detailed clinical evaluation in certain subjects is reasonable and with a lower threshold of intervention than one might use for general health care. For example, rapidly growing and/or symptomatic masses in patients with neurofibromatosis merit resection because of potential malignant transformation within a neurofibroma. Similarly painful and dramatic deformity in Paget disease should be viewed with concern about underlying osteosarcoma. Superficial or deep abnormalities of skin or soft tissues in patients with a history of prior radiation therapy should also be regarded with suspicion, given the known increased risk of sarcoma.

# CLINICAL PRESENTATION, EVALUATION, STAGE CLASSIFICATIONS

## Local Presentation

Sarcomas of the head and neck present in multiple ways depending on the numerous potential anatomic sites where disruption of function and contour may result. Local management starts with imaging and physical examination to determine whether soft tissue lesions originate superficial or deep to the investing fascia at the local site and whether bone tumors are intramedullary or have invaded into the extraosseous compartment. Evidence of bone, vascular, or neural invasion (uncommon) should be excluded.

Lesions may originate in the upper aerodigestive tract, paranasal sinus, and skull base with symptoms referable to these areas (e.g., nasal symptoms including obstruction or discharge and ocular proptosis from direct invasion in paranasal sinus tumors; cranial nerve abnormalities in lesions arising in the skull base or masticator space; alteration of voice or airway compromise for laryngeal and hypopharyngeal lesion lesions). Tumors originating in the subcutaneous tissues of the face, neck, or scalp can initially present with a superficial mass.

Both bone and cartilage tumors often present with pain in addition to symptoms of mass and compression. Pain generally relates to infiltration and expansion of bone. In lower-grade lesions, pain can be of long duration and characterized as a prolonged aching sensation, sometimes present for several years. Most often, they present as a slow growing mass or with looseness of dentition. Because of the potential to also arise in the skull base and paranasal sinuses, a wide variety of symptoms are also possible, depending on tumor site. These include cranial neuropathy and visual disturbance (including ophthalmoplegia and proptosis) in addition to pain, the latter being evident in about half the cases.

## Metastatic Manifestations

Most sarcomas present with localized disease and metastases are present in only 10% of cases at the time of diagnosis. Generally, the patient is asymptomatic and staging investigations (computed tomography [CT] chest) are needed to demonstrate the metastatic process as the predominant risk is to the lungs. Regional lymph node involvement is unusual but is represented most frequently in certain histologic subtypes, most notably rhabdomyosarcoma, epithelioid, alveolar soft part, clear cell, and synovial sarcomas. Rarely, remote bone marrow metastases are apparent but are seen almost exclusively in rhabdomyosarcoma with associated lymphadenopathy. In osteosarcoma, bone metastases may be present in the absence of lung involvement but this is exceptional.

## Evaluation

***Initial Assessment.*** Successful outcome starts with reliance on basic principles and understanding the behavior of the disease and the necessary steps to be undertaken. The overall management of head and neck soft tissue sarcoma is summarized in the treatment algorithm (Fig. 29-3). Before embarking on treatment, histologic confirmation of the diagnosis is necessary. All soft tissue masses deep to the investing fascia should be considered to be sarcoma until proven otherwise. The same vigilance is needed for bone lesions but here the opinion of an experienced diagnostic radiologist is required. Both bone and soft tissue lesions should be staged with cross-sectional imaging before the biopsy to avoid compromising the planning of appropriate management.

***Establishing the Diagnosis.*** Fine-needle aspiration biopsy (FNAB) is useful for establishing the presence of recurrence (both local and metastatic). However, its use as a primary diagnostic tool is controversial and should only be used where a cytopathologist with extensive experience in sarcoma is available. Core-needle biopsy under local anesthesia provides a more consistent tissue specimen and cell preparation compared with fine-needle aspiration. In our experience, open biopsy of soft tissue sarcoma is rarely indicated but yields a diagnosis when needle biopsy is unsuccessful (about 10% of cases).

Interventional radiologists are often requested to biopsy deep-seated lesions using ultrasound or CT guidance. An atraumatic biopsy close to critical structures or where the lesion is difficult to palpate can be accomplished. The radiologist should collaborate with the oncologists who will resect or irradiate the lesion. Needle tracts are potential sites of tumor contamination and the surgeon and radiation oncologist should be involved in planning the optimal biopsy route and be aware of potential contamination.

***Imaging Local Disease.*** Both CT scan and magnetic resonance imaging (MRI) are used widely. CT provides better bony detail than MRI, but MRI provides multiplanar images without losing specificity and is likely the best instrument for tumor definition with optimal tissue contrast. Therefore, in those situation where it is important to visualize the matrix of a lesion, CT is preferred. This usually occurs in flat bones including the calvarium. Plain radiography is also useful for bony lesions but has largely been replaced by CT. Both have the advantage of exhibiting calcification in tumor which may be characteristic of certain histologies (e.g., chondrosarcoma and synovial sarcoma). Malignant bone lesions will frequently present with marked permeative bone destruction, ill-defined transition to normal bone, aggressive periosteal reaction,

(c) 2014 Wolters Kluwer. All Rights Reserved.

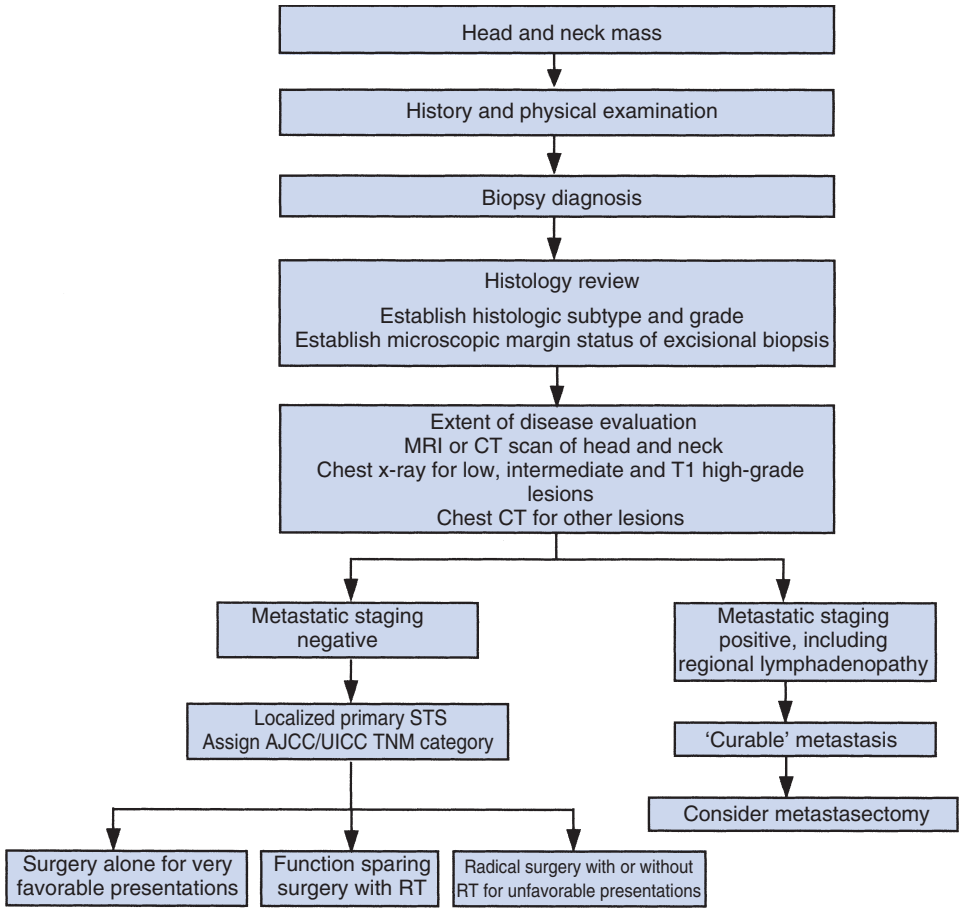

**FIGURE 29-3.** Flow schema for the assessment and management of soft tissue sarcoma (STS) of the head and neck. Because of the heterogeneity of tumor and anatomical sites, individualization is also needed. Thus some diseases, such as rhabdomyosarcoma, may need additional investigations (e.g., bone marrow examination)—see text for details of management. MRI, magnetic resonance imaging; CT, computed tomography; AJCC, American Joint Committee for Cancer; UICC, International Union Against Cancer; TNM, tumor, node, metastasis; RT, radiation therapy.

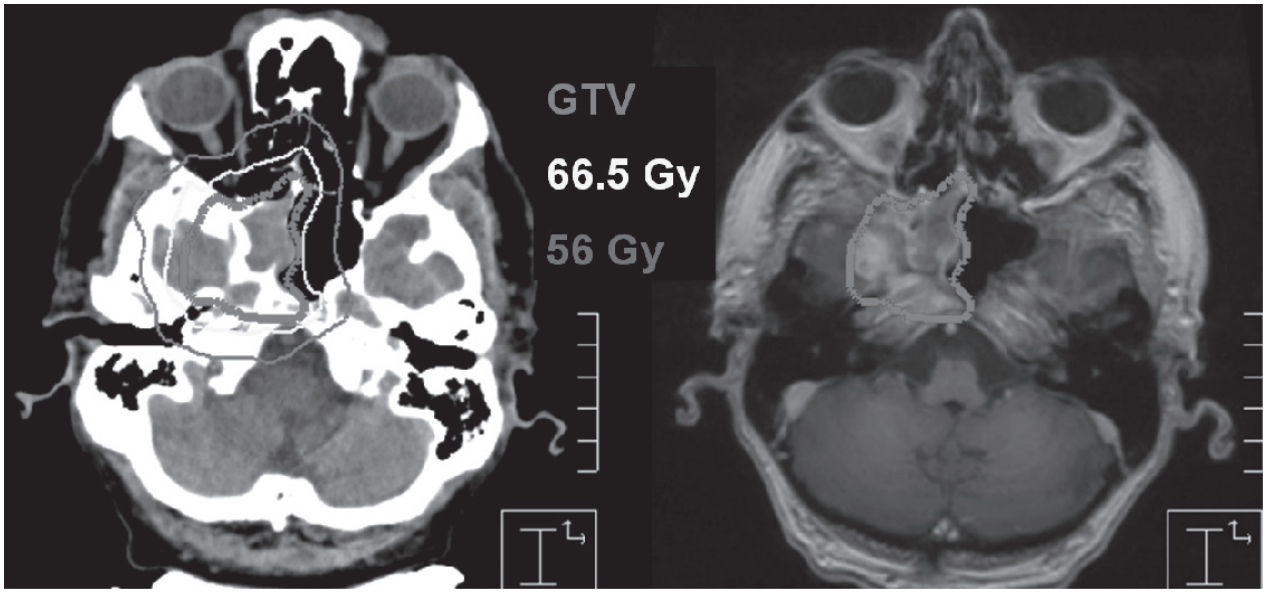
and an accompanying soft tissue mass. In the end, it is our impression that MRI generally provides superior depiction of intra- and extraosseous tumor in most malignant tumors of bone. Axial imaging complemented by either coronal or sagittal imaging planes using T1- and T2-weighted SPIN echo sequences most often provides accurate depiction of intra- and extraosseous tumor. To improve conspicuity, these sequences could be augmented by fat-suppressed pulse sequences. The maximum dimension of the tumor must be measured prior to any treatment.

In soft tissue sarcoma, low signal intensity on T1-weighted images and a high signal on T2-weighted images are the usual appearances and can be readily separated from normal soft tissue structures. Again lesion size should be recorded.

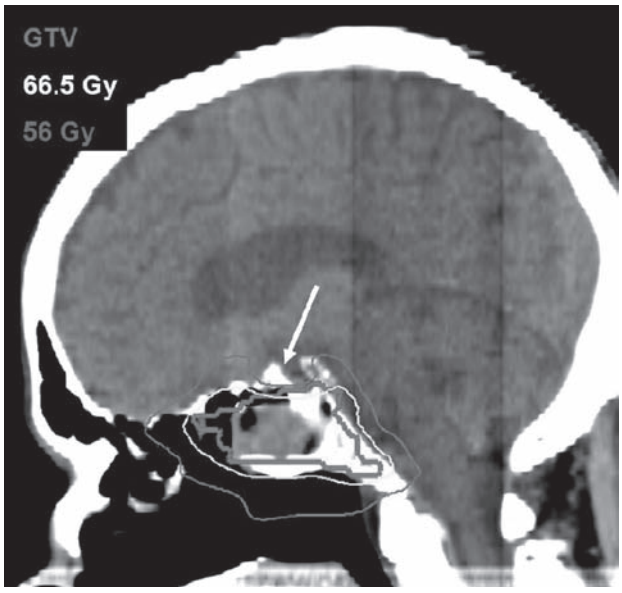
Although the diagnostic evaluation may be equally served by CT or MRI, the treatment-planning requirements (e.g., for both surgery and radiotherapy) frequently require additional information provided by the multiplanar capability of MRI and provides additional advantages through MRI/CT image-fusion techniques for radiotherapy treatment planning (Fig. 29-4).

Radionuclide bone scanning is a sensitive indicator of osteoblastic activity but lacks specificity. It can demonstrate multiple lesions but may also overestimate the extent of intramedullary infiltration when compared with MRI scanning.



Positron emission tomography (PET) uses radiotracers specific to biologic processes to produce images of regional tissue metabolism with fluorodeoxyglucose, the most commonly employed radiotracer for this purpose. However, the contribution of PET imaging to routine management is currently uncertain. New tracers are being evaluated that may refine the differing roles for PET imaging that include evaluation of (a) the grade and extent of local disease including the potential for "skip" lesions in adjacent bone and (b) the response to initial (i.e., neoadjuvant) treatment as a surrogate to prognosticate on future outcome. It does seem that high- versus low-grade lesions may be distinguished and may even provide an imaging technique for biopsy guidance; in addition, response prediction to induction treatments seems to be possible.[27–30]

***Evaluation of Metastasis.*** For metastatic staging, CT of the chest is required, excepting very low-grade lesions where a plain chest radiograph is sufficient. If the underlying diagnosis is rhabdomyosarcoma, a bone scan and bone marrow biopsy is also necessary. Angiography is only rarely required in the evaluation of sarcomas. PET scan is also not widely used but may have applicability in identifying unusual sites of metastases in high-risk subsets (e.g., recurrent high-grade tumors).[31] Technetium scintigraphy is the examination of choice for evaluating the entire skeleton to determine whether there are multiple lesions and is particularly important for diseases with high propensity for bone metastasis such as Ewing sarcoma. Occasionally, intrapulmonary osteoblastic metastases may be demonstrated.



## Staging Classifications

Both soft tissue and bone sarcomas are classified according to the TNM stage classification (7th edition).[21] The classification has provided the possibility of combining a number of relevant factors including those addressing behavior (by means of inclusion

D

**FIGURE 29-4.** *Continued*

of grade) and anatomic factors.[32] However, a major limitation of the staging system is that it does not take into account the anatomic and histologic heterogeneity of these lesions. The system is also optimally designed to stage extremity tumors and is also applicable to the head and neck although lacks subtlety since the T-category size criterion dwarfs the anatomic sites of origin in the head and neck, which tend to be much smaller. An additional issue concerns rhabdomyosarcoma, where two separate descriptions of disease extent exist.

### *Soft Tissue Sarcoma*

*"Ordinary" Soft Tissue Sarcoma.* The relative rarity of STS, the anatomic heterogeneity of these lesions, and the presence of >30 recognized histologic subtypes of variable grade have made it difficult to establish a functional system that can accurately stage all forms of this disease. The American Joint Committee on Cancer (AJCC) TNM (7th edition) staging system[21] is the most widely employed staging system for STS and is unusual within the overall TNM classification system in that, like the bone classification, it incorporates histologic grade with anatomical disease characteristics. The soft tissue classification employs a three-tiered grading system based largely on the wish to incorporate the French system.[21] In general, the classification is based on an ascending hierarchy of risk depending on whether a lesion is deemed to have no adverse features for relapse or one, two, or three factors present represented by size partitioned at the 5-cm break point, grade (three-tiered system), and lesion depth as "a" (superficial tumor arising outside the investing fascia) or "b" (a deep tumor that arises beneath the fascia or invades the fascia) (Table 29.4).

*Rhabdomyosarcoma.* For nonpleomorphic rhabdomyosarcoma (RMS), the description of disease extent has traditionally been by a postoperative surgical classification developed by the North American Intergroup Rhabdomyosarcoma Study Group (IRSG) more than two decades ago (Table 29.5). This is not always relevant in the head and neck as such lesions will frequently be treated with aggressive chemoradiotherapy protocols (Fig. 29-5). Indeed, most lesions would be unresectable and thus classified as group III at diagnosis. They are most often parameningeal in location, considered an "unfavorable" site by the IRSG system, and thus labeled as stage 3. The International Society of Pediatric Oncology (SIOP) has suggested a TNM presurgical staging system more in keeping with contemporary TNM staging for soft tissue sarcoma including a T-category breakpoint at 5 cm (Table 29.6).[33] This process of staging prior to treatment is also being introduced in North America.[22] Regardless

**TABLE 29.4 American Joint Committee on Cancer (AJCC) TNM Classification (7th Edition) of Soft Tissue Sarcomas**

**Primary tumor (T)**

| | |
|---|---|
| TX | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| T1 | Tumor 5 cm or less in greatest dimension |
| | T1a, superficial tumor |
| | T2b, deep tumor |
| T2 | Tumor >5 cm in greatest dimension |
| | T2a, superficial tumor |
| | T2b, deep tumor |

*Note:* Superficial tumor is located exclusively above the superficial fascia without invasion of the fascia; deep tumor is located either exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia.

**Regional lymph nodes (N)**

| | |
|---|---|
| NX | Regional lymph nodes cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Regional lymph node metastasis |

*Note:* Presence of positive nodes (N1) in M0 tumors is considered Stage III.

**Distant metastasis (M)**

| | |
|---|---|
| MX | Distant metastasis cannot be assessed |
| M0 | No distant metastasis |
| MI | Distant metastasis |

**TABLE 29.5 Intergroup Rhabdomyosarcoma Study Group Postsurgical Grouping Classification**

**Group 1:** Localized disease, completely excised and no residual microscopic disease

A. Confined to the site of origin, completely resected
B. Infiltrating beyond site of origin, completely resected

**Group 2:** Total gross resection

A. Gross resection with evidence of microscopic local residual disease
B. Regional disease with involved lymph nodes, completely resected with no microscopic residual disease
C. Microscopic local and/or nodal residual disease

**Group 3:** Incomplete resection or biopsy with gross residual disease

**Group 4:** Distant metastases

of the classification used, adequate imaging of regional lymph nodes is imperative in patients in RMS.

***Bone Sarcoma.*** The AJCC TNM classification of bone tumors (Table 29.7) considers maximum lesion size (with a break point at 8 cm) and the presence discontinuous tumors in the same bone without other distant metastasis. Of interest, metastasis to nonpulmonary sits are distinguished from M1 disease based on lung involvement alone. The staging system is applicable to all primary malignant tumors of bone except multiple myeloma, malignant lymphoma (both having different natural history), and juxtacortical osteosarcoma and chondrosarcoma (both with much more favorable prognosis).[21]

## TREATMENT OF SOFT TISSUE SARCOMA

The benchmark for local control rates for extremity sarcomas rests at approximately 90% in modern series, and the overall 5-year survival of patients with STS can be expected to be in the range of 60%,[34] although this will vary as a function of prognostic factors from case to case. Unfortunately, series of head and neck sarcoma have usually not achieved these high local control rates. Mendenhall et al.[35] recently performed a systematic literature review and showed that the local control rate after surgery alone or combined with radiotherapy is approximately 60% to 70%. The probability of local control is influenced by histologic grade, tumor size, and surgical margins. Patients with high-grade tumors and/or positive margins have improved local control if adjuvant radiotherapy is used. Distant metastases manifest in about 10% to 30% of patients, figures that are somewhat lower than extremity lesions and is probably explained by the smaller size of lesion in the head and neck that presents earlier due to proximity to critical functional and cosmetic anatomy. The 5-year overall and cause-specific survival rates ranges from 60% to 70% and seems to be influenced by age, histologic grade, previous treatment of tumor, invasion of deep structures, and adequacy of surgery. The disappointing results in head and neck STS has been attributed to the traditional

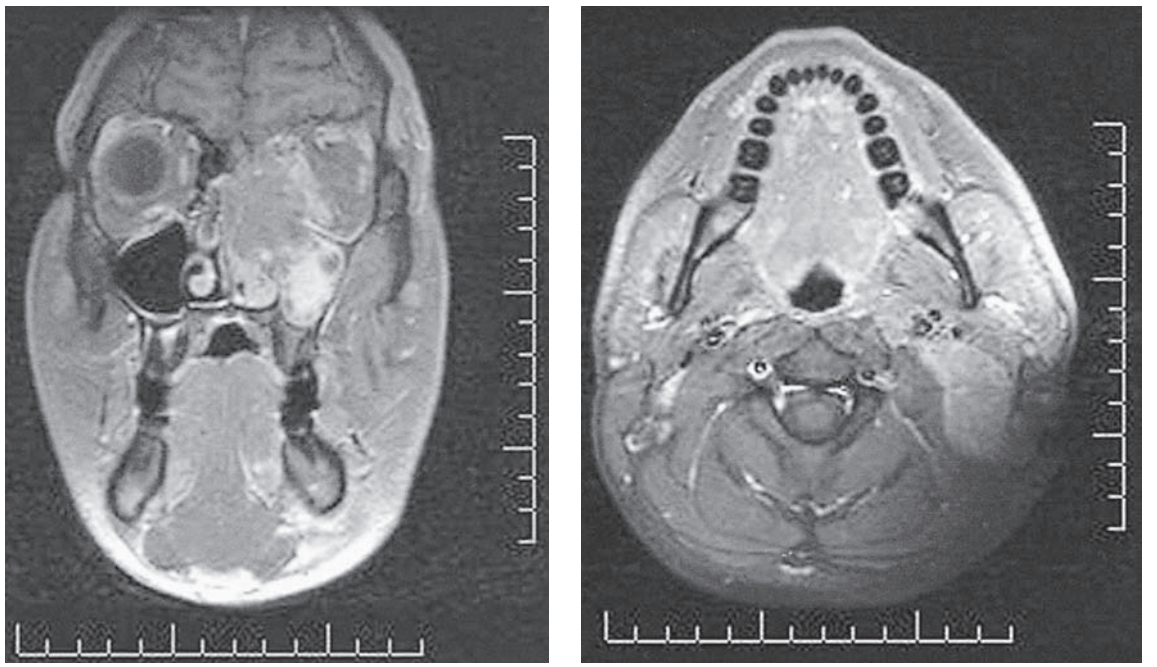

**FIGURE 29-5.** Magnetic resonance image of an alveolar rhabdomyosarcoma of the ethmoid sinus in a young adult. **A:** coronal view showing extensive orbital invasion; **B:** axial view showing concurrent extensive regional lymphadenopathy; **C:** complete response following combination chemotherapy with cyclophosphamide, actinomycin-D, vincristine (CAV), and etoposide with ifosfamide. Although consolidation radiotherapy commonly achieves local-regional control in these responsive tumors, such patients are at extremely high risk of failure in bone marrow, lung, and leptomeningeal sites.

C

**FIGURE 29-5.** *Continued*

inability to deliver aggressive treatments because of their location in the critical anatomy of the head and neck. It may also relate to problems in delivering care for these rare diseases, if undertaken in the absence of a full multidisciplinary team. However, properly deployed principles and approaches should be able to achieve results in the head and neck that are comparable to similar lesions in extremity sites. Several randomized controlled trials have collectively established important milestones in the evolution of the local management of STS. With one exception, these trials have focused on extremity lesions and around the themes of surgery and adjuvant radiotherapy. These results are also highly relevant to the head and neck because of the similarity of biologic behavior of STS across body sites, even if the different histologic subtypes are not equally distributed by site.

**TABLE 29.6 International Society of Pediatric Oncology (SIOP) Presurgical Staging Classification (Clinical and Radiologic Staging)**

| Stage | Tumor | Node | Metastases |
|---|---|---|---|
| I | T1a or T1b | N0, Nx | $M_0$ |
| II | T2a or T2b | N0, Nx | $M_0$ |
| III | Ant T | N1 | $M_0$ |
| IV | Any T | Any N | $M_1$ |

T1, Confined to the anatomic site of origin; T2, Extension and/or fixation to surrounding tissue; (a), ≤5 centimeters in diameter; (b), >5 centimeters in diameter; Nx, Unknown nodal status; N0, No nodes present clinically; N1, Regional nodes present; Mo, No distal metastasis; Mo, Metastasis present.

**TABLE 29.7 American Joint Committee on Cancer (AJCC) TNM Classification (7th Edition) of Bone Sarcomas**

**Primary tumor (T)**

| | |
|---|---|
| TX | Primary tumor cannot be assessed |
| T0 | No evidence of primary tumor |
| T1 | Tumor (maximum dimension) ≤8 cm at time of diagnosis |
| T2 | Tumor (maximum dimension) >8 cm at time of diagnosis |
| T3 | Skip metastases-two discontinuous tumors in the same bone with no other distant metastases |

**Regional lymph nodes (N)**

| | |
|---|---|
| NX | Regional lymph nodes cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Regional lymph node metastasis to be considered equivalent to distant metastatic disease (see $M_{1b}$ below) |

*Note:* Because of the rarity of lymph node involvement in sarcomas, the designation NX may not be appropriate and could be considered N0 if no clinical involvement is evident.

**Distant Metastasis (M)**

MX = Distant metastasis cannot be assessed

M0 = No distant metastasis

M1 = Distant metastasis

M1a = Lung-only metastases

M1b = All other distant metastases including lymph nodes

**Stage Grouping**

| | | | | |
|---|---|---|---|---|
| Stage IA | G1,2 | T1 | N0 | M0 |
| Stage IB | G1,2 | T2 | N0 | M0 |
| | G1,2 | T3 | N0 | M0 |
| Stage IIA | G3,4 | T1 | N0 | M0 |
| Stage IIB | G3,4 | T2 | N0 | M0 |
| Stage III | G3,4 | T3 | N0 | M0 |
| Stage IVA | Any G | Any T | N0 | M1a |
| Stage IVB | Any G | Any T | N0/N1 | M1b |

## Surgery

***Major Ablation Versus Conservation Management.*** In the 1970s, it became apparent that RT in combination with surgery could achieve equivalent results to more ablative surgery in STS. This observation was confirmed in a trial that randomized high-grade sarcoma of the extremities to receive amputation versus a limb-sparing operation followed by adjuvant RT.[36] The result of this trial, combined with numerous institutional reports, heralded a new era in STS management.

***Extent of Surgery and Characterization of Margins.*** An important component of contemporary management is the value of imaging in demonstrating the radial extent of sarcoma within the compartment or site of origin and, together with radiotherapy, permits conservation of much of the surrounding soft tissue without increased local failure. Of more importance than the description of the type of surgery is the actual extent of viable residual disease remaining after surgery. This variable (the amount of residual viable disease remaining in the wound following resection) can never be known exactly, but is probably best represented by expert pathologic assessment of the surgical margin. Characterization of the margin guides the need for adjuvant RT for those tumors with insufficient normal tissue at the surface to reliably prevent local recurrence. Patients with positive margins of resection have inferior local control in STS and this prevails in the head and neck to the same degree as in other sites.[37]

The cause of positive margins is rarely discussed. The policy in STS surgery should be to achieve negative surgical margins, and this is best achieved by performing surgery at an experienced referral center. More recently, we have also shown, in a blinded study using a prospective data base, that a small isolated positive resection margin, planned from the outset by the multidisciplinary team with the intention of sparing a critical anatomic structure (e.g., at a major nerve, vessel, or bone), has a favorable outcome provided radiotherapy is administered (local recurrence 3.6%, 95% CI, 0–10.4) compared with an "unplanned excision" margin-positive situation (local recurrence 31.6%, 95% CI, 10.7–52.5).[38] Substantial contamination with tumor seeding in a hypoxic environment may mean that subsequent radiotherapy is less capable of eliminating tumor seeding in the "unplanned excision" circumstance.

***Evidence for Using Surgery Alone.*** Although the evidence is compelling that major ablation is avoidable in most cases, it is also helpful to consider whether adjuvant radiotherapy is needed to achieve conservation management, in comparison with surgery alone. This issue is complicated by case heterogeneity but a subgroup of patients undoubtedly do not need RT based on several sources of evidence, although none reported in the head and neck specifically. These rely on single-institutional experience with practices involving degrees of selection including subcutaneous or intramuscular presentation, or extramuscular lesions with favorable resection margin status. However, most deep sarcomas in all sites are referred with lesions significantly expanding out of a single muscle unit or have undergone biopsy prior to referral and therefore need radiotherapy combined with surgery. The approach is less applicable in the head and neck because the proximity to critical anatomy makes it less likely to achieve sufficient clearance to have confidence that surgery alone would eradicate disease, and there remains the added concern that local failure in head and neck STS confers extremely adverse outcome. The latter includes mortality directly from progressive local disease,[39] a phenomenon not relevant to extremity lesions.

## Radiotherapy

***Adjuvant Radiotherapy.*** Adjuvant RT with conservative surgical resection has been evaluated in two randomized clinical trials.[40,41] Yang et al. at the National Cancer Institute (NCI) randomized high-grade extremity lesions following limb-sparing surgery to receive adjuvant RT or no further treatment following the surgery. Chemotherapy was also used depending on grade. The local control for those receiving RT was 99% compared with 70% in the control group ($p = 0.0001$).[41] The results were similar for high- and low-grade tumors. Adjuvant RT, using brachytherapy (BRT), was also evaluated in a second randomized trial at Memorial Sloan-Kettering Cancer Center with a similar effect in high-grade lesions.[40] Of interest, no improvement in local control was evident in the low-grade tumors, potentially related to slowly cycling cells not entering the radiosensitive phases of the cycle during the short BRT-dwell time.[40]

For head and neck STS, relatively high rates of local relapse in different treatment settings have historically been reported by numerous institutions, as compared with extremity STS and surgical excision is often constrained by anatomical considerations. The probability of local control is influenced by histologic grade, tumor size, and surgical margins and appears to be improved by adjuvant radiotherapy.[35] However, if the principles used in other sites are applied in the head and neck, where tissue preservation is paramount, the results should be similar. Advantages to a combined modality approach are evident in a series where local control was 52% in those treated with surgery alone versus 90% in those treated with combined radiotherapy and surgery.[42] Additional evidence from our institution indicates that head and neck STS patients with clear surgical margins or microscopic residuum had similar local control rates (26% and 30% failure, respectively), provided radiotherapy was administered (Fig. 29-6).[39]

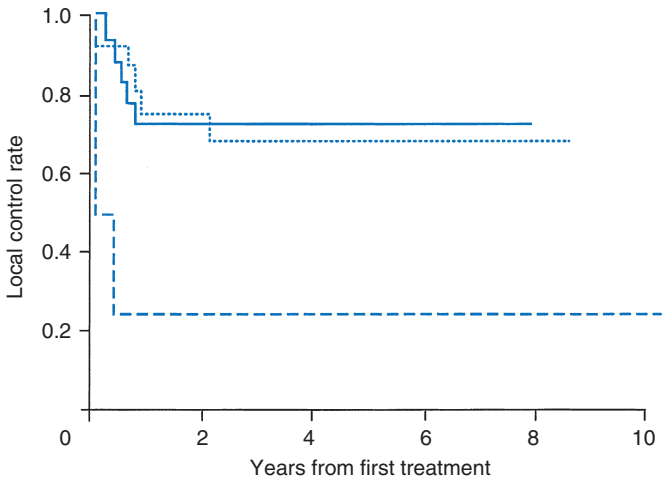

**FIGURE 29-6.** Actuarial estimate of local control rate in soft tissue sarcoma of the head and neck by surgical margins. Histopathologically clear (*solid line*), microscopically positive (*dotted line*), and gross disease (*dashed*) line are shown for patients treated with curative intent following surgical resection.

*Source:* Data reproduced with permission from Le Vay J, O'Sullivan B, Catton C, et al. An assessment of prognostic factors in soft-tissue sarcoma of the head and neck. *Arch Otolaryngol Head Neck Surg.* 1994;120:981–986.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Indeed these outcomes for radiotherapy following R0/R1 resections approach those achieved in extremity sarcoma. Finally, a prospective series of high-risk cases has been treated on a consistent combined modality protocol with preoperative radiotherapy.[43] The results are comparable to extremity sarcoma of similar histology and are certainly superior to our historical series.[39,43]

***Timing of Radiotherapy (Preoperative vs. Postoperative Radiotherapy).*** Preoperative RT promotes collaboration between the surgical and radiation oncologist and facilitates a complete management plan to be fashioned prior to any surgical intervention. Preoperative RT is also delivered to an undisturbed and potentially better oxygenated tumor site and permits administration of lower dosages and smaller fields of radiation without compromising local control. These observations were confirmed in our randomized trial comparing preoperative and postoperative radiotherapy in extremity soft tissue sarcoma. Local control was equivalent in both groups (93%).[44] Others have suggested that preoperative RT has advantages in certain situations especially for gross disease at referral and large tumors. However, preoperative RT is often delivered on a partially representative biopsy and may interfere with future histopathologic analysis. Additional concerns about pre-op RT include the increased risk of wound complications in some anatomic sites, but not at all in others.[44] Flaps are also commonly used in the reconstruction, and wound-healing problems do not occur with the frequency evident with preoperative radiotherapy in extremity lesion.[43] In fact, in the combined modality approach to head and neck STS, preoperative radiotherapy is particularly suited because of the smaller RT volumes and lower doses to critical anatomy in difficult surgical access locations, especially in the base of skull (Fig. 29-7). At present, our guidelines for using preoperative radiotherapy are (a) the need to maximally restrict RT volumes in some anatomic sites (e.g., head and neck), (b) the desire to minimize RT dose in some situations (e.g., where critical neurologic tissues are in close proximity), and (c) the desire to not irradiate new tissues, especially vascular reconstructions vulnerable to the effects of high-dose postoperative RT.

***Radiotherapy Alone in Soft Tissue Sarcoma.*** Historically, patients treated with radiotherapy alone for gross disease do not achieve the same outcome although approximately 25% are controlled (see Fig. 29-6),[39] with similar observations by Tran et al.[42] At the same time, this may be the only option of management in selected adverse presentations in the head and neck where surgical management is not feasible (see Fig. 29-4). Recently, Kepka et al. updated a historical series of patients with tumors in any anatomic site at the Massachusetts General Hospital ($n$ = 112) who underwent radiotherapy for gross disease. Local control at 5 years was 51%, 45%, and 9% for tumors <5 cm, 5 to 10 cm, and >10 cm, respectively. Patients who received doses of <63 Gy had inferior 5-year outcomes compared with those receiving higher doses including local control: 22% versus 60%; disease-free survival: 10% versus 36%; and overall survival rates: 14% versus 52%.[45] Kepka et al. also noted a rise in complications at doses of 68 Gy or more, which appears to provide a therapeutic window. It is possible that the outcomes of these problematic cases may be improved by more precise delivery methods, such as intensity-modulated radiation therapy (IMRT) (see Fig. 29-4) or particle beam with protons or carbon ion, thereby permitting higher doses without the same danger to normal tissue.[45,46] Chemotherapy may further enhance local control based on evidence from some of the randomized trials (see "Influence of chemotherapy on local control" below). A recent report also appeared to suggest a better outcome following radiochemotherapy with ifosfamide compared with radiotherapy alone or radiotherapy combined with other radiosensitizers in localized unresectable soft tissue sarcoma.[47]

**FIGURE 29-7.** Leiomyosarcoma of the skull base with optic nerve compression. Such patients are preferentially managed at the authors' center with preoperative radiotherapy to limit not only the volume of radiotherapy but also the dose that is administered because of the constraints imposed by the presence of critical adjacent anatomy (i.e., the optic chiasm). In addition, chemotherapy may be added in an additional attempt to enhance local control.[53] This patient was managed in this fashion although the orbit required exenteration primarily but the optic chiasm and opposite optic nerve and eye were protected and the patient remains disease free with 7-year follow-up.

One exception to the almost universal need for combined surgery and radiotherapy in STS is in the treatment of rhabdomyosarcoma, where control with radiotherapy alone with chemotherapy is an expected result because of the unusual radioresponsive nature of these lesions. The use of a conservative tissue conserving approach may be preferable in such patients if surgery is very problematic, given the very high risk of distant metastasis in these patients.

***Radiotherapy Modality.*** Two methods of RT delivery are commonly employed: EBRT in the ambulatory setting and brachytherapy (BRT). No randomized data compare these modalities directly, and it is unclear how similar the selection criteria are for both approaches. As noted earlier, both have been compared with surgery alone. BRT has several advantages over EBRT including a shorter overall treatment time (e.g., classically 4–6 days vs. 5–6.5 weeks), and treatment can be initiated sooner following surgery when clonogen numbers are at a minimum. In the head and neck, additional potential advantages include the ability to treat close to critical anatomy such as the spinal cord. The concerns about lack of effect for low-grade tumors was noted earlier, a feature not apparent with EBRT.

EBRT may include photons or particle beam (electrons, protons, neutrons, or carbon ions). Protons have similar radiobiologic effects to photons. Their main advantage is when tumors lie in direct proximity to critical structures due to the ability to achieve more accurate targeting. High linear energy transfer radiation such as neutrons confer radiobiologic advantages over photons, which include reduced repair of radiation damage in tumor

(c) 2014 Wolters Kluwer. All Rights Reserved.

cells, sensitivity of cancer cells to RT throughout the cell cycle, and less protection offered to hypoxic cancer cells. However, any such advantages are tempered by late damage because the usual repair processes in action with fractionated radiotherapy do not occur and they have not become widely available due to lack of spatial targeting. More recently carbon-ion radiotherapy has emerged as an option due to the associated high linear transfer excellent dose localizing properties in comparison with other ion species and seem especially promising in the management of unresectable disease.[46] A more traditional alternative is the use of intraoperative RT (IORT). The major interest for IORT has been in retroperitoneal sarcoma, but experience in other sites, especially the head and neck, is minimal.

***Radiotherapy Dose Fractionation.*** EBRT prescriptions for postoperative RT depend on the tumor grade and involvement of the surgical margin but typically use 60 and 66 Gy for low- and high-grade tumors, respectively, with a "shrinking field" techniques following 50 Gy at 1.8 to 2 Gy per fraction. In the head and neck, critical structures in the target volume frequently require doses to be curtailed to 45 to 50 Gy in components of the target volume to minimize the occurrence of catastrophic sequelae (e.g., blindness or paralysis). At most institutions the preoperative dose is 50 Gy in daily fractions over approximately 5 weeks (Fig. 29-8) as used in our recent randomized trial.[44] Sparing of late effects may be expected with smaller fraction size in altered fractionation protocols and may be important when critical structures are irradiated. However, an improvement in therapeutic gain remains unproven from this strategy in STS.

Unresected disease being treated with the goal of long-term control should receive at least 70 Gy in 35 fractions or equivalent (see Fig. 29-4).

***Radiation Target Volume.*** STS generally respect barriers to tumor spread in the site of origin, such as bone, interosseous membrane, major fascial planes, and so forth. Thus, the margins of radiation therapy must be wide, especially along the direction of the involved musculature but care must be taken to ensure that the fascial planes are appropriately recognized and encompassed in the radiation target volume. In the preoperative setting, the gross tumor volume (GTV) is typically represented by the radiologically defined tumor. Some sarcomas have extensive peri-tumor edema which extends along fascial planes and may lie at some distance from the primary tumor. A recent study correlating radiologic imaging features to pathologic examination showed that the edema often contains viable tumor cells.[48] A zone of potential microscopic disease beyond the GTV comprises the clinical target volume (CTV) and should include the edema although this can influence the size of the treatment volume considerably. For postoperative RT planning, the high-risk target area includes the surgical field containing all the tissues handled during the surgical procedure, including scars and drain sites. Again, an additional zone

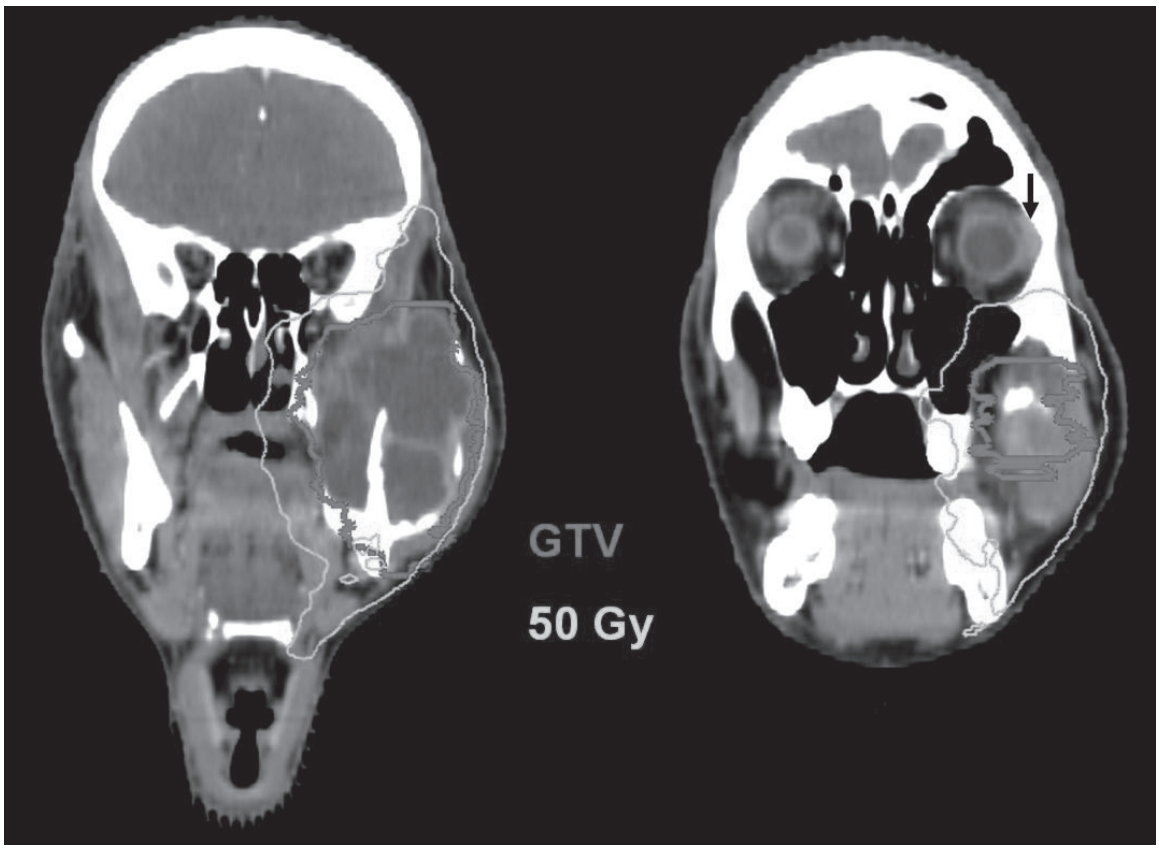

**FIGURE 29-8.** Coronal projections of an intensity-modulated radiation therapy (IMRT) plan to delivery preoperative radiotherapy (50 Gy in 25 fractions). This patient was initially treated with neoadjuvant chemotherapy for this large synovial sarcoma. Outlined in red is the coronal projection of gross target volume (GTV) for the two illustrative coronal slices and the 50 Gy isodose line (*green*) that encompasses a target that includes the superior extension into the temporalis region **(left)**. The right side of the figure shows a plan that illustrates the conformality achieved in treating this complex target in order to avoid overdose to critical anatomy within the adjacent orbit, including the lacrimal gland (*arrow*).

(c) 2014 Wolters Kluwer. All Rights Reserved.

beyond this comprises the CTV. Typically, in STS RT planning, the recommended CTV margins beyond high-risk areas are approximately 5 cm[44] although it is recognized this is often not feasible in the complex anatomy of the head and neck. Bone, interosseus membranes, and fascial planes are considered barriers to tumor spread and permit RT margins to be narrower. In contrast, the BRT protocol at Memorial Sloan Kettering Cancer Center (MSKCC) uses margins of only 2 cm around the surgical bed[40] although cases may not always be selected similarly for EBRT and BRT protocols.

Other than for the individual histologic subtypes at risk of regional lymph node involvement, elective irradiation of the neck is not ordinarily recommended in STS.

## Adjuvant Chemotherapy

***Rationale.*** Various rationales underpin the use of adjuvant chemotherapy in STS. Firstly, the efficacy of cytotoxic agents can be expected to be greater in the setting of a low tumor burden (e.g., microscopic potential disease) compared to the high (visible) tumor burden associated with overt metastatic disease. Secondly, chemotherapy might be better tolerated in association with a low tumor burden. Thirdly, the growth fraction is postulated to be high in tumors with a low tumor burden and decreases with increasing tumor size. This is relevant because tumors with a high growth fraction are believed to be more sensitive to chemotherapy. Finally, although generally considered a strategy to enhance metastatic outcome, there is also the potential to improve local control in circumstances where optimal local control strategies cannot be used because of constraints resulting from sensitive anatomical locations.

***Meta-analysis of Randomized Trials.*** The individual data from the 1,568 patients randomized in all 14 trials that addressed the role of doxorubicin-based adjuvant chemotherapy in STS were combined in a landmark individual patient data (IPD) meta-analysis.[49] Problems related to the meta-analysis have been discussed,[50] and there is some disagreement about whether the results should be interpreted with respect to whether adjuvant chemotherapy should be used routinely in STS.[50,51] In the meta-analysis, the figures for distant relapse-free interval and overall recurrence-free survival were significantly in favor of the use of adjuvant chemotherapy. However, and most importantly, the difference in overall survival, the ultimate aim of adjuvant chemotherapy, was not significantly different between the chemotherapy and the control groups ($p = 0.12$) (Table 29.8). The suggested potential absolute benefit was 4% at 10 years representing a possible survival improvement from 50% to 54% ($p = 0.12$). Thus, based on these results, routine use of chemotherapy would result in 96% of patients receiving chemotherapy with its intrinsic side effects, but with only a modest benefit accrued to the population.[50]

Only 3 trials in the meta-analysis were of a relatively large sample size, that of the European Organization for the Research and Treatment of Cancer (EORTC), the Scandinavian Sarcoma Group (SSG), and the Gynecological Oncology Group (GOG).[52–54] However, given the heterogeneity of STS, even these three studies may be too small to render definitive conclusions. In part, this may arise from inclusion of cases with minimal or only small risk of metastatic failure thereby diluting the power of the studies to detect an effect which may exist only for those patients at substantial risk of metastasis. Most trials addressed other body sites, although head and neck STS were included to varying degrees in half of the studies, including those examining doxorubicin alone versus controls[52,55–57] or doxorubicin combination chemotherapy versus controls.[53,58,59]

More recently, a literature based meta-analysis, and consequently less statistically robust than its IPD counterpart, was performed including the 14 trials mentioned above with an additional 4 randomized trials included, for a total of 1,953 patients.[60] A combination of doxorubicin and ifosfamide was used in five trials. The mean follow-up was 4.9 years and the absolute improvement for OS was 6% in favor of the chemotherapy (40% vs. 46%, $p = 0.003$). Chemotherapy also reduced local recurrence by 4% (19% vs. 15%) and distant recurrence by 9% (37% vs. 28%). These results need to be verified in a further individual patient data meta-analysis. Again, clinicians must balance the short- and long-term toxicity of combination chemotherapy with doxorubicin and ifosfamide with the absolute advantage to survival. However, notable exceptions are that all patients with nonpleomorphic rhabdomyosarcoma, and Ewing sarcoma in the case of bone tumors, deserve multiagent chemotherapy. Both diseases are discussed later in the chapter.

**TABLE 29.8 Hazard Ratios for Individual Patient Data Meta-analysis in 1,568 Patients for 14 Trials of Doxorubicin-based Chemotherapy in Adult Soft Tissue Sarcoma**

| Outcome | Hazard Ratio | 95% Confidence Intervals | *p* Value |
|---|---|---|---|
| Local RFI | 0.73 | 0.56–0.94 | 0.016 |
| Distant RFI | 0.70 | 0.57–0.85 | 0.0003 |
| Overall recurrence-free survival | 0.75 | 0.64–0.87 | 0.0001 |
| Overall survival | 0.89 | 0.76–1.03 | 0.12 |

RFI, Recurrence-free interval.

*Source:* Data from reference Sarcoma Meta-analysis Collaboration. Adjuvant chemotherapy for localised resectable soft-tissue sarcoma of adults: meta-analysis of individual data. *Lancet.* 1997;350:1647–1654, with permission.

***Influence of Chemotherapy on Local Control.*** Of interest, the largest trial in the meta-analysis (that of the EORTC) compared the outcome of adjuvant CYVADIC chemotherapy with control in 468 patients. The relapse-free survival was significantly better after CYVADIC (56% vs. 43% for controls; $p = 0.007$) and local recurrence was significantly reduced by CYVADIC (17% vs. 31%; $p = 0.01$).[53] This favorable result in this subset analysis appeared to be confined to head, neck, and trunk tumors. In contrast, distant metastases rates were similar in both arms as were overall survival rates (63% vs. 56%; $p = 0.64$). Thus, there is the potential for adjuvant chemotherapy to improve local control in this high-risk group of STS, where local control has traditionally not been as satisfactory as with STS overall and surgery and radiotherapy cannot be administered with the same freedom as other anatomical sites.

***Additional Data.*** Since the publication of the original individual patient data meta-analysis in 1997, another important study was reported from Bologna, Italy, and is included in the literature based meta-analysis reported by Pervaiz and colleagues.[60] The inclusion criteria for this trial were appropriately restricted to very adverse tumors (confined to large high-grade lesions) and a very intensive cytotoxic regimen (5 cycles of 4'-epidoxorubicin 60 mg/m$^2$ days 1 and 2 and ifosfamide 1.8 g/m$^2$ days 1 through 5, with hydration, mesna, and granulocyte colony-stimulating factor) compared with no systemic treatment.[61] The disease-free

(c) 2014 Wolters Kluwer. All Rights Reserved.

and overall survival rates were statistically improved at preliminary analysis, and at the time of reporting.[61,62] However, by the time of publication, the metastatic rate in both arms of the randomized trial was virtually identical (44% and 45%).[61,63] Unfortunately, this raises the question whether the potential value of aggressive chemotherapy may largely be in delaying the manifestation of distant metastasis, but not in their prevention. This study is of particular interest because a dose-intensive chemotherapy regimen was administered to a high-risk group patients.

***Recommendation for Individual Patients.*** At this time, given the overall results of the individual patient data meta-analysis, and the uncertain nature of this recent positive trial of the Bologna trial, postoperative chemotherapy cannot be considered standard therapy for patients with localized soft tissue sarcoma. We have not adopted systemic chemotherapy for routine use and have preferred to intensify local control strategies by maximizing the completeness of resection and delivering accurate and intensive adjuvant radiotherapy. On the other hand, we feel that chemotherapy should continue to be evaluated in randomized controlled trials in head and neck and other body sites wherever possible. Additional comments about individual selected histologic types should also be considered especially for synovial sarcoma which some believe may readily respond objectively to chemotherapy. Evidence of a true benefit is lacking; nonetheless, many centers may employ chemotherapy for the larger synovial sarcomas given the adverse risk of distant metastases in these patients with responding tumors.[64]

## Clinical Management of Selected STS Subtypes

***Undifferentiated Pleomorphic STS (Formerly MFH).*** As noted earlier, this entity has held a historical position in the management of STS. Nevertheless, despite its relegation to a diagnosis by exclusion, many tumors still fall into this category and clinicians are still faced with the challenge of treating this group of patients which probably still forms one of the largest group of malignant soft tissue tumors. Like most sarcomas, the head and neck is one of the rarer locations for the tumor. One of the larger series was described by Clark and colleagues from the M.D. Anderson Cancer Center (MDACC) and addressed 95 patients managed between 1973 and 2005. The median age at diagnosis in their report was 53 years (range, 3–90 years); 69% of the patients were men. The parotid or neck was the most common subsite (35%), and 23% of the cases were associated with prior radiation exposure. With a median follow-up of 34 months, 32 (39%) of the 83 patients treated at MDACC with curative intent had a recurrence (isolated local recurrence in 18, isolated distant recurrence in 8, both local and distant recurrence in 5, and regional recurrence in 1). For patients treated with curative intent, 5-year overall, disease-free, and disease-specific survival rates were 55%, 44%, and 69%, respectively. Management should follow the principles described generally for STS with a strong emphasis on multidisciplinary assessment and treatment.[65]

***Angiosarcoma.*** Angiosarcoma, a rare soft tissue sarcoma, is unusually well represented in the head and neck (approximately half of all angiosarcomas), and most often as a lesion in the scalp or malar skin with the lower face only rarely involved.[66] Patients typically present in their seventh to eighth decade and males outnumber females by a factor of 3:1. The clinical manifestation of the disease is a mixture of macular, nodular, and ulcerative lesion some of which present as "blood blisters."[67] The most frequent presentation therefore is with diffuse purple maculae on the scalp with edema and bleeding. Lesions often seem multifocal with considerable distance between apparent separate nodules of ulceration or patchy macularity of purplish hue. Involvement of the eyelid and periorbital tissues is particularly problematic.

Local control is an overwhelming problem because of the difficulty deciding the optimal extent of surgical and radiotherapy margins from gross tumor and local recurrence beyond the treatment areas seems to be invariable. Regional node metastasis is more frequent than in most other sarcoma subtypes in the head and neck. Distant metastasis is also frequent, especially to lung, but bone and liver are also affected more often than expected. As with other soft tissue sarcoma, treatment has often comprised radiation therapy and surgery. All too frequently, these tumors fail beyond surgical and/or radiotherapy fields and it becomes debatable if wide surgical excision is benefiting many of these patients given the inexorable out-field recurrences in those cases with multifocal disease. Indeed, the sinister behavior of these lesions warrants evaluation of new approaches of a technical, biologic, or combined modality nature.

Historically, the 5-year survival ranges between 10% and 30%[68] and the median survival remains at approximately 8 months.[67] A recent report from the MDACC suggested that primary local management with combined modality therapies is associated with improved local control including disease-specific survival of 46% and overall survival of 43% at 5 years.[69] The authors also provide useful comments concerning radiotherapy target margins encompassing the gross disease and techniques that may be employed with emphasis on wide field margins to encompass established and potential sites of disease. Paclitaxel and doxorubicin remain important choices in the treatment of advanced disease.[69–73] Bevacizumab, a humanized monoclonal antibody to vascular endothelial growth factor (VEGF), is an attractive agent to consider in this aggressive vascular tumor given its ability to inhibit tumor growth. Koontz et al. recently reported promising results in two patients using neoadjuvant bevacizumab combined with radiation therapy.[74] Similarly, multityrosine kinases targeting similar pathways are continued to be explored.[75,76]

***Hemangiopericytoma.*** Hemangiopericytoma, with origin from the pericytes, is a rare soft tissue neoplasms but a disproportionate number (about 20%) is located in the head and neck. Often unpredictable, a true diagnosis of malignant hemangiopericytoma remains a diagnosis of exclusion, and pathologists are reluctant to predict behavior, in contrast to most sarcomas where prognostic factors are relatively reliable. Sinonasal hemangiopericytomas are reputed to be biologically less aggressive tumors than those in other anatomic sites. However, we have seen adverse outcome and metastasis in such lesions and would advise against undercautious approaches to management (see Fig. 29-1). Fletcher has indicated that unlike most so-called hemangiopericytomas elsewhere, these head and neck lesions, typically originating in the nasal cavity or paranasal sinuses, are of true pericytic origin[77] and that perhaps this provides a distinction from apparently similar lesions in other anatomic sites. Potentially, this may explain the more favorable behavior of the head lesions compared with others; alternatively, the putative, less detrimental behavior may merely be a reflection of the fact that these tumors likely present earlier within the confines of the nasoethmoid region due to earlier resulting symptoms and are therefore smaller than their counterparts elsewhere. Histologically, tumor cells are arranged around relatively prominent, small, thin-walled blood vessels. The vessels form a "staghorn pattern" and contain perivascular hyalinization (Fig. 29-9).

Sinonasal hemangiopericytoma often presents with nasal obstruction and epistaxis and appears as a grey polypoid mass that bleeds briskly on manipulation. Wide local excision is the treatment of choice. In contemporary management, this may be accomplished endoscopically, though supplementary radiotherapy may be needed if an oncologic resection is not possible.

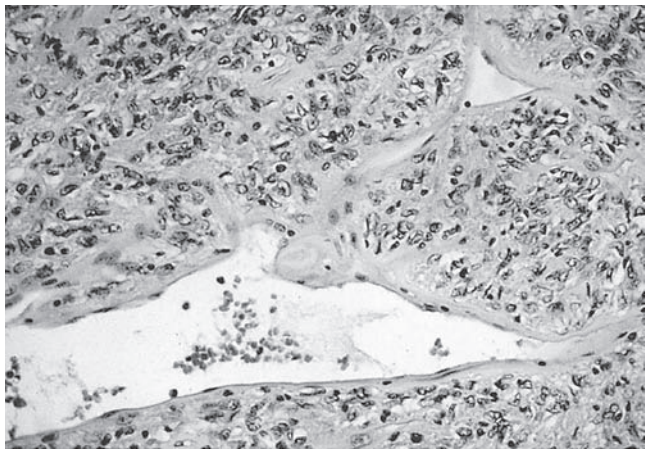

**FIGURE 29-9.** Photomicrograph of hemangiopericytoma. Dilated sinusoidal vascular channels, surrounded by tumor cells with indistinct cellular outlines ("staghorn" or "antler" configuration) is a hallmark of this tumor of "unpredictable" behavior (also see Fig. 29-1).

*Source:* Provided by Dr David Howarth, Staff Pathologist, Sarcoma Site Program, Princess Margaret Hospital and Mount Sinai Hospital, University of Toronto.

Preoperative treatments with radiotherapy or embolization may also be considered. Although a low-grade malignancy, metastases have been reported in 3% of cases with a similar incidence of death. Metastases usually occur in lung, bone, and rarely in locoregional lymph nodes.

***Synovial Sarcoma.*** Synovial sarcomas are of interest for several reasons. The name is a misnomer because such lesions virtually never originate from intra-articular or synovial tissue but have origin from undifferentiated or pluripotent mesenchymal cells. Specific translocations have assisted in their classification and may have prognostic significance (see "Classification of STS Subtypes" earlier). Location in the prevertebral, parapharyngeal, and retropharyngeal spaces is most typical and may explain the common presenting complaint of neck pain reported in a series from the MDACC, the largest single-institution cohort.[64] These tumors can also be seen elsewhere in the head and neck, including neck and tongue, and rarely may originate from the temporomandibular joint which is distinctive as synovial sarcoma almost never arises from an actual synovial joint despite the suggestive name. An enhanced incidence of lymph node involvement has been reported. Calcification in the tumor is common (evident in about half of cases and often seen radiologically; therefore, care must be taken to exclude papillary thyroid carcinoma because of the epithelial appearance of biphasic tumors and the presence of calcification) (see Fig. 29-2). Treatment approaches should follow the generic principles for the management of STS described earlier. In addition, as observed above, synovial sarcoma is notably sensitive to chemotherapy,[64] occasionally manifesting complete responses to ifosfamide and doxorubicin, and multicenter trials of adjuvant therapy are therefore warranted.

***Dermatofibrosarcoma Protuberans.*** Dermatofibrosarcoma protuberans (DFSP), as the name suggests, is an elevated nodular ("protuberant") lesion arising from the dermis with characteristic slow but persistent growth over many years. An analysis of the Surveillance, Epidemiology, and End Results (SEER) database from 1992 to 2004 showed that DFSP comprises 18.4% of all cutaneous sarcomas with an equal gender predisposition.[78] Although borderline to low grade in histologic appearance, it has a propensity for local recurrence after simple excision. Typical manifestations are of a red- to purple-colored lesion on the upper trunk, especially in proximity to the clavicular regions where it is frequent on the shoulder and supraclavicular regions of the head and neck. Not infrequently, small satellite lesions are evident at the site or bordering a skin graft following an unsuccessful previous excision. Management is best with wide surgical margins or more conservative cosmesis facilitating surgery with adjuvant EBRT following which the recurrence rate is extremely low.[79] Adjuvant radiotherapy should certainly be considered in cases of recurrence especially when disease is escaping control by traditional surgical approaches to prevent escalation to more adverse histology. Controversy exists regarding surgical margin width and excision techniques. Recent data indicate that relatively narrow surgical margins (median 2 cm) permits primary closure in 69% of patients and is associated with a very low recurrence rate (1%).[80] Mohs surgery is also advocated by some investigators. The recent observations of response to imatinib (STI 571, Gleevec) in DFSP predicted by the presence of the t(17;22) translocation which fuses the *COL1A1* collagen gene to platelet-derived growth factor receptor (*PDGFR*)[81] provides possibilities for molecular target therapies. In general, however, the typical cases fare extremely well with surgery alone or supplemented with adjuvant radiotherapy and these should remain the conventional management approaches at this time for curable disease.[79]

***Liposarcoma.*** While liposarcoma represents one of the most common STS, like the previous or current entity recognized by the term MFH, it has no particular significance in the head and neck and the principles of management for STS outlined later should be applied. As in other body sites, the most favorable outcome is associated with the well-differentiated subtype. The myxoid variant is present in 40% to 50% of all cases. Round-cell admixture and pleomorphic histology are associated with a poor prognosis. Of interest, myxoid liposarcoma may demonstrate unusual natural history with metastasis to extrapulmonary soft tissue sites (e.g., the retroperitoneum, chest wall, pleura, and pericardium being typical).[82] Such remote metastasis to unusual sites may masquerade as isolated "second sarcomas" but share identical lineage to the original primary by virtue of monoclonality confirmed by analysis of TLS-CHOP or EWS-CHOP rearrangements.[83] Another unique feature of this tumor is an unusually high response to radiotherapy compared with other STS.[84]

A detailed report of head and neck liposarcoma from the MDACC showed that both disease-specific and overall survival rates were higher in patients with well-differentiated or myxoid tumors compared with patients with round-cell or pleomorphic tumors. In fact, crude disease-specific survival was 100% for well-differentiated liposarcomas and myxoid liposarcomas versus 60% for round-cell tumors and only 45% for pleomorphic liposarcomas. This finding highlights the importance of grading and subtyping these tumors to accurately prognosticate and select appropriate treatment.[85]

### Rhabdomyosarcoma

*Clinical Issues.* A recent report examined head and neck rhabdomyosarcoma diagnosed between 1973 and 2007 in the SEER program and found an increasing annual incidence of 1.16%.[86] The authors also indicate that, despite reported advantages in overall and disease-free survival, population-based analyses seem not to have demonstrated substantial improvement over the past three decades. Prognosis is largely dependent on disease extent at diagnosis although multivariate analysis has consistently shown that young age (e.g., <10 years at diagnosis) and lack of *FOXO1* translocation t(1;13) or t(2;13) is associated with improved survival.[86] Although most tumors are diagnosed in children (age 0–9 years: 46%; 10–19 years: 23%) almost one-third

**TABLE 29.9 Definition of Sites of Origin of Rhabdomyosarcoma of the Head and Neck**

| Site | Relative Proportions | Definition, Where Appropriate |
|---|---|---|
| Orbit | 25% | |
| Parameningeal | 50% | Nasopharynx, nasal cavity, paranasal sinuses, middle ear, mastoid, pterygoid fossa, and any parameningeal site with extension into a parameningeal location |
| Nonparameningeal site | 25% | |

*Source:* Data from Stevens MCG. Malignant mesenchymal tumours of childhood. In: Souhami RL, Tannock I, Hohenberger P, et al., eds. *Oxford Textbook of Oncology.* 2nd ed. Oxford, UK: Oxford University Press; 2002:2525–2538, with permission.

of head and neck rhabdomyosarcomas are identified in adults (age 20–55 years: 23%; >55 years: 8%) This tumor is the fifth most common cancer in children.[22] The most common sites of origin are the head and neck (about 40%) and the genitourinary tract (about 20%).[33] Among head and neck lesions, one-quarter affect the orbit, one-half are parameningeal (Table 29.9), and the remainder are in other sites.[33] The site of origin is important because it provides information concerning patterns of spread and relapse. Thus, orbital lesions, although presenting with dramatic early orbital content displacement, rarely manifest regional node metastasis or distant disease and are associated with an excellent outcome. In contrast, parameningeal sites provide significant risk of intracranial extension and leptomeningeal metastasis as well as distant disease. The initial evaluation of rhabdomyosarcoma is similar to regular STS but should include bone scan and bone marrow examination as the risk is moderate and the prognosis unfavorable. Increasingly, $F^{18}$-FDG-PET is being used to stage and assess response in RMS.[87] Treatment of these children and young adults is arduous and associated not only with a considerable burden of toxicity experienced by the individual at the time, but also with late sequelae.[33] Because most of these patients are young children, the principal dilemma concerns the use of disfiguring local treatments. On the one hand, surgery, an immediate and potentially major intrusion, usually results in cosmetic and function loss and is hardly ever advisable. On the other hand, radiotherapy has a high probability for growth and tissue maldevelopment, secondary malignancy, cataracts, and hypopituitarism later. Philosophically, only one local treatment should be employed where feasible and with the minimum possible intensity. In many ways the role of chemotherapy has been to facilitate this, in addition to treating micrometastatic disease.

*Surgery.* The role of surgery is very limited given the great sensitivity of these lesions to chemotherapy and radiotherapy and may only be reasonable in select nonorbital and nonparameningeal sites. It should only be performed at diagnosis in the absence of metastasis to lymph nodes or distant sites as prompt chemotherapy is the most critical intervention required to realize a favorable outcome. "Secondary surgery" to achieve local control following initial chemotherapy is reasonable but should be conservative. In general, radiotherapy is used most often in the head and neck sites.[33] In the young adult, where growth arrest and structural abnormalities from radiotherapy are not an issue, we only recommend surgery for the smallest lesions in favorable sites in the primary nonsalvage situation. Frequently, radiotherapy would also be added to sterilize the field and treat potential lymph node regions since this risk is high in our experience of treating young adults (see Fig. 29-5).

*Chemotherapy.* Over several decades, a complex and impressive series of trials addressing the role of chemotherapy predominantly have been completed through cooperative group mechanisms in North America and Europe and chemotherapy has improved the outcome of this disease. Its purpose is to both ameliorate the risk of distant metastasis manifestation and reduce the extent of subsequent surgery or radiotherapy (or even eliminate them).

The classic drugs have been vincristine (V), actinomycin-D (A), and cyclophosphamide (C). In addition, doxorubicin (adr) has been used in some schedules, or alone, though its role in initial therapy is uncertain.[33] Combinations have included VA, VAC (the most established), and VACadr. Recent approaches, especially in Europe, have involved substitution of ifosfamide for cyclophosphamide although the superiority of one over the other remains unproven. Ifosfamide is frequently used in combination with etoposide. These strategies are often intended to overcome drug resistance especially in advanced disease protocols. The standard of care in North America for young patients with nonmetastatic head and neck RMS would include VAC; however, we often use the combination of ifosfamide and etoposide while radiotherapy is being administered following initial induction with VACadr because of prohibitive normal tissue sensitization doxorubicin. Whenever possible, young adults with RMS should be offered enrolment onto clinical trials, most often sponsored by pediatric cooperative groups to ensure standardization of therapy.

*Radiotherapy.* Radiotherapy alone (meaning with chemotherapy) is a very effective strategy to effect local control, achieving rates in the order of 90% with doses of approximately 45 to 60 Gy at conventional daily fractionation of 2 Gy per day. In children, it is highly desirable to maintain doses at a minimum. In consequence, research is exploring the lower dose limits that can be used safely. The potential to use doses $< 40$ Gy is being considered in very select situations for lesions outside of the head and neck, although there is also concern that this may be insufficient, especially for adverse situations such as the alveolar subtype or in the face of overt clinic disease. Other strategies have included altered fractionation employing lower dose per fraction with the potential to exploit radiobiology strategies for additional normal tissue protection. The current standard is to provide doses in the order of 45 to 54 Gy and where possible use doses in the 45-Gy range. In the full-grown patient, our usual approach is to prescribe 60 Gy to sites of gross disease, while administering 50 Gy to potential areas of involvement, including the nodal regions at risk.

Radiotherapy target volumes are problematic especially in parameningeal sites where local failure and leptomeningeal relapse is possible. Thus, wide margins intracranially are considered but are associated with major potential sequelae.[33] Radiotherapy volumes should also consider coverage of the lymph nodes at risk or involved in these adverse parameningeal sites.

*Results.* Since the introduction of combination chemotherapy, survival outcome has improved dramatically from approximately 25% to 5-year survival rates of approximately 70%. The rates exceed 80% for embryonal and are somewhat lower (~65%) for alveolar (translocation-positive) and lower again for undifferentiated lesions. Good prognostic factors include favorable sites, such as nonparameningeal or orbit in the head and neck, and lack of intracranial extension or bone erosion.[88] As yet unexplained is the observation that the different histologic subtypes have an intrinsically worse prognosis in adults compared with children.[86,89] Adults may manifest extremely unfavorable behavior including

sanctuary site metastasis and bone marrow replacement not long following initial combined modality treatment including aggressive adjuvant chemotherapy.

## TREATMENT OF BONE SARCOMAS OF THE HEAD AND NECK

The management of bone sarcomas in the head and neck suffers even more than STS from the paucity of data since they are even rarer. Approaches are again extrapolated from the more usual body sites, predominantly the limbs. Local treatment is again compromised by the proximity to important anatomic structures making resection and radiotherapy more challenging than elsewhere. The situation differs from STS in that radiotherapy is much less established as a component of treatment in bone tumors, and chemotherapy is more established in osteosarcoma and the very rarely seen Ewing tumors.

### Osteosarcoma

***Background.*** Few centers see more than one case of head and neck osteogenic sarcoma annually and differences in reported outcome appear to relate to the rarity of the disease, case selection, and variable practice patterns. Moreover, histologic grade strongly influences outcome and comparison and prediction of outcome and behavior appear to be particularly vulnerable to treatment selection bias.[90,91] Although generally considered more favorable than other osteosarcomas, possibly because of lower histologic grade, agreement is not uniform about whether the risk of metastasis is less than in long-bone tumors. The pertinent data concerning this tumor were thoroughly reviewed recently and showed that overall reported survival rates are approximately 60% to 70%.[92] At the same time, local relapse in head and neck lesions remains a grave sequel. The recent NCDB report showed a year disease-specific survival rate of 60%.[15] Factors associated with a poor prognosis were age older than 60 years; nonmandibular tumor location; tumor size >6 cm; histologic type of tumor; advanced disease stage; nonsurgical initial therapy; and positive margins of resection. The 5-year survival figures for some of these factors are shown in Table 29.10.

***Surgery.*** The foundation of local treatment is surgery and, like osteosarcoma elsewhere, should be accomplished with clear resection margins. Most usually, this follows neoadjuvant chemotherapy (see subsequent text). The principles of resection and reconstruction should be observed including anticipation of the routes of spread into difficult areas in the head and neck and skull base (Fig. 29-10). The local resection should be planned with a very clear definition of tumor extent, particularly the intramedullary component. MRI is particularly useful to delineate both intramedullary extent and any extraosseous component. Intraoperatively, tumor clearance is confirmed by pathologic examination of marrow biopsy at the resection site; similarly, verification of completeness of resection is recommended in doubtful areas such as tissues adjacent to neurovascular structures in proximity to the tumor. Any biopsy scars or other access routes for disease to "track" from the primary site should also be excised.

#### Radiotherapy

*Adjuvant Radiotherapy.* At times, only marginal resection is feasible and other options for local management must be considered. Revision surgery where feasible is advisable because the outlook for these patients is bleak. Although radiotherapy is intuitively attractive, the reality is that adjuvant radiotherapy for high-risk osteogenic sarcoma does not appear to confer the high rates of local control seen in oncology in general. Nevertheless, we feel it should be considered in these adverse situations even though it was not found to be of benefit in two systematic reviews of the

**FIGURE 29-10.** Chondroblastic osteosarcoma of the vertical mandibular ramus with temporomandibular joint destruction and invasion of masticator apparatus and infratemporal fossa in a 25-year-old male. The soft tissue component has virtually "exploded" the bone. This patient did not experience local control following postinduction chemotherapy surgery and later failed combined surgery with proton beam radiotherapy. Progressive pulmonary metastases developed that were refractory to all chemotherapy until gemcitabine achieved complete and sustained remission of local and metastatic disease for some years.

literature.[90,91] As noted earlier, a significant problem affecting the literature of this disease is selection bias in the choice of adjuvant treatments and it remains possible that radiotherapy may provide valuable delay in progression. Indeed, the results of evaluation of radiotherapy indicate that it either confers no significant value[91] or is associated with worse outcome[90] because of selection of cases due to unresectability or residual disease after surgery.

Guadagnolo et al. described a series at the MDACC treated with gross total resection alone (92 patients) or combined with adjuvant radiotherapy (27 patients) from 1960 to 2007. Fourteen patients (12%) had recurrent lesions. Adjuvant radiotherapy to a median dose of 60 Gy (range, 50–66 Gy) was given to 27 patients (preoperative in 5 and postoperative in 22). Multivariate analysis revealed that only margin status predicted overall survival. Thirty-eight patients had positive or uncertain margins; 27 were treated with surgery alone, and 11 patients received adjuvant radiotherapy. The use of adjuvant radiotherapy did not improve local control in patients with negative margins ($p = 0.48$) but did improve local control for those with positive or uncertain margins ($p = 0.006$).[93] Furthermore, the use of radiotherapy for patients with positive resection margins resulted in improved overall survival in this report.

DeLaney et al.[94] described an overall local control rate at 5 years of 68% (±8.3%) in 41 patients in whom surgical resection with widely negative margins is not possible. Seventeen of these patients also had their tumor arising in the head and neck and 8 were of spinal origin. They concluded that RT can help provide local control of osteosarcoma for patients and appears most effective in situations in which microscopic or minimal residual disease is being treated.[94]

Another unusual approach that originated in extremity osteosarcoma offers prospect for combining systemic treatment with radiotherapy. Machak et al.[95] described an experience of neoadjuvant chemotherapy administered with EBRT in a consecutive series of 31 of 187 patients with nonmetastatic osteosarcoma who had refused surgery. In the subgroup with a pronounced response to chemotherapy, the 5-year survival after chemoradiotherapy was 90%. These results suggest that the disappointing effect of standard doses of radiotherapy on osteosarcoma may not apply in the setting of effective response to chemotherapy. Notwithstanding these selected results, they must still be balanced against the potential of late adverse outcomes, including local and metastatic recurrence, as well as deleterious normal tissue effects, even if the theoretical promise of this nonsurgical approach is to enhance function and quality of life.

It would seem from these retrospective results that the role of radiotherapy has not been explored adequately, as the actual contribution is only modest in some series and more robust in others and the studies themselves seem to be confounded by selection bias. What are needed are controlled trials, but it would be most improbable that this will ever be explored in a randomized prospective fashion, even through a multicenter mechanism, because of disease rarity. At the same time, the role of radiotherapy is not likely to be considered in osteogenic sarcoma of the limbs where the local control rate is at least 90% following neoadjuvant chemotherapy and limb salvage surgery, and wide application of adjuvant radiotherapy is unnecessary.

Finally, if radiotherapy is employed it should follow identical principles described earlier for STS. In essence, routes of spread and location of tumor including potential tissues contaminated by surgery, biopsy, or tumor invasion/incursion should be considered in the planning volumes. Adequate doses are also necessary and should probably exceed 60 Gy in the postoperative setting, even when only microscopic disease is present because of the known reputation for relative radioresistance.

*Radiotherapy Alone.* At the present time, the literature does not provide any convincing evidence that radiation as a sole modality is useful for the local management of osteosarcoma. It should therefore be confined to the experimental approach or may need to be reserved for palliation. Unfortunately, in our experience it has not been successful for the latter. One promising strategy is the use of carbon-ion radiation therapy that is only available at a few highly specialized facilities worldwide. Jingu and colleagues described a small series that achieved a 3-year local control rate of 85.7% for unresectable osteosarcoma treated with 70.4 GyE, but the result was much inferior with lower doses.[46]

### Adjuvant Chemotherapy

*Adjuvant Chemotherapy for Osteosarcoma in General.* A number of trials have established the routine use of chemotherapy in extremity osteosarcoma, although initially controversy existed about whether the apparent survival benefits could relate to improvements in other aspects of the illness and not to the use of systemic treatment. Specifically, a change in natural history was posited as contributing combined with more aggressive staging and surgical intervention for metastases, as well as better local surgery. The discordant views were addressed by the completion of the Multi-institution Osteosarcoma Study[96] in which patients were randomized to observation only (instead of systemic therapy) or multiagent chemotherapy (Rosen T10 protocol). In Rosen protocols, a variety of drugs were used (methotrexate, doxorubicin, bleomycin, actinomycin-D, and cyclophosphamide

(c) 2014 Wolters Kluwer. All Rights Reserved.

given repeatedly for up to 1 year) including cisplatin for "poor responders" (see below). A significant improvement in disease-free survival was observed in favor of the chemotherapy arm of the trial although overall survival was not apparently different in the initial report of the trial. A putative influence of salvage treatment may have explained the early observation, but with later follow-up a survival advantage in favor of early chemotherapy was apparent.[97]

Recently, however, Allison et al. comprehensively reviewed all significant published data regarding osteosarcoma and outcome in the modern medical era in an attempt to evaluate treatment progress over time. The study specifically excluded head and neck osteosarcoma and low-grade lesions in general. In total, 5-year overall survival was reported in 47,227 nonmetastatic, high-grade osteosarcoma patients aggregated from 264 series. Published survival improved dramatically from 1960s to 1980s and then leveled, or in some measures decreased. Recurrence rates decreased in the 1970s and then leveled. Though significant gains have been made in the past, no improvement in published osteosarcoma survival has been seen since 1980, highlighting the importance of a new strategy in the systemic management of this still very lethal condition.[98] To what degree these results apply to the general management of head and neck osteosarcoma remains unclear, given the more favorable biology of this tumor compared with the more common presentations of the disease.

As noted, a variety of agents have been used have been used in the chemotherapy of osteosarcoma. Currently, high-dose methotrexate-based chemotherapy with leucovorin rescue, doxorubicin, and cisplatin are accepted active agents, though the ideal combination remains to be defined.[99] Because of toxicity of prolonged chemotherapy, the European Osteosarcoma Intergroup performed a multicenter randomized study comparing 12 months of multiagent methotrexate-based chemotherapy versus 6 courses of doxorubicin/cisplatin. Survival appeared comparable for both groups.[100] More recently, ifosfamide has emerged as an active agent but questions remain about optimal scheduling and dosage. Ongoing trials are in progress evaluating these questions and include the use of hematopoietic growth factors such as granulocyte-stimulating factor (G-CSF) in intensification protocols.

An additional approach has involved the combination of the immunomodulator liposomal muramyl tripeptide phosphatidylethanolamine (MTP-PE) with postoperative chemotherapy. A statistically significant overall survival advantage and a non-significant trend in event-free survival have been reported in a randomized trial employing this strategy.[101] Despite this, reservations remain concerning the exact role of this novel immunomodulator approach.[99]

There still remains uncertainty about whether neoadjuvant chemotherapy is superior to prompt postoperative chemotherapy in terms of survival benefit. Neoadjuvant chemotherapy permits the potential for early eradication of micrometastatic disease, delivery of chemotherapy to an intact blood supply, and assessment of the effectiveness of the preoperative chemotherapy regimen used. The latter has become an important principle in the management of osteogenic sarcoma through assessment of histologic response after systemic chemotherapy. It also appears to facilitate surgery and was pivotal in the introduction of limb preservation for osteosarcoma of limb bones. In osteosarcoma of the extremities, completeness of histologic response to neoadjuvant chemotherapy (e.g., <5%–10% tumor viability at surgical resection) has been correlated with improved survival. Whether modulating chemotherapy in poor responders offers benefit remains unknown and was the subject of a recently completed international randomized controlled trial (EURAMOS I). The results of this trial will not be available for a few years.

*Adjuvant Chemotherapy in Head and Neck Osteosarcoma.* Although important trials have been completed in extremity osteosarcoma, prospective studies in the head and neck are lacking and treatment has been inconsistent. As a result, there is disagreement about its role in the seemingly more favorable osteosarcomas of the mandible and maxilla compared with extremity lesions. Remarkably, in this rare condition, two independent "quasi" meta-analyses of the retrospective data regarding the role of adjuvant chemotherapy were reported simultaneously.[90,91] In both studies, the authors described their methodology in detail, which were similar in restricting cases to those where individual patient data were available in the reports chosen for analysis. In this way, actuarial estimates of outcome could be calculated and proportional hazards techniques applied to estimate risk and to attempt to control for prognostic variables. Of importance, both studies report the conclusion that radiotherapy seemed to be unhelpful, bearing in mind the caveats mentioned earlier and that the inherent biases of retrospective studies that cannot be completely controlled for.

In addition, however, the authors reached different conclusions regarding the efficacy of systemic chemotherapy. On the one hand, Kassir and colleagues concluded that the role of chemotherapy in head and neck osteosarcoma remains unproven.[90] In contrast, Smeeles and colleagues maintained that chemotherapy does improve survival and advocated for the adoption of the same chemotherapy protocols as used for long-bone primary sites.[91] It turns out that an important distinction separates the two studies. Kassir et al. accepted all nonmetastatic patients whereas Smeeles et al. restricted entry to those studies that reported on surgical margins. Both the variables "involved margins" and "chemotherapy," when adjusted for each other turned out to be significant.[102] Although it is of interest to observe the findings by Smeeles et al., we would also caution that neither the "margin status" nor the "response to chemotherapy" are known at baseline when a patient first presents at diagnosis, and the patients who performed well in their study following chemotherapy are already selected by virtue of favorable responses to surgery (i.e., clear margins). Moreover, the margin status could itself be complicated by whether there was a favorable response to preoperative chemotherapy. In other words, we still do not have strong evidence about what to recommend for a given patient presenting for the first time until after surgery has been performed, and in most cases after induction chemotherapy as well. In the NCDB report, no substantial difference in the 5-year survival rate was noted between treatment with surgery alone (74.7%) and surgery with adjuvant chemotherapy (71.3%).[15]

***Recommendation for Individual Patients.*** Notwithstanding the discussion concerning the evidence about the role of adjuvant chemotherapy in osteogenic sarcoma and the possible more favorable behavior compared with long-bone lesions, it is our view that certain of these lesions can manifest sinister behavior (see Fig. 29-10) and we would routinely advise systemic chemotherapy in fit patients. This is administered using a neoadjuvant/induction approach. Of interest, despite their results suggesting a lack of benefit, Kassir et al., influenced by their observation of relatively poor prognosis for these lesions, provide similar recommendations to ours.[90] Our general approach to management of head and neck osteosarcoma is summarized in the algorithm (Fig. 29-11).

## Chondrosarcoma

***General Comments.*** Chondrosarcomas make up 10% of malignant bone tumors and is the second most common sarcoma arising in bone (after osteosarcoma). Chondrosarcoma also comprises <10% of these primary bone malignancies in the

(c) 2014 Wolters Kluwer. All Rights Reserved.

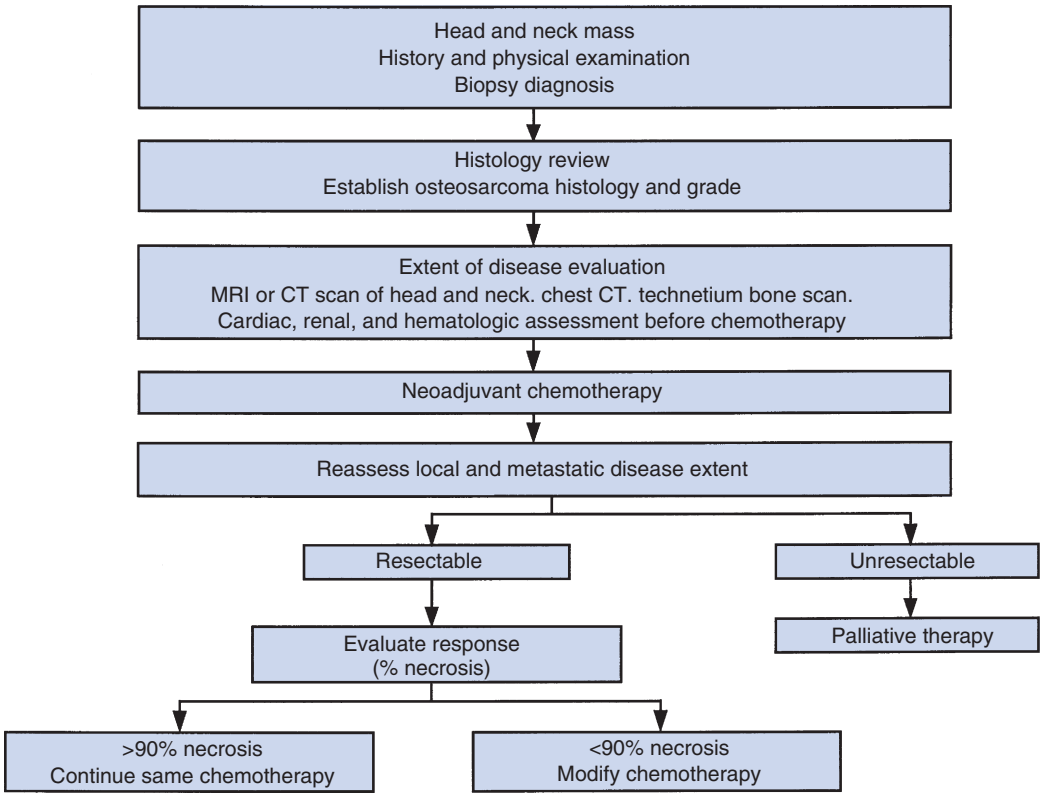

**FIGURE 29-11.** Flow diagram for the management of osteosarcoma of the head and neck using usual approach of induction chemotherapy with pathologic response assessment.

head and neck. In this location, it presents a broad spectrum of tumors of similar histology but widely dissimilar behavior and demographic character. For example, age and gender distribution vary by histologic subtype and site. In the National Cancer Data Base Report, older age (>50 years) was most prevalent among laryngotracheal cases (90%) and among men.[16] In contrast, women and patients younger than 50 years were more likely to be associated with lesions of the osseous head and neck skeleton including the sinonasal region. These demographic differences in a large contemporary database indicate that head and neck chondrosarcoma encompasses subgroups of dissimilar cancers and the great heterogeneity of presentation and biology, as well as potential management strategies, makes it difficult to summarize outcome succinctly. The NCDB analysis also demonstrated that decreased survival was statistically associated with advanced-stage, higher-grade, and the histologic subtypes myxoid or mesenchymal.

***Surgery.*** All evidence about the management of chondrosarcoma of the head and neck would support the use of surgical excision as the primary treatment when possible. In addition, the surgery should concentrate on the primary tumor following the principles outlined for osteosarcoma, including adequacy and verification of complete excision and meticulous staging prior to excision. These principles will not be repeated other than to emphasize that wide excision beyond the pseudocapsule is required since chondrosarcomas tend to have microscopic fingerlike extensions and have a notorious propensity to seed the wound with later nodular recurrence if the tumor is violated. In addition, neck dissection is not indicated because of the overall low incidence of regional metastases (~5%).[16]

### *Adjuvant Treatment*

*Adjuvant Chemotherapy.* The management of osteosarcoma and chondrosarcoma differ in two significant ways, both relating to the use of adjuvant treatments. Firstly and for reasons of efficacy, chemotherapy is not ordinarily a component of management of chondrosarcoma, in contrast with osteosarcoma. The exception is in the mesenchymal subtype where chemotherapy was used in the majority of mesenchymal chondrosarcoma cases (57.5%) in the NCDB series and has been our policy at Princess Margaret Hospital.[103] By extrapolation, chemotherapy would be used as for osteosarcoma or Ewing.

*Adjuvant Radiotherapy.* Radiotherapy, usually a doubtful addition to the treatment of osteosarcoma, can be a very effective adjunct to the treatment of chondrosarcoma where there is concern about the adequacy of resection, although it is acknowledged opinions vary as to its value. At our center, we have always regarded positive resection margins as an indication for adjuvant radiotherapy[104] and would expect similar outcome to high-risk positive-margin STS following combined surgery and radiotherapy. Goda et al. reported the outcome of 60 patients with extracranial high-risk chondrosarcoma who underwent surgery and RT between 1986 and 2006. Sites included pelvis/lower extremity (48%), chest wall (22%), spine/paraspinal (17%), and head and neck (13%). Overall, median tumor size was 7 cm (range, 1–22 cm) and at least 40% had positive resection margins with a reasonable number with overt gross tumor remaining following resection. Preoperative radiotherapy (median, 50 Gy) and postoperative radiotherapy (median, 60 Gy) were used in 40% and 60% patients, respectively. The crude local control rate was 90%. Patients with R0, R1, and R2 resections had local control of

(c) 2014 Wolters Kluwer. All Rights Reserved.

100%, 94%, and 42%, respectively. The 10-year overall survival, progression-free survival, and cause-specific survival were 86%, 80.5%, and 89.4%, respectively.[104]

Both adjuvant radiotherapy and radiotherapy as a sole modality (see below) should follow similar principles regarding planning, dose-fractionation parameters, and target volumes as outlined for STS and osteosarcoma. Of interest, the use of radiotherapy is not altogether unusual having been used as a component of management in >20% of cases in the large NCDB report,[16] which would follow our general recommendations.

***Radiotherapy Alone.*** Radiotherapy as sole modality is also capable of long-term control of chondrosarcomas in difficult locations, such as the clival regions, although here opinions may vary about whether this is best accomplished with proton beam radiotherapy, heavy ions, or IMRT. Ten-year control rates in the order of 70% to 80% have been reported from excellent centers using proton beam radiotherapy. Our approach is to use radiotherapy as the sole modality in cases where the lesion is not resectable without great risk to the patient. Examples would include the need to sacrifice the critical vascular supply in clival lesions and especially where the lesion is of small volume (Fig. 29-12).

***Results of Management of Chondrosarcoma.*** As noted earlier, the grade of the lesion and the accessibility for treatment are important determinants of outcome. In the NCDB, survival rates appeared similar regardless of the site of disease and are profoundly influenced by the grade of the lesion. The 5-year disease-specific rates generally exceed 80%. The beneficial outcomes are clearly related to the fact that grade 1 (50%) and grade 2 (37%) were the predominant subtypes with grades 3 and 4 representing only 8% and 4%, respectively, since superior outcome for patients with lower-grade tumors (93.2%) compared with higher-grade tumors (67.3%) ($p = 0.0265$) (Table 29.11).[16] Individual series have not reported as favorable outcomes for the higher-grade lesions.

### *Special Situations in Head and Neck Chondrosarcoma*

*Chondrosarcoma of the Larynx.* Chondrosarcoma is the most common sarcoma of the larynx. Usually, it presents as a mass originating on the posterior cricoid lamina eventually resulting in airway compromise and voice dysfunction (Fig. 29-13). This neoplasm is particularly indolent in behavior, carrying an extraordinarily favorable outcome in terms of survival. Generally, in the older age group (>50 years), >90% of cases are low-grade lesions, and males are most frequently affected. Complete laryngectomy is virtually always curable but more conservative approach as suggested by the Mayo Clinic report appears more appropriate given the excellent survival rates.[105,106] In their series, only 14% received total laryngectomy. Despite a high recurrence rate among patients treated without total laryngectomy by either "complete external removal" (27% recurrence rate) or by "subtotal external removal" (67% recurrence rate), acceptable 5-year survival (90.1%) and 10-year survival (80.9%) resulted from salvage surgery. The results when compared with expected survival for a controlled population appear to show no detriment to survival

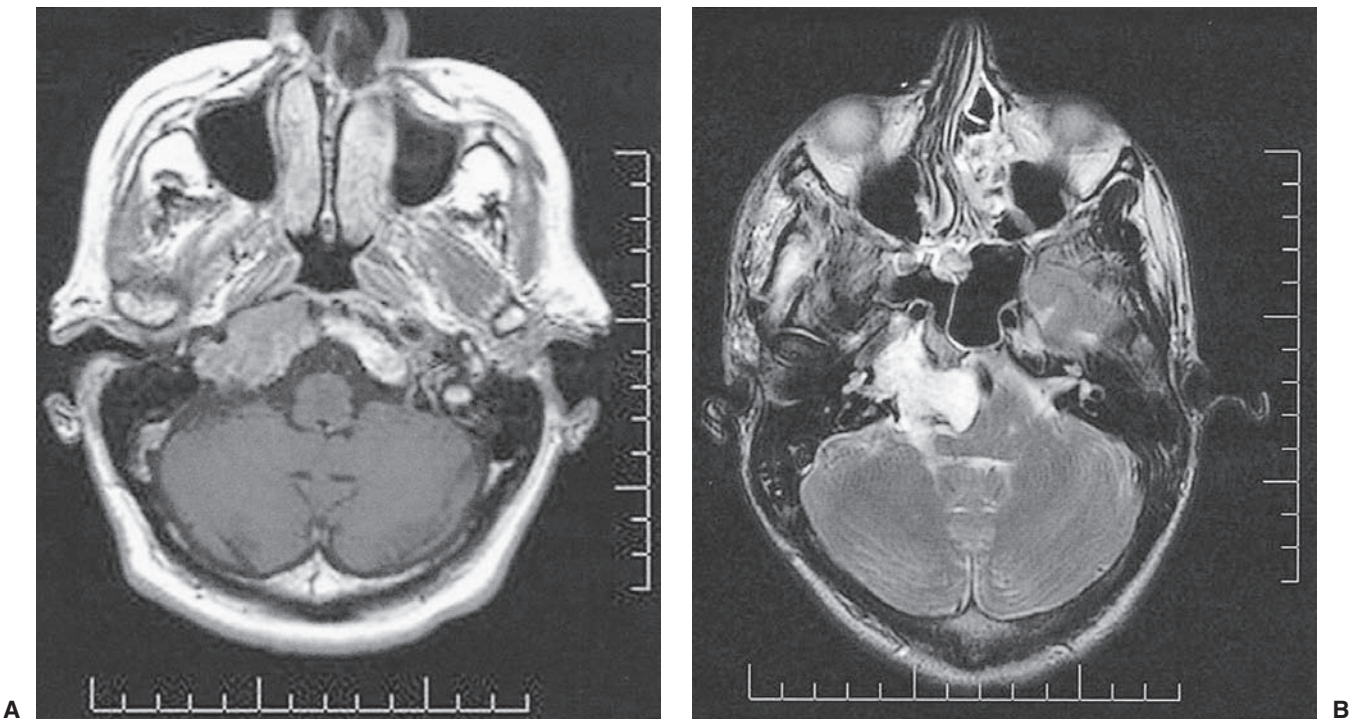

**FIGURE 29-12.** Magnetic resonance imaging (MRI) of two cases of chondrosarcoma of the petroclival region. In one, an enhancing mass is seen destroying the right side of the clivus. The right internal carotid artery is incorporated within the mass at the skull base and through the petrous portion. The patient was treated with stereotactic intensity-modulated radiation therapy (IMRT) to a high-fractionated dose and remains asymptomatic with 12 years of follow-up **(A)**. The second case **(B)** exhibits a chondrosarcoma of the petroclivus complicating Maffucci syndrome (see text for details). This 21-year-old male was managed with surgery followed by postoperative stereotactic IMRT to minimize the dose as much as possible to the juxtaposed brain stem (limit of 55 Gy fractionated to a small portion of the brain stem was achieved with this technique). He is also well with >10 years of follow-up.

because of the chondrosarcoma (Fig. 29-14). We normally explain to patients that postoperatively radiotherapy following conservation laryngeal surgery should improve the ultimate likelihood of larynx retention even though an improvement in survival cannot be realized by this approach.

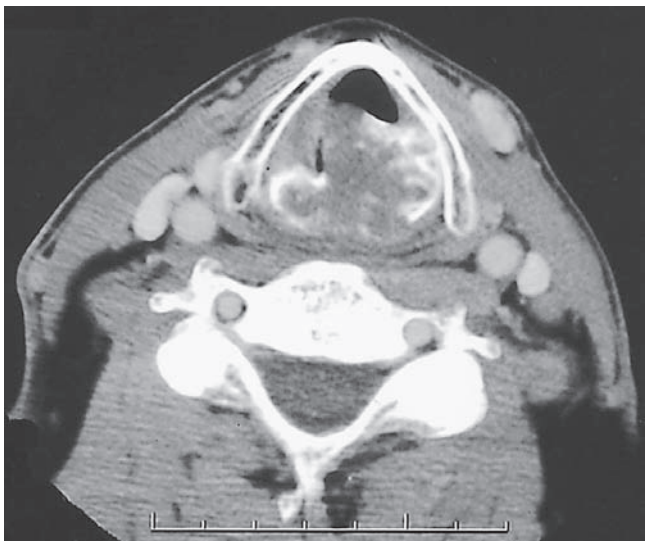

**FIGURE 29-13.** Contrast-enhanced computed tomography axial view of a typical low-grade chondrosarcoma of the posterior cricoid lamina in a middle-aged male. Note airway reduction by the calcified and well-demarcated lesion. Although recommended intralesional resection with likely prospect of future and repeated reexcisions, he received postoperative radiotherapy by one of the authors (BO'S), at patient's request to minimize risk of local failure. He remains well without recurrence with good voice 11 years later.

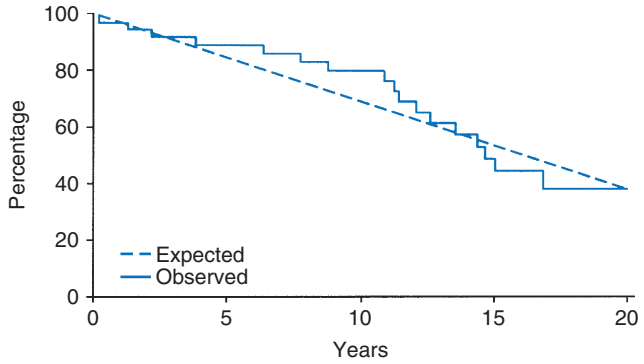

**FIGURE 29-14.** Survival curve for chondrosarcoma of the larynx treated at the Mayo clinic compared with normal population survival.

*Source:* Reproduced with permission from Lewis JE, Olsen KD, Inwards CY. Cartilaginous tumors of the larynx: clinicopathologic review of 47 cases. *Ann Otol Rhinol Laryngol.* 1997;106:94–100.

*Skull Base Chondrosarcomas.* Although rare, chondrosarcomas often arise in the skull base including clivus and petrous temporal bone. Such lesions pose particularly severe problems including pain or gradually progressive features of brain stem compression from intracranial intrusion (e.g., cranial nerve dysfunctions especially sixth nerve at the outset). The only favorable aspect is that they are, like the majority of chondrosarcomas, usually of low-grade histology.

Given the grave significance of chondrosarcomas in these locations, and the inability to perform a complete excision in the majority of cases (see Fig. 29-12), suitable patients with skull base primaries should be referred to specialized centers for consideration of expert skull base surgery in conjunction with specialized radiotherapy approaches including particle beam therapy, or stereotactic photons treatments with or without IMRT. A number of small series have shown that a combination of surgical debulking and high-dose precision radiotherapy results in durable local control in a large proportion of skull base chondrosarcomas (in excess of 80%) with modest late toxicity. The outcome of lesions <25 mL in volume is particularly impressive especially if adequate doses are administered with a combination of photons and protons to approximately 70 Cobalt Gray Equivalent (CGE).[107] Others have reported similar impressive results[108] and are also apparent in smaller series with either protons or fractionated stereotactic radiotherapy,[109,110] and more recently carbon ions.[111] Such series generally also combine radiotherapy with surgery. Evaluation of this literature is problematic as it is frequent to that outcome of skull base and cervical spine chordoma is reported together with that of chondrosarcoma. The literature is also changing in this regard as technology involves including the use of carbon ion that is only available at a very few centers worldwide.[46,111] Schulz-Ertner et al. recently described their experience of treating 54 patients with low-grade and intermediate-grade chondrosarcomas of the skull base using carbon-ion radiation therapy (RT) between 1998 and 2005. All patients had gross residual disease following surgery. The actuarial local control rates were 96.2% and 89.8% at 3 and 4 years; overall survival was 98.2% at 5 years. Only one patient had grade 3 toxicity.[111]

*Mesenchymal Chondrosarcoma.* This subtype tends to be more aggressive locally and has a higher rate of metastasis. Survival tends to be lower as a consequence, and it is most commonly managed with multimodality approaches. As noted earlier, this would ordinarily include a similar chemotherapy approach as used for osteosarcoma in addition to surgery and radiotherapy.[103]

## Ewing Sarcoma

***General Comments.*** Earlier, we mentioned that this tumor is exceptionally rare in the head and neck. The disease afflicts children predominately but is rarely seen below the age of 5 and in patients older than 30 years. About 25% of patient present with distant metastasis, most often to bone.

Multimodality treatment is strongly recommended consisting of external-beam radiation, and/or surgery, and multiagent chemotherapy. We cannot emphasize too strongly the need for multidisciplinary assessments in such patients from the start, especially to make sure that the disease is adequately documented with CT and MRI before treatment is initiated. Chemotherapy is usually the first intervention, and it is usually several months before radiotherapy or surgery is performed. By that time the situation will have changed and the true areas of risk may long since have been disguised in the chemotherapy response.

Although radiotherapy is highly effective, recent evidence has drawn attention to the problem of local failure in bulky disease, effects on bone growth, and second malignancies following radiotherapy.[112] Surgery should therefore also be considered in the management of different situations. We would emphasize that, with the current state of knowledge, chemotherapy alone should not be regarded as a standard to control gross tumor.

A recent report of a small series from the University of Florida has emphasized a strong role for radiotherapy in combination with multidrug chemotherapy instead of tumor debulking surgery when oncologic excision is not possible.[17] These authors also advocate strongly for achieving local control irrespective of treatment modality and local management philosophy. In essence, they suggest that local control may have a role in reducing distant metastasis which was exceptionally uncommon in their series of head and neck Ewing sarcoma.[17]

***Radiotherapy.*** Appropriate radiotherapy target volumes should include the entire bone that was involved as well as any extraosseous soft tissue component of the tumor. Treatment planning should be based on the original tumor volume before chemotherapy. Classically, an initial 5-cm margin beyond disease and bone has been recommended for Ewing sarcoma.[113] However, as in STS and chondrosarcoma head and neck planning, this needs to be tailored to the suitability of the anatomic region. Care must be taken to protect critical organs in the head and neck and the "classic" approach will rarely be used. Additional boost to the original area of visualized gross disease is also highly recommended.

Whenever a partial bone resection is undertaken, radiotherapy is indicated to the microscopic areas and a boost applied to any gross residual disease as noted above.

Doses of radiotherapy should exceed 50 Gy in 1.8 to 2 Gy per fraction for gross disease and need to be tailored to the critical organs at risk, the bulk of disease at the start of chemotherapy, the response to chemotherapy, and how complete any contemplated resection may be. Generally conventional daily fractionated radiotherapy is used, but studies of smaller dose per fraction altered fractionation are being tested to assess ability to minimized late-responding tissue damage.

***Surgery.*** Surgery should allow radiotherapy to be avoided entirely in low-volume disease. Concern about resection margins is an indication that radiotherapy is needed, which hopefully can be administered with lower dose as the gross disease will have been resected. This may be particularly helpful in the vicinity of critical anatomy and, in that circumstance, a preoperative radiotherapy approach may have advantages for the reasons described earlier for other tumors. We feel that very large disease is an indication for combined treatment (surgery and radiotherapy), but small volume disease is best managed with radiotherapy as the sole local modality unless disease is limited and surgery can be accomplished with wide margins obviating the need for radiotherapy. Alternatively, where radiotherapy is compromised with respect to dose and/or volume considerations, surgery should also be considered.

***Chemotherapy.*** Chemotherapy is critical to the improvements that have been seen in the management of Ewing sarcoma in recent decades. The classical approach is a five-drug regimen of vincristine, doxorubicin, and cyclophosphamide alternating with ifosfamide and etoposide.[114] Most recently, interval compression of chemotherapy delivered every 2 weeks has demonstrated improvement in 5-year event-free survival from 65% to 73%.[115] The treatment of head and neck Ewing tumors would follow the same principles as tumors located at other sites with local control being offered prior to completing the first half of chemotherapy.

# MANAGEMENT OF LOCAL RECURRENCE AND METASTASIS

This important area is discussed in the context of local recurrence following definitive local management. In some situations, this may be associated with regional lymph node (rarely) or with distant metastasis. More commonly, distant metastasis will manifest as disease confined to the lungs as the first manifestation of recurrence. In general, distant metastasis at presentation should be approached using similar principles.

## Local Recurrence

***General Approach.*** Appropriate treatment of an isolated local sarcoma recurrence can result in cure, or prolonged disease-free survival, and the approach to management should be similar to that taken with a primary tumor. However, effective management is often complex and influenced by tumor location and extent, and any prior local therapy. We have outlined an approach to the evaluation and management of locally recurrent soft tissue sarcoma (Table 29.12).[116] Assessment must include a knowledge of all prior surgery, including resection margins achieved as well as previous radiotherapy and chemotherapy. A biopsy is necessary both to confirm the diagnosis and to determine change in tumor character from the original lesion.

***Adjuvant "Naïve" Recurrence.*** In patients with STS not previously treated with radiotherapy or chemotherapy, combined modality therapy should be used especially because these can generally be administered safely. In STS, the potential for adjuvant chemotherapy to enhance local control may mean it could have a role in local salvage as it is improbable that it was used initially. In osteogenic sarcoma, this should include consideration of induction chemotherapy as described earlier for primary tumors and additional radiotherapy considered if resection margins remain a concern. In the case of soft tissue sarcoma and chondrosarcoma, we would generally recommend preoperative radiotherapy because of the better opportunity to spare critical structures since there is limited opportunity for tissue sparing due to prior resection of tissues in addition to contamination by previous surgery. Adequate postoperative radiotherapy following further surgery would also be appropriate but more problematic.

***Recurrence with Prior Adjuvant Therapy.*** For previously treated lesions, individualization is needed. Prior irradiated STS and chondrosarcomas would generally undergo tumor bed implantation with brachytherapy catheters in conjunction with a wide local excision. If resection margins are closer than 1 cm, brachytherapy is administered 5 to 7 days postoperatively. Osteosarcomas

**TABLE 29.12 Schema for the Management of Locally Recurrent Sarcoma**

| Context of Local Recurrence | Recommended Approach |
|---|---|
| No prior chemotherapy and/or radiotherapy | Consider combined approach with external-beam radiotherapy. In osteogenic sarcoma, consider induction chemotherapy with pathologic response assessment |
| Prior radiotherapy | Combined approach with brachytherapy |
| Critical structure involvement | Consider preoperative radiotherapy |
| | Ablative approach may need to be considered |
| In the presence of metastases | Multiple metastases—palliative treatment possibly including aggressive local treatment |
| | Few resectable metastases—local management as for nonmetastatic context with metastasectomy |

*Source:* Modified from Catton C, Swallow CJ, O'Sullivan B. Approaches to local salvage of soft tissue sarcoma after primary site failure. *Semin Radiat Oncol.* 1999;9:378–388, with permission.

should undergo chemotherapy if this is still possible bearing in mind prior treatment. This is followed by resection and potentially additional radiotherapy considered if resection margins remain a concern as radiotherapy is unlikely to have been used at initial management.

***Local Recurrence with Metastasis.*** Concurrent metastases are occasionally identified with local relapse. Patients who recur with multiple symptomatic metastases after a short disease-free interval are best managed with palliative approaches. Aggressive surgical palliation is rarely indicated in this situation, but local excision of a small or superficial recurrence may delay or prevent the development of local complications. The occasional patient presenting with local recurrence and limited systemic disease may benefit from aggressive treatment, especially after a long disease-free interval. This should include local salvage according to the principles outlined above, in addition to consideration of metastasectomy as described below.

## Metastatic Disease

***Surgery for Metastases.*** Sarcomas of both bone and soft tissue show an unusual predilection for metastasis to the lung, including disease isolated to the chest at presentation or recurrence. In selected cases, pulmonary metastasectomy has the potential to be a curative although distant disease at other sites is unlikely to be cured, excepting soft tissue metastasis in liposarcoma. However, treatment of metastatic bone disease is unfortunately palliative.

***Chemotherapy for Metastases.*** Systemic therapy is available in the metastatic setting though the choice of drug and timing of treatment initiation in incurable, locally advanced or metastatic STS remains debatable. Bramwell et al. performed a meta-analysis on data on 2,281 participants from eight Randomized Clinical Trials (RCTs) from reports of single-agent doxorubicin versus doxorubicin-based combination chemotherapy and concluded that single-agent doxorubicin was the optimal therapy. Median survival ranged from 7.7 to 12.0 months with single-agent doxorubicin ranged and 7.3 to 12.7 months with combination chemotherapy.[117] Recently, a randomized trial confirmed that a novel tyrosine kinase inhibitor, pazopanib, improved the disease-free and overall survival of patients with metastatic STS.[118] Pazopanib is now approved for use in patients with advanced sarcoma in the United States.

Advanced osteosarcoma remains difficult to treat, and chemotherapy alone does not appear to be curative for inoperable metastatic disease. There have been no controlled studies designed to demonstrate the benefit of chemotherapy at recurrence in terms of adding to salvage rates. Also, unlike the case for many STS cases, many osteosarcoma patients will already have been treated with active agents.

***Recommendation for Individual Patients with Metastases.*** In the absence of additional data, and in view of the potential to salvage a modest number of patients, pulmonary metastasectomy may also be considered in appropriate patients. Generally, we choose patients with a long disease-free interval (preferably at least 2 years from initial treatment), relatively few lesions (>4 lesions is less likely to be successful), and where clear margins are likely to be obtained. Occasionally, postoperative radiotherapy is administered for microscopic residual disease in an accessible site using similar principles to those described for radiotherapy of primary lesions. Appropriate cases should be identifiable through regular surveillance chest imaging following prior treatment of the primary tumor. We also advise resection for bilateral as well as unilateral disease recognizing that the latter is more likely to be favorable. Systemic therapy may also be used to control disease progression especially if symptomatic in otherwise fit and usually young patients. Resection may be considered subsequently.

In practice, it is often beneficial to allow a period of observation once metastases have been detected prior to any intervention to appreciate the biology of the disease. This is because additional initial subclinical metastases may manifest subsequently, thereby permitting selection of the more favorable cases that may benefit from resection. The thoracic surgeon must also determine whether a lateral thoracotomy approach should be chosen versus a median sternotomy as the latter provides the opportunity to examine both lungs for additional palpable lesions that may not have been detected by imaging.

# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett

Almost all varieties of sarcoma occur in the head and neck, and virtually all warrant imaging prior to treatment. When the tumor is small, the site of origin can often be determined, such as bone or muscle, which can help predict the pathology, but biopsy will nevertheless be required. Fine-needle aspiration is often inadequate for diagnosis, thus a core biopsy or open biopsy may be required. When an image-guided core biopsy is performed, the needle tract should be documented, as well as the skin entry site, as there is the potential for seeding of tumor and the surgeon may elect to resect the tract.

As with all tumors of the head and neck, the goal of imaging is to reveal the full extent of local disease, the presence of cervical lymphadenopathy, and the presence of distant metastases, so that an optimal treatment plan can be made. For certain sarcomas, complete resection of the tumor is a primary goal for improved prognosis when there are no distant metastases,[1,2,3] and imaging is used to guide the surgeon. Often CT and MRI are complementary. CT is superior for visualizing bony destruction as well as the tumor matrix. MRI is better at visualizing the soft tissue boundaries of the lesion, although often this can be difficult when there is peritumoral edema.

Rhabdomyosarcoma is the most common malignancy of striated muscle cell origin in the head and neck[4] and certainly the most common in children.[5] About one-third arise in the orbit and the rest elsewhere in the head and neck. They are typically not surgical lesions, but are treated with combined chemotherapy and radiation therapy. Defining the full local extent of the tumor on imaging studies is thus essential for setting up the radiation fields. These tumors are most often very bright on T2-weighted images, are isointense to muscle on T1-weighted images, and enhance with contrast (Fig. 29-15). Necrosis is commonly seen in larger tumors (Fig. 29-16). Other malignant mesenchymal sarcomas are rare. One such tumor is the synovial cell sarcoma, which despite its name does not arise from joints (Fig. 29-17).

Osteosarcomas have a very characteristic imaging appearance on CT where the bone is destroyed and replaced by tumor which grows an osteoid matrix (Fig. 29-18). A sunburst periosteal reaction can often be seen. Adjacent soft tissue invasion is common. On MRI, the calcified osteoid matrix is dark on T1- and T2-weighted images (Fig. 29-19).

Chondrosarcomas have a different matrix as seen on noncontrast CT. This matrix typically consists of thin arcs and rings of calcium (Fig. 29-20), although not infrequently no matrix will be seen in the lesion. On MRI, the characteristic feature is the very high signal seen on T2-weighted images. These lesions are more commonly seen at the skull base, usually laterally at the petroclival fissure (Fig. 29-21).

Postradiation sarcomas can be seen in the head and neck, typically 10 to 20 years following treatment. These lesions usually have a different appearance from the original tumor, raising suspicion for a radiation-induced sarcoma (Fig. 29-22). Debnam et al.[6] published a useful paper about the spectrum of imaging findings seen in radiation-induced sarcomas.

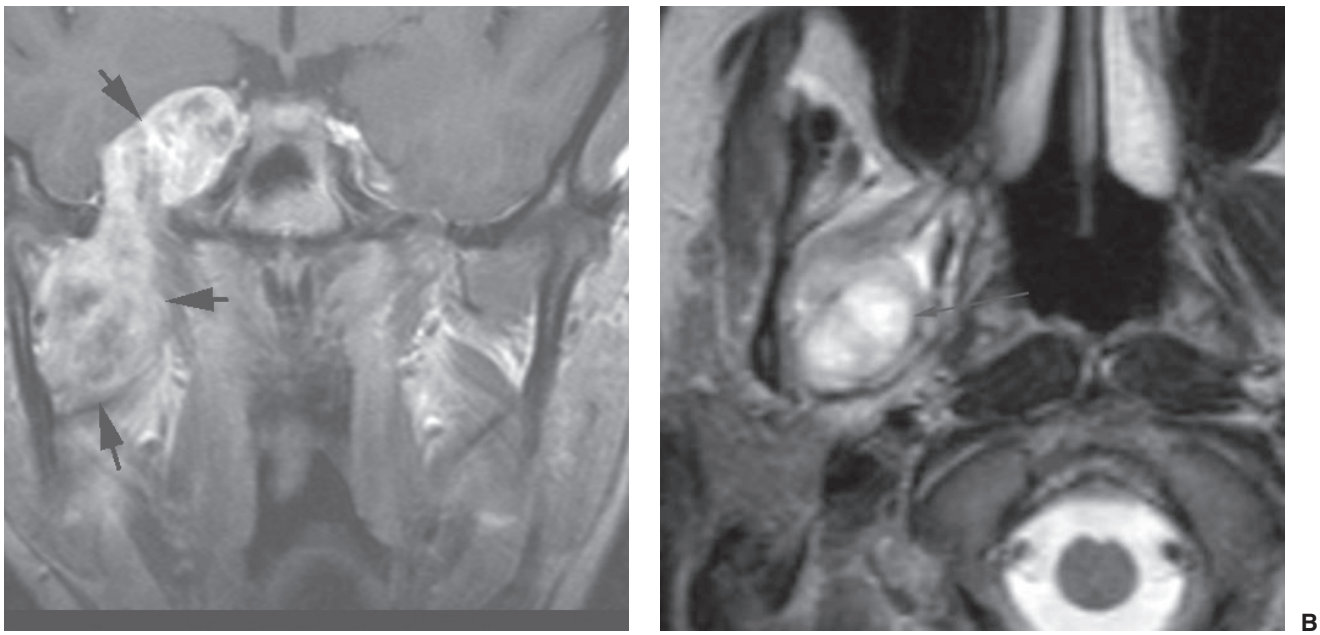

**FIGURE 29-15. A:** Coronal postcontrast MRI shows an avidly enhancing rhabdomyosarcoma (*arrows*) that spread along V3 through foramen ovale. **B:** Axial T2-weighted MRI shows the typical very high signal (*arrow*) seen in rhabdomyosarcomas.

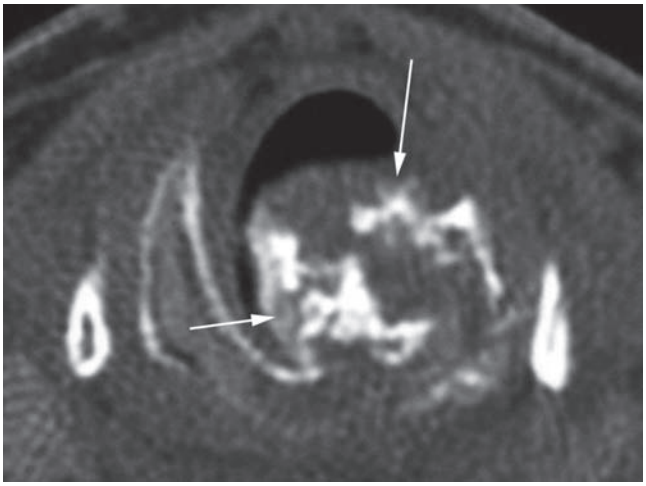

**FIGURE 29-20.** Axial noncontrast CT scan shows a chondrosarcoma of the cricoid cartilage which demonstrates rings and arcs (*arrows*) of calcified matrix.

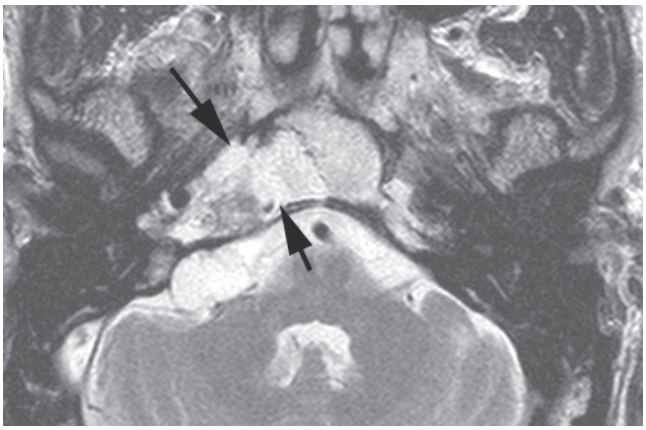

**FIGURE 29-21.** Axial T2-weighted MRI of a chondrosarcoma centered at the petroclival fissure. This lesion is very bright on T2-weighted images.

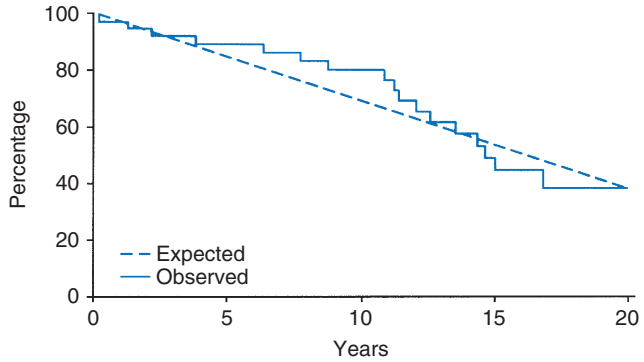

**FIGURE 29-22.** Treatment-related sarcoma. Enhanced axial computed tomography of the mid neck shows a heterogeneously enhancing mass (*arrows*) that developed within the irradiated field several years after nasopharynx cancer. Neck dissection yielded malignant fibrous histiocytoma.

Soft tissue sarcomas of the head and neck have variable radiotracer uptake on FDG-PET, which limits its use for surveillance imaging posttreatment for certain sarcomas. Metabolic activity correlates with the grade of malignancy.[7]

CHAPTER 30

Matthew G. Fury and David G. Pfister

# Systemic Targeted Therapy for Recurrent and Metastatic Head and Neck Squamous Cell Cancer

This chapter reviews chemotherapy options for patients with recurrent and metastatic (R/M) head and neck squamous cell cancer (HNSCC) and discusses several avenues of clinical research for this patient population.

For locoregional recurrence of disease, surgical resection or ablative procedures may provide long-term disease control in a minority of patients.[1] In select patients, reirradiation may be applied, although most patients do not experience durable disease control.[2] Further details regarding resection and reirradiation are noted elsewhere in other chapters. Selected patients with limited metastatic lesions may also be considered for surgical resection if their performance status allows, or ablative procedures if surgery is not planned.[3–4]

For patients with R/M disease that is not deemed suitable for local therapy, systemic therapy given with palliative, not curative, intent is appropriately considered. In patients with lung-only metastasis(es), it may be difficult to clearly distinguish metastatic disease from a new lung primary. Clinical factors may help differentiate these two possibilities. For patients in whom the primary was an oropharynx tumor associated with the human papillomavirus (HPV), detection of HPV in the lung lesion can be used to help establish the diagnosis of metastatic disease.[5]

As reviewed later in this chapter, several drugs have activity in HNSCC. However, no single chemotherapeutic agent has consistently or conclusively demonstrated superiority in terms of overall survival when compared with another drug in randomized clinical trials. It should be noted that the interpretability of some randomized trials, particularly the older ones, is compromised by modest sample sizes that increase the risk of false negative results. The selection of systemic therapy for patients with R/M HNSCC takes into account many variables, including patient's performance status, medical comorbidities, and prior treatment history.[6] For example, single-agent palliative therapy may be appropriate for minimally symptomatic patients with low-volume disease or frail patients with a decreased performance status, whereas doublet or triplet chemotherapy regimens may be appropriate for fit patients with more symptomatic or higher-volume disease. Table 30.1 lists clinical factors that appear to predict outcomes among patients with R/M HNSCC.[7–10] Tumor status with regard to the presence or absence of the HPV has robust associations with response to therapy, and prognosis in patients with locally/regionally advanced disease,[11] but the potential impact of HPV status on outcomes in the R/M disease setting has not been clearly established.

## CONVENTIONAL CYTOTOXIC AGENTS

### Platinum Agents and Antimetabolic Agents

Cisplatin was among the first agents to demonstrate significant activity against HNSCC.[11] A randomized phase III trial with a $2 \times 2$ factorial design ($n = 116$ subjects) compared (a) cisplatin, (b) bleomycin, (c) cisplatin + bleomycin, and (d) no chemotherapy.[13] Among all patients treated with chemotherapy, the response rate was 25%. Treatment with cisplatin versus "no chemotherapy" was associated with a 10-week improvement in median overall survival.[12] Subsequent studies generally have not included a "no chemotherapy" group, due to both logistical and ethical concerns about such designs after this initial proof-of-principle.

Cisplatin and methotrexate have antitumor efficacy as single agents for patients with advanced HNSCC. In a randomized comparison ($n = 44$ patients) of cisplatin versus methotrexate in patients with recurrent HNSCC, response rates (P, 29%; M, 24%) and median survivals (~ 6 months) were similar in both arms.[14] Cisplatin and methotrexate yielded comparable median survival times (18 and 20 weeks, respectively) in a randomized study for patients ($n = 100$) with advanced head and neck cancer.[15]

The PF (cisplatin, 5-fluorouracil) regimen achieved a response rate of 70% in a single-institution study,[16] although response rates were lower in subsequent studies. A three-arm randomized comparison of (PF vs. P vs. F, $n = 249$ subjects) demonstrated superior response rate in the PF group (PF, 32%; P, 17%; F, 13%), but hematologic toxicity was also higher for PF, and median survival was approximately 5.7 months for all study arms.[17]

Cytotoxic chemotherapy combination regimens historically have yielded higher objective response rates compared with monotherapy, but generally do not improve overall survival for patients with R/M HNSCC. The combination regimens, generally, are associated with increased treatment-related toxicities compared with monotherapy, which is a major concern in the palliative setting. For example, the EORTC randomized 382 subjects patients with R/M HNSCC to either PF versus CABO (cisplatin, methotrexate, bleomycin, and vincristine) versus cisplatin monotherapy.[18] PF and CABO yielded the higher response rates (PF, 31%; CABO, 34%; P, 15%) at the expense of greater hematologic and nonhematologic toxicity, but there was no significant difference in overall survival among the three arms.

Carboplatin is generally well tolerated and may be preferable to cisplatin due to favorable adverse event profile as palliative

therapy for some patients with advanced head and neck cancer. In a phase II study for patients ($N = 31$) with R/M HNSCC, carboplatin monotherapy was associated with a response rate of 26%.[19] In a subsequent study, carboplatin achieved a response rate of 24% among 29 subjects with recurrent HNSCC.[20]

A three-arm randomized trial ($n = 261$ subjects) compared PF versus carboplatin plus 5-fluorouracil (CbF) versus methotrexate (M).[21] The starting Cb dose was 300 mg/m$^2$, with guidelines for carboplatin dose escalation to achieve grade 2 myelosuppression. Response rates by group were PF 32%, CbF 21%, and M 10%. Adverse events were also more common in the PF group, and there was no significant difference in median overall surival between the three groups. Limitations of this study include (a) it was not statistically powered to provide a definitive comparison of PF versus CbF, (b) it used a dosing strategy Cb that is not used widely in clinical practice, and (c) the PF schedule was every 3 weeks and the CbF schedule was every 4 weeks.[21]

Table 30.2 summarizes results from selected clinical trials involving platinum-based regimens for patients with R/M HNSCC.

## Paclitaxel and Docetaxel

Early nonrandomized studies of taxane monotherapy demonstrated impressive objective response rates (paclitaxel, 40%; docetaxel 42%) among patients who had not received prior chemotherapy for R/M HNSCC.[22,23] The combination of cisplatin

plus paclitaxel (PT) was compared with PF in a randomized study ($n$ = 218 subjects). No significant difference in response rate (PF, 27%; PT, 26%) or overall survival (PF, 8.7 months; PT group, 8.1 months) was observed between the two groups. Gastrointestinal and hematologic toxicities were less common with PT.[24] PT and PF both became accepted as palliative regimens for patients with R/M HNSCC. In the context of concerns about the tolerability of cisplatin-based chemotherapy among some patients with R/M HNSCC, carboplatin plus paclitaxel has been evaluated in phase II studies, both in every 3 week[25,26] and weekly[27] dosing schedules. However, there has not been a rigorous prospective comparison versus cisplatin-based doublets in this patient population.

Another attempt to improve chemotherapy results has been the utilization of three-drug combinations utilizing a third drug in addition to a platinum compound and a taxane. TIP (paclitaxel, ifosfamide, cisplatin),[28] TIC (paclitaxel, ifosfamide, carboplatin),[29] and modified TPF (docetaxel, cisplatin, 5-fluorouracil)[30] were associated with encouraging response rates in (44%–59%) in phase II studies, but median survival times (8.8–11 months) were not clearly superior to those achieved with doublet chemotherapy with R/M disease.[24]

## Other Cytotoxic Agents that Have Been Evaluated for R/M HNSCC

Weekly vinorelbine achieved response rates of 7.5% and 16% in two phase II studies and was generally well tolerated.[31,32] Ifosfamide monotherapy also demonstrated palliative activity (response rates 4%–26%) in R/M HNSCC patients who had received prior chemotherapy.[33]

Pemetrexed is a multitargeted antifolate, which inhibits multiple enzymes involved in both pyrimidine and purine synthesis, including thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyl transferase (GARFT). Gemcitabine is a pyrimidine antimetabolite, which is anabolized into a diphosphate form, which inhibits ribonucleotide reductase and a triphosphate form which is incorporated into the DNA, thereby blocking DNA replication.

A phase II study evaluated pemetrexed (500 mg/m$^2$ IV q21 days) in 35 patients with locally advanced or metastatic HNSCC not amenable to curative surgery or radiotherapy. Patients did not receive supplementation with vitamin B12 or folate. The objective response rate was 27% and median overall survival was 7.3 months.[34] The activity of pemetrexed against HNSCC might be viewed as somewhat surprising, in view of the apparent low efficacy of this agent against squamous cell cancer (SCC) of the lung.[35] This discordance underscores the risks of assuming that the activities of chemotherapeutic agents against R/M HNSCC and against SCC of lung will always be similar.

In R/M HNSCC, gemcitabine monotherapy was evaluated in two phase II trials. In a study of 47 patients with R/M HNSCC, the overall response rate was 13%.[36] In a more recent trial, no objective responses were seen among 26 patients with R/M HNSCC.[37] The results of these two small studies indicate that the activity of single-agent gemcitabine is low in R/M HNSCC, and gemcitabine monotherapy is rarely used in the management of these patients. It should be noted, however, that gemcitabine is an active drug in patients with R/M nasopharynx cancer and is regularly used in this disease setting.[38,39]

Based on preclinical evidence of synergy and encouraging phase I results[40] the combination of gemcitabine and pemetrexed was evaluated in phase II studies in this patient population. In a study for 25 patients with R/M HNSCC, pemetrexed plus gemcitabine was administered every 2 weeks with vitamin support. Treatment was generally well tolerated, but the objective response rate was only 16%, indicating no evidence of additive or synergistic effects with these two drugs.[41] Similarly, in another study of pemetrexed plus gemcitabine q2W, only two responses (one confirmed) were seen among 17 patients with R/M HNSCC.[42]

Pemetrexed has shown encouraging efficacy when combined with bevacizumab[43] and remains of significant interest for further study. Pemetrexed plus cisplatin has been compared with cisplatin alone in a large, double-blind randomized trial in 795 patients with R/M HNSCC. There was no significant difference between the arms with regard to overall and progression-free survival, although on subset analyses, the combination arm had superior survival outcomes in performance status 0 and 1 patients and those with oropharynx primary tumors.[44] However, in the absence of randomized data to demonstrate superiority to other agents commonly used in the management of R/M HNSCC or a clear advantage when used in combination therapy, use of pemetrexed outside of a clinical trial in this patient population is not currently recommended.

Irinotecan resulted in objective responses in approximately 20% of subjects as first-line therapy for R/M HNSCC, but was not active as second-line therapy.[45] Neither vinorelbine, ifosfamide, nor irinotecan has been evaluated in a randomized phase III study for R/M HNSCC. Older cytotoxic agents such as bleomycin, vinblastine, cyclophosphamide, and adriamycin also have activity,[46] but these agents have largely been supplanted in the contemporary era by the platinum agents, taxanes, 5-fluorouracil, methotrexate, and cetuximab (Table 30.3).

## Antiepidermal Growth Factor Receptor Agents

The epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase that is expressed by most HNSCC tumors, and high levels of EGFR expression are associated with inferior clinical outcomes.[47,48] The receptor can be activated by a variety of ligands, including EGF, transforming growth factor alpha (TGF-α), and amphiregulin. The activated receptor forms homodimers or heterodimers with other ErbB family members, resulting in activation of the tyrosine kinase domain, stimulation of cell DNA synthesis, and cell proliferation through stimulation of multiple pathways. Two strategies of EGFR inhibition have been studied in clinical trials: monoclonal antibodies directed against the outer domain of the EGFR and small molecule inhibitors of the intracellular tyrosine kinase domain. Cetuximab is the only EGFR-targeting agent with approval from the United States Food and Drug Administration for the treatment of HNSCC.

Cetuximab, a human-murine chimeric immunoglobulin G (IgG1) monoclonal antibody, binds to the extracellular domain of EGFR.[49] As weekly monotherapy (400 mg/m$^2$ loading

**TABLE 30.3 Chemotherapeutic Agents Commonly Used in the Management of R/M HNSCC**

| Class | Agent |
|---|---|
| Platinum | Cisplatin, carboplatin |
| Taxane | Paclitaxel, docetaxel |
| Antimetabolite | 5-Fluorouracil, methotrexate |
| EGFR inhibitor | Cetuximab |

(c) 2014 Wolters Kluwer. All Rights Reserved.

dose, followed by 250 mg/m$^2$ weekly) for patients with advanced platinum-refractory HNSCC, cetuximab achieves objective radiographic response rates of 10% to 13% in phase II studies.[50,51] Similar efficacy and tolerability has been observed with single-agent cetuximab 500 mg/m$^2$ every 2 weeks for patients with R/M HNSCC.[52]

A randomized phase III study compared cetuximab plus cisplatin versus placebo plus cisplatin among 123 patients who had not received any prior chemotherapy for R/M HNSCC. Objective response rate favored the cetuximab arm (26% vs. 10%, $p = 0.03$), but progression-free survival and overall survival did not differ significantly between the groups.[53]

However, in a larger randomized trial, cetuximab improved the efficacy of standard platinum-based chemotherapy for patients with R/M HNSCC. The EXTREME trial randomized R/M HNSCC patients ($N = 442$) with either cisplatin or carboplatin plus 5-fluorouacil compared with the same chemotherapy options with the addition of weekly cetuximab, including 6 months of maintenance cetuximab among responding patients tolerating therapy in the latter arm. Choice of cisplatin or carboplatin was per investigator discretion. Patients had not received any prior therapy for R/M. The cetuximab plus platinum doublet, compared with the platinum doublet alone, was associated with a significantly improved response rate (36% vs. 20%), progression-free survival (5.6 vs. 3.3 months), and overall survival (10.1 vs. 7.4 months).[54]

Panitumumab is a fully humanized IgG2 monoclonal antibody directed against the extracellular domain of EGFR. A large (657 patients) randomized phase III study of the addition of panitumumab to the PF doublet was deemed negative because there was no significant improvement in overall survival associated with the addition of this antibody to the doublet.[55] Of interest, and discussed later in this chapter, on subsequent subset analysis, survival benefit was demonstrated in the HPV-negative subgroup as assessed by p16 status.

Zalutumumab, a fully humanized IgG1 anti-EGFR monoclonal antibody, was evaluated in a randomized phase III study for patients with noncurable HNSCC. Patients ($n = 286$) were randomly assigned to either weekly zalutumumab + best supportive care or best supportive care with optional methotrexate. Zalutumumab, versus the control group, did not result in a significant increase in overall survival (6.7 vs. 5.2 months, $p = 0.06$), which was the primary endpoint of the study.[56] As such, cetuximab remains the only monoclonal against EGFR that is commercially available for HNSCC patients in the United States.

Several inhibitors of the EGFR tyrosine kinase domain have been evaluated for patients with advanced HNSCC. In a phase II trial of gefitinib 500 mg/day ($n = 47$ subjects), the objective response rate was 10.6% and median survival was 8.1 months.[57] In a randomized phase III comparison with methotrexate, gefitinib (at either 500 or 250 mg/day) did not improve overall survival compared with methotrexate,[58] but the risk of tumor-hemorrhage events was greater on the gefitinib arms (11.4% and 8.5%, respectively) than with methotrexate (1.9%).

Erlotinib is an orally available, reversible, and selective inhibitor of the EGFR tyrosine kinase that is currently approved for the treatment of refractory non-small cell lung cancer (NSCLC). In a phase II study ($n = 115$ subjects), erlotinib yielded a major response rate of 4% among patients with R/M HNSCC.[59]

Preclinical studies have suggested that resistance to EGFR inhibitors may be related to activity of other ErbB family members.[60] Strategies to broadly inhibit ErbB signaling are being explored clinically. Lapatinib, a dual inhibitor of EGFR and ErbB2 tyrosine kinases, is commercially available for the treatment of some women with advanced breast cancer. In a phase II study for patients with R/M HNSCC (27 subjects with prior exposure to EGFR inhibitor and 15 subjects with no prior exposure to EGFR inhibitor), no objective responses were seen.[61] Afatinib, a potent inhibitor of the tyrosine kinase domains of EGFR, ErbB2, and ErbB4, is an investigational agent that is being studied for several tumor types. Afatinib was compared with cetuximab in a randomized phase II study for patients with R/M HNSCC ($n = 124$ subjects). The confirmed partial response rate was higher in the afatinib group versus the cetuximab group, but progression-free survival did not differ between the two arms.[62]

## CLINICAL RESEARCH REGARDING NOVEL MOLECULAR TARGETS

### PI3 Kinase/Akt/mTOR Pathway

EGFR and other transmembrane receptors converge to control a variety of intracellular signaling pathways, such as the phosphoinositide-3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway. Activation of the pathway may be due to somatic mutation in the gene encoding the catalytic subunit of PI3K (*PIK3CA*), activation of receptor tyrosine kinases upstream of PI3K, loss or inactivation of the PTEN suppressor gene, or genetic lesions in Akt or other downstream signaling molecules.[63–65] The mTOR, a serine/threonine kinase, is a major downstream effector that resides in two multiprotein complexes (mTORC1 and mTORC2) that regulate transcription, protein translation, metabolism, cell growth, and survival.[66]

The importance of the PI3K/Akt/mTOR pathway in HNSCC was demonstrated in a study by the Head and Neck Cancer Tissue Array Initiative.[67] The tissue microarray ($n = 547$ cores) was interrogated with antibodies directed against key signaling molecules in head and neck cancer, including p53, the EGFR, and components of the Akt-mTOR pathway. Alterations of the PI3K/Akt/mTOR pathway were found in most cases. Expression levels of phosphorylated AKT and pS6 were significantly higher in HNSCC tumors, compared with normal mucosa, across all degrees of differentiation. An unsupervised clustering approach demonstrated that the pathway often appeared to be activated in the setting of negative staining for phosphoryated EGFR.[67] This suggests that activation of the PI3K/Akt/mTOR pathway may occur independently of EGFR activation in many HNSCC patients, although the inherent technical limitations of immunohistochemistry prevent any definitive conclusions. These findings may provide insight into the relatively low-to-modest clinical efficacy of EGFR inhibition strategies in this disease[68] and suggest that downstream inhibition of mTOR merits further study as a potential therapeutic strategy in HNSCC.

Rapamycin, the prototypic mTORC1 inhibitor, demonstrates modest antiproliferative effects against HNSCC cell lines, with IC50s in the range of 5 to 20 $\mu$M.[69] In HNSCC xenografts, dramatic tumor growth inhibition was achieved with temsirolimus[70] or rapamycin.[71] Because it is probable that mTOR inhibitors will have no better than modest clinical activity against HNSCC when given as single agents, the true utility of these agents may derive from their ability to potentiate the antitumor effects of other cytotoxic chemotherapeutic agents.

In 1995, Mills and coworkers reported that rapamycin enhanced the cytotoxic effects of cisplatin against a human leukemia cell line (HL-60) and an ovarian cancer cell line (SKOV3).[72] Subsequent preclinical studies demonstrated additive or synergistic effects when mTOR inhibitors were combined with platinum or taxane chemotherapy agents in studies of NSCLC, breast cancer, and HNSCC cell lines.[69,73,74] mTORC1 inhibition appears

(c) 2014 Wolters Kluwer. All Rights Reserved.

to reverse resistance to paclitaxel in a cervical cancer cell line (CaSki)[75] and cisplatin in a lung cancer cell line (SCLCSR2).[76]

Temsirolimus and everolimus are two mTORC1 inhibitors that are commercially available for the treatment of patients with advanced renal cell carcinoma (everolimus also has an indication for progressive neuroendocrine tumors of pancreatic origin) and are under investigation for patients with head and neck cancer and other malignancies. In a phase I study of everolimus + low-dose weekly cisplatin, partial response was observed in one patient with sinus carcinoma metastatic to lung, and prolonged stable disease was observed in a patient with metastatic oropharyngeal squamous cell carcinoma.[77] Weekly everolimus was well tolerated when combined with weekly paclitaxel in a phase I study, and no significant pharmacokinetic interaction between the mTOR inhibitor and paclitaxel was identified.[78] In a pharmacodynamic study, the ability of temsirolimus to inhibit mTOR activity was demonstrated in posttreatment tumor biopsies with reduced expression of two key signaling molecules downstream of mTORC1, pS6, and p4E-BP1.[79] A phase I/II study of temsirolimus, plus weekly carboplatin and paclitaxel, recently completed the dose-escalation portion of the study and is enrolling patients on the phase II portion of the study (ClinicalTrials.gov identifier: NCT01016769).

One potential mechanism of resistance to mTOR inhibitors such as temsirolimus appears to involve enhanced phosphorylation of Akt due to loss of negative feedback of S6 kinase on growth factor receptors.[80,81] Enhanced phosphorylation of Akt during treatment with mTOR inhibitors has been demonstrated in cancer cell lines and in patients with glioblastoma, breast cancer, and colorectal cancer.[80,82]

Enhancement of Akt phosphorylation inhibits apoptosis by at least two mechanisms, both of which involve stabilization of members of the Bcl-2 antiapoptotic family of proteins (Bcl-2, Bcl-xL, Mcl-1). First, there is indirect evidence that Akt stabilizes Mcl-1. Stabilization of Mcl-1 during treatment of cells with rapamycin appears to coincide with feedback activation of Akt.[83,84] Second, a downstream effect of enhancement of phosphorylation of Akt is enhancement of phosphorylation of eIF4E, which regulates cap-dependent translation of Bcl-2 family members.[81] Preclinical evidence demonstrates that eIF4E promotes cell survival by enhancing translation of Bcl-2, Bcl-xL, and/or Mcl-1 in cancer cell lines.[85,86]

To overcome resistance to mTOR inhibitors, preclinical models have explored combined inhibition of mTOR and the Bcl-2 family of proteins. In small cell lung cancer cell lines that are resistant to rapamycin, reduction of Bcl-2 expression (either with an antisense construct or a Bcl-2 specific inhibitor) rendered the cells sensitive to apoptosis with rapamycin treatment.[87] In a murine xenograft model of NSCLC, combined treatment with rapamycin and ABT-737 (an inhibitor of Bcl-2 and Bcl-xL) in the setting of radiation therapy (RT) achieved significantly greater tumor growth delay, compared with radiation therapy plus either drug alone.[88]

In summary, resistance to mTOR inhibition may be associated with paradoxical activation of Akt and eIF4E due to loss of negative feedback, resulting in increased translation and/or stabilization of antiapoptotic Bcl-2 family members. In preclinical models, downregulation or inhibition of Bcl-2 family members sensitizes cancer cell lines and xenograft tumor models to rapamycin-induced apoptosis.[87–91] As such, one research strategy to overcome resistance to mTOR inhibition would be to combine with inhibitors of Bcl-2 family of proteins.

The foregoing considerations have focused on mTOR and downstream components of the pathway. More recently, direct inhibitors of the upstream portion of the PI3K/Akt/mTOR pathway have entered early clinical studies. These include pure PI3K inhibitors such as BKM120 and GDC-0941,[92–94] dual PI3K/mTOR inhibitors such as BEZ235 and PKI-587,[95–97] and Akt inhibitors such as MK-2206.[98] All of these compounds are of significant interest for further study in HNSCC. Figure 30-1 is a simplified representation of the PI3K/Akt/mTOR pathway that includes pharmacologic inhibitors of key signaling proteins in the cascade.

## Angiogenesis

Increased tumor expression of vascular endothelial growth factor A (VEGF-A) is associated with a poor prognosis in HNSCC. In a meta-analysis of 12 studies which evaluated VEGF-A expression in HNSCC ($n$ = 1,002 patients), VEGF-positivity was associated with a 1.88-fold higher risk of death at 2 years.[99] Preclinical and

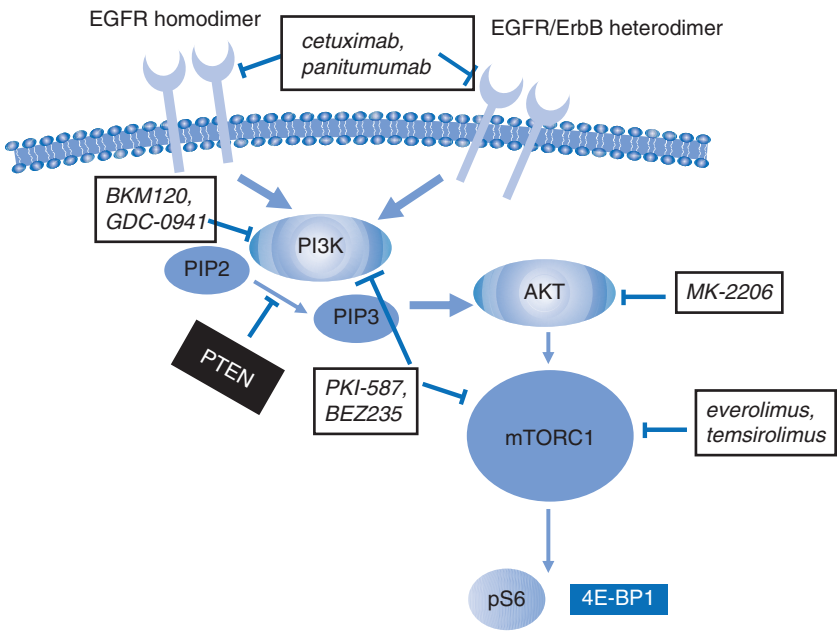

**FIGURE 30-1.** Simplified schematic illustration. EGFR homodimers and EGFR/ErbB heterodimers activate PI3 kinase, which favors the conversion of phosphatidylinositol bisphosphate (PIP2) to phosphatidylinositol triphosphate (PIP3), with subsequent activation of Akt and mTORC1. Two well-characterized phosphorylation targets of mTORC1 are eIF4E-binding protein (4E-BP1) and p70 S6 kinase 1 (S6K1), which regulate translation of proteins required for G1-S phase progression in the cell cycle. Monoclonal antibodies directed against the extracellular domain of EGFR (e.g., cetuximab, panitumumab) represent the most clinically advanced strategy to inhibit this pathway in HNSCC at present. Small molecules to inhibit intracellular processes in this cascade are under investigation, including PI3 kinase inhibitors (e.g., BKM120, GDC-0941), Akt inhibitors (e.g., MK-2206), mTORC1 inhibitors (everolimus, temsirolimus), and dual PI3 kinase/mTOR inhibitors (PKI 587, BEZ235), among others. (See color insert.)

(c) 2014 Wolters Kluwer. All Rights Reserved.

early clinical studies support a model in which cross-talk between EGFR and VEGF pathways enhances tumor growth and angiogenesis in HNSCC. In studies with the A431 squamous carcinoma cell line, treatment with cetuximab resulted in dose-dependent reduction of VEGF expression *in vitro*.[100] In pilot data from a clinical study for patients with R/M HNSCC, the combination of cetuximab and bevacizumab yielded objective tumor responses in 4 of 15 (27%) evaluable patients.[101] Although preliminary, these data suggest that the combination of cetuximab and bevacizumab may yield additive efficacy in HNSCC.

The combination of cetuximab plus bevacizumab with chemotherapy has been associated with decreased efficacy in colorectal cancers harboring K-RAS mutations,[102] but K-RAS mutations are uncommon in HNSCC. In an analysis of 197 HNSCC specimens, K-RAS exon 12 mutations were encountered in 3.5% of cases.[103] These results are consistent with other smaller studies, which found that K-RAS mutation is uncommon in HNSCC.[104–106] These results argue against extrapolation of the clinical trial experience regarding cetuximab plus bevacizumab in colorectal cancer to HNSCC.

The combination of bevacizumab with EGFR inhibitors provides a research strategy to potentially improve efficacy. In a phase I/II study of bevacizumab + erlotinib for patients with R/M HNSCC, seven partial responses were observed among 48 evaluable patients in the phase II portion of the study. Three patients had serious bleeding events of grade III or higher. Among 11 patients with available tissue for research studies, higher baseline expression of phosphorylated VEGF receptor-2 in tumors and phosphorylated EGFR in endothelial cells appeared to be associated with efficacy.[107] In a phase II study for patients with R/M HNSCC, the combination of cetuximab + bevacizumab yielded a partial response rate of 18% (8 responses among 45 patients). Grade III hemorrhage occurred in 2 patients.[108] The Eastern Cooperative Oncology Group (ECOG) is currently conducting a randomized phase III study to evaluate the efficacy of bevacizumab added to standard chemotherapy for patients with R/M HNSCC (ClinicalTrials.gov identifier: NCT00588770).

Several small molecule inhibitors directed against the kinase domain of VEGF receptor 2 have been evaluated. Semaxanib (SU5416) yielded only one partial response among 31 patients with advanced head and neck cancer, and the median survival was 6.25 months.[109] Sunitinib is a potent inhibitor of the kinase domains of VEGF receptors 1, 2, and 3, PDGFR $\alpha$ and $\beta$, and KIT. It has been evaluated in three phase II studies for patients with R/M HNSCC, but two of these studies failed to provide any suggestion of clinically significant efficacy.[110,111] In the third study of sunitinib in advanced head and neck cancer ($n = 38$ subjects), there was one partial response and there were five unconfirmed partial responses, but there were four fatal hemorrhage events.[112] Sorafenib has a broad target profile, including potent inhibition of B-Raf and VEGF receptors 1, 2, and 3. Combining the results of two separate phase II studies of sorafenib for patients with advanced head and neck cancers,[113,114] there were only two partial responses among 67 patients evaluable for response, but treatment was generally well tolerated and there was evidence that this agent might merit further study due to the potential to achieve disease stabilization in some patients.

## Other Targeted Agents under Investigation in R/M HNSCC

Met is the transmembrane cell surface receptor for hepatocyte growth factor (HGF).[115] Hepatocyte growth factor appears to be secreted by stromal cells, leading to paracrine activation of HN tumors expressing Met.[116] Upon ligand binding, the receptor dimerizes and the intracellular tyrosine kinase domain is activated. Downstream effects can include activation of the PI3K/Akt pathway and the MAPK pathway, among others.[117] Met is expressed in most HNSCC tumors, and *MET* gene amplification was detectable in 13% (3 of 23) tumor tissues in one report.[118] Activating mutations in the tyrosine kinase domain have been described in approximately 10% to 12% of HNSCC tumors,[118,119] but the incidence of these mutations may be lower in primary tumors than in metastatic lesions.[120,121] Recent whole exome sequencing indicates that the incidence of *MET* mutations in primary HNSCC tumors is very low.[122,123]

Foretinib (formerly XL880) is an orally available multikinase inhibitor targeting inhibitor of Met, VEGF receptor 2, and others. Foretinib has been evaluated in a phase I study[124] and in a phase II study for patients with R/M HNSCC that recently completed accrual (NCT00725764). Preclinical studies suggest that the efficacy Met inhibition may be enhanced in the context of concurrent inhibition of EGFR, Src, or cytotoxic chemotherapy.[118,125,126] These combinations have not yet been tested in the clinic for patients with R/M HNSCC. Study of combined Met and EGFR inhibition in HNSCC may be particularly compelling, in view of the demonstration in NSCLC that *MET* amplification leads to resistance to EGFR tyrosine kinase inhibition.[127]

Src is a nonreceptor tyrosine kinase that regulates a wide variety of cellular processes including proliferation, survival, adhesion, motility, and invasion.[128,129] Increased Src activity has been detected in a variety of head and neck cancers and other tumor types.[129,130] Inhibition of Src activity in a human HNSCC cell line reduced cell proliferation and invasion in comparison with control cells.[131,132] In studies with dasatinib, a small molecule inhibitor of Src family kinases, HNSCC cell lines were markedly more sensitive to growth inhibition than were NSCLC cell lines.[133] Single-agent phase II trials of orally available Src kinase inhibitors saracatinib[134] and dasatinib[135] failed to demonstrate single-agent activity for either of these agents. However, based on preclinical data that Src may mediate resistance to cetuximab,[136,137] the combination of dasatinib and cetuximab is being evaluated in a phase II study for patients with advanced HNSCC (NCT01488318).

# PREDICTING RESPONSE TO TARGETED THERAPY

The development of rash during treatment with cetuximab appears to be associated with antitumor efficacy, but there are no clinical or molecular factors that can reliably predict which patients will benefit from cetuximab prior to the initiation of therapy. An association between the development of rash and favorable clinical outcome with EGFR inhibitor treatment has been described in many,[50,53,57,59] but not all,[54] studies of these agents in R/M HNSCC. Prophylactic treatment of rash has been associated with decreased incidence and intensity of dermatologic toxicity among colorectal cancer patients treated with panitumumab.[138] As such prophylactic management of skin toxicity becomes more widespread in clinical practice for patients with head and neck cancer, the clinical associations between rash and tumor response may become less evident.

Molecular markers to predict sensitivity or resistance to cetuximab are needed in R/M HNSCC. Mutations in *EGFR* are clinically useful predictors of response to EGFR tyrosine kinase inhibitors in lung cancer adenocarcinoma,[139] but *EGFR* mutations are uncommon in HNSCC in the Western world.[140] Other candidate biomarkers are being explored in this disease. *EGFR* gene amplification was not associated with outcomes in patients treated with a platinum doublet plus cetuximab in the EXTREME study.[141] It is possible that the contribution of cytotoxic

(c) 2014 Wolters Kluwer. All Rights Reserved.

chemotherapy may have confounded any association between gene amplification and response to cetuximab. It would be interesting to explore if *EGFR* gene amplification might be associated with efficacy in study of R/M HNSCC patients treated with cetuximab monotherapy.

EGFR variant III (EGFRvIII) contains an truncated extracellular EGF-binding domain and is under active study as a potential biomarker for response to EGFR inhibitors. The incidence of EGFRvIII in HNSCC tumors was 42% (14 of 33 specimens) in a single-institution retrospective study.[142] A recent study of R/M HNSCC tumors also detected EGFRvIII in 42% specimens and suggested that the presence of EGFRvIII may be associated with better disease control, independent of whether patients received erlotinib-based treatment or not.[143] The association between EGFRvIII and response to EGFR inhibitors in R/M HNSCC merits further study.

It is not known if HPV status might be associated with efficacy of anti-EGFR therapy in patients with R/M HNSCC. In subgroup analysis of SPECTRUM (the previously reviewed phase III study of platinum/5-fluorouracil [PF] with or without panitumumab for R/M HNSCC),[55] HPV status was indirectly assessed by immunohistochemical detection of p16, a biomarker for HPV status. Tissue was available for p16 testing in 377 subjects. Among patients with p16-negative tumors, the addition of panitumumab to the platinum doublet was associated with a significant improvement in overall survival (11.8 vs. 8.6 months, panitumumab plus PF vs. PF, respectively; $p = 0.02$).[144] Among patients with p16-positive tumors, there was no significant difference in survival associated with the addition of panitumumab.[144] These data have only been presented in abstract form. The observation that patients with p16-negative tumors, but not p16-positive tumors, may benefit from panitumumab should be viewed as hypothesis-generating only at this time.

Other potential biomarkers for resistance or sensitivity to EGFR inhibitors in HNSCC have been described. Heparin binding EGF-like growth factor (HB-EGF) is an EGFR ligand that is expressed at higher levels in the plasma of patients with R/M HNSCC than in patients with newly diagnosed disease and may be associated with resistance to EGFR inhibitors.[145] The potential role of genetic polymorphisms in response to EGFR inhibitors is currently not well understood. A study of HNSCC cell lines evaluated a specific genetic polymorphism, the number of CA nucleotide repeats in intron one of *EGFR*. The number of CA dinucleotide repeats was associated with levels of EGFR mRNA and protein and response to erlotinib.[146] While the foregoing considerations have focused on the impact of EGFR inhibition on signaling pathways in tumor cells, the role of cell-mediated cytotoxicity in patients treated with cetuximab is also under investigation.[147] A specific polymorphism of Fc gamma receptor IIIa on effector cells appears to be associated with the cytotoxicity of cetuximab against HNSCC cell lines and merits further study in clinical trials.[148]

## CONCLUSION

The main classes of drugs for the management of patients with R/M HNSCC are platinum agents, taxanes, antimetabolites, and the EGFR inhibitor cetuximab. The selection of therapy takes into consideration numerous variables, including prior treatment, extent of disease, medical comorbidities, and goals of care. The EXTREME study highlights the potential of targeted agents to improve the efficacy of standard chemotherapy for patients with R/M HNSCC,[54] but there remains a clear need for the development of improved treatments. Many targeted agents are under clinical investigation, and a central challenge of these efforts is to develop clinical and molecular markers to identify patients most likely to benefit from a given therapy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

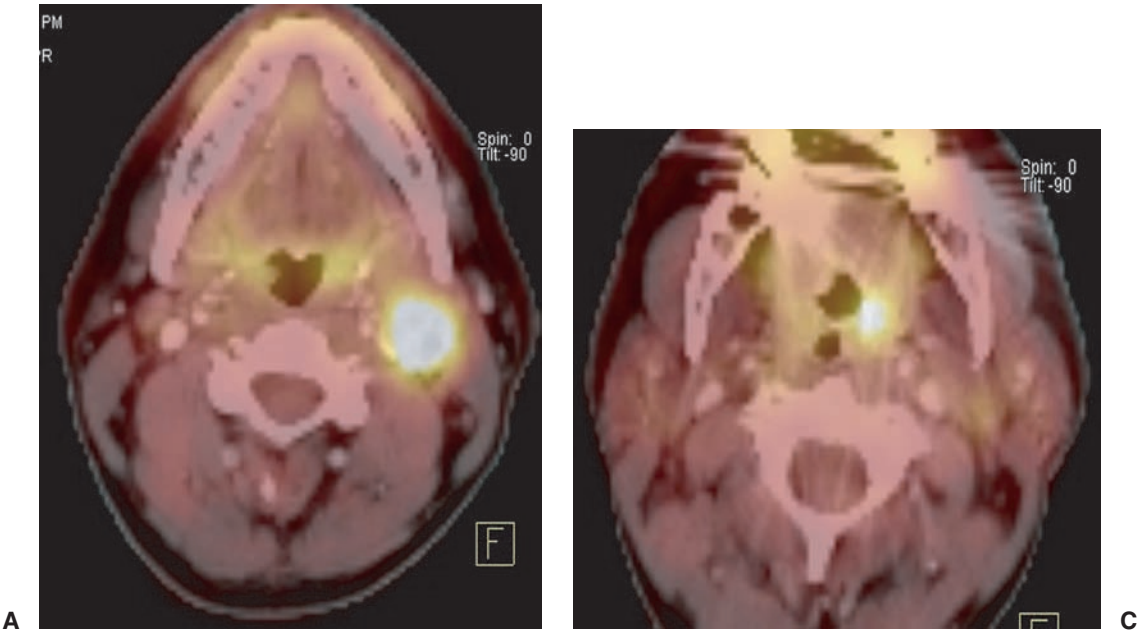

**FIGURE 4-17.** Axial PET-CT (**A**) performed in patient with a biopsy-proved nodal metastases shows uptake in the left level II lymph node. PET-CT (**C**) shows focal uptake in the left tonsil that was suspicious for a primary site. The patient underwent a left tonsillectomy, and pathology revealed squamous cell carcinoma. PET, positron emission tomography; CT, computed tomography.

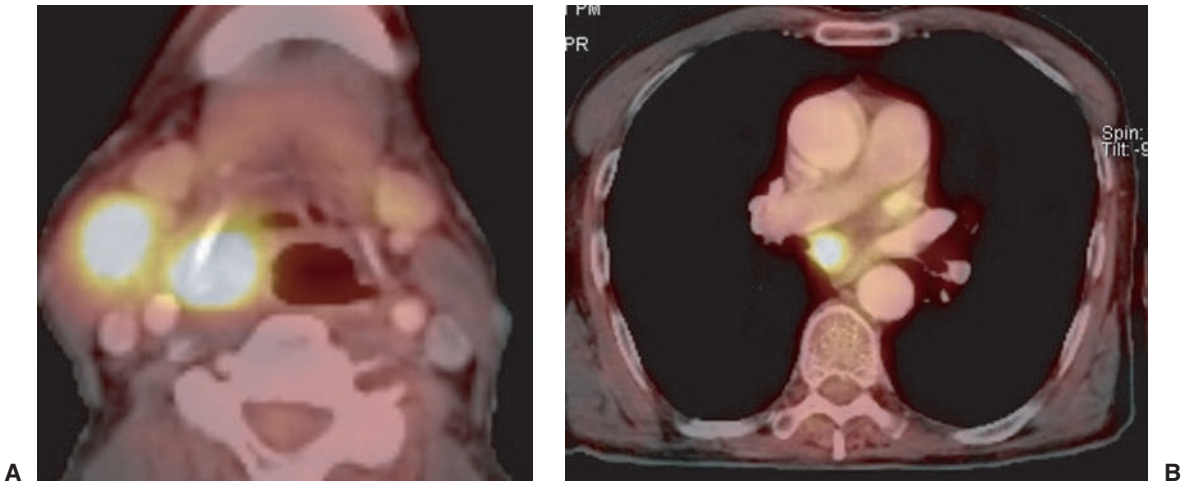

**FIGURE 4-18.** **A:** PET-CT performed in a patient with a known right pyriform simus carcinoma and level II nodal disease shows uptake at the primary site and lymph node. **B:** There is also abnormal uptake in a mediastinal lymph node, which is not detected in standard cross-sectional imaging. PET, positron emission tomography; CT, computed tomography.

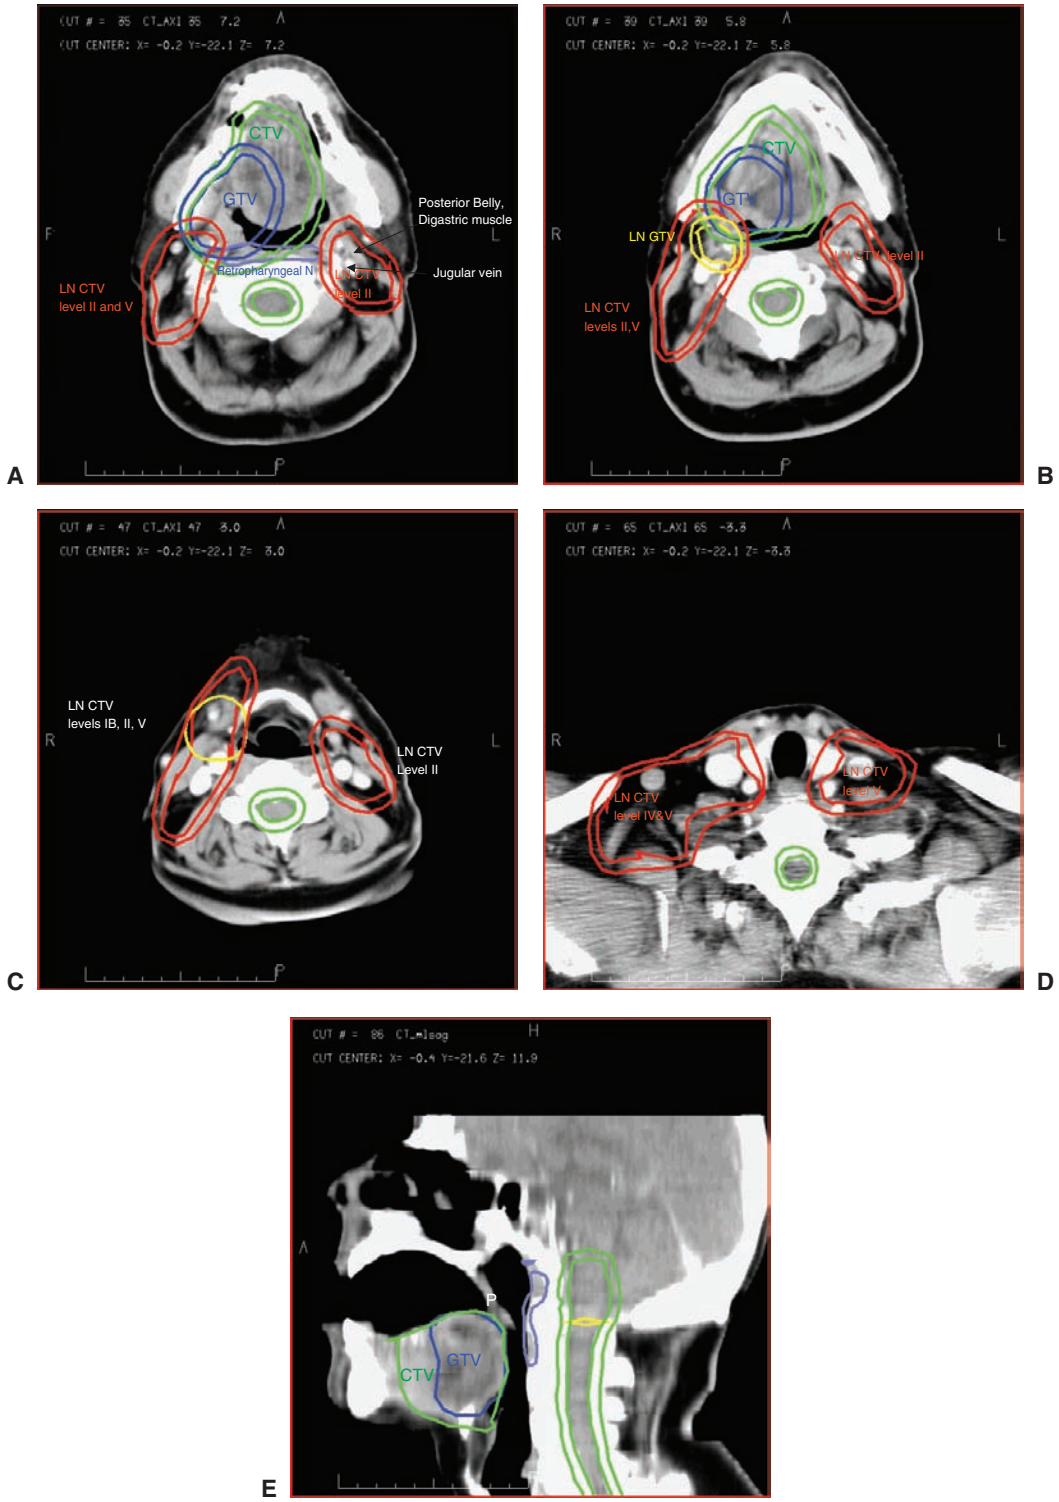
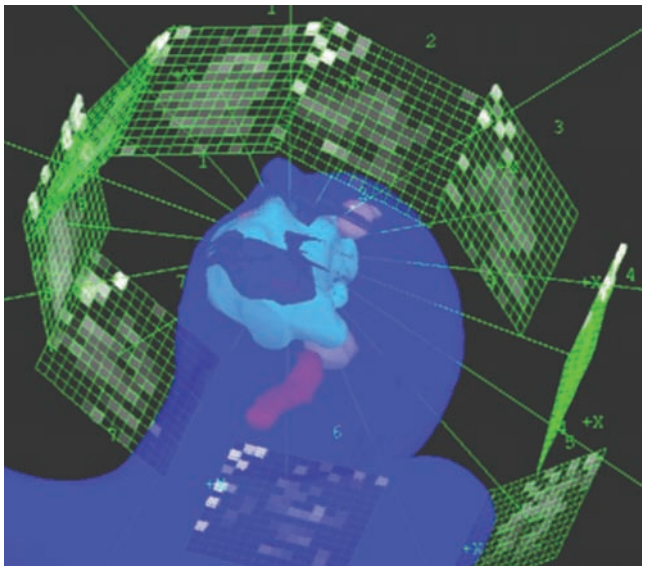
(c) 2014 Wolters Kluwer. All Rights Reserved.





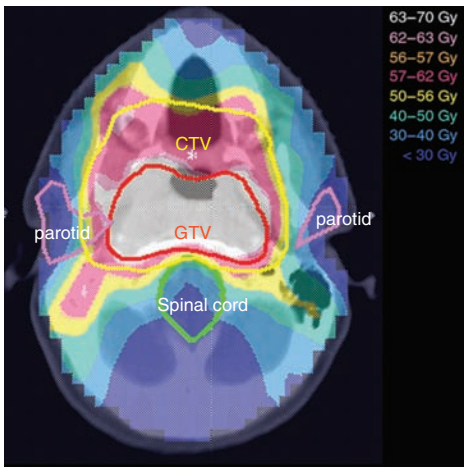


**FIGURE 5-1.** The targets outlined on planning CT in a case of stage T2, N1 carcinoma of the right tonsil, involving the lateral base of the tongue. The GTV, primary tumor CTV, and lymphatic GTV and CTVs are each expanded uniformly by 0.5 cm to yield the corresponding PTV. **A:** Level II nodal targets in the ipsilateral neck, and the retropharyngeal nodes bilaterally, are outlined through the base of the skull. Level II nodes in the contralateral neck are outlined up to the level in which the posterior belly of the digastric muscle crosses the jugular vein. Cephalad to this level, only the ipsilateral (LT) level II nodal CTVs and the retropharyngeal nodes are outlined. In cases where the contralateral neck contains clinical or radiologic evidence of metastasis, or in the case of nasopharyngeal cancer, level II is outlined through the base of the skull bilaterally. **B:** Nodal metastasis in the LT neck is outlined as a nodal GTV, expanded to yield its PTV. **C** and **D:** In the ipsilateral lower neck, nodal levels IV and V are included in the CTV. Only level IV is outlined in the contralateral lower neck (the contralateral neck did not have clinical evidence of metastasis). **E:** A sagittal reconstruction of the CT may help in the assessment of the extent of disease. On axial images, it is difficult to distinguish the soft palate from the base of tongue that contains the targets. The sagittal view facilitates the exclusion of the soft palate (*P*) from the targets. CT, computed tomography; GTV, gross tumor volume; CTV, clinical target volume; PTV, planning tumor volumes.

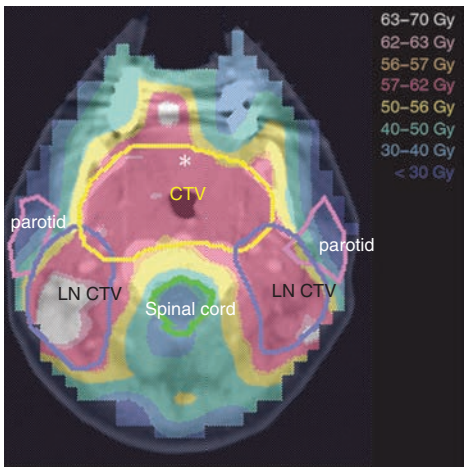
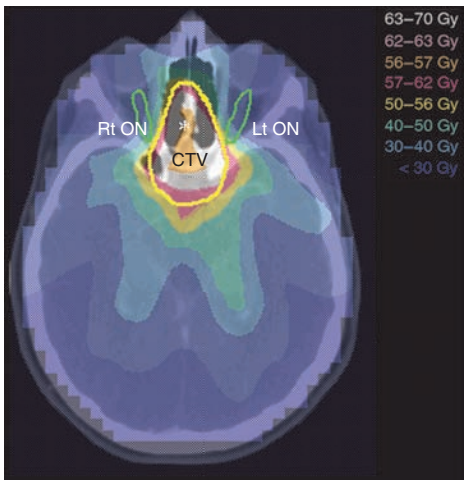


(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 5-2.** Beam arrangement for IMRT using an MLC. Nine coplanar, equidistant beams are used, each containing 1 × 1 cm or 0.5 × 0.5 cm pencil "beamlets." IMRT, intensity-modulated radiotherapy.



A

B

C

**FIGURE 5-3.** Targets and doses in IMRT of nasopharyngeal cancer. **A:** The GTV was outlined following registration of the planning CT with diagnostic MRI. The CTV includes the base of the skull, the posterior paranasal sinuses, the clivus, and the parapharyngeal space. **B:** Caudal to the GTV, the CTV contains the parapharyngeal and posterior pharyngeal space through midtonsils. Level II nodal CTV is outlined through the base of the skull bilaterally. **C:** The CTV encompasses the sphenoid and cavernous sinuses in locally advanced cases. Limiting the dose to the optic pathways is an important objective of planning. IMRT, intensity-modulated radiotherapy; GTV, gross targe volume; CT, computed tomography; CTV, clinical target volume.

(c) 2014 Wolters Kluwer. All Rights Reserved.

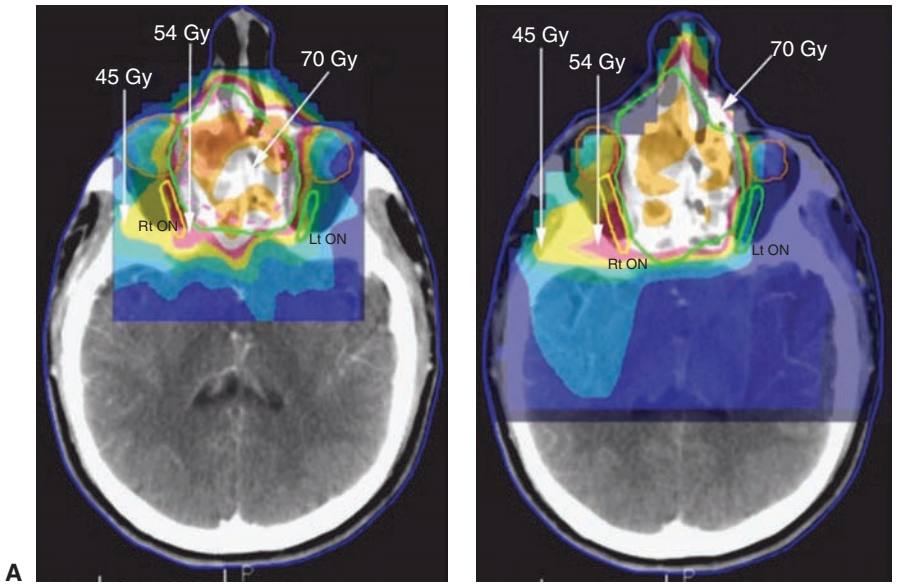


**FIGURE 5-4.** **A** and **B:** Isodoses of IMRT for advanced paranasal sinus cancer. Sparing the optic pathways was a major planning objective. IMRT, intensity-modulated radiotherapy.

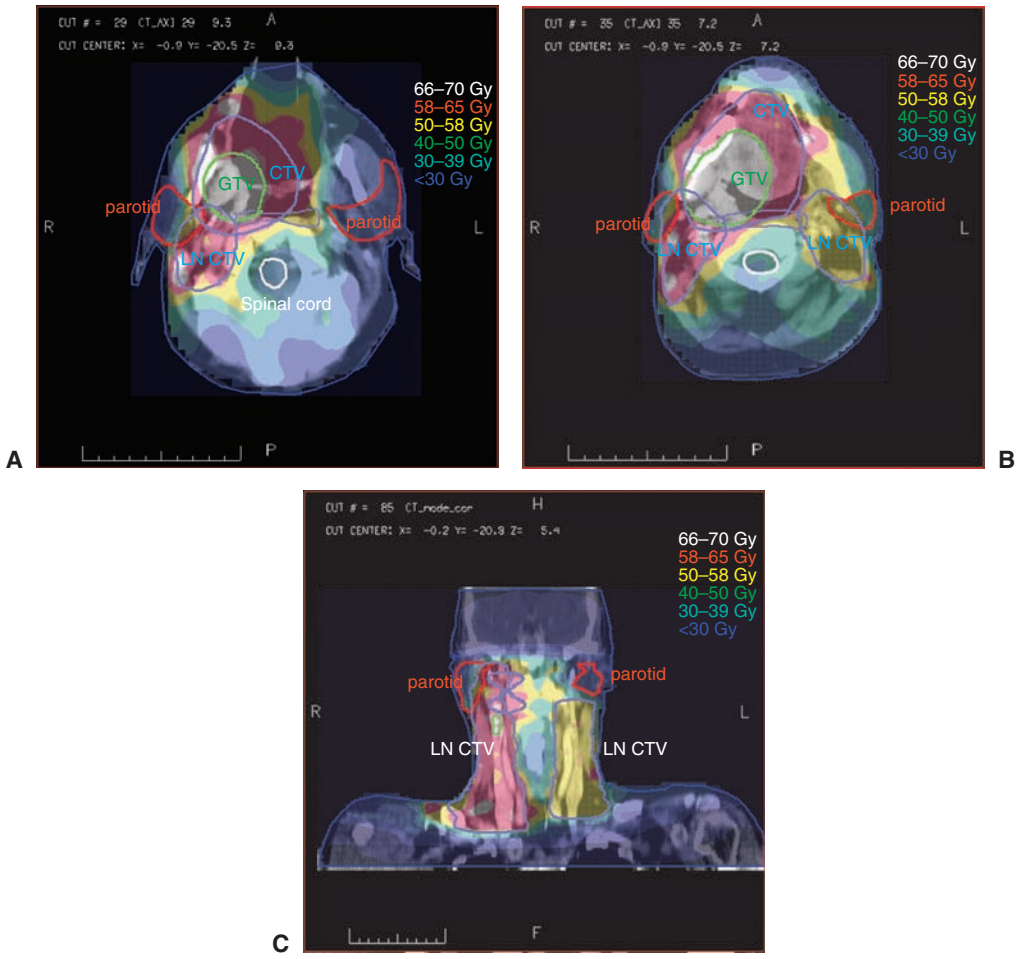

**FIGURE 5-5.** **A** to **C:** Isodoses of IMRT for the patient described in Figure 5.1. The contralateral parotid gland received a low dose (mean 17 Gy) and the ipsilateral gland a moderate dose (mean 32 Gy). IMRT, intensity-modulated radiotherapy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

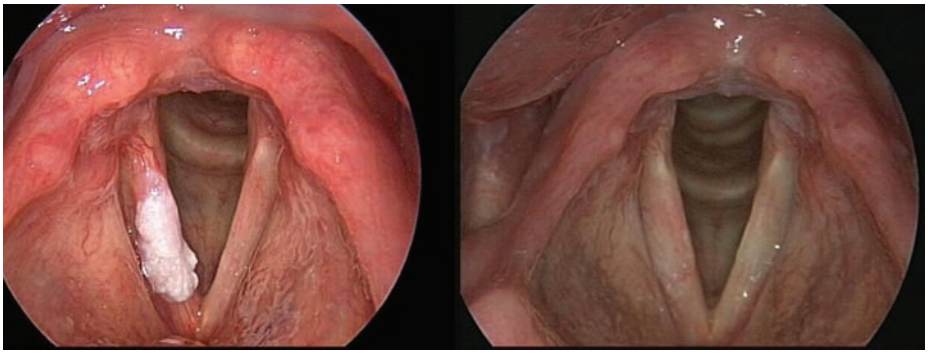

**FIGURE 6-3.** Preoperative **(left)** and postoperative **(right)** views of a T1 verrucous carcinoma resected via transoral laser microsurgery. The surgical defect is not evident, despite submucosal resection down to the vocal ligament. Adaptive remodeling of the larynx after transoral laser microsurgery may provide better functional outcomes that expected, when the proper lesion is choice. No radiation therapy was given.

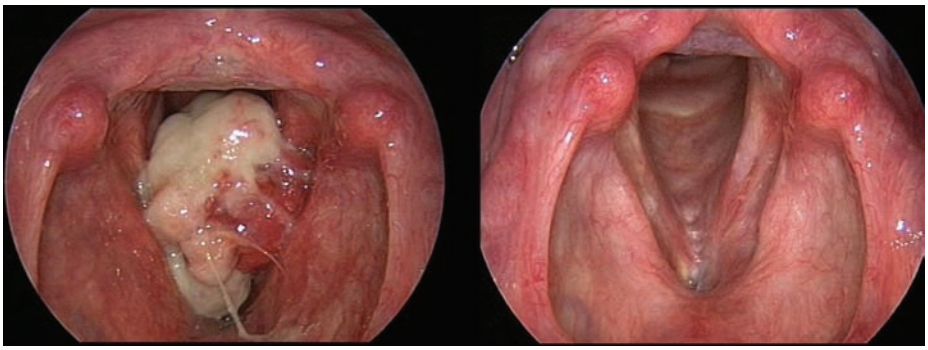

**FIGURE 6-4.** Preoperative **(left)** and 3-year postoperative **(right)** views of a squamous carcinoma of the larynx. CT imaging staged this as a T3 lesion, though the tumor was pedunculated from the undersurface of the left false cord. The tumor was resected via transoral laser microsurgery and no postoperative radiation therapy was given.

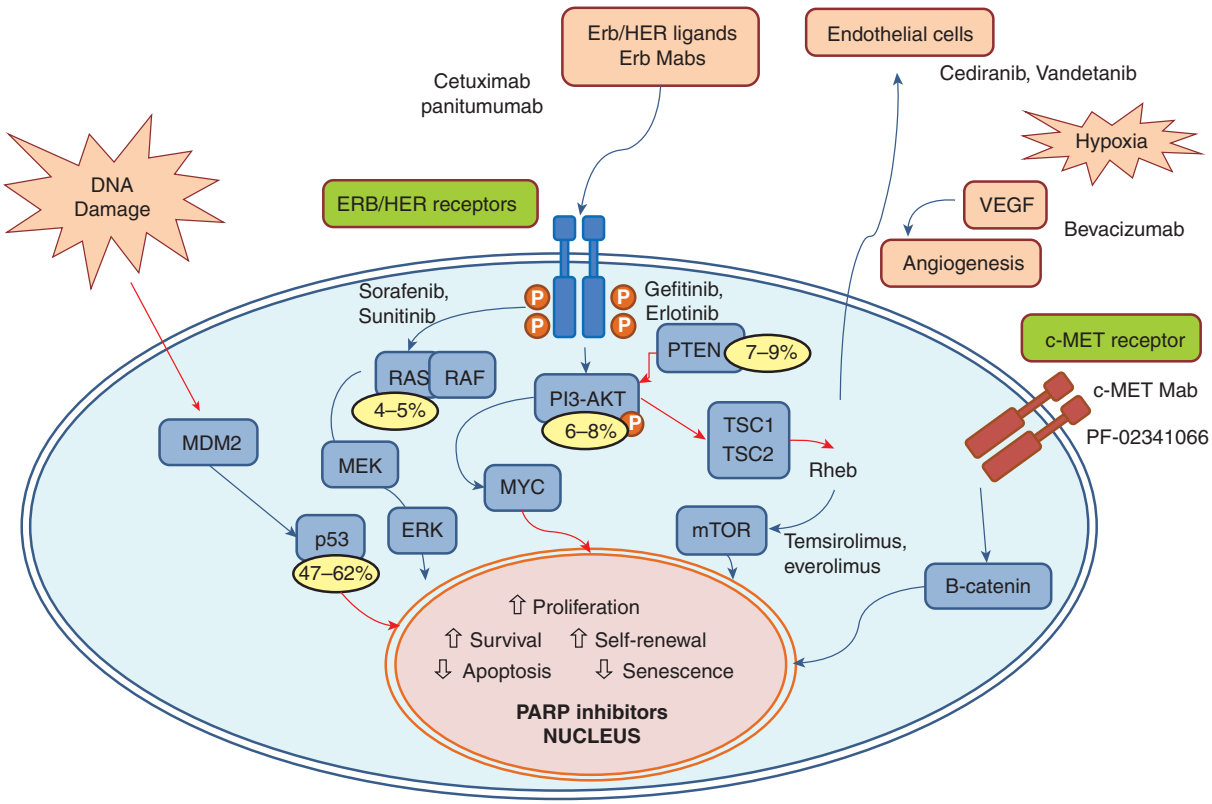

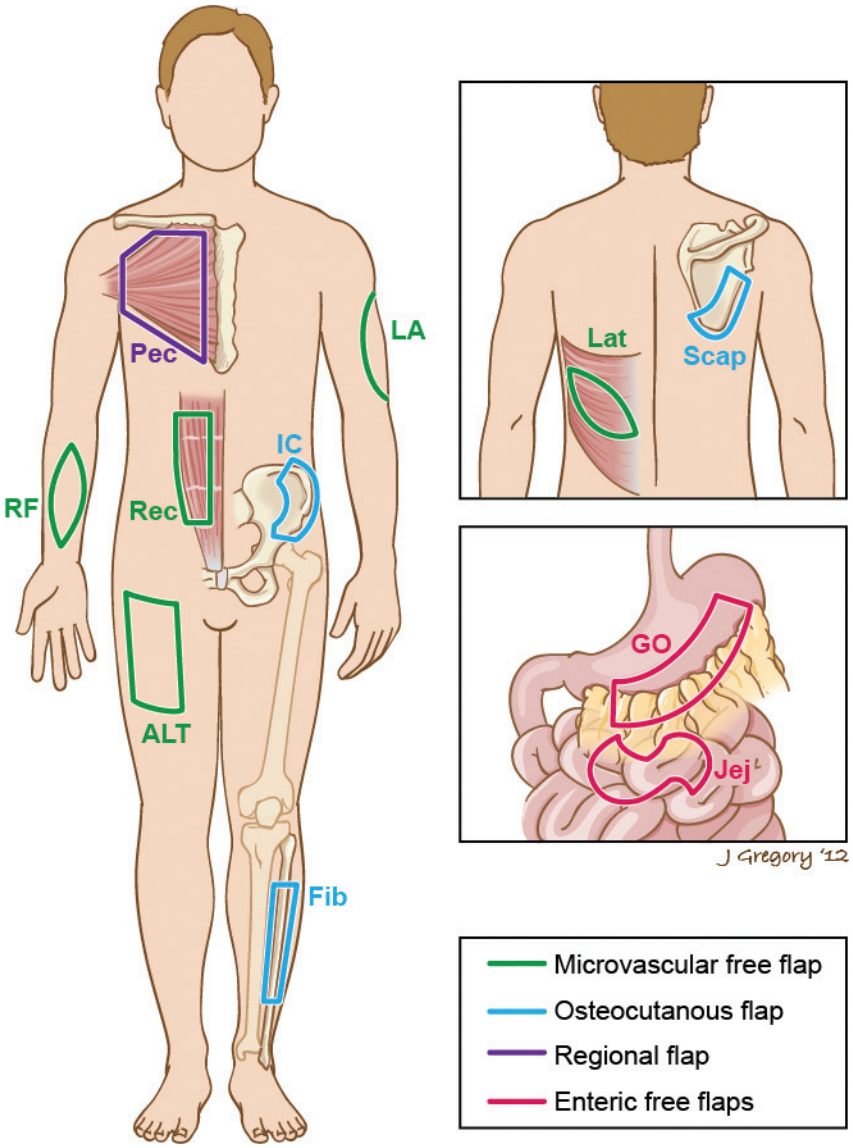

**FIGURE 7-1.** Selected pathways, targeted agents, and mutations important in squamous cell carcinoma of the head and neck. Red arrow, inhibitory activity; blue arrow, stimulatory activity; yellow circles; frequency of mutated genes; bold names, targeted drugs; PARP, poly(ADP-ribose)polymerases.

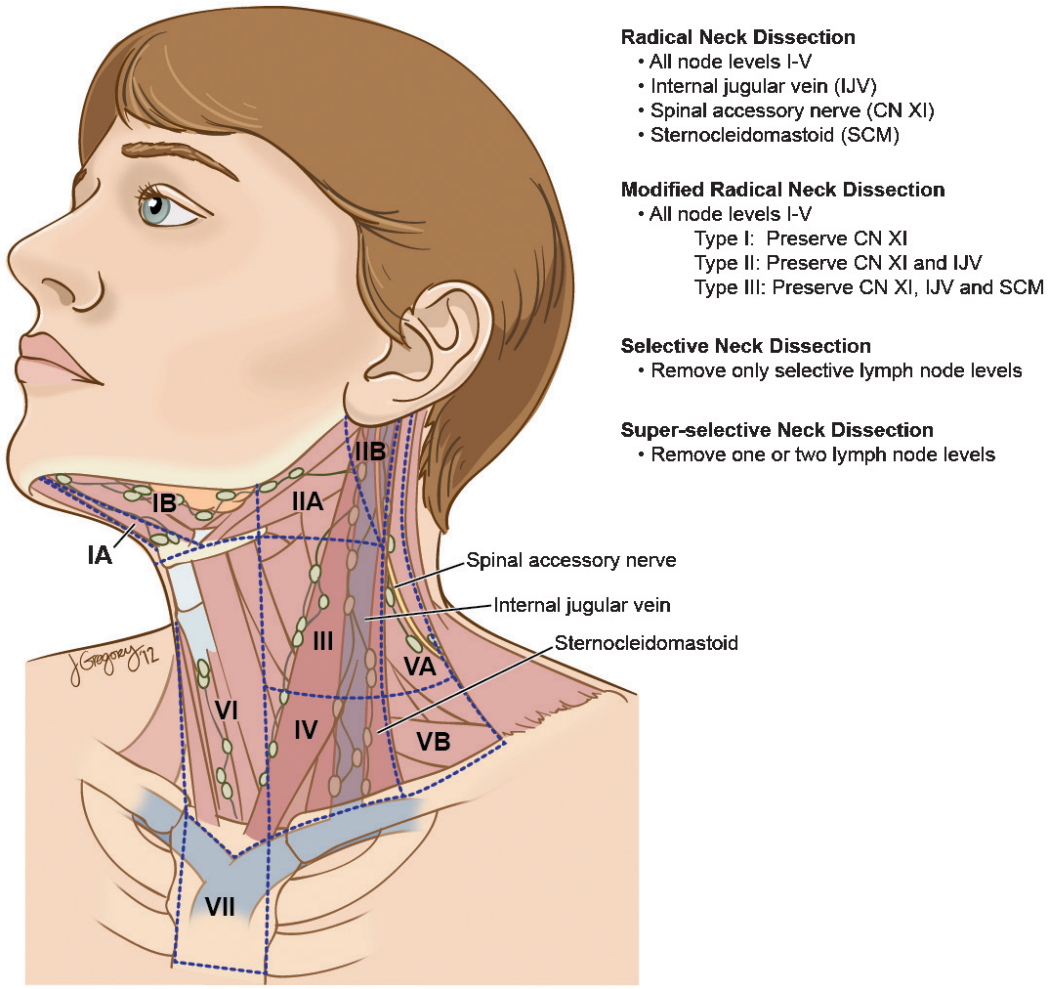

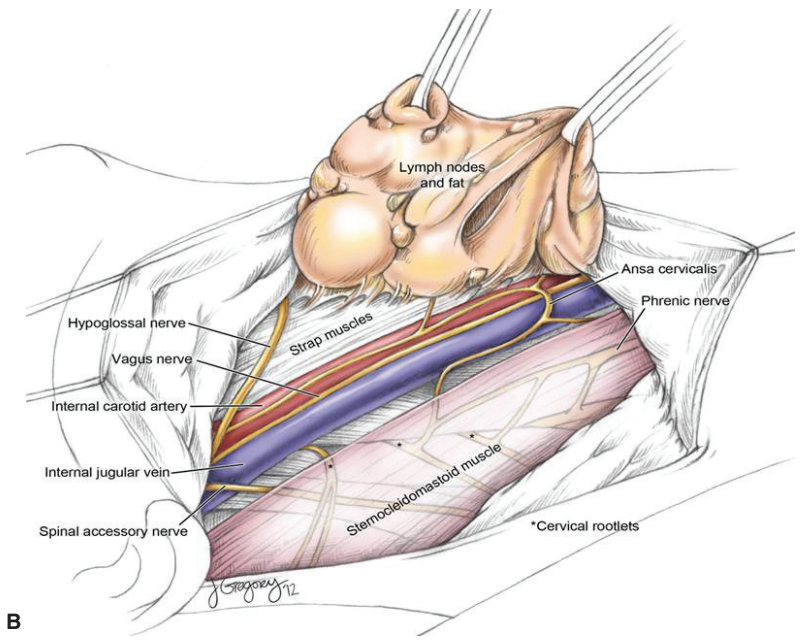

**FIGURE 14-1.** Nodal delineation for the electively treated node-negative and node-positive neck. On the left, are nodal stations delineated in a node-negative neck. On the right, are target delineation of level II nodal level up to the skull base in a node-positive neck. On the left, is shown the target delineation of level II in an electively treated neck. Note the differences in the superior margin allows substantial sparing of the parotid gland. RP, retropharygeal node; ICA, internal carotid artery; JV, jugular vein; PG, parotid gland; PB of JGD, posterior belly of the jugulodigastric muscle; BP, brachial plexus. See Table 14.10 for boundaries of nodal stations.

**FIGURE 14-3.** Selective neck dissection. **B:** Illustration of selective removal of lymph node levels II, II, and IV.

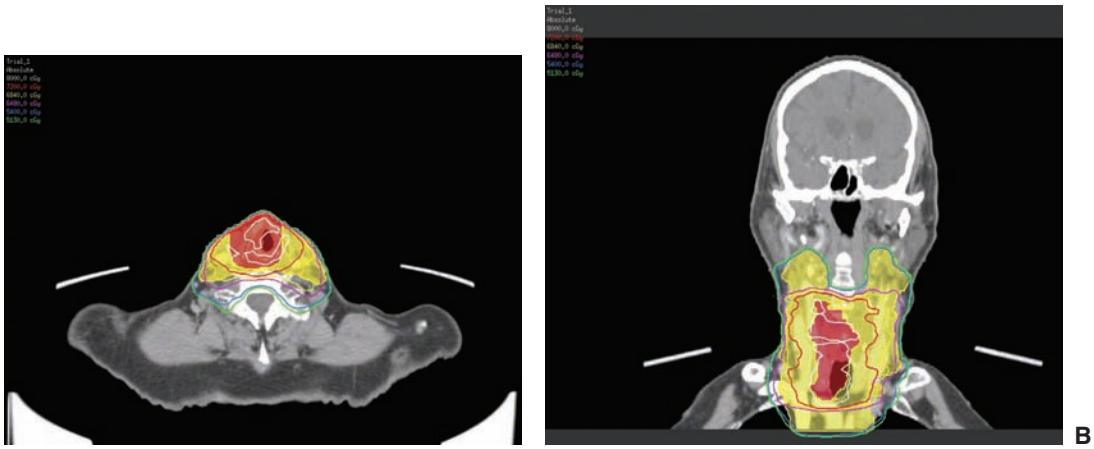

**FIGURE 15-10.** **A & B:** Patient with a T0N2B squamous cell carcinoma from an unknown primary site with left neck adenopathy. The patient is treated with IMRT with 6-MV X-rays. The oropharnyx and positive nodes receive 64.8 Gy at 1.8 Gy per once-daily fraction. The gross disease is boosted to 70 Gy. The standard-risk clinical target volume (SR-CTV) receives 50 Gy. **A)** Axial contour; **B)** Sapittal contour. A PET-CT is obtained after radiotherapy and a left dissection is performed if the response is incomplete.

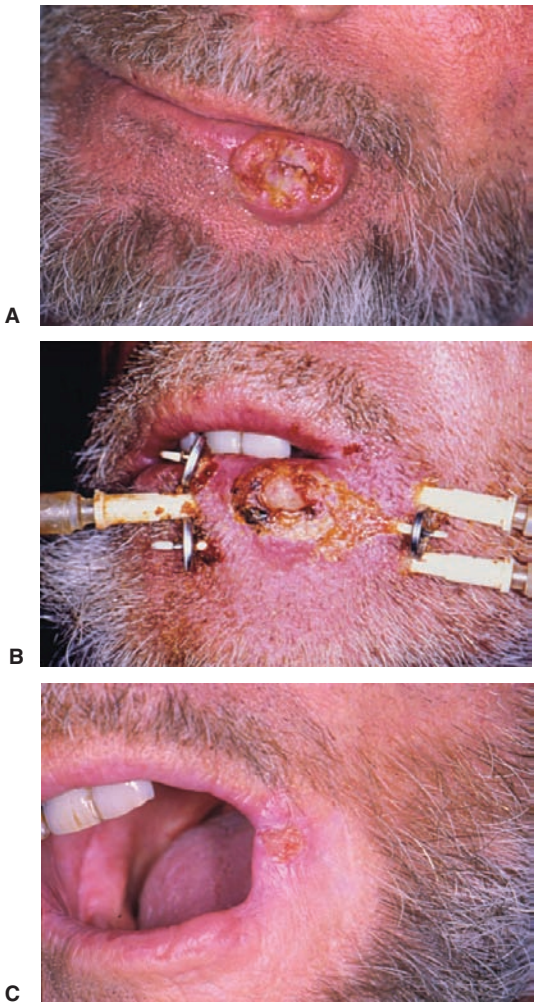

**FIGURE 16-33.** Patient had a 2.5-cm squamous cell cancer of the left side of the lower lip, near the lip commissure. Radiation was selected as the primary treatment due to the enhanced functional and cosmetic result in this particular case, given location near commissure. **A:** The lesion is seen. **B:** Patient had implantation of $^{192}$Ir via afterloading angiocatheters. A single plane implant was used and the catheters were 1 cm apart. A total of 6,000 cGy in 6 days was delivered. This photograph was taken on Day 6, just after source removal. The lesion has already regressed. **C:** Six months after implant. Patient has no evidence of disease.

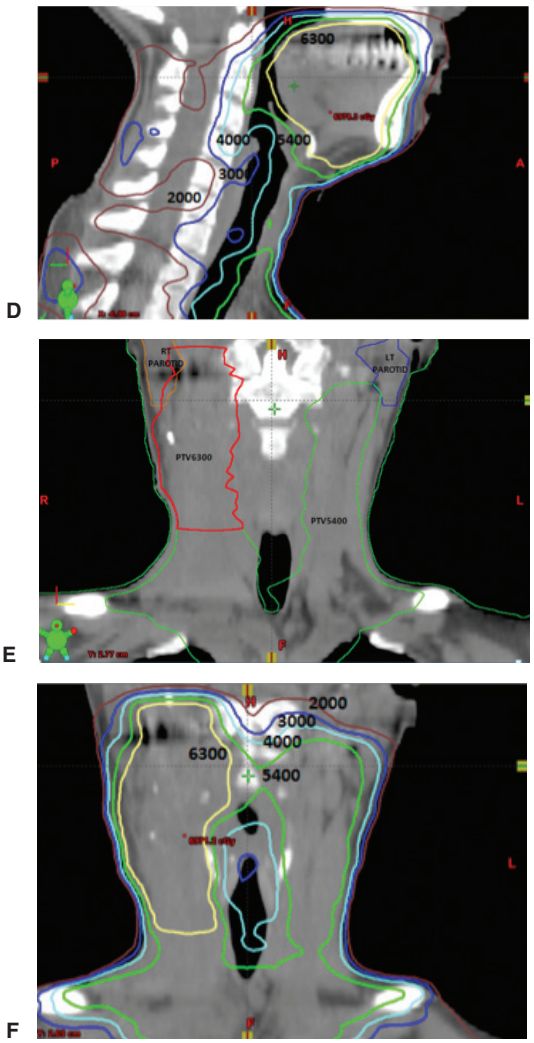

**FIGURE 16-36.** **D:** Same midsagittal CT slice as **C.** For ease in visual display, the contours have been removed, but the isodose curves for 6,300, 5,400, 4,000, 3,000, and 2,000 cGy are shown. Note the relative protection of the posterior pharyngeal wall. **E:** Coronal CT display showing PTV 63 and PTV 54. PTV 63 encompasses the right upper neck levels 2 and 3 in this display. The PTV 54 encompasses the right lower neck as well as the entire left neck. Note the sparing of the left (contralateral parotid gland). **F:** Same coronal CT display as **E**. As in prior figures, the contours are removed and the isodose lines are shown.

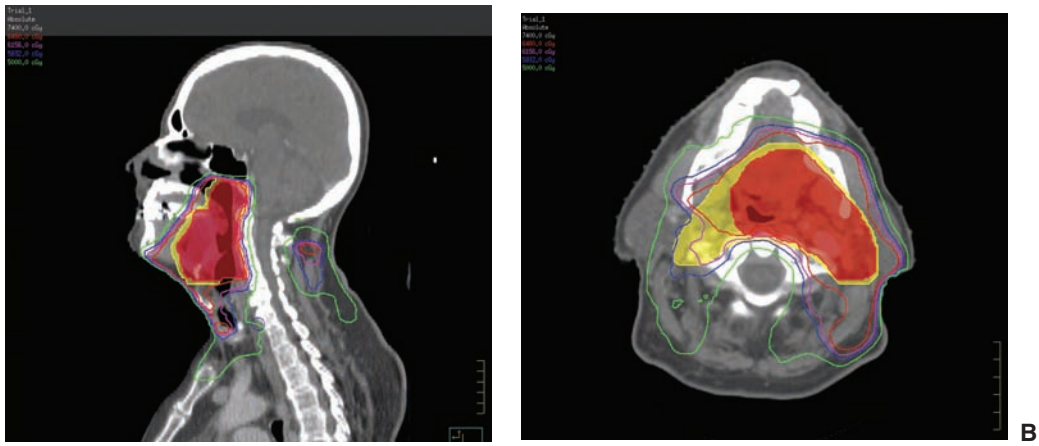

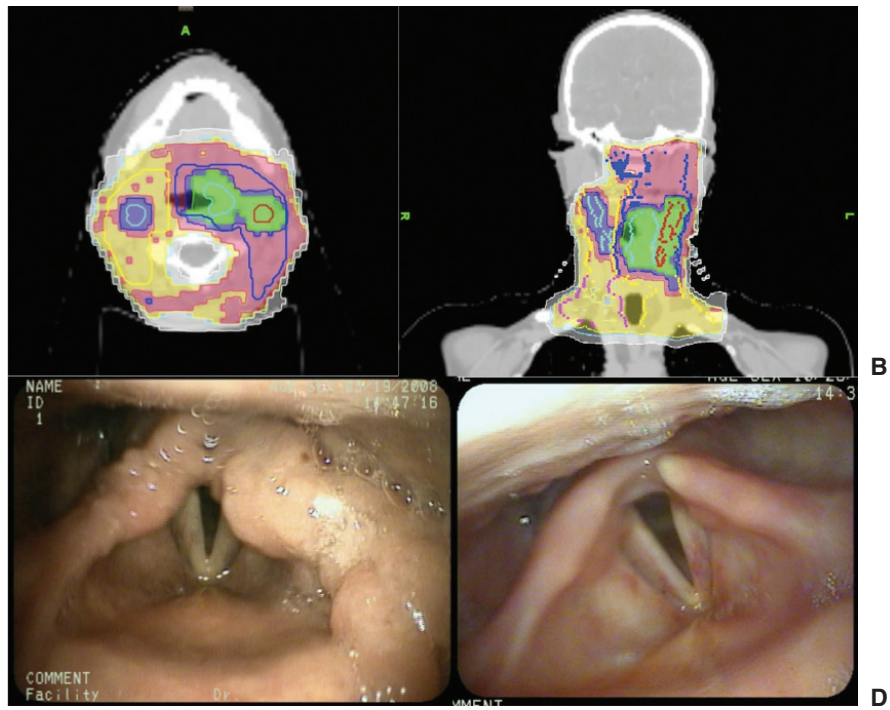

**FIGURE 18-25.** **A & B:** Patient with a T3N0 squamous cell carcinoma of the glottic larynx. The patient is treated with 6-MV X-rays with IMRT. The high-risk clinical target volume (HR-CTV) receives 70 Gy at 2 Gy per once-daily fraction or its equivalent using altered fractionation. The standard-risk CTV (SR-CTV) receives 54 Gy. **A)** Axilla contour; **B)** Control contour.

**FIGURE 19-9.** Axial (**A**) and coronal (**B**) dose distributions of a patient with a T3N2b SCC of the left pyriform sinus and aryepiglottic fold, treated with helical tomotherapy on protocol RTOG 0522. Turquoise contour represents the primary GTV, with involved left node contoured in red, both encompassed by a 70 Gy dose-cloud. Elective nodal areas received doses of 66 Gy (purple), 60 Gy (pink), and 56 Gy (yellow). Sparing of the right parotid is demonstrated on the coronal image. Panel (**C**) demonstrates the primary tumor prior to treatment via endoscopic examination, with complete response demonstrated at 3 years follow-up in panel (**D**).

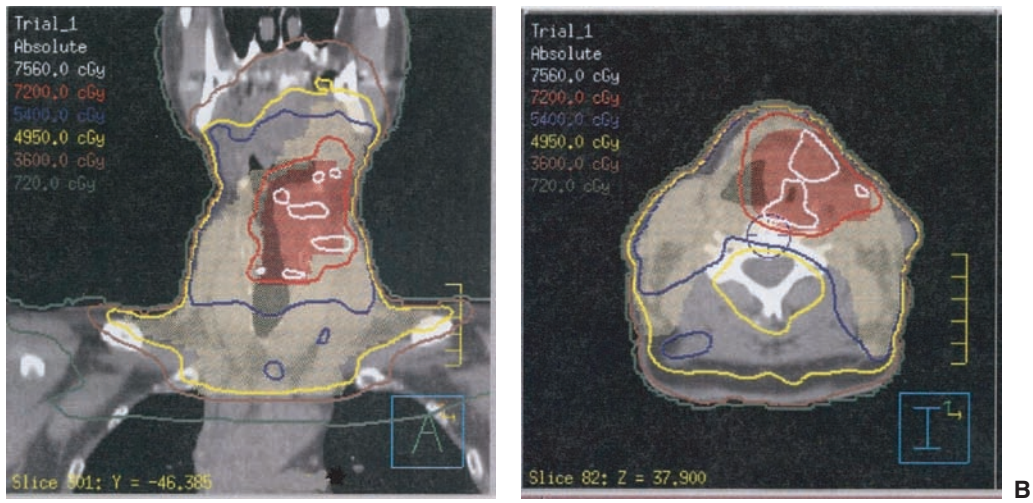

**FIGURE 19-28.** A seventy-nine-year-old man with a T3N2B squamous cell carcinoma of the left pyriform sinus. The gross tumor received 72.0 Gy in 42 fractions using the concomitant boost technique. The moderate risk volumes received 54.0 Gy. The patient received seven cycles of concomitant weekly cisplatin. The mean dose to the right parotid was 25.1 Gy.

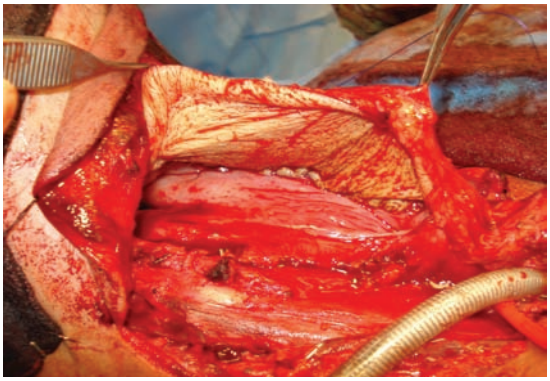

**FIGURE 19-30.** Pharyngeal reconstruction after total laryngectomy and partial pharyngectomy.

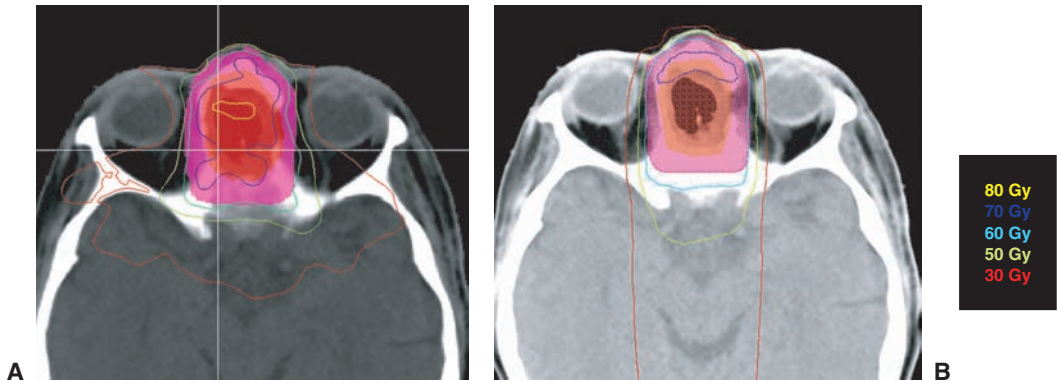

**FIGURE 21-1.** An example of an ethmoid sinus tumor being planned using **(A)** IMRT and **(B)** 3D-CRT. Notice that the 70-Gy isodose line (dark blue) coverage is superior in the IMRT versus the 3D-CRT plan. In addition, there is superior sparing of the optic chiasm when compared with the 3D-CRT plan. IMRT, intensity modulated radiation therapy; 3D-CRT, three-dimensional conformal radiotherapy.

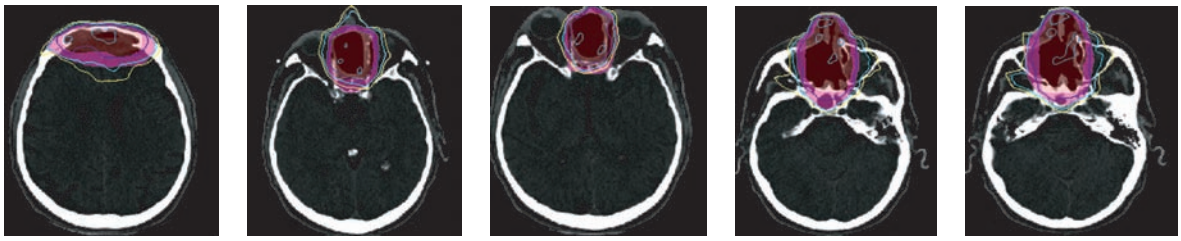

**FIGURE 21-9.** An example of different axial slices showing contours of a patient with ethmoid sinus tumor who underwent craniofacial resection. Red is the clinical target volume, which encompassed the preoperative GTV plus postoperative bed, whereas magenta is the PTV. Light blue is the 60-Gy prescription isodose line. GTV, gross tumor volume; PTV, planning target volume.

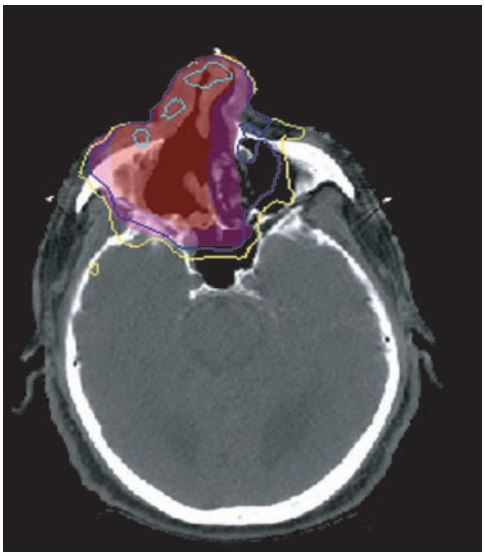

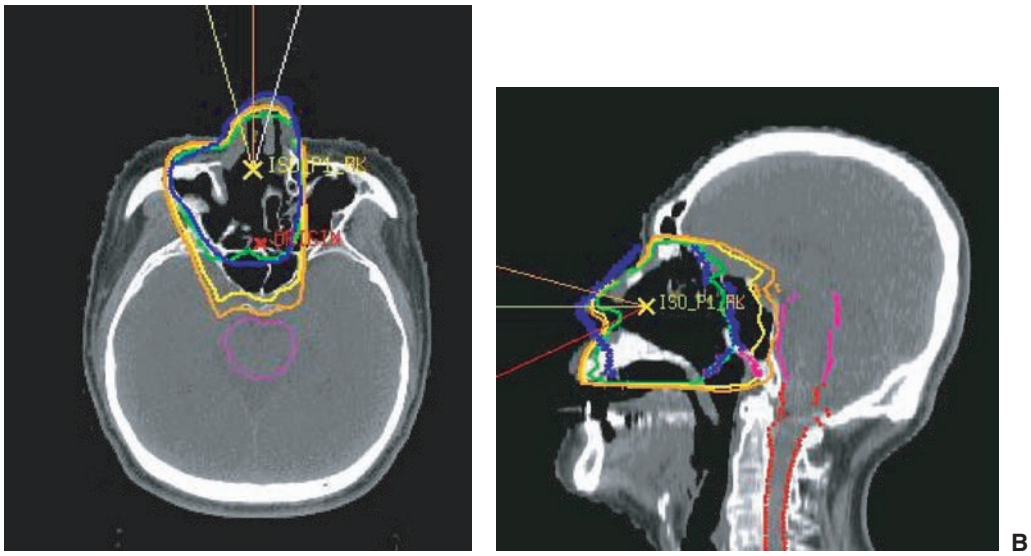

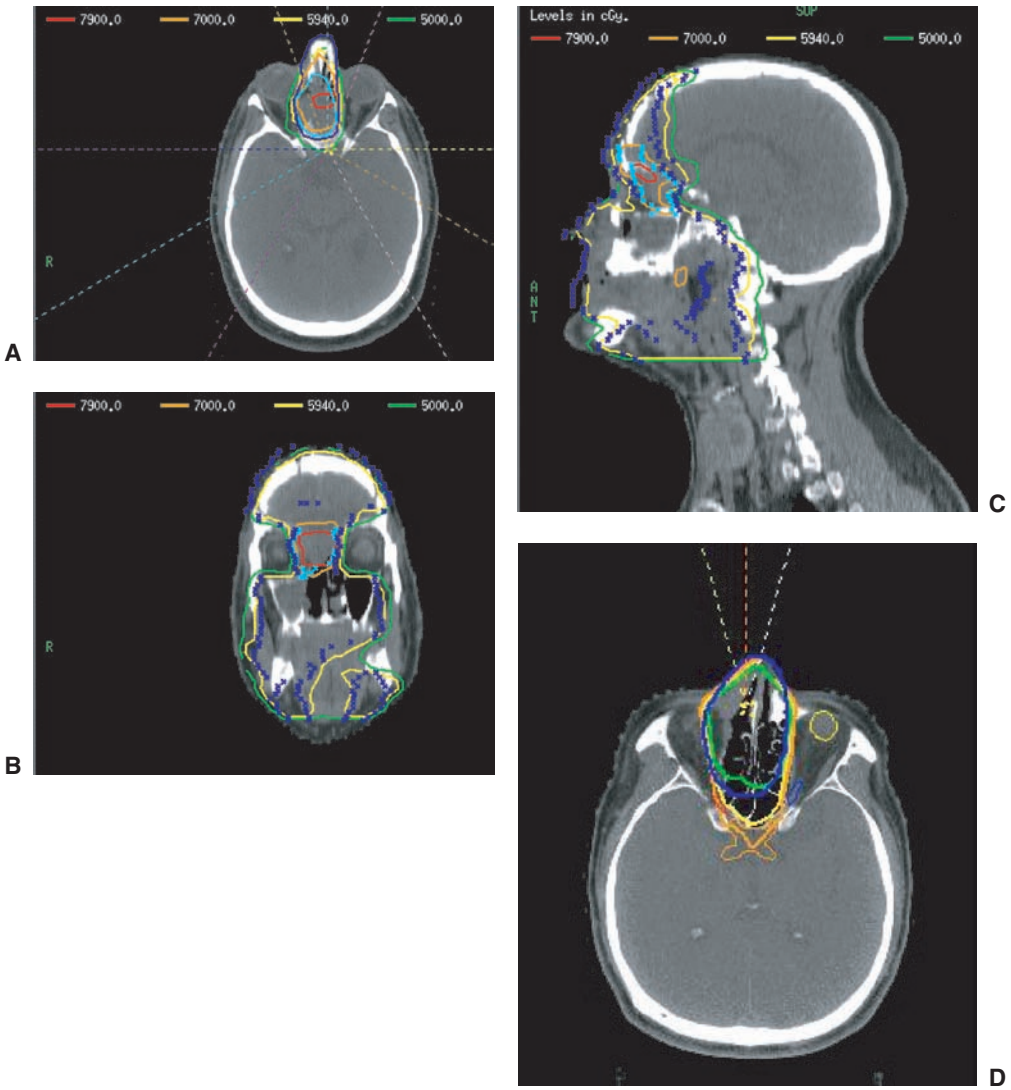

**FIGURE 21-10.** An example of a patient with maxillary sinus tumor who underwent craniofacial resection. Red is the clinical target volume which encompassed the preoperative GTV plus postoperative bed, whereas magenta is the PTV. Dark blue is the 60-Gy isodose line, whereas yellow is the 54-Gy isodose line. GTV, gross tumor volume; PTV, planning target volume.

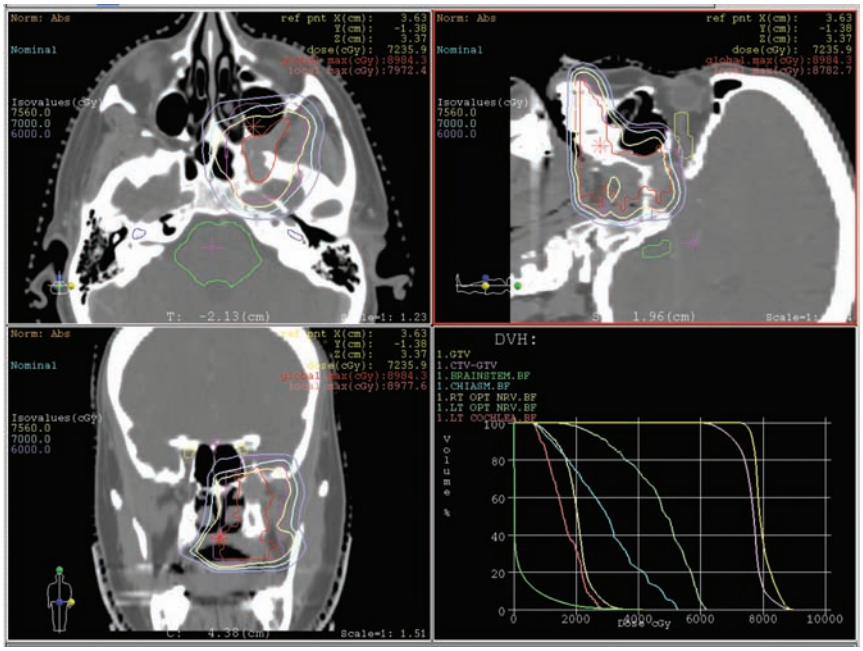

**FIGURE 25-14.** Definitive proton therapy for an unresectable adenoid cystic carcinoma of the hard palate with gross involvement of V2. Note the restriction of the irradiated volume to the defined CTV and relative sparing of the optic structures and the brain stem. There is no fall off or compromise of dose in the deepest part of the skull base. This patient is NED 6 years after 75.6 GyE to the GTV.

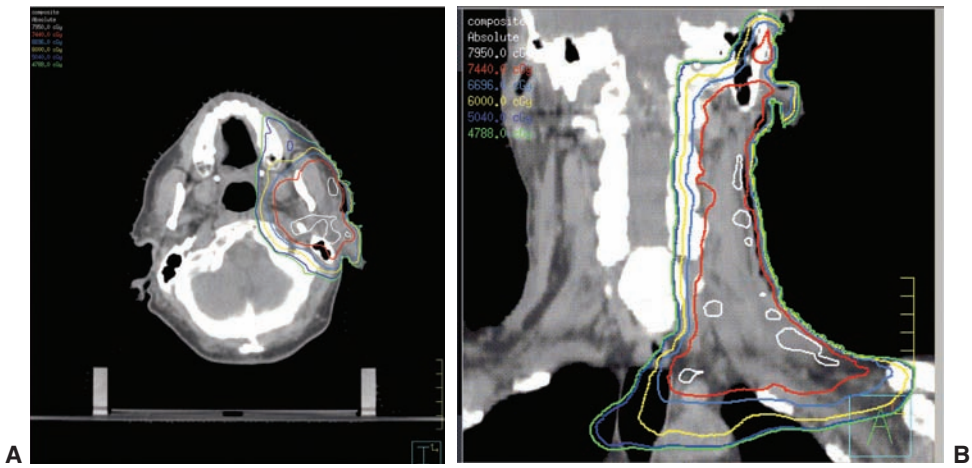

**FIGURE 25-26.** The patient underwent a left parotidectomy and neck dissection for a $T_3N_{2B}$ high-grade mucoepidermoid carcinoma of the left parotid gland. Although a gross total dissection was achieved, margins were microscopically positive. Postoperative IMRT was used to treat the left parotid bed and neck to 74.4 Gy in 62 twice-daily fractions. **A:** Axial dose distribution. **B:** Coronal dose distribution.

**FIGURE 27-9.** Computed tomography angiogram of a patient with a large paraganglioma. **A:** Volumetric surface rendering shows anterolateral displacement of the internal carotid artery and narrowing of its lumen. Note the filling of the internal jugular vein with contrast posterior to the common carotid artery, demonstrating the high flow within this tumor.

C D

**FIGURE 27-20.** Fifty-year-old female with an incapacitating jugulotympanic paraganglioma causing tinnitus and dizziness causing gait instability and nausea. Due to the size of the lesion and proximity to the seventh and eighth cranial nerve, a stereotactic fractionated radiation therapy approach was recommended to minimize risk of iatrogenic neuropathy. Dosimetry is seen in axial **(C)** and coronal views **(D)**.

A B

**FIGURE 27-24.** Intensity-modulated radiation therapy (IMRT) for ipsilateral tumor. The patient is a 34-year-old man found to have a right glomus vagale and a right glomus tympanicum. The patient was treated with IMRT and received 45.0 Gy in 25 fractions. The mean right parotid dose was 21.5 Gy and the mean left parotid dose was 3.0 Gy. Follow-up with magnetic resonance imaging (MRI) revealed the paragangliomas to be stable 1 year after IMRT (**A:** sagittal; **B:** coronal).

(c) 2014 Wolters Kluwer. All Rights Reserved.

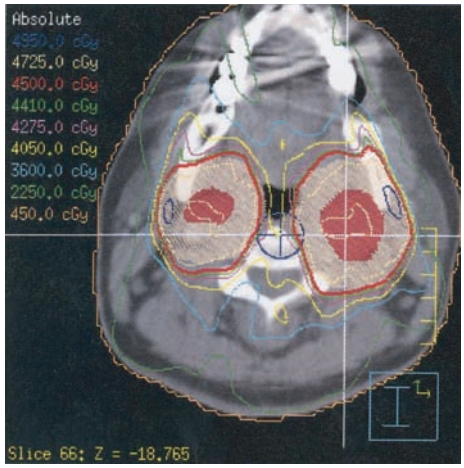

**FIGURE 27-25.** The patient is a 33-year-old woman with bilateral glomus vagale paragangliomas. She received 45 Gy in 25 fractions with 6-mV x-rays using intensity-modulated radiation therapy (IMRT). The mean parotid doses were 18.4 Gy and 20.2 Gy, respectively. Follow-up computed tomography (CT) at 1 year revealed no evidence of progression.

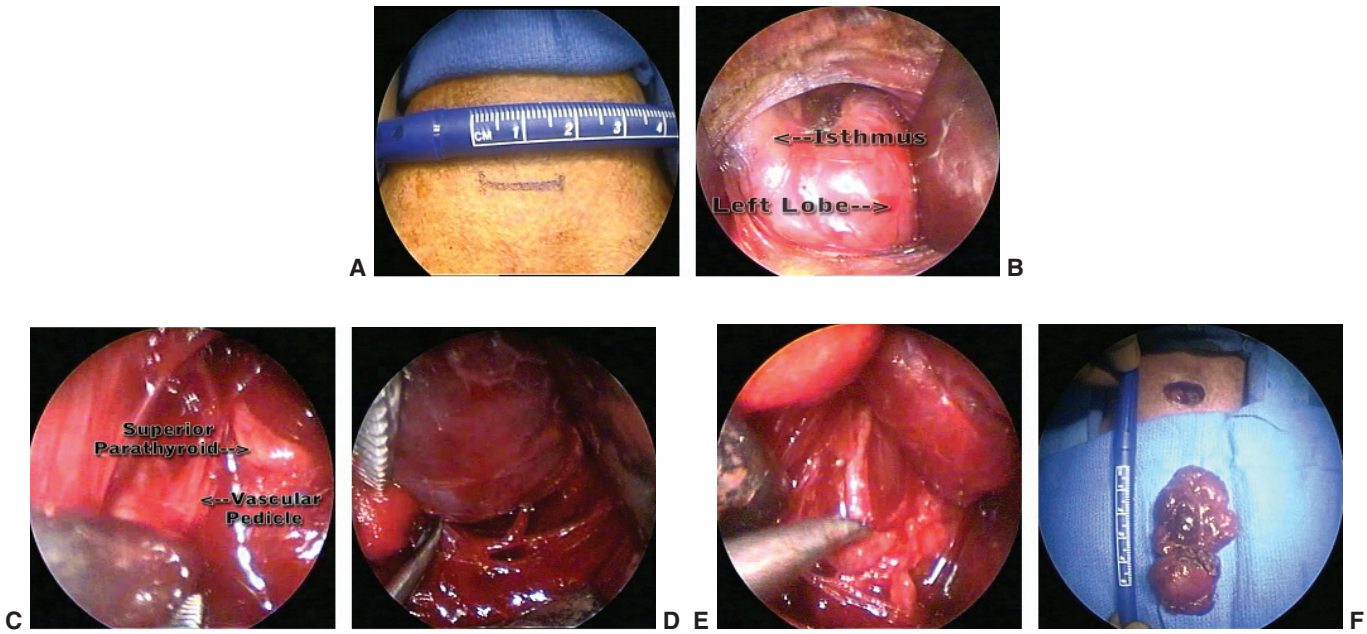

**FIGURE 28-30.** Minimally invasive thyroidectomy (MIVAT). **A:** Incision; **B:** Exposure via the midline raphe; **C:** Superior pedicle dissection; **D:** Inferior pedicle dissection; **E:** Recurrent laryngeal nerve dissection; **F:** Removed specimen.

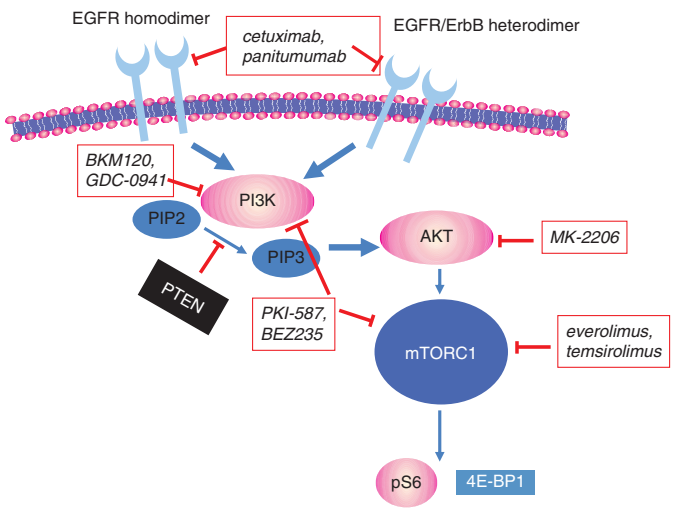

**FIGURE 30-1.** Simplified schematic illustration. EGFR homodimers and EGFR/ErbB heterodimers activate PI3 kinase, which favors the conversion of phosphatidylinositol bisphosphate (PIP2) to phosphatidylinositol triphosphate (PIP3), with subsequent activation of Akt and mTORC1. Two well-characterized phosphorylation targets of mTORC1 are eIF4E-binding protein (4E-BP1) and p70 S6 kinase 1 (S6K1), which regulate translation of proteins required for G1-S phase progression in the cell cycle. Monoclonal antibodies directed against the extracellular domain of EGFR (e.g., cetuximab, panitumumab) represent the most clinically advanced strategy to inhibit this pathway in HNSCC at present. Small molecules to inhibit intracellular processes in this cascade are under investigation, including PI3 kinase inhibitors (e.g., BKM120, GDC-0941), Akt inhibitors (e.g., MK-2206), mTORC1 inhibitors (everolimus, temsirolimus), and dual PI3 kinase/mTOR inhibitors (PKI 587, BEZ235), among others.
