Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

*With great love, I dedicate this book to my wife, Ilene. I am so grateful for all that she has done to support me in our lives together. Without her, this book, and most everything else that I have accomplished, would not exist.*

*LBH*

*In each of the three previous editions of this book, I mentioned my family in the dedication ritual—those members alive and those who are but fond memories. My thoughts were reflective of affection and respect, those very emotions implicit in the current endeavor. I am confident, then, that all—past and present—will or would have conceded that my professional accomplishment are to a great extent related to the thousands of my patients who have made the journey through the anguish of cancer, some successfully, others not; and the ultimate dedication should be to them. Their plight has been the essence of my mission in life, and my admiration of their courage is at the very core of my contribution to this book. I thank them for trusting me in the hour of their misfortune.*

*RBS*

*With love and affection, my contribution to this book is dedicated to Diana, my wife and partner.*

# SPECIAL DEDICATION

## Dr. Waun Ki Hong, MD, FACP, DMSc

We are honored to gratefully acknowledge Dr. Waun Ki Hong, who, with Lou Harrison and Roy Sessions, conceived and was a founding editor of *Head and Neck Cancer: A Multidisciplinary Approach*. In many ways, this textbook is a literary projection and reflection of Dr. Hong. He has been and continues to be devoted to learning, scholarship, and the comprehensive evaluation and care of the broad spectrum of cancer patients. He has been a keen innovator and a leader paving the way to multidisciplinary thinking, utilizing physical examination skills, new imaging technologies, and creative colleagues from other specialties to develop and test new treatment strategies. He has long been engaged in blending the skills and talents of clinicians and clinical investigators to foster advances in patient care, constantly challenging the status quo.

Dr. Hong is Professor and Head of the Division of Cancer Medicine and Vice Provost for Clinical Research at The University of Texas MD Anderson Cancer Center. He obtained his medical degree from the Yonsei University School of Medicine, Korea, a medical residency at the Boston Veterans Affairs (VA) Medical Center, and fellowship in medical oncology at Memorial Sloan-Kettering Cancer Center of New York. He is an American Cancer Society professor and the Samsung Distinguished University Chair in cancer medicine. As the elected president of the AACR in 2001, he was influential in expanding the organization's international membership, and he has played an immense role in promoting multidisciplinary translational cancer research among physician-scientists worldwide. He has also played a pivotal role in shaping national public policy for cancer care and research in his commitment to the work of the National Cancer Institute. He has been the lead editor for numerous books, authored major treatises, and published 700 articles in scientific journals.

One story illustrates Dr. Hong's innovative thinking. As a young medical oncologist at the Boston VA, in 1979, he was one day called to the operating room by Stuart Strong, who was about to perform a total laryngectomy on a patient with clinical stage T4 squamous cancer. Dr. Hong had administered induction chemotherapy, and a wondrous, complete tumor response had occurred—so, now what to do? Of course, this led to formal clinical trials and, ultimately, the VA Cooperative Group study that showed the curative potential for chemotherapy and radiation, a nonsurgical and organ-preserving strategy that continues to be practiced in various platforms and, with many modifications later, throughout the world to benefit thousands of patients. He is renowned for seminal research in the role of retinoids in normal tissue biology and carcinogenesis, the broad area of chemoprevention of cancer, and importantly in the development of the methodology for cancer-prevention trials. His work has impacted the conduct of medical care for patients at risk of upper aerodigestive tract, breast, gastrointestinal, and genitourinary malignancies. Most recently, he spearheaded a remarkable new strategy for the systemic treatment of patients with advanced solid cancers. In the setting of progressive non–small cell lung cancer, in patients previously exposed to conventional therapies, he developed a platform for a fresh tumor biopsy at the time of enrollment and then an assignment to experimental therapies based on molecular assessments. He demonstrated that the approach is workable and has provided a blueprint for the conduct of future trials of molecular-targeted therapy across several solid tumors.

A centerpiece of current work is devotion to and mentoring of junior colleagues and fellows. Dr. Hong works vigorously within the MD Anderson fellowship program, with physician leaders and the fellows and students. Still directly caring for patients, he always has time to put his hand on young shoulders and show them the way. He sincerely cares about the future of both patients and the doctors who treat them.

To Dr. Hong, we offer our deepest appreciation for your devotion to and study of cancer medicine and for being a role model for the young and not-so-young, for all of us.

# PREFACE

We take considerable pride in the fact that the integrity of *Head and Neck Cancer: A Multidisciplinary Approach (HNC)* has been retained through four consecutive editions. HNC I (1999) started a crescendo of learning for all of us, and with each subsequent book, we sought and found ways to do a better job. The planners have always been keenly in tune with the concept that a continuance of book quality must never be based on previous laurels and accolades. As a means of separating this statement from the theoretical, we cite the example of the first edition of HNC that won a prestigious international literary award, by which we were certainly humbled and honored. To assume that to be the apogee of quality, however, would almost certainly have been followed in subsequent editions by a diminution of substance and book vitality. Unlike dated works of literature, such as fiction and history, a book like HNC is a relentlessly moving target, and failure to continually address the rapidly evolving science within the relevant body of knowledge would invite obsolescence. Accordingly, we have launched every new edition with this attitude and these realizations. Each time, the challenges were substantial, but were surmounted.

We set out to create the standard of excellence in the head and neck oncology literature, but subsequently came to realize that it is as much of a challenge to sustain the high level achieved as to create it. Our retrospective analysis of the elusive reasons for the achievement invariably led us back to several key axioms: First, literary vitality and dynamism are best achieved by a formula of staggered rotations of authors; that is to say, partial change for a given edition. This practice injects new thinking into a text while fostering continuity from edition to edition, and additionally, generates an important byproduct by incorporating fresh young academics from the rich talent pool available. Properly energized, these new contributors approach their task with a serious sense of responsibility to the book, to the profession, and ultimately to cancer patients. Another key to the formula is the avoidance of repeating the same book that seems to result from merely tweaking old data, only to have repeated the same chapter, rather than critically reading and rethinking each that was in the previous edition—not necessarily always starting from scratch, but at a minimum, divesting treasured thoughts and words that are better captured by change. Noted authors are often loath to do this, and finding an appropriate compromise with the editors represents the sine qua non of literary collaboration. Thus, each edition has been a fresh, new book. However, although new, each is largely grounded in our long-held philosophy that continues to recognize and emphasize scholarship and academic integrity, places equal importance on "why" and "how to," and embraces the notion that in the contemporary world of oncology, the overall goal should be to maximize the chance for cure, but not at any cost; that is to say, quality of life and death issues must take center stage in all cancer management decisions and strategies. Treatment that was once based almost solely on mechanical audacity and elegance has matured to include intellectual creativity. That is not meant to suggest that surgery, radiation, medical treatments, and other standard methods are no longer important, but instead, it is the recognition that science—molecular and genetic—is the critical part of the present and the future canon. In this, the fourth edition of *HNC*, the reader will note that there are several key chapters that go well beyond their respective predecessor chapters in addressing the scientifically relevant material of the particular subject discussed. That being said, in this edition of *HNC*, we have also significantly increased and improved the technique sections. We believe, then, that throughout multiple editions, we have adapted and have embraced change, brevity, and efficiency, the combination of which makes this latest work a readable and imminently practical companion for all students of head and neck oncology.

As in the last edition, we have made extensive use of algorithms and guidelines in the quest for standardization of workup and management strategies. While doing so, we have attempted to incorporate flexibility in order to accommodate the substantial variability between patients. And finally, as proof that the book's title is more than a catchy marketing ploy, the reader will easily discover that the multidisciplinary philosophy of dealing with this dreaded complex of diseases is embedded throughout the corpus of the work.

Collaborating with a world-class publishing organization improves the entire working environment in undertaking such a substantial endeavor, and as it relates to the team at Lippincott Williams & Wilkins, this is most assuredly an understatement.

Finally, we feel that words alone fail to describe the heartfelt gratitude of the editors for the time commitment and other sacrifices of the authors who have labored to finalize this project. As usual, the busiest of scholars have somehow found time to hammer out yet another project despite their already saturated agendas—we thank them and their families for paying the substantial personal price to thus enrich the scientific literature.

# ACKNOWLEDGMENTS

First, we would like to thank the wonderful staff at Lippincott Williams and Wilkins. This especially includes Mr. Jonathan Pine, whose wisdom has guided us through several editions. We would also like to thank Senior Product Manager Emilie Moyer and Development Editor Martha Cushman.

The editors want to express their deep appreciation and respect to Mr. John Battis, who has been an indispensable partner in the last three editions of this textbook. His commitment to perfection and professionalism is a hallmark that all of us should aspire to achieve.

# PERSONAL THOUGHTS ON BEING AN ONCOLOGIST

This fourth edition of our textbook will be my last as an editor. My regret in stepping down relates mainly to the loss of the association with my co-editors and the publisher. Our professional chemistry will be a fond memory throughout the balance of my life. However, the inexorability of life's accrual and retirement are real, and my pathway is clear. In signing off, however, I have asked for the indulgence of my co-editors by allowing me to write a personalized essay of sorts. I thank them for graciously accepting this departure from the norm in which I expound on matters thus far only slightly addressed in our literature.

For appropriate reasons, psychosocial and ethical matters that are relevant to the moral foundation and behavior of oncologists have been infrequently mentioned in the literature. Mainstream cancer textbooks have always been devoted to the disease—its biology, pathology, pathogenesis, treatment, etc., without dwelling on the transcendental matters that relate to interaction with and care of cancer patients. Such a statement is in no way intended as an indictment of what has been written; instead, it is merely an acknowledgment of fact. In this discussion, therefore, I have attempted to touch on some of the more important of these issues, and in doing so I seek to create an imperative for oncologists that includes sensitivity and intuitiveness, in addition to intellectualism and technical skills. These thoughts are not limited to a particular oncology specialty; instead, they apply consistently to the entire cancer playbook. Unquestionably, esoteric thoroughness is beyond the capacity of this overview, but it is my hope that the reader will be stimulated to pursue further studies and deeper consideration of these matters.

Especially as it pertains to the medical profession, the desire to serve fellow humans is vocational, and the inherently strong and consuming passion required to function at this level goes well beyond routine ambition. This intensity is even more relevant to the life of an oncologist—whether focused on radiation, surgery, medical, or psycho-oncology; all are tethered to potentially insatiable emotional demands of a very needy patient population. While potentially appealing to one's vanity, these demands—unique in medicine—can consume an idealistic oncologist who is incapable of compartmentalization of life's priorities.

Being a *physician* is a privilege, and sober responsibilities go with the title. Caring for cancer victims magnifies this sobriety because the typical patient—frightened, vulnerable, and threatened to the core—justifiably expects compassion, a commitment to excellence, a seriousness of purpose, and an ethos of integrity and humanity from the cancer team in general, and especially from the cancer physician.[1] Whether justified or not, when responsible for cancer patients, the stakes are generally perceived to be higher than those associated with other maladies. Not surprisingly, being an oncologist involves a life with little room for frivolity or casualness, and at a minimum, dilettantish physicians who value style over substance should avoid the oncology specialties. Obviously, style and substance are not mutually exclusive, but in the personality of oncologists, the former must be substantially subordinated to the latter. Aspirants to these specialties must realize that to perform in this arena is neither an ordinary responsibility nor a casual commitment; none in medicine should be, but with cancer, there is usually heightened passion and drama. What is euphemistically labeled *the cancer experience* is can be an extraordinary test for physician and patient alike.

It is essential, then, for those on this career path to understand that oncologists are required to function with a heightened emotional capability—often in an atmosphere of sadness and fear. At a minimum, it's challenging to care for patients whose dependence, vulnerability, and psychological fragilities are extraordinary. Acceptance of this fact is fundamental to "Oncology 101." With that said, given the correct physician motivation, the experience can be deeply rewarding and the lifestyle very workable.

Even though most sophisticated cancer teams include psychiatric and other support colleagues, their participation, no matter how effective, should not preclude the involvement of the whole team; said another way, the emotional responsibilities of the oncologist are in no way mutually exclusive from those of the psycho-oncologist or social worker. Essentially, the psychological support from the cancer team should be circumferential.

The psychic issues at play between the oncologist and the patient are inextricably intertwined—and by the physician understanding the patient better, and by the patient understanding what is faced by the physician, *the cancer experience* is enhanced.

For starters, the repeated witnessing of agony and death can be emotionally erosive, and the personal price paid by oncologists can be substantial. That said, many of the contemporary treatment strategies are successful, and the rewards seem to consistently replenish our spirit. It is important, however, to recognize a consistent human characteristic present in the scenario just described; dealing with the travails associated with cancer can lead to an involuntary response of self-protection in which oncologists unintentionally shield themselves emotionally by being remote from their patients. This is similar to other human behavior in which barriers are erected out of fear of emotional pain. It is my observation that young physicians are more prone to such emotional defensiveness, but with maturation and self-analysis, many come to realize that the real rewards for a doctor come from the bonding and the affection that they sought to avoid in their younger years.

With emotional maturation, the oncologist hopefully begins to appreciate the rewards of success—not by always conquering the disease mind you, because unfortunately such is not the case—but by finding the human connection that helps guide and support patients in their time of extreme need. It has always amazed me how much genuine affection and gratitude cancer patients are capable of doling out. So when others remark that it must be discouraging to be an oncologist, my response is that while emotional and sometimes even depressing, quite the opposite from discouragement is the norm. On the contrary, gratification and satisfaction are abundant.

Absent an emotional commitment on the part of the oncologist—that is, failing to lower those self-imposed protective barriers—both the patient and the physician suffer. In fact, it is my unscientific observation that the latter's failure to commit can lead to crippling professional unhappiness. Those considering oncology as an avenue of study should, therefore, be self-analytical in this regard; if one is unwilling to commit emotionally, a psychologically less demanding specialty should be considered.

From the patient's standpoint, the psychic plight cannot be overstated. Admittedly, the intensity of fear—that most primordial of emotions—varies with the degree of seriousness of the malignancy and also from patient to patient. With some exceptions, however, these instinctive feelings are consistent and

(c) 2014 Wolters Kluwer. All Rights Reserved.

strong. How various patients handle and respond to these feelings is a subject of study that the emotionally astute oncologist must address. Most have no special training in psychology, and the level of perceptiveness and concern for the more spiritual aspects of doctor–patient interactions is largely inherent to the physician's persona.

The fears of these patients vary from simple to complex and range from low grade to paralytic. Whether cured or not, the cancer victim often dwells on a kaleidoscope of perceived threats—financial matters, family well-being, loss of dignity, pain, deformity, dependency with lose of autonomy, being abandoned and alone, and obviously death itself—all of which can be catalyzed by an emotionally uninvolved cancer team that minimizes these deeply rooted concerns. The take-home message of this general subject is as with raising children, needs differ from one individual to the other—some patients require more attention, some less; and if a physician does not have the flexibility to cater to this diverse emotional appetite, they should work in another specialty of medicine.

In addition to compromising their own chance of achieving professional fulfillment, the unwillingness of an oncologist to contribute to the emotional equation between doctor and patient often stymies the latter's ability to develop hope. This is no small consideration because, in the practical world of cancer medicine, there is nothing psychologically more valuable for a patient than hope—but only when it is realistic and honest. Better for the doctor to be noncommittal than to encourage false hope, which is deceptive, and perhaps even a betrayal of sorts.

The importance of the relationship between hope and trust of one's physician is extraordinary, especially when discussing cancer—the two are closely linked. To trust is to have faith and confidence not only in the integrity and unselfishness, but especially the beneficence of the person in charge; bottom line, "Will my doctor do and advise what is best for me, and not because of curiosity or a result of stubbornness." For the oncologist to find a balance between empathy and guidance throughout the cancer journey is the sine qua non of good leadership—a quality that should be practiced by those who have accepted the responsibility for cancer victims. The paradigm is straightforward: good doctor/patient relations come out of honest and forthright dialog that is based on realism rather than paternalistic avoidance of unpleasant news. Such a relationship begets trust, which in turn begets acceptance of the inevitable as the patient is led to the conclusion of care, whether it is improvement or death. In order to accommodate this paradigm, however, hope must be redefined. Let me explain just what I mean.

Too often, physicians misunderstand hope by thinking only in terms of cure or remission. This flawed concept is common in the ever-optimistic oncology community—surgical, radiation, and medical alike. Hope can also be for a good death; for time to mend interpersonal bonds that are in disrepair; for resolution of feelings about divinity and a life after death; and, yes, for comforting loved ones who will be left behind. Never mind what the medical team deems important, the patient should be the author of the new standard, and it is the job of the physician to incorporate that into the dialog and the relationship. As a result of trust and creditable dialogue, a patient should be able to completely rely on unselfish guidance in making practical choices, especially at the end of life. In this state of mind, one is better able to find closure in life and an acceptance of death, both of which add tranquility to the final stage of existence.

Oncologists—even those with the best of intentions—too often fight *the battle* to excess, and in an effort to do something, use up valuable end-of-life time and resources. It is my belief that this desperate behavior in a sense reflects our society's refusal to admit the existence of death's power, and perhaps even death itself, and in this high-tech biomedical era, when the tantalizing possibility of miraculous cure is dangled before patient and family, the temptation to see therapeutic hope is great, even in those situations when common sense would suggest otherwise.[2]

So as to take this out of the realm of speculation, I point to a study reported in the *Annals of Internal Medicine*[3] that used patients from California and Massachusetts as a study cohort. All were 65 and older, and had died as a result of their cancer. In more than 20% of the study group, chemotherapy had been administered within 3 months prior to their death, and significantly, the cancer's likelihood of responsiveness to chemotherapy did not seem to influence whether dying patients received chemotherapy at the end of life. Use of chemotherapeutic agents was similar for patients with breast, colon, and ovarian malignancies and even for those with cancers that are generally considered unresponsive to chemotherapy, such as melanomas and those of the pancreas, liver, and kidney.[4] Circumstantial data from another study[5] showed that 20% of the Medicare cancer patients with metastasis who were analyzed had been started on a new chemotherapy regimen within two weeks of death. The implications of this are far reaching and profound and among cynics surely suggest monetary motives. One is left to speculate how these data would differ in a population of uninsured patients. In evaluating what seems like a system's error, the obvious question is that if there are incentives for oncologists to try more treatment despite minimal odds for success, why can't the reverse be implemented; that is to say, why can't there be disincentives to go for that long shot.

In deciding how much treatment is enough, the cancer physician must repeatedly address the question of what is in the best interest of the patient—that is to say, he/she should act with beneficence. Even if what is done turns out to be the wrong strategy, if the motive was in quest of the patient's benefit, it is morally defensible. This sounds simplistic, but in fact, pride, vanity, and other unresolved or perhaps even unrecognized psychic forces within a physician can complicate a patient's life and death. Physicians, like other talented and intelligent people, are not immune to the insecurity that seeks reassurance of their abilities, and whether realized or not, part of their self-image depends on success and failure in patient care. Additionally, many physicians are extraordinarily competitive, and the instinct to fight on can be strong. Some oncologists seem to feel obligated to explore every avenue of treatment, no matter how unlikely the benefit. Aside from this being void of beneficence, it is financially an unsupportable strategy. My plea in this regard is for an early reality check, since the treatment decisions made near the end of life are prone to propel a dying person in a senseless direction. That being said, it is important to concede the need for certain palliative surgical techniques that are humanely applicable to those approaching death. For example, in selective circumstances, operations such as a gastrostomy, a colostomy, or a tracheostomy can diminish the misery associated with intestinal and airway compromise. Active palliative care—surgery and occasionally targeted radiation therapy included—has an important role, provided implementation is based on humaneness and beneficence.

A vulnerable cancer patient's reliance on their oncologist can be extraordinary, and it is not unusual for the patient to look to that physician for advice and counsel on a variety of health-related matters—psychiatric, nutritional, and some unrelated to the primary disease of concern. This role of the "perceived expert" on all medical matters must be handled with tact, realism, humility, and always with graciousness and generosity. It's a simple thing to disavowal expertise, but while doing that, to show obvious interest by offering suggestions on some questions and by promoting appropriate referrals when indicated. In this day and age of subspecialization, it is important to remind ourselves that we are still physicians and we should still attempt to look after and care for the "whole patient."

(c) 2014 Wolters Kluwer. All Rights Reserved.

It should always be remembered that during the final approach to death, the oncologist is often the go-to person for a variety of matters. While much of patient concerns can and will be handled by the supporting team, many of the questions asked are well within the purview of a mature and receptive oncologist. The patient and family should feel as if their physician is involved with and overseeing almost everything that's happening, and importantly, the oncologist especially should welcome discussing death with a cancer victim. From a patient's perspective, who is better to talk to about death? With a well-crafted discussion, there often follows an element of surrender to the reality of death, understandably sometimes accompanied by anxiety, but usually without terror. More often, the surrender is followed by acceptance and a sense of calm—in the vernacular of the hospice philosophy, a tranquil comfort, rather than turbulence and rampant fear of the unknown. This passage from realization to acceptance is essential to the willingness of a patient to cease trying to hold their mortality at bay.

This whole general subject provides much material for contemplation and reflection, and I suggest the following intellectual itinerary for the reader who's emotional and intellectual maturation should ideally be a dynamic process: what ought a cancer patient reasonably expect of the system, the cancer team, and especially, the cancer physician? What ought a cancer physician be able to expect of the patient? What are the physician's responsibilities to the patient—to the family? How much information about the disease is enough; how much is too much; and importantly, how much is too little? Where do optimism and encouragement end and the gravitas of realism begin? How specific and how graphic should the doctor be? Is pessimism allowed, and if so, should it be shared with the patient? How forcefully should the case be made for the recommended treatment; that is to say, should the physician attempt to alter the patient's search for autonomy when they are disinclined to follow physician recommendations? What is the cancer physician's role when treatment fails, or because of the advanced state of the disease, when no treatment is given? How important are quality of life and quality of death; and specifically what is the cancer physician's role in the dying process? Is death solely within the dominion of spiritual forces, or is there a place for the physician as a taker of life—that is to say, the catalyst to death; and, if not an active player, should a physician even introduce the possibility of induced patient death, that is, suicide? The Oath[6] that we have lived by clearly says "No" to the taking of life by the physician; but should this part of the Oath be adapted in search of modern relevance? That certainly has happened in several European countries, and in three states in America (Washington, Oregon, and Montana), in which there are laws condoning varying degrees of physician involvement with induced patient death, a high percentage of which are related to uncured cancer. Finally, because of the natural instinct for self-protection, is it justified for the cancer physician to remain emotionally detached, and in doing that, fail to provide an intensity of feeling that might be more helpful to the patient during treatment and even on into the dying process?

These questions and many others randomly flow through the lexicology of cancer management. The answers often cannot be rigid because so much of human nature varies from individual to individual—patient and physician alike—and there should be a somewhat tailored approach for the individual patient. With that said, however, a consistent pattern ideally should underlie it all, and the standards by which these questions are answered should be established by a medical profession that understands and advocates what is right as opposed to what is wrong.

CHAPTER 1

Bruce M. Wenig and Jean-Marc Cohen

# General Principles of Head and Neck Pathology

The surgical pathologist is an integral member of the clinical team that administers to the head and neck cancer patient. The pathologist's role is multifactorial. In the simplest of terms, it is his/her job to render the correct diagnosis. However, that "final" goal is not an isolated achievement, nor is the diagnosis the sole responsibility placed on the surgical pathologist. There are numerous factors that go into the diagnosis of cancer, not the least important of which are what type of cancer is it, how invasive is the tumor, are the surgical margins free of involvement, is there metastatic disease, and are there any pathologic features that may allow for predicting the biologic behavior for a given tumor.

This chapter will be an overview of the pathologic issues relative to head and neck cancer. The chapter will be divided into two sections. Section I will be an overview of the general principles of the pathology of head and neck neoplasms. Section II will focus primarily on head and neck squamous cell carcinoma (HNSCC), including the parthologic findings of precursor lesions of HNSCC, invasive squamous cell carcinoma (SCC), and variants of SCC. Due to limitations of space, the pathology of salivary gland neoplasms, neuroendocrine neoplasms, thyroid and parathyroid lesions, and mesenchymal and hematolymphoid neoplasms will not be included in this chapter. The reader is referred to other chapters in this textbook discussing these subjects.

## THE SURGICAL PATHOLOGY REPORT AND THE TISSUE SPECIMEN

The pathology report is the document that contains the pathologist's diagnosis for a given surgical or cytologic specimen. The pathology report not only contains the diagnosis of the tumor but may also include the type, differentiation, and histologic grade of the tumor, the extent of disease, including whether the tumor is invasive (*in situ* vs. submucosal invasion), whether the surgical margins are involved by tumor, whether there is neural or lymphvascular space invasion, and whether nodal metastases and extranodal extension is present. In addition, the pathology report may contain the results of any adjunct studies that assist in establishing the diagnosis. Therefore, the pathology report includes information of prognostic and therapeutic import. Further, the pathology report is a legal document that becomes a part of the patient's medical record. The College of American Pathologists (CAP) has established guidelines (referred to as checklists) for the reporting of human cancers. These guidelines include cancers of all body sites. The most recent guidelines for the reporting of cancers of the head and neck, including the thyroid gland, are detailed in Tables 1.1 through 1.6.

The final histologic diagnosis is not an isolated achievement or the sole responsibility of the pathologist. In addition to the final diagnosis, the pathology report contains the gross and microscopic description of the specimen. For small specimens such as a biopsy, the gross description is relatively simple and straightforward. For larger surgical resections, like those often required for the head and neck cancer patient, the surgical specimen may be large and complex in its details. The complexity of the surgical specimen necessitates that the pathologist has a good functional understanding of the surgical anatomy of the region. It is the responsibility of the pathologist to properly evaluate the gross specimen and to describe in detail the gross characteristics of the tumor to include its relationship to the surrounding structures. Equally important is the proper sectioning of the specimen. Improper sectioning will result in erroneous evaluation of the specimen. To this end, the surgeon and pathologist must work in unison, especially in appropriately orienting a large resection specimen and determining the key aspects of the specimen (e.g., surgical margins) that require special attention. The sections that are taken by the pathologist will ultimately indicate whether the tumor involves the surgical margins or whether the surgical margins are free of tumor. The issue of surgical margin involvement will impact on the necessity for additional surgical intervention and/or the utilization of adjuvant therapy. Therefore, the proper gross evaluation of the specimen, including the sectioning for histologic evaluation, is a critical component in the overall management of the head and neck cancer patient.

It should be obvious that the pathologist's role as a member of the clinical team goes beyond the histologic evaluation of a tumor and the assigning of a name (i.e., a diagnosis). Certainly, the diagnosis of the tumor is important, but there are multiple additional factors that are equally important, perhaps even more important to the overall management and prognosis of the head and neck cancer patient. These issues will be discussed in detail later in this chapter.

The pathologist is entirely dependent on the tissue sampling that is received from the surgeon.

Without the appropriate material, a diagnosis cannot be rendered. This is true for neoplastic, as well as nonneoplastic lesions. In general, necrotic or ulcerated tissue should be avoided as the diagnostic yield from this material, at best, is low. The viable tissue surrounding or deep to the ulcerated or necrotic tissue should be sampled. The most common types of neoplastic proliferations

**Protocol web posting date: June 2012**
LARYNX (SUPRAGLOTTIS, GLOTTIS, SUBGLOTTIS): Incisional and Excisional Biopsy, Resection
Select a single response unless otherwise indicated.

Specimen (select all that apply)
- Larynx, supraglottis
- Larynx, glottis
- Larynx, subglottis
- Other (specify): _____
- Not specified

Received
___ Fresh
___ In formalin
___ Other (specify): _____

Procedure (select all that apply)
___ Incisional biopsy
___ Excisional biopsy
___ Resection
- ___ Endolaryngeal excision
- ___ Transoral laser excision (glottis)

___ Supraglottic laryngectomy
___ Supracricoid laryngectomy
___ Vertical hemilaryngectomy (specify side): _____
___ Partial laryngectomy (specify type): _____
___ Total laryngectomy
___ Neck (lymph node) dissection (specify): _____
___ Other (specify): _____
___ Not specified

***Specimen Integrity**
*___ Intact
*___ Fragmented

**Laryngectomy (required only if applicable)**
___ Open
___ Unopened

Specimen Size
Greatest dimensions: ___ × ___ × ___ cm
*Additional dimensions (if more than one part): ___ × ___ × ___ cm

Pathologic Staging (pTNM)
*Note: The phrases in italics include clinical findings required for AJCC staging. This clinical information may not be available to the pathologist. However, if known, these findings should be incorporated into the pathologic staging.*

*TNM Descriptors* (required only if applicable) (select all that apply)
___ m (multiple primary tumors)
___ r (recurrent)
___ y (posttreatment)

Primary Tumor (pT)
___ pTX: Cannot be assessed
___ pT0: No evidence of primary tumor
___ pTis: Carcinoma *in situ*

**For All Carcinomas Excluding Mucosal Malignant Melanoma**

*Primary Tumor (pT): Supraglottis*
___ pT1: Tumor limited to one subsite of supraglottis *with normal vocal cord mobility*
___ pT2: Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) *without fixation of the larynx*
___ pT3: Tumor limited to larynx *with vocal cord fixation* and/or invades any of the following: postcricoid area, preepiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage
___ pT4a: Moderately advanced local disease. Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (eg, trachea, soft tissues of neck including deep extrinsic muscle of tongue, strap muscles, thyroid, or esophagus)
___ pT4b: Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

*Primary Tumor (pT): Glottis*
___ pT1: Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) *with normal mobility*
___ pT1a: Tumor limited to one vocal cord
___ pT1b: Tumor involves both vocal cords
___ pT2: Tumor extends to supraglottis and/or subglottis *and/or with impaired vocal cord mobility*
___ pT3: Tumor limited to the larynx *with vocal cord fixation* and/or invades paraglottic space and/or minor thyroid cartilage erosion (eg, inner cortex) (Note H)
___ pT4a: Moderately advanced local disease. Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (eg, trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus) (Note H)
___ pT4b: Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

*Primary Tumor (pT): Subglottis*
___ pT1: Tumor limited to subglottis
___ pT2: Tumor extends to vocal cord(s) *with normal or impaired mobility*
___ pT3: Tumor limited to larynx *with vocal cord fixation*
___ pT4a: Moderately advanced local disease. Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (eg, trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
___ pT4b: Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

*Regional Lymph Nodes (pN)#*
___ pNX: Cannot be assessed
___ pN0: No regional lymph node metastasis
___ pN1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 1.1 College of American Pathologists (CAP) Check Lists for Cancers of the Larynx (Continued)**

___ pN2: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
___ pN2a: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
___ pN2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
___ pN2c: Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
___ pN3: Metastasis in a lymph node more than 6 cm in greatest dimension
___ No nodes submitted or found

*Number of Lymph Nodes Examined*
Specify: _____
___ Number cannot be determined (explain): _____

*Number of Lymph Nodes Involved*
Specify: _____
___ Number cannot be determined (explain): _____
* Size (greatest dimension) of the largest positive lymph node: _____

[#]*Superior mediastinal lymph nodes are considered regional lymph nodes (level VII). Midline nodes are considered ipsilateral nodes.*

Distant Metastasis (pM)
___ Not applicable
___ pM1: Distant metastasis
* Specify site(s), if known: _____
* Source of pathologic metastatic specimen (specify): _____

**For Mucosal Malignant Melanoma**

*Primary Tumor (pT)*
___ pT3: Mucosal disease
___ pT4a: Moderately advanced disease. Tumor involving deep soft tissue, cartilage, bone, or overlying skin
___ pT4b: Very advanced disease. Tumor involving brain, dura, skull base, lower cranial nerves (IX, X, XI, XII), masticator space, carotid artery, prevertebral space, or mediastinal structures

*Regional Lymph Nodes (pN)*
___ pNX: Regional lymph nodes cannot be assessed
___ pN0: No regional lymph node metastases
___ pN1: Regional lymph node metastases present

*Distant Metastasis (pM)*
___ Not applicable
___ pM1: Distant metastasis present
* Specify site(s), if known: _____
* Source of pathologic metastatic specimen (specify): _____

* Additional Pathologic Findings (select all that apply)

**Pathologic Staging (pTNM)**

**TNM Descriptors (required only if applicable) (select all that apply)**
___ m (multiple primary tumors)
___ r (recurrent)
___ y ( posttreatment)

**Primary Tumor (pT)**
___ pTX: Cannot be assessed
___ pT0: No evidence of primary tumor
___ pTis: Carcinoma *in situ*

**For All Carcinomas Excluding Mucosal Malignant Melanoma**
**Primary Tumor (pT): Maxillary Sinus**
___ pT1: Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
___ pT2: Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
___ pT3: Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
___ pT4a: Moderately advanced local disease. Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
___ pT4b: Very advanced local disease. Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve ($V_2$), nasopharynx, or clivus

**Primary Tumor (pT): Nasal Cavity and Ethmoid Sinus**
___ pT1: Tumor restricted to any one subsite, with our without bone invasion
___ pT2: Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with our without bone invasion
___ pT3: Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
___ pT4a: Moderately advanced local disease Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
___ pT4b: Very advanced local disease. Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve ($V_2$), nasopharynx, or clivus

*Regional Lymph Nodes (pN)#*
___ pNX: Cannot be assessed
___ pN0: No regional lymph node metastasis
___ pN1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
___ pN2: Metastasis in a single ipsilateral lymph node, more than 3cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral nodes, none more than 6 cm in greatest dimension
___ pN2a: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
___ pN2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
___ pN2c: Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
___ pN3: Metastasis in a lymph node more than 6 cm in greatest dimension

___ No nodes submitted or found

*Number of Lymph Nodes Examined*

Pathologic Staging (pTNM)
*Note: The phrases in italics include clinical findings required for AJCC staging. This clinical information may not be available to the pathologist. However, if known, these findings should be incorporated into the pathologic staging.*
TNM Descriptors (required only if applicable) (select all that apply)
___ m (multiple primary tumors)
___ r (recurrent)
___ y (posttreatment)

Primary Tumor (pT)
___ pTX: Cannot be assessed
___ pT0: No evidence of primary tumor
___ pTis: Carcinoma *in situ*

**For All Carcinomas Excluding Mucosal Malignant Melanoma**

*Primary Tumor (pT): Oropharynx*
___ pT1: Tumor 2 cm or less in greatest dimension
___ pT2: Tumor more than 2 cm but not more than 4 cm in greatest dimension *without fixation of hemilarynx*
___ pT3: Tumor more than 4 cm in greatest dimension *or with fixation of hemilarynx* or extension to lingual surface of epiglottis

*(continued)*

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 1.4 College of American Pathologists (CAP) Check Lists for Cancers of the Pharynx (Continued)**

___ pT4a: Moderately advanced local disease. Tumor invades larynx, deep/extrinsic muscle of tongue, medial pterygoid muscles, hard palate, or mandible[#]
___ pT4b: Very advanced local disease. Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base, or encases carotid artery
[#]*Note: Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of larynx.*

*Primary Tumor (pT): Nasopharynx*
___ pT1: Tumor confined to nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension[#]
___ pT2: Tumor with parapharyngeal extension[#]
___ pT3: Tumor invades bony structures of skull base and/or paranasal sinuses
___ pT4: Tumor with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, or with extension to the infratemporal fossa/masticator space
[#]*Parapharyngeal extension denotes posterolateral infiltration of tumor.*

Primary Tumor (pT): Hypopharynx
___ pT1: Tumor limited to one subsite of hypopharynx and/or 2 cm or less in greatest dimension
___ pT2: Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation of hemilarynx
___ pT3: Tumor measures more than 4 cm in greatest dimension *or* with fixation of hemilarynx or extension to esophagus
___ pT4a: Moderately advanced local disease. Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue[#]
___ pT4b: Very advanced local disease. Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
[#]*Note: Central compartment soft tissue includes prelarnygeal strap muscles and subcutaneous fat.*

Regional Lymph Nodes (pN)
___ pNX: Cannot be assessed
___ pN0: No regional lymph node metastasis

Regional Lymph Nodes (pN): Oropharynx and Hypopharynx[#]
___ pN1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
___ pN2: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
___ pN2a: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
___ pN2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
___ pN2c: Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
___ pN3: Metastasis in a lymph node more than 6 cm in greatest dimension

___ No nodes submitted or found

*Number of Lymph Nodes Examined*
Specify: _____
___ Number cannot be determined (explain): _____

*Number of Lymph Nodes Involved*
Specify: _____
___ Number cannot be determined (explain): _____
* Size (greatest dimension) of the largest positive lymph node: _____

[#]*Note: Metastases at level VII are considered regional lymph node metastases. Midline nodes are considered ipsilateral nodes.*

*Regional Lymph Nodes (pN): Nasopharynx*[#]
___ pN1: Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa[##]
___ pN2: Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa[##]
___ pN3: Metastasis in a lymph node greater than 6 cm and/or to supraclavicular fossa[##]
___ pN3a: Greater than 6 cm in dimension
___ pN3b: Extension to the supraclavicular fossa[##]

___ No nodes submitted or found

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 1.4 College of American Pathologists (CAP) Check Lists for Cancers of the Pharynx (Continued)**

*Number of Lymph Nodes Examined*
Specify: ____
___ Number cannot be determined (explain): _____

*Number of Lymph Nodes Involved*
Specify: ____
___ Number cannot be determined (explain): _____
* Size (greatest dimension) of the largest positive lymph node: ____

#*Metastases at level VII are considered regional lymph node metastases. Midline nodes are considered ipsilateral nodes.*
##*Supraclavicular zone or fossa is relevant to the staging of nasopharyngeal carcinoma and is the triangular region defined by three points: (1) the superior margin of the sternal end of the clavicle, (2) the superior margin of the lateral end of the clavicle, (3) the point where the neck meets the shoulder (see Figure 1-3, no. 2). Note that this would include caudal portions of Levels IV and VB. All cases with lymph nodes (whole or part) in the fossa are considered N3b.*

Distant Metastasis (pM)
___ Not applicable
___ pM1: Distant metastasis
* Specify site(s), if known: _____
* Source of pathologic metastatic specimen (specify): _____

**For Mucosal Malignant Melanoma**

*Primary Tumor (pT)*
___pT3: Mucosal disease
___pT4a: Moderately advanced disease. Tumor involving deep soft tissue, cartilage, bone, or overlying skin.
___pT4b: Very advanced disease. Tumor involving brain, dura, skull base, lower cranial nerves (IX, X, XI, XII), masticator space, carotid artery, prevertebral space, or mediastinal structures.

*Regional Lymph Nodes (pN)*
___pNX: Regional lymph nodes cannot be assessed
___pN0: No regional lymph node metastases

of the upper aerodigestive tract (UADT) originate from the surface epithelium. A critical parameter utilized by the pathologist in differentiating a reactive or benign surface epithelial lesion from a malignant neoplasm is the presence or absence of stromal invasion. Adequate sampling should therefore include the depth of the tissue so that the pathologist can evaluate the epithelial-to-stromal interface, and an assessment for the presence or absence of stromal invasion can be made. Without an adequate epithelial-to-stromal interface, a diagnosis cannot be made, resulting in frustration for the pathologist, surgeon, and, most importantly, the patient. The deficiency of proper sampling leads to diagnostic and therapeutic delays. Further, tissue sampling of any anatomic site results in secondary pathologic changes that may cause diagnostic dilemmas for the pathologist.

The sampling of lymph nodes should include the largest node available as the diagnostic yield will be greatest as compared to a more accessible but smaller lymph node. Another issue in tissue sampling is the proper fixation of a specimen. Once a surgical specimen is removed, the surgeon should not delay in placing the specimen in the appropriate fixative. Excessive delay in placing the surgical specimen in fixative will result in autolytic and other artifactual alterations in the tissue. In general, the fixative that is most used by pathologists is formaldehyde. However, some specimens, especially lymph nodes removed for a possible diagnosis of lymphoma, may require special fixation. Some lymphoid-related antigens are lost by prior fixation so that in certain situations, the pathologist will want unfixed or fresh tissue in order to perform specific immunohistochemical, flow cytometric, or molecular biologic studies. The pathologist should be notified and consulted relative to the proper handling of the surgical material. Similarly, if it is anticipated that electron microscopy or cytogenetic evaluation will be required to assist in the diagnosis, then special fixatives, such as gluteraldehyde for electron microscopy and tissue culture medium (e.g., RPMI media, an acronym for Roswell Park Memorial Institute, where it was developed), will be required. When such circumstances are anticipated, the pathologist should be notified prior to the procedure that the specimen may require special handling.

The surgeon or any member of the surgical team should not bisect or section a tumor once it is excised from the patient. This may cause problems for the pathologist in the gross evaluation of the specimen, in appropriate tissue sectioning, and in appropriate tissue fixation. Such improper handling of the excised tissues may compromise the excised specimen. The gross evaluation, sectioning, and histologic examination of the surgical specimen falls under the purview of the pathologist. The surgeon should sample or remove sufficient tissue for diagnosis and send it to the pathologist intact, properly labeled, and with any specific requirements or requests that may be needed (e.g., specific surgical margins). The relationship of the surgeon and the pathologist is not adversarial, but should be collegial, with both specialists working in unison. Only in this way will the primary goal be achieved (i.e., optimal patient care).

# SECTION I
# General Principles of Head and Neck Neoplasms

## CLASSIFICATION OF HEAD AND NECK CANCERS

The general classification of malignant tumors of the head and neck are detailed in Tables 1.7 through 1.11.

**TABLE 1.7 Classification of Epithelial Malignancies of the Head and Neck**

- Cutaneous epithelial malignant tumors
  - Squamous cell carcinoma
  - Basal cell carcinoma
  - Verrucous carcinoma
  - Malignant cutaneous adnexal tumors
- Mucosal epithelial malignant tumors
  - Squamous cell carcinoma
    - Keratinizing type
    - Nonkeratinizing type
  - Variants of squamous cell carcinoma including
    - Papillary squamous cell carcinoma
    - Verrucous carcinoma
    - Spindle cell squamous carcinoma
    - Basaloid squamous cell carcinoma
    - Oropharyngeal (HPV-associated) squamous cell carcinoma
    - Nasopharyngeal carcinoma
      - Keratinizing
      - Nonkeratinizing
        - Differentiated type
        - Undifferentiated type
    - Adenosquamous carcinoma
    - "Lymphoepithelial" or undifferentiated carcinoma
    - Others
  - Adenocarcinomas
    - Surface mucosal origin
    - Mucoserous gland origin

**TABLE 1.8 Classification of Neuroectodermal Tumors of the Head and Neck**

- Tumors of the dispersed neuroendocrine cell system (DNES) (as it applies to the head and neck)
- Central DNES
  - Olfactory neuroblastoma
- Peripheral DNES
  - Malignant melanoma
  - Neuroendocrine carcinomas
    - Carcinoid tumor (well-differentiated neuroendocrine carcinoma)
    - Atypical carcinoid (moderately differentiated neuroendocrine carcinoma)
    - Small-cell carcinoma undifferentiated neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)
    - Large-cell neuroendocrine carcinoma
  - Merkel cell carcinoma
  - Peripheral nerve sheath tumors (schwannoma, neurilemoma, and malignant peripheral nerve sheath tumors)
  - Paragangliomas
  - Others

**TABLE 1.9 Classification of Mesenchymal Malignancies of the Head and Neck**

- Soft tissue
- Lymphoproliferative
  - Malignant lymphomas (Non-Hodgkin and Hodgkin)
- Skeletal muscle
  - Rhabdomyosarcoma
- Nerve
  - Malignant peripheral nerve sheath tumors
- Vascular/lymphatic
  - Angiosarcoma
  - Malignant hemangioendothelioma
  - Kaposi sarcoma
- Pericytic
  - Hemagiopericytoma
- Smooth muscle
  - Leiomyosarcoma
- Fibrous tissue
  - Fibrosarcoma
  - Malignant fibrous histiocytoma
- Notochord cell remnant
  - Chordoma
- Undefined mesenchymal cell
  - Synovial sarcoma
  - Alveolar soft part sarcoma
- Matrix-producing malignacies
- Bone
  - Osteosarcoma
- Cartilage
  - Chondrosarcoma
  - Odontogenic

## TERMINOLOGY

The cell of origin for a given neoplasm (benign or malignant) is its histogenesis. In head and neck malignancies, the most common type of malignant tumor is one that arises from the surface squamous epithelium. Squamous epithelial malignant tumors are carcinomas. However, the head and neck is rich in nonsquamous epithelial–derived structures, so that epithelial malignancies (carcinomas) may originate from salivary glands (major and minor), cutaneous adnexae, thyroid follicular epithelium, as well as parathyroid glands. Gland-forming tumors are termed adenocarcinomas. In addition to being rich in epithelial structures, the head and neck also contains abundant nonepithelial structures. These nonepithelial components include bone, cartilage, muscle (skeletal and smooth), nerves, vascular channels, and lymphoid structures. Any one of these nonepithelial or mesenchymal structures may give rise to a malignant tumor. Malignant neoplasms of mesenchymal structures are sarcomas, whereas malignant lymphoproliferative neoplasms are (malignant) lymphomas. Finally, the head and neck contains neuroectodermal (peripheral and central) elements, including melanocytes, neuroendocrine cells, Schwann cells, paraganglia, and olfactory neuroepithelial cells, any one of which may give rise to malignant tumors, such as malignant melanomas, neuroendocrine carcinomas, malignant

    - Angiosarcoma
    - Leiomyosarcoma
    - Malignant peripheral nerve sheath tumors
    - Others
  - Parathyroid gland
    - Parathyroid carcinoma

peripheral nerve sheath tumors, malignant paragangliomas, and olfactory neuroblastomas.

The discussion on terminology would not be complete without detailing the alterations of the surface epithelium that may represent the precursor change(s) heralding the malignant transformation of that epithelial structure. The reader is referred to the appropriate section in part II of this chapter that discusses this subject.

## HISTOLOGIC DIFFERENTIATION AND GRADE

The more a tumor recapitulates the appearance of the cell and/or tissue layer from which it arises, the better differentiated it is. This definition applies to virtually all malignant tumors, and perhaps it is most applicable to squamous epithelial tumors. A well-differentiated squamous carcinoma is one that has obvious keratinization and intercellular bridges. The keratinization appears as layered acellular eosinophilic material or appears within the cytoplasm of the cell as "glassy" eosinophilic deposits. Intercellular bridges are best viewed under oil-immersion magnification but can be seen on high magnification as very thin lines lying in between (outside) the cells and connecting these cells to each other (Fig. 1-1). As a tumor becomes less differentiated, it "loses" its histologic similarities to its cell of origin. A poorly differentiated squamous carcinoma has little, if any, keratinization, and the presence of intercellular bridges becomes less distinct or absent (Fig. 1-2). In this setting, direct derivation from the surface epithelium and/or the overall growth pattern assist in defining this tumor as an SCC. The same definitions of differentiation apply to gland-forming malignant tumors (adenocarcinomas) and to mesenchymal malignant tumors.

The phenotypic extreme on the poorly differentiated end of the spectrum may result in a "dedifferentiated" or "undifferentiated" tumor that loses its light microscopic similarities to its cell of origin. It is this type of neoplasm that often necessitates special pathologic studies (e.g., immunohistochemistry) to determine its histogenesis. A common example of this in head and neck sites is the spindle cell squamous carcinoma (SCSC). This high-grade variant of squamous carcinoma is characterized by the presence of a malignant spindle cell neoplastic infiltrate. The malignant spindle cells are devoid of keratinization and intercellular bridges. The histologic appearance of the spindle-shaped cells, the growth pattern including interconnecting and ramifying fascicles, and the absence of squamous epithelial features, simulate the appearance of several malignant mesenchymal neoplasms; hence, earlier terminology of these tumors as carcinosarcomas and sarcomatoid carcinomas. Immunohistochemistry plays an important role in defining this tumor and assisting in the final diagnosis. In the majority of cases, SCSCs will be cytokeratin positive. However, in addition to losing its phenotypic characteristics, tumors that are poorly differentiated may also lose their genotypic markers (i.e., epitopes), resulting in (false) negative immunohistochemical findings. In the situation of SCSCs, immunohistochemical markers of epithelial differentiation may not be present, yet this tumor is still epithelial in origin (see Section II under Spindle Cell Squamous Carcinoma).

(c) 2014 Wolters Kluwer. All Rights Reserved.

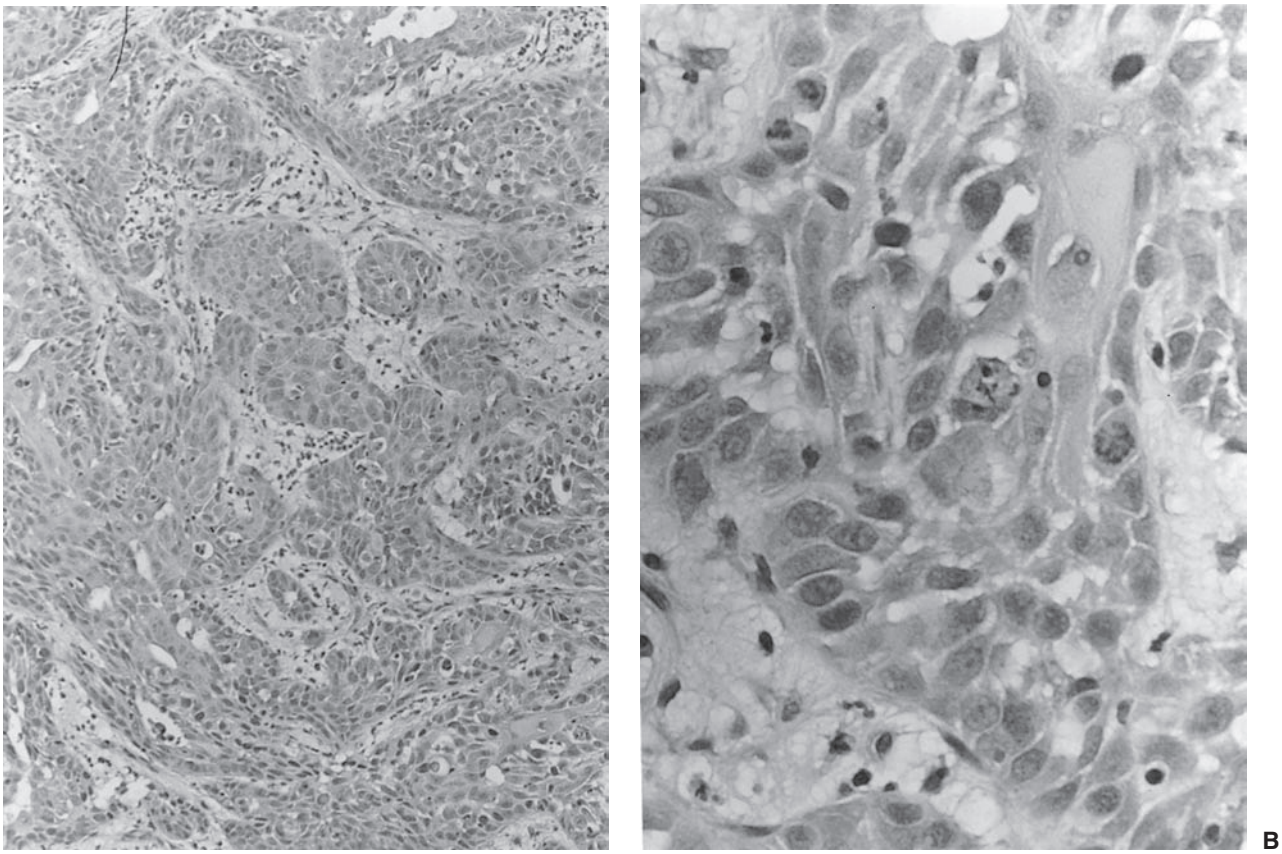

**FIGURE 1-1.** Well-differentiated squamous cell carcinoma. This tumor is invasive and is associated foci of individual cell keratinization **(A)** and intercellular bridges **(B)**.

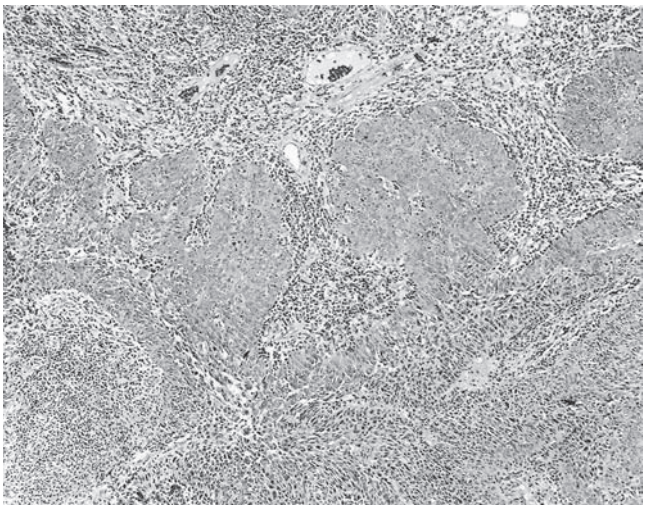

**FIGURE 1-2.** Poorly differentiated squamous cell carcinoma. In contrast to the previous illustration, the invasive neoplasm seen here lacks evidence of squamous differentiation (e.g., keratinization or intercellular bridges). However, the overall growth pattern is one that is seen in association with squamous cell carcinomas. Although not shown in this illustration, this neoplasm was identified as arising from the surface epithelium establishing its diagnosis as a squamous cell carcinoma.

The histologic grade of a tumor is dependent on its differentiation. The better differentiated a tumor is, the lower its histologic grade. A well-differentiated SCC is considered grade I, whereas a poorly differentiated SCC is a grade III. It stands to reason that better differentiated tumors tend to be DNA diploid or near DNA diploid with a lower cell proliferation rate (doubling time) and the less likelihood to have aggressive behavior (locoregional recurrence or metastasis) in comparison to less differentiated and/or anaplastic tumors.[1] This is not universally true. The extent and depth of invasion, and perhaps metastatic potential, may have no bearing on the histologic grade of a tumor so that a histologic grade I SCC can be a high clinical-stage cancer, while a histologic grade III SCC may be a low clinical-stage cancer. Nevertheless, prognostic correlation has been shown between histologic grade and clinical stage of SCCs of the UADT.[2–8] In a multivariate analysis, Wiernik et al.[1] showed that tumor grading was an independent significant factor in the prediction of prognosis. These authors evaluated 1,315 patients with laryngeal SCC followed for a 10-year period and showed a highly significant difference between the survival and tumor-free rates for those with well-differentiated laryngeal SCC versus patients with anaplastic cancers, with the former having a better outcome than the latter.[1]

## ADJUNCT TOOLS IN THE DIAGNOSIS OF HEAD AND NECK TUMORS

As described in the preceding section, the more a tumor recapitulates the appearance of its cell of origin, the better differentiated that tumor will be. Specific phenotypic characteristics for a given

(c) 2014 Wolters Kluwer. All Rights Reserved.

tumor, as seen by light microscopy, may immediately define that tumor type. For the pathologist, the light microscopic features of a malignant tumor that includes origin from the surface epithelium with the formation of keratin and intercellular bridges define an SCC. Given these features, the pathologist does not need to employ additional studies in determining the histogenesis of that tumor. Other examples may include a gland-forming tumor (adenocarcinoma), a melanin-rich malignant tumor (malignant melanoma), a tumor that is forming bone (osteosarcoma), and so on. However, not infrequently, the histogenesis of a malignant neoplasm is not readily apparent by light microscopy. The fact that the tumor is malignant may not be in dispute, but due to the absence of differentiation (undifferentiation), the histogenesis of the tumor becomes a guessing game. This is problematic to the pathologist who wishes to categorize a tumor by its cell of origin. More importantly, the exact tumor type may require specific treatment protocols and have specific prognostic import. It is under these circumstances that the pathologist will use additional studies to determine the histogenesis of a given tumor and therefore establish the correct diagnosis. Included among these studies are relatively simple tools such as histochemistry, immunohistochemistry, and electron microscopy, to more sophisticated molecular biologic and cytogenetic testing.

## Histochemistry and Immunohistochemistry

There are numerous histochemical stains that the pathologist can use in the identification of various chemicals, including stains for epithelial mucins (e.g., mucicarmine, periodic acid Schiff with and without diastase, others), stains for pigments and minerals (e.g., melanin, iron, lipofuscin, argentaffin, and argyrophil), stains for microorgansisms (e.g., acid fast bacilli, Grocott methenamine silver, periodic acid Schiff, Gram, Warthin-Starry, and others) and stains for connective tissue components (e.g., reticulin, elastic, alcian blue, phosphotungstic acid hematoxylin, and others). The results of these stains can be of critical importance in the diagnosis and differential diagnosis of nonneoplastic and neoplastic lesions, including benign and malignant neoplasms. The reader is referred to texts on diagnostic histochemistry for a more in-depth discussion.[9]

Immunohistochemistry is the application of an immunologic procedure (antigen–antibody reaction) allowing for the recognition of intracellular molecular components (antigens) by light microscopic evaluation. Fresh tissue is optimal for immunohistochemical studies. However, in most instances immunohistochemistry can be performed on formalin-fixed, paraffin-embedded tissue (FFPE), including archival material.

Based on the light microscopic appearance of a tumor, a panel of antibodies is used and algorithms followed in the differential diagnosis of a given neoplasm. It should be noted that there are very few tumor-specific markers. Examples of such tumor-specific markers include thyroglobulin for lesions of thyroid follicular cell origin and prostein for lesions of prostatic origin. As such, immunohistohemical reactivity alone is often not diagnostic but requires correlation with the clinical history, light microscopic features, and histochemical findings in order to arrive at the correct diagnosis. The list of imunohistochemical markers and their diagnostic utility is too numerous to be included. For a discussion on the use of immunohistochemistry in head and neck lesions and in endocrine organ lesions, the reader is referred to other texts.[10,11]

## Electron Microscopy

The role of electron microscopy in diagnostic surgical pathology has waned over the decade since the advent of immunohistochemistry. Presently, ultrastructural evaluation plays a limited role in tumor diagnosis, but is still used in those cases where light microscopy and immunohistochemistry may not provide the definitive answer as to the tumor type. More recently, the techniques of immunohistochemistry and electron microscopy have been wed to offer the best of both worlds.

## Flow Cytometry

Flow cytometry attempts to quantitate relative DNA content distributions in tumors and, thereby, attempt to assess at the cellular level the potential biologic behavior of a given tumor.[12]

For flow cytometric measurement of DNA content (DNA ploidy), cell suspensions made by disaggregating solid tissue or paraffin-embedded tissue sections, fine-needle aspirates, or body fluids are used and are passed ("flowed") in a linear stream through a laser beam for analysis. This analysis, resulting from the evaluation of thousands of cells per minute and consisting of up to 20,000 cell events, includes DNA histograms that relate to three phases of the cell cycle. Flow cytometry is extensively used for hematopoietic malignancies. Less often, flow cytometry has been used for solid tumors, including head and neck malignancies.[13–20] In general, these studies showed that increased recurrence rates, shorter relapse times, distant metastasis, and shorter survival rates were present in those HNSCC with high DNA indices, high-percent S-phase fraction, high proliferation rates, and DNA aneuploid tumors. The flow cytometric analysis of HNSCC needs to be viewed with caution as results do not always correlate with outcome.[21–23]

## Molecular Biology

***Cytogenetics.*** Cytogenetic analysis allows for the detection of clonal chromosomal aberrations, many of which may be diagnostic for a particular tumor type. The value of cytogenetic evaluation in head and neck epithelial malignancies is of questionable utility. However, evaluation of specific chromosomal abnormalities may be extremely valuable in the diagnosis of hematologic malignancies,[24] in undifferentiated small round cell malignancies and in soft-tissue tumors.[25]

Molecular techniques used in evaluating for chromosomal aberrations include polymerase chain reaction (PCR), comparative genomic hybridization (CGH), *in situ* hybridization (ISH), and DNA microarrays.[26] PCR is used for isolating and exponentially amplifying a fragment or sequence of interest of DNA via enzymatic replication. PCR is an *in vitro* technique, it can be performed without restrictions on the form of DNA, and it can be extensively modified to perform a wide array of genetic manipulations. PCR is used to amplify specific regions of a DNA strand; this can be a single gene, just a part of a gene, or a noncoding sequence. Most PCR methods typically amplify DNA fragments of up to 10 kilo base pairs (kb), although some techniques allow for amplification of fragments up to 40 kb in size.

CGH is a technique used to visualize losses and gains of chromosomal segments using DNA extracted from tumor tissue.[26] CGH is a powerful tool for screening tumors for genetic changes. The principles of ISH include the use of DNA probes complementary to genomic sequences of interest that are generated, labeled, and then hybridized to target tissue.[26] The different modalities of ISH include fluorescent *in situ* hybridization (FISH) and chromogenic *in situ* hybridization (CISH).[26,27] FISH or CISH signals can be identified in the nuclear compartment of cells. Aside from genes mapping to the sex chromosomes (ie, X and Y) in men, two copies of each gene are present in normal cells (ie, diploid genome) FISH/CISH generate two signals for any given probe.[27] As such, ISH can be used to identify aneusomy or numerical aberrations (i.e., gain or loss of a chromosome, gene gains, amplifications, and deletions) and structural chromosomal aberrations

(c) 2014 Wolters Kluwer. All Rights Reserved.

(i.e., chromosomal translocations).[27] The advantages of FISH/CISH over conventional cytogenetics include that they can be applied directly to interphase nuclei rather than requiring tissue culturing or mitotic cells and can be applied to many samples, including fresh samples, frozen samples, cytologic specimens, formalin-fixed material, and paraffin-embedded material, including archival material and tissue microarray sections.[27] Arguably, the greatest utility of ISH relative to head and neck cancers is in the identification of Epstein-Barr virus–encoded RNA (EBER) in nasopharyngeal carcinomas (NPCs), differentiated types and nasal-type NK/T cell lymphomas, and in the detection of high-risk human papilloma virus in the setting of oropharyngeal carcinomas. Further, since NPC, differentiated types, and oropharyngeal carcinomas may metastasize as occult primary tumors, the utility of ISH for EBER and HPV16 has expanded to include metastatic carcinomas to the cervical neck from occult primary cancers (see later in this chapter).

DBNA microarrays can be used to determine expression of multiple genes in a single reaction. DNA microarrays utilize a multiplex-spotted microarray technology where thousands of oligonucleoltide probes corresponding to human genes are spotted on a solid surface (gene chip) or on microscopic beads.[26] The intensity of the signals is proportional to the abundance of specific cDNA in a given specimen.[26]

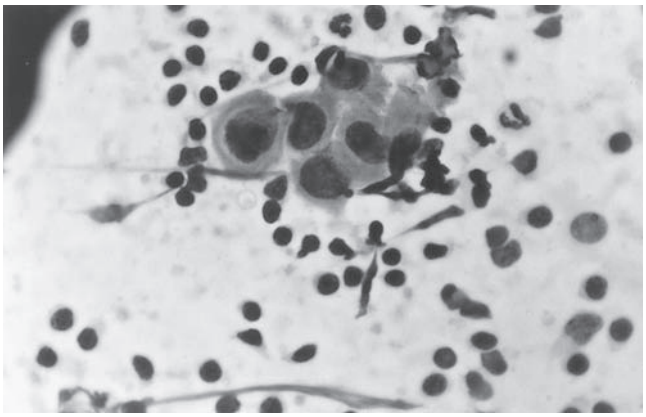

**FIGURE 1-3.** Fine-needle aspiration biopsy of a neck mass (lateral cervical lymph node) showing malignant cells with squamous features diagnostic for metastatic squamous cell carcinoma. Panendoscopic evaluation and biopsy identified the primary cancer to be of (ipsilateral) tonsillar origin.

## FINE-NEEDLE ASPIRATION BIOPSY

Fine-needle aspiration biopsy (FNAB) is a safe, inexpensive, rapid, and accurate procedure in the evaluation of almost any mass lesion. In the head and neck, FNAB is extensively utilized. The accessibility of the neck, salivary glands, thyroid gland, and orbit makes FNAB of lesions of these structures very practical. As such, FNAB is often the initial diagnostic procedure used in the assessment of a head and neck mass, but it should not be the sole determinant by which a major operative resection is performed. FNAB is an invaluable diagnostic modality in the evaluation of a mass in the head and neck providing cytologic diagnosis that assists the clinician in the appropriate management of the patient. Touch-imprint cytology represents the pressing or "touching" of a microscopic slide against the cut surface of a tissue specimen followed by immediate fixation and staining. Imprint cytology may be especially helpful in the diagnosis of hematolymphoid lesions, in the evaluation of small biopsy specimens, or in biopsy material that is distorted and/or crushed. Several studies have found that touch-imprint cytology is as sensitive as, and perhaps more reliable than, frozen section in the detection of micrometastases, especially in fatty lymph nodes that may be difficult to cut.[28–30] Further, on-site assessment by a pathologist or in the frame of a FNAB clinic reduces the false negative diagnosis and inadequacy rates and increases the cost-effectiveness of fine-needle aspiration (FNA).[31,32]

For details on the technique of FNAB, the reader is referred to more comprehensive texts of cytopathology. This section will be a brief overview of FNAB of the specific anatomic sites of the head and neck.

### Neck Mass

FNAB is a useful tool in the evaluation of a neck mass. The causes of neck masses and/or enlarged cervical lymph nodes are many, including reactive lymphadenopathies, infectious and granulomatous lymphadenitis, primary neoplasms (non-Hodgkin and Hodgkin lymphomas), and metastatic tumors (Fig. 1-3). In several reported studies that included a large number of cases, 25% to 60% of the aspirated enlarged lymph nodes showed reactive changes that were subsequently confirmed to be benign by either excisional biopsy or by close clinical follow-up of the patients who had benign clinical outcomes.[33–37] In patients with known primary malignancies originating elsewhere or suspected of metastatic disease to cervical lymph nodes, FNAB is an extremely useful diagnostic tool, as the presence of nonlymphoid neoplastic cells is readily identifiable.[38] In several series of FNAB of lymph nodes, metastatic cancer represented approximately 50% of the reported cases.[32–37]

The diagnostic accuracy rate for FNAB diagnosis of non-Hodgkin malignant lymphoma ranges from 83% to 94%[38,39] while that for Hodgkin disease is from 83% to 98%.[40,41] FNAB findings in conjunction with flow cytometry and/or immunohistochemistry enables the subclassification of many non-Hodgkin lymphomas.[42,43] FNAB can also be used in separating low-grade from high-grade non-Hodgkin malignant lymphoma. In a study by Russell and colleagues,[44] the authors had difficulty distinguishing among the low-grade malignant lymphomas, but had no difficulty separating the low-grade from the high-grade malignant lymphomas by FNAB. Although the diagnostic accuracy for Hodgkin disease is high, the accuracy for subtyping the Hodgkin lymphoma is not, reported in one study to be 58%.[43] A cytologic specimen cannot provide certain details relative to malignant lymphomas, including the architectural growth (i.e., follicular vs. diffuse), and it is very difficult to subtype Hodgkin disease by FNAB.[43] Therefore, a presumptive diagnosis in an enlarged lymph node of malignant lymphoma made by FNAB should be followed by excisional biopsy with histopathologic evaluation. The excised lymph node should include the largest identifiable node to allow for histopathologic evaluation, as well as for immunohistochemical and molecular biologic studies. In general, the diagnostic accuracy for the presence of a tumor (sensitivity) and for the absence of a tumor (specificity) in lymph nodes is high, ranging from 87% to 100% and 88% to 98%, respectively.[37,39,45]

### Salivary Glands

There are innumerable causes for enlargement of a salivary gland, including many nonneoplastic and neoplastic (benign and malignant) proliferations. By far, the most common salivary gland tumor is a benign mixed tumor (pleomorphic adenoma). Therefore, the diagnostic accuracy of a salivary gland tumor is usually high. The diagnostic accuracy of FNAB of salivary gland

(c) 2014 Wolters Kluwer. All Rights Reserved.

tumors has been reported to include a sensitivity of 92%, specificity of 100%, and accuracy of 98%.[46]

In general, the diagnosis of most salivary gland tumors by FNAB can be readily accomplished. However, a diagnosis by FNAB of certain specific salivary gland tumors, such as adenoid cystic carcinoma (ACC), low-grade polymorphous adenocarcinomas, and others, should be made with extreme caution. The cytologic features seen in these tumors can also be identified in benign mixed tumors. Further, it should be noted that when the differentiation of a benign from a malignant salivary gland tumor is based on the presence or absence of invasive growth, and not on the cytologic appearance, that FNAB will not generate this information. It could be argued that any mass lesion of the salivary gland will ultimately require surgical intervention, obviating the need for FNAB. Nevertheless, FNAB remains an excellent screening tool for salivary gland tumors, more often than not yielding enough information to guide the surgeon in his/her therapeutic approach. Despite the potential limitations of FNAB in the diagnosis of salivary gland tumors, it still remains an accurate diagnostic tool, quite comparable to frozen section diagnosis.[47,48]

## Thyroid Gland

As with salivary gland tumors, the thyroid gland is readily accessible so that there is much practical utility in the FNAB of thyroid gland lesions. FNAB of the thyroid represents the first-line diagnostic procedure in the evaluation of a patient with a thyroid mass. The main purpose of thyroid gland FNAB is to distinguish between patients with benign thyroid nodules that can be followed clinically from patients with neoplastic (benign or malignant) proliferations that require surgical intervention.[49] Not all solitary lesions of the thyroid require surgical intervention. FNAB may then offer the necessary diagnostic information for those lesions that can be nonsurgically monitored as compared to those thyroid lesions that do require surgical removal.[50] The diagnostic accuracy of thyroid FNAB is well established. The ability of thyroid FNAB to yield a positive aspirate in the presence of a neoplasm (sensitivity) (Fig. 1-4) and to be negative in the absence of a neoplasm (specificity) is high, reported in several large series to be over 90%.[50–53] Ultrasound guided FNAB with on-site evaluation can increase the sensitivity and specificity of thyroid FNAB in lesions that are difficult to palpate.[54] Of note, approximately 2% to 15% of smears are unsatisfactory for evaluation.[55] In satisfactory smears, a thyroid tumor is diagnosed as benign in greater than 60% of cases, malignant in approximately 5%, and suspicious in the remainder of cases.[49] Of the suspicious cases, approximately 20% prove to be malignant following surgical resection.[55] The accuracy of thyroid FNAB compares favorably to that of frozen section diagnosis.[56–58] In a study of 359 patients with thyroid nodules evaluated by FNAB and frozen section, Hamburger and Hamburger[59] report that in <1% of patients (3 cases) did frozen section influence the surgical procedure.

Similar to the challenges faced by the cytopathologist with FNAB of salivary glands, there are diagnostic limitations of thyroid gland FNAB, including those thyroid lesions in which the differentiation of a benign from a malignant tumor is not predicated on the cytologic appearance but requires the identification of capsular or vascular invasion (i.e., follicular adenomas vs. follicular carcinomas). In this situation, cytology alone is not diagnostic and FNAB does not allow for this determination. It should be noted that oxyphilic changes (so-called Hürthle cells) represent a descriptive term and are not diagnostic for any specific thyroid lesion. Numerous thyroid lesions contain Hürthle cells, including lymphocytic thyroiditis, adenomatoid nodules, follicular adenomas, follicular carcinomas, papillary carcinoma, and medullary carcinoma. Therefore, the presence of Hürthle cells on the FNAB of a thyroid lesion is not, in and of itself, diagnostic.

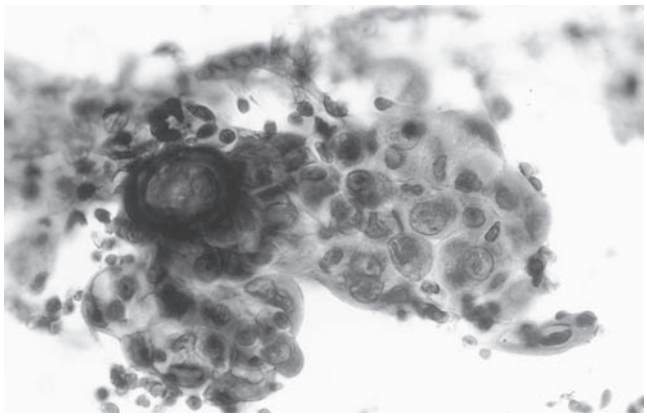

**FIGURE 1-4.** Fine-needle aspiration biopsy of a thyroid mass diagnostic for thyroid papillary carcinoma.

Despite these potential limitations, FNAB is accurate in the diagnosis of thyroid tumors. Pathologic alterations seen in permanent sections of resected thyroid lesions following FNAB may result in worrisome histologic features that may be mistaken for malignant neoplasm.[60,61] The post-FNA histologic changes occur in numerous lesions such as adenomatoid nodules, follicular adenoma and its variants, follicular carcinoma and its variants, papillary carcinoma and its variants, and hyperplastic lesions. Based on the type of reaction seen, post-FNA alterations may include acute or chronic type changes.[62] Acute changes are usually identified within 3 weeks from the FNA to surgical removal and may include hemorrhage with hemosiderin-laden macrophages and granulation tissue (these represent the most common findings), localized follicular destruction, capsular alterations, atypical cytologic features with necrosis and mitoses, and nuclear atypia that typically occurs near the needle tract and includes nuclear enlargement with clearing of the nuclear chromatin. Chronic changes are usually identified more than 3 weeks from the FNA to surgical removal and may include squamous or oxyphilic metaplasia, infarction, capsular alterations with foci of pseudoinvasive growth, vascular alterations, including artifactual implantation or "invasion" of tumor cells, dilated vascular spaces with thrombosis, organization and papillary endothelial hyperplasia and endothelial cell atypia.[62,63] Additional changes may include cyst formation with papillary growth, fibrosis, calcifications, and cholesterol granulomas. Oxyphilic cells occurring in all settings (metaplasia, follicular adenoma, follicular carcinoma, or papillary carcinoma) may be more sensitive to trauma due to the oxygen-sensitive mitochondria that predominate in these cells. Any compromise to the oxygen supply of the oxyphilic cells may result in degenerative changes, including hemorrhage, infarction, and papillary degeneration.

## Orbital Lesions

Orbital FNAB is an accurate and beneficial procedure in the evaluation of orbital lesions, obviating the need for extensive surgery to arrive at a diagnosis. Orbital FNAB allows for the evaluation of deeply situated unresectable tumors that in the past required extensive surgery in order to generate material for diagnosis. Kennerdell et al.[64] evaluated 156 orbital lesions by FNAB and reported that 80% contained diagnostic material, 18% were insufficient for evaluation, and 2% were either false positive or false negative. These authors indicate that insufficient aspirates were the result of a fibrous lesion, a lymphoproliferative process in which there were insufficient cells for diagnosis or an orbital

(c) 2014 Wolters Kluwer. All Rights Reserved.

apical location. According to Kennerdell et al.[64] the most common orbital lesions reported in their series were carcinomas (primary and metastatic), lymphoproliferative lesions, and inflammatory diseases. The accuracy of orbital FNAB is high. Char et al.[65] in a study of uveal melanomas, report an 89% positive identification rate. Shields, in a series of 159 cases of FNA of intraocular lesions, obtained an adequacy rate of 88%, a sensitivity rate of 100%, and a specificity rate of 98%.[66] Complications of orbital FNAB may include diffuse retrobulbar hemorrhage, blindness (transient or permanent), globe perforation, and brain-related complications.[64] All serious complications occurred due to faulty techniques, reaffirming the importance of experience in FNAB.

## FROZEN SECTIONS

Frozen section analysis plays an important part in the treatment of the head and neck cancer patient. The appropriate use of intraoperative consultations (frozen sections) usually results in a definitive diagnosis with immediate therapeutic impact while the patient is in the operating room. The accuracy of frozen sections has been analyzed for general surgical cases,[67–73] as well as specifically for head and neck surgery.[74–80] The studies on general surgical cases and otolaryngologic cases show similar findings with a 95% to 98% diagnostic accuracy rate, a 2% to 4% error rate (including <2% false negative and <1% false positive), and less than 4% of cases being deferred for permanent section evaluation. Diagnostic errors may occur due to improper sampling, technical flaws, interpretive inaccuracies, and faulty communication.[67,72,75,78,79]

Among the determinations made by frozen section analysis are (a) the evaluation of adequacy of surgical margins of resection, (b) the differentiation between nonneoplastic, benign, and malignant proliferations, (c) the evaluation of lymph nodes for the presence of metastatic disease, (d) the determination of specimen identification and specimen adequacy, including the verification of such organs as the parathyroid glands, and (e) the determination of whether a given case requires special diagnostic testing best performed on frozen material, such as for lymphomas.

Arguably, the most common request of the pathologist by the head and neck surgeon at the time of intraoperative consultation is the assessment of the surgical margins. Successful local control of a malignant tumor depends on complete surgical excision of all the disease. There are many factors that impact on the assessment of the surgical margins, including the type of surgical specimen, proper orientation of the specimen, proper sectioning of the specimen, and, obviously, the correct interpretation of the histopathologic changes. Unfortunately, even in the best situations an intraoperative report of negative margins may be followed a few days later by a permanent section diagnosis of positive margins. Byers et al.[81] reported on the results of frozen section in 216 patients with neoplasms of the oral cavity, oropharynx, and hypopharynx. Three groups were identified, including 68% of the patients in whom the tumors were initially adequately resected on the basis of negative surgical margins, 23% of the patients who had positive surgical margins that necessitated additional surgical resection to assure the presence of negative surgical margins, and the remaining 9% of patients in whom negative free margins by frozen section could not be obtained.[81] The follow-up of these three groups included local recurrence rates of 14.4%, 20%, and 80%, respectively, with the third group having the worst survival rates. Byers and colleagues concluded that the probability of local recurrence in head and neck cancer is reduced when the resection margins are determined by intraoperative frozen section consultation.[81] The use of intraoperative frozen sections will also allow the surgeon to extend the surgical resection without loss of orientation of the operative field, a potential problem when additional surgery is required in a second operation.[81] Further, carcinoma remnants that have not been completely removed in the initial operation are often difficult to identify macroscopically, making their removal in a second operation more difficult.[82] Spiro and colleagues[80] reported an intraoperative frozen section diagnostic accuracy of 89% for oral tongue cancer. These authors found that the diagnostic accuracy was the same whether the sample was taken from the patient or from the surgical specimen.

It must be noted that a diagnosis of margin(s) negative for carcinoma by frozen section analysis does not guarantee complete tumor removal. Limitations include the choice of biopsy sampling sites and the fact that frozen section results are not always confirmed by permanent sections.[82] Ord and Aisner[83] evaluated the accuracy of frozen section in assessing margins in 49 patients with oral cancer resections. These authors found a frozen section accuracy rate of 99%; however, 7 patients had final margins that were positive but had not been diagnosed as such at the time of the frozen section. Errors in interpretation and in sampling accounted for these discrepancies. Cooley et al.[84] found five discrepancies in 249 frozen sections of laryngeal SCC in which the frozen diagnosis was negative but the permanent sections revealed dysplasia or carcinoma *in situ* (CIS). These authors found that insufficient leveling of the frozen block resulted in these discrepancies. Their recommendation was that in examining margins for laryngeal SCC the frozen section tissue should be completely sampled by examining several levels at the time of frozen section. Spiro et al.[80] reported that of the 131 samples taken intraoperatively whose margins were reported as negative, 13 were later reported to be positive following permanent sections. Although the frozen section diagnosis of surgical margins are extremely accurate, they are not entirely reliable in eliminating positive margins in the final diagnostic report.

Frozen section consultations on mucosal surface lesions can be useful, especially in differentiating inflammatory and neoplastic lesions. Histologic grading of a mucosal malignancy (i.e., SCC) may be problematic and is not advocated by frozen section. Artifactual distortion and sampling limitations may lead to erroneous conclusions relative to the histologic differentiation of the carcinoma. Postirradiation alterations may lead to false-positive diagnosis due to the presence of bizarre cytologic alterations in the epithelium, minor salivary glands, fibroblasts, skeletal muscle, and endothelial cells.[85,86]

A mass lesion of virtually every head and neck anatomic site may initially be viewed by the surgical pathologist at the time of frozen section consultation. Among the head and neck sites, salivary gland lesions, thyroid gland lesions, parathyroid gland lesions, cervical neck masses, and mucosal-based lesions are often assessed by frozen section. As discussed in the previous section on FNAB, with the increased use of FNAB, the utilization of frozen sections, particularly for salivary gland and thyroid gland tumors, has diminished. For frozen section consultation of head and neck lesions, the reliability in the diagnostic accuracy of salivary gland tumors has been the most questioned.[87–91] However, Gnepp et al.,[92] in a review of 301 salivary gland lesions evaluated by frozen section, reported a diagnostic accuracy rate of 98% with an adjusted accuracy rate of 95.7% when deferred diagnoses were included. These authors report that this overall accuracy was comparable to that for other regions of the body.[92] Further, Luna indicates that the frozen section diagnoses of salivary gland tumors "present no more serious problems than do frozen section diagnoses elsewhere in the body."[93]

Frozen section evaluation has also been extensively utilized for thyroid lesions. The lesions that are usually identifiable at frozen section include thyroid papillary carcinoma, widely invasive follicular carcinoma, anaplastic carcinoma, and medullary carcinoma. Problems arise in the frozen section diagnosis of a

(c) 2014 Wolters Kluwer. All Rights Reserved.

single encapsulated thyroid mass that has a follicular growth pattern. The differential diagnosis in this setting would include a follicular adenoma, follicular carcinoma, and the follicular variant of thyroid papillary carcinoma. The differentiation of a follicular adenoma from a follicular carcinoma is predicated on the presence or absence of capsular and/or vascular space invasion. This finding may be present only in a very limited aspect of the tumor. Sampling this area at frozen section would be purely fortuitous as, macroscopically, the invasive foci are not discernible. Thyroid papillary carcinomas in permanent sections often display characteristic ground-glass appearing nuclei, which is a function of tissue fixation in formalin. As such, ground-glass nuclear changes are not present in frozen sections as frozen section tissue is performed on fresh tissue and not on tissue that has been formalin fixed.[94] Rosen et al.[95] point out that the relatively low sensitivity of frozen section diagnosis of thyroid carcinomas relates to these issues. Kingston et al.[96] reported on the role of frozen section in distinguishing benign from malignant thyroid follicular neoplasms. Using the final histologic diagnosis as seen in permanent sections as the gold standard, these authors report that frozen section was accurate in 79% of the cases in differentiating follicular adenoma from follicular carcinoma with a sensitivity of 52% and a specificity of 100%; an incorrect diagnosis of a benign lesion was reported in 21% of the patients.[96] Kingston et al.[96] compared the accuracy of frozen section diagnosis to the accuracy of using clinical factors alone to predict malignancy, including age >50 years, tumor size >3 cm, and a history of previous neck irradiation. These three clinical features were shown by Davis et al.[97] to be strong predictors of malignancy in thyroid follicular neoplasms. Kingston et al.[96] found an equally low sensitivity between frozen section and clinical parameters, ranging from 38% to 53%, in predicting malignancy, but that frozen section resulted in a much higher specificity and positive predictive value than any of the clinical parameters. These authors recommended the continued use of frozen section for thyroid follicular lesions as a guide to the required extent of surgery.[96] At present, there are major academic centers that do not routinely perform intraoperative consultations on thyroid lesions. However, the use of cytologic evaluation coupled with tissue sectioning in the intraoperative consultation of thyroid lesions greatly assists in the diagnosis of thyroid lesions, especially for thyroid papillary carcinoma.

The frozen section diagnosis of lymph nodes is considered to be extremely accurate. Gnepp, in a review of the literature, reported an accuracy rate of 98.9%, excluding deferred diagnoses, with a 0.1% false-positive rate and a 1% false-negative rate.[98] It should be noted that the lymph nodes represent the most frequently deferred specimen in frozen section diagnosis, especially in the diagnosis of a lymphoma. In general, the diagnosis of a carcinoma in a lymph node is not problematic at frozen section. Lymph node frozen section has also been utilized for accurate staging of the head and neck patient. Rassekh et al.[99] compared intraoperative node examination (palpation and inspection) to frozen section diagnosis in the identification of metastatic disease to cervical lymph nodes, thereby evaluating the surgeon's ability to predict nodal stage. These authors prospectively studied 108 necks in 79 patients and reported that the overall reliability for intraoperative staging (palpation and inspection) was 59.3% (64 of 108) as compared to 92.3% (24 of 26) for frozen section biopsy, representing a highly significant difference ($p < 0.005$).[99] Although frozen section biopsy was not performed on all cases, Rassekh et al.[99] concluded that upstaging the neck without frozen section biopsy is much less reliable and that frozen section biopsy is needed prior to converting a selective node dissection to a radical or modified radical neck dissection. Manni and van den Hoogan[100] reached a similar conclusion.

As with any surgical procedure, there are contraindications for the utilization of frozen sections. Frozen section consultation should not be used (a) when the frozen section diagnosis will not have any impact on surgery such as satisfying the curiosity of the surgical team; (b) if the tissue specimen is small and additional sampling is not planned (in which situation, frozen sections may be equivocal and/or the material is artifactually distorted by the frozen section technique hampering histologic evaluation following permanent sections); (c) for heavily calcified or ossified tissue; (d) for certain lesions such as small cutaneous melanocytic lesions and lymphoproliferative lesions requiring special handling or extensive histologic evaluation for diagnosis.

## HISTOPATHOLOGIC PARAMETERS IN THE ASSESSMENT OF HEAD AND NECK TUMORS

### Surgical Resection Margins

The evaluation of surgical margins of resection for the presence or absence of lesional tissue falls under the purview of the surgical pathologists. However, how the specimen is removed and the orientation of the specimen is the responsibility of the surgeon. This is particularly true for those cases in which the tumor is initially excised and the designated margins are separately removed, the tumor is removed in multiple parts or the specimen is a complex *en bloc* excision requiring proper orientation by the surgeon for those margins that are of critical concern. Once removed and properly oriented, the specimen becomes the responsibility of the surgical pathologist.

In brief, the designated margins are painted with India ink or other similar colored pigments, and then sections are submitted for histologic examination. Despite the stringent environment that goes into the processing of tissue, the dye is retained and the pathologist, by microscopic examination, can evaluate the relationship of the tumor to all surgical margins of the resection. Specimens in which no tumor or dysplasia is present at the surgical margins of resection are considered as completely excised. "At the margin of resection" means that the neoplastic cells are seen in contact with or lie within millimeters of the pigment that was painted along the margin prior to sectioning (Fig. 1-5). In

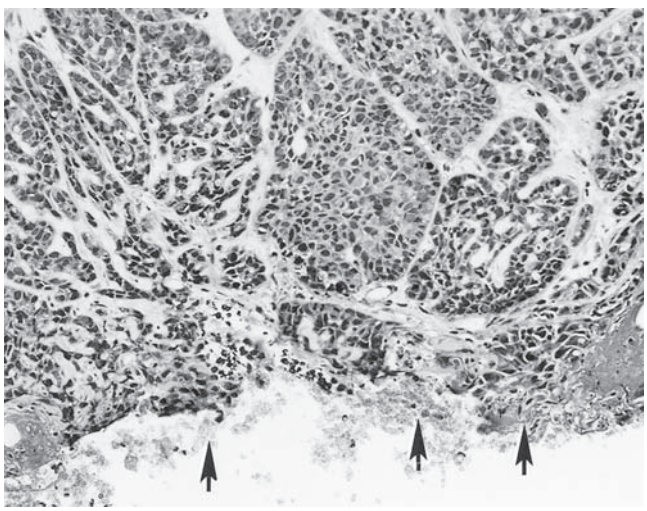

**FIGURE 1-5.** The malignant neoplasm shown in this illustration is identified in continuity with the edge of the resection margin. The latter, seen at the bottom of the illustration, is delineated by the presence of pigment (*arrowheads*). As such, this tumor is "at the margin of resection" and is incompletely excised.

(c) 2014 Wolters Kluwer. All Rights Reserved.

this situation, the specimen is considered incompletely excised, requiring a wider excision in order to be assured that all viable tumor cells have been adequately removed.

There is some discrepancy in the literature as to what constitutes a positive or negative resection margin. Although some authors only include invasive carcinoma at the margin as positive, excluding CIS, dysplasia, and gross residual disease,[101] most pathologists would agree with the classification of positive margins set forth by Loree and Strong.[102] In their review of 398 patients with primary oral cavity carcinoma, Loree and Strong[102] classified positive margins into four categories, including lesional tissue was within 0.5 cm of the surgical margin (so-called close margins), dysplastic epithelium at the margin, CIS at the margin, and invasive carcinoma at the margin. Suffice it to say that the evaluation of dysplasia under optimal circumstances can be subjective, let alone at the time of frozen section where tissue distortion and artifact create additional diagnostic difficulties potentially resulting in misdiagnoses, including overdiagnosis and underdiagnosis.

The presence of lesional tissue within 0.5 cm of the inked surgical margin irrespective of whether it is invasive carcinoma or CIS/severe dysplasia places a patient at a nearly equal risk for local recurrence.[103] The question of how wide a tumor should be excised is the responsibility of the surgeon. However, for some specimens such as the laryngeal SCC, free margins up to 2 mm may be sufficient (Fig. 1-6), whereas a similar tumor at another site, such as the hypopharynx, where submucosal spread may be more of a problem, and the oral cavity, wider margins (5–10 mm) are optimal. The incidence of positive surgical margins is quite variable, ranging from as low as 3%[104] in some studies to as high as 60% in other studies.[105] Certainly, this variability in "positive surgical margins" is dependent on multiple factors, not the least important of which may be the definition of what constitutes a positive margin.

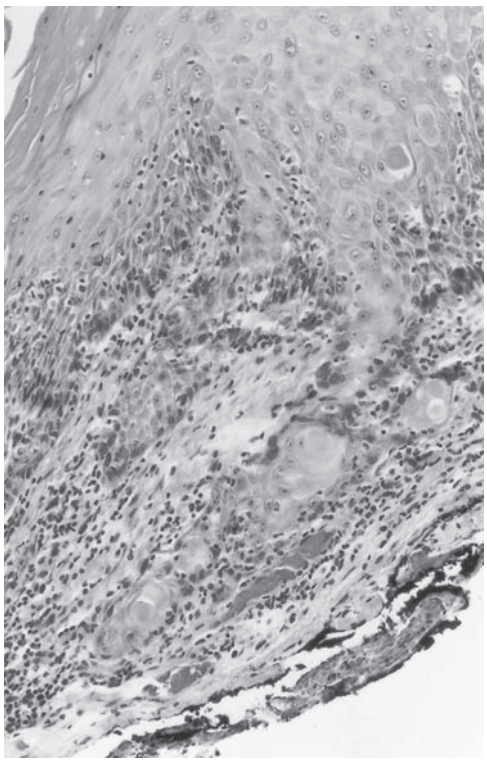

**FIGURE 1-6.** Laryngeal squamous cell carcinoma measuring approximately 2 mm from the inked surgical resection margin **(bottom)**.

Jacobs et al.[106] found that of the entry population of 696 patients in their study, 112 patients (16%) with stage III and IV resectable tumors had positive surgical margins. These authors indicate that the 16% represented a national average rather than an institutional incidence.[106] In comparison to patients with negative margins, patients with positive margins had a significantly higher rate of local failure (21% vs. 9%, $p = 0.0003$) and distant failure (20% vs. 12%, $p = 0.42$), but a similar incidence of regional (nodal) failure.[106] Patients with positive surgical margins were most often seen in nonglottic primary cancers and with increasing incidence as the N stage increased. The positive-margin patients of higher N stage had a higher rate of distant metastasis and died more rapidly than positive-margin patients with lower nodal status.[106] The survival of the positive-margin patients was approximately one half of the negative-margin patients. The addition of chemotherapy did not significantly alter the survival of positive-margin patients.[106] These authors reported a median survival of 19 months in patients with positive margins essentially equating to the expected outcome for patients with inoperable cancer.

Scholl et al.[107] reported that in 54 of 268 patients (20.1%) with lingual SCC, the carcinoma was not initially completely removed (i.e., positive margins at frozen section). When additional surgery resulted in negative margins, the local recurrence rate was worse than if the initial margin was negative. Scholl et al.[107] also found that positive mucosal margins were more often present in T1 and T2 tumors, and soft-tissue margins were more common in T3 and T4 lesions. Looser et al.[104] reported that 71% of patients with positive margins had recurrent disease at the primary site in comparison with 32% of patients with the tumor-negative margins. Spiro and colleagues[80] reported an intraoperative frozen section diagnostic accuracy of 89% for oral tongue cancer. These authors reported that the diagnostic accuracy was the same whether the sample was taken from the patient or from the surgical specimen. Positive or close margins (within one high-power field) was associated with a significant increase in local recurrence ($p < 0.003$).[80] Other studies have shown that implications of a positive surgical margin for SCC of the head and neck are associated with increased local failure and decreased survival rates.[102,108]

An additional factor that impacts on local recurrence is tumor size. The lower the clinical stage and/or pathologic class, the better the ability to achieve local control and the overall better survival rates.[81,104] Loree and Strong found that the incidence of positive margins was directly proportional to the increasing tumor size.[102] Scholl and colleagues, in their evaluation of oral tongue SCC, indicate in the presence of complete surgical removal of all disease to include macroscopic disease and histologically negative margins without neural invasion (NI) that adjunctive therapy does not improve local control as compared to surgery alone.[107] van Es and colleagues[109] reported that for T1 and T2 carcinomas of the mobile tongue and the floor of mouth, the single most important parameter in determining local recurrence is the histopathologic evaluation of margin status and that other histopathologic parameters were essentially irrelevant in predicting recurrence.

The presence of positive margins does not always translate into failure of local control; however, the overwhelming majority of patients with recurrent disease at the primary site have positive margins. The ability to completely resect a squamous carcinoma of the head and neck weighs heavily in the surgeon's decision to utilize surgery in the attempt to eradicate the cancer, and the presence of disease (gross or microscopic) at the surgical margins represents a key prognostic feature for patient survival. Batsakis notes that 5% to 10% of carcinomas resist the surgical goal of clear margins regardless of T stage.[110] He further notes that the survival of patients with free margins is related to the

(c) 2014 Wolters Kluwer. All Rights Reserved.

T stage of their carcinoma.[110] The identification of negative margins is not a guarantee for the absence of local recurrence. The larynx perhaps is an outlier in regard to positive-margins and local recurrence. As compared to extralaryngeal mucosal sites, patients with primary laryngeal SCC with positive surgical margins have a significantly lower incidence of local recurrence. Bauer et al.[111] reported that of a total population of 111 patients with laryngeal SCC, 39 (35%) had positive surgical margins. Of these 39 patients, 7 (18%) developed local recurrence, whereas 4 of the remaining 72 patients (6%) with negative margins developed local recurrence.[111] These findings suggest that margin status and local recurrence are site dependent and assists in explaining why surgeons are more apt to accept nearer margins for laryngeal carcinoma (free margins up to 2 mm), but require wider margins (5–10 mm) for carcinomas of extralaryngeal mucosal sites. Among the extralaryngeal sites with significant recurrence rates following negative surgical margin determination are the oral cavity and pharynx, including the hypopharynx.[81,104] Intraoral sites with negative margins but significant recurrence rates include the palate, the tonsil, the buccal mucosa, the tongue, the gingiva, the floor of the mouth, and the lip.[104]

## Factors Impacting on Margin Status and Prognosis

Certainly, this variability in "positive surgical margins" is dependent on multiple factors, not the least important of which may be the definition of what constitutes a positive margin. The factors that may impact on whether a margin is positive or negative, and on prognosis (control of disease) include the following:

- Clinical stage
- Tumor size
- Pattern of invasion
- Adjuvant therapy
- Histopathologic evaluation
- Site dependency
- Soft-tissue margins

More recently, Brandwein-Gensler et al.[112] suggest that resection margin status alone is not an independent predictor of local recurrence nor should resection margin status alone be used as the sole variable in deciding whether adjunctive radiation therapy is required; rather, the need to give adjunctive radiation is suggested to be based on the following parameters:

- Positive margins
- Perineural invasion
- Osseous invasion
- Histologic risk assessment that includes score based on worst pattern of invasion:
  - Patterns of invasion include
    - 1 = invasion in broad pushing front
    - 2 = invasion in "finger-like" broad pushing pattern or separate large tumor islands
    - 3 = invasive tumor islands of tumor at periphery greater than 15 cells/island
    - 4 = invasive tumor islands of tumor at periphery smaller than 15 cells/island or strands of tumor cells in single cell filing pattern regardless of island size
    - 5 = satellites of dispersed tumor infiltrates of any size with 1 mm or greater distance of intervening normal (nonfibrotic) tissue at the tumor–host interface
  - Perineural invasion
  - Lymphocytic response

According to Brandwein-Gensler et al.,[112] histologic assessment results in stratification of patients into low-risk, intermediate-risk, and high-risk categories that define recommendations for adjuvant radiotherapy (Table 1.12). To date, this classification scheme has not been universally accepted or applied.

Mucosal margins are not the only tissue margins. Surgical margins of resection may include all soft-tissue components, including adipose tissue, skeletal muscle, bone, and neural structures. The latter are of particular concern in those tumors that have a propensity for neurotropism, such as ACC of salivary glands. Bone, in particular the osseous margins of resection of the mandibular region, pose an especially significant issue in

**TABLE 1.12 Risk Assessment for Oral Squamous Cell Carcinoma**

| Histologic Variable | 0 | 1 | 3 |
|---|---|---|---|
| Perineural invasion | None | Small nerves | Large nerves |
| Lymphocytic response | Continuous band | Large patches | Little to none |
| Worst pattern of invasion at interface[a] | 1, 2 or 3 | 4 | 5 |

| Risk Score[b] | Risk for LR | Overall Survival Probability | Adjuvant Treatment with RT |
|---|---|---|---|
| 0 | Low | Good | No benefit |
| 1 or 2 | Intermediate | Intermediate | No benefit |
| 3–9 | High | Poor | Beneficial regardless of 5-mm margins |

Source: Adapted from Brandwein-Gensler M, Teixeira MS, Lewis CM, et al. Oral squamous cell carcinoma: histologic risk assessment, but not margin status, is strongly predictive of local disease-free and overall survival. *Am J Surg Pathol.* 2005;29:167–178, with permission.

[a]Patterns of invasion: 1 = invasion in broad pushing front; 2 = invasion in "finger-like" broad pushing pattern or separate large tumor islands; 3 = invasive tumor islands of tumor at periphery greater than 15 cells/island; 4 = invasive tumor islands of tumor at periphery smaller than 15 cells/island or strands of tumor cells in single cell filing pattern regardless of island size; 5 = satellites of dispered tumor infiltrates of any size with 1mm or greater distance of intervening normal (nonfibrotic) tissue at the tumor–host interface.

regard to carcinomas of the alveolar ridge, the floor of mouth, the lower buccal sulcus, and the lower retromolar region. Carcinomas of these sites are among those with the highest rate of recurrence. As such, the evaluation of the mandibular bone for the presence and extent of involvement is a key determinant in patient management.[113] The clinical determination of mandibular involvement is not reliable since one third of histologically proven carcinomatous invasion of the mandible showed no clinical indication of (preoperative) bone involvement.[114] Spread of oral carcinoma to the mandible typically occurs by direct invasion rather than by metastasis, by lymph-vascular space spread, or via nerves. The frozen section assessment is difficult given the inherent difficulties in performing frozen section on bone. Touch preparations or imprints of the osseous stump can be performed. Evaluation of the nonosseous soft tissue is not a reliable indicator vis-à-vis osseous involvement. In their evaluation of local control of oral and oropharyngeal carcinomas with clinically determined mandibular bone involvement, Dubner and Heller[115] found a 19% recurrence rate following marginal mandibulectomy and 6% following segmental mandibulectomy. In this study, local recurrence was not dependent on tumor size, N stage, invasion of the mandible, or radiotherapy. In those patients who recurred following segmental mandibulectomy, the recurrent disease was present within extraosseous soft tissues.

## Tissue Shrinkage and Surgical Margins

The reliability of measuring the resection margins is impacted by postremoval changes, especially related to tissue shrinkage. It is obvious that obtaining adequate tumor-free surgical margins is critical for the successful management of the cancer patient. Any discussion on surgical resection margins would not be complete without a discussion on tissue shrinkage in the pathologic processing of resected tissues. Disparate surgical margin lengths of resected specimens between the *in vivo* measurements by the surgeon and the *in vitro* measurements by the pathologist have been reported for head and neck resection specimens[116,17] and non–head and neck resection specimens.[118–121] Johnson et al.[116] found a mean tissue shrinkage of 31% ($p < 0.0001$) from the initial *in situ* measurement by the surgeon to the final microscopic assessment of oral cavity and lingual surface mucosal margins by the pathologist. These authors reported that to obtain 5 mm of histopathologically clear margin, an *in situ* margin of resection of at least 8 to 10 mm needs to be taken. In their evaluation of oral SCCs, Beaumont and Hains[117] found a reduction of 46% from the planned surgical margin before resection to the microscopically measured margin following pathologic preparation (minimum of 10 mm measured *in situ* surgical margin and average of 5.8 mm margin following fixation). These authors reported significant differences in the longitudinal diameter of the whole specimen from *in situ* to fresh states ($p < 0.0004$) and in the diameter of the tumor from the fresh state to fixed states ($p < 0.0000$), with the most significant shrinkage reported from the fresh state to the fixed state with a mean shrinkage of 4.82 mm. Goldstein et al.,[119] in their evaluation of colorectal resection specimens, found that bowel segments shrank to a median length of 3 cm or 40% of their original *in vivo* length after being removed from the patient and left in an unfixed state for 10 to 20 minutes. After formalin fixation, the free-floating ends shrank an additional 0.85 cm. Overall, after fixation, colon segments shrank 57% of their original *in vivo* length. However, the majority of the tissue shrinkage occurred within the first few minutes after removal of the specimen, and only 30% of the tissue shrinkage was attributed to formalin fixation. Similarly, Johnson et al.[116] found that the greatest proportion of shrinkage occurred immediately upon resection. Although there are very few studies assessing the shrinkage of tissue margins, it is apparent that a significant amount of tissue shrinkage occurs from the moment the tissue is excised to the time the pathologist reviews the histologic preparation of the excised tissues. Such tissue shrinkage should be taken into account and accommodated for by the surgeon at the time of the operation.

# PATHOLOGIC TNM SYSTEM FOR THE CLASSIFICATION OF MALIGNANT TUMORS

The American Joint Committee on Cancer (AJCC) utilizes a staging system to describe the anatomical extent of a malignant tumor.[122] This assessment of tumor includes three components: T for the extent of the primary tumor; N for the presence or absence of regional lymph node metastasis; and M for the presence or absence of distant metastasis. This classification system includes both clinical and pathologic parameters, and often these parameters will coincide. The following section will include the pathologic parameters utilized in the TNM staging system for malignant tumors supplemented by pathologic features not necessarily part of the TNM system but which may impact on prognosis and treatment.

## Tumor Size, Thickness, and Location

The TNM system utilized tumor size (T) to indicate the extent of disease. Lower T-staged tumors measure less than 2 cm; intermediate-staged tumors measure between 2 and 4 cm; higher staged tumors measure more than 4 cm.[122] It is generally considered that the size of a tumor represents an independent variable in its prognosis. Larger tumors (T3 and T4) have been reported to correlate with increased local recurrence as well as with decreased 2- and 5-year survival rates.[81] However, larger tumors are not necessarily indicative of a worse prognosis, and smaller tumors do not necessarily confer an indolent biologic behavior. Some head and neck tumors, such as in the oral cavity, may have a large surface component (high T stage), but these tumors are only superficially invasive and have a favorable prognosis. Similarly, large tumors of the thyroid gland measuring more than 5 cm may be entirely encapsulated with an associated favorable outcome. Conversely, small head and neck tumors may be deeply invasive and have a poor prognosis despite their small size. Some examples of this phenomenon occur with small cell (oat cell) neuroendocrine carcinomas of the head and neck, extranodal angiocentric T-cell malignant lymphomas of the sinonasal tract, and mucosal malignant melanomas. Therefore, while there is some validity to a larger malignant tumor conveying a worse prognosis, this is not universally true and should not unequivocally be utilized as an independent variable of prognosis.

The predictive value of tumor thickness and/or quantitative measurement of depth of invasion has been utilized for cutaneous malignant melanomas.[123,124] A similar quantitation does not apply for mucosal malignant melanomas.[125] Studies of SCCs of the UADT have attempted to correlate the extent of invasive cancer with the likelihood of cervical lymph node metastasis and/or prognosis.[126–130] The findings in these studies vary in predicting at what depth of infiltration an SCC is more apt to metastasize. Spiro et al.[126] retrospectively evaluated the predictive value of tumor thickness in T1, T2, and T3 N0 SCCs of the oral tongue and the floor of the mouth. Tumor thickness >2 mm correlated best with treatment failure, manifested as the presence of regional node metastases in 38% of the patients with tumors >2 mm as compared to 7.5% for tumors ≤2 mm (minimal follow-up of 2 years). They concluded that in the N0 patient, tumor thickness of >2 mm, regardless of tumor size, merited elective neck

(c) 2014 Wolters Kluwer. All Rights Reserved.

dissection. Mohit-Tabatabai et al.[127] found a strong statistical correlation between tumor thickness and regional metastasis. In their study, patients with floor-of-mouth squamous cancers stage as T1 or T2 and N0 with thickness measuring ≤1.5 mm, 1.6 to 3.5 mm, and >3.5 mm had corresponding regional metastases in 2%, 33%, and 60%, respectively (mean follow-up of 69 months).[127] They concluded that floor-of-mouth cancers measuring more than 1.6 mm should have elective neck dissections.[127] Other studies of oral cancers have also shown a statistical correlation between the depth of invasion and the presence of regional metastasis although the depth of tumor varied in each study.[131–133] However, there are a number of studies in which a statistical correlation could not be found between tumor thickness and nodal metastasis or prognosis.[129,134,135] Karas et al.[130] examined the relationship of tumor thickness as determined in biopsy specimens with the tumor thickness in the final resected specimens in patients with floor-of-mouth cancers. They found that in biopsy specimens with tumor thickness of ≤1 mm that the tumor thickness in the final specimens would be <2 mm ($p = 0.055$) and that tumor thickness of >2 mm in the biopsy material measured >3.5 mm in the final specimen ($p = 0.0001$).[130] They suggested that the information from the biopsy samples could be extrapolated and correlated with the findings of other investigators who correlated tumor thickness in oral cavity cancers with likelihood of regional metastasis, to suggest the possible needs for prophylactic neck dissection. In the study by Karas et al.,[130] tumor thickness measuring between 1 and 2 mm were too variable to be of predictive value.

In regard to other sites, Baredes et al.[136] found that in 44 patients with variably staged soft-palate SCCs (7 as T1, 14 as T2, 16 as T3, and 7 as T4), none of the patients with a tumor thickness of <2.86 mm had nodal metastasis, 60% of patients with tumor thickness >2.86 mm but <3.12 mm had metastatic disease, and all patients with tumors >3.12 mm had nodal metastasis. They concluded that there was a significant correlation between tumor thickness and the presence of nodal disease and that this association was more direct than that between T stage and nodal disease.[136] Baredes et al. also reported that thicker lesions had poorer survival.[136] Frierson and Cooper[128] evaluated 187 SCCs of the lower lip and found that the tumor thickness strongly correlated with nodal metastasis. For Frierson and Cooper,[128] nodal metastasis occurred in 74% of patients with cancers measuring ≥6 mm, suggesting that lip squamous cancers of that thickness need elective neck dissections. Moore et al.[137] and Urist et al.[138] also identified depth of invasion and tumor thickness as important prognostic parameters in upper aerodigesive tract cancers. More recently, Zitsch et al.[8] reviewed a series of 1,252 patients with lip cancer over a 47-year period. These authors did not measure tumor thickness, but among multiple parameters available in 1,036 patients, they found tumor size impacted on prognosis, with those lip cancers measuring >3 cm (T2 or greater) having a higher rate of nodal metastases (16%) than patients whose tumors measured <3 cm (6%).[8] Further, the range of 5-year survival rate for patients whose tumors measured >3 cm was 30% to 50%, in contrast to 90% 5-year survival rates for patients whose tumors measured <3 cm.[8] Based on their findings, they suggested aggressive management for lip cancer ≥3 cm.

The location of a tumor in the UADT may have an impact on the depth of invasion and potential for metastatic disease. As an example, the glottic area of the larynx quantitatively has less vascular spaces than other anatomic sites of the larynx. Therefore, for histologically similar carcinomas of equal invasive growth, those arising in the glottic area may be less likely to metastasize as compared to supraglottic or subglottic cancers due to less availability of vascular spaces in this anatomic site. This may also apply to other mucosal sites of the head and neck. However, tumor location does play an extremely important factor in tumor identification and in prognosis. Cancers that present earlier in the course of disease will have a better prognosis than those cancers that remain undetectable until they present at a more advanced stage of disease. Some examples of the former include tumors that present in areas that are visible to the patient (e.g., cutaneous sites of the head and neck) or result in symptomatology in the earlier stages of disease (e.g., true vocal cord). Patients with cancers of these sites may be diagnosed and treated while their tumors are still of a lower clinical stage and/or in areas that are readily accessible to complete surgical resection or radiation therapy without functional compromise or involvement of vital structures. In contrast, patients who have cancers that arise in areas in which symptoms may not develop early or whose symptomatology simulates nonspecific pathologic processes, such as cancers of the hypopharynx, the paranasal sinuses, and the middle ear, may only be detected in the advanced stages of disease with large tumors, extensive invasive growth, involvement of vital structures, difficult localization for complete removal, portending a poor outcome. Cerezo et al. found strong statistical correlation between the site of the primary tumor and prognosis.[139] In a multivariate analysis of 492 patients with squamous carcinoma of the head and neck, these authors found that patients with primary tumors of the larynx and the nasopharynx had higher survival rates than patients with carcinoma of the oropharynx, the mobile tongue, the floor of mouth, the retromolar trigone, and the hypopharynx.[139] They correctly attributed this discrepancy to the ability to control locoregional disease and/or better tumor response to therapy (surgery, radiation, or chemotherapy). Dworek and collegues[140] evaluated 250 patients with advanced head and neck cancer and found that patients with hypopharyngeal carcinoma were at greater risk of developing distant metastasis than were patients with carcinoma of the oral cavity, the oropharynx, and the larynx.

## Lymph-Vascular Space Invasion, Neurotropism, and Soft-Tissue Invasion

The presence of tumor within lymphatic spaces and/or blood vessels (Fig. 1-7) does not necessarily indicate that metastatic disease is present or will develop. However, several studies have

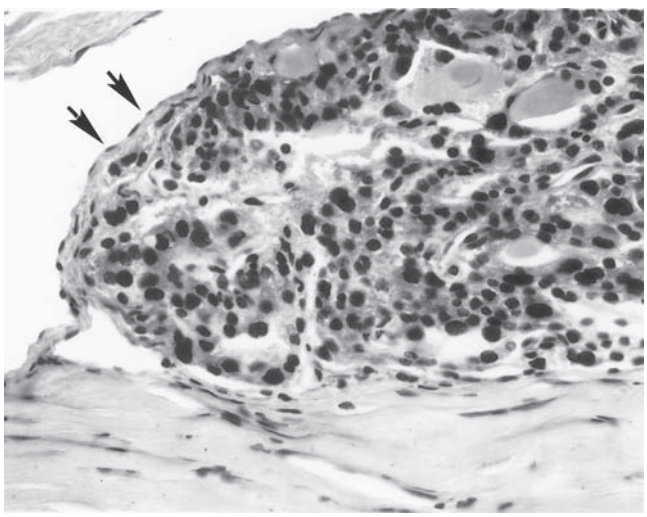

**FIGURE 1-7.** Parathyroid carcinoma showing vascular space invasion. Toward the left side of the illustration the endothelial cells lining this vascular space are seen (*arrowheads*) but become attenuated or lost due to the intravascular invasion of this tumor.

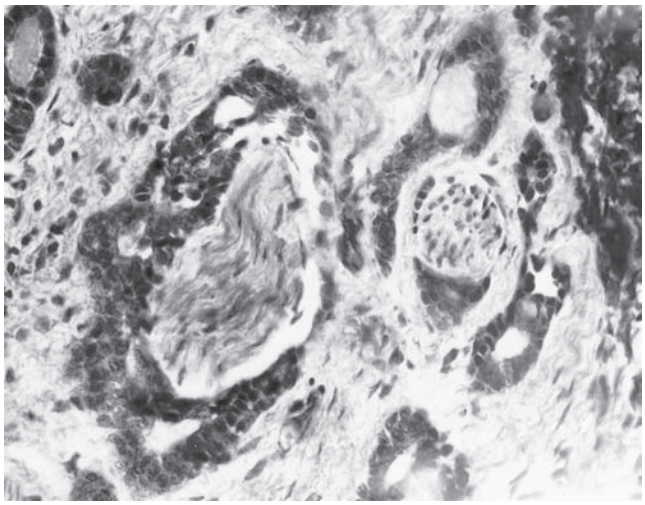

**FIGURE 1-8.** Adenoid cystic carcinoma of the parotid gland showing perineural invasion.

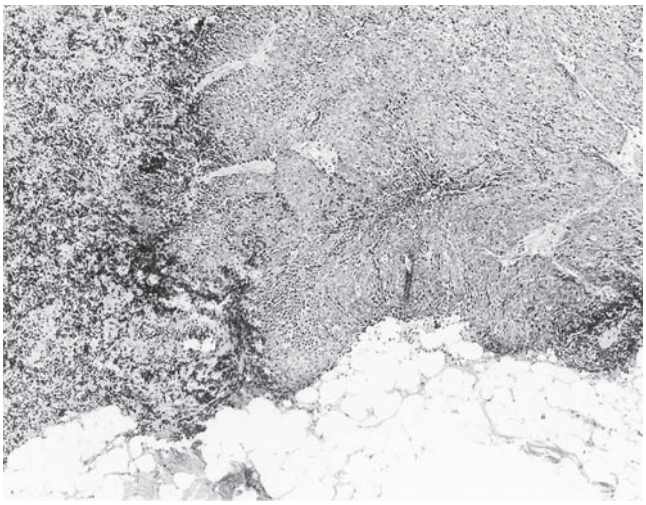

**FIGURE 1-9.** Metastatic carcinoma to a cervical neck lymph node with extracapsular extension. The remnant of the lymph node is seen at the left. Most of the lymph node has been replaced by metastatic carcinoma, which shows extension into perinodal adipose tissue (lower portion of illustration). Extracapsular spread is considered an adverse prognostic finding.

demonstrated a statistical correlation between the identification of vascular space invasion and nodal metastasis.[129,141–143] Sarbia and coworkers[144] evaluated the incidence and prognostic significance of blood-vessel invasion (BVI), lymph-vessel invasion (LVI), and neural invasion (NI) in SCC of the esophagus. These authors found a higher incidence of all three variables in higher pathologic and clinical-stage tumors than in patients with lower pathologic and clinical-stage tumors. Further, 5-year survival rates were significantly lower in patients with BVI and LVI than in patients without these findings.[144] These authors report no prognostic significance with the presence of NI (Fig. 1-8). Nevertheless, the presence of neurotropism in SCC of various UADT sites should be considered an adverse finding in head and neck malignancies indicative of a tumor's biologic aggressiveness as determined by an increased incidence of local recurrence, nodal metastasis, and/or decreased patient survival.[128,135,145–147] Similarly, extension into soft-tissue structures such as fat and muscle, or cartilaginous and osseous invasion by SCC of the head and neck generally indicates a higher clinical-stage tumor associated with a higher incidence of nodal metastasis.[143,148] It has been felt that hyaline cartilage is resistant to invasive cancer[149] and that in the larynx, there is preferential invasion of squamous carcinoma into ossified cartilage as compared to nonossified cartilage. However, Michaels has not found this to be true.[150] Michaels identified extensive invasion of laryngeal squamous carcinoma into nonossified cricoid and thyroid cartilage.[150] The invasion and destruction of bone by cancer is thought to be performed by osteoclasts mediated by prostaglandins[151] rather than by the direct action of the invasive cancer.

## Lymph Nodes

The presence of lymph node and/or distant metastasis is correlated with increased morbidity and mortality in association with most malignancies. For head and neck metastatic carcinoma to lymph nodes, several factors may have prognostic significance, including the presence of extracapsular extension by the tumor, site of nodal metastasis, number of lymph nodes with metastatic disease, node fixation, and tissue response to metastatic tumor. The presence of nodal metastasis with extension of the tumor outside the capsular confines of the lymph node and into perinodal soft tissues (extracapsular spread or ECS) (Fig. 1-9) is generally considered an adverse finding associated with increased risk of recurrent disease, increased risk of distant metastasis, and a reduction in long-term survival by up to 50%.[139,143,152–162] ECS is further subdivided based on whether the extracapsular spread was found microscopically or whether this feature was evident by gross examination. Macroscopic ECS is associated with an even greater risk of recurrent disease than by microscopic determination alone.[43,163] Further, lymph nodes measuring more than 3 cm demonstrate a >75% incidence of ECS.[152,156,158,159] Johnson et al.[164] advocate the use of postoperative adjuvant therapy (radiation and/or chemotherapy) in the presence of transcapsular extension. Similarly, Leemans and colleagues in two separate studies advocate the use of adjuvant systemic therapy in patients with ECS.[160,161] Myers et al.[162] reaffirm that ECS is the most significant predictor of both regional recurrence and the development of distant metastasis, accounting for decreased survival of patients with SCC of the oral tongue. Of the 260 patients in their study, 146 patients (55%) were pathologically node negative (pN0), 75 patients (28%) were pathologically node positive without ECS (pN+/ECS–), and 45 patients (17%) were node positive with ECS (pN+/ECS+). Following the order of pN0, pN+/ECS–, and pN+/ECS+, the 5-year disease-specific and overall survival rates for the pN0 patients were 88% and 75%; pN+/ECS– were 65% and 50%; and pN+/ECS+ were 48% and 30%. The overall recurrence rates were 19.8%, 34.2%, and 51.1%, respectively; the regional failure rates were 11.5%, 19.2%, and 28.9%, respectively; and the distant metastases rates were 3.3%, 8.2%, and 24.4%, respectively. Based on their findings, the authors advocate the use of intensive regional and systemic adjuvant therapy for patients with ECS.

The role of ECS as a prognosticator and adjuvant therapy determinant in human papilloma virus–related oropharyngeal squamous cell carcinoma (OPSCC) was recently reported by Sinha et al.[165] These authors evaluated 152 p16-positive primary OPSCC patients with pathologically positive necks. At a median follow-up of 43 months, the presence of ECS was not associated with poorer disease-free survival in multivariate analyses. Overall and in the presence of ECS or even soft-tissue metastasis,

(c) 2014 Wolters Kluwer. All Rights Reserved.

adjuvant CRT was not associated with better disease-free survival over radiotherapy alone. In addition, matched analyses in patients with and without ECS for T-stage, surgical margins, and adjuvant therapy showed no significant reduction in disease-free survival for the presence of ECS versus the absence of ECS or reduced disease-free survival for the administration of adjuvant radiotherapy alone versus CRT in ECS-positive patients. In conclusion, Sinha et al. concluded that ECS was not prognostic. Adjuvant CRT versus radiotherapy alone produced no improvement in disease-free survival for ECS-positive patients. The authors propose that de-escalated adjuvant therapy should be considered for patients with p16-positive OPSCC who undergo surgery and that routinely reported ECS should not be used to justify adjuvant chemotherapy.[165]

The site of metastatic disease may impact on overall prognosis. Patients with a nodal metastasis to the lower neck area have a worse prognosis than patients in whom the metastatic deposits are limited to the upper neck.[153,166,167] McLaughlin et al.[168] found that abnormal retropharyngeal adenopathy, as determined by radiographic assessment (CT scan, MRI), was a predictor of outcome in SCC of the head and neck. Patients with squamous carcinoma of the head and neck of varying T stages (I–IV) and varying N stages (N0–N3), followed for a minimum of 2 years, had rates of neck relapse and distant metastasis that were significantly higher with retropharyngeal adenopathy[168]; the rates of 5-year relapse-free survival and absolute survival were significantly lower.[168]

The prognostic implication of whether metastatic tumor is found in a single lymph node or whether multiple nodes harbor disease has been debated. A number of studies have found that there is no prognostic significance in the absolute number of positive lymph nodes.[169,170] However, other studies have found prognostic significance in the number of lymph nodes containing metastatic cancer, showing an inverse relationship between the absolute number of lymph nodes containing metastatic cancer and survival.[139,140,152,156,157,160,161,171] Doweck et al.[140] in their study on 250 patients with advanced head and neck cancer reported that the most accurate predictor of distant metastasis was the number of neck levels with clinical evidence of disease. Patients with more than one level of nodal metastases had an odds ratio of 3.17 for having distant metastasis. Of these patients, 36% had distant metastasis compared with 17.9% if only one level of the neck was involved and 10.2% if the neck was negative. There is no specific cut-off in the number of positive lymph nodes associated with decreased survival. In a number of studies, the involvement by metastatic tumor in 3 or more lymph nodes appeared to be a predictor of distant metastasis and decreased survival.[139,160,161] Olsen et al.[143] found no significance when the number of lymph nodes involved was between 1 and 3, but when 4 or more lymph nodes were positive for metastatic tumor, there was a significant statistical correlation with 2-year recurrence-free survival (51% with at least 4 lymph nodes compared with 79% with 1–3 positive lymph nodes). Spiro et al.[171] reported that the presence of bilateral nodal metastases is an adverse prognostic finding associated with a worse prognosis in comparison to patients with unilateral metastatic disease. Mamelle et al.[172] retrospectively evaluated 914 patients with SCC of various head and neck sites who underwent lymph node dissection, in an attempt to determine prognostic factors relative to nodal disease. These authors reported that in a multivariate analysis, the most significant prognostic factors were the site of the positive node in or out of the sentinel node area ($p < 0.001$) and the number of positive nodes ($p < 0.001$), and that a more accurate approach was obtained by combining both factors.[172] The presence of nodal metastasis in 4 or more lymph nodes located out of the sentinel node area was associated with decreased 5-year survival rates and increased likelihood of metastatic disease.[172] These authors reported that in the multivariate analysis, extracapsular spread was a nonsignificant risk factor in survival or distant metastatic spread ($p = 0.09$), but was significant in their univariate analysis ($p < 0.001$).[172]

## Distant Metastasis

Distant metastasis by hematogenous spread to visceral sites from a head and neck squamous carcinoma most commonly includes spread to the lungs, the liver, and bone.[173] Distant metastatic tumor from a head and neck squamous carcinoma carries ominous clinical import generally heralding the demise of the patient over relatively short periods of time despite all attempts at controlling disease.[174] Among the factors that may be associated with distant metastatic tumor are the histologic type of cancer, tumor size, and the status of cervical lymph node involvement. Several of the high-grade variants of squamous carcinoma, including the basaloid SCC and adenosquamous carcinoma, often present as large tumors that are deeply invasive associated with nodal and distant metastasis. The reason for this aggressive behavior at presentation is not completely understood.

Both the tumor size (T stage) and the cervical node involvement (N stage) have been shown to have a high incidence of distant metastases.[139,161,175–177] In addition to N stage, the number of lymph nodes involved, the number of lymphatic chains involved, and the presence of extracapsular spread have all been shown to be associated with an increased incidence of distant metastasis.[139,140,157,160,161] Cerezo et al.,[139] in a multivariate analysis of 492 patients with metastatic neck disease from squamous cell carcinoma of the head and neck, found that when 3 or more lymph nodes had metastatic disease the distant recurrence-free survival was reduced to 41% as compared to 84% when 1 lymph node was involved and 57% when 2 lymph nodes were involved. These same authors also found that when 2 or more lymphatic chains contained metastatic tumor, the distant recurrence-free survival was reduced to 40% as compared to 74% when 1 lymphatic chain was involved.[139] In an autopsy study of 112 patients who had SCC of the head and neck, Nishjima et al.[173] found that nodal status was a significant prognostic factor in the presence of distant metastases. Of the 41 patients (37%) in their study who were found to have distant metastases at the time of death, 26 patients (63%) had evidence of cervical lymph node metastases, which represent a positive correlation between nodal status and development of distant metastases ($p < 0.01$). Nishijima et al. further combined their patients into those who had tumor at the primary site with those who had tumor in cervical lymph nodes (classified as cancerous lesions above the clavicle), and found that of these 82 patients 43% had distant metastases ($p < 0.05$). These authors concluded that distant metastasis occurred most frequently in patients with residual or recurrent disease in the neck. Nishijima et al. reported no correlation between the T and N stages, anatomic site of the primary tumor, presence or absence at controlling disease at the primary site with the frequency of developing distant metastases. The authors indicate that in their patients, the T and N stages were determined at the time of the initial examination (when the patients were alive). Irrespective of the T or N stage, these patients ultimately died of their tumors, and so it was felt that the initial T and N stages may not have played a significant role in the analysis of patients who died of advanced disease.[173]

Skin involvement by mucosal SCC of the head and neck is uncommon and is usually an indication of advanced or recurrent disease.[178] Cole and McGuirt[179] have shown that cutaneous involvement from a primary mucosal SCC has adverse prognostic implications. These authors found that the presence of direct cutaneous extension from a mucosal SCC was associated with a mean survival of 7 months while intradermal lymphatic spread carried

(c) 2014 Wolters Kluwer. All Rights Reserved.

a mean survival of 3 months; involvement of facial skin had an overall better prognosis than when there was involvement of neck skin with 12-month and 3-month median survival, respectively.[179]

## Second Malignancy

As compared to the standard population, the head and neck cancer patient is at greater risk (10–30 times) of developing a second primary malignancy[180] with the frequency varying from <5%[181] to as high as 36%[182] with many studies in the 15%-to-25% range.[183–185] Criteria used in defining multiple primary carcinomas include that the tumors be separate and distinct (at least 2 cm apart) without any dysplasia in the intervening mucosa and that the second primary tumor does not represent a metastasis or recurrent tumor.[181] The diagnosis of a second primary tumor such as in the lung includes the presence of a solitary lesion that is histologically distinct from the primary tumor.[185] Second primary malignancies occurring within a 6-month period from the discovery of the primary cancer are termed synchronous tumors, whereas second primary malignancy that occurs after the 6-month period from the discovery of the first tumor are referred to as metachronous tumors. Most of the second malignancies develop in other upper aerodigestive tract mucosal sites.[183,184,186] Non–head and neck sites in which second malignancies develop include the lungs,[184–186] the esophagus,[148,185,187] and the bowel.[184,186] Most often, the histology of the second primary malignant neoplasm is a squamous carcinoma,[185,187] but other histologic types such as adenocarcinomas may occur.[186] Some of the high-grade variants of SCC, including the basaloid cell squamous carcinoma and adenosquamous carcinoma, are notorious for the presence of multiple concurrent primary tumors in mucosal sites of the head and neck at the time of initial presentation.

Factors that may play a significant role in the development of a second malignancy include the site of the original primary cancer, the age of the patient, the size of the primary tumor, the status of regional lymph nodes, and the use of tobacco and alcohol. Head and neck second malignancies are more likely to develop when the primary cancer is in the oral cavity, the hypopharynx, or the oropharynx than if the index tumor is of laryngeal origin.[184–186] Patients who developed their tumors prior to 60 years of age may be at greater risk of developing a second primary malignancy.[185,186] Jones et al.[186] showed that patients with lower stage index tumors (T1 and T2) and patients who had no nodal metastasis (N0) at the presentation of their index tumor were more likely to develop a second malignancy than patients with higher stage index tumors and patients who did have nodal metastasis at the presentation of their index tumor ($p$-values of $< 0.0001$ and 0.0003, respectively). Lippman and Hong[188] also identify the threat of a second malignancy in early stage head and neck index cancer patients. Patients with index tumors of the head and neck who smoke tobacco (>20 pack years) and consume alcohol were at significant increased risk of developing a second malignancy than head and neck cancer patients who did not.[185] Survival rates after the second cancer are influenced by the site of the second malignancy and persistent use and abuse of tobacco and alcohol.[185] Second malignancies of the lung and the esophagus portend a significantly worse prognosis than second malignancies of other head and neck sites with 5-year survival rates from the diagnosis of the second malignancy of 2% (for lung) and 3% (for esophagus) versus 20% for second head and neck malignancies.[185] Continued use of tobacco and alcohol also adversely affected survival rates with 5-year survival rates of 5% for smokers versus 20% for nonsmokers, and 6% for drinkers versus 27% for nondrinkers.[185]

The site of the second malignancy differs for different index tumors. Head and neck, and esophageal second primary malignancies are more prevalent after oral cavity and pharyngeal index tumors, whereas the development of a second primary tumor of the lung was most common after a laryngeal index tumor.[184,186] Haughey et al.[184] suggest a shared mucosal susceptibility between the index tumor and the second malignancy to account for this phenomenon. A common "digestive tract axis" is shared between the oral cavity, the pharynx and the esophagus, whereas the larynx and the lung share a common "respiratory tract axis." This shared mucosal susceptibility is a variation on the "field cancerization" concept, which highlights the importance of carcinogen activation of an entire exposed mucosa.[189–197]

The critical issue for the clinicians in the evaluation and planned treatment of the head and neck cancer patient is to be acutely aware of the possibility that the patient has or will develop a second primary malignancy. The diagnosis of a primary head and neck cancer should initiate panendoscopic evaluation of the entire UADT, as well as the lower aerodigestive tract and esophagus to exclude the possibility of a synchronous second primary cancer, with vigilant follow-up care given the possibility of developing a metachronous cancer. The results of these findings may ultimately impact on the diagnostic approach, treatment protocol, and prognostic impact for that patient. The development of a second primary malignancy is in all likelihood a multifactorial process combining genetic and environmental risks.

# SECTION II
# Squamous Cell Carcinoma

In the head and neck region, the most common lesion encountered by the otolaryngologist and the pathologist relate to alterations of the surface squamous epithelium. This section will focus on the squamous epithelial alterations of the UADT, including precursor lesions, SCC, and selected variants of SCC.

## DYSPLASIA AND INTRAEPITHELIAL NEOPLASIA

Dysplastic or intraepithelial neoplastic changes represent a spectrum of abnormal epithelial maturation and cellular aberrations that may or may not precede an invasive carcinoma. Dysplasia is synonymous with atypia. The uterine cervix represents the paradigm for the histologic grading of dysplastic changes. Typically, uterine cervical dysplasias are nonkeratinizing lesions. Similar to the uterine cervix, the grading of UADT intraepithelial dysplasia includes mild, moderate, and severe depending on the extent of involvement of the surface epithelium although the most common type of dysplastic lesions are keratinizing ones. In general, the lower the degree of dysplasia, the less likely the transformation to an invasive carcinoma, whereas higher-grade dysplasias are more likely to progress to invasive carcinoma. In the UADT, particularly in the larynx and the oral cavity, severe dysplasia as defined histologically by the presence of full-thickness intraepithelial dysplasia (i.e., CIS) is not a prerequisite for the development of an invasive SCC.[198,199] In the UADT, where keratinizing dysplasias are more common than "classic" or nonkeratinizing dysplasia, invasive carcinoma may develop in the presence of dysplastic changes limited to the basal zone without full-thickness intraepithelial dysplasia.[199]

## CARCINOMA *IN SITU*

As classically defined, CIS represents full-thickness mucosal intraepithelial dysplastic change without violation of the basement membrane. For all intents and purposes, severe

(c) 2014 Wolters Kluwer. All Rights Reserved.

dysplasia is synonymous with CIS. As previously noted, in the upper airways, CIS (as classically defined) is not a requirement prior to the development of an invasive SCC. The latter may arise from the basal epithelial layer in the absence of overlying dysplastic changes. Therefore, in this setting, the definition of CIS can be expanded to include those lesions in which the mucosal alterations are so severe that there would be a high probability for the progression to an invasive carcinoma if left untreated. Extension of the dysplastic process to involve the mucoserous glands is still considered as CIS and not invasive carcinoma.

## EARLY, SUPERFICIALLY, OR MICROSCOPIC INVASIVE SCC

Microinvasive carcinoma (MIC) represents squamous carcinoma in which there is penetration of the basement membrane with invasion of the carcinoma into the underlying submucosal compartment. There is no uniformity among pathologists as to how to histologically define MIC.[198] The various histologic definitions of MIC include small number of cells below the basement membrane, invasion through the basement membrane, invasion through the basement membrane limited to 1 to 2 mm of the basement membrane without angioinvasion, and invasion no more than 0.5 mm from the basement membrane with no angioinvasion. The identification of superficial or MIC is significant given the presence of vascular spaces high in the lamina propria and the potential, even in the presence of "early" invasive cancer, for metastatic disease. Relative to HNSCC, invasive carcinoma may develop in the setting of nonkeratinizing dysplasia as a continuum from CIS or more often develops in the setting of keratinizing dysplasia in which CIS is not a prerequisite for the development of invasive carcinoma with invasive carcinoma arising from a surface epithelium in which there may be dysplastic alterations limited to the basal zone area (so-called "drop off" carcinoma) (see subsequent text).[199]

## PRECURSOR LESIONS

Precursor lesions to squamous epithelial lesions of the UADT present diagnostic challenges in that the majority of dysplastic epithelial changes are of the keratinizing type to which the continuum of mild to moderate to severe dysplasia to invasive carcinoma that characterizes the nonkeratinizing dysplasias does not consistently apply. This results in problems in the histologic grading of these changes and raises questions about what constitutes a diagnosis of severe dysplasia. In this context, the justification of using the designation CIS relative to keratinizing dysplasia becomes questionable.

Leukoplakia, erythroplakia, and speckled leukoplakia are not histopathologic terms. The qualitative intraepithelial alteration in a malignant direction is referred to as dysplasia. Dysplasia is for all intents and purposes synonymous with atypia although dysplasia has been used in relation to architectural abnormalities, while atypia has been used for cytomorphologic changes.

Histologic criteria for the diagnosis of intraepithelial neoplasia of the UADT include both cytomorphologic and maturation abnormalities. These alterations include the proliferation of immature or "uncommitted" cells characterized by a loss of cellular organization or polarity, nuclear pleomorphism (variations in the size and shape of the nuclei), increase in nuclear size relative to the cytoplasm, increase in the nuclear chromatin (hyperchromasia) with irregularity of distribution, and increased mitoses, including atypical forms in all epithelial layers. The dysplastic changes may or may not be associated with keratosis and/or dyskeratosis. The location of the architectural and cytomorphologic changes within the epithelium represents key diagnostic parameters in the assessment of UADT epithelial dysplasia.

The paradigm for grading epithelial dysplasia is the one used for the uterine cervix. In the uterine cervix, the "classic" or nonkeratinizing form of dysplasia commonly occurs. The increasing gradations of cervical dysplasia include mild (CIN I), moderate (CIN II), and severe (CIN III), with the latter representing full-thickness replacement of the squamous epithelium by atypical, small, immature basaloid cells and is referred to as carcinoma *in situ* (CIS) (Fig. 1-10). This grading scheme is reproducible and is clinically useful. However, the "classic" or nonkeratinizing dysplasia of the uterine cervix is uncommon in the UADT, especially in the glottic larynx. In contrast, most of the intraepithelial neoplasias of the UADT are keratinizing dysplasias. Using the definition of CIS of the uterine cervix that requires loss of maturation of squamous epithelium, a keratotic lesion cannot be CIS because keratosis requires maturation of the squamous epithelium. Therefore, the use of the specific term CIS in keratinizing dysplasias has been questioned and is likely inappropriate in this setting. A more appropriate designation is of severe keratinizing dysplasia.[199]

The criteria for evaluating keratinizing dysplasias are less defined, and the diagnosis of severe keratinizing intraepithelial dysplasia remains controversial. The definition of severe dysplasia in the UADT, especially in the glottic larynx, is broader than the highly reproducible pattern seen in the uterine cervix and includes a microscopically heterogeneous group of lesions. In the setting of keratinizing dysplasia where surface maturation is retained with only partial replacement of the epithelium by atypical cells, severe dysplasia includes those lesions in which the epithelial alterations are so severe that there would be a high probability for the progression to an invasive carcinoma if left untreated (Fig. 1-11). Severe dysplasia shows the presence of aberrant cell maturation with dyskeratotic cells and mitotic figures with or without atypical forms above the basal zone. These alterations often occur in the presence of surface keratinization (Fig. 1-12). In the evaluation of UADT dysplasia, the presence

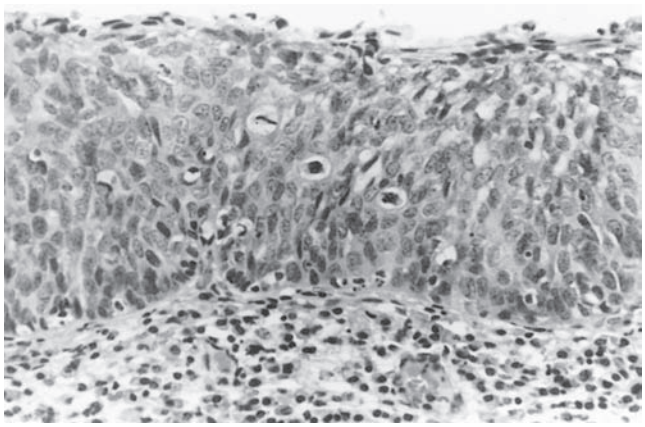

**FIGURE 1-10.** Laryngeal (glottic) carcinoma *in situ* "classic" or nonkeratinizing type. There is full-thickness dysplasia with replacement of the squamous epithelium by atypical, small, immature basaloid cells, including numerous mitotic figures in the absence of surface keratinization. The dysplastic cells are confined to within the surface epithelium and do not penetrate the basement membrane into the submucosa.

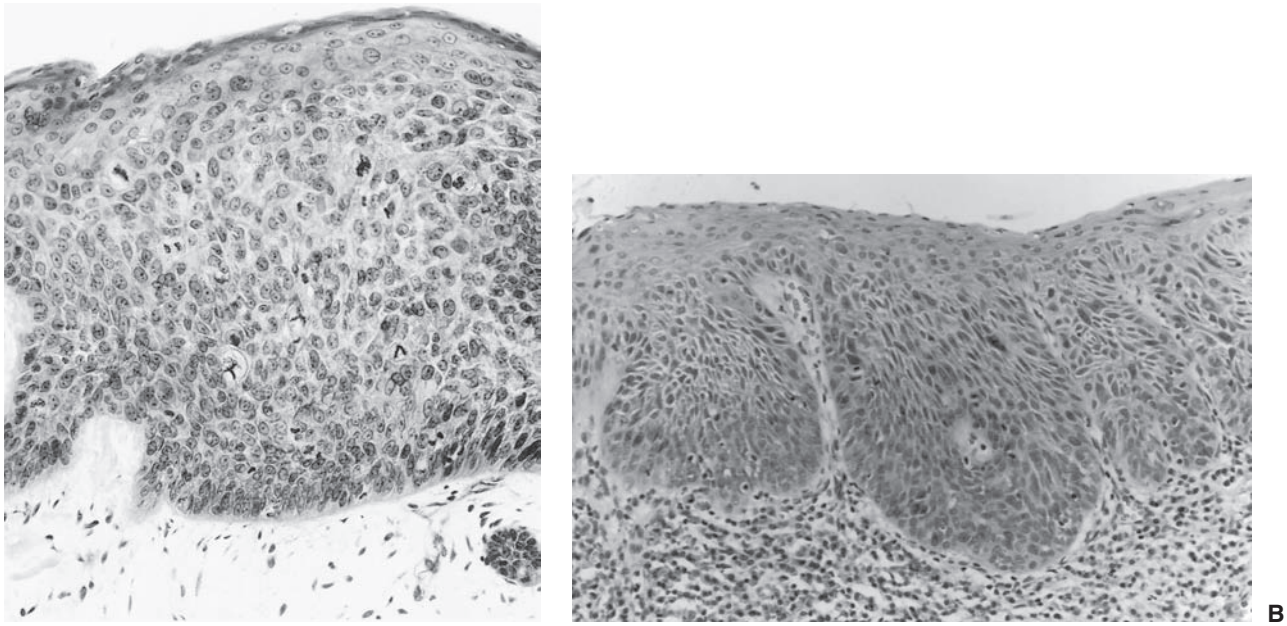

**FIGURE 1-11.** **A:** Laryngeal (glottic) keratinizing dysplasia. Surface maturation is retained with replacement of the squamous epithelium by atypical cells, including numerous suprabasal mitotic figures. Although there is no full-thickness dysplasia, the lesion is considered as severe dysplasia given that the epithelial alterations are so severe that there is a high probability for the progression to an invasive carcinoma if left untreated. **B:** Similar alterations as those seen in **(A)**, but the downward growth of the bulbous adds concern for the evolution to invasive carcinoma.

**FIGURE 1-12.** Laryngeal biopsy showing keratosis and severe dysplasia with superficial invasion. This epithelium does not show full-thickness dysplasia (i.e., carcinoma *in situ*). The dysplastic alterations are limited to the lower portion of the epithelium but is still considered severe, and the angulated downward extension of this severely dysplastic epithelium is sufficient to consider this as superficially invasive.

of surface keratinization is not significant; however, finding dyskeratotic cells represents an important clue to the presence of significant dysplasia.

## GRADING EPITHELIAL DYSPLASIA OF THE UADT

The histopathologic interpretation and grading of epithelial dysplastic changes in the UADT are imprecise and subjective. Given the complexities in the issues relative to UADT intraepithelial lesions, confusion and misunderstandings may occur between the clinician and the pathologist that may result in inappropriate management of the patient. Uniformity in terminology is desirable so that there is a correlation between the pathologic diagnosis and the clinical import of that diagnosis. In an attempt to standardize the terminology of UADT intraepithelial lesions using a grading system akin to that of the cervical mucosa, Crissman and Zarbo[200] used the terminology of squamous intraepithelial neoplasia (SIN) with SIN I equivalent to mild dysplasia, SIN II to moderate dysplasia, and SIN III to severe dysplasia. Similar gradations but using the terminology of laryngeal intraepithelial neoplasia (LIN) have been proposed.[201] More recently, the Ljubljana classification of laryngeal precancerous lesions was proposed.[202] In this system, the terms used include simple hyperplasia (i.e., keratosis without atypia), abnormal hyperplasia (i.e., keratosis with atypia), atypical hyperplasia (i.e., severe dysplasia), and CIS. These systems have conceptual validity, but may not be entirely applicable from a practical standpoint in the UADT. At present, the WHO recommends grading dysplastic epithelial alterations of the UADT as mild, moderate, and severe dysplasia depending on the degree and extent of cellular and maturation alterations that are present.[203]

Regardless of the terminology employed, close interaction between the pathologist and the clinician is required so that each

(c) 2014 Wolters Kluwer. All Rights Reserved.

individual understands the impact of their respective findings and the import to the patient in therapy and prognosis.

## Risk of Progression

The end point for the grading of dysplasia is to convey to the clinician what the potential biologic behavior of a given epithelial lesion is. Keratotic epithelium without dysplasia carries a very low risk of developing subsequent carcinoma with reported incidences of 1% to 5%.[198,203] In contrast, keratotic epithelium with dysplasia is associated with an increased risk for the subsequent progression or development of premalignant or overtly carcinomatous changes varying from 11% to 18% of cases.[198,203] This risk of malignant transformation represents an increase of three to five times as compared to carcinoma arising in keratotic lesions without atypia. Bouquot and Gnepp[204] found greater variability relative to risk progression of keratosis with and without atypia in their review of the literature. Nevertheless, the potential value in grading keratotic dysplasias is apparent from Barnes's review of the literature[198] in which the risk for developing invasive carcinoma in mild, moderate, and severe dysplasia was 5.7%, 22.5%, and 28.4%, respectively. Bauer and McGavran[205] indicated that if enough sections are taken, MIC will be found in laryngeal lesions that have keratosis with cytologically atypical cells.

Another important point to recognize is the clinical concern attached to a diagnosis of severe keratinizing dysplasia. This clinical concern is due to the fact that severe dysplasia is often multifocal and frequently occurs adjacent to or near synchronous foci of invasive carcinoma. Further, this form of dysplasia has a rate of progression to invasive carcinoma that is greater than that of "classic" CIS.[206–208] A diagnosis of severe dysplasia requires therapaeutic intervention, as well as clinical evaluation of the entire UADT to exclude the possible presence of additional foci of dysplasia or carcinoma.

In general, mild dysplasia is felt to be reversible alterations. Circumstantial evidence supports the idea that preinvasive dysplasias are potentially reversible following cessation or removal of an instigating factor such as tobacco use. The problem of predicting the malignant potential of a dysplastic lesion is greatest in cases of moderate dysplasia. It is virtually impossible to differentiate the moderately dysplastic lesions that are reversible from those that represent the earliest forms of neoplastic transformation. Therefore, a diagnosis of moderate dysplasia should engender enough concern to the clinician to warrant close patient follow-up. Recurrence or persistence of this dysplasia may be indicative of malignant transformation. Further, there are no significant differences in the progression to invasive carcinoma between keratinizing moderate dysplasia and keratinizing severe dysplasia so that treatments for these dysplasias are essentially similar.[198] As such, it may be prudent to adopt a similar approach to the two-tier histologic classification scheme used in the grading of uterine cervical dysplasia to dysplasias of the UADT including:

1. Low-grade squamous intraepithelial lesion for mild dysplasia
2. High-grade squamous intraepithelial lesion for moderate and severe dysplasias

The determination of whether a mild to moderate dysplasia is reactive or neoplastic, although a desirable goal, is not always achievable. The clinically abnormal lesions that show limited cytologic and maturation abnormalities falling under the designation of reactive atypias or hyperplastic lesions represent reversible changes that rarely, if ever, progress to carcinoma. These lesions are responsive to conservative management. Epithelial hyperplasia (acanthosis) is a common finding and can be seen without atypia or in association with atypia. In hyperplasia, there usually is an irregular contour to the basal zone, and there may be protrusion of the epithelium below adjacent epithelium, possibly suggesting an MIC. A diagnosis of MIC should be reserved for those examples in which there is definitive evidence of dissociated squamous cells at the epithelial-to-stromal interface. Epithelial hyperplasias may be caused by an infectious agent (e.g., fungi), and fungal stains may be useful to identify the causative microorganism.

## MICROINVASIVE, SUPERFICIAL, OR "EARLY" INVASIVE SCC

Microinvasive SCC is a cancer that infiltrates into the superficial compartment of the lamina propria. As simple as this may appear, the diagnosis of superficially invasive SCC can be subjective, with no unanimous definition among pathologists. For laryngeal lesions, some authors consider microinvasive cancer to include the presence of scattered malignant cells within the submucosa just below the basement membrane[209] or within 1 to 2 mm of the basement membrane,[200,210,211] whereas other authors feel that MIC is present when tongues or discrete foci of malignant epithelium invades through the basement membrane.[212] Barnes defines MIC as invasive SCC that extends into the stroma no more than 0.5 mm as measured from the adjacent (nonneoplastic) epithelial basement membrane.[198] Irrespective of its specific definition, a diagnosis of MIC excludes those lesions that are restricted to the surface epithelium or carcinoma *in situ* (Tis) and those carcinomas that are deeply invasive into muscle and cartilage, and extralaryngeal structures (T2 or greater tumors). Also, the presence of lymph-vascular space invasion would exclude a diagnosis of MIC. Of note, extension of the dysplastic process to involve the seromucinous glands is still considered as CIS and not invasive carcinoma (Fig. 1-13). The clinical manifestations

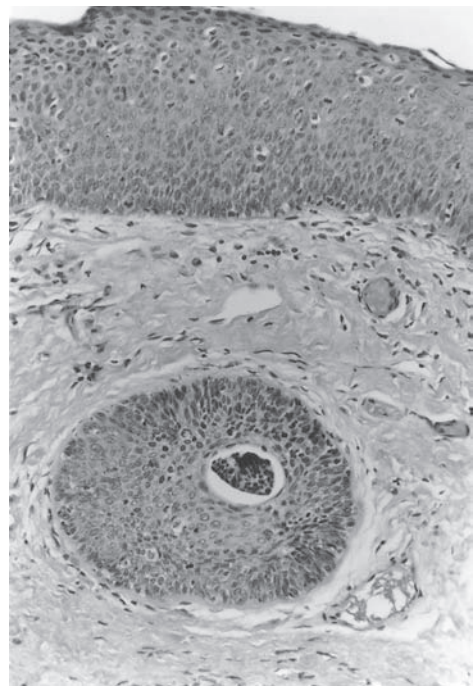

**FIGURE 1-13.** Laryngeal (glottic) carcinoma *in situ* of the surface epithelium with extension of the dysplastic process to involve the seromucinous glands. The extension to seromucinous glands is still considered as carcinoma *in situ* and not invasive carcinoma.

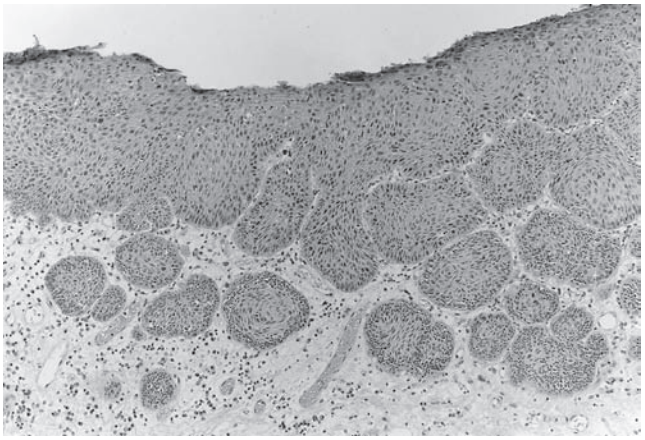

**FIGURE 1-14.** Laryngeal (glottic) microinvasive squamous cell carcinoma developing as a continuum from carcinoma *in situ*.

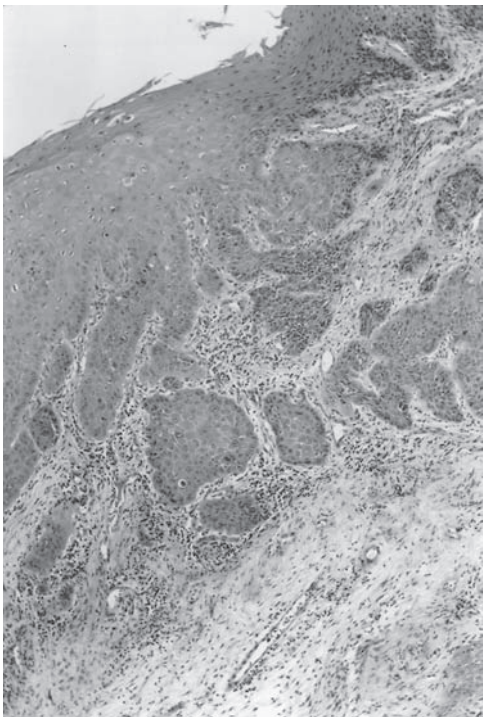

**FIGURE 1-15.** Laryngeal (glottic) invasive squamous cell carcinoma developing from the basal zone of the surface epithelium in which most of the epithelium is free of dysplastic changes (so-called drop-off carcinoma).

and appearance of microinvasive SCC are similar to those of CIS. In the larynx, full-cord mobility is present. Any dysfunction in vocal cord mobility (fixation), by definition, means muscle invasion, which excludes a diagnosis of microinvasive cancer.

Histologically, MIC can occur in two unrelated phases. The first is the development from and as a continuum of CIS (Fig. 1-14). The second is invasion from an epithelium demonstrating no evidence of CIS. In the UADT, particularly in the larynx, severe dysplasia (i.e., CIS) is not a prerequisite for the development of an invasive SCC. Such invasive carcinomas "drop off" or "drop down" from the basal cell layer, with the overlying mucosa showing no evidence of dysplasia (Fig. 1-15). In all examples of invasive carcinoma, the invasive nests must be cytologically malignant with dysplastic changes, dyskeratosis, and mitotic figures, including atypical forms. The tumor nests have an irregular outline with infiltrative borders. The presence of invasive cancer generally results in stromal induction or a desmoplastic host response that includes edematous change immediately around the tumor nests with granulation tissue and fibrosis.

Microinvasive cancer is a biologically malignant lesion potentially capable of gaining access to lymphatic or vascular channels in the lamina propria that may result in metastatic disease. For MIC of the laryngeal glottis, several studies have shown that the clinical significance is similar to CIS/severe dysplasia and that with appropriate therapy, progression of disease from a microinvasive to a more invasive carcinoma does not occur.[207,209–212] This may be due to the earlier clinical manifestations produced by glottic cancers leading to an earlier diagnosis of cancer before it has invaded into deeper aspects of the larynx. Glottic microinvasive cancers are generally not associated with metastatic disease due to the fact that the glottic portion of the larynx has quantitatively less lymph-vascular spaces as compared to the supra- and subglottis. In contrast to the laryngeal glottis, supraglottic MICs are associated with metastatic disease in approximately 20% of patients.[213]

## INVASIVE SCC

The clinical (gross) appearance of invasive SCC is quite variable and includes ulcerated, flat, exophytic, verrucoid or papillary growths. The histologic appearance of invasive SCC may be as variable as the gross appearance without specific correlation between the gross appearance and the histopathologic findings. Invasive SCC of the UADT includes keratinizing and nonkeratinizing carcinomas varying from well to poorly differentiated. Severe dysplasia/CIS of the surface epithelium may be a common component found in association with invasive SCC; this component need not be present. For all types of SCC, the presence of invasion is diagnostic of a malignancy. Invasion can be as single (dyscohesive) cells or small irregular aggregates or can appear as large cords or cohesive aggregates. In addition, a desmoplastic stromal response and foreign body reaction to keratin in the stroma may assist in identifying invasion. Invasive cancer will efface the normal architecture and may be associated with lymph-vascular space invasion, neurotropism, and invasion into muscle, bone, and cartilage. Once the cancer invades beyond a few millimeters or extends into muscle, cartilage, or other soft-tissue components outside the anatomic structure from which it originates, the tumor is a higher clinical-stage neoplasm with the potential for a more aggressive behavior. Immunohistochemical studies have shown that the presence or absence of basement membrane components around invasive cancer correlated with the pattern of tumor invasion.[214] The pattern of tumor invasion (single cell vs. large cords) represents an inherent biologic parameter of tumor aggressiveness.[200,214]

### Pitfalls in the Diagnosis of Invasive SCC

Sampling is a major issue in the evaluation of SCC of the UADT. In the absence of adequate representative tissue, including epithelial-to-stroma interface, one should be circumspect relative to a diagnosis of SCC. Pitfalls in the diagnosis of SCC include pseudoepitheliomatous hyperplasia,[199,215] necrotizing sialometaplasia,[199,216] juxtaoral organ of Chievitz,[199,216] and radiation atypia.[199]

(c) 2014 Wolters Kluwer. All Rights Reserved.

***Histologic Prognostic Indicators.*** The histologic findings that may impact on the prognosis in HNSCC include (a) status of the surgical resection margins, (b) tumor size, thickness, and location of the lesion, (c) pattern of invasion, (d) involvement of lymphvascular spaces, (e) invasion of soft-tissue structures, including nerves, bone, and cartilage, (f) nodal metastasis with or without extranodal extension of tumor, (g) distant metastasis, (h) host response, (i) neovascularization, and (j) presence of multiple malignancies.

## MORPHOLOGIC SUBTYPES OF SCC

There are numerous variants of HNSCC (Table 1.13). The diagnostic criteria and diagnostic problems associated with some of these specific subtypes of HNSCC will be discussed.

### Papillary (Exophytic) SCC

Papillary (exophytic) SCC represents an uncommon but distinct subtype of head and neck SCC.[217–219] The demographics for this subtype of SCC are similar to those of conventional SCC with the tendency to affect men more than women and occurring in adults with a mean age in the seventh decade of life. Papillary SCCs predilect to the larynx, the oral cavity, the oro- and the hypopharynx, and the sinonasal tract.[217–219] The larynx is the most common site of occurrence. Symptoms vary according to the site of involvement. Papillary SCC usually arise de novo without identification of coexisting benign lesion such as a papilloma, although association with precursor papilloma or occurrence in patients with previous history of a papilloma at the site of the papillary SCC have been reported.[219] Human papillomavirus (HPV) by ISH and PCR have been detected in papillary SCC.[219]

Papillary SCC is most often seen as a solitary lesion with an exophytic or papillary growth. Tumor size may range from 2 mm up to 4 cm. Histologically, papillary SCC has filiform growth with finger-like projections and identifiable fibrovascular cores or a broad-based bulbous to exophytic growth with rounded projections resembling a cauliflower-like growth pattern in which fibrovascular cores can be seen but tend to be limited to absent (Fig. 1-16). The squamous epithelium is cytologically malignant, and this malignant epithelium identifies these tumors as carcinomas separating them from papillomas. Surface keratinization is generally limited and often absent. Definitive invasion may be difficult to demonstrate in biopsy specimens, with the carcinomatous epithelium suggesting an *in situ* process rather than invasive carcinoma. However, the extent of growth with the formation of a clinically appreciable exophytic mass goes beyond the general concept of an *in situ* carcinoma. These tumors should be considered as being invasive even in the absence of definitive stromal invasion.

**TABLE 1.13 Head and Neck Squamous Cell Carcinoma (SCC) and Variants**

| Adenoid SCC |
| Adenosquamous carcinoma |
| Others |

### Verrucous Carcinoma

Verrucous carcinoma (VC) is a highly differentiated variant of SCC with locally destructive but not metastatic capabilities. VC affects men more than women and generally occurs in the sixth and seventh decades of life. VC can occur anywhere in the UADT. The most common sites of occurrence in descending order include the oral cavity, the larynx, the nasal fossa, the sinonasal tract, and the nasopharynx.[220–222] Symptoms vary according to site: larynx—hoarseness is the most common complaint, less frequent symptoms include airway obstruction, hemoptysis, dysphagia; oral cavity—mass with or without pain; sinonasal tract—airway obstruction; nasopharynx—dysphagia. The most common site of occurrence in the larynx is the glottic area. Oral cavity VCs most commonly arise on the buccal mucosa and the gingiva.

The etiology of VC remains speculative and includes tobacco smoking or chewing. Viral-induction appears to be a legitimate etiologic factor in the development of VC, but a causal relationship has not been clearly identified. The active role of HPV is

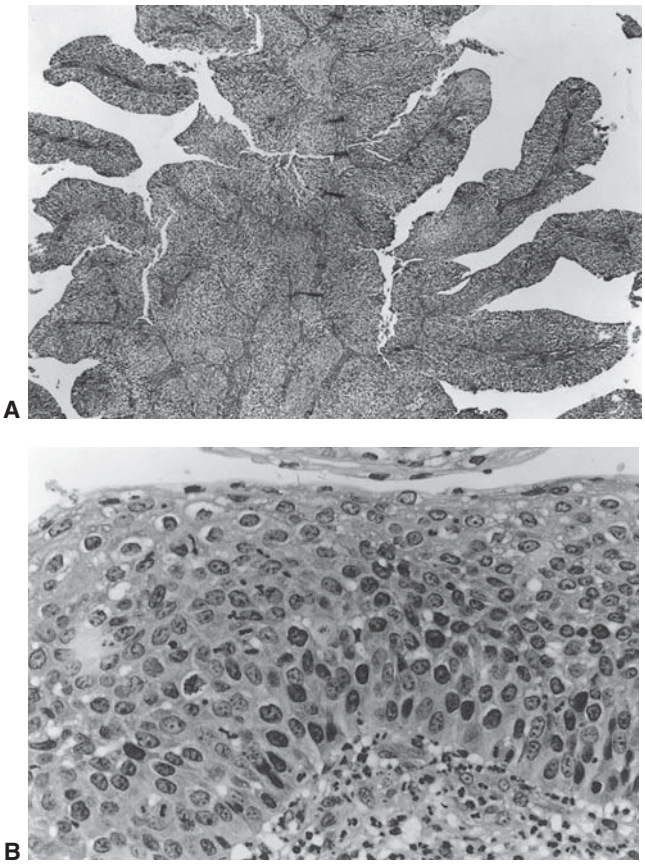

**FIGURE 1-16.** Papillary squamous cell carcinoma. **A:** Papillary epithelial neoplasm with fibrovascular cores devoid of surface keratinization. **B:** Higher magnification shows the presence of cytologically malignant epithelial cells.

(c) 2014 Wolters Kluwer. All Rights Reserved.

more likely as a promoter in the multistep process of carcinogenesis in squamous cells of the UADT.[223–225]

VC appear as tan or white, warty, fungating or exophytic, firm to hard masses of varying size measuring up to 9 to 10 cm in diameter. In general, the tumors are attached by a broad base. The histologic appearance of VC is that of a benign-appearing squamous cell proliferation requiring the following characteristics for diagnosis: (a) uniform cells without dysplastic features or mitoses; (b) marked surface (ortho)keratinization ("church-spire" keratosis); (c) broad or bulbous rete pegs with a pushing but not an infiltrative margin (Fig. 1-17). A mixed chronic inflammatory cell infiltrate composed of lymphocytes, plasma cells, and histiocytes may be prominent along the adjacent stroma. The pathologic diagnosis of VC may be extremely difficult, requiring multiple biopsies over several years prior to identification of diagnostic features supporting appropriate interpretation. Both clinicians and pathologists should be aware of this fact. To this end, adequate biopsy material is critical to interpretation and should include a good epithelial–stromal interface. The pathologist should not over interpret a verrucoid lesion as a carcinoma without seeing the relationship of the more superficial aspects of the lesion to the underlying stroma.

## Spindle Cell Squamous Carcinoma

Spindle cell squamous carcinoma (SCSC) is defined as a tumor composed of conventional SCC (*in situ* or invasive carcinoma) associated with a malignant spindle cell stromal component. Synonyms have included "sarcomatoid" carcinoma, carcinosarcoma, pleomorphic carcinoma, metaplastic carcinoma, collision tumor, pseudosarcoma, and Lane tumor. The preferred terminology is spindle cell squamous carcinoma.

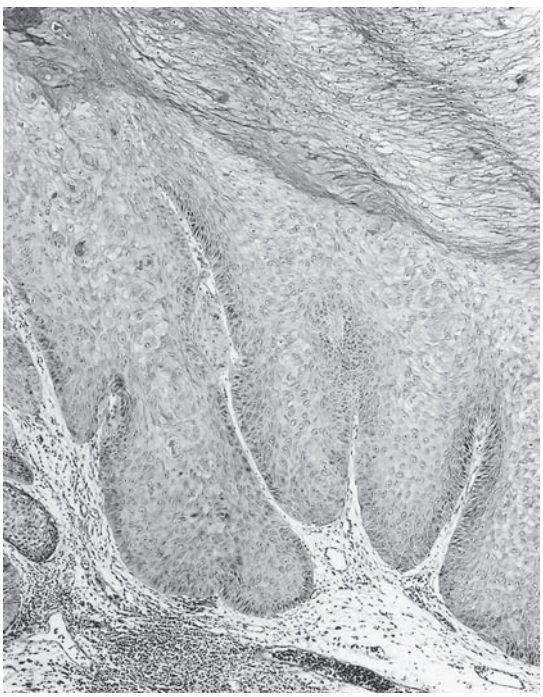

**FIGURE 1-17.** Verrucous carcinoma of the larynx characterized by an epithelial proliferation of uniform cells without dysplastic features or mitoses, marked surface keratinization, and broad or bulbous rete pegs pushing downward into the submucosa.

The overwhelming majority of SCSC occur in men (85%) most frequently in the sixth to eighth decades of life.[198] SCSC can occur anywhere in the UADT. The most common sites in descending order of occurrence include the larynx (true vocal cords > false vocal cords and supraglottis), the oral cavity (lips, tongue, gingiva, floor of mouth, buccal mucosa), the skin, the tonsil, and the pharynx. Symptoms vary according to site: larynx—hoarseness, voice changes, airway obstruction, dysphagia; oral cavity or skin—mass or nonhealing sore with or without pain; sinonasal tract and nasopharynx—airway obstruction, pain, epistaxis, discharge, facial deformity, unilateral otitis media, orbital symptoms. There is no specific correlation with known risk factors (alcohol, tobacco, or environment/occupation). SCSC has been reported in areas of prior irradiation.

SCSC is often a grossly polypoid or fungating mass commonly found in the larynx, the hypopharynx, the oral cavity, and the sinonasal tract. Variations in the gross appearance may correlate with the primary site of occurrence: larynx—polypoid or exophytic; sinonasal/nasopharynx—fungating and/or ulcerative. SCSC are firm, tan-white, gray or pink mass varying in size from 1 to 6 cm.

The histologic features that define SCSC include the identification of a malignant undifferentiated spindle cell proliferation and the presence of a conventional squamous cell component (Fig. 1-18). The latter includes either *in situ* squamous carcinoma or frankly invasive differentiated squamous carcinoma. The spindle cell component generally is the dominant cell type. The spindle cell proliferation is usually hypercellular and pleomorphic with large, hyperchromatic nuclei, prominent nucleoli, and many mitoses (typical and atypical). Necrosis is not uncommon. The spindle cell proliferation may be sparsely cellular (hypocellular) with marked stromal collagenization (so-called collagenized SCSC), but nuclear pleomorphism and mitotic figures are still present. The growth pattern varies and includes fascicular, storiform, or palisading; an associated myxomatous stroma may be present. Heterologous elements, including bone and cartilage, may be present and may even be malignant (chondrosarcomatous or osteosarcomatous foci).

The spindle cells are cytokeratin immunoreactive in the majority of cases,[227–231] but in up to 40% of cases may be cytokeratin negative.[229] Cytokeratin staining may vary from focal to diffuse. p63, a marker for squamous cells (as well as myoepithelial cells), may be a useful adjunct to cytokeratin staining in

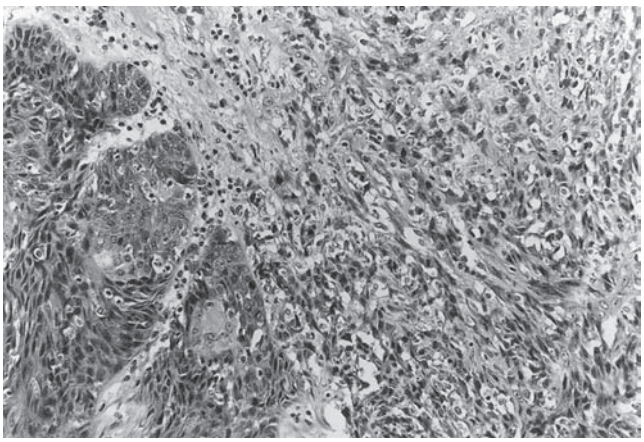

**FIGURE 1-18.** Laryngeal (glottic) spindle cell squamous cell carcinoma. The neoplastic infiltrate includes differentiated squamous cell carcinoma **(left)** intimately associated with a malignant spindle-shaped and pleomorphic cellular component.

(c) 2014 Wolters Kluwer. All Rights Reserved.

identifying the spindle cells as being of epithelial (ie, squamous cell) origin. Expression of vimentin and various myogenic markers (desmin, actins) have been reported.[229–232]

## Basaloid SCC

Basaloid squamous cell carcinoma (BSCC) is a high-grade variant of SCC with a predilection to the supraglottic larynx, the hypopharynx, the base of the tongue, and the palatine tonsil.[233,234] BSCC is histologically characterized by an invasive neoplasm composed of basaloid cells intimately associated with either a dysplastic squamous epithelium, *in situ* SCC, and/or invasive SCC.

BSCC occurs more commonly in men than in women and predominantly occurs in the sixth to seventh decades of life. These tumors have a predilection for the hypopharynx (pyriform sinus), the larynx (supraglottis), and the tongue. Symptoms depend on the site of occurrence and include hoarseness, dysphagia, pain, or a neck mass. Etiologic factors include excessive alcohol and/or tobacco use. The cell of origin has not definitively been identified, but in all probability is a single totipotential cell capable of divergent differentiation and located either in the basal cell layer of the surface epithelium or within seromucous glands. BSCC of nonoropharyngeal sites are typically not associated with human papillomavirus 16 (HPV16), but BSCC of the oropharynx (i.e., base of tongue and tonsil) are associated with HPV16 (see later).

Grossly, these tumors are described as firm to hard, tan-white mass often with associated central necrosis, measuring up to 6.0 cm in greatest dimension. Infrequently, they may be exophytic in appearance. Histologically, BSCC is often a deeply invasive neoplasm, although shallow biopsies may belie the depth and extent of invasion and may not be representative of the lesion leading to erroneous classification. BSCC is composed of basaloid cells with an associated squamous component and demonstrating a variety of growth patterns, including solid, lobular, cribriform, cords, trabeculae, and gland-like or cystic growth (Fig. 1-19). The basaloid cell component is the predominant cell type and consists of cells with pleomorphic, hyperchromatic nuclei, scanty cytoplasm, and increased mitotic activity (Fig. 1-19). Peripheral nuclear palisading may be present. Comedonecrosis is seen in the center of the neoplastic lobules. Intercellular deposition of a hyalin or mucohyalin material can be seen similar in appearance to the reduplicated basement membrane material that is seen in some salivary gland tumors. Infrequently, a spindle cell component may be identified and true neural-type rosettes may rarely be present.[235] The squamous component includes dysplastic squamous epithelium, foci of abrupt keratinization, *in situ* SCC, or invasive SCC. The squamous foci typically are a minor component (Fig. 1-19), may be focally present, and may be absent in biopsies. Continuity with the surface epithelium may be seen.

Immunoreactivity is consistently present with epithelial markers, including cytokeratins (AE1/3, 34$\beta$E12, CAM5.2), EMA, and

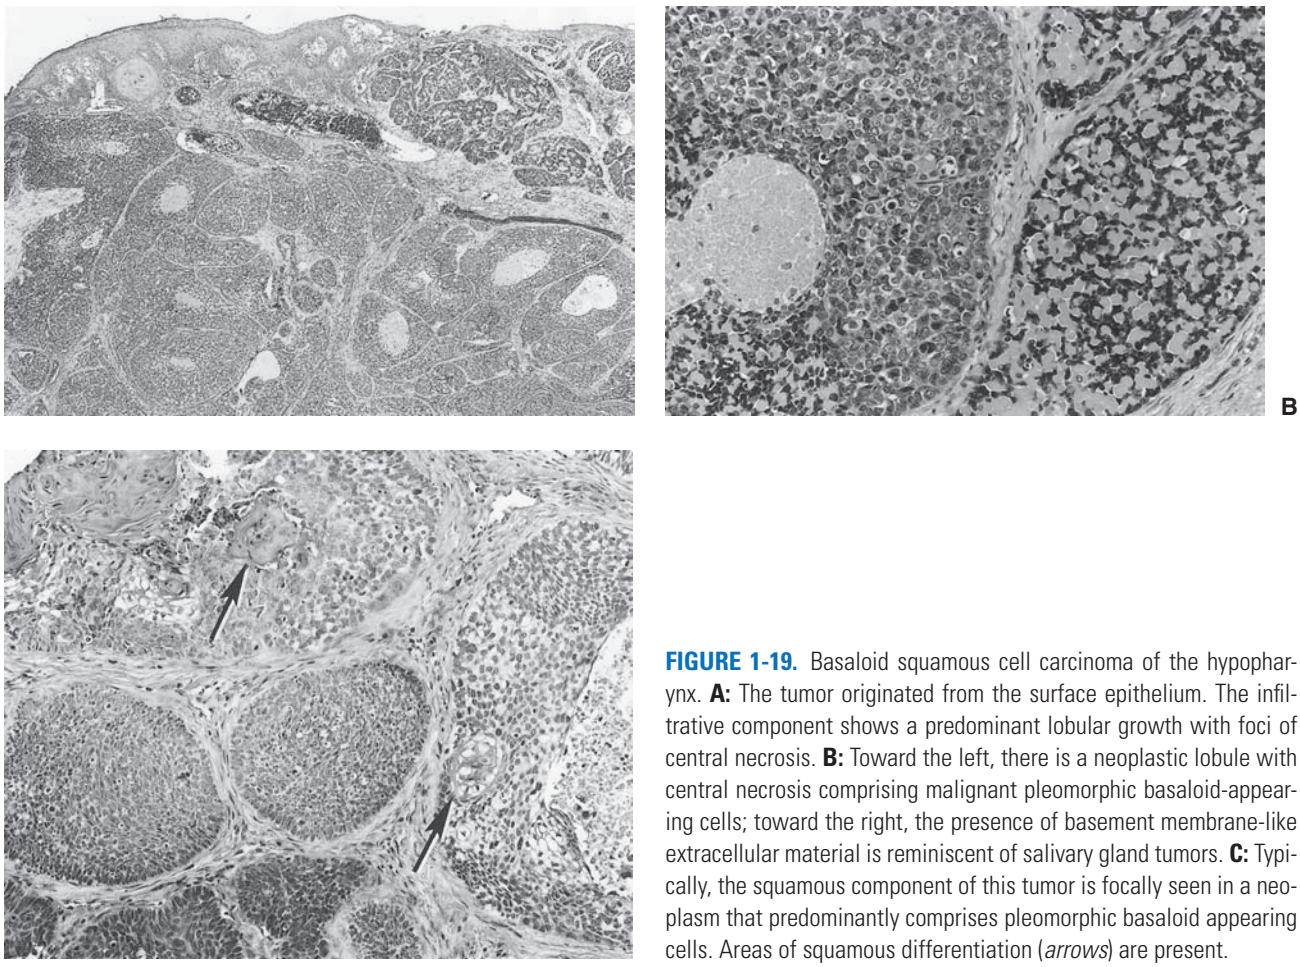

**FIGURE 1-19.** Basaloid squamous cell carcinoma of the hypopharynx. **A:** The tumor originated from the surface epithelium. The infiltrative component shows a predominant lobular growth with foci of central necrosis. **B:** Toward the left, there is a neoplastic lobule with central necrosis comprising malignant pleomorphic basaloid-appearing cells; toward the right, the presence of basement membrane-like extracellular material is reminiscent of salivary gland tumors. **C:** Typically, the squamous component of this tumor is focally seen in a neoplasm that predominantly comprises pleomorphic basaloid appearing cells. Areas of squamous differentiation (*arrows*) are present.

(c) 2014 Wolters Kluwer. All Rights Reserved.

CEA. Neuroendocrine markers (i.e., chromogranin and synaptophysin) are typically negative, but may rarely be present.[236]

## Sinonasal Undifferentiated Carcinoma

The original definition for SNUC was reported by Frierson et al.[237] as a high-grade malignant epithelial neoplasm of the nasal cavity and paranasal sinuses of uncertain histogenesis with or without neuroendocrine differentiation but without evidence of squamous or glandular differentiation. Subsequently, the WHO classification defines SNUC as a highly aggressive and clinicopathologically distinctive carcinoma of uncertain histogenesis that typically presents with locally extensive disease; it is composed of pleomorphic tumor cells with frequent necrosis and should be differentiated from lymphoepithelial (and other) carcinomas or olfactory neuroblastoma.[238]

There is a male predominance (2-3:1).[238,239] SNUCs occur over a wide age range, from the third to the ninth decades of life, with a median at presentation in the sixth decade.[237,239] Generally, SNUC are extensive at presentation and involve multiple sites, including the nasal cavity, one or more paranasal sinuses, the orbit, the skull base, and the brain.[237,240] Most patients have unilateral disease, but bilateral disease may occur. Typically, patients present with multiple symptoms that include nasal obstruction, epistaxis, proptosis, visual disturbances (e.g., diplopia), facial pain, and symptoms of cranial nerve involvement. A rather characteristic clinical phenomenon is that patients with SNUC develop symptoms usually of relatively short duration (weeks to months). Radiographic studies (CT scan, MRI) often demonstrate a large (sinonasal) mass typically with local invasive growth extending beyond its bony confines with involvement of orbital and/or cranial bones.[239] Intracranial extension may occur.

SNUC is a tumor of uncertain histogenesis. It seems likely that SNUC arises from the Schneiderian epithelium and, therefore, is of ectodermal derivation. However, although speculative, given overlapping clinical, light microscopic, immunohistochemical, and ultrastructural features with olfactory neuroblastoma and neuroendocrine carcinoma, the cell of origin may be related to both the Schneiderian membrane and the olfactory epithelia. On the basis of finding neuroendocrine features by immunohistochemistry and electron microscopy, Mills[241] suggested that SNUC may be a neuroendocrine carcinoma with classification essentially equivalent to the pulmonary large cell (neuroendocrine) carcinoma.

There are no known etiologic agents. SNUCs are typically negative for Epstein-Barr virus (EBV)[242,243] even though there are reports of EBV RNA identified in Asian and Italian patients with SNUC, but not in other Western patients with SNUC.[244,245] p16 immunoreactivity has been reported in SNUCs, suggesting a possible link to HPV, but in these cases HPV DNA was not detected.[246] Although no specific etiology is linked to the development of SNUC, cigarette smoking and nickel exposure have been identified in patients with SNUC.[247] Deletion of the retinoblastoma gene has been implicated in the development of SNUC.[247]

SNUCs are usually large tumors typically measuring >4 cm in greatest dimension and tend to be fungating with poorly defined margins and with invasion into adjacent structures and/or anatomic compartments, including bone destruction. The histologic appearance is characterized by a hypercellular proliferation with varied growth, including trabecular, sheet-like, ribbons, solid, lobular, and organoid patterns (Fig. 1-20). Surface involvement may be seen in the form of severe dysplasia/CIS, but often there is ulceration, which precludes evidence of surface epithelial derivation. The cellular infiltrate consists of polygonal cells composed of medium- to large-sized, round to oval, hyperchromatic to vesicular nuclei, inconspicuous to prominent nucleoli, and a varying amount of eosinophilic appearing cytoplasm with poorly defined cell membranes, although in some examples distinct cell borders may be present; occasionally, cells with clear cytoplasm can be identified. The nuclear-to-cytoplasmic ratio is high. Increased mitotic activity is present, including atypical mitoses, and there is often prominent tumor necrosis (confluent areas and individual cells) and apoptosis (Fig. 1-20). Lymph-vascular

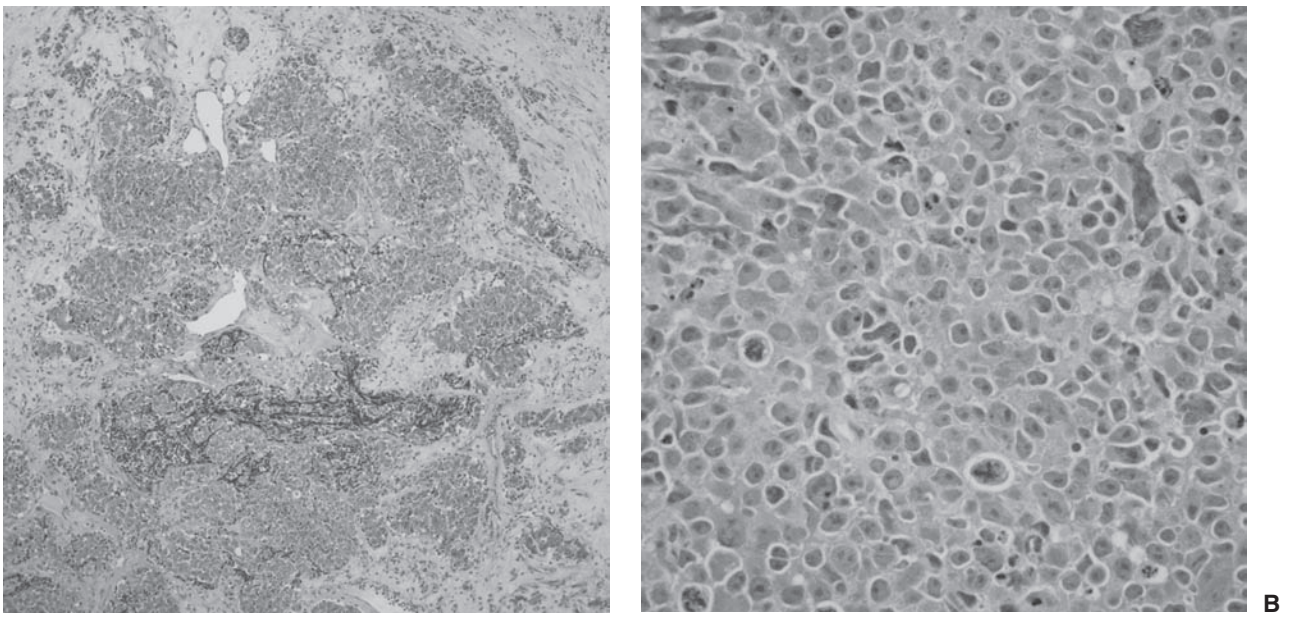

**FIGURE 1-20.** Sinonasal undifferentiated carcinoma. **A:** Hypercellular and infiltrative neoplasm showing trabecular and lobular growth. **B:** At higher magnification, the cellular infiltrate includes pleomorphic round to oval, hyperchromatic and pleomorphic nuclei, prominent nucleoli, increased mitotic activity, and individual cell necrosis. These tumors lack any evidence of cellular differentiation by light microscopy and are consistently immunoreactive (diffusely and intensely reactive) with cytokeratin (not shown).

invasion and neurotropism are often present. Squamous or glandular differentiation is not present. Neurofibrillary material and true neural rosettes are not identified.

The immunohistochemical antigenic profile may vary from case to case, but SNUCs are consistently immunoreactive with epithelial markers, including pankeratins and simple keratins. Variable reactivity can be identified for p63.

## Viral-Related HNSCC

There is increasing evidence that HPV and EBV play a pathogenic role in a subset of head and neck squamous cell carcinomas (HNSCC). HPV, in particular the high-risk type 16 (HPV-16), is present in most oropharyngeal carcinomas (i.e., base of tongue, tonsils), and for those oropharyngeal cancers positive for high-risk HPV, HPV16 is detected in greater than 90% of cases.[248,249]

For NPCs, EBV is associated with the nonkeratinizing types of NPCs, including both differentiated and undifferentiated subtypes in practically 100% of cases irrespective of the ethnic background of the patient. The most reliable detection method for EBV is ISH for EBV-encoded early RNA (EBER) present in cells latently infected by EBV and can facilitate the diagnosis of NPC.

The viral-related HNSCCs may be termed HPV–head and neck squamous cell carcinoma (HPV-HNSCC) and EBV-associated head and neck squamous cell carcinoma (EBV-HNSCC). Such designations are not as yet universally accepted, but have merit given their unique clinical, pathologic, therapeutic, and prognostic implications associated with these cancers.

## Oropharyngeal Nonkeratinizing SCC (HPV-associated SCC)

Approximately 20% to 25% of SCCs of the UADT are related to HPV infection, and the incidence of HPV-associated HNSCC is rising.[248] In contrast, the incidence of HPV-unrelated HNSCC has stabilized or is decreasing with the decreasing use of tobacco products. The majority of HPV-associated SCC of the UADT occur in the oropharynx predominantly arising at the base of the tongue or palatine tonsil.[250] The propensity for HPV to infect the base of tongue and the tonsil might be due to greater accessibility of the virus to the basal and proliferating squamous cells in these locations possibly secondary to epithelial disruption.[251]

HPV-associated oropharyngeal SCC represents a unique subtype of HNSCC frequently occurring in patients with no known risk factors for HNSCC (i.e., nonsmokers and nondrinkers), in younger aged patients, and associated with a better outcome (better overall and disease-specific survival) than non-HPV-associated HNSCCs (Table 1.14). Further, these carcinomas are highly curable even in the presence of advanced disease. Symptoms associated with HPV-associated oropharyngeal SCC often relate to a mass. However, these cancers may be small and clinically/radiographically difficult to detect. Further, HPV-associated oropharyngeal SCC frequently develop early neck metastasis and may present as metastatic cancer to a cervical neck lymph node from an unknown primary site. PET/CT scan plays an important role in the imaging evaluation of these cancers, in particular in trying to localize/identify the primary oropharyngeal carcinoma.

The HPV-associated HNSCC are nonkeratinizing carcinomas characterized by basaloid cell morphology (Fig. 1-21). The carcinoma often grows in solid sheets, trabecula, cords, and nests, but individual infiltrative cells can be seen. These carcinomas are often cystic with central areas of necrosis and frequently metastasize as cystic metastatic carcinomas (Fig. 1-21). In the absence of a known primary carcinoma, such cystic neck masses may be considered branchial cleft cysts with malignant transformation, a diagnosis of questionable existence. The neoplastic cells include marked nuclear pleomorphism with increased mitotic activity, including atypical mitoses. Focal keratinization may present. Typically, the extent of keratinization is limited but in some cases more extensive keratinization may be present. Given their basaloid morphology including features of a histologic higher grade carcinoma, such carcinomas (whether on FNA or biopsy) have been erroneously designated as poorly differentiated. In fact, these nonkeratinizing carcinomas are considered better differentiated carcinomas recapitulating the crypt epithelium from which they may arise. It should be noted that the initial designation of these cancers as "basaloid"[253] may result in confusion with basaloid SCC, which is a high-grade variant of conventional SCC predilecting to the hypopharynx (i.e., piriform sinus) and the supraglottic larynx not associated with HPV (or EBV). The oropharyngeal nonkeratinizing carcinomas are often associated with a dense benign lymphocytic cell infiltrate. These cancers

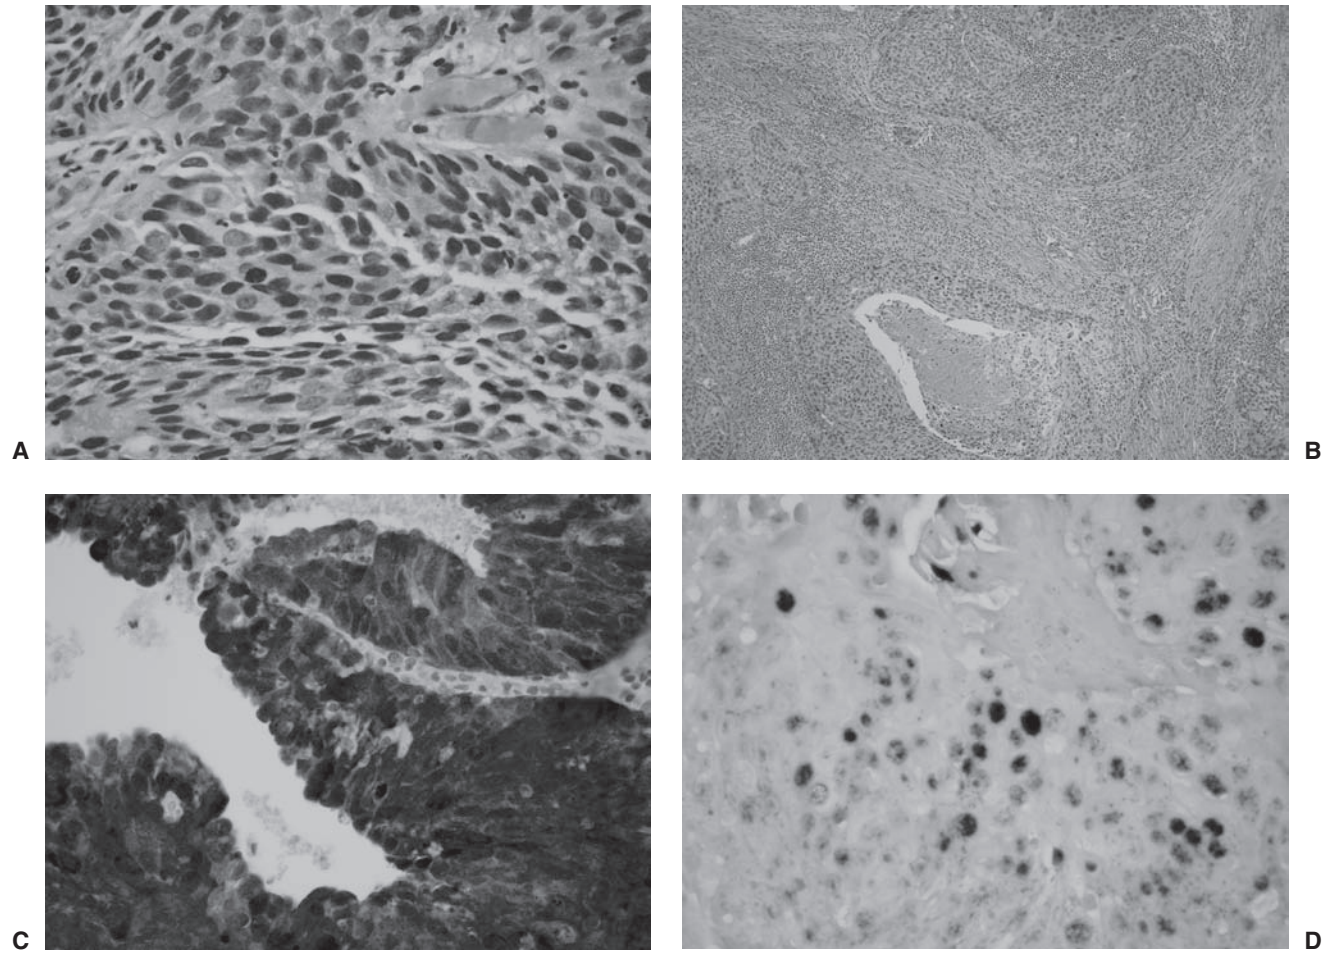

**FIGURE 1-21.** HPV-associated SCCs are predominantly/exclusively nonkeratinizing carcinomas characterized by: **A:** basaloid cell morphology; **B:** solid and solid growth central areas of necrosis; **C:** p16 immunoreactivity (nuclear and cytoplasmic); and **D:** HPV *in situ* hybridization.

may invade without associated desmoplasia and, as such, the neoplastic cells may be obscured by the associated lymphocytic cell infiltrate. Oropharyngeal HPV-associated SCCs may include papillary growth. Alternatively, these carcinomas may show growth patterns and cytomorphologic characteristics similar to nasopharyngeal nonkeratinizing carcinoma undifferentiated type carcinoma including syncytial growth and cells with enlarged vesicular nuclei and prominent nucleoli.[255] Although this morphology overlaps with the EBV-associated NPCs, this subset of oropharyngeal carcinomas are associated with HPV rather than EBV.[255]

The neoplastic cells of oropharyngeal nonkeratinizing carcinomas are immunoreactive for cytokeratins, including AE1/AE3, CAM5.2, and CK5/6. Such cytokeratin immunoreactivity may be extremely helpful in identifying the malignant cells in the presence of obscuring benign lymphoid infiltrate. Oropharyngeal nonkeratinizing carcinomas are positive for HPV16 and the presence of HPV16 represents a reliable predictor of origin from the oropharynx.[256] At present, there is no standard assay for HPV detection. Detection methods include immunohistochemical staining of surrogate biomarkers (i.e., p16 protein) (Fig. 1-21), DNA ISH (Fig. 1-21), and PCR-based (consensus and type-specific; real-time assays to quantify viral load). The presence of p16 immunostaining correlates with the presence of HPV16. The reactivity pattern for p16 includes nuclear and cytoplasmic staining and is usually diffuse and strongly reactive. P16 IHC can be performed on aspiration material and on tissue sampling.[256,257] In a comparison of detection methods, Singhi and Westra found that in comparison to PCR-based methods, ISH is more practical and they recommended combined IHC and ISH testing.[258] Using the combined strengths of HPV ISH and p16 IHC, these authors reported that (a) given the sensitivity approaching 100%, negative p16 staining serves to identify HPV-16 negative cases that would not benefit from additional analysis; (b) given specificity approaching 100%, positive HPV-16 ISH reduces number of false-positive cases by p16 staining alone; (c) p16+/HPV-16 singles out a subset of tumors requiring more rigorous analysis for other HPV types (consensus hybridization probe) and detects extended panel of HPV types. Using a combined approach including IHC and ISH, Singhi and Westra found HPV detected in a remarkably high percentage of oropharyngeal SCC (82%), which was greater than reported prevalence ranging from 19% to 72%.[258]

Guidelines for p16 and/or HPV testing in head and neck carcinomas may include the following:

- In an oropharyngeal biopsy showing atypical basaloid cells, the presence of p16 confirms the diagnosis of HPV-associated HNSCC;

**TABLE 1.15 World Health Organization (WHO) Classification of Nasopharyngeal Carcinoma**

| |
|---|
| WHO Type I |
| Keratinizing squamous cell carcinoma |
| WHO Type II |
| Nonkeratinizing differentiated |
| Nonkeratinizing undifferentiated |
| Basaloid squamous cell carcinoma |

- In tumors with overlapping morphology (e.g., basaloid SCC), the presence of p16 helps confirm the diagnosis of HPV-associated HNSCC;
- In the presence of cervical nodal metastatic disease p16 staining would confirm the diagnosis of metastatic cystic SCC, localize the primary site of origin (i.e., oropharynx), and establish the tumor classification.

HPV-associated HNSCC have unique therapeutic and prognostic parameters. HPV-HNSCC are radioresponsive tumors associated with a better outcome (better overall and disease-specific survival) and are highly curable even in the presence of advanced disease.[259,260] Factors that may be in play relative to their better outcome include the possibility of absence of field cancerization and presence of enhanced radiation sensitivity.

## Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is a SCC arising from the surface epithelium and subtyped according to the World Health Organization (WHO) into two histologic variants: keratinizing and nonkeratinizing (Tables 1.15 and 1.16).[261] The nonkeratinizing type is further subdivided as being "differentiated" and "undifferentiated." The current WHO classification retains the terminology of the 1991 classification and adds the category of basaloid SCC to this classification.[262] NPC, by definition, takes origin from the nasopharyngeal mucosa and shows evidence of squamous differentiation by light microscopy, immunohistochemistry, or electron microscopy. Therefore, the use of this term is to the exclusion of all other malignant tumors that may arise in this region, including adenocarcinomas (minor salivary gland origin and nonsalivary gland origin). Synonyms for NPC include lymphoepithelioma, Rigaud and Schmincke types of lymphoepithelioma, and transitional carcinoma. The designation *lymphoepithelioma* is a misnomer. This is a tumor entirely of epithelial origin with a secondary associated benign lymphoid component. Use of the term lymphoepithelioma may result in confusion with a diagnosis of malignant lymphoma. The prior numerical designations of WHO types 1 (SCC), 2 (nonkeratinizing carcinoma), and 3 (undifferentiated carcinoma) are no longer used. It should be noted that, although they share the unfortunate designation of "undifferentiated," there is no relationship between the sinonasal undifferentiated carcinoma (see subsequent text) and the nasopharyngeal undifferentiated carcinoma. These tumors are anatomically distinct with differing therapeutic approaches and biologic outcome. The terms should not be used synonymously, nor should the tumors be confused clinically and pathologically. Basaloid SCC also occurs in the nasopharynx, representing another histologic subtype of NPC.[262]

Overall, NPC is an uncommon neoplasm in the United States, accounting for approximately 0.25% of all cancers.[263,264] In China, it accounts for 18% of all cancers,[265] and 1 in 40 men develop NPC before the age of 72.[266] NPC affects men more than women and occurs over a wide age range, but is most common in the fourth to sixth decades of life. Less than 20% of cases occur in pediatric age groups. Pediatric NPC is most common in northern and central Africa, accounting for 10% to 20% of all cases, whereas only approximately 2% of NPC in China occur in children.[267–270] Irrespective of the histologic type, the clinical presentation is similar and includes the presence of an asymptomatic cervical neck mass typically localized to the posterior cervical triangle or the superior jugular nodal chain, with additional clinical signs and symptoms that include nasal obstruction, nasal

**TABLE 1.16 Nasopharyngeal Carcinoma**

| | Keratinizing Squamous Cell Carcinoma | Nonkeratinizing, Differentiated Type | Nonkeratinizing, Undifferentiated Type |
|---|---|---|---|

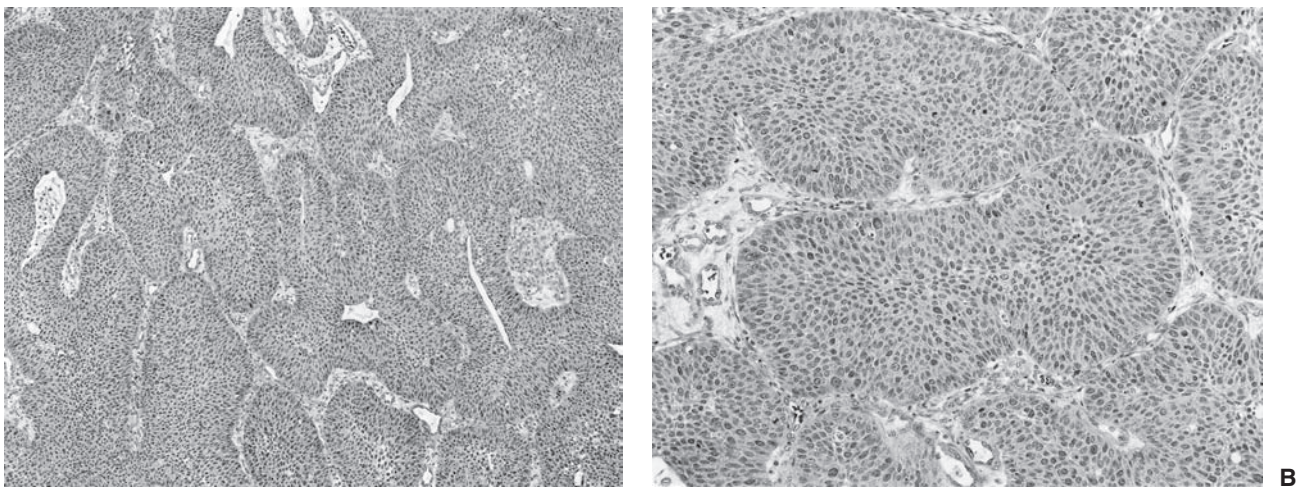
discharge, epistaxis, pain, serous otitis media, otalgia, hearing loss, and headache.[271] The signs and symptoms are often subtle and nonspecific, and thereby may cause a delay in the diagnosis, often resulting in clinical presentation at an advanced stage of disease. Up to 25% of patients may experience cranial nerve involvement.[272] The lateral wall of the nasopharynx (fossa of Rosenmüller) is the most common site of occurrence followed by the superior posterior wall.[270]

Multiple interactive etiologic factors have been linked to the development of NPC. Genetic and geographic factors play an important role in the genesis of NPC. There is an increased incidence of NPC in China, especially in southern (Kwantung province) and northern provinces and Taiwan.[265] Although the incidence among Chinese people decreases after emigration to low-incidence areas, it still remains higher than in non-Chinese populations.[265,273]



Perhaps the most important link to the development of NPC is the EBV.[265,274,275] There is a strong association between certain NPCs and the presence of EBV, indicating a probable oncogenic role of EBV in the development of NPC.[275] Both the nonkeratinizing and undifferentiated types of nasopharyngeal squamous carcinoma are linked with the presence of EBV DNA. Molecular biologic analysis of NPC by either ISH for EBER or PCR detects EBV DNA or RNA in 75% to 100% of NPC.[276,277] This is not true of the keratinizing subtype, in which the detection of EBV genomes is variable and, if present, is generally limited to scattered dysplastic intraepithelial cells.

Three histologic types are recognized based on the predominant appearance.[278] The keratinizing conventional squamous carcinoma is characterized by the presence of keratinization and intercellular bridges and graded as well, moderately, or poorly differentiated. A desmoplastic response is typically found in response to invasive growth by this histologic type of NPC. The keratinizing NPC represents approximately 25% of all NPC and rarely occurs in patients below 40 years of age.[279]

The nonkeratinizing carcinomas show little to no keratinization and have a growth pattern similar to transitional cell carcinoma of the bladder, including stratified cells with sharp delineation from the surrounding stroma (Fig. 1-22). Well-defined cell borders and vague intercellular bridges may be present; rarely, an occasional keratinized cell may be identified. Typically, there is an absence of a desmoplastic response to invasive growth. These tumors may undergo cyst formation with associated necrosis and may metastasize as such to the cervical neck region. Further, the primary carcinomatous focus may be small and lie within the submucosa (e.g., in crypt epithelium) with an overlying intact, nondescript surface epithelium representing an occult primary carcinoma. This type of NPC is the least common, representing approximately 12% of all NPC.[279]

The undifferentiated type of NPC represents approximately 60% of all NPC[279] and is the most frequent tumor type seen in pediatric age groups.[268] The neoplastic cells are characterized by the presence of round nuclei, prominent eosinophilic nucleoli, dispersed nuclear chromatin, and scant eosinophilic to amphophilic cytoplasm (Fig. 1-23). Keratinization is absent. Increased mitoses, including atypical forms, are present. A prominent nonneoplastic lymphoid component composed of mature lymphocytes and plasma cells is seen in association with the malignant epithelial cellular infiltrate, although in any given example there may be a relative absence of an associated lymphoplasmacytic cell infiltrate. This tumor type may have a syncytial growth with cohesive or nested cells or has a diffuse cellular infiltrate composed of noncohesive cells. The diffuse pattern is the one that is difficult to differentiate from a malignant lymphoma by light microscopy (Fig. 1-23). The Regaud and Schmincke types of NPC refer to those neoplasms with a syncytial versus individual cell growth pattern, respectively. These designations and their correlated growth have no bearing on the biology of the disease. The infiltrative growth of this tumor generally does not produce a host desmoplastic response. This may be problematic in biopsy samples as the tumor may be overrun by the benign lymphohistiocytic cell infiltrate and thus is easily overlooked. Similarly, metastasis to cervical lymph nodes may not elicit a desmoplastic response in the involved lymph node.

Since the distinction between the nonkeratizing differentiated and the nonkeratinizing undifferentiated is of no clinical or prognostic significance, subclassification into differentiated and undifferentiated subtypes is optional.[262] Shanmugaratnam et al.[280] reported that in their study, 26% of the NPC had features of more than one tumor type. In such a situation, classification is according to the dominant component. It should be noted that the histologic distinction among the three types of NPC may not always be clear, with overlapping histology in any given tumor.

**A** **B**

E

**FIGURE 1-23.** *Continued*

All three histologic types of NPC are immunoreactive with cytokeratin, including pan-cytokeratins and high-molecular-weight cytokeratins; weak immunoreactivity is present for low-molecular-weight cytokeratins (Fig. 1-23). The nonkeratinizing carcinomas, differentiated and undifferentiated, are highly associated with EBV as detected by ISH for EBER (Fig. 1-23).

## Metastatic Cervical Carcinoma to the Neck with an Unknown Primary

MCCUP is the histologic diagnosis of metastatic carcinoma without a diagnosis of a primary tumor.[281] Aside from oropharynx and nasopharynx, metastatic SCC to neck lymph nodes may originate from any mucosal site in head and neck. MCCUP is most frequently diagnosed between the fifth and seventh decades with a peak incidence in the sixth decade of life.[282] However, HPV-associated MCCUP occurs in younger patients than does non-HPV-associated SCC. MCCUP can present anywhere within the neck, but the jugulodigastric lymph node group is the most common location. Specifically, level II is most commonly followed by levels I and III.[282] An isolated nodal mass in the submental triangle is rarely carcinoma. Patients typically present with a painless neck mass that has enlarged over recent months. The mass is often fixed and usually present for <6 months in duration. MCCUP may be bilateral enlargement in 10% of patients.

Once a metastasis is diagnosed, the primary carcinoma can be sought and the workup attempting to find the primary carcinoma. Approximately 30% of patients never have the primary carcinoma identified.[282] About 30% of patients with metastatic SCC show exclusively cystic metastases. It should be noted that a primary carcinoma in the tonsil or the base of the tongue may be very small (<0.1 cm), making detection difficult. Further, there is no correlation with the size of the primary carcinoma, which may be very small (1–2 mm), and the metastasis, which may be large (>1 cm).

The histologic features for metastatic keratinizing SCC include the presence of keratinization in the majority of carcinoma. The histologic grades include well, moderately, and poorly differentiated. In poorly differentiated SCC, evidence of keratinization may be minimal. This type of carcinoma is typically associated with desmoplastic tissue response. The pattern of carcinoma and presence of desmoplasia contrast with features seen in nonkeratinizing and undifferentiated SCC.

Metastatic nonkeratinizing SCC often appears as cystic metastasis with central necrotic material (Fig. 1-24). The carcinoma shows ribbon-like or band-like, uniformly thick epithelium lining cystic spaces, frequently thrown into papillary folds or projections. An endophytic pattern can be seen with budding into lymphoid stroma. There is an absence of maturation toward the cyst lumen with a loss of cellular polarity, disorganization, and enlarged cells showing a high nuclear to cytoplasmic ratio. Significant nuclear pleomorphism focally or diffusely can be found. Limited keratinization may be present, and the presence of keratinization does not exclude a diagnosis of nonkeratinizing SCC. Transitional-like epithelium with limited atypia may be present, showing remarkably bland-appearing epithelium. Such benign-appearing epithelium suggests a possible diagnosis of a branchial cleft cyst.

Metastatic undifferentiated carcinoma may appear as cystic metastasis with central necrotic material. Syncytial growth in the form of cohesive nests can be identified. The neoplastic cells are characterized by enlarged nuclei with vesicular chromatin and prominent nucleoli. Limited keratinization may be present, and the presence of keratinization does not exclude diagnosis of undifferentiated carcinoma. A desmoplastic response may be absent, and the neoplastic cells may be overrun and obscured by benign lymphocytes.

The immunohistochemical staining of these carcinomas include consistent positive reactivity for cytokeratins as well as p63 (nuclear) staining. HPV-associated SCCs are p16 positive (nuclear and cytoplasmic staining) (Fig. 1-24). P16 immunoreactivity represents a reliable predictor of origin from the oropharynx (i.e., tonsil, base of tongue). P16 immunostaining can be performed on cytologic and/or surgical resection material.[256,257] Oropharyngeal carcinomas with morphology of nasopharyngeal-type undifferentiated carcinoma may be p16-positive and EBER negative.[255] Such carcinomas may metastasize as MCCUP so workup should include both p16 and EBER staining. EBV-associated SCC are EBER-positive (nuclear staining) and p16 negative.

Controversy exists between the diagnosis of metastatic cystic SCC versus a carcinoma arising in a branchial cleft cyst (branchiogenic carcinoma). Martin et al.[283] established the criteria for the diagnosis of a branchiogenic carcinoma, including the following: (a) the metastatic tumor occurs along the line extending from a point anterior to the tragus along the anterior border of the sternocleidomastoid muscle to the clavicle; (b) the histology supports origin from a branchial cleft-derived structure; (c) the histology supports carcinoma arising in the wall of an epithelium-lined cyst; (d) a minimum of 5-year follow-up demonstrates no evidence of a primary source for this neoplasm. Despite the fulfillment of these criteria, it is highly unlikely that carcinoma arises in a branchial cleft cyst.[284–286] Rather, all these cystic nodal lesions represent metastatic SCC most often originating from a primary tumor in the oropharynx (i.e., Waldeyer tonsillar ring).[286] The primary oropharyngeal carcinoma may be so small as to defy clinical detection, but nevertheless is capable of metastasizing. It should be noted that unlike oropharyngeal carcinomas, branchial cleft cysts have been p16 negative in a limited number of cases evaluated to date.[287] The histology of branchial cleft cysts includes the presence of benign epithelium lining cystic spaces, usually showing intimate admixture of epithelium with stroma. Maturation is noted without atypia or mitotic figures. Branchial cleft cysts lack associated desmoplasia or thickened fibrous capsule and are typically p16 and EBER negative.[250,287] The existence of primary branchiogenic carcinoma has sufficiently been challenged as to render it nonexistent.

# SALIVARY GLAND MALIGNANT NEOPLASMS

The classification of malignant salivary gland tumors is listed in Table 1.10. A discussion of the full spectrum of malignant salivary gland tumors is beyond the scope of this chapter. A select group of malignant salivary gland tumors will be discussed.

(c) 2014 Wolters Kluwer. All Rights Reserved.

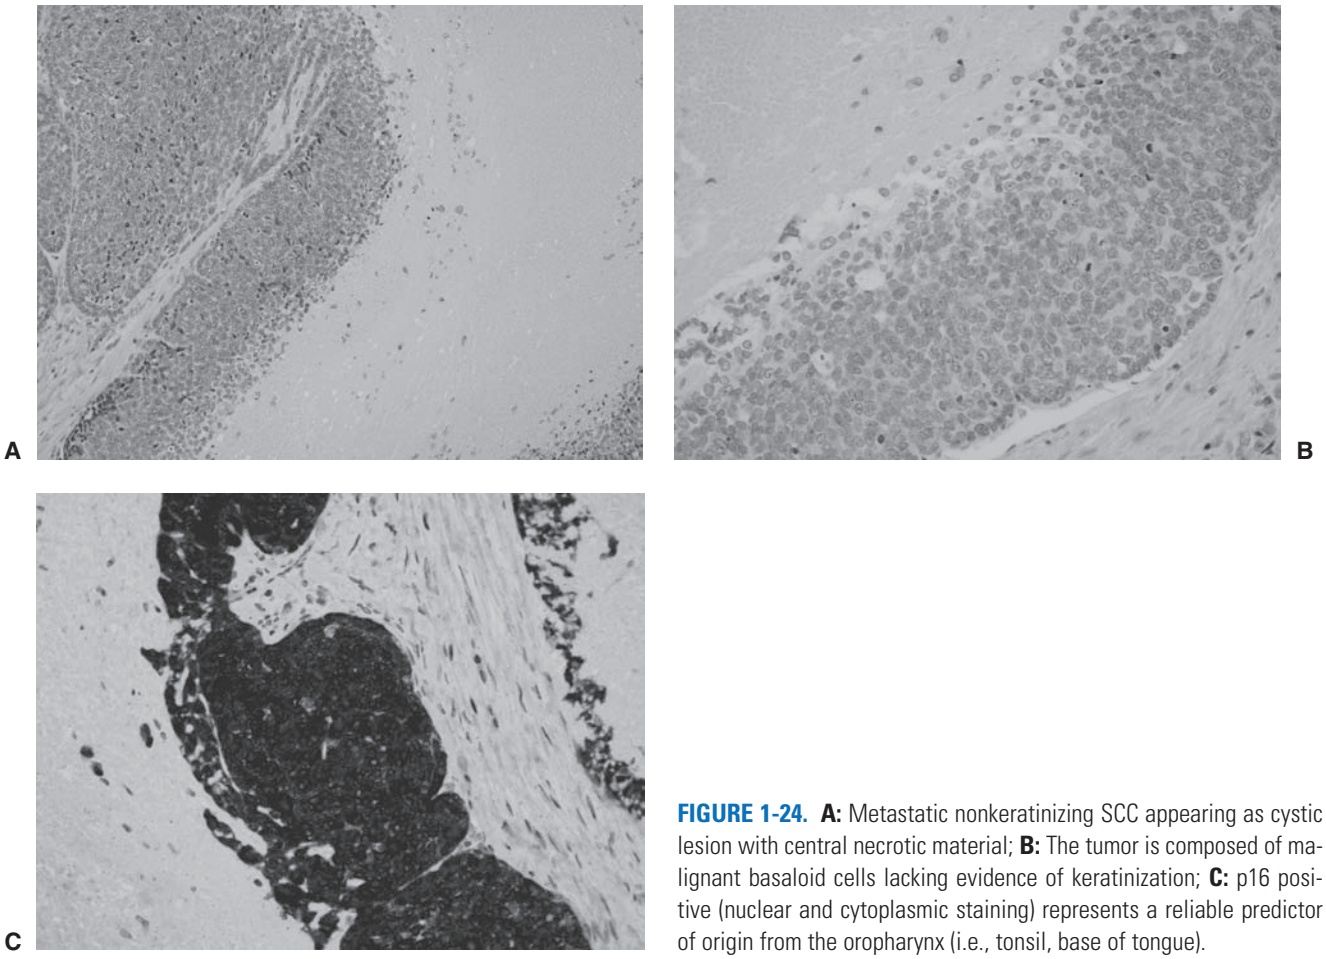

**FIGURE 1-24.** **A:** Metastatic nonkeratinizing SCC appearing as cystic lesion with central necrotic material; **B:** The tumor is composed of malignant basaloid cells lacking evidence of keratinization; **C:** p16 positive (nuclear and cytoplasmic staining) represents a reliable predictor of origin from the oropharynx (i.e., tonsil, base of tongue).

## Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC) is a malignant epithelial salivary gland neoplasm composed of a variable admixture of epidermoid, mucous, and other types of cells, including intermediate, columnar, and clear cells. MEC is the most common malignant salivary gland tumor and is second to pleomorphic adenoma as the most frequently occurring neoplasm among all salivary gland tumors. MEC represents approximately 30% of all malignant salivary gland tumors of both major and minor salivary glands and approximately 10% to 15% of all salivary gland neoplasms.[288,289] In the pediatric age group, MEC represents the most common malignant salivary gland neoplasm. MEC occurs in both the major and the minor salivary glands. Among the major glands, MEC is most common in the parotid gland; the most common minor salivary gland involvement occurs in the palate. MEC are uncommon primary tumors of the sinonasal tract and nasopharynx.

Grossly, MEC are unencapsulated or incompletely encapsulated, round to oval, predominantly solid, tan-white to pink mass measuring from <1 up to 12 cm in greatest dimension. Cysts of variable size and prominence can be seen on sectioning of the tumor. The basis for histologic grading of MEC into low, intermediate, and high categories is dependent on the architectural growth pattern, the cellular components, and the cytomorphology in a given tumor (see below). The characteristic histologic features for all grades of MEC include the presence mucous cells, epidermoid cells, and intermediate cells. The mucous cells are identified lining cystic spaces or admixed within nests or solid areas with epidermoid cells, and are large or balloon-shaped with distinct cell borders composed of pale-staining or foamy appearing cytoplasm with peripherally placed, small, dark-staining nuclei. The epidermoid cells form nests and/or solid areas in conjunction with the mucous cells, have a pavement-like arrangement, and are polygonal-shaped with vesicular nuclei and abundant eosinophilic cytoplasm. Individual cell keratinization may be seen; however, keratin (squamous) pearls, extensive keratinization, and intercellular bridges do not predominate. The absence of keratin (squamous) pearls, extensive keratinization, and intercellular bridges assists in separating MEC from such tumors as adenosquamous carcinoma. Extracellular mucous pools or "cysts" may be seen, which may infiltrate adjacent salivary gland and/or connective tissue. The intermediate cells are round to oval, contain small, dark-staining nuclei, and have scanty, eosinophilic cytoplasm. Cellular pleomorphism, mitoses, necrosis, and hemorrhage are generally absent. A variable degree of local invasion may be seen; however, NI is not normally a component of the low-grade MEC. Clear cells composed of round to oval cells with distinct cell borders, peripherally placed, small, dark nuclei and their hallmark clear cytoplasm may be seen and infrequently may predominate.

The microscopic grading of MEC remains a debatable subject. Suggested criteria for the histologic grading of MEC have included (single or in combination) the proportion of the tumor

(c) 2014 Wolters Kluwer. All Rights Reserved.

composed of cystic spaces relative to solid growth, proportion of cell types, degree of maturation of cell types, mitotic rate, extent of invasiveness, including pattern of invasion, neurotropism and vascular space invasion, and the presence of necrosis.[290]

Brandwein et al.[291] devised an alternative grading scheme that included an intracystic component less than 25%, tumor front invades in small nests and islands, pronounced nuclear atypia, lymph-vascular invasion, bony invasion, 4 or more mitoses, perineural invasion, and necrosis assigning numerical values for each feature. In a retrospective study, Auclair et al.[290] analyzed the grading criteria for 143 minor salivary gland MEC. These authors found that the most useful features for histologic grading, particularly in predicting high-grade tumors, were an intracystic component of <20% (predominantly solid growth), 4 or more mitotic figures per 10 high-power fields, cellular anaplasia, necrosis, and NI.[290] The low-grade tumors had numerous cystic spaces formed by a variety of cell types with rare mitoses and bland cytomorphology. The intermediate grade tumors had cellular anaplasia, with either cystic spaces comprising <20% of the tumor or NI.[290] The percentage of cell types did not correlate with behavior. Auclair et al.[290] suggested a quantitative grading system based on the specific histologic features such that tumors with a total point score of 0 to 4 were considered low grade, 5 to 6 were intermediate grade, and 7 or more were high grade. The results of their published study as well as an ongoing study of major salivary glands[289] show that microscopic grade was influential in prognosis. Combining the results of their research, Ellis and Auclair[289] report that of 305 patients with low-grade MEC of major and minor salivary gland, 10 (3.3%) died of disease; of 31 patients with intermediate-grade MEC, 3 (9.7%) died of tumor; and of 41 patients with high-grade MEC, 9 (46.4%) died of tumor. It is noteworthy that the grade of MEC in the submandibular gland is not felt to be as reliable a predictor of behavior as compared to other salivary gland sites[292]; Ellis and Auclair[289] report that metastatic disease or patient death occurred in 6 of 23 patients (26%) with low-grade MEC of submandibular gland origin.

Histochemical studies demonstrate the presence of intracytoplasmic mucin (diastase-resistant, PAS-positive, and mucicarmine positivity) in the mucous cells. The epidermoid cells may be faintly PAS positive but are mucicarmine negative. The intermediate cells and clear cells show no staining with either PAS or mucicarmine. The immunohistochemical staining includes cytokeratin, epithelial membrane antigen (EMA), and p63 positivity but S-100 protein, glial fibrillary acidic protein (GFAP), and muscle-specific actin and carcinoembryonic antigen (CEA) are at best variably positive and more often negative.

Recently, the MECT1/MAML2 translocation has been identified in a large proportion of MECs of the salivary gland.[293] MECT1/MAML2 has emerged as a favorable prognosticator. MECT1/MAML2 translocation is present in 66% of MECs and is negative in 100% of non-MEC and is negative for translocation. Low- to intermediate-grade MEC have a higher frequency of translocation (75%) than high-grade MEC (46%) ($p = 0.039$). Translocation-positive cases have a better disease-specific survival (log rank $p = 0.026$), although 2 patients still died of disease. Within high-grade MEC, MECT1/MAML2 positive tumors had lower rates of anaplasia ($p = 0.001$) and mitotic counts ($p = 0.012$). MECT1/MAML2 translocation is considered highly specific for MEC and imparts a better prognosis. This translocation is frequent even within high-grade MEC (seen in lethal cases, suggesting that translocation status should not supersede conventional parameters). Two distinct subgroups within high-grade MEC have been identified, including translocation-positive tumors and translocation-negative tumors, and the latter may actually be more appropriately categorized as another tumor type (e.g., adenosquamous carcinoma).

## Acinic Cell Adenocarcinoma

Acinic cell adenocarcinoma (ACA) is a low-grade malignant epithelial salivary gland neoplasm characterized by a variety of histologic growth patterns and the tendency for at least some of the neoplastic cells to recapitulate the appearance of normal serous acinous cells characterized by the presence of cytoplasmic (zymogen type) secretory granules. In the Armed Forces Institute of Pathology (AFIP) experience, ACA represents approximately 18% of all primary malignant salivary gland neoplasms and 6.5% of all salivary gland neoplasms.[294] In the pediatric age group, ACA represents the second most common malignant salivary gland neoplasm next to MEC, representing 12% of all cases of ACA in the AFIP files.[294] Given the fact that the parotid gland is entirely composed of serous-type acini, the most common site of occurrence is the parotid gland, in which >80% of all cases are found.[294] ACA may also be identified in the submandibular in up to 4% of cases. The remaining sites of occurrence include intraoral minor salivary glands and, less frequently, in minor salivary glands in other sites of the upper respiratory tract. Sublingual gland involvement is rare.

ACA are well-demarcated and/or encapsulated tumors, round or multilobulated, soft to rubbery, tan-gray to yellow or pink mass usually measuring <3.0 cm in greatest diameter, but occasionally may reach sizes up to 13 cm. Most neoplasms have a homogeneous appearance but may be cystic and hemorrhagic. Recurrent neoplasms are less well demarcated and tend to be multinodular in appearance. Histologically, ACA are circumscribed tumors characterized by a variety of growth patterns, including solid, microcystic, papillary-cystic, and follicular. The solid and microcystic type is the most common pattern consisting of either sheets of tumor cells in an organoid arrangement or numerous small cystic spaces. The papillary-cystic and follicular are the least common patterns consisting of variable-sized cystic spaces associated with papillary projections supported by a fibrovascular core or follicular spaces resembling thyroid parenchyma containing eosinophilic proteinaceous material lined by cuboidal to columnar cells. ACA are also noteworthy for their cytologic variations, including acinar, intercalated ductal, vacuolated, clear, and nonspecific glandular. Acinic cells are characterized by a polyhedral shape with small, dark, eccentrically placed nuclei and abundant basophilic granular cytoplasm characteristic of serous acinar cell differentiation. This production of cytoplasmic zymogen-like secretory granules readily identifies acinar differentiation, and these cells predominate in well-differentiated tumors. In contrast to normal acinar cells, neoplastic acinar cells are polygonal rather than triangular or trapezoidal, have greater cellular and nuclear variability, and have hyperchromatic to vesicular-appearing nuclei. Further, there are no striated ducts or retention of the normal lobular architecture seen in nonneoplastic acini. More than 40% of ACA acinar cells are of the predominant cell type[293]. The intercalated duct cells are cuboidal or columnar with centrally placed, small, dark nuclei and eosinophilic to amphophilic cytoplasm. Vacuolated cells contain cytoplasmic vacuoles that may be numerous and small, or few and large, distending the cell membranes. The clear cells are round to oval with distinct cell borders, peripherally placed, small, dark nuclei and the hallmark clear cytoplasm, the result from fixation and/or tissue processing. Nonspecific glandular cells are round to polygonal with round basophilic to vesicular nuclei and have amphophilic to eosinophilic cytoplasm. For all cell types, cellular pleomorphism and mitotic activity are limited, and, typically, the stroma is scant, but occasionally may be dense and hyalinized. A prominent lymphoid component composed of mature lymphocytes, including lymphoid follicles, can be seen.

Acinar cells and intercalated duct cells show diastase-resistant, PAS-positive intracytoplasmic granules; mucicarmine and alcian

(c) 2014 Wolters Kluwer. All Rights Reserved.

blue are typically negative but may be weakly positive. The presence of some intracytoplasmic mucicarminophilic material can be seen in acinic cell adenocarcinoma and does not exclude the diagnosis. Vacuolated cells, clear cells, and nonspecific glandular cells are PAS, mucicarmine, and alcian blue negative. Intraluminal and extracellular PAS positive and mucicarmine positive material may be present. Immunostaining is nonspecific and include cytokeratins reactivity, variable immunoreactivity for S-100 protein, and vimentin; p63, calponin, and actins are negative. A low proliferation rate is seen by Ki-67 (MIB1) staining.

## Mammary Analogue Secretory Carcinoma

Mammary analogue secretory carcinoma (MASC) is a recently described distinctive low-grade salivary gland malignant neoplasm with features resembling acinic cell adenocarcinoma and low-grade cystadenocarcinoma and displaying strong similarities to secretory carcinoma of the breast.[295] It is more common in men than women and primarily arises in the parotid gland; less commonly, MASC may arise in minor salivary glands. Microscopically, the tumors have a lobulated growth pattern and are composed of microcystic and glandular spaces with abundant eosinophilic homogeneous or bubbly secretory material. The intratubular secretory material is diastase-resistant, PAS-positive and mucicarmine negative. The immunohistochemical staining profile includes consistent immunoreactivity for mammaglobin, BRST-2, S100 protein, vimentin, CK7, CK19, STAT 5a, and MUC1. The t(12;15) (p13;q25) ETV6-NTRK3 translocation is identified.[296] In contrast, acinic cell carcinomas are generally not reactive for mammaglobin, BRST-2, S100 protein (4/12), and vimentin although STAT 5a and MUC1 staining can be seen in a majority of cases. There is an absence of t(12;15) (p13;q25) ETV6-NTRK3 translocation.

## Adenoid Cystic Carcinoma

ACC is a malignant epithelial salivary gland neoplasm characterized by its histologic appearance, tendency to invade nerves, and its protracted but nonetheless relentless clinical course. In major salivary glands, ACC primarily involve the parotid and submandibular glands. ACC is the most frequently encountered malignant neoplasm of the submandibular gland. Minor salivary gland involvement may occur throughout the upper respiratory tract, where it most frequently involves the palate; other intraoral sites of involvement include the tongue, the lower lip, the retromolar-tonsillar pillar region, and the sublingual gland. ACC may also occur in the ceruminal glands of the external auditory canal as well as representing 50% of all lacrimal gland neoplasms.

Grossly, ACC may be circumscribed, unencapsulated or partly encapsulated, solid, rubbery to firm, tan-white to gray-pink mass measuring from 2 to 4 cm in its greatest dimension. The histologic appearance of ACC is that of an unencapsulated, infiltrating neoplasm with varied growth patterns consisting of cribriform, tubular/ductular, and solid. Individual neoplasms may have a single growth but are characteristically composed of multiple patterns, any one of which may predominate. The most common pattern is the cribriform type, considered the "classic" pattern, demonstrating arrangement of cells in a "Swiss cheese" configuration with many oval or circular spaces. These spaces contain basophilic mucinous substance or hyalinized eosinophilic material. The tubular type has cells arranged in ducts or tubules. The ducts or tubules contain faintly eosinophilic mucinous material. Cribriform and tubular patterns often occur together. The least common pattern is the solid type, composed of neoplastic cells arranged in sheets or nests of varying size and shape. There is little tendency to form cystic spaces, tubules, or ducts.

Irrespective of the growth pattern, the neoplastic components are the same, consisting of fairly uniform-sized cells with small, hyperchromatic round to oval to angulated nuclei, scant amphophilic to clear cytoplasm, and indistinct cell borders. The nuclear-to-cytoplasmic ratio is about 1:1. The majority of the neoplastic cells are abluminal-type cells of myoepithelial differentiation. The cystic spaces seen in the cribriform or classic type are pseudocysts, which are extracellular and lined by replicated basement membrane. Scattered among these abluminal cells are ductal cells which surround small true lumens (glands). True duct-like lumens are an infrequent feature of ACC, but are most frequently seen in the ACC with a tubular growth. In the solid pattern, the cell population is dominated by the basaloid myoepithelial cells. The interstitial stroma, from which the epithelial component is sharply demarcated, varies in appearance from myxoid to hyalinized. Cellular and nuclear pleomorphism, necrosis, and mitotic activity are limited in the cribriform and tubular patterns. However, these features are more frequently seen in the solid pattern. Common to all histologic variants is the proclivity for nerve invasion (neurotropism), including peri- and intraneural invasion. However, ACC are not the only salivary gland tumor with neurotropism. Invasion of adjacent issue structures can also be seen.

Histochemical features of ACC include the presence of diastase-resistant, PAS-positive, and mucicarmine-positive material within the pseudocysts. Alcian blue staining is also present within the pseudocysts. Immunohistochemistry of ACC varies depending on the cellular component, with the myoepithelial cells showing cytokeratin, vimentin, p63, S-100 protein, and actin (muscle-specific) positivity with variable and GFAP reactivity. The ductal cells show cytokeratins, EMA, and CEA positivity. C-kit immunoreactivity is present in ACC, but it is not a unique marker for ACC and can be seen in other malignant salivary gland neoplasms, including (but not limited to) polymorphous low-grade adenocarcinoma (PLGA).

## PLGA of Minor Salivary Gland Origin

PLGA is a low-grade malignant epithelial neoplasm arising from the minor salivary glands, characterized by a varied architecture (polymorphous), bland cytomorphology, infiltrative growth, and indolent biologic behavior.

The tumors are polypoid or raised, round to oval, mucosal-covered masses ranging in size from 1.0 to 6.0 cm in their greatest dimension. In general, the mucosa remains intact; however, scattered surface ulceration may occur. The histologic appearance is that of a well-circumscribed but unencapsulated tumor characterized by morphologic diversity, cytologic uniformity, and infiltrative growth. The polymorphic nature of these lesions refers to the variety of growth patterns that include solid, trabecular, glandular, ductular, and tubular; cribriform and cystic patterns can be seen, but generally do not predominate. These patterns may be identified within the same lesion and from lesion to lesion. The presence of small tubular structures with a distinct central lumen lined by a single layer of cuboidal cells is a characteristic feature. A pattern of cell growth in which the cells are arranged in a single row termed "Indian file" can be seen and is often located at the periphery of the tumor. A focal papillary pattern can be identified. PLGA is composed of cuboidal to columnar isomorphic cells with indistinct cell borders that have uniform ovoid to spindle-shaped nuclei and small and inconspicuous nucleoli. The nuclear chromatin pattern varies from vesicular to stippled, but basophilic nuclei can also be identified. Scant to moderate amounts of eosinophilic to amphophilic cytoplasm can be seen, and occasionally clear cytoplasmic changes predominate. The tumor stroma varies from mucoid to hyaline to mucohyaline, and in some cases tumor nests are separated by a fibrovascular stroma. Neurotropism (peri- and intraneural) is found in the majority of

(c) 2014 Wolters Kluwer. All Rights Reserved.

tumors; perivascular invasion can also be seen with tumor nests often arranged in concentric fashion around these structures. In addition, the tumor may infiltrate the surface epithelium, residual minor salivary glands, and/or connective tissue components (bone, cartilage, muscle, and adipose tissue). Mitotic figures are rare and necrosis is not seen. Other histologic changes that may be identified include intratubular calcifications (psammoma-like bodies), pseudoepitheliomatous hyperplasia of the surface epithelium, and squamous metaplasia within the tumor. Squamous metaplasia can be identified following FNAB.

Intraluminal mucin can be identified by diastase-resistant, PAS-positive material; however, only focal intracytoplasmic mucin is seen. The immunohistochemical reactive pattern for PLGA may include reactivity for cytokeratins, EMA, CEA, p63, calponin, S100 protein, vimentin, muscle-specific action, GFAP, and C-kit. PLGA show a low proliferative index by Ki-67 (MIB1) staining.

## Salivary Duct Carcinoma

SDC is a high-grade malignant epithelial salivary gland neoplasm arising from the excretory ducts, histologically resembling ductal carcinoma of the breast. SDC may occur as a *de novo* neoplasm unrelated to any other salivary gland neoplasms, or, not infrequently, it is the malignant component identified in a carcinoma ex pleomorphic adenoma.

The majority of SDCs are poorly circumscribed and infiltrative, but may occasionally appear circumscribed. Cut section reveals a tan-white to gray-yellow solid mass ranging in size from 1 to 10 cm in its greatest dimension; on average, these tumors measure 3.5 cm. Cystic spaces filled with necrotic material may be identified.

The histologic features of SDC include the presence of an intraductal and infiltrating neoplasm with a variety of growth patterns, including cell nests, nodules, or lobules with central comedo-type necrosis, cribriform, solid, cystic, and papillary; multiple growth patterns can be seen in any given tumor. Comedo-type necrosis is a characteristic but not pathognomonic finding. Larger nodules tend to be cystic and irregular in shape. The appearance may suggest growth confined to within ducts (intraductal), but features of invasive growth include much larger size of the cystic foci as compared to normal ducts (intralobular and interlobular), presence of stromal fibrosis, and absence of normal (nonneoplastic) salivary gland parenchyma within the neoplastic foci.

The neoplastic cells of SDC are large, cuboidal to polygonal, with round, often centrally situated hyperchromatic nuclei and eosinophilic cytoplasm; eosinophilic nucleoli may be prominent, and oncocytic cytoplasmic changes may be present. Nuclear pleomorphism is present, and increased mitotic activity and necrosis are commonly seen. Cribriform pattern is reminiscent of intraductal mammary carcinoma and includes so-called "Roman bridge" pattern characterized by bands of neoplastic carcinoma demonstrating an admixture of abluminal cells lining pseudocysts and scattered epithelial cells lining small duct-like spaces, a pattern not seen in salivary duct carcinoma. The papillary pattern includes projections of neoplastic epithelium with fibrovascular cores; apocrine-like apical globules may be present. Psammoma-like bodies may be present. Squamous metaplasia may be identified. Stromal changes include the presence of fibrosis, often dense or sclerotic, as well as a mixed lymphoplasmacytic cell infiltrate. Invasive growth includes angioinvasion, NI, and invasion of adjacent salivary gland parenchyma and surrounding soft-tissue structures, including adipose tissue, skeletal muscle, and overlying skin.

Histologic variants include sarcomatoid, micropapillary, mucin rich, osteoclast-type giant cell and low grade (see subsequent text under low-grade cribriform cystadenocarcinoma). The sarcomatoid variant is characterized by a salivary duct carcinoma with associated malignant spindle-shaped and pleomorphic cell infiltrate; heterologous elements such as osteosarcomatous foci may be present. Similar findings can be seen in SCSC and are not indicative of a mixed carcinoma and sarcoma (i.e., carcinosarcoma). The micropapillary variant is characterized by a salivary duct carcinoma with associated clusters of morula-like epithelial cells with fibrovascular cores, reported to be more aggressive than "conventional" salivary duct carcinoma. The mucin-rich variant is characterized by conventional salivary duct carcinoma with associated lakes of extracellular mucin within which are nests or islands of neoplastic epithelium. The osteoclast-like giant cell variant is characterized by conventional salivary duct carcinoma with associated osteoclast-like giant cells, the latter resembling the cells seen in giant cell tumor of bone. In contrast to the cells in a giant cell tumor, the osteoclast-like giant cells in salivary duct carcinoma are immunoreactive for epithelial markers and androgen receptor.

Histochemical staining may include the presence of intracytoplasmic diastase-sensitive, PAS-positive material. Intracytoplasmic mucicarmine staining is usually negative, but intraluminal mucicarminophilic material may be present. Immunohistochemical reactivity includes the following: the presence of staining for cytokeratins (low and high molecular weight), CK7, EMA, and CEA positive; the presence of androgen receptor, which represents a very helpful diagnostic finding for SDC; HER-2/neu (c-erbB-2) being positive (membranous staining) in a majority of cases; chances of BRST2 being positive; estrogen and progesterone receptor markers being positive in a minority of cases; S100 protein and markers indicative of myoepithelial differentiation, including calponin, p63, smooth muscle actin and vimentin, typically being negative. Similar to its use in ductal carcinomas of the breast, myoepithelial markers have been used to identify a peripheral nonneoplastic myoepithelial layer that, if identified, may indicate a tumor to be confined to within a duct (intraductal carcinoma) as opposed to absent staining that may indicate an infiltrative process; however, reactivity with stromal myofibroblasts may suggest myoepithelial layering and, therefore, an intraductal process when in fact the carcinoma is invasive. Rare documentation of neuroendocrine differentiation, as evidenced by the presence of chromogranin and synaptophysin reactivity, may be identified. Prostate-specific antigen and prostatic acid phosphatase may be reactive. SDC shows a high proliferative index ranging from 25% to 80% by Ki-67 (MIB1) staining.

CHAPTER 2

Joshua D. Hornig, Barry T. Malin, and Brendan O'Connell

# Clinical Evaluation of the Head and Neck Cancer Patient

## GENERAL APPROACH TO THE HEAD AND NECK CANCER PATIENT

Clinical evaluation of the patient with head and neck cancer entails multiple challenges for the physician. In the context of an initial clinical encounter, the caregiver needs to collect the findings that will guide diagnosis, while also establishing a constructive therapeutic relationship with the patient and family members, addressing acute intervention needs, and outlining and initiating a plan for further diagnostic workup and treatment. The imperatives that the physician must address in the evaluation of the head and neck cancer patient may be considered as 12 *Key Tasks*, as outlined in Table 2.1. An accurate and comprehensive examination must be performed. A complete medical history should be undertaken, with special attention paid to key risk factors, including prior cancer history, smoking history, alcohol intake, extent of sun exposure, reflux, industrial or occupational exposures, and immunosuppression. Cardinal signs and symptoms associated with head and neck cancer include lesions or masses, persistent hoarseness, mouth or throat pain, dysphagia, odynophagia, hoarseness or dysphonia, dyspnea, stridor, unilateral otalgia or hearing loss, aspiration, weight loss, or cranial nerve deficits. Assessment and documentation must be performed of the patient's overall medical and functional status, which may influence the suitability of specific treatments such as surgical resection or radiotherapy. Critical information regarding previous treatments must be collected, including previous oncologic surgeries, chemotherapy treatments, or prior radiotherapy. If the patient has had prior radiotherapy, key elements of therapy must be documented, including treatment portals, dosages, fractionation, treatment duration and compliance, and specifics regarding prior surgical or chemotherapeutic interventions obtained.

A provisional diagnosis or differential should be established with rapid formulation of a plan of care and clear delineation of the next steps required. At the same time, the treating physician must be vigilant in assessing areas in which immediate intervention may be necessary, such as treating pain, airway management, or addressing severe nutritional deficiencies. Assessment and treatment of pain is an important aspect of the clinical evaluation of the head and neck cancer patient, although insufficient attention is often paid to this aspect of care. In a recent meta-analysis of studies on pain among patients with cancer, den Beuken and colleagues found that >50% of patients had inadequately treated pain; when considered by cancer type, patients with head and neck cancer had the highest prevalence of insufficient pain management at 70%.[1]

A comprehensive evaluation of the head and neck cancer patient typically involves adjunctive measures such as radiographic imaging and cytopathologic tissue analysis. However, physical examination of the head and neck and history-taking by the evaluating clinician retain a central role in shaping further assessment and treatment. For example, patient age is a key factor to be considered in evaluating the patient with a solitary neck mass. Whereas the overwhelming majority of neck masses in young patients are either infectious or inflammatory in origin, most neck masses in adults involve neoplasia. Although benign pathologies are common in young patients with cystic neck masses, >80% of patients over the age of 40 who present with such findings are ultimately found to have carcinoma.[2] The clinician should be highly suspicious of the diagnosis of branchial cleft cyst or thyroglossal duct cyst in patients older than 40 with no prior history of symptoms; >30% of patients over 40 initially diagnosed with branchial cleft cyst subsequently prove to have cystic metastases of squamous cell carcinoma.[3]

As part of the initial visit, head and neck cancer patients should be engaged with a team of professionals dedicated to providing guidance and support through their course of care, including an oncology nurse, nurse practitioner or physician assistant, and patient navigator. Such multilayered staffing in the management of head and neck cancer patients improves treatment compliance and overall satisfaction with care.[4] If the patient is a smoker, provision of smoking counseling and offering treatment or referral to smoking cessation resources is necessary at the initial visit, as persistent smoking during treatment is an independent risk factor for poor treatment outcome.[5]

In many cases, patients will present having already been told that they have a head and neck cancer or they may have a strong suspicion of such a diagnosis. There is wide variation regarding patients' desires regarding the detail in which they want cancer diagnoses described and the degree of specificity with which they want prognostic information delivered.[6] Although legal and ethical standards in the United States regarding informed consent demand full disclosure, it is incumbent upon the clinician to attempt to furnish such information in an optimal manner for individual patients. The obligation to full disclosure does not obviate the responsibility of the provider to attempt to tailor the delivery in accordance with patient preferences and sensitivities.[7,8]

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 2.1 12 Key Tasks in the Initial Evaluation of the Head and Neck Cancer Patient**

- Perform comprehensive head and neck examination; additional physical examination as indicated.
- Elicit complete HPI and symptom description.
- Delineate risk-factor profile (e.g., smoking history, sun exposure, radiation exposure, etc.).
- Assess overall medical and functional status in the context of possible treatment options.
- Engage a care team (cancer nurse, cancer nurse practitioner, and cancer patient navigator) to provide patient support and guidance.
- Ascertain critical information regarding prior therapies and start process to obtain such data if not available at the time of initial consultation.
- Recognize and address needs for urgent intervention: airway compromise, aspiration risk, inadequately treated pain, severe malnutrition, and hemorrhage risk.
- Obtain biopsy specimens, as indicated and feasible in office setting.
- Express recognition of the patient's concerns regarding diagnosis and acknowledgment of the impact regarding stress, anxiety, fear, and grief on patients and their loved ones.
- Initiate multidisciplinary board review and key referrals as indicated: medical oncology, radiation oncology, speech and swallow therapy, maxillofacial surgery/prosthodontics, pain management, anesthesiology/medicine, social work, financial/benefits counseling, smoking cessation resources.
- Order directed imaging and laboratory studies.
- Clearly identify and explain next steps in diagnosis and treatment in terms appropriate for the individual patient.

## PHYSICAL EXAMINATION

Thorough physical examination is critical in the evaluation of the patient with possible head and neck cancer. A complete physical examination of the entire head and neck is essential, regardless of suspected primary site. Appropriate steps should be taken prior to the initiation of the physical exam in order to develop and enhance patient comfort and rapport. Appropriate hand washing should precede examination, and adherence to universal precautions should be maintained. These actions promote trust between patient and physician. Physical examination should begin with attention to the general appearance of the patient. Information regarding a patient's overall health, mood and affect, hygiene, and smoke exposure may be gained with simple observation.

In addition to visualization of anatomic structures of the head and neck, manual palpation is a critical tool for assessment of the head and neck. Palpation should routinely be performed of the neck and oral cavity. Bimanual palpation is necessary for comprehensive evaluation of the floor of mouth and submandibular areas. Palpation techniques can yield critical information regarding submucosal extension, fixation, and tumor thickness. Any abnormal or concerning findings should be described in relation to key landmarks and anatomic subsites, so as to facilitate accurate communication with other providers and appropriately document changes over time.

### Examination of the Skin

Examination should begin with assessment of facial structures; any gross asymmetry or facial swelling should be noted. Thorough external inspection of the patient's skin for any suspicious lesions is performed. Particular attention should be given to sun-exposed areas, including the external auricles and the posterior neck. The scalp and other hair-bearing areas should be closely inspected, as lesions in these areas often escape notice. All pigmented lesions and nevi should be examined closely for color variation, border quality, asymmetry, and ulceration.

### Examination of the Ear

Examination of the ear and temporal bone is a required portion of the assessment. The skin overlying the external ear and mastoid region is inspected and palpated when appropriate. Following inspection of the external ear, otoscopic examination should be performed to assess the external auditory canal, tympanic membrane, and middle ear space. The presence and quality of any otorrhea or evidence of effusion is noted. Subjective pain associated with aural discharge is particularly concerning for underlying malignancy. In an adult presenting with unexplained unilateral or bilateral serous otitis media, fiberoptic endoscopic assessment should be performed to rule out obstruction of the Eustachian tube by a nasopharyngeal mass.

### Examination of the Nose

Anterior rhinoscopy is performed under direct visualization with a nasal speculum and a headlight or head mirror. With exposure enhanced by appropriate speculum technique, the anterior nasal cavity and its contents are visualized, including the vestibule, anterior septum, floor of the nasal cavity, inferior turbinate, middle turbinate, and middle meatus. The presence of secretions, masses, obstruction, scabbing, or active bleeding should raise suspicion for sinonasal pathology.

### Examination of the Oral Cavity

The oral cavity begins anteriorly at the skin/mucosal junction of the vermillion border of the lips. The hard/soft palate junction, the anterior tonsillar pillar, and circumvallate papillae form a plane posteriorly, which separates the oral cavity from the oropharynx. The oral cavity is divided into the following subsites: the lips, buccal mucosa, floor of mouth, retromolar trigone, oral tongue, hard palate, and alveoli. Oral cavity examination is best performed with two tongue blades and a head light or head mirror. The use of a handheld light source is discouraged, as it prevents the examiner from using both hands to manipulate oral cavity contents.

Examination should begin with external inspection of the lips and then proceed to thorough intraoral examination. When asking the patient to open their mouth, the presence of trismus should be noted, as it suggests pterygoid muscle involvement. The buccal mucosa, gingiva, gingivobuccal sulci, the retromolar trigone, and overall state of dentition are then assessed. The tongue is then grasped with a gauze pad and gently manipulated to allow full visualization of the ventral, dorsal, and lateral surfaces. The lateral surfaces should be inspected for lesions and palpated to assess for induration. With the tongue pulled superiorly, the floor of the mouth should be inspected and manually palpated; submucosal masses in the floor of the mouth should raise suspicion for minor salivary gland tumors. Midline protrusion and lateral excursion of the tongue should be tested; atrophy of one side or asymmetric protrusion raises suspicion for tongue invasion or cranial nerve XII involvement. Inspection and palpation of the hard palate is performed.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Oral cavity examination requires assessment of all mucosal surface changes suggestive of potential or *premalignancy*: leukoplakia, erythroplakia, lichen planus, oral submucosal fibrosis, discoid lupus erythematosus, and dyskeratosis.[9] The most common sites for premalignant lesions include the buccal mucosa, lower gingiva, tongue, and floor of mouth.[10] Adjunctive screening methods including toludine blue application, fluorescence, and brush biopsy have not proven to be of unequivocal benefit in enhancing detection of oral malignancy,[11] but early findings regarding the potential application of optical coherence tomography in early detection are promising.

## Examination of the Oropharynx

The oropharynx extends from the level of the soft palate to the hyoid bone and has four distinct subsites: soft palate, tonsillar region, base of tongue, and posterior and lateral oropharyngeal wall. The soft palate should be examined for mucosal lesions and submucosal fullness or swelling. Elevation of the soft palate should be symmetric and can be assessed by asking the patient to say "ah"; asymmetric elevation should raise suspicion for CN X involvement. The tonsillar region consists of anterior and posterior tonsillar pillars encompassing the palatine tonsils. The anterior tonsillar pillar and tonsil represent the most common sites for primary tumors of the oropharynx. Asymmetrically hypertrophied lymphoid tissue, particularly in the palatine tonsils, should raise suspicion. The lateral and posterior pharyngeal walls are inspected; medialization of the lateral oropharynx may represent mass effect from an entity in the parapharyngeal space, which lies posterolateral to the tonsil. Palpation of the base of tongue is paramount as direct examination of this area is limited. Submucosal lesions may be missed on indirect visualization, but can often be palpated with good manual examination techniques. The base of tongue, pharyngoepiglottic folds, and vallecula should be inspected during indirect laryngoscopy with either mirror examination or fiberoptic endoscopy, as discussed below.

## Examination of the Neck and the Parotid Region

Examination of the neck is paramount in the evaluation of head and neck cancer. All levels of the neck, including the supraclavicular region, should be palpated to assess for the presence of lymphadenopathy. The anatomy of the neck is divided into six levels, as described in Table 2.2.[12] Size, mobility, and location of suspected malignant lymph nodes should be carefully documented in relation to these levels. The thyroid should be palpated for the presence of distinct nodules or gross enlargement. Standing behind the patient and having them swallow facilitates identification of irregularities of the thyroid lobes. The parotid glands, the preauricular lymph nodes, and the postauricular lymph nodes should be palpated. A mass in the parotid may represent primary neoplasm, metastatic lymph node, a cyst, or an inflammatory process. If the patient presents with a neck mass without an obvious primary, the index lesion can be identified in most cases on the basis of a comprehensive examination. In cases where the primary lesion is not discovered on initial physical exam, further workup with adjunctive imaging (CT, MRI, or PET/PET-CT), tissue sampling, operative endoscopy, and immunohistochemical or molecular studies as indicated will facilitate ultimate discovery of the primary lesion in 97% of patients.[13]

**TABLE 2.2 Anatomic Boundaries of the Levels of the Neck**

| | |
|---|---|
| Level IA (submental) | Bound by lateral edge of the anterior bellies of the digastric muscles and the hyoid bone. |
| Level IB (submandibular) | Bound by mandible, anterior belly of the digastric muscle, and the stylohyoid muscle. |
| Level IIA and Level IIB (upper jugular) | Bound by the skull base superiorly and hyoid bone inferiorly, the stylohyoid muscle medially, and the posterior border of the sternocleidomastoid muscle (SCM) laterally. Level IIA is anterioinferior to the spinal accessory nerve, while level IIB is posterosuperior to the spinal accessory nerve. |
| Level III (midjugular) | Bound by the hyoid superiorly, the inferior border of the cricoid cartilage inferiorly, the lateral border of the sternohyoid muscle medially, and the posterior border of the SCM laterally. |
| Level IV (lower jugular) | Bound by inferior border of the cricoid cartilage superiorly, the clavicle inferiorly, the lateral border of the sternohyoid muscle medially, and the posterior border of the SCM laterally. |
| Level VA and Level VB (posterior triangle) | Bound by the convergence of the SCM and trapezius muscle superiorly, the clavicle inferiorly, the posterior border of SCM medially, and the anterior border of the trapezius muscle laterally. Level VA is located superior to the level of the inferior aspect of cricoid cartilage; Level VB is located inferior to this horizontal plane. |
| Level VI (anterior or central compartment) | Bound by the hyoid bone superiorly, the suprasternal notch inferiorly, and the carotid arteries laterally. |

## Neurologic Examination

Complete neurologic examination should be performed with a focus on the cranial nerves (CN). Cranial nerve deficits may be indicators of underlying neoplastic processes and require further workup. Any paresis of the facial nerve (CN VII) must be characterized in accordance with the House-Brackmann grading scale. The House-Brackmann scale (Table 2.3) has been adopted by the American Academy of Otolaryngology–Head and Neck Surgery as the universal standard for the clinical assessment of facial nerve function.[14] Characterization of facial nerve deficits using the House-Brackmann scale facilitates accurate communication between providers and clear documentation of symptom progression. However, it should be noted that the House-Brackmann scale was developed and tested in neuro-otologic setting and has only limited usefulness in assessing tumors of the head and neck. Nevertheless, it is a common grading system that is now universally known and it does help with communication to other health professionals.

## Fiberoptic Endoscopy

The nasopharynx, portions of the oropharynx, larynx, and hypopharynx cannot be assessed by unaided physical examination. These areas can be visualized using either mirror techniques or

(c) 2014 Wolters Kluwer. All Rights Reserved.

**TABLE 2.3 House-Brackmann System of Grading Facial Nerve Paralysis**

| Grade | Description | Characteristics |
|---|---|---|
| I | Normal | Normal facial function |
| II | Mild dysfunction | Gross: weakness on close inspection, normal symmetry and tone at rest, may have slight synkinesis |
| | | Motor: moderate to good facial function, complete closure of the eye with minimal effort, slight asymmetry of the mouth |
| III | Moderate dysfunction | Gross: obvious but not disfiguring difference between the two sides of the face, normal symmetry and tone at rest, noticeable but not severe synkinesis, contracture, hemifacial spasm |
| | | Motor: slight to moderate forehead movement, complete eye closure with effort, weak mouth with medium effort |
| IV | Moderately severe dysfunction | Gross: disfiguring asymmetry and/or obvious weakness, normal symmetry and tone at rest |
| | | Motor: no forehead movement, incomplete eye closure, asymmetric mouth with maximal effort |
| V | Severe dysfunction | Gross: barely perceptible motion, asymmetry at rest |
| | | Motor: no forehead movement, incomplete eye closure, slight mouth movement |
| VI | Total paralysis | No movement |

fiberoptic endoscopy. Fiberoptic endoscopy provides the most accurate visualization of these areas, allowing for assessment of primary lesions and evaluation of airway status. The nose is typically anesthesized with topical anesthetic spray and decongested with a vasoconstrictive spray. A flexible laryngoscope is passed through both nasal cavities and into the nasopharynx.

The nasopharynx extends from the skull base superiorly to the soft palate inferiorly and communicates with the nasal cavity through the choanae. Midline posterior pharyngeal mucosa and the nasopharyngeal lymphoid tissue should be assessed. Posterior pharyngeal wall fullness raises suspicion for retropharyngeal pathology. The scope is then angled to view the lateral wall and its contents including epithelial mucosa, the Eustachian tube orifice, the posterior lip of the opening of the Eustachian tube or *torus tubarius*, and the fossa of Rosenmüller lying behind the *torus tubarius*. The lateral wall must be carefully inspected with particular attention given to the fossa of Rosenmüller, as nasopharyngeal tumors have a predilection for this site.[15] The scope should then be angled inferiorly, and the base of tongue and the vallecula inspected. Protrusion of the tongue facilitates complete examination of the vallecula and the base of tongue. Advancing the tip of the scope until it is just above the epiglottis allows for visualization of the larynx and the hypopharynx.

The larynx is divided into three subsites: the supraglottis, glottis, and the subglottis. The supraglottic region includes the epiglottis, the false vocal cords, the ventricles, the arytenoid cartilages, and the aryepiglottic folds. The glottis consists of the true vocal cords and anterior commissure. The supraglottic and glottic larynx are examined for any mucosal lesions or submucosal masses. It is vital to fully visualize the anterior cords and anterior commissure. Bilateral cord involvement, cord mobility, and involvement of surrounding subsites should all be documented. True vocal fold mobility is assessed by having the patient phonate, pant, and breathe quietly. Although clinical staging is partially based on cord mobility, in the setting of impaired cord movement, it is critically important to attempt assessment of the cricoarytenoid unit, which may represent a more specific involvement, rather than a mass effect related to deep muscle invasion. The cricoarytenoid is the basic functional unit of the hemilarynx, and mobility of the cricoarytenoid is often the critical factor determining patient eligibility for organ-preserving laryngeal surgery.[16] Unfortunately, discrimination of vocal cord movement restriction due to paraglottic space involvement or mass effect of bulky lesions from true cricoarytenoid fixation based upon endoscopic examination is difficult, and evaluation in the operating room is often required.

The subglottis begins 5 to 10 mm below the free edge of the true vocal folds. Primary tumors of the subglottis are rare. However, transglottic extension of superior lesions has important staging and prognostic implications. Visualization of the subglottis may be obscured by glottic pathology, and comprehensive evaluation of the subglottis is not possible in the office examination.

The hypopharynx extends from the hyoid bone superiorly to the esophageal introitus inferiorly. It is continuous with the oropharnyx and sits just behind the larynx. The hypopharynx is divided into three distinct subsites: the piriform sinus, posterior pharyngeal wall, and postcricoid region. Adequate visualization of the hypopharynx in the office setting may be difficult. Having the patient perform a Valsalva maneuver may enhance visualization due to clearance of pooled secretions. The majority of tumors that arise in the hypopharynx are SCC or an SCC-variant.[17]

The larynx and hypopharynx may alternatively be visualized with rigid endoscopy. Patients with sensitive gag reflexes may need to be sprayed with topical anesthesic intraorally. Rigid nasal endoscopy with angled scopes allows for optimum visualization of the nasal cavity and should be performed in any patient with suspected skull-base or sinonasal tumors. Stroboscopic examination of the glottis allows for enhanced visualization of true vocal cords, and subtle changes in mucosal wave dynamics may be detected; it is especially valuable in judging the depth of glottic lesions.

Physical examination findings, considered in the context of patient's symptomatology and risk factor profile, form the basis for further workup. In most cases, comprehensive evaluation of suspicious findings will require adjunctive imaging. Prior to treatment, definitive tissue diagnosis must be obtained by fine needle aspiration (FNA), core needle biopsy, or open biopsy. Operative endoscopy with biopsy may also assist in securing definitive tissue diagnosis and achieving accurate staging.

# IMAGING MODALITIES

Prior to therapeutic intervention, precise tumor staging is critical. Accurate staging is generally best achieved with a combination of clinical evaluation and radiologic imaging. Pretreatment imaging assists in staging by helping to delineate tumor origin, size, extension, and presence of locoregional metastases. Imaging facilitates preplanning by defining the relationship between masses and nearby vital structures such as blood vessels and cranial nerves, and may also detect possible signs of malignancy not readily appreciable by physical examination such as ill-defined tumor borders, cartilage invasion, bone erosion, perineural spread, and multifocality. Traditionally, computed tomography (CT) and magnetic resonance imaging (MRI) have been the standard imaging modalities employed in the workup of head and neck cancer patients. More recently, positron emission tomography (PET) has emerged as a powerful tool in the diagnosis and management of these patients. Ultrasound (US) is radiation sparing and useful in the performance of directed biopsies, and is currently the first-line imaging modality for most thyroid and salivary lesions. Scintigraphy currently has a limited role in the evaluation of thyroid nodules. Emerging technologies in biologic neuroimaging, such as proton MR spectroscopy, CT-perfusion, perfusion-weighted MRI, and diffusion-weighted imaging, utilize biologic behavior patterns such as tumor cellularity and perfusion to depict additional imaging dimensions.

## Chest X-Ray (CXR)

PA and lateral CXRs are indicated prior to any endoscopy or surgical intervention requiring general anesthesia. A CXR may assist in identifying cardiac pathology, chronic pulmonary disease, synchronous lung cancer, or distant metastases. However, CT and PET-CT are superior to CXR in ruling out second lung primaries and distant metastases.

## Computed Tomography (CT)

CT is often the initial study of choice in evaluation of head and neck masses. Advantages include relative availability and cost-effectiveness relative to MRI and PET scanning along with rapid image acquisition. CT is a powerful tool for depicting the deep tissue of the aerodigestive tract, and thus complements endoscopic evaluation of mucosal lesions.[18] CT is also a suitable means of radiologic staging of neck disease; however, modern CT and MRI scanners appear to have comparable effectiveness in staging the neck,[19] with CT and MRI demonstrating similar sensitivities (82% and 85%, respectively) and specificities (80% and 90%, respectively) in detecting cervical lymph node metastases.[20] CT is indicated in laryngeal and hypopharyngeal cancers and is particularly useful in determining the extent of bone involvement in oral cavity, oropharyngeal, and sinonasal tumors. Thoracic spiral CT is frequently used to assess early synchronous lung cancer or distant metastases.

## Magnetic Resonance Imaging (MRI)

MRI is the preferred imaging modality for evaluation of sinonasal and nasopharyngeal tumors. MRI is capable of differentiating inflammatory sinus disease from neoplasms and is superior to CT in detecting intraorbital and intracranial extension of nasopharyngeal cancers.[21] MRI is very accurate and far more sensitive than CT for detection of perineural tumor extension. MRI is limited in its ability to detect subtle skull-base erosion, while CT with bone algorithm is highly sensitive for detection of bony erosion of sinus walls and skull base.[22]

MRI is the most accurate imaging technique for assessment of salivary gland masses. MRI has superior soft-tissue resolution with the capacity to accurately reveal local extension of a tumor and demonstrate perineural tumor spread.[23] CT with bone algorithm is superior in determining the extent of bone destruction and thus may be of value if bony fixation or invasion is suspected. MRI can have important advantages in the depiction of oral cavity and oropharyngeal tumors. Tumors at these sites can be difficult to identify on CT because of the adjacent dense mandible and dental amalgam artifact. MRI is less affected by dense bone and dental artifact allowing for visualization of even small tumors. Furthermore, MRI is superior for assessment of tumor spread into the bone marrow. Disadvantages of MRI include the relatively long imaging time required to obtain high spatial resolution images. Prolonged imaging time often leads to significant motion artifact, making accurate interpretation of imaging difficult; this is particularly frequent at the laryngeal and hypopharyngeal levels.[21]

## Positron Emission Tomography (PET)

Positron emission tomography (PET) takes advantage of the increased metabolic rate of tumors and the resultant increased absorption of 18F-flourodeoxyglucose when compared to normal tissue. PET has become widely utilized in both initial staging and follow-up of patients with head and neck cancer. Recent evidence suggests that PET has a higher sensitivity and specificity for staging cancers of the head and neck when compared to CT and MRI. PET can provide additional information in roughly one-third of patients who have undergone previous CT or MRI with equivocal findings.[24–26] A prospective, histopathologically controlled study demonstrated that PET is superior to CT, MRI, and US in detecting cervical lymph node metastases.[4] PET imaging can identify synchronous primary neoplasms that may be missed with conventional imaging techniques. Whole-body scanning with PET-scanning has clear advantages in terms of ability to detect distant metastases. Lastly, patients with clinically evident nodal disease and unknown primaries despite application of conventional imaging techniques and clinical investigation should undergo PET imaging. In such cases, the PET scanning allows for identification of the primary site of tumor in 10% to 72% of cases.[27,28]

The role of PET in posttreatment surveillance of head and neck cancer has also expanded in recent years. Studies have demonstrated that PET is superior to CT and MRI in the detection of posttreatment persistence or recurrence of head and neck squamous cell carcinoma.[29] Positive posttreatment PET findings also provide important prognostic information regarding relapse-free and overall survival.[30] Terhaard et al. advocate PET as the initial step in evaluation of all patients with suspected local recurrence. Given that a negative PET is highly reliable for all sites, negative PET scan may preclude the need for biopsy in many cases.[31,32]

An important limitation of standard PET is limited resolution of anatomic detail. However, combined PET-CT techniques permit near-synchronous image acquisition and combine the anatomic detail of CT with the whole-body sensitivity of PET. Initial studies demonstrated that fused PET-CT improved anatomic localization of PET abnormalities and reduced the number of equivocal PET findings.[33] When the diagnostic accuracy of PET for detection of head and neck cancer is compared to that of PET-CT, PET-CT improves accuracy and alters treatment plans in 18% of cases.[24] In the initial diagnostic workup of head and neck cancer patients, utilization of PET-CT alters treatment plans in 30% of cases. In posttreatment surveillance, PET-CT reduces the fraction of false-positive studies compared to PET alone while maintaining a very

(c) 2014 Wolters Kluwer. All Rights Reserved.

high NPV.[34] By consolidating imaging acquisition, PET-CR also reduces overall scan time compared to independent application of imaging modalities. PET/CT is thus emerging as the optimal diagnostic modality in many cases based on evidence of its superiority to either modality alone for initial evaluation, radiologic staging, and surveillance for disease recurrence.[25,26]

## Ultrasound (US)

US is the preferred imaging modality for assessment of suspected benign salivary gland tumors and thyroid nodules. It is relatively inexpensive when compared to CT and MRI and spares the patient administration of radiation. Further it is safe, noninvasive, and readily available at most clinical sites for point-of-care evaluation and facilitation of fine-needle aspiration biopsy. US is the initial study of choice for suspected benign salivary gland tumors, as it can characterize tumor size, border regularity, vascularity patterns, multifocality, and adjacent lymphadenopathy. However, US is unsuitable for assessing perineural spread, extraglandular invasion of bone or soft tissue, and oropharyngeal or retropharyngeal nodal metastases, which should be evaluated with MRI if suspected.[35] A disadvantage of US is that its accuracy in assessment of salivary gland lesions is significantly operator-dependent, and interpretation of US images can be more challenging than corresponding MRI or CT images for those without extensive experience.

US is also the most useful imaging technique for assessment of thyroid nodules. High-resolution US can detect lesions as small as 3 mm. Sonographic features suggestive of thyroid nodule malignancy include microcalcifications, marked hypoechogenicity, poorly defined margins, direct invasion through the thyroid capsule, and central vascularity.[36,37] Microcalcifications have a reported PPV for carcinoma of up to 70% and are the most concerning sonographic finding.[37] The American Thyroid Association (ATA) recommends preoperative neck US on all patients undergoing thyroidectomy for biopsy-proven malignancy. The ATA also recommends surveillance cervical US 6 to 12 months posttreatment and periodically thereafter depending on risk factors and thyroglobulin status.[38]

US may be employed for diagnostic imaging and guidance of biopsy in both the radiology suite and the clinician's office. Although the utilization of portable US in evaluation of the head and neck in both outpatient and emergency settings is commonplace in Europe,[39] it is much less frequently utilized in the United States. It is, however, becoming increasingly available to clinicians as an adjunctive modality, which may be selectively utilized as part of the initial evaluation of the head and neck cancer patient. This trend has been encouraged recently by the introduction of smaller, less expensive high-resolution ultrasound machines into the marketplace. The selective application of US technology in the office setting is increasingly being viewed as "an important extension of the physical exam," which allows clinicians to further investigate concerning findings by "seeing pathology below the skin" in real time without irradiation.[40]

Portable US can be used in the office setting for evaluation of neck masses, cervical lymphadenopathy, salivary gland masses, parathyroid adenomas, and thyroid nodules. US can provide key information regarding a pathologic entity of the neck, including size, cystic quality, presence of solid elements, vascularity, and relationship to critical structures. US characteristics of cervical lymph nodes that are concerning for malignancy include size > 1 cm (except for the jugulodigastric node whose upper limit of normal size is 1.5 cm), round shape (nonpathologic lymph nodes tend to be oval with a 2:1 diameter ratio), irregular margins, focal necrosis, node clustering, loss of hilar architecture, anechoic echogenicity, peripheral nodal vascularity, focal vascularization defects, and microcalcification.[41,42]

The scope of use of US within the office setting is expected to increase as units become smaller and less expensive. Several manufactures now offer laptop-sized models suitable to head and neck applications, and handheld units, which are already in use in other clinical settings, are on the horizon.[43] At present, the primary barrier to increased usage of office-based US is adequate training and credentialing for nonradiologists.[44] However, performance of head and neck US by the treating physician in the office setting can have important benefits in terms of treatment planning and surveillance.[45] New US techniques, including elastography and sonoelastrography, are likely to improve the accuracy of office-based testing. Lyschik and colleagues recently reported a 98% sensitivity and 92% accuracy rate utilizing US sonoelastrography to determine malignancy in cervical lymph nodes.[46]

## Scintigraphy

Scintigraphy is a nuclear medicine technique in which uptake of radiotracers by select tissues can be measured. Its routine use in the evaluation of thyroid nodules has significantly decreased, and its utility in the workup of thyroid carcinoma is limited. Iodine-123 and technetium-99m pertechnetate are radiotracers commonly used to evaluate thyroid nodules. Hyperfunctioning nodules are more likely benign, while hypofunctioning nodules are more suspicious for malignancy. The reported risk of cancer is 1% to 4% for a hot nodule and 15% to 25% for a cold nodule.[47] However, since scintigraphy cannot reliably identify malignancy, it is of limited value in routine evaluation of the thyroid nodule. Whole body iodine-123 scanning can be performed as a posttreatment test and can provide information related to the presence of metastatic disease, completeness of surgical resection, and disease recurrence. Whole-body scanning is indicated for follow-up of patients at high or intermediate risk for persistent disease after radioactive iodine therapy.[38] Scintigraphy with Technetium-99m Sestamibi, a parathyroid tissue-localizing agent, is the imaging modality of choice for the initial localization of parathyroid lesions.[48]

## Fine-Needle Aspiration

Fine-needle aspiration (FNA) is the preferred tissue sampling method for initial evaluation of neck masses or thyroid nodules. FNA may be performed using either manual palpation techniques or under image guidance. Systematic review of FNA cytology from all head and neck sites, including pooled analysis of over 2,700 specimens, reported sensitivity, specificity, and accuracy levels of 89.5%, 98.5%, and 95.1%, respectively.[49] Addition of US guidance to FNA yields increased sensitivity, specificity, and accuracy, while decreasing nondiagnostic sampling rates by approximately 50%.[50,51] Multiple studies have suggested that the use of on-site adequacy assessment by cytopathologists improves the diagnostic yield of US-guided FNA.[52–54] However, recent evidence suggests FNA in the office setting under US guidance by surgeons with experience in US techniques may afford comparable results in terms of diagnostic yield and accuracy.[55]

Thyroid nodules detected by US should be selectively sampled via FNA on the basis of size and the presence of suspicious findings on US. Current guidelines mandate FNA of lesions >1 to 1.5 cm. Concerning findings on US include the following: microcalcifications, hypoechoic nodules, irregular or lobulated margins, intranodal vascularity, lymphadenopathy, or disruptions in the fascial sheath suggestive of extrathyroidal extension; FNA may be deferred at the physician's discretion if the nodule is purely cystic with no solid elements on US.[56] A multicenter study of 849 nodules revealed the following prognostic value for malignancy of sonographic criteria: hypoechogenicity

(c) 2014 Wolters Kluwer. All Rights Reserved.

(sensitivity = 87%; PPV = 61%); shape (sensitivity = 40%, PPV = 78%); spiculation (sensitivity = 49%; PPV = 82%); and microcalcification (sensitivity = 44%, PPV = 78%).[57] An oft-overlooked step is the submission of accompanying clinical information that can assist the cytopathologist in interpretation of findings and reduce the rate of nondiagnostic findings. The National Cancer Institute (NCI) guidelines mandate that office-based thyroid FNA specimens be submitted with the data listed in Table 2.4.[58]

## DIRECTED LABORATORY STUDIES

Routine laboratories include a complete metabolic panel (CMP) and complete blood cell count (CBC) for all patients undergoing workup for suspected head and neck cancer. Head and neck cancer patients are frequently anemic; thus documentation of CBC is important in the pretreatment period and should be periodically followed throughout treatment. Coagulation studies are indicated in anticipation of surgical intervention. Heavy alcohol use and malnutrition are relatively prevalent among patients with head and neck cancer. Assessment of nutritional markers such as albumin, prealbumin, and Fe studies may help identify at-risk patients and allows for pretreatment nutrition optimization planning.[59] Baseline thyroid function tests should be obtained prior to initiation of treatment. Liver function tests are sometimes used as part screening workup for metastatic disease, but have very poor PPV when used for screening purposes.[60] In patients with suspected nasopharyngeal carcinoma, antibody titers against Epstein-Barr virus antigens may be useful as an accessory diagnostic test.[61]

## DELIVERING DIFFICULT MESSAGES TO PATIENTS AND FAMILIES

A key element of the initial interaction with head and neck cancer patients is how the clinician addresses the fears and concerns of patents and their families. Although the physician may desire to defer discussion of diagnosis and possible treatment until after workup is complete and a firm diagnosis is determined, this is often not possible. Patients will often arrive having already received a diagnosis of cancer or may strongly suspect such a diagnosis. Moreover, a significant proportion of patients will have previously been afflicted with a head and neck cancer. Thus, the process of dealing with the possibility (or certainty) of a cancer diagnosis generally begins during the initial interaction with the patient. The potential consequences of the manner in which a cancer diagnosis or prognosis is communicated should not be underestimated. Studies have documented that the manner in which critical prognostic information is communicated to patients and families has a demonstrable impact on long-term patient outcomes.[62] A recent systematic review found that poor caregiver performance in terms of delivering bad news to cancer patients results in increased stress and anxiety levels, more severe adjustment difficulties, and worse overall disease outcomes.[63] Dunn has characterized the delivery of bad news to patients and families regarding head and neck disease as an *invasive procedure*,[64] regarding which clinicians should employ the same level of care and concern for adverse impact as they would use for other invasive interventions.

For patients who ultimately receive a diagnosis of the cancer, the impact of receiving such news is determined not just by the exchange in which they are specifically informed of their diagnosis and prognosis, but in the context of their overall relationship and experience with the cancer caregiver. Schaepe describes patients' experience of learning and accepting a cancer diagnosis as a clinical *process* that may unfold over the course of multiple clinical interactions starting with *first impressions* of the caregiver and culminating in a *realization event* for the patient.[65] Initial assessment and evaluation is the key initial step in the process that plays a determinative role in shaping patient experience, irrespective of whether a specific diagnosis is explicitly delivered at that time.

Loge and colleagues assessed factors determining patients' satisfaction regarding disclosure of a cancer diagnosis and found the factor with the most statistical impact to be patient perception that their physician was *engaged* and *personally interested* in their care. Perceived level of physician interest was significantly more impactful than the amount of time spent with the physician or whether patients completely understood their diagnosis.[66] Using an open-ended interview method, Back and colleagues found that the most important qualities perceived by cancer patients regarding the delivery of cancer diagnoses by providers was *recognition* and *guidance*: patients wanted their clinicians to recognize and acknowledge their experiences in receiving such news, to provide specific guidance regarding the next steps in treatment, and to repeatedly move back and forth between these modes as needed by the patient during the course of the clinical encounter.[67] Although the delivery of bad news must be calibrated to the needs of the individual patient, common themes have emerged in the literature on delivering cancer diagnoses that should inform the provider's approach; Baile and colleagues developed the 6-step SPIKES protocol to help caregivers deliver bad news in accordance with evidence-based standards (Table 2.5).[68]

In communicating the implications of a cancer diagnosis, the clinician should strive to treat the patient with the appropriate

cultural sensitivity and an appreciation of the culturally specific manner in which patients and their families may interpret and respond to a cancer diagnosis and how patients from different backgrounds may deal with issues such as pain and quality of life.[69] In non-Western cultures, cancer illness tends to be a more collective experience involving the entire family, and there is accordingly a more inclusive and consensus-oriented approach to receipt of prognostic information and medical decision making. A recent systematic review of published literature on breaking bad news of cancer found that the most significant differences in patient preferences across cultures involved degree of specificity regarding the involvement of family members in delivery of a cancer diagnosis; less than 30% of Asian patients desired detail regarding life expectancy as compared to >60% of non-Asians.[70] In some Asian societies, the diagnosis of cancer has extremely grave culturally specific implications, and patients and their families may be inclined to view a cancer diagnosis as inevitably terminal and thus view treatment measures as futile. It is thus critically important for providers to attempt to incorporate cultural factors in their approach both to communicating diagnostic and prognostic information and to formulating treatment plans.

## PRETREATMENT PLANNING

Head and neck cancer involves a heterogenous group of pathologic entities, with wide variation in terms of histopathogenesis, tumor biology, required pretreatment workup, optimal treatment modality, prognosis, and quality-of-life implications.[71] Given this complexity, successful management of this disease process requires a concerted multidisciplinary approach. Comprehensive treatment of head and neck cancer patients involves participation by an array of specialists: head and neck surgeons, radiation oncologists, medical oncologists, neuroradiologists, head and neck pathologists, oral pathologists, endocrinologists, facial plastic and microvascular reconstructive surgeons, oral surgeons, maxillofacial prosthodontists, dental pathologists, speech pathologists, social workers, nutritionists, occupational therapists, nursing coordinators, research coordinators, nurses, and others. Coordinating such interdisciplinary care can be challenging, but is necessary in order to furnish optimal patient care.

In most institutions, weekly head and neck tumor boards have emerged as the institutional structure for coordinating the interdisciplinary care of head and neck cancer patients, and recent studies have examined the impact of multidisciplinary tumor boards on the provision of head and neck cancer care. In addition to providing a structured, regular mechanism for interdisciplinary collaboration, tumor boards also provide a forum for reevaluation of outside radiology and pathology findings. A prospective study evaluated 120 consecutive patients presented at a multidisciplinary head and neck tumor board and compared "preconference" and "postconference" diagnosis, stage, and treatment plan. The diagnosis, stage, or treatment was changed in approximately one out of every four patients reviewed. Of these patients, 68% (roughly 18% of the total study population) had their treatment plan altered.[72] In regard to reinterpretation of radiographic studies, a retrospective review of 136 patients demonstrated that review of outside imaging studies by dedicated specialists led to changes in findings in 41% of cases; 34% of patients had a change in T, N, and/or M staging. Furthermore, changes in radiographic findings almost always altered treatment decisions and affected prognosis in 95% of patients.[73] A retrospective review of 213 patients with locally advanced head and neck cancer demonstrated that overall survival in patients managed with tumor board recommendations was comparable to that reported in randomized clinical trials.[74]

Multidisciplinary tumor board participation in evaluation and treatment planning is thus now the standard of care for management of head and neck cancer patients in most settings. Evidence from the literature demonstrates multiple benefits from routine engagement of multidisciplinary tumor boards, including improved staging accuracy, greater accordance with clinical practice guidelines, improved communication between providers, enhanced cost-effectiveness of care, shorter time lapse from diagnosis to initiation of treatment, and improved clinician and patient satisfaction.[74–77]

## CONCLUSIONS

This chapter outlines the required steps in the initial evaluation of head and neck cancer patients and describes the resources available to the clinician in planning further workup and treatment. However, it must be stressed that there is no such thing as a *routine* visit for the head and neck cancer patient. The complexity of the pathologic entities involved and the enormity of the potential impact on patients and their families precludes the adoption of a facile approach to evaluation, treatment, or patient interaction. Head and neck conditions have profound effects on patients because, in addition to the specter of cancer, fundamental qualities of life are often affected, including appearance, facial identity, and key functions of living including breathing, eating, and speaking.[78] Undertaking the treatment of patients with head and neck cancer demands that the clinician maintain both vigilance and vigor in providing the best possible care.

CHAPTER 3

Sung Kim, Benjamin D. Smith, and Bruce G. Haffty

# Prognostic Factors in Patients with Head and Neck Cancer

## INTRODUCTION

Treatment of head and neck cancer requires accurate risk stratification in order to determine the type and extent of therapy and the expected clinical outcome. Physical exam, diagnostic imaging studies, and pathologic review enable the clinician to determine the size and extent of the primary tumor, the status of cervical lymph nodes, and the likelihood of distant metastatic disease, thus generating an accurate tumor, lymph node, metastasis (TNM) stage for each patient. In addition to TNM staging, other clinical and pathologic factors not routinely incorporated into the staging system have been shown to influence response to therapy and eventual outcome. These factors may be categorized as follows: (a) prognostic factors related to the primary tumor, (b) prognostic factors related to the cervical lymph nodes, (c) prognostic factors related to patient demographics, and (d) prognostic factors related to the patient's general medical condition.

In addition to clinical and pathologic factors, recent interest has focused on identifying molecular factors that may influence clinical outcome. These molecular markers not only provide useful prognostic information, but also serve as targets for novel pharmacotherapies that antagonize cellular proliferation by interfering with specific cellular processes. Molecular factors that influence tumor behavior fall into several broad categories, including proto-oncogenes, tumor suppressor genes, growth factors, immune-related factors, loss of heterozygosity at various genetic loci, total cellular DNA content, and parameters related to the kinetics of *in vivo* tumor growth. Finally, the correlation of human papilloma virus (HPV) has been crucial to furthering our understanding of this new and important subset of cancers. This will be discussed in detail in Chapter 12.

When considering prognostic factors in head and neck cancer, several specific outcomes merit attention. In addition to disease-free and overall survival, the relationship between a specific prognostic factor and local recurrence, regional recurrence, and distant metastatic disease must be considered. Factors specifically related to local recurrence may necessitate wider surgical resection, external beam radiotherapy dose escalation or altered fractionation, or the use of a brachytherapy boost to the primary tumor bed. Factors specifically related to regional recurrence may prompt prophylactic neck dissection or radiotherapy in the clinically N0 neck or determine the type of neck dissection selected in patients with clinically positive cervical lymph nodes. Finally, factors predictive of distant metastases may prompt more aggressive screening for concomitant distant metastases before local-regional treatment[1] and influence the decision to offer systemic therapy.

## FACTORS RELATED TO THE PRIMARY TUMOR

### Tumor Dimensions

Tumor size and extent of invasion determine clinical and pathologic T stage for head and neck squamous cell carcinomas (HNSCC). T stage is determined clinically by measuring the maximal surface diameter of a mucosal neoplasm or pathologically by measuring the maximal cross-sectional diameter of a resected tumor. Because tumors arising from mucosal surfaces do not conform to spherical geometry, the maximal tumor diameter does not perfectly correlate with either tumor depth or tumor volume.

As the primary determinant of T stage, maximum tumor diameter has traditionally been considered an important risk factor for the presence of concomitant nodal metastases, local recurrence, and poor survival. For example, in two studies conducted on a total of 603 patients with HNSCC, Magnano et al. found that T stage was a consistent, independent predictor of pathologically positive cervical lymph nodes.[2,3] In addition, pathologic maximal tumor diameter has been shown to predict local recurrence in tumors arising from the lower lip,[4] oral cavity and oropharynx,[5] and larynx.[6] Finally, most studies,[5,7–10] though not all,[11] have shown a univariate association between either clinical or pathologic tumor diameter and survival.

One limitation of using tumor size as a prognostic determinant was highlighted by Moore et al., who stratified 155 patients with oral SCC based on surface diameter of the primary tumor.[7] Eighty-four percent of patients with tumors ≤2 cm survived disease free for 3 years, compared with 52% of patients with tumors larger than 2 cm. However, no significant differences in survival existed between tumors with surface diameters in the following three groups: 2.1 to 3 cm, 3.1 to 4 cm, and >4 cm. Thus, although a gross trend exists between surface diameter and survival, this trend does not follow a simple dose–response relationship. In a follow-up study conducted on 151 patients with oral and oropharyngeal SCC, Moore et al. found that tumor thickness was a more consistent predictor of concomitant nodal metastasis and 3 year disease free survival than tumor surface diameter.[12]

(c) 2014 Wolters Kluwer. All Rights Reserved.

The correlation between tumor thickness and risk of concomitant cervical lymph node metastases has been confirmed in multiple studies.[4,13–20] The critical thickness, above which the risk of nodal metastasis increases substantially, varies depending upon the specific anatomic site involved, perhaps due to variation in density of lymphatic channels.[21] Nevertheless, for most anatomic subsites, the critical thickness ranges from 3 to 5 mm depending upon the specific study. For example, a recent study of 105 patients with clinically node negative oral cavity tumors reported that the risk of occult nodal metastasis was 10% if the tumor thickness was ≤5 mm, compared to 46% if the tumor thickness was >5 mm.[14] Furthermore, in a series of 76 patients with carcinoma of the tongue who all received neck dissection, Woolgar demonstrated that the mean reconstructed thickness of tumors with pathologically positive cervical lymph nodes was 19 mm, compared to 10 mm in patients without metastases.[22] Tumors with a large mucosal surface area but minimal invasion were not at increased risk of nodal metastases. In such cases, clinical and pathologic T stage may overestimate the likelihood of concomitant nodal disease.

In addition to consideration of maximal tumor diameter and thickness, utilization of computed tomography (CT) enables the calculation of total tumor volume. In a series of 63 patients with supraglottic primaries treated with primary irradiation, Mancuso et al. found that tumor volume calculated from pretreatment CT scans was an independent predictor of local control, with local control rates of 89% in tumors <6 $cm^3$ versus 52% for tumors ≥6 $cm^3$.[23] Furthermore, in a study of 103 patients with supraglottic SCC, tumor volume as calculated from pretreatment CT was a stronger predictor of local-regional failure than clinical T stage in multivariate analysis.[24] Hence, calculation of tumor volume using diagnostic imaging provides important prognostic information that can supplement traditional clinical staging for tumors of the larynx. In contrast, T stage, rather than tumor volume estimated from diagnostic imaging studies, appears to be a better predictor of local control for tumors of the oropharynx and hypopharynx treated with definitive radiation.[25]

## Margin Status

The presence of residual carcinoma at the margins of surgical resection is an important risk factor for local recurrence in HNSCC. Although the presence of positive margins may indicate an error in surgical judgment at the time of resection, it may also imply a more biologically aggressive tumor that extends microscopically through the muscle bundles, submucosal lymphatics, and perineural spaces.[26] The precise definition of "positive margins" varies depending on the study and may include invasive tumor involving the initial surgical margin, invasive tumor involving the final surgical margin, invasive tumor approaching within 5 mm of the final surgical margin, carcinoma *in situ* involving the final surgical margin, or dysplasia involving the final surgical margin. Guidelines used in the United Kingdom define "negative" margins as invasive tumor more than 5 mm away from the surgical margin, "close" margins as invasive tumor within 1 to 5 mm from the surgical margin, and "positive" margins as tumor <1 mm from the surgical margin.[21]

In a review of resections for head and neck cancer performed at Memorial-Sloan Kettering Cancer Center, Looser et al. classified 1,775 cases according to final margin status.[27] After excluding patients with gross residual disease, they identified 62 patients with microscopically positive margins, defined as either cancer within 0.5 cm of the margin, marked atypia or premalignant changes in the margin, carcinoma *in situ* in the margin, or invasive carcinoma in the margin. Interestingly, patients in all four of these groups experienced increased local recurrence rates, ranging from 64% in patients with invasive cancer at the margin to 85% for patients with carcinoma *in situ* at the margin, compared to a local recurrence rate of 32% in patients with negative margins.

Many other studies have confirmed the prognostic importance of margin status in HNSCC. The presence of positive margins has been shown to predict local or local-regional recurrence for the following sites: lower lip,[4] oral cavity,[28–30] buccal mucosa,[31] oral tongue,[13,32] oral and oropharyngeal tongue,[33,34] base of tongue,[35] oral cavity and oropharynx,[36] larynx,[37,38] and all sites combined.[39–43] Furthermore, the presence of positive margins predicts poor overall survival in univariate analysis for the following sites: oral cavity,[30] oral tongue,[44] oral and oropharyngeal tongue,[34] oral cavity and oropharynx,[45] base of tongue,[35] supraglottic larynx,[46] larynx,[8,38,47] and all sites combined.[39,40,48,49] Whether or not margin status is an independent predictor of survival remains somewhat controversial, with two studies confirming an independent association,[38,49] but six others failing to find an association.[5,8,9,39,46,50] Margin status has not been shown to predict regional or distant recurrent disease.

Given the negative prognostic implications of positive margins, Byers et al. demonstrated that use of intraoperative frozen sections can identify those patients with initially positive margins and thus allow resection of additional tissue to remove residual carcinoma and reduce the risk of local recurrence.[48] In this cohort of 216 patients with SCC arising from the oral cavity, oropharynx, and hypopharynx, patients with initially positive margins on frozen section received additional resection to achieve final negative margins. Local recurrence in this group was 13%, compared with a local recurrence rate of 12% in patients with negative margins on initial frozen section. Patients with positive final margins suffered from an 80% local recurrence rate. Hence, use of intraoperative frozen section analysis of surgical margins may result in a clinically significant reduction in local recurrence.

However, in a follow-up study of 268 patients with SCC of the tongue, those patients with initially positive margins that were ultimately rendered negative experienced an increased risk of local recurrence and death compared to patients with initially negative frozen section margins.[26] Thus, the authors recommended use of postoperative radiotherapy in all patients with initially positive frozen section margins. One additional concern regarding the use of intraoperative frozen sections to determine margin status is potential inaccuracy, with one study reporting a 14% (7/49) false negative rate for oral cancer.[51]

For those patients with persistently positive margins, postoperative external beam radiotherapy remains an important component of therapy. However, even with combined modality therapy, most investigators,[31,39,42,52] although not all,[53] report an increased incidence of local recurrence in those patients with positive margins. One important factor influencing local control in patients with positive margins is the dose of postoperative radiotherapy, as Zelefsky et al. noted a 7-year local control rate of 92% in patients who received ≥60 Gy, compared with 44% in patients receiving <60 Gy.[53] In addition, interest has grown in using postoperative brachytherapy, either alone or following postoperative external beam radiotherapy, to improve local control in patients with positive margins.[54–57] Beitler et al. reported 29 patients with microscopically close or positive margins after curative surgery treated with postoperative external beam radiotherapy to a median dose of 60 Gy followed by $^{125}$I permanent implant designed to deliver a cumulative lifetime dose of 120 to 160 Gy to the high-risk target volume.[57] This treatment strategy resulted in a 92% 2-year actuarial local control rate and clearly merits further study. Finally, growing evidence from two large randomized trials indicates that the addition of cisplatin (100 mg/$m^2$ on days 1, 22, and 43) to postoperative radiation improves local-regional control and perhaps overall survival for patients with positive surgical margins.[58–60]

## Malignancy Grading

Pathologists have long recognized the potential prognostic significance of cellular morphology in squamous cell carcinoma. In 1920, Broders proposed a four-tiered grading system for carcinoma of the lip that was based on the proportion of the neoplasm resembling normal squamous epithelium.[61] This grading system provides an easily assessed scheme for assessing tumor differentiation and roughly correlates with prognosis, as poorly differentiated tumors are more likely to recur and reduce survival.[30,46,62–68] Broders' grading system has been criticized, however, for its subjectivity and for its failure to consistently predict survival in multivariate modeling.[9,30,46,69,70] The lack of independent significance of Broders' grading system may be due to the association between higher grade (more poorly differentiated) and advanced stage.[71]

In 1973, Jakobsson proposed a semiquantitative grading system that considered not only histologic parameters of the tumor cell population but also the host–tumor interface.[72] Parameters describing the tumor cell population included structure and growth of the neoplasm, degree of keratinization, nuclear pleomorphism, and the frequency of mitoses. The tumor–host interface was assessed for mode of invasion, degree or stage of invasion, vascular invasion, and lymphoplasmacytic cellular response. When this classification system was applied to a series of 42 laryngeal SCCs treated with radiotherapy, tumors with high malignancy grade were more likely to recur and result in death with disease. However, in a subsequent multivariate analysis conducted on 77 patients with oropharyngeal cancer, Crissman et al. found that invasion pattern was the only histologic parameter that independently predicted survival.[73] None of the other histologic parameters, either independently or as a composite score, were significant predictors of outcome.

In 1987, Anneroth et al. reviewed efforts to devise a malignancy grading system and proposed that grading consist of six morphologic features: degree of keratinization, nuclear polymorphism, number of mitoses, pattern of invasion, stage of invasion, and lymphoplasmacytic infiltration.[74] In 1989, Bryne et al. applied Anneroth's grading system to only the most anaplastic fields in the most invasive areas of the tumor (Table 3.1).[75] In two cohorts of 68 and 61 patients with oral SCC, Bryne's invasive cell grading was a highly significant, independent, and reproducible predictor of survival.[75–77] Those patients with a total malignancy score between 5 and 10 experienced a 57% 5-year survival, compared to a 19% 5-year survival in patients with malignancy scores >10. In contrast, Broders' grading system failed to correlate with survival in both cohorts. The authors concluded that histologically invasive regions might be responsible for the clinical behavior of HNSCC. Further study of invasive cell grading (ICG) conducted by other groups has shown that a high ICG score strongly predicts the presence of occult cervical metastases and extracapsular extension (ECE).[17,22,78] Due to the strong correlation between ICG and concomitant nodal metastases, this factor should be considered in decisions regarding elective treatment of the clinically negative neck.

In addition to assessment of malignancy grade, many studies have attempted to determine which individual histologic parameters contribute most strongly to prognosis. Several studies suggest that pattern of invasion may predict outcome independent of other histologic parameters. Tumors that infiltrate in small groups or cords of cells, or infiltrate with marked cellular dissociation, may behave more aggressively. For example, Spiro et al. found that oral tongue SCCs with a high-grade pattern of invasion were more likely to present with concomitant nodal metastases, develop distant metastases, and result in death.[32] In addition, for oral carcinoma that invades the mandible, high-grade invasion pattern increases the rate of mandibular margin positivity and local recurrence and results in a fourfold increased risk of death with disease in multivariate analysis.[79] The correlation of aggressive invasion pattern with poor local-regional control[4,33,80–83] and survival[10,45] has been noted in several other studies.

In addition to pattern of invasion, lymphoplasmacytic infiltration of the tumor bed has been considered as a potential independent marker of prognosis. In a study of 396 patients with HNSCC, multivariate analysis revealed that the presence of a lymphocytic tumor infiltrate decreased the risk of concomitant

**TABLE 3.1 Invasive Cell Grading System**

| | Score | | | |
|---|---|---|---|---|
| **Morphologic Feature** | **1** | **2** | **3** | **4** |
| Degree of keratinization | Highly keratinized (>50% of the cells) | Moderately keratinized (20%–50% of the cells) | Minimal keratinization (5%–20% of the cells) | No keratinization (0%–5% of the cells) |
| Nuclear polymorphism | Little nuclear polymorphism (>75% mature cells) | Moderately abundant nuclear polymorphism (50%–75% mature cells) | Abundant nuclear polymorphism (25%–50% mature cells) | Extreme nuclear polymorphism (0%–25% mature cells) |
| Number of mitoses (high-power field) | 0–1 | 2–3 | 4–5 | >5 |
| Pattern of invasion | Pushing, well-delineated infiltrating borders | Infiltrating, solid cords, bands, and/or strands | Small groups or cords of infiltrating cells | Marked and widespread cellular dissociation in small groups and/or in single cells ($n < 15$) |
| Lymphoplasmocytic infiltration | Marked | Moderate | Slight | None |

cervical lymph node metastases, whereas a plasmacytic infiltrate increased the risk.[2] In addition, several studies have reported a correlation between lymphocyte infiltration and improved local-regional control.[81,84,85]

Basaloid SCC (BSCC) is a rare variant of SCC that has historically been thought to be chemo- and radiosensitive, with similar-to-better loco regional control than "typical" SCC, but with higher risk of distant metastases. Soriano reported a case control series of BSCC versus SCC treated with various modalities and reported that loco regional recurrence caused death in only 15% of the BSCC patients versus 51% of the SCC patients. Distant metastasis, however, occurred in 45% versus 7%, respectively.[86] Thariat reported a case control series of radiated patients with BSCC versus poorly differentiated (PSCC) or well-differentiated SCC (WSCC). The loco-regional control for BSCC, PSCC, and WSCC was similar at 81%, 86%, and 82%, respectively; distant metastases free survival was worse for BSCC at 71%, 86%, and 86%, respectively, but not significantly so.[87]

Why the seeming inconsistency that BSCC is considered an aggressive variant of SCC, yet HPV-associated SCC is more commonly BSCC but has a better prognosis? It may be that BSCC is a more heterogeneous disease than previously recognized. Certainly the demographics of the BSCC patient are evolving: whereas the typical BSCC patient has been thought to be in his 60s or 70s, with history of frequent, intense tobacco use and alcohol use, recent cases have also affected young women without a significant tobacco or alcohol history, suggesting a causal link between BSCC and HPV-associated SCC.[88] Therefore, BSCC may have a dual nature similar to SCC, depending on factors such as HPV status and tobacco and alcohol use.

## Perineural Invasion

Infiltration of perineural spaces occurs in up to 52%[89] of HNSCCs and was first noted to influence surgical and adjuvant treatment strategies by Ballantyne et al. in 1963.[90] Perineural invasion (PNI) may result in dysphagia secondary to involvement of the vagal trunk[91] or pain and paresthesias along the territories of the glossopharyngeal or trigeminal nerves.[91,92] CT findings suggestive of PNI include obliteration of the fat within the pterygopalatine fossa, enlargement of neural foramina, and increased enhancement in the region of Meckel's cave.[93] In addition, a study of 48 patients with oral tongue, base of tongue, or floor of mouth SCC utilized CT to identify the presence of vascular and/or PNI with a sensitivity of 88% and a specificity of 83% using criteria including "aggressive" tumor margins, invasion of the sublingual space, and direct adjacency to the lingual vasculature.[94]

PNI may be mediated by the presence of nerve cell adhesion molecule (N-CAM) on the surface of squamous carcinoma cells, which engages in homophilic binding with N-CAM expressed in neural and perineural tissues. In two studies of 76 and 66 patients with HNSCC, expression of N-CAM on the surface of neoplastic cells was significantly associated with PNI detected on review of pathologic sections.[95,96]

Numerous clinical studies have identified PNI as an important predictor of poor prognosis. In tumors arising from the lower lip,[4,97,98] oral tongue,[99] oral cavity,[20,89,100,101] larynx,[102] and all sites combined,[2,3] the presence of PNI is associated with a higher risk of metastasis to regional lymph nodes. Furthermore, following definitive treatment of HNSCC, the presence of PNI in the primary tumor is associated with poor local control,[4,89,103,104] regional control,[64] local-regional control,[81,84,105,106] cause-specific survival,[89,105] and overall survival.[44,105] PNI has been associated with an increased risk of distant metastasis in some,[107] though not all,[108] studies.

The association between PNI and local recurrence may result from either centrifugal or centripetal propagation of malignant cells along perineural spaces and away from the primary tumor. Most primary tumors will only disseminate up to 2 cm along the perineural space,[109] although PNI 12 cm from the primary tumor has been reported.[90] As a result, PNI may allow malignant cells to evade surgical excision or radiotherapy and result in local recurrence. In addition, the association between PNI and regional recurrence implies that these tumors may be more biologically aggressive. The association between *perineural* invasion and tumor aneuploidy, a known marker of poor prognosis, lends support to this hypothesis.[110]

Despite the clear importance of PNI, the percentage of mucosal HNSCCs positive for PNI varies widely in the literature, from 5%[104] to 52%.[89] This discrepancy may result from a tendency to identify PNI only when large, named nerves are involved. However, although PNI of small, unnamed nerves may not result in clinical symptoms, the relationship between PNI and prognosis appears to be independent of nerve diameter.[89] Hence, all HNSCC pathologic specimens should be closely examined for PNI, even in nerves <1 mm in diameter.

## Vascular Invasion

Vascular invasion, defined as the presence of neoplastic epithelium within an endothelial-lined channel, occurs in over 50% of HNSCCs.[5,22,111] As with tumor depth and pattern of invasion, the presence of vascular invasion may identify tumors with an aggressive biologic nature due to their ability to invade normal anatomic structures. Indeed, vascular invasion has been shown to correlate with the presence of concomitant cervical metastases in both univariate[20,22,45,103,111] and multivariate models.[2,3,99,112] In addition, the presence of vascular invasion in the primary tumor specimen has been noted to increase the risk for subsequent local regional recurrence in oral cavity, oropharyngeal, and laryngeal SCC treated surgically.[5,64,103] However, in a large series of 226 patients treated with surgery and postoperative radiotherapy, vascular invasion did not correlate with local-regional control, suggesting that postoperative radiotherapy may mitigate the poor prognosis associated with vascular invasion.[106] Vascular invasion has also been associated with increased risk of distant metastatic disease.[5,69]

## Imaging

$^{18}$F-fluorodeoxyglucose (FDG) PET scan is a functional test that combines a positron-emitting nuclide with a glucose molecule, thereby revealing areas of increased glucose metabolism. PET/CT scans are commonly performed prior to therapy to determine extent of disease, and afterward to assess response and need for further treatment.

The utility of a posttreatment PET has been well studied. Isles performed a meta-analysis of radiated patients who received posttreatment FDG PET scans. The weighted mean pooled sensitivity, specificity, PPV, and NPV of posttreatment PET for the primary site was 94%, 82%, 75%, and 95%, respectively. At the neck, the corresponding numbers were 74%, 88%, 49%, and 96%, respectively. They reported that sensitivity was greater for scans performed 10 weeks or longer after completion of therapy.[113] Gupta also performed a meta-analysis; his corresponding numbers for the primary site were 79.9%, 87.5%, 58.6%, and 95.1%, respectively, and for the neck 72.7%, 87.6%, 52.1%, and 94.5%, respectively. Scans performed ≥12 weeks after therapy had moderately higher diagnostic accuracy.[114]

Moeller prospectively compared posttreatment PET/CT with contrast-enhanced CT in radiated patients. Patients were imaged with PET/CT and CT prior to and 8 weeks after radiation.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Though postradiation maximum SUVs were significantly higher in nonresponders compared with responders, the positive and negative predictive values for PET/CT were similar to CT alone. In order to improve the PPV of the postradiation scans, they stratified patients into high-risk (HPV negative, nonoropharynx primary, tobacco history) and low-risk categories. In the high-risk patients, PET/CT outperformed CT alone, especially in terms of accurately detecting residual nodal disease, where the PPV for PET/CT was twice that of CT alone (75% vs. 37.5%).[115]

Whether pretreatment PET/CT reveals loco-regional versus metastatic disease is clearly prognostic, but the predictive value of pretreatment SUV in localized disease is controversial. Moeller found no significant difference in the pretreatment SUVmax at the primary site or lymph nodes between responders and nonresponders.[115] Higgins came to a similar conclusion, but did report that increased pretreatment SUVmean at the primary site correlated with disease-free survival.[116] Imsande found that SUVmax at the primary site correlated with overall survival, whereas Demirci found that disease-free survival correlated with nodal (but not primary site) SUVmax.[117,118] Tang[119] evaluated metabolic tumor volume (MTV) on pretreatment PET-CT and concluded that MTV was an independent predictor of outcomes. Specifically, MTV $>17$ cm$^3$ was associated with a greater risk of both disease progression and death. Lim[120] also reported that primary tumor MTV was predictive of local failure, distant metastases, and overall survival.

In conclusion, a negative posttreatment PET/CT that is appropriately timed portends a favorable prognosis and may be especially helpful in higher-risk patients. A positive result is less reliable, probably due to the possibility of a false positive due to residual inflammation or infection.

# FACTORS RELATED TO THE CERVICAL LYMPH NODES

## Number of Positive Lymph Nodes

The number, size, and location of positive cervical lymph nodes define the N stage for HNSCC and provide important information regarding prognosis and selection of treatment. The number of cervical lymph nodes histologically positive for squamous cell carcinoma provides one of the simplest, and perhaps most important, prognostic markers in head and neck cancer. Mamelle et al. retrospectively reviewed 914 patients who received cervical lymph node dissection as a component of initial therapy for oral cavity, oropharyngeal, hypopharyngeal, and laryngeal SCC.[121] Patients with palpable lymph nodes >3 cm underwent radical lymph node dissection, and all other patients underwent selective neck dissection on sentinel nodes with immediate pathologic evaluation. Those patients with positive sentinel nodes then received ipsilateral modified radical neck dissection and contralateral selective neck dissection. Thus, all patients, regardless of their clinical N stage, received pathologic evaluation of their cervical lymph nodes. Those patients with positive cervical lymph nodes received 50 Gy to the neck with a 15 Gy boost in areas of extracapsular spread. In this study, lymph node number exhibited a strong dose–response correlation with distant metastasis and survival (Fig. 3-1). In multivariate analysis stratified by tumor site and patient age, number of positive nodes was a significant, independent predictor of survival. Furthermore, although extracapsular spread and node location (upper vs. middle vs. lower neck) were significant predictors of survival in univariate analysis, after controlling for number of positive lymph nodes,

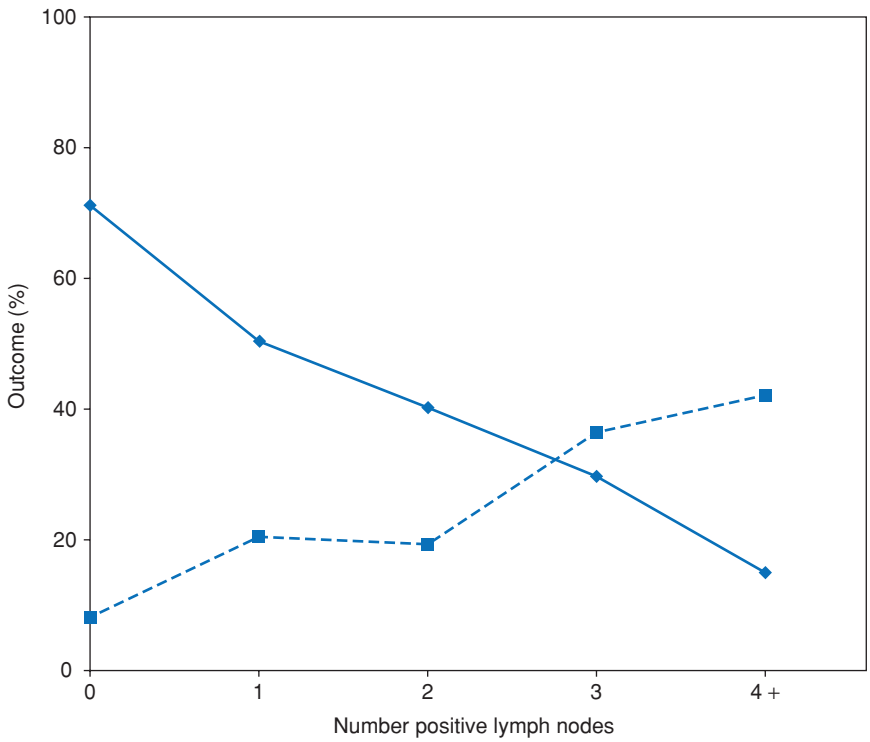

**FIGURE 3-1.** Number of positive cervical lymph nodes as a predictor of distant metastasis and 5-year overall survival in a cohort of 914 patients undergoing lymph node dissection for a primary head and neck squamous cell carcinoma.

they lost their prognostic significance. Thus, with this particular treatment algorithm, the number of positive nodes emerged as an important, independent predictor of prognosis.

The importance of positive cervical nodes has been noted in many other studies and appears to correlate with risk of regional recurrence and distant metastasis. Studies have demonstrated a correlation between increasing number of positive nodes and regional recurrence in patients with advanced SCC who receive postoperative radiotherapy,[122] patients who do not receive radiotherapy,[64] patients with oral cavity[30] and hypopharyngeal or lateral epilaryngeal primary tumors,[123] and patients who receive neck dissection for mucosal HNSCC from any site.[124,125] Furthermore, number of positive nodes clearly predicts risk of distant metastatic disease for all sites of HNSCC.[11,108,121,126–130] Number of positive nodes predicts both regional recurrence[64] and distant recurrence,[129] even after controlling for other prognostic variables in multivariate analysis.

Finally, the number of positive cervical lymph nodes consistently correlates with survival in univariate analysis for all major sites of HNSCC.[9,30,62,122,123,126,131–135] The relative importance of ECE versus number of positive nodes remains somewhat controversial. In addition to the Mamelle et al. study,[121] Moe et al. found the number of positive nodes to predict poor survival independent of ECE in 159 patients with advanced laryngeal cancer.[11] However, cohorts of 136 patients with clinically node positive oral cavity cancer[63] and 281 patients with supraglottic cancer[46] found that ECE, not number of positive nodes, was an independent predictor of poor survival. Differences in treatment modalities and stratification of pathologic variables may explain some of the differences noted in these studies. Regardless, patients with either multiple positive lymph nodes or ECE are at higher risk for recurrence and should be considered for aggressive therapy.

## Extracapsular Extension

ECE occurs in roughly 60% of patients with positive cervical nodes and is of paramount importance in predicting patient outcomes.[136,137] A recent study of 337 patients reported a strong association between the presence of ECE and clinical N stage, with ECE present in 10.5% (18/171) of clinical N0 patients, 35% (26/75) of clinical N1 patients, 55% (35/64) of clinical N2 patients, and 74% (20/27) of clinical N3 patients.[135] The extent of ECE can be stratified into the following three levels based on the morphology of the involved cervical lymph nodes: (a) macroscopic extracapsular spread with involvement of adjacent anatomic structures such as the internal jugular vein or skeletal muscle, (b) macroscopic extracapsular spread confined to the perinodal fibro-adipose tissue, and (c) microscopic extracapsular spread.[22] A recent study of 96 dissected cervical lymph nodes with ECE measured the maximum distance from the capsule border to the farthest extent of the tumor.[138] The mean extension was 2.2 mm, and in 96% of lymph nodes the maximum extension was <5 mm. Rarely, the extension measured up to 9 mm. These findings have important implications for target delineation in the setting of intensity modulated radiation therapy to treat lymph nodes at high risk for ECE.

As a general marker of tumor invasiveness and biologic aggressiveness, some authors have proposed that the presence of ECE in cervical lymph nodes may predict recurrence at the primary site. This hypothesis remains unresolved, as two studies conducted on a total of 207 patients with laryngeal cancer noted a significant association between ECE and local recurrence,[139,140] but two other studies conducted on a total of 392 HNSCC patients failed to confirm this association.[123,136]

Regardless of its relationship with local recurrence, ECE is a significant determinant of prognosis due to its association with increased risk of recurrence in the neck and distant metastatic disease. For example, in a review of 284 patients with HNSCC who received neck dissection as a component of initial therapy, the presence of gross or microscopic ECE tripled the risk of neck recurrence in multivariate modeling.[64] In addition, patients with gross ECE were 1.5 times more likely to develop regional recurrence when compared to patients with microscopic ECE, although this trend did not reach statistical significance. Many other series have confirmed this relationship for the following sites: oral tongue,[22] oral cavity and oropharynx,[5,29] hypopharynx and lateral epilarynx,[123] pyriform sinus,[9] supraglottic larynx,[139,141] larynx,[140,142,143] and all sites combined.[70,122,124,125,144] The association between ECE and regional recurrence is independent of other prognostic variables in HNSCC.[64,125,142]

The presence of ECE also increases the risk of distant metastatic disease. In a review of 281 patients who received a neck dissection as a component of initial therapy for HNSCC, the presence of ECE tripled the risk of distant metastasis as the first site of failure (19.1% in ECE positive patients vs. 6.7% in ECE negative patients).[127] These findings have been reproduced in several large studies.[108,126,128,135,145] Currently, it is unclear whether the relationship between ECE and distant metastatic disease is independent of the number, size, and location of positive cervical lymph nodes.

In addition, ECE is a significant predictor of poor disease-free, cause-specific, and overall survival. In a retrospective study of 281 patients with supraglottic SCC treated with surgery with or without postoperative radiotherapy, pathologic N0 patients experienced a 5-year overall survival of 65%, compared to 49% in node-positive patients without ECE and 20% in node-positive patients with ECE.[46] In a multivariate model, the presence of ECE conferred the highest risk of death, resulting in a sixfold increased risk of death when compared with node-negative patients. In contrast, patients with positive nodes but no ECE experienced a threefold increased risk of death. This independent association between ECE and poor cause-specific or overall survival has been confirmed for the following sites: oral cavity,[63] oral cavity and oropharynx,[5] supraglottic larynx,[62] larynx and hypopharynx,[143] and all sites combined.[49,125,142]

The importance of ECE as compared to other pathologic factors was underscored in a prospective randomized clinical trial conducted by Peters et al. that evaluated radiation dose in the postoperative setting.[146] In this trial, patients with ECE experienced significantly higher local-regional recurrence rates than patients without ECE. In addition, in the subset of patients without ECE, only those patients with four or more adverse risk factors experienced a local-regional recurrence rate comparable to those patients with ECE. Adverse factors examined included oral cavity primary, close or positive margins, PNI, two or more positive nodes, largest node >3 cm, Zubrod score ≥2, and delay in starting radiotherapy. As a result, the study authors concluded that ECE is the dominant pathologic risk factor in HNSCC. Furthermore, this study showed that, in patients with ECE, local-regional control increased from 52% to 74% as dose increased from 57.6 to 63 Gy. No such dose–response was evident for patients without ECE, suggesting that tumors with ECE require a higher dose of postoperative radiation to achieve adequate local-regional control.

Due to the poor prognosis associated with ECE, several investigators have explored the potential benefit of postoperative chemoradiation in this patient population. The first randomized data to support a benefit of chemoradiation was reported by Bachaud et al. in 1996.[147] This trial included 83 patients with histologically documented ECE treated with surgery and postoperative radiation with or without concurrent cisplatin (50 mg given weekly with radiation for seven to nine cycles). The addition of cisplatin lowered the risk of local-regional recurrence, from 41% in the radiation alone group down to 23% in the chemoradiation

(c) 2014 Wolters Kluwer. All Rights Reserved.

group. Subsequently, large multicenter trials conducted by the Radiation Therapy and Oncology Group (RTOG) and the European Organization for the Research and Treatment of Cancer (EORTC) randomized patients with high-risk, resected head and neck cancer to receive postoperative radiation or postoperative radiation with concurrent cisplatin (100 mg/m$^2$ given on days 1, 22, and 43).[58,59] A *post hoc* pooled analysis revealed that the addition of cisplatin was specifically beneficial for patients with ECE, lowering the relative risk of local-regional recurrence by 50% and also improving overall survival.[60] The updated data on the RTOG 9501 Intergroup Phase III trial has failed to show an overall benefit to the addition of chemotherapy, with a median follow-up of 9.4 years.[148] However, the subgroups with positive resection margins or extracapsular spread did have improved loco regional control with the addition of chemotherapy.

## Node Location

The anatomic location of positive cervical lymph nodes has been classically described by dividing the neck into five anatomic levels.[149] Level I refers to nodes within the submandibular and submental triangles. Levels II, III, and IV refer to the chain of nodes along the upper, middle, and lower third of the jugular vein, respectively. Level V refers to nodes along the spinal accessory nerve and within the posterior cervical triangle. Using these categories, Mamelle et al. defined sentinel nodes as those nodal groups that provide the primary lymphatic drainage for a particular site within the head and neck.[121] Thus, sentinel nodes for oral cavity tumors were defined as levels I, II, and III; and sentinel nodes for oropharyngeal, hypopharyngeal, and laryngeal tumors were defined as levels II and III. Applying this classification to cervical node pathologic specimens from 914 HNSCC patients, Mamelle et al. found that the presence of nodal metastases outside the sentinel node region independently decreased 5-year survival by more than 50% and nearly doubled the rate of distant metastasis. Furthermore, node location inside versus outside of the sentinel area predicted survival independent of number of positive nodes and extracapsular spread. The increased risk of regional recurrence, distant recurrence, and death associated with positive low cervical lymph nodes has been noted in several other studies of patients with HNSCC.[11,36,123,129,131,132,134,150,151] Setton[152] reported that low-lying cervical metastases (levels IV, VB) were independent predictors of distant metastasis. Finally, de Bree et al. found that 33% of HNSCC patients with low jugular lymph node metastases showed evidence of concomitant distant metastatic disease on preoperative CT of the thorax.[1] Clearly, patients with positive lymph nodes outside of the sentinel node regions merit aggressive preoperative screening for distant disease and are at increased risk of treatment failure and death following aggressive local-regional therapy.

## Node Size

The diameter of the largest metastatic cervical lymph node contributes to the assessment of N stage in HNSCC and may correspond with total tumor burden. In a review of 250 radical neck dissection specimens, Carter et al. found that pathologic nodal size >2 cm correlated with increased risk for regional recurrence.[125] However, several other studies have failed to determine a relationship between node size assessed clinically or pathologically and either regional recurrence or local-regional recurrence.[36,38,124] In contrast, Mamelle et al. found that nodal size increased the risk of distant metastases, with patients having nodal diameter <3 cm experiencing a distant metastasis rate of 22%, compared with 35% for patients with nodal diameter between 3 cm and 6 cm and 49% for patients with nodal diameter >6 cm.[121] Furthermore, in a multivariate analysis of clinical parameters only, node size was a significant predictor of poor overall survival. In contrast, other studies have not found an independent relationship between pathologically assessed nodal size and survival when other relevant pathologic variables are considered.[9,38,125,143] Thus, the diameter of the largest positive cervical lymph node may serve as a helpful clinical predictor of outcome, but may not exert an independent prognostic when other pathologic factors are considered.

## Pathologic Residual Disease on Neck Dissection After Chemotherapy

In Chapter 14, there is a comprehensive discussion of all aspects of neck management. In the current era of definitive, concomitant chemotherapy-radiation therapy, neck dissection is often used exclusively when there is suspicion of residual disease on PET-CT performed about 3 months after treatment. This is discussed at length in Chapter 14. For this subset of patients, the presence of pathologic residual disease in the neck after chemotherapy has prognostic value.[153] Hu also reported the prognostic value of pathologic residual neck disease in patients who have planned neck dissections after chemotherapy. In both subsets, there is an adverse impact on risk of distant metastasis and disease-free survival.

# DEMOGRAPHIC PARAMETERS

## Age

Age is a commonly considered covariate and is known to influence outcome in certain types of cancer. For example, patient age and attendant comorbidities may influence the vigor of the immune response directed against the tumor and the patient's ability to tolerate maximal therapy. In addition, head and neck cancers arising in patients at either extreme of the age continuum may result from different etiologic agents and thus manifest different clinical outcomes. For example, Schantz et al. found that cultured lymphocytes from nonsmoking young adults with HNSCC were more susceptible to bleomycin-induced chromosome damage than lymphocytes from older smokers with HNSCC and healthy controls, suggesting that genetic susceptibility to environmental carcinogens may influence the risk of HNSCC in young adults.[154] Recently, investigators have noted a striking increase in the incidence of tongue and tonsillar cancer in adults under 40 years of age, thus prompting additional interest in the risk factors, natural history, and optimal treatment of HNSCC in the young.[155] The relationship of HPV to these malignancies has become well established and is covered later in this chapter as well as in Chapter 12.

Risk factor profiles indicate that young adults with HNSCC are less likely to report prior exposure to tobacco or alcohol and more likely to be female.[156,157] With respect to clinical outcome, Siegelman-Danieli et al. examined a retrospective cohort of 87 oral tongue SCC patients, 30 of whom were 45 years of age or younger at the time of diagnosis.[157] In this study, age did not influence relapse rates, cancer-free survival, or overall survival in both univariate and multivariate analysis. Similarly, Verschuur et al. conducted a retrospective case-control study on 185 previously untreated HNSCC patients under the age of 40 who were matched to controls based on tumor site, sex, and date of presentation.[156] Age did not influence cause-specific survival in univariate or multivariate analysis. However, older patients were twice as likely to develop second primary SCCs of the upper aerodigestive tract (14% vs. 7%), possibly due to their increased use of tobacco products. The effect of young age remains controversial, however, as a recent report on 1,030 HNSCC patients found that the recurrence risk was 50% less for patients under the age of

(c) 2014 Wolters Kluwer. All Rights Reserved.

40 as compared to those over the age of 40, even after controlling for TNM stage, primary tumor site, and comorbidity.[158] Therefore, the current literature suggests that young patients experience a prognosis that is either similar to or slightly better than that experienced by older patients. Because HPV status was not known in most prior studies, its effect on this cohort is difficult to assess.

Head and neck cancers in elderly populations also present a different epidemiologic profile. In a study of 161 elderly patients with HNSCC, Leon et al. found that patients over the age of 70 were less likely to use tobacco and alcohol and more likely to be female.[159] The decreased consumption of tobacco and alcohol in elderly HNSCC patients correlates with a lower incidence of *p53* mutations in this population.[160] With respect to survival, Leon et al. demonstrated that although elderly laryngeal cancer patients experienced worse overall survival, cause-specific survival was not influenced by patient age. Furthermore, in a prospective study of 203 head and neck cancer patients, advanced age correlated with worsening 2-year overall survival in univariate analysis, but this association was not significant when adjusted for TNM stage and the presence of comorbid illness.[161] Finally, a population-based case-control study that included over 5,000 patients found that, after adjusting for stage, elderly patients age 70 years and older did not experience significantly worse cause-specific survival than their younger counterparts.[162] Thus, although elderly HNSCC patients may present with different risk factor profiles and are at increased risk of death from comorbid illness, they are not at an increased risk of death from cancer and should receive curative treatment if possible.

Though their cancers may not necessarily act worse stage for stage, the patients themselves may have difficulty withstanding the most toxic treatments. For example, chemoradiation is associated acutely with skin and hematologic toxicities, fatigue, mucositis, dysphagia, odynophagia, xerostomia, and change in taste. The meta-analysis of chemotherapy in head and neck cancer (MACH NC) reported that the benefit of adding concurrent chemotherapy to radiation decreased with advancing age. There was a significant OS advantage for patients up to 70 years old, but not for patients 71 and older.[163] In a more recent publication, MACH NC breaks down the benefit by primary site in addition to age.[164]

## Sex

Sex is not generally considered a significant determinant of survival in patients with head and neck cancer. Indeed, most large series have failed to find a significant difference in outcome with respect to sex.[66,165–170] In contrast, one relatively large study conducted on 278 patients with stage I to IV laryngeal cancer found an independent association between sex and survival.[38] In this study, female patients experienced a 76% 3-year overall survival, compared to 63% in male patients. However, the disease-free interval was nearly identical, 60.4 months in women and 59.7 months in men. Thus, it is likely that the survival benefit experienced by women was more likely due to sex-specific differences in the distribution of comorbid illness rather than sex-specific differences in tumor behavior.

## Race

Data from the National Cancer Institute's SEER registry indicate that both the incidence of HNSCC and its disease-specific mortality are higher in Black males than White males.[171] In contrast, such race-based differences are not apparent among females. Race-based differences in stage at presentation may account for the increased burden of HNSCC mortality among Black males. For example, in a cohort of 295,022 patients with HNSCC reported by the National Cancer Database, 40% of African Americans presented with stage IV disease, compared with 24% of Whites and 26.4% of Hispanics.[71] Other factors that may contribute to increased disease-specific mortality in Black males may include a higher prevalence of alcohol abuse and lack of health insurance.[172] In studies that have adjusted for both disease-related and socioeconomic-related factors, Black race does not appear to be associated with increased disease-specific mortality, suggesting that the biologic aggressiveness of HNSCC does not fundamentally differ between White and Black patients.[161,172] However, one study has shown that Black race is associated with a higher risk of distant metastatic disease even after adjusting for relevant covariates,[173] and this finding merits further study.

Recently, Settle et al. proposed an alternative reason for Black HNSCC patients' worse prognosis. They looked retrospectively at data from the phase 3, multicenter TAX 324 trial of induction chemotherapy followed by concurrent chemoradiation in HNSCC patients. The racial disparity in overall survival was due entirely to the subgroup of patients with oropharyngeal cancer, in which the OS for Whites versus Blacks was 69.4 months and 25.2 months, respectively ($p = 0.0006$). OS was not reached in the HPV-positive patients versus 26.6 months in the HPV-negative patients (hazard ratio [HR] 5.1; $p < 0.0001$). Whites were significantly more often HPV-16 positive than Blacks, 34% versus 4% ($p = 0.0004$). Furthermore, survival was similar for Whites versus Blacks in nonoropharyngeal sites and in HPV-negative patients.[174] This study represents one of the very first biologic rather than socioeconomic rationales for difference in racial outcomes in HNSCC.

## Alcohol and Tobacco Exposure

Tobacco and alcohol use have long been recognized as important risk factors for the development of HNSCC. Exposure to these carcinogens results in specific molecular insults that promote neoplasia. For example, cigarette smoking has been associated with overexpression of the proto-oncogene bcl-2, a protein known to inhibit apoptosis.[175] In addition, concurrent use of alcohol and tobacco has been associated with a high rate of nonspecific mutations in the tumor suppressor gene *p53*.[176] Perhaps as a result of these deleterious mutations, prior or continued use of alcohol and tobacco in patients with head and neck cancer is a risk factor for poor outcome. Furthermore, use of these substances has been associated with immunosuppression, malnutrition, and impaired tissue oxygenation resulting in hypoxic radioresistance.

The most rigorous exploration of the relationship between alcohol consumption and outcome in head and neck cancer patients resulted from a prospective study of 649 patients who received in-depth questioning near the time of diagnosis regarding alcohol consumption, treatment for alcoholism, abstinence from alcohol prior to the diagnosis of cancer, and alcohol-related health problems.[66] The authors utilized the Michigan Alcoholism Screening Test (MAST) to devise a three-tier alcohol severity staging system to allow rapid risk stratification of head and neck cancer patients. Stage A included nonalcoholics and abstinent (less than one drink per week) alcoholics without a history of alcohol-related systemic health problems. Stage B included abstinent alcoholics with a history of alcohol-related systemic health problems and alcoholics currently drinking without a history of alcohol-related systemic health problems. Stage C included alcoholics currently drinking with a history of alcohol-related systemic health problems. Patients in stages B and C were more likely to die from any cause following treatment for HNSCC. In addition, after adjusting for other potential predictors of survival, stage C patients were two times more likely than stage A patients to die from HNSCC. The authors speculated that alcohol intake may influence outcomes by contributing to immunosuppression and malnutrition.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Of note, this study provided indirect evidence that interventions to eliminate alcohol intake may help to improve outcomes. After controlling for relevant covariates, alcoholics abstinent at the time of diagnosis were half as likely to die as alcoholics who were currently drinking. Eighty percent of abstinent alcoholics had received formal treatment for their alcoholism, either through inpatient programs or Alcoholics Anonymous.

The interaction between cigarette smoking and response to radiotherapy was demonstrated in a prospective study of stage III to IV HNSCC patients treated with primary irradiation with or without concomitant 5-fluorouracil.[177] Any smoking during the 6½-week course of radiotherapy decreased the complete response rate from 74% to 45%, the 2-year survival rate from 66% to 39%, and the median survival from 30 to 16 months. In addition, mortality was influenced by the length of time between smoking cessation and initiation of treatment, with a risk reduction of 40% for those patients who quit <12 weeks prior to diagnosis and of 70% for patients who quit more than 1 year prior to diagnosis. In multivariate analysis, smoking was the only significant predictor of survival, with those who abstained 2.5 times more likely to survive. The authors speculated that the deleterious impact of smoking may be related to lower levels of natural-killer-cell activity, reduced cell-mediated immunity, and increased blood carboxyhemoglobin concentrations, resulting in tissue hypoxia and increased radioresistance.[178] The adverse effect of continued smoking during radiotherapy has also been noted in two studies conducted on patients with T1 and T2 glottic carcinomas treated with primary radiation.[179,180] In addition to mortality, continued smoking doubles the risk of long-term complications in patients with T1 glottic cancer treated with primary radiation.[181]

To evaluate the effect of alcohol and tobacco consumption on the risk of second primary malignancies, Day et al. conducted a nested case-control study composed of 80 case patients with second cancers and 189 sex- and survival-matched oral cancer patients free of second cancers.[182] The risk of a second primary tumor of the aerodigestive tract (oral cavity, pharynx, larynx, esophagus, and lung) increased with both number of cigarettes smoked per day and years of cigarette smoking, peaking at odds ratio of 4.7 for those patients who smoked 40 or more cigarettes per day for 20 or more years. Similarly, consumers of 15 or more beers per week experienced a 3.8-fold increased risk of aerodigestive tract second primary tumors when compared to nondrinkers or light drinkers (0–4 drinks per week). There was little or no excess risk for hard liquor and wine drinking.

Day et al. also investigated the relationship between cessation of smoking or drinking at the time of diagnosis and risk of second primary tumor. Cessation of smoking at the time of diagnosis did not decrease the risk of second primary tumors within the first 5 years after diagnosis. However, risk was significantly reduced 5 years after smoking cessation. Thus, smoking cessation at the time of diagnosis may reduce the long-term risk of second primary tumors. No clear trend existed between cessation of alcohol consumption and risk.

Due to the well-documented deleterious effects of tobacco and alcohol use, in addition to data suggesting that abstinence from these substances may improve outcomes, substance abuse counseling and cessation programs should be integrated into the care of head and neck cancer patients.

# FACTORS RELATED TO THE PATIENT'S GENERAL MEDICAL CONDITION

## Comorbidity

Comorbidity refers to the presence of other diseases, illnesses, or conditions not directly related to the index cancer. Although not included in TNM staging, comorbidity directly influences the care of cancer patients, selection of treatment modalities, and evaluation of treatment effectiveness. Multiple instruments have been utilized to characterize comorbidity in head and neck cancer patients, and no single instrument has been consistently shown to be superior.[183] Using a four-tiered classification (none, mild, moderate, and severe), Piccirillo found that 24% of head and neck cancer patients suffer from moderate or severe comorbidity.[184] Examples of moderate comorbidity include poorly controlled hypertension, old stroke with residua, and history of an alcoholic seizure. Examples of severe comorbidity include congestive heart failure or myocardial infarction within the last 6 months, recent stroke, and severely decompensated alcoholism. In a prospective study of 1,086 patients with primary head and neck cancer, the presence of comorbidity was a significant, independent predictor of 2-year survival, even after controlling for age, sex, race, and stage.[184] As compared to patients without comorbidity, the mortality HR was 1.9 for patients with moderate comorbidity and 2.5 for patients with severe comorbidity. Similar results were reported in a study of 9,386 elderly Medicare beneficiaries with HNSCC.[185]

Given the importance of comorbidity as a predictor of survival, efforts have been made to develop new systems for staging head and neck cancer that combine TNM staging with symptom-severity and comorbidity indices. The general scheme for such a staging system of oral cavity cancer is presented in Figure 3-2. Of note, the most advanced stage, stage D, is determined solely by the presence of severe comorbidity or moderate or severe symptom severity. Hence, advanced TNM stage alone is not sufficient to merit placement in the worse prognostic category. Utilizing multivariate modeling, the investigators convincingly demonstrated that this model was more strongly predictive of disease-free and overall survival than TNM staging alone in a retrospective cohort of 277 patients with oral cavity SCC.[186] Similar results were obtained in other retrospective studies conducted on oral cavity,[187] oropharyngeal,[188] and laryngeal[189] cancers. Clearly, the combination of comorbidity, symptom severity, and TNM stage holds promise for more accurate prognostication in head and neck cancer and merits prospective validation.

## Nutritional Status

Malnutrition is common in patients with head and neck cancer and attributable to a number of causes including poor dietary habits, excessive alcohol consumption, local tumor effects, tumor-induced cachexia, and the effects of various therapies.[190] In 1984, Goodwin and Torres applied a prognostic nutritional index to a retrospective cohort of 50 consecutive patients with advanced head and neck cancer to determine whether nutritional status influenced postoperative complications and survival.[191] The prognostic nutritional index considers serum albumin, serum transferrin, triceps skin-fold thickness, and cutaneous delayed hypersensitivity to mumps, streptokinase-streptodornase, or candida. This index was generated from retrospective review of 161 patients undergoing gastrointestinal surgery and then prospectively validated in 100 patients as an indicator of risk for postoperative complications.[192] Goodwin and Torres found that 89% (8/9) of patients with prognostic nutritional index >39% suffered major postoperative complications, compared to 14% (4/29) of patients with prognostic nutritional index ≤39%. In addition, 64% (9/14) of the patients with prognostic nutritional index >39% died of their disease within 1 year, compared to 28% (10/36) of patients with prognostic nutritional index ≤39%.

The relationship between nutritional status, postoperative complications, and survival has been further explored in several prospective studies. In an analysis of six different nutritional parameters, 10% weight loss in the 6 months preceding surgery was the only significant, independent predictor of major

*Source:* From Pugliano FA, Piccirillo JF, Zequeira MR, et al. Clinical-severity staging system for oral cavity cancer: five-year survival rates. *Otolaryngol Head Neck Surg.* 1999;120:38–45, with permission.

postoperative complications in a cohort of 64 patients with T2-4 carcinomas of the oral cavity, oropharynx, hypopharynx, and larynx.[193] In a subsequent study, 5% weight loss in the 6 months preceding initial treatment for advanced HSNCC was identified as an independent predictor of poor disease-specific survival in men but not women.[194]

Given the strong evidence for an association between malnutrition and an increased risk of postoperative complications, interest has grown in evaluating the benefits of nutritional support. A meta-analysis of 28 trials revealed that preoperative parenteral nutrition lowers the risk of major surgical complications and surgical mortality for patients with gastrointestinal cancers,[195] yet a small randomized trial of preoperative tube feeding in 49 severely malnourished head and neck cancer failed to show a similar benefit.[196] An observational study of 1,073 patients treated with definitive radiation therapy on RTOG 90-03 examined the correlation between baseline nutritional support (BNS), radiation toxicity, and survival.[197] BNS was defined as either oral supplements, enteral feedings, or parenteral nutrition used by the patient prior to beginning radiation. BNS was associated with a slightly lower risk of grade 3 or 4 radiation-induced mucositis: 34% with BNS versus 40% without BNS. However, even after adjusting for potential confounders, BNS was associated with a highly significant 1.5-fold increased risk of local-regional failure. This finding generated the hypothesis that nutritional support of head and neck cancer patients, though beneficial for their general medical condition and for minimizing toxicity of therapy, may actually exert a deleterious effect on cancer outcomes by providing the cancer with nutrients needed to resist the effects of radiation therapy. This hypothesis clearly merits further prospective study.

## Anemia

Anemia commonly occurs in patients with head and neck cancer and may be due to a number of causes, including comorbid illness, intraoperative blood loss, toxicity from chemotherapy and/or radiation, and malignancy-associated anemia of chronic disease. Anemia is commonly thought to enhance radioresistance via enhancing tumor hypoxia. Numerous retrospective studies have suggested a strong association between anemia and inferior local-regional control and survival among patients treated for HNSCC (Table 3.2).[198–217] This association has been reported for patients with both early and advanced disease treated with a variety of treatment modalities, including radiation alone, chemoradiation, surgery and postoperative radiation, and surgery alone. The finding that anemia correlates with inferior local-regional control among patients treated with

surgery alone suggests that anemia may influence outcome in head and neck cancer patients independent of its influence on hypoxic radioresistance.[205]

The optimal timepoint to assess anemia for the purposes of prognostication is unclear and varies widely throughout the literature (Table 3.2). Options include pretreatment hemoglobin, midradiation hemoglobin, postoperative hemoglobin, and drop in hemoglobin concentration during radiation. Due to colinearity in these measures, they all likely confer some degree of prognostic significance. The optimal hemoglobin cutpoint for defining anemia is also unclear, ranging from 10 to 14 g/dL, depending on the study (Table 3.2). Denis et al. used an ROC curve to conclude that 12.5 g/dL is the best cutpoint for predicting mortality.[215] In addition, at least two studies have shown a strong dose-response relationship when hemoglobin is divided into quartiles,[212,213] suggesting that a single cutpoint for defining anemia may be inadequate.

Given the strong association between anemia and adverse outcomes, two randomized trials were launched to assess the benefit of treating anemic patients with recombinant erythropoietin (EPO) during radiotherapy. The first study, a double-blind, placebo-controlled randomized trial reported by Henke et al. in 2003, found that administration of epoetin-$\beta$ increased the median hemoglobin concentration from 11.7 g/dL pretreatment to 14.8 g/dL posttreatment.[218] However, patients who received epoetin-$\beta$ experienced inferior local-regional control (HR, 1.62; 95% confidence interval [CI], 1.22–2.14) and inferior overall survival (HR, 1.39; 95% CI, 1.05–1.84). This study has been criticized due to unequal distribution of certain covariates among the study arms. RTOG 99-03 similarly found that taking epoetin increased hemoglobin concentration, by 1.66 g/dL in the experimental arm compared with 0.24 g/dL decrease in the control arm ($p = 0.0001$). However, there was no statistically significant difference in the primary endpoint of local-regional failure (LRF) or overall survival.[219]

The possibility that exogenous EPO could exert a deleterious effect on control of HNSCC has prompted research into possible mechanisms. Winter et al. demonstrated that 99% of HNSCCs express the EPO receptor,[220] and Lai et al. reported that treatment of HNSCC cell lines with EPO increased invasion and proliferation.[221] Further, a secondary analysis of the trial reported by Henke et al. examined the interaction of EPO administration with EPO receptor expression among 154 patients treated at a single institution.[222] In this study, 67% of tumors had moderate or strong expression of the EPO receptor and were considered EPO receptor positive. Among EPO receptor positive tumors, administration of EPO was associated with an increased risk of local-regional failure (relative risk, 2.07; 95% CI, 1.27–3.36). In contrast, among EPO receptor negative tumors, administration of EPO did not affect local-regional control (relative risk, 0.94; 95% CI, 0.47–1.90). The *p*-value for the interaction of EPO administration with EPO receptor expression was 0.08, suggesting that EPO administration exerts a deleterious effect only among tumors that are EPO receptor positive.

In summary, although there is a strong association between anemia and adverse outcomes, there is little evidence to suggest that modification of anemia through administration of growth factors produces a clinical benefit. Clinicians should be cognizant that administration of EPO may stimulate tumor growth and should therefore utilize extreme caution when considering this medication.

## MOLECULAR PROGNOSTIC FACTORS

The vast array of molecular factors studied in head and neck cancer can be divided into several broad categories. Proto-oncogenes code for proteins that promote cellular proliferation. A proto-oncogene is transformed into an oncogene when its protein product becomes unresponsive to the normal regulatory processes that control cell division. Activation of proto-oncogenes occurs by point mutations, chromosomal translocations, or gene amplification. At the cellular level, an oncogene exerts a dominant phenotype over its proto-oncogene counterpart because only one copy of an oncogene is necessary to promote neoplasia. In contrast, tumor suppressor genes (antioncogenes) inhibit cellular proliferation. At the cellular level, both copies of a tumor suppressor gene must be disabled to promote neoplasia. Another class of markers includes proteins and growth factors that mediate the interaction between neoplastic cells and their local microenvironment. In addition to these specific molecular markers expressed in neoplastic cells, other factors such as tumor ploidy and the rate of tumor cell proliferation may yield important prognostic information. This chapter will focus on molecular markers that may become important targets for new pharmacotherapies.

(c) 2014 Wolters Kluwer. All Rights Reserved.

***p53.*** *p53* is a transcription factor with tumor suppressor function that negatively regulates the cell cycle and serves to protect the integrity of the genome. Its gene resides on chromosome 17p13 and is composed of 11 exons spanning 20 kb in length.[223] Activation of *p53* occurs in response to a variety of cellular stressors, such as DNA damage, hypoxia, and cell cycle aberrations.[224] Such stressors lead to $p^{14ARF}$-mediated increases in *p53* protein levels, which can result in several different cellular events, including G1 arrest, apoptosis, or senescence. *p53* mediates G1 arrest through transactivation of at least two genes: $p21^{WAF1/CIP1}$, an inhibitor of the G1 cyclin-dependent kinases essential for the G1/S transition, and GADD45, a gene implicated in growth arrest and DNA excision repair.[225–227] *p53* induction also results in apoptosis, presumably when the extent of DNA damage exceeds the capacity of cellular repair mechanisms.[228] Thus, *p53* protects the cell from propagating mutations to subsequent generations and is considered the "guardian of the genome."[229]

Loss of *p53* function may contribute to tumor aggressiveness by promoting resistance to radiation and chemotherapy, accelerated growth in hypoxic conditions, and tumor neovascularization. When compared to cells with wild-type *p53*, *p53* mutant cell lines exhibit more resistance to ionizing radiation and certain chemotherapeutic agents.[230–232] This evidence led to the hypothesis that tumors lacking a functional *p53* gene will exhibit a radioresistant and chemotherapy-resistant phenotype due to a deficiency in DNA damage-induced apoptosis.[227] This hypothesis has been strengthened by experiments conducted in *p53* mutant cell lines derived from HNSCCs. Transfection with an adenoviral vector or a liposomal system containing a functional *p53* gene resulted in a dose-dependent increase in radiation sensitivity, restoration of the G1 checkpoint, and induction of apoptosis.[233–236] *p53* may also mediate hypoxia-induced apoptosis. Graeber et al. demonstrated that mutations in *p53* reduce hypoxic cell death and confer a competitive advantage to cells growing in a hypoxic environment.[237] Thus, mutations in *p53* may increase the number of hypoxic cells, conferring hypoxia-mediated radioresistance. Finally, loss of *p53* function results in the down-regulation of thrombospondin-1, an inhibitor of angiogenesis.[238] Indeed, a strong correlation between *p53* overexpression, a surrogate marker for *p53* gene mutation, and both elevated tumor microvessel density and vascular endothelial growth factor (VEGF) expression has been reported in HNSCC.[239,240] As a whole, the data from basic science studies support the hypothesis that *p53* mutations contribute to biologically aggressive tumor behavior by conferring resistance to radiotherapy and chemotherapy and by promoting angiogenesis.

Inactivation of *p53* is a common event in HNSCC and may result from spontaneous or tobacco-induced mutations[176] or from sequestration by cellular proteins such as mdm2[241] or the E6 viral oncoprotein of HPV.[242] Detection of *p53* mutations has been attempted through both protein-based and DNA-based techniques. Many studies have utilized immunohistochemistry (IHC), capitalizing on the differential expression of wild type and mutant *p53*. Wild-type *p53* has a half-life of 20 minutes, whereas many *p53* mutations confer stability to the protein and thus result in higher intracellular levels detectable via IHC.[223] Unfortunately, this technique often fails to detect nonsense or frameshift mutations that result in *p53* protein truncation.[243] Furthermore, induction of wild-type *p53* in response to DNA damage can result in sufficient quantities for IHC detection. Saunders et al. sequenced all coding exons of the *p53* gene from 39 laryngeal SCCs and found that *p53* IHC resulted in a 64% concordance, 42% false positive rate, and 23% false negative rate.[244] Larger studies that examined only the conserved regions of the *p53* gene reported 59% to 71% concordance with IHC.[243,245] Thus, although relatively simple and inexpensive, IHC is not an accurate method for detecting *p53* mutations.

DNA-based techniques for detection of *p53* mutations have focused on exons 5 to 8, a highly conserved region that codes for a DNA-binding domain.[223] However, recent studies have found that 20% to 25% of *p53* gene mutations lie outside the conserved region,[244,246] although these mutations may not influence *in vivo* *p53* function. Finally, loss of heterozygosity at the *p53* gene locus has been examined using polymorphic markers and fluorescent *in situ* hybridization (FISH).[247–249]

Recent studies correlating *p53* mutation with outcome in HNSCC have suggested that *p53* mutations, as assessed via direct sequencing, are associated clinically with resistance to radiotherapy and chemotherapy (Table 3.3).[160,244,246,250–255] In the largest study to employ direct sequencing, Koch et al. evaluated the prognostic significance of *p53* mutations in exons 5 to 9 in 110 HNSCCs treated with either primary or postoperative radiotherapy.[160] These tumors spanned all major sites for HNSCC and included all clinical stages. In multivariate analysis, patients with *p53* mutations were 2.4 times more likely to develop local-regional recurrence, equal to the risk of local-regional recurrence conferred by the presence of positive cervical lymph nodes. In contrast, *p53* expression as assessed via IHC failed to correlate with any outcome variable.[243] Similarly, two other studies showed that *p53* mutation, but not protein overexpression, predicted poor local-regional control and survival in cohorts composed of 58 and 68 patients with HNSCC, most of whom received radiotherapy.[250,253] Furthermore, a study conducted on 22 recurrent HNSCCs previously treated with radiation found that 21 of the 22 recurrences had evidence for *p53* inactivation by either gene mutation, mdm2 overexpression, or HPV infection.[256]

In addition to the relationship between *p53* mutation and response to radiotherapy, several groups have considered the relationship between directly sequenced *p53* mutations and response to chemotherapy. In a cohort of 105 patients with HNSCC treated with platinum- and fluorouracil-based induction chemotherapy, Temam et al. directly sequenced all coding regions of the *p53* gene from biopsy specimens taken prior to the initiation of chemotherapy. Multivariate modeling revealed that tumors with a mutant *p53* gene were 70% less likely to experience major response to chemotherapy and, independently, tumors with high levels of *p53* protein expression were 60% less likely to experience a major response.[246] The correlation between *p53* overexpression and resistance to chemotherapy persisted in the subset of patients with wild-type *p53*, suggesting that *p53* IHC conveys independent prognostic information in patients treated with chemotherapy. An additional study conducted on 106 HNSCC patients treated with cisplatin and 5-fluorouracil neoadjuvant chemotherapy screened for *p53* mutations using denaturing gradient gel electrophoresis (DGGE) on PCR products from exons 4 to 9 of the *p53* gene followed by direct sequencing of those exons that demonstrated a variant DGGE pattern.[254] In agreement with Temam et al. this study found that *p53* mutation was the only significant predictor of response to chemotherapy in multivariate analysis, with *p53* mutant tumors 63% less likely to respond to chemotherapy. At least three other studies have reported a correlation between *p53* overexpression and poor survival in HNSCC patients who receive chemotherapy.[255,257,258] Thus, strong evidence supports a role for *p53* alterations in predicting poor initial response and long-term survival following treatment with chemotherapy.

At least one group has considered whether the location of *p53* mutations influences the clinical phenotype of HNSCC. Erber et al. sequenced exons 5 to 8 and assessed for loss of heterozygosity at the *p53* allele in 86 oral cavity, oropharyngeal, hypopharyngeal, and laryngeal SCCs, stage I to IV.[252] All patients received surgical resection, and 79% (68/86) received postoperative radiotherapy. Twenty-eight percent (24/86) of tumors

exhibited a mutation within structural components of the *p53* gene, and 15% (13/86) of tumors exhibited mutations within regions critical for DNA binding of the *p53* protein. DNA contact mutations were associated with nodal positivity, advanced stage, and poor recurrence-free and overall survival in univariate analysis. Furthermore, in the subset of stage IV patients, the presence of contact mutations correlated with poor overall survival. No such correlation between structural mutations and stage at presentation or outcome was observed. These results imply that *p53* mutations resulting in the specific loss of DNA binding and thus transcriptional regulation result in radioresistance and particularly poor survival. Clearly, the clinical significance of specific *p53* mutations merits further study.

Given the association between *p53* mutation and adverse outcomes, multiple groups have investigated the potential benefit of *p53* gene therapy, and phase III clinical trials are currently ongoing in the United States.[259] In China, a recombinant human adenovirus in which the E1 region has been replaced by the *p53* expression cassette has been trademarked Gendicine and approved for clinical use.[260] To date, approximately 3,500 patients have received this gene therapy in China.[261] However, data on the effectiveness of this intervention in the English literature is sparse.

## Angiogenesis-Related Markers

Angiogenesis, the sprouting of new blood vessels from a preexisting endothelium, enables the growth of tumors beyond microscopic size.[262,263] Many growth factors and cytokines, including the VEGF family, basic and acidic fibroblast growth factor (bFGF, aFGF), interleukin-8 (IL-8) and platelet-derived endothelial cell growth factor (PD-ECGF) have been shown to promote angiogenesis.[264] The VEGF family consists of five members including VEGF, P1GF, VEGF-B, VEGF-C, VEGF-D, and the Orf virus VEGFs (VEGF-E).[265] Of these factors, VEGF plays a pivotal role in vasculogenesis and angiogenesis, and VEGF-C is a potent inducer of lymphangiogenesis.[266] Receptors for the VEGF family include VEGFR-1, VEGFR-2, and VEGFR-3, also known as *flt*, KDR/*flk-1*, and *flt4*, respectively.[265] VEGFR-1 and VEGFR-2 are expressed on vascular endothelium, whereas VEGFR-3 is expressed in the lymphatic endothelium.[265]

VEGF, a 34-50 kDa dimer composed of two identical disulfide-linked subunits that arise from differential splicing of a single gene,[267] is frequently expressed in HNSCC[268] and has received the most study as a potential mediator of angiogenesis. Overexpression of VEGF may result from hypoxia-induced upregulation of transcription and eIF4E-mediated upregulation of translation.[269–271] Because hypoxic tumors display increased radioresistance, VEGF protein levels may serve as a surrogate marker for hypoxic radioresistance. Furthermore, angiogenic activity may influence a tumor's metastatic potential by exposing it to a greater endothelial surface area, thus increasing the likelihood of hematogenous or lymphatic dissemination.[272] In addition, once a tumor has formed a distant micrometastasis, it must recruit a vascular supply in order to proliferate to a clinically relevant size.

Angiogenic activity can be assessed in archival tumor tissue directly by staining with antibodies targeted against proteins that reside on endothelial cells, such as Factor VIII, CD-31, CD-34, and CD-105, in order to calculate the density of microvessels in the tumor bed. In addition, expression of angiogenesis-promoting factors has been assessed via IHC and ELISA. Expression of both VEGF and PD-ECGF has been reported to correlate with microvessel density (MVD) in HNSCC.[239,240,273]

Elevated tumor MVD as assessed via IHC has been shown to correlate with risk for concomitant cervical lymph node metastasis in oral cavity[274–276] and nasopharyngeal carcinomas.[277,278] Furthermore, elevated MVD has been shown to correlate with risk of regional relapse in clinically N0 oral cavity carcinomas treated with surgery.[279,280] These studies strongly suggest that the finding of high MVD in the primary tumor suggests a higher risk of concomitant nodal metastasis. In contrast, studies are mixed regarding the potential correlation of elevated MVD with either local-regional control or survival.[281–283] However, a recent study of 127 HNSCC patients suggested that endothelial expression of CD-105 (endoglin), which is a marker of neovascularization, was strongly correlated with poor disease-free and overall survival.[284] In contrast, expression of CD34, which is commonly expressed on both quiescent and proliferating endothelial cells, was not associated with outcome, suggesting that the proliferating endothelial component is the primary determinant of tumor behavior.

Direct assessment of angiogenic factor expression offers another approach to the study of tumor angiogenesis. High levels of VEGF and PD-ECGF have been shown to correlate with the presence of concomitant nodal metastases in both nasopharyngeal and oral cavity carcinomas.[276–278,285] Furthermore, expression of VEGF-C in the primary tumor and VEGFR3 on lymphatic endothelium both correlate with risk of nodal metastasis, suggesting that lymphangiogenesis may increase the likelihood of spread to the cervical lymph nodes.[285,286]

Expression of VEGF has also been shown to correlate with local-regional recurrence, distant metastasis, and poor survival.[287] A critical meta-analysis of 12 studies including 1,002 patients concluded that high levels of VEGF expression assessed via IHC correlated with a highly significant 1.88-fold increased risk of 2-year mortality.[288] Given the strong, reproducible association between elevated expression of VEGF and adverse outcomes, phase I/II clinical trials are now ongoing to assess the possible therapeutic benefit of anti-VEGF therapy, such as bevacizumab.

## Cyclin D1

Cyclin D1, also known as PRAD1, is a proto-oncogene located on chromosome 11q13[289] that serves as the rate-limiting controller of G1-phase progression through the cell cycle.[290] In response to extracellular mitogens, cyclin D1 levels increase and complex with the cyclin-dependent kinases cdk4 or cdk6 in order to mediate progression through G1 by phosphorylation of the retinoblastoma protein. Cyclin D1 is the most commonly amplified oncogene in HNSCC, with approximately 35% of tumors revealing increased gene copy number in FISH analysis.[291] Overexpression of cyclin D1 shortens the G1 interval and reduces the cell's dependence on mitogens for proliferation. For example, overexpression of cyclin D1 in a human epithelial breast cancer cell line reduced the fraction of cells entering quiescence under conditions where growth factors were limited, resulting in accelerated growth.[292] Such observations suggest that overexpression of cyclin D1 may increase the aggressiveness of certain cancers by desensitizing cellular proliferation to inhibitory signals.

Although the literature remains somewhat mixed, a growing body of evidence suggests a relationship between cyclin D1 amplification and poor prognosis (Table 3.4).[293–299] In patients with clinically negative cervical lymph nodes, expression or amplification of cyclin D1 in the primary tumor increases the risk of cervical nodal metastasis by four- to eightfold.[300,301] Bova et al. found cyclin D1 overexpression to predict increased risk for poor disease-free and overall survival in 148 patients with stage I to IV oral tongue SCC treated with surgery (52 patients received postoperative radiotherapy).[296] Similarly, Michalides et al. found that cyclin D1 overexpression was an independent predictor of shortened disease-free interval in 115 stage I to IV HNSCCs treated with surgery (73 received postoperative radiotherapy).[293]

**TABLE 3.4 Prognostic Significance of Cyclin D1 in Head and Neck Cancer**

| Author | Description of Patients | Treatment Given | Marker | % Positive | Multivariate Analysis | Local Control | Survival | Notes |
|---|---|---|---|---|---|---|---|---|
| Michalides et al.[293] | 115 Stage I–IV HNSCC | Primary surgery (72 received post-op RT) | IHC | 50% | Yes | No | DFS ($p = 0.05$) | Overexpression correlates with recurrence when all sites considered |
| Muller et al.[294] | 280 Stage I–IV HNSCC | 201 Surgery + post-op RT | 11q13 amplification | 57% | Yes | NR | No | |
| | | 79 Surgery alone | | 35% | | NR | No | |
| Pignataro et al.[295] | 149 Stage I–IV laryngeal SCC | Surgery (63 received post-op RT) | IHC | 32% | Yes | NR | DFS ($p = 0.02$) OS ($p = 0.06$) | Cyclin D1 expression associated with alcohol and tobacco consumption |
| Bova et al.[296] | 148 Stage I–IV oral tongue SCC | Surgery (53 received post-op RT) | IHC | 68% | Yes | NR | DFS ($p = 0.05$) OS ($p = 0.02$) | Cyclin D1 expression plus loss of *p16* expression associated with worst prognosis |
| Mineta et al.[297] | 94 Stage I–IV tongue SCC | Surgery (not otherwise specified) | IHC | 19% | No | NR | OS ($p = 0.04$) | |
| Yoo et al.[298] | 30 T1-2, N0 laryngeal SCC, nonrecurrent | Radiotherapy | IHC | 67% | No | Yes ($p = 0.02$) | NR | Low cyclin D1 levels predicted local recurrence |
| | 30 T1-2, N0 laryngeal SCC, recurrent | | | 37% | | | | |
| Hwang et al.[299] | 65 Stage I–IV nasopharynx cancer | Radiotherapy | IHC | 66% | Yes | Yes ($p = 0.01$) | NR | Low cyclin D1 levels predicted local recurrence |

CSS, cause-specific survival; CTX, chemotherapy; DFS, disease-free survival; HP, hypopharynx; HNSCC, head and neck squamous cell carcinoma; IHC, immunohistochemistry; NR, not reported; OC, oral cavity; OP, oropharynx; OS, overall survival; RT, radiotherapy; SCC, squamous cell carcinoma.

In addition, Pignataro et al. demonstrated that cyclin D1 overexpression independently doubled the risk of tumor relapse in 149 stage I to IV laryngeal SCCs treated with surgery (63 received postoperative radiation).[295]

In contrast, some evidence suggests that cyclin D1 overexpression may actually increase the sensitivity of tumors treated with definitive radiation. For example, Yoo et al. and Hwang et al. reported that high cyclin D1 protein levels were associated with a threefold reduction in the risk of local-regional recurrence among patients with laryngeal[298] and nasopharyngeal[299] cancers treated with definitive radiation. In summary, for patients treated with surgery with or without postoperative radiation, strong evidence suggests that cyclin D1 upregulation correlates with poor disease-free and overall survival in HNSCC. In contrast, for patients treated with primary radiation, upregulation of cyclin D1 may be correlated with improved local-regional control, and further study is needed to characterize the effect of cyclin D1 levels on radiosensitivity.

## EGFR and TGF-α

The receptor tyrosine kinase epidermal growth factor receptor (EGFR) and its ligand transforming growth factor-alpha (TGF-$\alpha$) are frequently overexpressed in HNSCC.[302,303] Activation of EGFR induces autophosphorylation, resulting in activation of several signaling pathways including Ras-MAP kinase, phospholipase C$\gamma$, phosphatidylinositol 3-kinase, and STATs (signal transducers and activators of transcription).[304–306] In HNSCC, autocrine activation of EGFR by TGF-$\alpha$ functions to promote cellular proliferation and inhibit apoptosis. For example, *in vitro* experiments

(c) 2014 Wolters Kluwer. All Rights Reserved.

conducted on HNSCC-derived cell lines demonstrated that inhibition of TGF-$\alpha$ with antisense oligonucleotides and inhibition of EGFR with antisense oligonucleotides, monoclonal antibodies, or specific inhibitors of EGFR kinase activity resulted in reduced cellular proliferation.[307,308] Furthermore, *in vivo* transfection of a vector expressing EGFR antisense oligonucleotides resulted in growth inhibition and induction of apoptosis in nude mice tumor xenografts.[309]

EGFR expression may also modulate tumor radioresistance. In murine tumors, Akimoto et al. found that the magnitude of EGFR expression positively correlated with increased radioresistance and inversely correlated with radiation-induced apoptosis.[310] Blockade of EGFR with the monoclonal antibody C225 enhances radiosensitivity of SCCs both *in vitro* and *in vivo*. In cell lines derived from HNSCC patients, concomitant C225 administration and radiotherapy enhances of radiosensitivity, in part because inhibition of EGFR results in down-regulation of antiapoptotic proteins such as Stat3 and thus promotes radiation-induced apoptosis.[311,312] Furthermore, *in vivo* experiments suggest that C225 inhibits repair of radiation-induced DNA damage and promotes tumor necrosis.[313,314]

In agreement with laboratory data, clinical studies have established a correlation of EGFR overexpression with poor prognosis and radioresistance (Table 3.5).[315–323] Initial evidence for the prognostic utility of EGFR levels was derived from Dassonville et al. who found that EGFR expression independently predicted poor relapse-free survival in 109 stage I to IV HNSCC patients treated primarily with either chemotherapy or surgery.[315] Maurizi et al. reported an independent relationship between EGFR protein expression and poor disease-free and overall survival in 140 stage I to IV laryngeal SCCs treated primarily with surgery.[316] Similarly, Grandis et al. utilized quantitative IHC to show that increasing levels of both TGF-$\alpha$ and EGFR predicted poor disease-free and cause-specific survival in a cohort of 91 stage I to IV HNSCCs[318] treated with surgery (56 received postoperative radiotherapy). Finally, Chung et al. used FISH in 75 patients with stage I to IV HNSCC to determine that patients with more than two copies per cell of the EGFR gene experienced a higher risk of progression and death.[322] Thus, the cumulative evidence suggests that EGFR protein overexpression or gene amplification is associated with poor prognosis.

Overexpression of EGFR has also been shown to correlate with radioresistance. For example, Ang et al. reported that, in a cohort of 155 patients with stage II to IV HNSCC treated with conventional radiotherapy on RTOG study 90-03, overexpression of EGFR was associated with poor local-regional control, disease-free survival, and overall survival in multivariate analysis.[319] In addition, growing evidence suggests that accelerating the course of radiotherapy may mitigate the adverse effect of EGFR overexpression on local-regional control. For example, Bentzen et al. reported a cohort of 304 patients with stage II to IV HNSCC randomized to receive either conventional daily radiation to a total dose of 66 Gy in 33 fractions over 45 days or continuous hyperfractionated accelerated radiation therapy (CHART) to a total dose of 54 Gy in 36 fractions over 12 days.[321] Patients with high EGFR expression derived a significant local-regional control benefit from CHART, whereas patients with low EGFR expression experienced similar local-regional control regardless of whether they received conventional radiation or CHART. Two other recent studies also suggest that a short overall treatment time may compensate for the adverse effects of EGFR.[320,323] One potential explanation for this observation is that EGFR may mediate accelerated repopulation late in the course of conventional radiotherapy, thus allowing EGFR-positive tumors to become increasingly resistant to radiation during the last few weeks of conventional treatment.

Emerging evidence suggests that targeting the EGFR receptor with either small molecule tyrosine kinase inhibitors such as erlotinib or monoclonal antibodies such as cetuximab results in clinical gains. In the locally advanced setting, a recent randomized trial of 424 patients with stage III to IV HNSCC revealed that median overall survival for patients treated with cetuximab and radiotherapy was 49.0 months versus 29.3 months in the radiotherapy-alone arm (HR, 0.73; 95% CI, 0.56–0.95; $p = 0.018$).[324] In the first-line recurrent/metastatic setting, the EXTREME trial found that adding cetuximab to platinum-fluorouracil significantly prolonged median OS from 7.4 months to 10.1 months (HR for death, 0.80; 95% CI, 0.64–0.99; $p = 0.04$) and median progression-free survival from 3.3 to 5.6 months (HR, 0.54; $p < 0.001$).[325] In addition, for patients with recurrent or metastatic disease that is refractory to first-line chemotherapy, cetuximab monotherapy has been shown to produce response rates ranging from 5% to 15%,[326] and the addition of platinum agents to cetuximab further improves response rates from approximately 18% to 26%.[327] These trials have provided the first conclusive evidence that molecularly targeted therapies can produce meaningful gains in the treatment of head and neck cancer.

## Human Papillomavirus

HPV is a small, circular DNA virus that infects basal cells in the squamous epithelium. HPV is transmitted through sexual contact and the recent rise in HPV-related HNSCC is thought to be due to increased oral sexual practices. D'Souza found that a high lifetime number of vaginal-sex partners (26 or more) was associated with oropharyngeal SCC (OR 3.1; 95% CI, 1.5–6.5), as was a high lifetime number of oral-sex partners (6 or more) (OR 3.4; 95% CI, 1.3–8.8).[328] HPV causes cancer by means of viral oncoproteins E6 and E7, which inactivate two human tumor suppressor genes, *p53* and *RB*. Though there are over 100 different subtypes of HPV, the vast majority of HPV-related HNSCC is related to HPV16, which is found in up to 90% of these cases. HPV-associated HNSCC patients are typically younger, more often white, nonsmokers, nonalcohol abusers, have higher socioeconomic status, with primary tumors more commonly in the oropharynx.[329,330]

Ang looked at patients treated on RTOG 0129, which randomized patients with advanced HNSCC treated with cisplatinum to either standard versus accelerated fractionation radiation therapy. While the radiation fractionation scheme made no significant difference in OS, subgroup analysis of the oropharyngeal SCCs revealed that the HPV-positive patients had better outcomes compared to HPV-negative patients (3-year OS, 82.4% vs. 57.1%; $p < 0.001$). Using recursive-partitioning analysis, they subdivided these patients into low, intermediate, or high risk of death on the basis of four factors: HPV status, greater or less than 10 pack-years of tobacco use, T stage, and N stage.[331] The improved prognosis of HPV-related HNSCC does not appear confined to patients treated with primary radiation, but extends to surgical patients as well.[332–334] How to take advantage of the improved prognosis of HPV-related HNSCC will be a major area of research in the coming years, specifically whether it is possible to de-escalate radiation dose or systemic therapy and maintain these patients' favorable prognosis. RTOG 1016 is a phase III trial randomizing patients with HPV-positive oropharyngeal SCC to concurrent cisplatinum radiation versus cetuximab radiation, the rationale being that if concurrent cetuximab can offer similarly excellent outcomes in this population, the toxicity of concurrent cetuximab is much less than concurrent cisplatinum.[335] HPV and its implications in head and neck cancer is also discussed in detail in Chapter 12.

## SUMMARY

Understanding the vast array of factors that contribute to the prognosis of patients with HNSCC enables an accurate assessment of patient risk and promotes the development of optimal treatment strategies. In addition, novel targeted therapies are emerging, which enable clinicians to mitigate the risk associated with adverse molecular factors.

CHAPTER 4

Jeffrey A. Bennett

# Radiologic Evaluation of the Head and Neck Cancer Patient

## INTRODUCTION

Cross-sectional imaging studies are an essential part of the care of the head and neck cancer patient, from initial diagnosis and staging to surveillance for cancer recurrence. This chapter will begin with a general discussion of normal imaging anatomy because this knowledge is very important for interpretation of the images. The appearance of pathology will then be addressed with emphasis on what needs to be in the radiology report. This includes a description of the full extent of the primary tumor, including which anatomic spaces of the head and neck are involved, whether or not there is bone or cartilage invasion, and whether there is perineural or perivascular spread of disease. What makes a lymph node positive or suspicious for cancer will be addressed, including extracapsular spread of disease and involvement of the dermal lymphatics. Finally, the identification of distant metastatic disease will be discussed. This approach to imaging is fundamental to the accurate staging of cancer and appropriate treatment, so that there will be no surprises at surgery and so that radiation portals can be optimally created. The pros and cons of the available imaging techniques, primarily computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET), will be discussed throughout the chapter. The reader is referred to the site-specific chapters in Section 2 for suggested CT and MRI protocols and imaging concerns specific to disease in those locations.

## IMAGING ANATOMIC CONSIDERATIONS

### Nasopharynx

The nasopharynx (Fig. 4-1) is the epithelium-lined most superior aspect of the pharynx and is supported and held open by the rigid and strong pharyngobasilar fascia. The superior boundary is the skull base at the floor of the sphenoid sinus and the upper portion of the clivus (Fig. 4-2). Anterolaterally are the medial pterygoid plates. The inferior boundary of the nasopharynx is at the level of the hard palate where it merges with the oropharynx. Anteriorly the nasopharynx is continuous with the nasal cavity by way of the posterior choanae. Posteriorly the nasopharynx is bordered by the retropharyngeal space, and posterior to that is the prevertebral space. Laterally the nasopharynx is separated from the fat-filled parapharyngeal space by the superior pharyngeal constrictor muscle and palatal muscles. The pharyngobasilar fascia is medial to the superior pharyngeal constrictor muscle and tensor veli palatini muscle. The levator veli palatini muscle is medial to the pharyngobasilar fascia and attaches to the Eustachian tube.

The torus tubarius is seen on axial sections at the level of the mid- and upper nasopharynx. It is made up of the distalmost part of the cartilaginous portion of the Eustachian tube, whose orifice

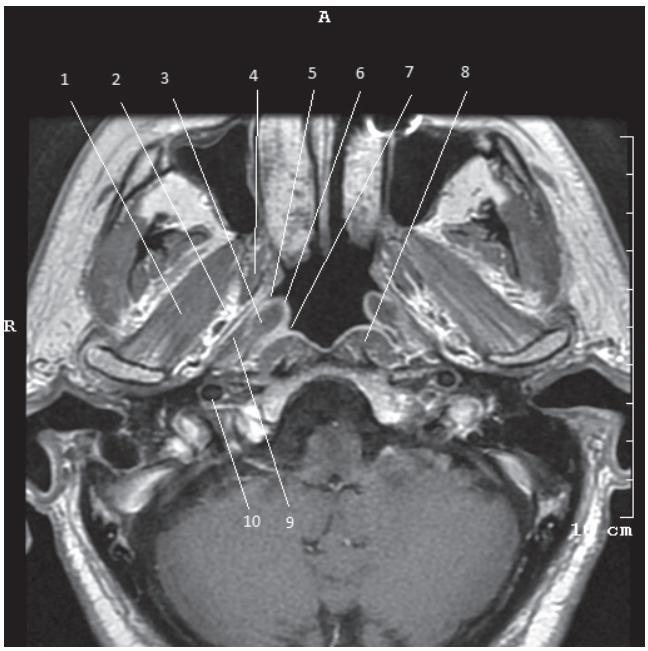

**FIGURE 4-1.** Axial T1-weighted postcontrast MRI through the nasopharynx demonstrating normal anatomy. *1*, lateral pterygoid muscle; *2*, fat in the prestyloid parapharyngeal space; *3*, torus tubarius made up of the cartilaginous end of the Eustachian tube; *4*, tensor veli palatini muscle; *5*, Eustachian tube orifice; *6*, mucosa over the torus tubarius; *7*, fossa of Rosenmüller; *8*, prevertebral flexor muscles; *9*, levator veli palatini muscle; *10*, carotid artery.

(c) 2014 Wolters Kluwer. All Rights Reserved.

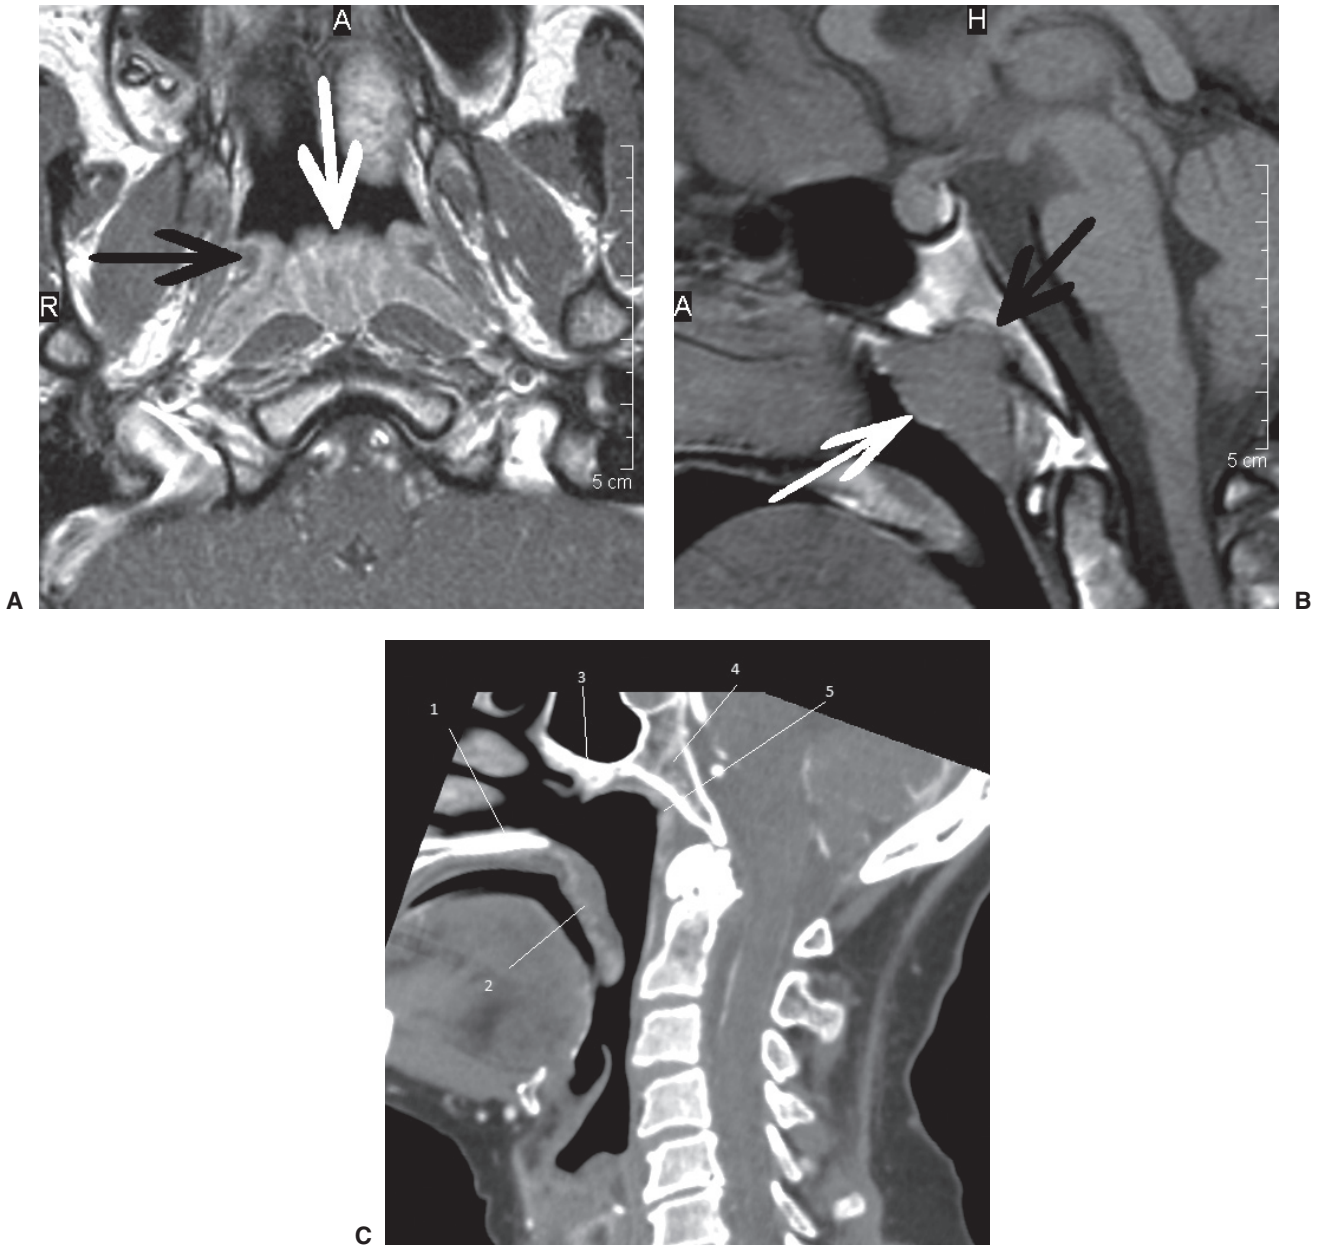

**FIGURE 4-2.** Axial T1-weighted contrast-enhanced MRI (**A**) at the level of the nasopharynx shows abundant lymphoid tissue (*white arrow*) lining the mucosa. This is normal in this 13-year-old patient. Notice the torus tubarius (*black arrow*). Sagittal noncontrast T1-weighted image in the same patient (**B**) shows the abundant adenoids (*white arrow*). The apparent scalloping of the cortex of the clivus (*black arrow*) is a normal variation. Midline sagittal postcontrast CT reformation (**C**) in a 75-year-old patient shows that the adenoids have atrophied. *1*, hard palate; *2*, soft palate; *3*, floor of the sphenoid sinus; *4*, clivus; *5*, nasopharyngeal mucosa with atrophied lymphoid tissue. MRI, magnetic resonance imaging; CT, computed tomography.

is just anterior to the torus tubarius. The Eustachian tube and the levator veli palatini muscle pass through an opening in the pharyngobasilar fascia called the sinus of Morgagni. This opening in the fascia provides a potential conduit for spread of nasopharyngeal carcinoma into the parapharyngeal space and to the central skull base.[1] The Eustachian tube connects the nasopharynx to the middle ear. In close to 50% of patients with a nasopharyngeal mass, the Eustachian tube becomes obstructed, leading to serous otitis media.[2] Thus, a finding of middle ear and mastoid opacification should prompt a search for a nasopharyngeal obstructive mass (Fig. 4-3).

The fossa of Rosenmüller is a mucosal recess located posterior to the tori and lateral to the flexor muscles of the neck, the longus coli and longus captitus muscles, which lie in the prevertebral space. Tumors that originate in the fossa of Rosenmüller are often clinically occult.

(c) 2014 Wolters Kluwer. All Rights Reserved.

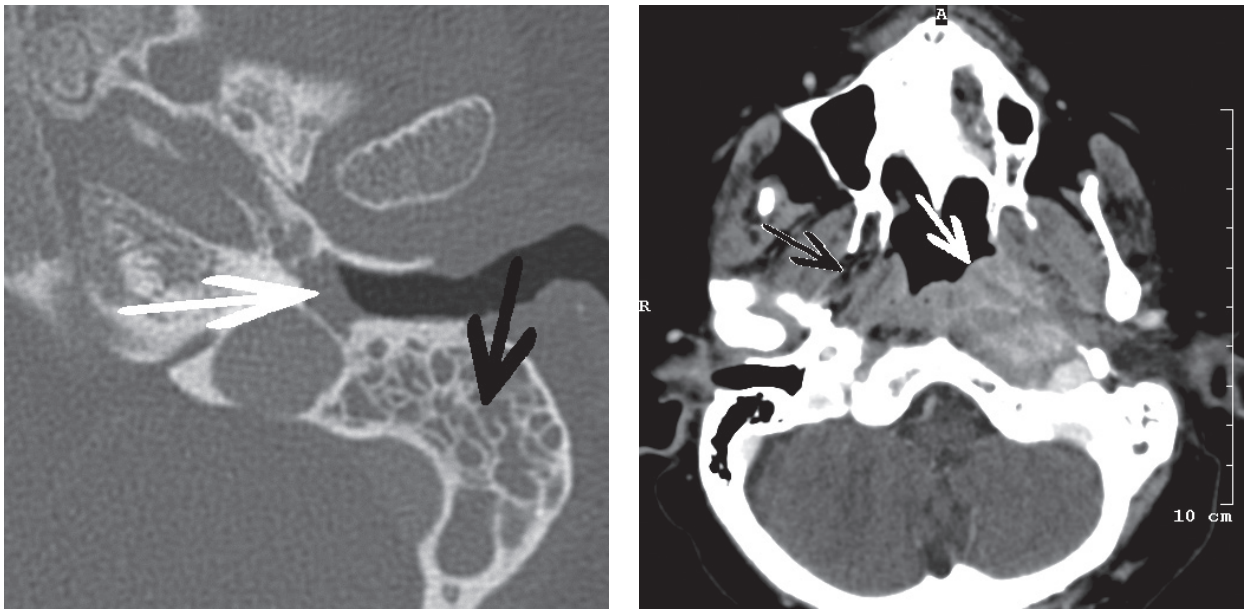

**FIGURE 4-3.** Axial CT scan with bone algorithm through the temporal bone (**A**) shows a serous otitis media (*white arrow*) and opacification of the mastoid air cells (*black arrow*). This unilateral finding in an older patient should prompt a search for a lesion causing obstruction of the Eustachian tube. Axial contrast-enhanced CT (**B**) in the same patient shows an aggressive nasopharyngeal mass (*white arrow*) which proved to be squamous cell carcinoma. Notice how the mass has extended into the prestyloid and retrostyloid parapharyngeal spaces causing obliteration of fat planes. The normal parapharyngeal space fat is seen on the opposite side (*black arrow*). CT, computed tomography.

Along the roof of the nasopharynx are the adenoids, or nasopharyngeal tonsil. This lymphoid tissue varies in appearance with age (Fig. 4-2), normally involuting by age 30, but can remain prominent in smokers and in patients with HIV.[3] As it appears similar in density to carcinoma on CT, when the finding is made of apparent lymphoid tissue infiltrating into the adjacent deeper tissue planes, a tumor should be suspected, as normal lymphoid tissue does not do this.

There is an extensive submucosal capillary lymphatic plexus in the nasopharynx, which explains the high incidence of positive lymph nodes in cases of nasopharyngeal squamous cell carcinoma.[4] Primary drainage is to the retropharyngeal lymph nodes and level 2 nodes.

The lateral retropharyngeal nodes of Rouviere lie in the retropharyngeal space medial to the carotid sheath and lateral to the flexor muscles of the neck. One to three nodes can normally be present on each side, usually at the level of C1, but they can be seen as low as the level of C3. The retropharyngeal nodes atrophy with age, possibly because of frequent upper airway infections in childhood. Normal retropharyngeal nodes in children measure 10 mm ± 2 mm and in adults measure 5 mm ± 2 mm (Fig. 4-4).

## Oropharynx

The oropharynx (Fig. 4-5) is bounded anterolaterally by the anterior tonsillar pillars, inferiorly by the pharyngoepiglottic folds, and superiorly by the soft palate, which is considered part of the oropharynx. The palatine tonsils are contained in the oropharynx as are the glossotonsillar sulci, which connect the lateral oropharyngeal wall with the tongue base. The anterior tonsillar pillar is made up of mucosa covering the palatoglossus muscle, whereas the posterior tonsillar pillar is made up of mucosa covering the palatopharyngeus muscle. In between these pillars is the tonsillar fossa containing the partially encapsulated palatine tonsil. This contains a variable amount of lymphoid tissue from side to side as well as with age. Lateral to the palatine tonsil is the fat-filled parapharyngeal space. This space gets smaller in its more inferior aspect where it communicates freely with the submandibular space.

The posterior third of the tongue, referred to as the tongue base, is also contained in the oropharynx. It extends from the circumvallate papillae to the vallecula. The mucosa of the vallecula and the anterior surface of the free margin of the epiglottis is part of the oropharynx, whereas the mucosa over the posterior surface of the free margin of the epiglottis is included in the supraglottic larynx (Fig. 4-6).

The lingual tonsil is incorporated into the mucosa of the tongue base. Like the adenoids and palatine tonsils, this lymphatic tissue has increased prominence with younger age and in smokers.

## The Oral Cavity and Floor of the Mouth

The oral cavity consists of the lips, anterior two-thirds of the tongue, and the hard palate. The hard palate and soft palate are best evaluated with imaging in the coronal plane. Also best evaluated in the coronal plane is the floor of the mouth, which lies between and includes the mucosa of the floor of the mouth and the mylohyoid muscle (Fig. 4-7). The mylohyoid muscle attaches to the mylohyoid line of the mandible and posteriorly to the hyoid bone. It is a U-shaped muscle with a median raphe in the midline and creates an opening posteriorly.

The submandibular space, actually part of the suprahyoid neck, is located below the mylohyoid muscle, although the submandibular gland itself extends around the posterior edge of the mylohyoid to enter the sublingual space in the floor of the mouth.

(c) 2014 Wolters Kluwer. All Rights Reserved.

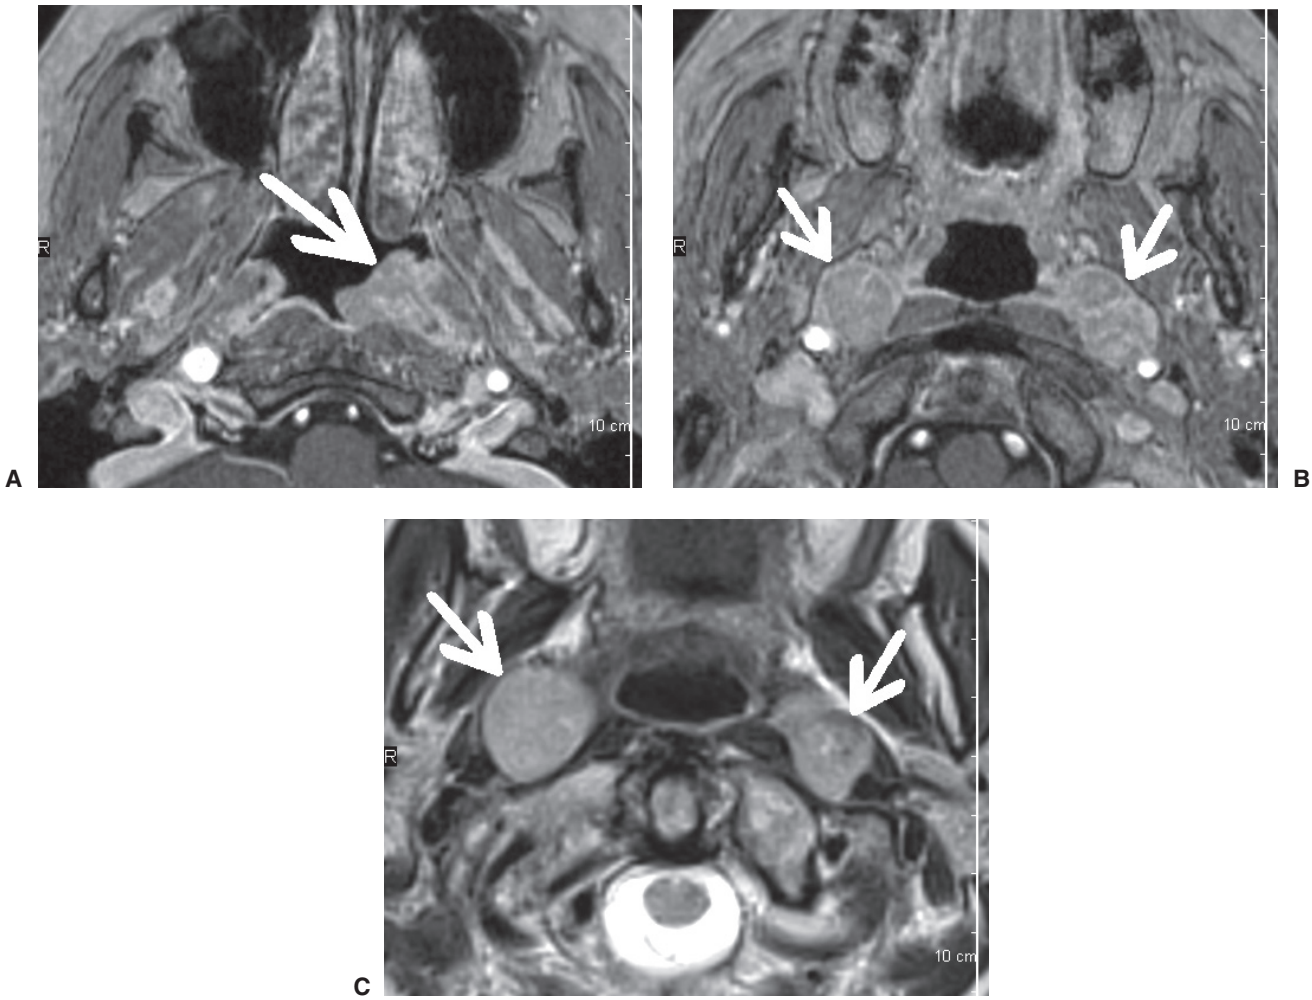

**FIGURE 4-4.** Axial T1-weighted contrast enhanced MRI (**A**) shows a left nasopharyngeal mass (*arrow*), which on biopsy proved to be squamous cell carcinoma. In the same patient, axial T1-weighted postcontrast MRI (**B**) and axial T2-weighted MRI at a slightly lower level (**C**) show bilateral bulky positive lateral retropharyngeal lymph nodes (*arrows*). MRI, magnetic resonance imaging.

The genioglossus muscles, which are extrinsic muscles of the tongue, and the geniohyoid muscles attach to the genial tubercles on the lingual surface of the mandible. Between these paired muscles is the midline septum of the tongue. The sublingual space containing the sublingual gland is located between these muscles and the mylohyoid. The submandibular duct, lingual nerve, and hypoglossal nerve all course through the sublingual space. The sublingual gland and lingual nerve, which is a branch of V3, course lateral to the hyoglossus muscle, whereas the lingual artery and vein and the hypoglossal nerve are medial to the hyoglossus muscle (Fig. 4-8). The lingual artery supplies blood to the tongue, with the lingual septum preventing much anastomosis across the midline.

The buccal mucosa is the mucosa of the cheek. The buccinator muscle lies deep to the mucosa and attaches to the maxillary alveolar ridge, the body of the mandible, and posteriorly inserts on the pterygomandibular raphe. The pterygomandibular raphe is a thick, vertically oriented fibrous band that also serves as the insertion of the orbicularis oris and superior constrictor muscles. It serves as a relative barrier to the spread of cancer. It lies deep to the mucosa of the retromolar trigone, which is the triangular mucosal surface behind the third mandibular molars and covers the ascending ramus of the mandible (Fig. 4-9). A surgical landmark superior to this region is the maxillary tuberosity, which is a bony bulge behind the third maxillary molar.

The mucosa covering the lingual alveolar surface and buccal alveolar surface of the maxilla and mandible is called the gingiva. The junction between the gingiva and buccal mucosa is called the upper and lower gingivobuccal sulcus, respectively, and is a common location in the oral cavity for squamous cell carcinoma to arise (Fig. 4-10).

## The Suprahyoid Neck

The compartmental organization of the neck is based on the superficial and deep fascial layers. On imaging studies, the fascia itself usually blends in with the structures it surrounds such as muscles and blood vessels.[5] However, fat contained in the spaces created between fascial boundaries is of low attenuation on CT scans and high signal compared to muscle on T1-weighted and fast spin echo T2-weighted images, and thus provides contrast that is very helpful for the localization of masses. The prestyloid parapharyngeal space, for example, contains mostly fat, although it also contains the ascending pharyngeal neurovascular bundle

**FIGURE 4-5.** Axial T2-weighted MRI shows the normal anatomy of the oropharynx. *1*, stylopharyngeus muscle; *2*, styloglossus muscle; *3*, medial pterygoid muscle; *4*, palatine tonsil; *5*, tongue base; *6*, masseter muscle; *7*, middle pharyngeal constrictor muscle; *8*, palatopharyngeus muscle; *9*, fat in the parapharyngeal space. MRI, magnetic resonance imaging.

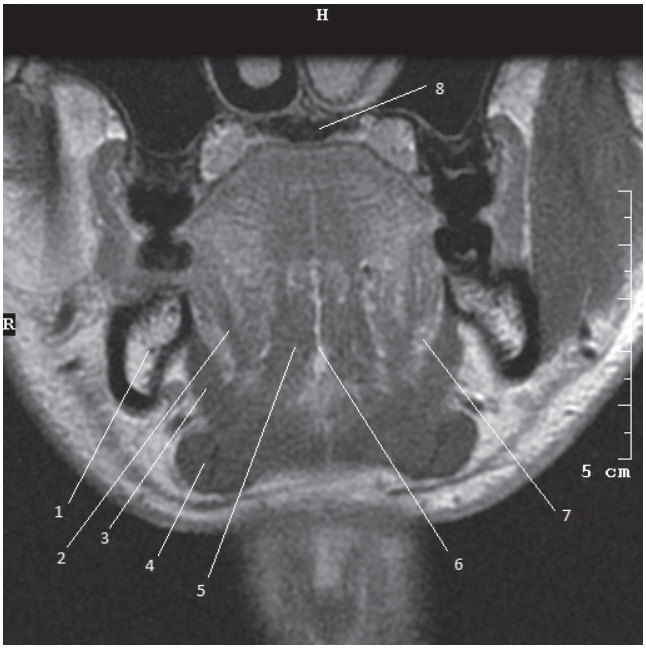

**FIGURE 4-7.** Coronal T1-weighted MRI with contrast through the oral cavity. *1*, mandible; *2*, hyoglossus muscle; *3*, mylohyoid muscle; *4*, anterior belly of the digastric muscle; *5*, genioglossus muscle; *6*, fatty midline septum of the tongue; *7*, sublingual space; *8*, hard palate. MRI, magnetic resonance imaging.

**FIGURE 4-6.** Axial contrast-enhanced CT scan at the level of the hyoid bone demonstrates a squamous cell carcinoma of the suprahyoid epiglottis (*white arrow*) since the cancer arises from the posterior mucosa of the free margin of the epiglottis. Mucosa on the anterior surface of the free margin of the epiglottis is part of the oropharynx and is continuous with the mucosa of the vallecula (*black arrows*). CT, computed tomography.

**FIGURE 4-8.** Axial contrast-enhanced CT through the floor of the mouth shows an aggressive infiltrating squamous cell carcinoma (*black arrow*), which encases the lingual neurovascular bundle (*white arrow*). The contralateral normal lingual artery can be seen just lateral to the genioglossus muscle. The tumor extends to the midline fatty septum of the tongue. CT, computed tomography.

(c) 2014 Wolters Kluwer. All Rights Reserved.

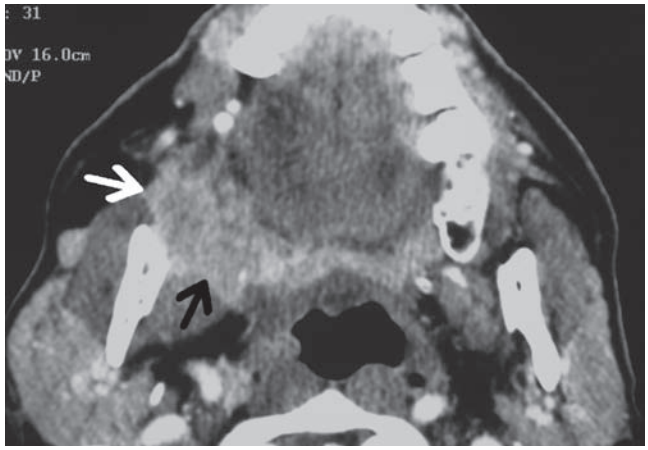

**FIGURE 4-9.** Axial contrast-enhanced CT scan shows a squamous cell cancer originating at the right retromolar trigone (*white arrow*) and extending along the glossotonsillar sulcus (*black arrow*) to the anterior tonsillar pillar. CT, computed tomography.

and the tensor muscle of the palate. This fat is easily visualized on imaging studies and will be displaced laterally by a nasopharyngeal or oropharyngeal mass, medially by a masticator space mass, and anteriorly by a retrostyloid parapharyngeal space mass (Fig. 4-11).

The medial boundary of the prestyloid parapharyngeal space is the buccopharyngeal fascia, which surrounds the superior

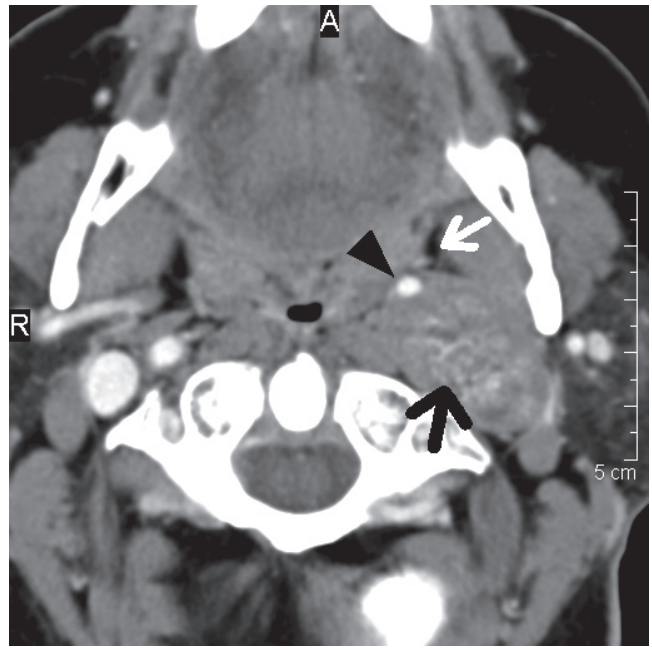

**FIGURE 4-11.** Axial contrast-enhanced CT scan shows a retrostyloid parapharyngeal space mass (*black arrow*), presumed to be a nerve sheath tumor. This has displaced the internal carotid artery (*black arrowhead*) anteriorly and has displaced the prestyloid parapharyngeal space fat anteriorly (*white arrow*). CT, computed tomography.

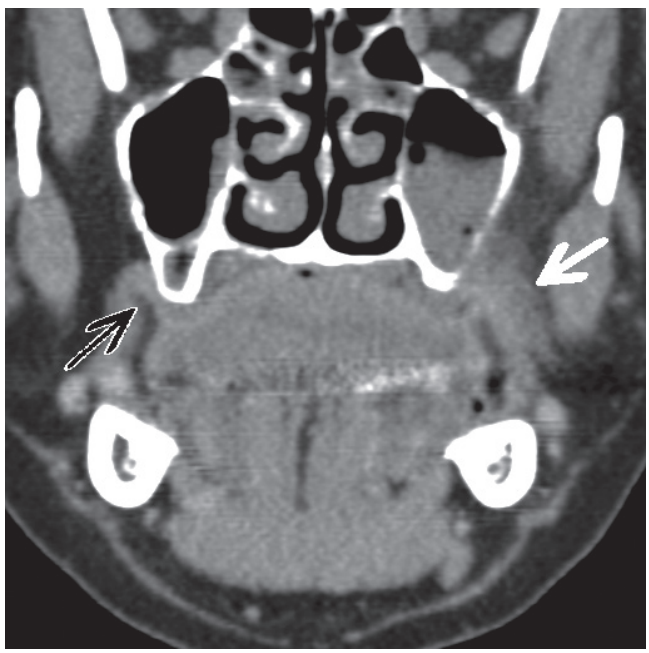

**FIGURE 4-10.** Coronal reformat of a contrast-enhanced CT shows a left glossotonsillar squamous cell carcinoma (*white arrow*), which has infiltrated the surrounding fat and eroded the lateral wall of the maxillary sinus. Compare the contralateral normal gingivobuccal sulcus (*black arrow*). CT, computed tomography.

constrictor muscle. Medial to this fascia superiorly is the previously described thick and strong pharyngobasilar fascia that encases the nasopharyngeal mucosa, lymphatic plexus, and some musculature. Deep to the buccopharyngeal fascia posteriorly is the prevertebral fascia, which encases the longus coli, longus capitus, and rectus capitus muscles contained in the prevertebral space. This space extends from the skull base to T3. Between the buccopharyngeal fascia and the prevertebral fascia is the retropharyngeal space.

The fascial layer that surrounds the styloglossus muscle, stylopharyngeus muscle, and stylohyoid muscle separates the prestyloid parapharyngeal space from the retrostyloid parapharyngeal space (see Fig. 4-5). The retrostyloid parapharyngeal space is sometimes called the carotid space, and is made up of several fascial layers. It contains the carotid sheath, in which resides the carotid artery, jugular vein, cranial nerves IX through XII, and the cervical sympathetic plexus, as well as lymph nodes along the vein.

The fascia covering the deep lobe of the parotid gland and the pterygoid muscles forms the boundary between the parapharyngeal space and the masticator space. The masticator space is essentially synonymous with the infratemporal fossa and is bounded laterally by the zygomatic arch and anteriorly by the posterior wall of the maxillary sinus. It contains the muscles of mastication, portions of the mandible, the internal maxillary artery, pterygoid venous plexus, and V3. The masticator space extends to the skull base where V3 passes through foramen ovale and the middle meningeal artery passes through foramen spinosum. There is a fat pad posterior to the maxillary sinus antrum, which is called the retroantral fat pad. This fat continues inferiorly as the buccal space, through which courses the parotid duct (Fig. 4-12).

The left buccal space is normal. *1*, superficial musculoaponeurotic system; *2*, facial vein; *3*, parotid duct; *4*, buccal space fat. CT, computed tomography.

## The Infrahyoid Neck

Central in the infrahyoid neck is the visceral compartment, which contains the larynx, hypopharynx, trachea, esophagus, thyroid, and parathyroid glands. Detailed imaging anatomy of the larynx will be discussed in the chapter dedicated to that organ.

The hypopharynx is continuous with the oropharynx superiorly, separated at the level of the hyoid bone and vallecula. It extends posterior to the larynx to end at the level of the cricopharyngeus muscle. On axial images, the postcricoid portion of the hypopharynx has a flattened ellipsoid shape (Fig. 4-13A,B). The inferior continuation of the hypopharynx is the esophagus, which has a more rounded shape posterior to the trachea (Fig. 4-13C).

The pyriform sinuses are paired lateral recesses of the hypopharynx, the anterior aspect of which abuts the paraglottic fat of the larynx (Fig. 4-13C). The most inferior extent, called the pyriform sinus apex, is at the level of the true vocal cords. Deep to the lateral mucosa of the pyriform sinuses is the thyroid membrane superiorly and the thyroid cartilage inferiorly. The medial wall of the pyriform sinus is the lateral surface of the aryepiglottic fold.

Posterior to the hypopharynx is the retropharyngeal space, which extends from the skull base to the mediastinum. Posterior to this is the thick prevertebral fascia, which surrounds the paraspinous muscles and forms a relatively strong barrier to the spread of disease.

The retropharyngeal space is in direct communication with the lateral compartments of the neck. The lateral compartments are also referred to as the vascular and paravisceral spaces and contain the carotid sheath containing the common and internal carotid arteries, the jugular vein and accompanying lymph nodes, and the vagus nerve, which runs in between the carotid artery and jugular vein. The lateral compartment of the neck also includes the sternocleidomastoid muscle.

The posterior compartment of the neck is made up of the cervical spine and paraspinal muscles.

## The Brachial Plexus

The brachial plexus is an area that is difficult to image with both CT and MRI because of the change in contour from a relatively thin neck to broad shoulders. Brachial plexopathies can occur following treatment of head and neck cancer and can present concern over whether the symptoms are from recurrent tumor or radiation neuritis. The brachial plexus can be seen in the region of the cervicothoracic junction as it courses between the anterior and middle scalene muscles (Fig. 4-14). When affected by radiation, the brachial plexus can enlarge, becoming edematous on T2-weighted images, and can enhance.

## CT VERSUS MR VERSUS PET-CT

Which imaging modality to choose depends on how pathology will appear compared to normal tissue and whether there is a contraindication to giving intravenous contrast. For example, a history of severe reaction such as anaphylaxis to iodinated contrast will limit the patient to a noncontrast CT scan or MRI. Severe renal insufficiency will limit the ability to give iodinated contrast for CT as it may worsen renal function, and gadolinium is typically not given when glomerular filtration rate is <30 because of the risk of nephrogenic systemic fibrosis.

Noncontrast CT is not optimal for head and neck cancer imaging because tumor often has the same density as muscle and lymphoid tissue. Inherent contrast between fat, which appears dark, and soft tissue is excellent, and visualization of cortical bone and cartilage erosion is excellent on thin-section CT (Fig. 4-15).

The addition of intravenous iodinated contrast is very helpful for CT because tumor usually enhances more than muscle, allowing differentiation. Many tumors incite an inflammatory reaction in the surrounding tissue, which will also enhance, allowing visualization of tumor compared to normal tissue. For practical purposes, the inflammatory reaction should be considered as tumor for treatment planning purposes, as it is impossible to differentiate the two on imaging studies. CT has advanced tremendously in terms of speed of imaging and coverage. Axial CT images can now be acquired in very thin sections, and software is commonly available to reconstruct these data in any plane, which was a former advantage of MRI.

MRI has the advantage over CT of being able to manipulate contrast by changing the imaging parameters. T1-weighted images give excellent inherent contrast between fat and soft tissue. This is particularly useful when looking for perineural tumor spread where the obliteration of fat at skull base foramina, for example, is a sign of tumor extension. Similar to CT, however, noncontrast T1-weighted images give poor contrast between tumor, muscle, and lymphoid tissue.

T2-weighted images tend to give good contrast between tumor and muscle, and fat suppression techniques can be very helpful for visualization of tumor. However, differentiation of tumor from lymphoid tissue may be difficult.

The administration of gadolinium shortens the T1 relaxation of enhancing tumor, and so is very helpful. T1-weighted images postgadolinium with fat suppression is a commonly used sequence for imaging the extent of tumor.

In general, the appearance of tumor compared to normal surrounding tissue depends on the tumor histology and its growth pattern. In terms of histology, the cellularity, nuclear to cytoplasm ratio, and stromal factors can affect the tumor's density on CT or signal intensity on MRI. Also affecting the tumor's appearance is the presence of microcysts, macrocysts, necrosis, hemorrhage, and calcification.

Tumors that are very cellular with large nuclei and little stroma, such as lymphoma, can be of higher attenuation than muscle on noncontrast CT and hyperintense to muscle on noncontrast T1-weighted images and hypointense on T2-weighted images. Squamous cell cancer tends to be slightly hyperintense

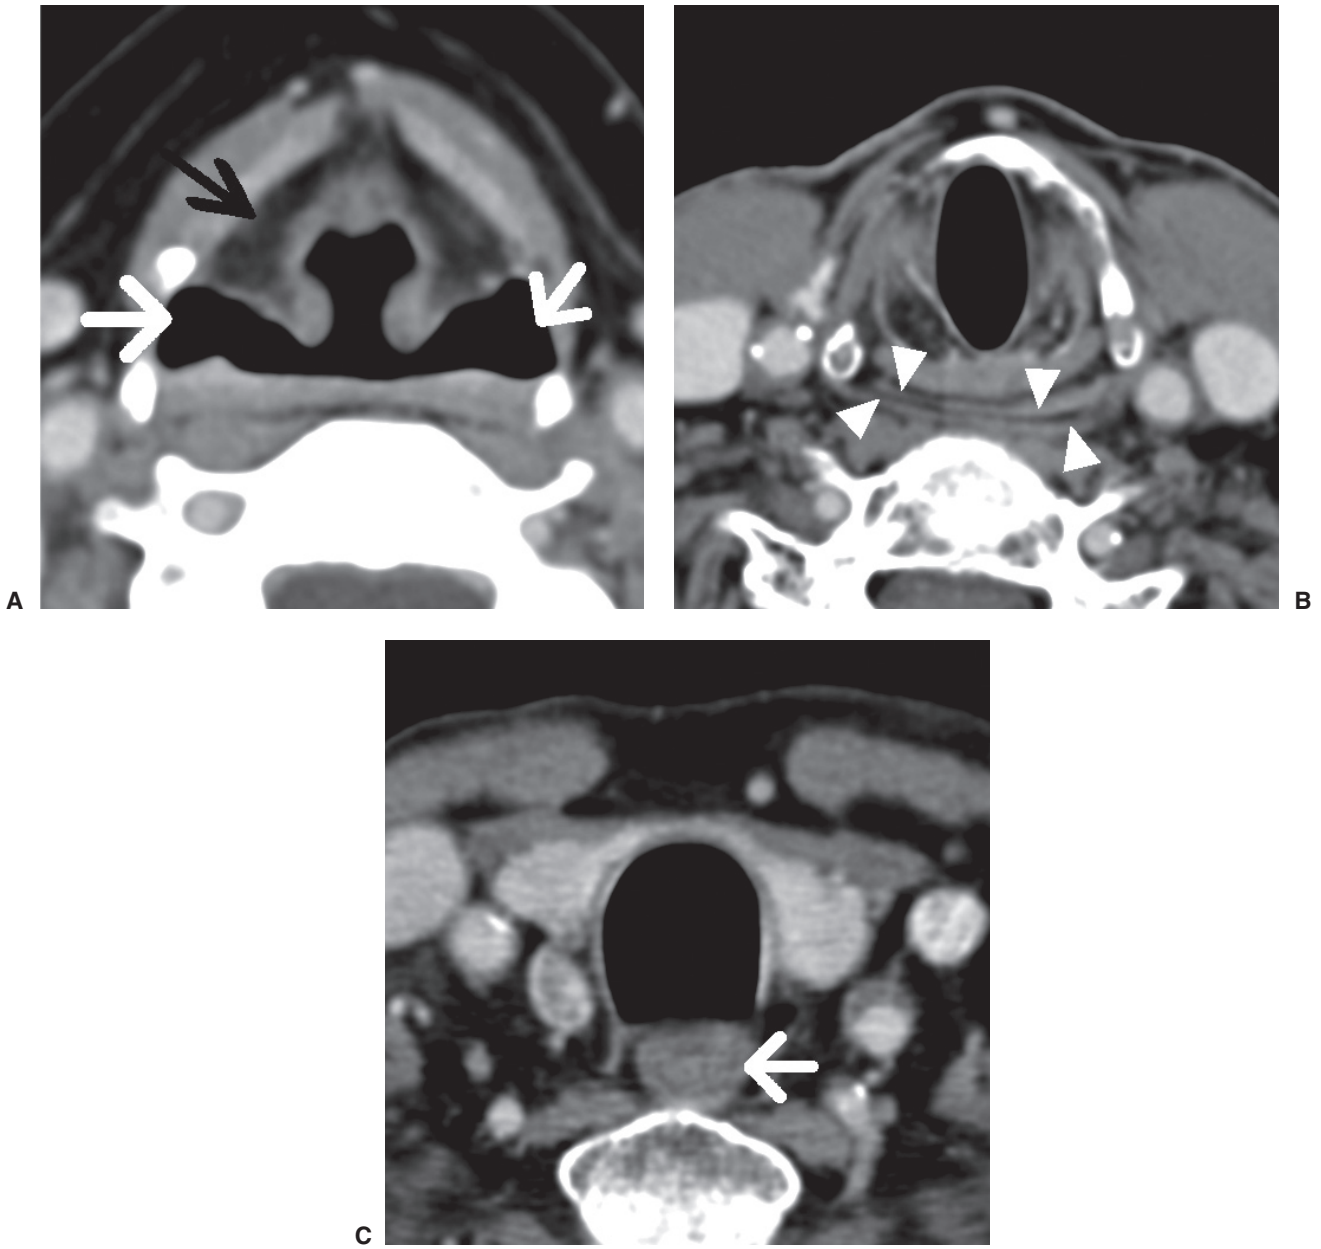

**FIGURE 4-13.** Axial postcontrast CT images of the hypopharynx. At the upper level of the hypopharynx (**A**) are the paired pyriform sinuses (*white arrows*). The paraglottic fat (*black arrow*) is well seen as a low attenuation region anterior to the aryepiglottic folds. **B:** At the postcricoid level, the hypopharynx appears as a thin ellipse (*arrowheads*). **C:** Posterior to the trachea the hypopharynx has merged into the esophagus, which appears as a rounded structure (*arrow*). CT, computed tomography.

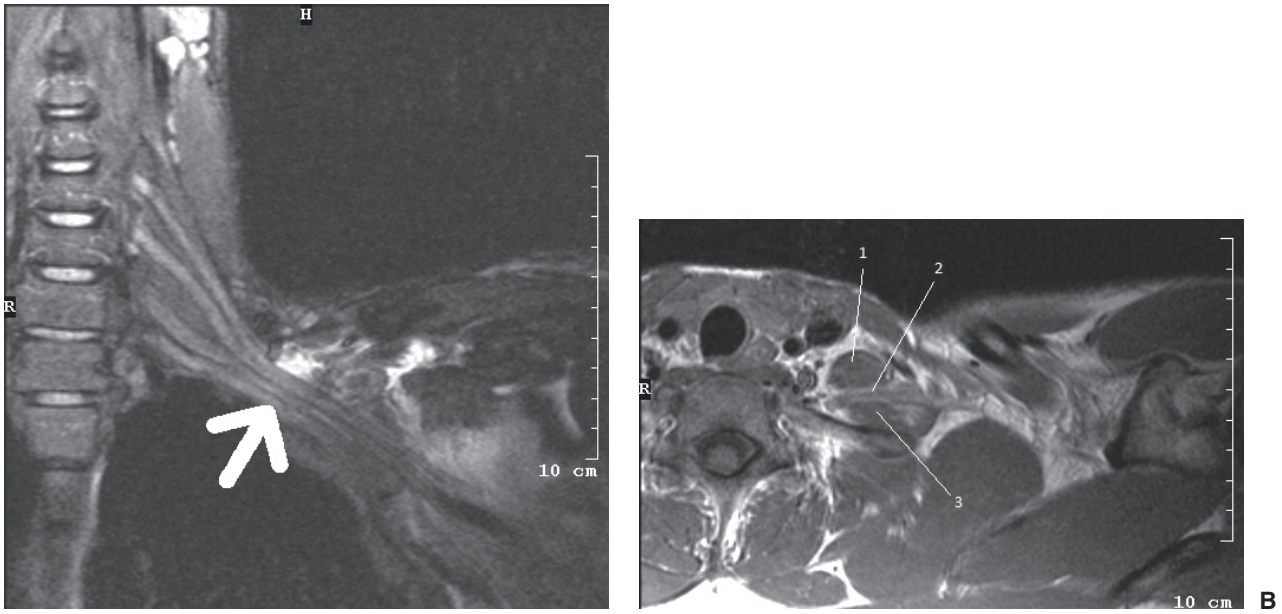
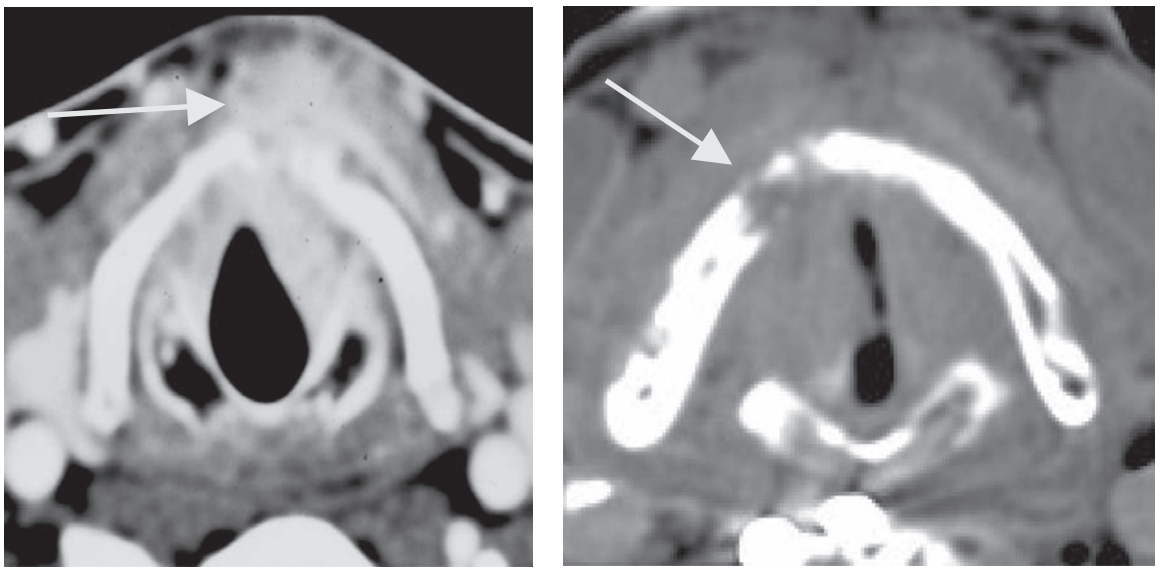


to muscle on T2-weighted images. The presence of microcysts or macrocysts can make the tumor hypointense to muscle on T1-weighted images and hyperintense on T2-weighted images. If the lesion is very dark on T2-weighted images, a fibrous matrix, hemorrhagic or calcified lesion, or lymphoma should be considered (Fig. 4-16).

FDG-PET has spatial resolution that does not allow for clear distinction of the full extent of the tumor, the presence of bone destruction, or perineural spread. It can be helpful in the workup of the unknown primary (Fig. 4-17), in determining positive lymph nodes, in determining the presence of distant metastatic disease (Fig. 4-18) and is especially useful in posttreatment surveillance scans. The use of PET-CT is described in more detail in the radiologic imaging concerns section of Chapter 10.

## PATTERNS OF TUMOR GROWTH



Tumors tend to grow as a sphere unless they are constrained by anatomic boundaries. When faced by boundaries, they grow along the path of least resistance. Hard tumors will remodel bone and push away vessels and nerves. Softer tumors can insinuate around structures such as vessels. Ultimately, malignant tumors will not respect boundaries and will directly invade structures.

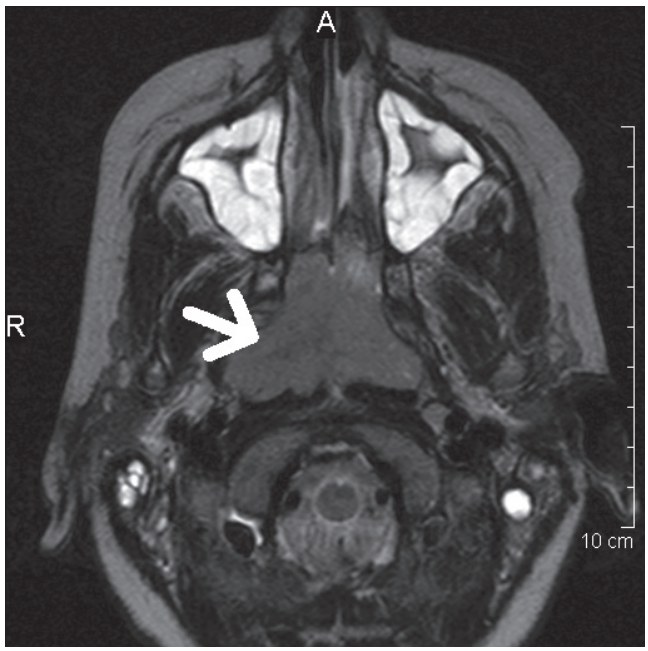

**FIGURE 4-16.** Axial T2-weighted MRI of a patient with nasopharyngeal lymphoma. Notice how low signal the tumor appears (*arrow*) compared to most pathology, which is usually bright on T2-weighted images. Compare the mucosal thickening in the maxillary sinuses. MRI, magnetic resonance imaging.

That being said, they prefer to grow along structures first, prior to invading them. For example, malignant squamous cell cancer can grow along fascial planes in the neck, including the fascia surrounding muscle bundles and along periosteal tissue, along neurovascular structures, and within the medullary spaces of bone. Therefore, when tissue fat planes between tumor and muscle, tumor and bone, or tumor and a vessel are obliterated on imaging, it does not necessarily mean that the muscle, bone, or vessel has been invaded. The tumor may just be growing along that structure's fascial lining. Fixation of a vessel can be assumed if tumor surrounds it by more than 270°.

Certain structures provide more of a boundary than others. For example, the pharyngobasilar fascia that holds the nasopharynx open is a thick structure and so is relatively resistant to tumor invasion compared to other thinner and weaker fascial planes such as the buccopharyngeal fascia. Cartilage is resistant to tumor invasion probably because it is hypovascular. When cartilage is invaded, it tends to happen at sites of ossification, where there are penetrating neurovascular bundles. Similarly, bone invasion tends to happen at sites of penetrating neurovascular bundles or at sites of muscle attachment.

Bone erosion is an important sign that invasion has occurred. CT is the best for detecting cortical erosions (Fig. 4-19). MR, particularly noncontrast T1-weighted images and fat-saturated postgadolinium T1-weighted images, is good for demonstrating tumor spread through bone marrow spaces. Increased bone density, or sclerosis, is indeterminate for tumor invasion.

## Perineural and Perivascular Spread of Tumor

Tumor can spread along the perineurium as well as along fascia surrounding vessels and muscles. For example, an oropharyngeal tumor can spread along the styloglossus and stylopharyngeus muscles to reach the carotid sheath. Superior growth of tumor can then reach the carotid canal and jugular fossa of the skull base.

Perineural spread is demonstrated on imaging by obliteration of fat planes, enlargement and enhancement of nerves, and erosion of bony foramina through which nerves pass. Certain structures are best imaged in the axial plane, such as the entrance of the mandibular nerve into the alveolar canal, the greater and lesser palatine foramina, and the pterygopalatine fossa. The connection between V3 and VII along the auriculotemporal nerve is also best seen in the axial plane (Fig. 4-20). Another connection between the fifth and seventh cranial nerves is along the greater superficial petrosal nerve from the pterygopalatine fossa (Fig. 4-21).

Spread of cancer along V3 to the trigeminal ganglion and cavernous sinus is better imaged in the coronal plane (Fig. 4-22). In general, MRI is superior to CT for imaging perineural spread of tumor.

## Lymphatic Spread of Tumor

The likelihood of tumor to spread along lymphatics is based on a number of factors. One is the location of the primary tumor. Certain sites are rich in lymphatic drainage such as the nasopharynx and so commonly present with positive nodes. Other sites, such as the true vocal cords, have relatively sparse lymphatic drainage. The overall size of the tumor and biological aggressiveness also affect the likelihood of finding positive lymph nodes.

The radiological features that define a positive lymph node are the enhancement pattern with presence of internal nonenhancing areas, and the periphery of the node, where indistinct borders are a sign of extracapsular spread of tumor. These features are more helpful than size of the node (Fig. 4-23). CT has been shown to be slightly superior to MR for the detection of small suspicious lymph nodes.[6] FDG-PET can also be very helpful. This topic is dealt with in greater detail in Chapter 10.

# POSTTREATMENT REACTIONS AND SCARRING VERSUS RECURRENT TUMOR

Posttreatment scans of head and neck cancer patients are among the most challenging imaging studies to interpret secondary to the distortion of normal anatomy from surgery and flaps and reactive tissue changes in response to surgery and radiation.

During radiation therapy tumor becomes edematous and necrotic, with the amount of peritumoral edema peaking at the end of treatment. Tissue then heals following the course of radiation but reactive mucosal edema and deep tissue space edema may persist for months. The inflammatory response is isodense to muscle on CT, isointense to hypointense in T1-weighted images, hyperintense on T2-weighted images, and enhances. In other words, this granulation tissue has imaging characteristics indistinguishable from tumor. The inflammatory response is FDG avid, so PET scanning generates too many false positives in the first 3 to 4 months following treatment.

The inflammatory response usually resolves in 3 to 12 months to form scar tissue, which is isodense to muscle and tumor on CT, but is low signal on both T1-weighted and T2-weighted images with slight enhancement.

General rules to follow in posttreatment imaging are that decreased size or disappearance of tumor indicates a good response to therapy. Focal residual masses are seen not infrequently on scans obtained >3 months posttherapy. Persistent enhancement

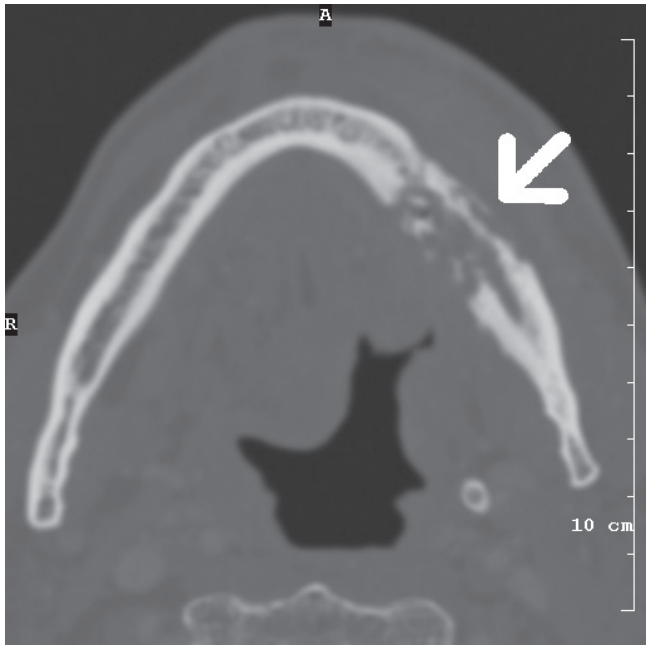

**FIGURE 4-24.** Axial CT scan with bone windowing shows typical findings of osteoradionecrosis (*arrow*) including fragmentation and tunneling. CT, computed tomography.

and T2 signal greater than muscle are suspicious findings for residual tumor, but nevertheless most of these masses still shrink or stabilize over time.[5] A negative PET scan is very encouraging in these cases.

Changes in nontumoral tissue are commonly encountered on the postradiation therapy scans. These include skin thickening and stranding in the fat from either lymphedema or perilymphatic fibrosis. Atrophy or fatty replacement of the major salivary glands, lacrimal glands, and lymph nodes that were in the radiation portal may be seen. Mucosal thickening in the paranasal sinuses and mastoid air cells in the radiation field is a common finding. These changes may all persist for years.

Bony changes on posttreatment scans also create diagnostic challenges. The surgical margins of partially resected bone usually heal in about 3 months with a smooth cortical margin. Osteoradionecrosis can occur months to years following radiation therapy. It typically can be distinguished from recurrent tumor by its fragmented nature with sloughing of cortical bone and endosteal tunneling (Fig. 4-24). Lucencies that develop between bone and hardware indicate loosening, but the cause may be osteonecrosis, infection, or tumor.

CHAPTER 5

Avraham Eisbruch

# Novel Radiation Therapy Techniques in the Management of Head and Neck Cancer

In traditional irradiation of head and neck cancer, the placement of the radiation fields and their shapes are based on the bony anatomy acquired by the simulator diagnostic-quality films. During the late 1980s, advancements in computer technology and imaging introduced methods to identify the targets on computed tomographic (CT) scans and display the radiation beams in three dimensions relative to the anatomy. In addition, calculation and display of the radiation dose distributions and methods to evaluate and compare rival plans using dose–volume histograms (DVHs) became available. The introduction of multileaf collimators (MLCs) facilitated an increase in the number of beams that could be delivered without a large extension of treatment time. Treatment could now be delivered from multiple angles, including noncoplanar directions, when required. The result was the emergence of three-dimensional conformal radiotherapy (3DCRT), which allowed better precision of irradiation delivery to image-based targets, and some improvements in the sparing of uninvolved critical organs. Early studies of the utility of 3DCRT in head and neck cancer examined cancer of the larynx,[1] nasopharynx,[2,3] hypopharynx,[4] and paranasal sinuses.[5] These studies demonstrated a significant benefit from 3DCRT such as better coverage of the tumors and reduced doses to critical tissue compared with standard techniques. A step forward has been gained in the mid-1990s by intensity-modulated radiotherapy (IMRT), which facilitated a higher degree of dose conformality and offered opportunities for additional clinical gains. More recently, imaging-guided radiotherapy (IGRT) has emerged, providing opportunities for better precision of patient setup and for tracking tumor regression and anatomic changes in the noninvolved tissue during the course of radiation. Tracking these anatomic changes may facilitate future replanning during the course of therapy to address them, a concept referred to as adaptive radiation therapy (ART). Other emerging technologies include new imaging modalities that provide opportunities to study the customization of the radiation dose depending on the expected tumor biology, and the use of heavy particles like protons or carbon ions, which offer additional advantages in dose conformality. In addition, technical innovations in the delivery of IMRT, such as tomotherapy and volumetric-modulated arc therapy (VMAT), provide specific improvements and introduce specific trade-offs compared with beamlet-based IMRT. Some recent experience has been gained with stereotactic radiotherapy using a robotic radiosurgery system for recurrent cancers near the base of the skull. These advancements will be described in this chapter, emphasizing the role of IMRT, for which ample clinical experience has accumulated.

## IMRT: GENERAL ASPECTS

IMRT implies the use of radiation fields for which intensity varies across the field, depending on the thickness of the target and the existence of critical organs or critical noninvolved tissue in their path. Treating the targets with multiple beams of varying intensity allows a relatively uniform dose in an irregularly shaped target while avoiding a high dose to the surrounding structures. Two technologic developments made IMRT possible: the introduction of computer-controlled MLCs and the development of computerized optimization or "inverse planning," which determines the intensity of the beams required to satisfy a specified set of dose distributions.

Currently, most IMRT delivery systems use conventional MLCs. Delivering IMRT using a conventional MLC can be made in a "dynamic" or "static" form. In the "dynamic" form, the leaves at each gantry position are swept across the target while the beam is on and their speed determines the radiation fluence. In "static" or "segmental" multileaf IMRT, each field consists of multiple segments with different intensities. These forms of IMRT are currently offered by most manufacturers of linear accelerators. A helical tomotherapy design has been developed at the University of Wisconsin and is similar in its operation to the helical CT, delivering essentially an infinite number of beams while the gantry rotates around the patient. This design has been available commercially in recent years.

The complexity of IMRT plans cannot usually be achieved by the forward, iterative process alone used in 3DCRT plans. Instead a computer-based optimization process, called *inverse planning*, is used. Inverse planning demands that the physician and planning team state the treatment goals, usually in terms of the dose and/or dose–volume goals for the targets, and the constraints for the critical normal tissue (the objective, or cost function). The computer attempts to achieve the desired outcome by iteration through numerous possible beam intensities. The desired solution is the dose distribution that minimizes the variance of the delivered dose relative to the objective function. For each target and noninvolved organ or tissue, an importance factor or weight is assigned, and the objective function is the sum of the variance terms representing each structure of interest, multiplied by the importance factor. Because the variance is the sum of the squares of the differences between the prescribed and the delivered doses, this approach is called a *quadratic objective function* and is the one used in most current optimization systems. A publication by the Intensity Modulated Radiation Therapy Collaborative Working

(c) 2014 Wolters Kluwer. All Rights Reserved.

Group summarized the consensus regarding IMRT planning, delivery, commissioning, radiation safety and quality assurance, and detailed recommendations about target volume and dose specification.[6] This publication is recommended for readers interested in more detailed discussions about the general aspects of IMRT.

## IMRT FOR HEAD AND NECK CANCER

The anatomy of the neck is complex, with many critical and radiation-sensitive organs in close proximity to the targets. Tight dose gradients around the targets that limit the doses to the noninvolved tissue, features characteristic of IMRT, are desirable and offer the potential for therapeutic gains. The sparing of uninvolved normal organs can offer significant improvement in outcomes. This includes major salivary glands, minor salivary glands dispersed within the oral cavity, the mandible, and the pharyngeal musculature as well as other organs pertinent to specific anatomic tumor locations. In the cases of nasopharyngeal and paranasal sinus cancer, critical normal tissue that may be partly spared using IMRT include the inner and middle ears, the temporomandibular joints, temporal brain lobes, and the optic pathways.

In addition to noninvolved tissue sparing, IMRT offers a potential for improved tumor control by reducing the constraints on the tumor dose due to critical organs, for example, the spinal cord, brain stem, and the optic pathways, which occasionally limit the tumor boost doses in conventional radiation therapy (RT). This is achieved by specifying a maximal dose to the critical organs and a high penalty in the optimization process if that dose is exceeded. In addition, IMRT eliminates the need for posterior neck electron fields, commonly used in conventional RT, and their associated dose deficiencies. IMRT in the head and neck is more feasible than in other sites as breathing-related organ motion is practically absent. However, there are other factors that need to be taken into account such as patient setup uncertainties, swallowing-related organ movements, and changes in target and organ positions related to tumor shrinkage and patient weight loss during therapy, detailed in the subsequent text.

### Patient Selection

Head and neck IMRT is work intensive and lengthens treatment time. Not every patient is expected to benefit; those who would benefit most are patients with paranasal sinus cancer where the targets are near the optic pathways, patients with oropharyngeal or nasopharyngeal cancer in whom standard RT fields would encompass most of the salivary glands, and patients in whom standard techniques would require a compromise in the tumor dose, due to proximity of the tumor to the spinal cord or the brain stem. Patients with laryngeal cancer and clinically noninvolved neck, receiving treatment to the larynx alone or requiring irradiation of the neck encompassing the jugulodigastric nodes but not extending to the base of the skull, may not benefit from IMRT compared with simpler techniques. The same applies to patients requiring irradiation to the ipsilateral neck alone. In recent years, there have been suggestions to use IMRT when the glottic larynx alone is treated, to spare the carotid artery and reduce the risk of development of an atheromatous plaque and subsequent brain stroke.[7,8] However, the utility and value of this uproach is not known and it is not practiced by most centers.

### Immobilization

Head and neck immobilization is typically performed using a thermoplastic mask with several attachment points to the treatment table and a head support. Several commercial systems are available. Typically, immobilization with these systems results in average daily setup errors of few millimeters.[9] These errors require an extension of the targets to ensure adequate irradiation (see "The Planning Tumor Volumes" in the subsequent text). It is important to extend the mask to include the lower neck and shoulders, if targets in the lower neck and the supraclavicular nodes are included in the IMRT plans. An alternative is to treat the lower neck with an anterior field and match this field with the upper neck IMRT fields using a split-beam technique. This strategy reduces the doses to the glottic larynx and to the skin of the lower neck and reduces treatment complexity, compared with whole-neck RT.[10] Such a strategy is recommended in cases where the risk of disease in the lower neck is low. In these cases, the head and upper neck alone need to be immobilized.

### Defining the Target: Imaging

In most cases, the simulation contrast-enhanced CT is in most cases the only imaging modality required for the delineation of the targets. Magnetic resonance imaging (MRI) is limited by its sensitivity to artifacts, difficulty in interpretation, long examination time, and cost. MRI is a necessary adjunct to CT for tumors close to the base of the skull, such as nasopharyngeal and paranasal sinus cancer. In these situations, MRI provides better details of tumor extension and the parapharyngeal and retropharyngeal spaces, compared with CT.[11] Fluorodeoxyglucose-positron emission tomography (FDG-PET) has recently been found to add significantly to the information gained from CT regarding the tumor extent in lung cancer.[12] In contrast, early series of head and neck cancer where CT, MRI, and FDG-PET were obtained, and surgery was then performed to validate the primary tumor extent and lymph node involvement, reported a rather limited benefit of FDG-PET compared with CT/MRI.[13] More recent studies have better defined the role of FDG-PET as a tool for target delineation in IMRT of head and neck cancer. Daisne et al. performed pretreatment CT, MRI, and FDG-PET on 29 patients with stage II to IV laryngeal and oropharyngeal cancers.[14] Nine of these patients subsequently underwent total laryngectomy, and these specimens were compared with coregistered radiographic images. There was no difference between total CT and magnetic resonance (MR) volumes, but GTVs obtained from FDG-PET were smaller than these two, and surgical specimens were even smaller, indicating overestimation of GTVs with all three imaging modalities. However, when examined in detail, despite overestimating in most dimensions, all three imaging modalities actually underestimated the mucosal extent of disease, highlighting the importance of the physical examination in determining the mucosal extent of tumors for treatment planning purposes. Another study, from Emory University, did not have pathologic correlation, but imaged 40 patients with FDG-PET and CT.[15] In this report, the target according to PET was smaller than the CT-defined target in 75% of cases, but larger in 18%. When the PET images were registered on the treatment plan constructed with only CT volumes, the PET-defined target was noted to be underdosed in 25% of cases. It is possible that the difference in the results of these two studies can be attributed to different thresholds for determining PET positivity. Whereas fixed thresholds have been commonly used, the group from the Universite Catholique de Louvain in Brussels, Belgium, has published work suggesting that the correct threshold depends on the signal-to-background ratio of each study and is typically between 36% and 73%.[16] The practice at the University of Michigan has been to combine the information gained from FDG-PET and CT (and MRI for tumors near the base of the skull) for a composite gross target, as the information gained from any single imaging modality cannot be considered gold-standard taking into account current published studies. In all cases, the findings of a careful clinical examination

(c) 2014 Wolters Kluwer. All Rights Reserved.

form the basis for assessing the extent of the primary tumor. For example, palpation of oropharyngeal tumors can assess their extent in a way that is complementary to imaging, especially the mucosal extent which is poorly assessed by imaging.[14]

## Selection and Outlining of the Targets

A major potential pitfall of IMRT is the failure to select and delineate the targets accurately. This is especially relevant in head and neck cancer, where a high risk of subclinical local and nodal disease exists and where adequate irradiation of the lymph nodes at risk is crucial for local-regional control and survival. For example, in standard three-field head and neck RT, the first echelon and the retropharyngeal nodes are treated routinely when the primary tumor is targeted. In contrast, these nodes will not be adequately irradiated by IMRT if they are not specified on the planning CT.

## Target Definitions in the Head and Neck

The GTVs consist of the primary tumor and lymph nodes with apparent or suspected metastasis. The primary tumor GTV is defined using radiologic and clinical assessment. Lymph node GTVs include nodes with radiologic criteria of involvement: diameter >1 cm (in the case of the jugulodigastric nodes, >1.1–1.5 cm), smaller nodes with spherical rather than ellipsoid shape, nodes containing inhomogeneities suggestive of necrotic centers, or a cluster of three or more borderline nodes.[17] The clinical target volume (CTV) surrounding the primary tumor consists of tissue perceived to contain microscopic, subclinical tumor extension. In addition to the primary tumor CTV, the lymphatic CTVs consist of nodal areas that are at risk of metastatic disease but do not match the radiologic criteria of involved nodes.

## Delineation of the Primary Tumor Clinical Target Volume

Factors used for assessing the extent of the CTV margins in each case include tumor site, size, stage, differentiation, and morphology (exophytic vs. ulcerative, infiltrative vs. pushing front). Rather than assign or expand the GTV uniformly, outlining of the CTV is recommended on the planning CT on slice-by-slice basis. Knowledge of the anatomic and clinical patterns of tumor extension and clinical judgment, as well as a familiarity with head and neck imaging, are necessary for accurate estimation of the CTV margins around the tumor. Specific recommendations for each tumor site have been detailed elsewhere.[18]

## Selection and Delineation of the Lymphatic Clinical Target Volumes

Our knowledge of the pattern and risk of lymphatic drainage from different head and neck sites is based on the classical anatomic work of Rouviere,[19] reviewed recently,[20] the assessment of the location and prevalence of clinical neck metastasis by Lindberg et al.,[21] and the large experience with elective neck dissections providing information about microscopic metastases, reported by Byers and Shah.[22,23] A division of the neck to six levels has been developed by surgeons from Memorial Hospital and revised by Robbins et al.,[24,25] allowing standardized and improved reporting of the nodal involvement and the surgical therapy of the neck. Adoption of this system for identification and outlining of the nodal CTVs for IMRT is highly recommended. It should be emphasized that the retropharyngeal nodes, which are not routinely dissected surgically, are not considered in the surgical neck levels classification, but are important targets in the irradiation of nasopharyngeal and other advanced head and neck cancer.[26] Reviews of the risk of metastases to each neck level[27] and of the neck levels at risk for each tumor site and stage[18] have recently been published. Several publications are recommended for identifying the neck levels on the planning CT scans. An imaging-based nodal classification, using CT- or MRI-based criteria that correspond to the surgical anatomic landmarks, has been developed by head and neck radiologists.[28] In addition, several articles have been published by radiation oncologists demonstrating how to outline the lymph node neck levels as CTVs on the planning CT scans[18,27,29–32] or axial MRI.[27]

In the postoperative cases, the surgical specimens provide information which helps in determining the neck levels at risk. Neck dissection disrupts some anatomic landmarks used to define the borders between the levels. On the other hand, the surgical bed is apparent on the CT scan and should be encompassed entirely within the CTV.[32] It is often impossible to distinguish between the primary tumor resection and the adjacent neck dissection bed, and they are encompassed within a unified CTV. Neck levels in which microscopic extracapsular lymph node extension has been found are considered high-risk volumes and are assigned a higher dose (see subsequent text). At these levels, the target may be extended to include the subcutaneous tissue.[33]

## The Planning Tumor Volumes

Once the GTVs and CTVs are outlined on the axial CT images, a uniform expansion of these targets is performed to obtain the planning tumor volumes (PTVs) that accommodate setup uncertainties. Typically, the magnitude of the margin is 5 mm, which means that an extra 5-mm rind of normal tissue around the target receives full dose. In a region with targets and organs at risk (OARs) in close proximity, reducing this margin can potentially reduce treatment-related toxicity. Indeed, it has been estimated that each 1 mm of margin adds 1.3 Gy of dose to the parotid gland, which are particularly sensitive to low doses of radiation.[34] To reduce setup uncertainty, many groups have advocated daily imaging, with a position correction if the displacement from the original plan exceeds a threshold value. At the University of Michigan, daily imaging and setup correction before each treatment fraction has reduced the setup error to 1 ± 1 mm, enabling a reduction in PTV margins to 3 mm. The importance of daily imaging and correction has been evident in studies which examined setup uncertainties: daily imaging is required if PTV margins are 3 mm, and every other day if the margins are 5 mm.[35] Whether imaging is performed by CT or by orthogonal portal imaging seems to be less important than the frequency of imaging and correction.[36] It should be noted that while setup uncertainties are usually measured in the upper neck, near the targets, they are frequently larger in the lower neck even if the shoulders are included in the immobilization device.

Doses are prescribed to the PTVs or to comparable "growth" areas in some commercial planning systems. When the targets are close to the skin, as may occur in postoperative case, the PTV may extend beyond the surface. In such a case, the PTV should be edited back to the surface. If the PTV extends to the skin and the skin is not at high risk, the external body contour may be defined as a noninvolved organ for the optimization system. This facilitates avoiding excessive dose to the skin.[37]

Similar to the expansion of the targets to yield the PTVs, there is a need to accommodate uncertainties regarding the critical normal organs, especially the spinal cord, brain stem, and the optic pathways, that may lie in regions of steep dose fall-off near the targets. This can be accomplished by expanding these organs uniformly, yielding the planning-risk volumes (PRVs). At the University of Michigan, the spinal cord is expanded by 0.3 cm to yield the spinal cord PRV. The maximal accepted doses

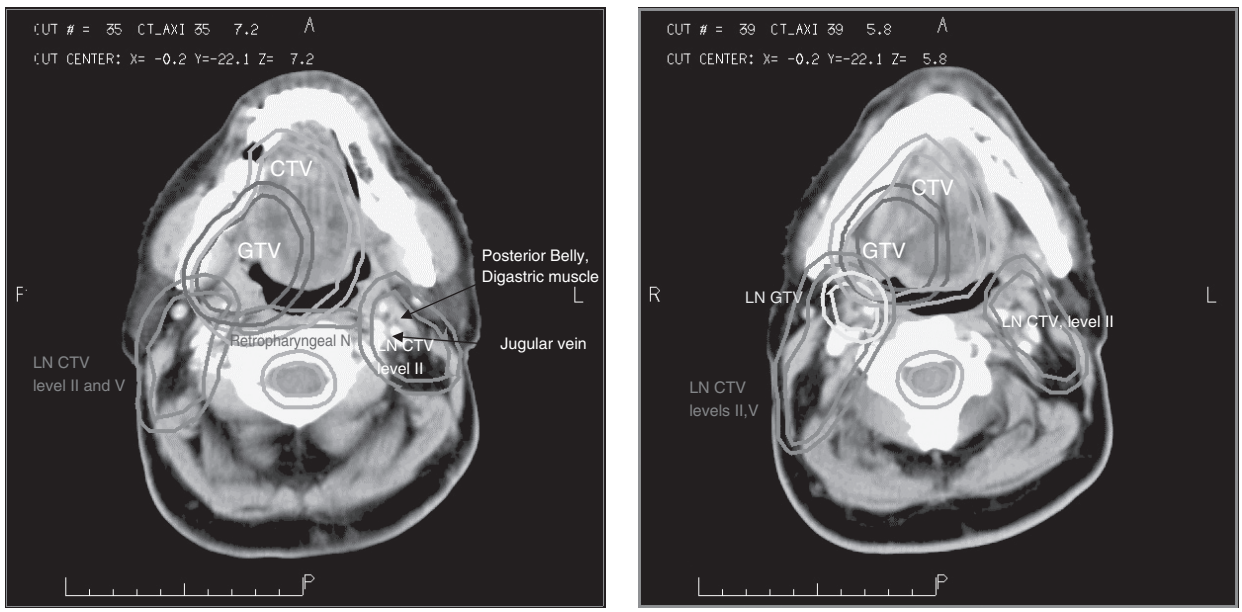
(c) 2014 Wolters Kluwer. All Rights Reserved.

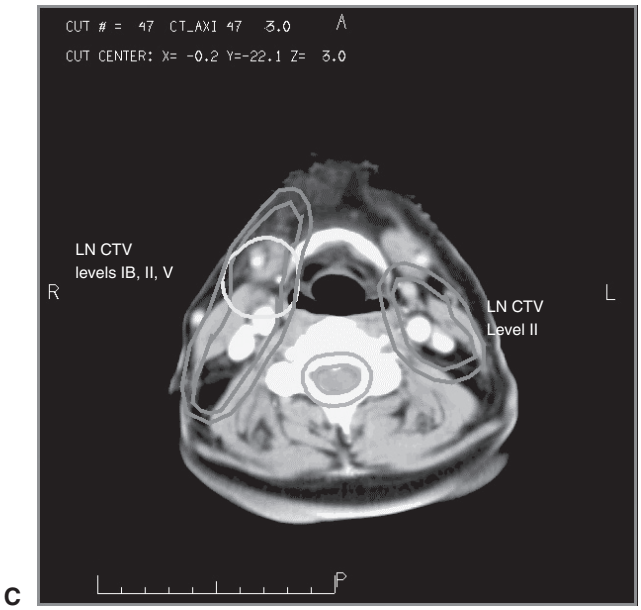
are 45 Gy to the spinal cord and 50 Gy to the PRV. Similarly, the optic nerves and chiasma are expanded for treatment plans of nasopharynx or paranasal sinus tumors.

An example of the delineation of the targets and noninvolved structures in a case of oropharyngeal cancer is provided in Figure 5-1.

## Dose Prescription and Specification and Normal Tissue Dose Constraints

The delivery of a single IMRT plan throughout the course of treatment provides better dose conformality compared with several consecutive plans, like the consecutive plans common in conventional radiotherapy, which consist of initial fields encompassing all targets followed with a boost to the gross tumor.[38] When a single plan is prescribed, the gross tumor PTV receives both a higher total dose and a higher dose per fraction compared with the PTVs of the subclinical disease. Owing to the differences in the daily fraction doses, a correction of the total dose to yield the normalized total dose (NTD) for a 2-Gy fraction regimen is required when the fraction dose is different from standard fractionation. An extensive discussion of this issue is provided by Mohan et al.[38] There are two general approaches to dose prescription. The first would be prescribing a total dose delivering standard fraction dose to the gross disease PTV, for example, 70 Gy over 35 fractions, and doses delivering low fraction doses to the subclinical disease PTVs: 63 Gy to the high-risk and 56 to 59 Gy to lesser-risk elective targets, which over 35 fractions would deliver fraction doses of 1.8 Gy and 1.6 to 1.7 Gy, yielding NTDs of 60 Gy and 50 to 54 Gy, respectively (the NTDs are calculated for late-reacting tissue, assuming an $\alpha/\beta$ of 3 Gy). When used for advanced disease, this schedule should be delivered concurrent with chemotherapy. The second strategy is to deliver a higher-than-standard fraction dose to the gross disease PTV, adjusting the total dose to yield NTD near 70 Gy, and standard fraction doses to the elective targets' PTVs. Such a strategy was adopted by the Radiation Therapy Oncology Group (RTOG) study of IMRT for oropharyngeal cancer (RTOG study H-0022). In this study, the gross disease PTV receives a total of 66 Gy in 30 fractions, 2.2 Gy/fraction. PTVs of high-risk subclinical disease receive 60 Gy, and low-risk PTVs receive 54 Gy, at 2.0 and 1.8 Gy/fraction, respectively. This results in the gross disease PTV receiving NTD of 70 Gy over 6 weeks, similar to the total time and dose delivered by accelerated RT regimen.[39] A more aggressive reported regimen delivers a total of 60 Gy in 25 fractions (2.4 Gy/fraction) to the gross disease and 50 Gy (2.0 Gy/fraction) to electively treated volumes, yielding an NTD of 66 Gy delivered over 5 weeks.[40] If we take into account the relatively large target dose inhomogeneity produced by IMRT, it would be apparent that large tissue volumes within the targets receive even higher fraction doses, and higher NTDs, than those calculated for the prescribed doses. A phase I dose escalation study was conducted at the Medical College of Virginia, in which the fraction size and the total dose





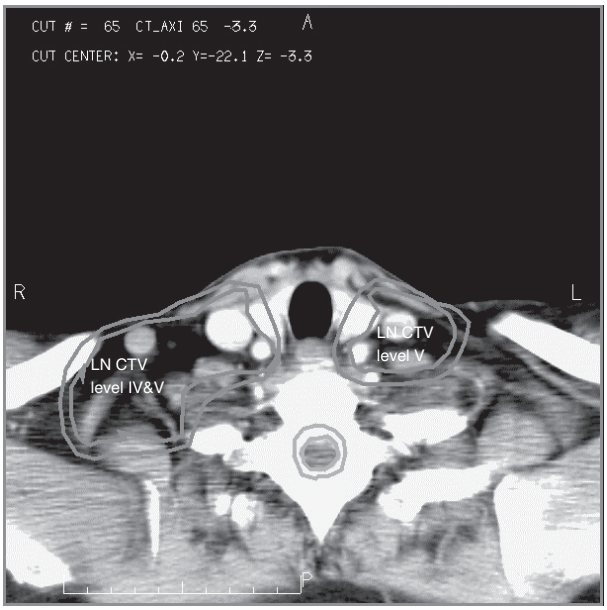


**FIGURE 5-1.** The targets outlined on planning CT in a case of stage T2, N1 carcinoma of the right tonsil, involving the lateral base of the tongue. The GTV, primary tumor CTV, and lymphatic GTV and CTVs are each expanded uniformly by 0.5 cm to yield the corresponding PTV. **A:** Level II nodal targets in the ipsilateral neck, and the retropharyngeal nodes bilaterally, are outlined through the base of the skull. Level II nodes in the contralateral neck are outlined up to the level in which the posterior belly of the digastric muscle crosses the jugular vein. Cephalad to this level, only the ipsilateral (LT) level II nodal CTVs and the retropharyngeal nodes are outlined. In cases where the contralateral neck contains clinical or radiologic evidence of metastasis, or in the case of nasopharyngeal cancer, level II is outlined through the base of the skull bilaterally. **B:** Nodal metastasis in the LT neck is outlined as a nodal GTV, expanded to yield its PTV. **C** and **D:** In the ipsilateral lower neck, nodal levels IV and V are included in the CTV. Only level IV is outlined in the contralateral lower neck (the contralateral neck did not have clinical evidence of metastasis). **E:** A sagittal reconstruction of the CT may help in the assessment of the extent of disease. On axial images, it is difficult to distinguish the soft palate from the base of tongue that contains the targets. The sagittal view facilitates the exclusion of the soft palate (*P*) from the targets. CT, computed tomography; GTV, gross tumor volume; CTV, clinical target volume; PTV, planning tumor volumes. **FIGURE 5-1.** *Continued*

to the gross disease PTVs were escalated.[41,42] It was postulated that limiting the high-dose treated volume to the target alone by IMRT may reduce the risk of late complications arising from large fraction doses.[40] However, critical normal tissues at risk in the head and neck, such as nerves, noninvolved mucosa, blood vessels, bone, and so on, are embedded within the targets and are at risk of late toxicity. In addition, these schemes may be associated with an excessive toxicity risk when they are combined with concurrent chemotherapy. As yet, the follow-up periods of published head and neck cancer IMRT series are not sufficient to assess the full risk of late complications arising from higher-than-standard fraction doses and total NTDs delivered to the targets. GTV dose escalation using IMRT should not, therefore, be practiced outside of careful and well-defined clinical trials.

Dose and dose–volume specifications are made to impose constraints on the DVHs of the targets, noninvolved tissue of interest, and nonspecified tissue outside the targets. RTOG protocol H-0022 specified the prescription dose as the dose that encompasses at least 95% of the PTV. No more than 20% of the PTV can receive >110% and no more than 1% of the PTV can receive <93% of the prescribed dose. To limit hot spots outside the targets, the protocol specifies that no more than 1% of the tissue outside the PTVs can receive >110% of the prescribed dose. This is done by adding a dose constraint for all nonspecified tissue (all tissue outside the targets and the specified organs) to prevent volumes of high dose outside the targets.

Dose constraints regarding critical organs are usually stated in terms of the maximal dose. Commonly applied constraints in the head and neck are maximal doses of 45 Gy to the spinal cord, 54 Gy to the brain stem, 70 Gy to the mandible, and 50 to 55 Gy to the optic pathway. These constraints were derived from standard irradiation, where the organ at risk receives irradiation at a

(c) 2014 Wolters Kluwer. All Rights Reserved.

standard daily fraction dose for part of the therapy course and is then fully shielded. In contrast, IMRT typically delivers lower daily fraction doses to these organs throughout therapy. In addition, the maximal dose derived from the DVH represents only a small organ volume, whereas standard RT delivers any specified dose homogeneously to relatively large volumes. In most instances, therefore, the same dose constraints are more conservative when applied to IMRT compared with standard RT. On the other hand, steep fall-off of doses near the critical organs may increase the risk of inadvertent overdosage to these organs due to motion and setup uncertainties. This issue can be addressed by a uniform expansion of the critical organs to yield the PRVs, as discussed in the preceding text. Organs with parallel functional architecture require specification of the mean dose or partial organ volume dose, rather than the maximal dose. Examples are the specification in RTOG protocol H-0022 of the maximal mean dose to the parotid salivary glands at 26 Gy, or limiting the dose to at least 50% of the gland volume to <30 Gy, and constraining the dose to two thirds of the larynx at <50 Gy.

Recommended dose constraints to specific organs are beyond the scope of this chapter. A recent effort by multiple clinicians and physicists, Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC), resulted in the publications of papers detailing normal tissue toxicity probabilities for critical organs based on actual data accumulated in the past decade.[43] These publications aimed specifically at guiding IMRT dose prescriptions and constraints for each critical organ.

## The Optimization Process

The PTVs and uninvolved organs lie in close proximity or overlap with each other. It is necessary to assign weighting factors (or penalty/importance factors) to each target and organ, which determine the relative importance of fulfilling their dose specifications or constraints. These weighting factors are derived following an iterative, trial-and-error process that requires refinement for each patient in order to produce an optimal plan. These factors differ among the various optimization systems. Examples of penalty factors for head and neck cancer plans were provided by several authors.[44,45] It was noted that because normal structure doses are penalized during optimization only if they exceed the limits set by the user, the constraints need to be more stringent than the clinical criteria.[45] At the University of Michigan, the optimization system uses a cost function that strives to minimize the dose to some noninvolved structures, in addition to setting a maximal dose constraint. This facilitates a reduction of the doses to these organs as much as possible, rather than settling at just below the maximal dose allowed.[46] Also, using a combination of linear and high-power objective functions (in addition to the quadratic objective function used in most commercial systems), strict head and neck target dose homogeneity can be achieved.[46]

In addition to the physical dose and dose–volume optimization criteria, several investigators examined the utility of biologic/clinical criteria as a basis for optimization in the head and neck. These investigations include optimization using the probability of uncomplicated tumor control,[47] tumor control probability (TCP) and normal tissue complication probability (NTCP),[48] and the equivalent uniform dose (EUD) concept, which is defined as the biologically equivalent dose that, if given uniformly, will lead to the same cell kill in the tumor volume as the actual nonuniform dose distribution.[49] The latter investigators found that optimization using EUD as the cost function is superior to optimization using dose or dose–volume. Biologic cost functions are expected to be superior to dose-based functions when the parameters of the biologic models, derived from clinical dose–response and dose-complication data, are known with greater confidence. An example is the optimization of advanced paranasal sinus cancer plans, where optic pathway NTCPs derived from patient complication data were used for the critical organ cost function.[50]

## The Number and Directions of The Beams

While tomotherapy uses arcs around the patient, IMRT using MLCs requires decisions regarding the number and orientation of the beams. It has been suggested early on that if the number of segments (or beamlets) is large enough, the direction of the beams is not important, and coplanar beams arranged at equidistance around the patient's head and neck would achieve satisfactory results. Most investigations of IMRT of head and neck with MLCs use this approach. The beam number should be odd, to prevent opposed beams which would increase hot spots near their entrance to the neck. Nine beams arranged at equidistance (40° apart) were found to be optimal: they provided better dose distributions than 5 or 7 beams, whereas 15 beams did not seem to improve the plans.[41] An optimization of the beam angles was found to be unnecessary by some authors,[41] whereas others reported an improvement in head and neck plans when optimized, noncoplanar beam angles were used.[51] This issue continues to be a subject of research. Current recommended field arrangement for IMRT of head and neck cancer with MLCs is nine equidistant, coplanar fields (Fig. 5-2), for patients with advanced tumors and complex anatomy like nasopharyngeal cancer. On the other hand, patients with prior tumors, or less complex anatomy, seven or even five coplanar nonopposed fields may achieve the planning objectives.

In patients without nodal disease in the lower neck, in whom the primary tumor resides in the nasopharynx, oropharynx, or oral cavity, treating the upper neck and primary tumor with IMRT while abutting the IMRT fields to an anterior–posterior low field containing a laryngeal block (split-field IMRT) reduces monitor units. It also reduces contouring and treatment time and can achieve better sparing of the larynx compared with whole-field IMRT.[52] However, if glottic larynx sparing is denoted by a higher weight (importance) in the optimization than full coverage of the

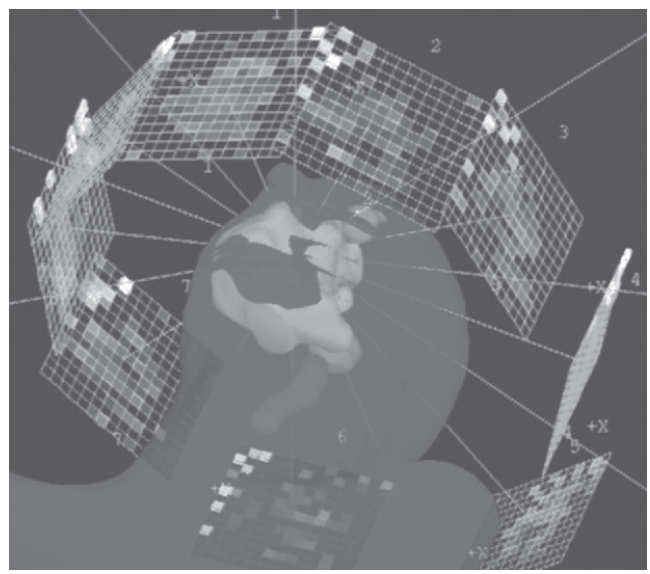

**FIGURE 5-2.** Beam arrangement for IMRT using an MLC. Nine coplanar, equidistant beams are used, each containing $1 \times 1$ cm or $0.5 \times 0.5$ cm pencil "beamlets." IMRT, intensity-modulated radiotherapy. (See color insert.)

(c) 2014 Wolters Kluwer. All Rights Reserved.

targets in the low neck, laryngeal avoidance can be as good.[53] The benefits of whole-field IMRT are mostly in cases with high-risk targets in the lower neck, where this method ensures adequate target coverage, while patients whose low-neck targets are at low risk are best treated with split-field IMRT.

## Clinical Results of IMRT Series: General

Most series reporting clinical results of tumor control rates following IMRT are still quite limited. They are either very heterogeneous regarding tumor sites and stages[26,31,33,54,55] have relatively small patient numbers or suffer from relatively short follow-up. Potential patient selection factors are probably the most important issues that should be considered in assessing the outcome in retrospective series of IMRT. IMRT is far more complex and time consuming compared with conventional radiotherapy. It also requires extensive skill and time commitment on the part of the radiation oncologist. It is likely that different selection factors play a role in each institution: patients who cannot tolerate lengthy treatment, those judged to be too sick to benefit from complex therapy, those requiring urgent start of therapy, and so on, may be selected to receive more simple, conventional treatment. These factors make any attempt to compare the results of different IMRT series, or even series of IMRT to series of conventional RT, futile. These issues have been demonstrated in a recent analysis from the University of Wisconsin, which assessed potential selection factors for patients treated with IMRT or conventional RT during the same time period.[56] They found that patients with T3–4 and N3 disease were less likely to be treated with IMRT. IMRT was found to be a significant prognostic factor improving tumor control rates; however, when the T stage was included in the model, the use of IMRT lost independent significance. Notably, although treatment results using IMRT were better than the results in the pre-IMRT era, there was also an improvement of tumor control rates in patients treated with conventional RT in recent years compared to those treated with conventional RT in the early 1990s.[56] Therefore, tumor control improvements in recent years may be related to factors like improvements in tumor imaging and chemotherapy, rather than solely to the introduction of IMRT. Because the use of IMRT becomes more common and the large majority, or all patients, at each institution are treated with IMRT, the potential bias due to patient selection factors in clinical series of IMRT is diminishing.

Another major clinical factor is the emergence of human papilloma virus (HPV)–related oropharyngeal cancers in the past decade, which have a better prognosis compared with the smoking-related oropharyngeal cancers that were prevalent in earlier decades. The modern series of IMRT which include oropharyngeal cancers are likely to report better oncologic results compared to previous series of conventional RT primarily due to this clinical factor, rather than due to any dosimetric superiority of the technique.

## Clinical Results of IMRT Series: Specific Sites

***Nasopharynx.*** IMRT of the nasopharynx represents opportunities in sparing many critical uninvolved structures and improved tumor coverage, as detailed in the preceding text. These improvements have been demonstrated in several treatment planning exercises in nasopharyngeal and oropharyngeal tumors, where IMRT plans were compared to "standard 3D" plans in the same patients.[45,55–57] However, in order to translate the advantage apparent in planning to a clinical benefit, it is crucial to outline the targets adequately. This may be more difficult in the case of nasopharyngeal cancer compared with other tumor sites. The GTV should be derived from an MRI that has been registered with the planning CT, as discussed previously. The CTV should encompass adequately potential subclinical tumor extension at the base of the skull. For example, the entire nasopharynx, the clivus, base of the skull, the pterygoid fossa, the parapharyngeal space, the inferior sphenoid sinus, and the posterior third of the nasal cavity and the maxillary sinuses (ensuring adequate margin to the pterygopalatine fossae) should be included. The CTV that encompasses the above regions can be modified according to the T stage. Lymph node CTVs should include level II nodes through the base of the skull, as well as levels III through V bilaterally, and the retropharyngeal nodes. Level IB should be included in the lymphatic CTV if level II is grossly involved (see references 18, 27, 29, 30 for details regarding the outlining of the neck lymph node levels on the planning CT). Specified critical tissue include the major salivary glands, the optic nerves and chiasm, the brain stem, the spinal cord, the inner ears, the temporomandibular joints, and the mandible. Options for the prescribed doses and constraints for noninvolved organs are detailed in a previous paragraph (see "Dose Prescription and Specification and Normal Tissue Dose Constraints"). An example of the targets and IMRT dose distributions in a case of nasopharyngeal cancer is provided in Figure 5-3.

A large clinical series of IMRT of nasopharyngeal cancer has been reported by investigators at the University of California in San Francisco (UCSF).[58] They reported 67 patients treated between 1995 and 2000. The GTV dose was 2.12 to 2.25 Gy/fraction to a total of 65 to 70 Gy and the CTV dose was 1.8 to 2.0 Gy/fraction to a total of 50 to 60 Gy. To prevent underdosing of the targets, the prescribed doses were typically the minimal doses encompassing the targets. The resulting delivered mean GTV dose was 74.5 Gy, at mean GTV fraction doses of 2.24 to 2.4 Gy. The resulting NTD (calculated for late-responding tissue) was 80 Gy. This regimen yielded excellent local-regional tumor control: 97% at median follow-up of 31 months, with reasonable acute toxicity. The authors stated that no excessive late effects were observed. However, longer follow-up is still required for adequate assessment of the late toxicity. These excellent tumor control rates have been preserved in a recent update of the UCSF data.[59] Excellent tumor control results have been reported by investigators conducting randomized studies of IMRT versus conventional RT for nasopharyngeal cancer.[60,61] Tumor-related outcomes of patients receiving IMRT or conventional RT were similar in these series, supporting our assumption that IMRT alone is not the only factor causing improved tumor control rates in recent years compared with previous eras. However, distant metastases remain a significant issue.[59,62] Efforts focused on decreasing the rates of distant metastases by using targeted biologic agents concurrent with chemotherapy and IMRT are under way at the RTOG.[63]

For reirradiation of nasopharyngeal cancer, IMRT offers dose distribution advantages as it significantly reduces the extent of irradiation of the previously irradiated tissue volume. Lu et al. has recently reported on the experience with reirradiation using IMRT for recurrent nasopharyngeal cancer.[64] Acute toxicity was acceptable and at a median follow-up of 9 months, the locoregional control rate was 100%. Although longer follow-up is necessary, the preliminary toxicity and local control data for these recurrent cases are promising.[64]

***Paranasal Sinuses.*** Similar to the nasopharynx, MRI is required for accurate delineation of the GTV when the tumor is near the base of the skull. Defining the extent of the CTV depends on the sinuses involved and tumor extent, discussed in detail elsewhere.[18] The main obstacle for adequate tumor irradiation is the proximity of the optic pathways to the target in advanced cases. In these cases, IMRT can provide adequate target coverage while sparing the optic pathways (Fig. 5-4). The group from Royal Marsden Hospital used MLC-based IMRT employing standard

(c) 2014 Wolters Kluwer. All Rights Reserved.

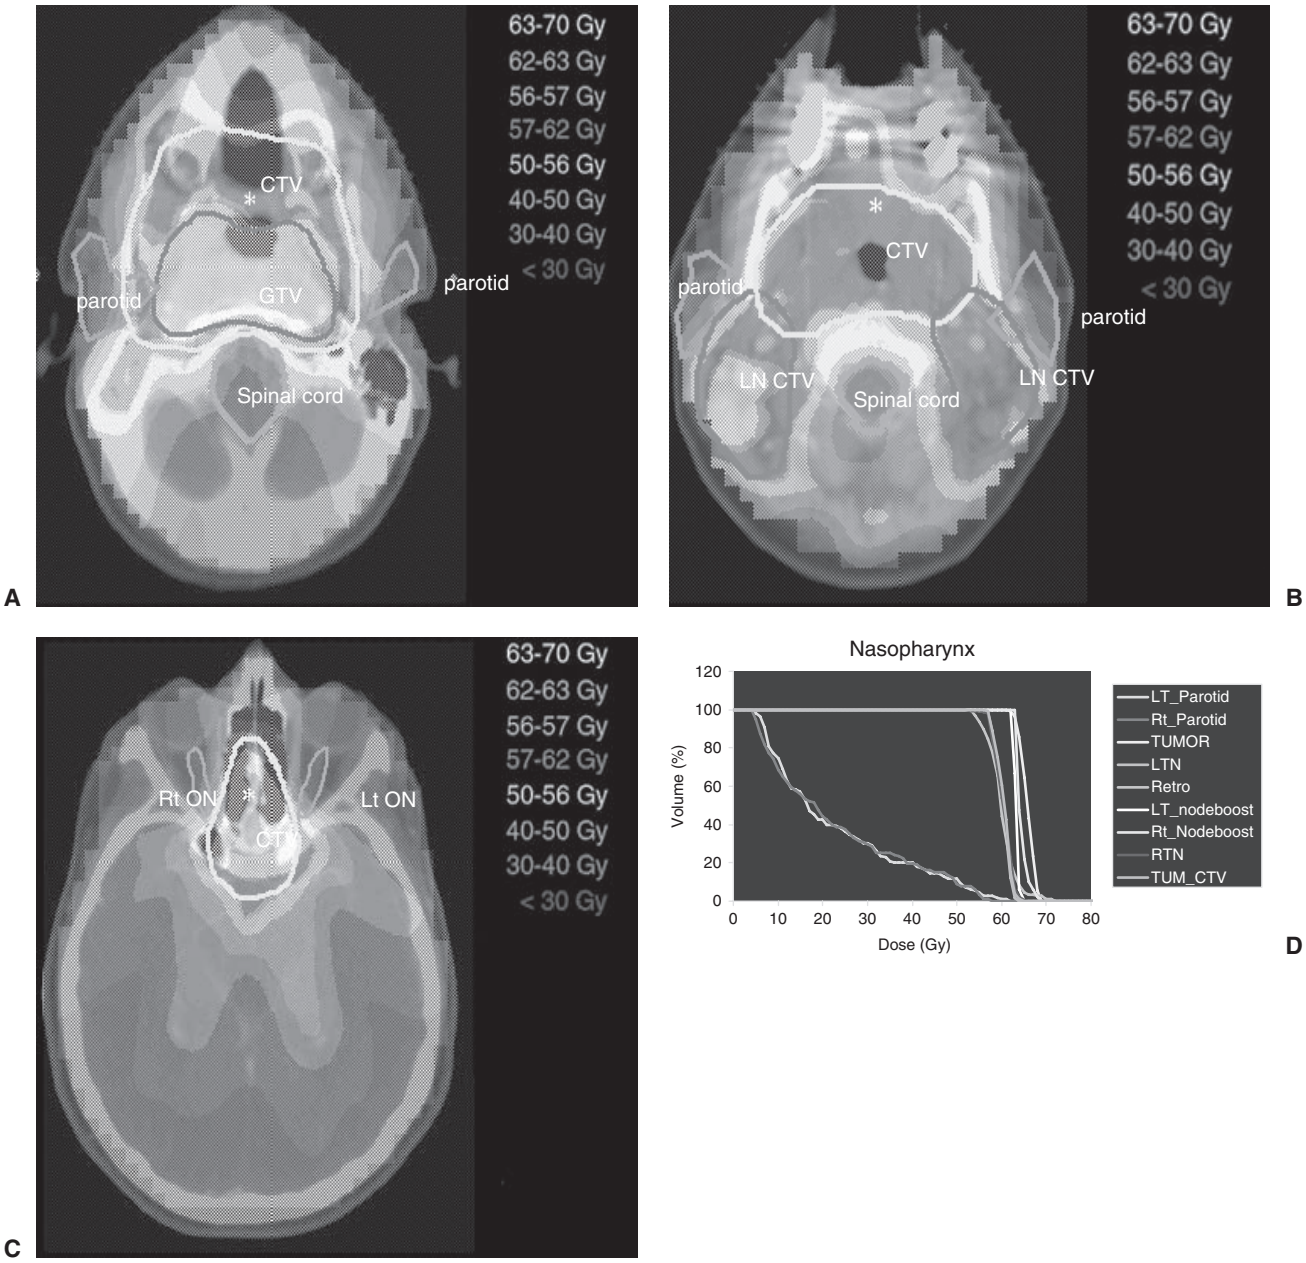

**FIGURE 5-3.** Targets and doses in IMRT of nasopharyngeal cancer. **A:** The GTV was outlined following registration of the planning CT with diagnostic MRI. The CTV includes the base of the skull, the posterior paranasal sinuses, the clivus, and the parapharyngeal space. **B:** Caudal to the GTV, the CTV contains the parapharyngeal and posterior pharyngeal space through midtonsils. Level II nodal CTV is outlined through the base of the skull bilaterally. **C:** The CTV encompasses the sphenoid and cavernous sinuses in locally advanced cases. Limiting the dose to the optic pathways is an important objective of planning. **D:** DVHs of the case described in Figure 5.3. Both parotid glands are spared while the targets are adequately irradiated. (See color insert for Parts **A**–**C**.) IMRT, intensity-modulated radiotherapy; GTV, gross targe volume; CT, computed tomography; CTV, clinical target volume; DVH, dose–volume histograms.

arrangement of beams: an anterior and two half-blocked lateral fields.[65] They found that compared with 3D conformal radiotherapy, using the same beam arrangement, IMRT reduced the dose to the optic nerves significantly and improved PTV coverage. MLC-based IMRT planning of patients with nonresectable maxillary sinus cancer at the University of Michigan revealed no substantial difference between plans using an anterior and two lateral fields, compared with nine equidistant beams arranged around the patient.[50] Therefore, the use of a field arrangement considered optimal in standard radiotherapy may provide benefits over IMRT by reducing beam numbers and reducing the complexity of treatment delivery. Significant improvement in the doses to the optic pathways, compared with 3D conformal RT plans, was noted. IMRT plans of 13 patients with unresectable paranasal sinus tumors demonstrated doses to the contralateral optic nerve and to the optic chiasm that were within known

(c) 2014 Wolters Kluwer. All Rights Reserved.

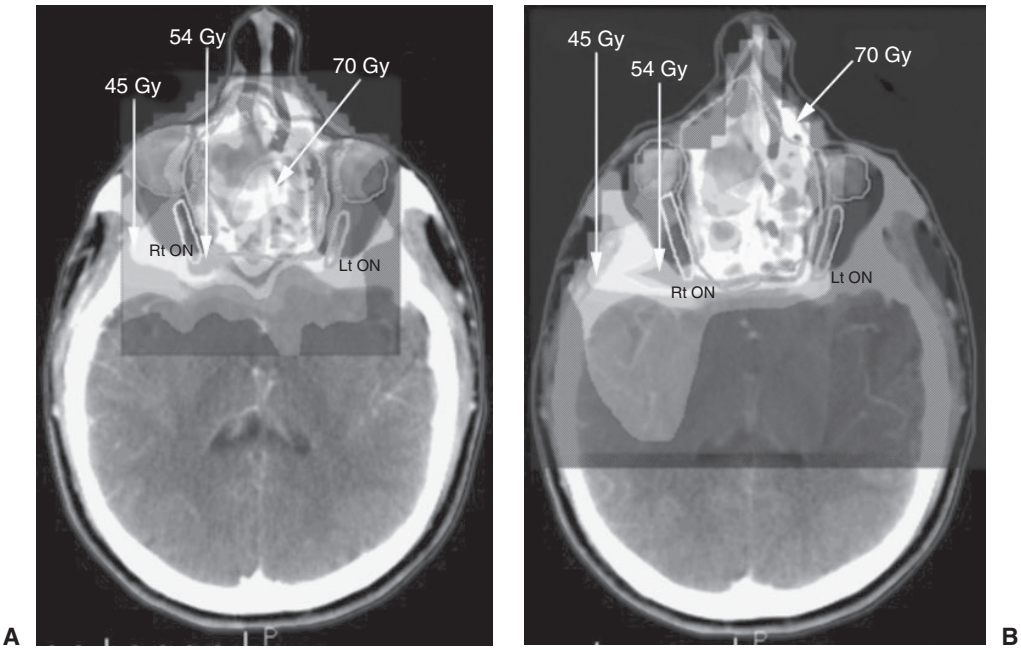

**FIGURE 5-4.** **A** and **B:** Isodoses of IMRT for advanced paranasal sinus cancer. Sparing the optic pathways was a major planning objective. IMRT, intensity-modulated radiotherapy. (See color insert.)

tolerance (<60 Gy), while the ability to spare the ipsilateral optic nerve depended on the anatomic relationships between the PTV and the nerve. Optimization using NTCP of the optic nerves as an objective function was found to facilitate planning and provide a basis for the assessment of the clinical trade-off between PTV coverage and ipsilateral optic nerve sparing.[50]

Large clinical series of IMRT for paranasal sinuses were reported from Ghent University in Belgium.[66] Thirty-nine patients were treated postoperatively and the 4-year actuarial local control after surgery and IMRT was >80% for patients with T1–4aN0M0 disease. Patients with adenocarcinoma of the ethmoid sinus who received IMRT were compared to historical control group of patients treated with two dimensional (2D)- or 3D-conformal noncoplanar techniques. Local recurrences occurred in all patients with cribriform plate invasion. The present IMRT implementation was clearly not able to reverse the dismal local control rates that are known to exist in stage T4b with cribriform plate invasion. By excluding patients with cribriform plate invasion, a patient group with good local control and survival could be selected; no conclusions should be drawn regarding the effect of IMRT on local control as compared to conventional techniques. However, in the IMRT group, there was a significant reduction in the incidence of severe dry-eye syndrome compared to previous techniques. Dose–effect analysis in the IMRT group showed that even at median doses of <30 Gy to the main lacrimal glands, mild forms of dry-eye syndrome could occur.[66]

***Oropharynx.*** Outlining of the primary tumor and lymph node CTVs and GTVs depend on tumor location and extent. In general, for lateralized tumors, the ipsilateral level II nodal CTV is outlined through the base of the skull. The contralateral nodes at highest risk are the jugulodigastric nodes in level II. On CT axial images, these nodes lie below the level in which the posterior belly of the digastric muscle crosses the jugular vein. This is also the uppermost extent of radical neck dissection. At the University of Michigan, the cephalad-most contralateral level II nodal CTV is outlined in these images. However, the contralateral nodal level II CTVs in patients with clinical evidence of nodal involvement in the contralateral neck, or in those with midline tumors, are outlined through the base of the skull. In all patients, if the retropharyngeal nodes are at risk they are outlined bilaterally through the base of the skull.[26] An example of the dose distributions obtained by IMRT in a case of oropharyngeal cancer is shown in Figure 5-5. Details of dose prescriptions, critical organ dose constraints, and quality assurance procedures for the treatment of early oropharyngeal cancer are provided in RTOG protocol H-0022, available at the website of RTOG.

Notwithstanding the limitations in interpretation of the results of published IMRT series, discussed earlier, all series of IMRT outcome of oropharyngeal cancer have reported outstanding local-regional control rates.[26,33,55,67] These series reported 2-year locoregional tumor control rates of 90% to 98% for patient populations consisting mainly of stage III to IV tumors. However, some of these series contain a mixture of definitively and postoperatively treated patients and variable ratios of patients treated with concurrent chemoirradiation or radiotherapy alone. The series from Michigan included patients with various nonnasopharyngeal tumor sites. Notably, having an oropharyngeal cancer site was the most significant favorable predictor of local-regional tumor control.[68] As detailed above (Clinical Results of IMRT Series: General), the emergence of HPV-related oropharyngeal cancer as the most common cancer in this anatomical site, and its improved prognosis compared to the smoking-related oropharyngeal cancer prevalent in previous decades, are the most likely explanation to the excellent tumor control results reported in IMRT series.

Some of the most reliable information gained from clinical series of IMRT for head and neck cancer in general, and oropharyngeal cancer in particular, relates to the pattern of tumor recurrences relative to the targets and the locally delivered doses. These data allow an assessment of the adequacy of target selection and delineation. In all reported cases, it seems that careful selection and delineation of the targets resulted in very few or no marginal or out-of-field recurrences. De Arruda et al. reported

(c) 2014 Wolters Kluwer. All Rights Reserved.

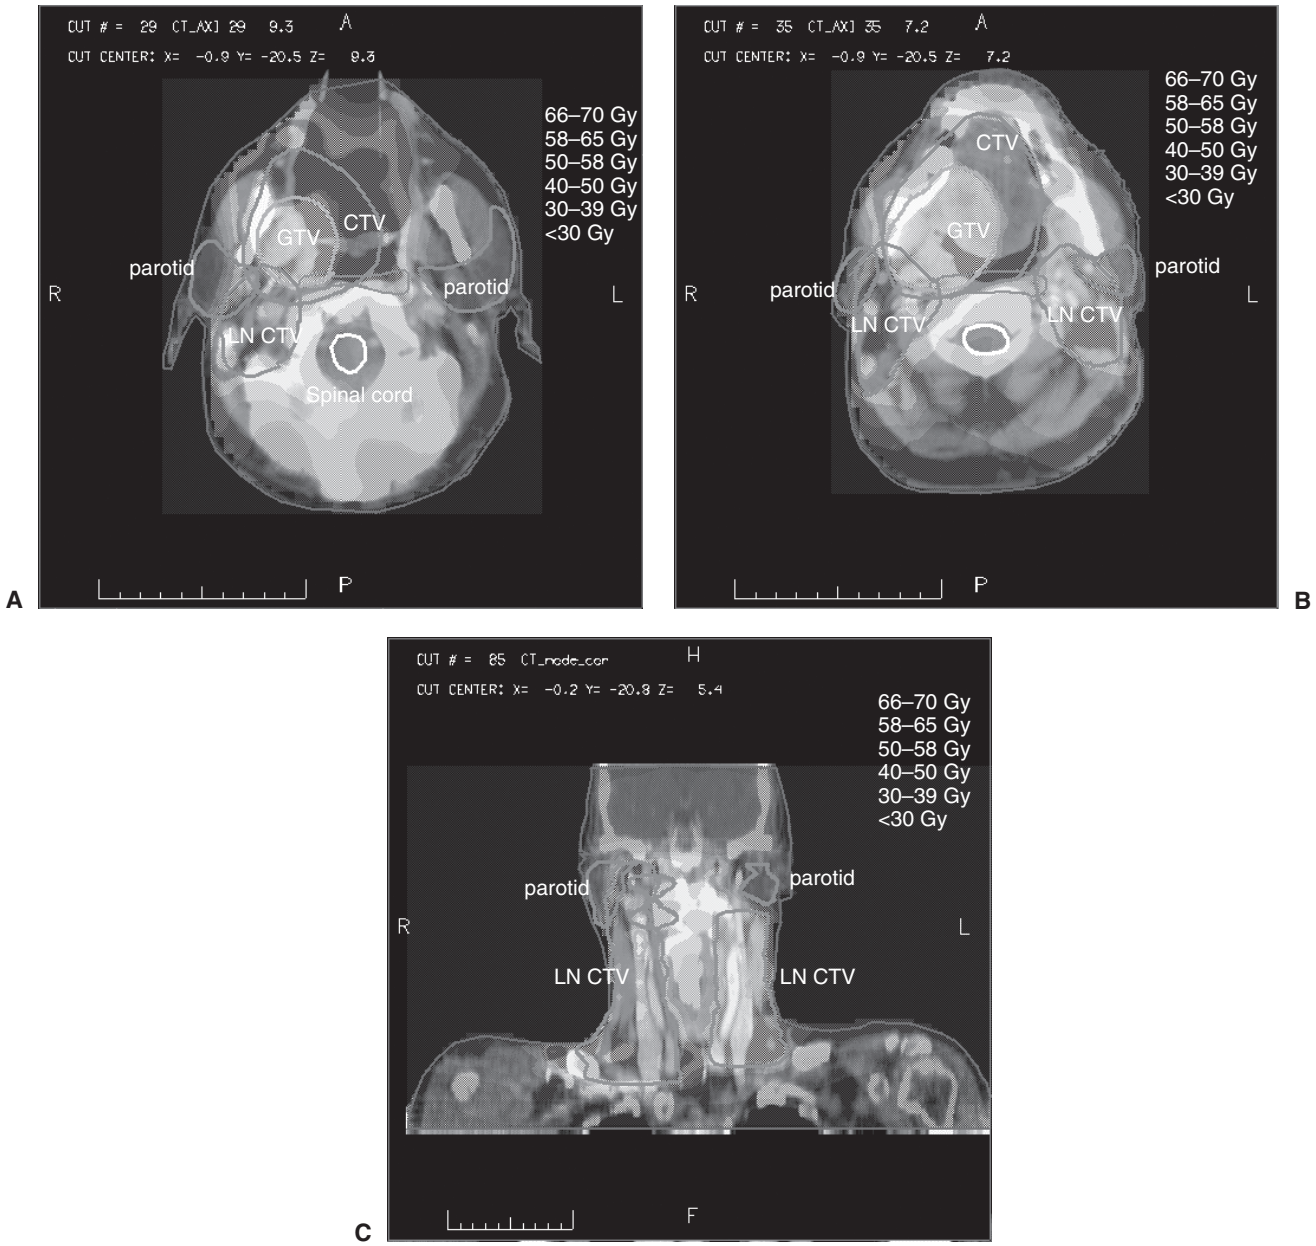

**FIGURE 5-5.** **A** to **C:** Isodoses of IMRT for the patient described in Figure 5.1. The contralateral parotid gland received a low dose (mean 17 Gy) and the ipsilateral gland a moderate dose (mean 32 Gy). (See color insert.) IMRT, intensity-modulated radiotherapy.

that all recurrences in their series were in-field.[67] Chao et al. reported that most marginal recurrences occurred in the lower neck, which was treated with an anterior field that was matched to the IMRT-treated upper neck.[33] At the University of Michigan, where most patients had oropharyngeal cancer, almost all recurrences occurred in-field, in high-risk volumes that had received the full prescribed doses.[26] At a median follow-up of 32 months, 21 local-regional failures (16%) occurred. Of these, 17 recurred in-field and 4 were marginal recurrences. After the first analysis of marginal recurrences, modifications in target delineation principles were made, following which no additional marginal recurrences were noted.[26] This demonstrates a learning curve, characteristic of complex therapies, and the likelihood that treatment outcome improves as the experience of the team using IMRT increases. Of note, no marginal recurrence occurred in the contralateral N0 neck where the cranial-most target included the subdigastric (jugulodigastric) nodes, confirming Rouviere's observations and the recent consensus recommendations.[19,69] Two marginal recurrences in the Michigan series were noted in the lateral retropharyngeal nodes (both occurred in patients with oropharyngeal cancer), in which the cranial-most extent of the retropharyngeal nodal targets was defined at the top of C1, according to Rouviere's observations of the locations of the lateral retropharyngeal nodes. Following these observations, we currently define the retropharyngeal nodes through the base of the skull. Interesting observations about marginal or out-of-field recurrences were reported by the series from the University of Iowa.[55] They found several cases of recurrences in the

(c) 2014 Wolters Kluwer. All Rights Reserved.

contralateral level I in patients with lateral oral cavity and oropharyngeal cancer, underscoring the need to include these nodes in locoregionally advanced oral cancer. As more data about marginal recurrences are accumulated, a better understanding and higher certainty are expected to be gained in defining the targets. This is expected to lead to improved tumor control and ability to spare noninvolved tissues even further.

***Larynx/Hypopharynx.*** IMRT can improve target dose homogeneity for laryngeal and hypopharyngeal squamous cell carcinoma (SCC) while reducing the dose to the normal tissues at risk[70–72] (Fig. 5-6). Clinical data on IMRT for laryngeal and hypopharyngeal SCC are, however, scarce and include limited numbers of patients within large heterogeneous series of multiple head and neck tumor sites.[26,33,55] In general, these series showed lower tumor control rates compared with oropharyngeal sites. Potential reason could be patient selection factors. For example, at the University of Michigan only laryngeal cancer patients with advanced nodal disease receive IMRT because for patients with nodal stage N0 to N1, the uppermost nodes at level II are the subdigastric nodes, which can be treated with conventional techniques while sparing most of the parotid glands and avoiding the oral cavity, as the retropharyngeal nodes or level II nodes near the base of the skull are not at risk in these patients.[26,68] A recent study reported the feasibility of a dose escalation trial in laryngeal SCCs using IMRT.[73] The potential perils associated with dose escalation of head and neck cancer using IMRT have been discussed earlier (see "Dose Prescription and Specification and Normal Tissue Dose Constraints").

## Noninvolved Organ Sparing with IMRT: Clinical Results

Most of the studies assessing clinical toxicity reduction using IMRT have concentrated on reduced xerostomia through the sparing of the parotid salivary glands. Data about dose response in the parotid glands are accumulating.[74–79] At the University of Michigan, it was initially found that the output related to the mean doses to the glands. The large majority of the glands receiving a mean dose of >26 Gy did not produce measurable saliva and did not recover, whereas glands receiving lower mean doses produced variable salivary output that increased over time.[74] One year after radiotherapy, parotid glands receiving a moderate dose (mean dose of 17–26 Gy) recovered, on average, to the pretreatment salivary production levels.[75] When the doses to the parotid glands were very low, as in cases of unilateral neck radiotherapy in which the contralateral glands received mean doses <10 Gy, an "overcompensation" of the damage to the ipsilateral glands was noted in the second year post therapy. In particular, the salivary flow rates from the contralateral glands exceeded, on average, their pretreatment flow rates. This finding motivates reducing the doses to the salivary glands to as low levels as possible. Data from other institutions suggest thresholds in the range of 20 to 40 Gy.[76–79] The common finding in all these data is that a relationship seems to exist between the mean doses to the glands and their residual salivary output. The reasons for this wide range include different methodologies in assessing the salivary flows as well as clinical factors, beyond the radiation dose, which affect the salivary output but have not been taken into account in most of these studies. These factors include dehydration, which is common in patients receiving head and neck radiotherapy, and various medicines found to affect the salivary flow rates significantly.[74,75] An additional important factor is one reported recently by investigators from the University Hospital in Groningen, the Netherlands.[80] They irradiated different parts of rat salivary glands using high-precision proton radiation and found regional differences in dose–salivary production relationships. Such regional differences are likely to exist in the human parotid glands, and they may be the reason for different results found by researchers using different radiotherapy techniques, which produce different dose distributions within the glands. Further research into intraparotid regional differences in sensitivity to radiation is required for better understanding of radiation limits. In addition, recent studies have demonstrated an anatomic shift of the parotid glands medially, correlated with weight loss during therapy, which may increase actual delivered doses compared with the planned ones (see "Tracking Anatomical Changes

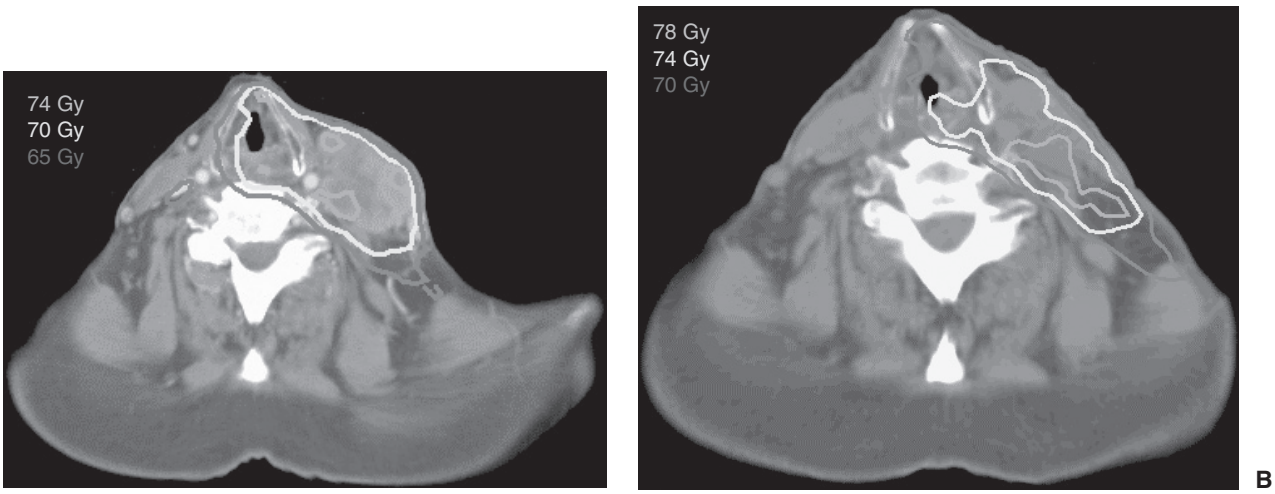

**FIGURE 5-6.** A case of laryngeal cancer stage T2N3 treated with IMRT concurrent with chemotherapy. Significant regression of the metastatic node was observed by week 4, in tandem with severe local skin toxicity. The doses produced by the original treatment plan **(A)** showed relative uniform dose distributions. Recalculating the dose distributions using the original IMRT plan for the new anatomy disclosed higher "hot spots" and skin doses than originally planned **(B)**. The case was replanned using the new CT, the hot spots were corrected, and the patient continued treatment using the new plan, resulting in improvement of the skin toxicity. IMRT, intensity-modulated radiotherapy.

During Radiotherapy"). The initial data from the University of Michigan related to patients in whom only the contralateral parotid glands were spared. More recently, efforts are made to spare the ipsilateral parotid glands as well, resulting in intermediate doses delivered to these glands, in the range of 30 to 40 Gy. A recent study comparing the dosimetry of the parotid glands to their salivary output in patients treated with these methods found a high agreement between the results in two different institutions. Rather than a threshold, this study found continuous reduction in salivary output as the mean doses increased: the dose causing 50% probability of grade 4 toxicity was found to be 39 Gy, and the dose causing 25% probability was 25 Gy.[81] Regardless of the dose threshold, it is now apparent not only that spared glands partly retain the salivary output but also that the output increases over time through at least 2 years after radiotherapy. In comparison, there is generally no improvement over time following standard radiotherapy in which most of the parotid glands receive full radiotherapy doses.

Once preservation of the salivary output is achieved, there are questions related to similar improvements in patient-reported xerostomia symptoms. The correlation between the salivary output from the major salivary glands and xerostomia symptoms is significant, but is not very high. Part of the reason for this less-than-straightforward relationship lies in the contribution of the minor salivary glands. These glands are scattered throughout the oral cavity, notably on the surface of the palate, and produce much of the salivary mucin. It has been found that the dose delivered to the oral cavity, serving as a surrogate for the residual function of the minor salivary glands (whose output cannot be measured) was an independent factor in patients' reported xerostomia after radiotherapy, similar to the importance of the doses to the major salivary glands.[75] An optimal practice is to add the sparing of the oral cavity as an objective in radiotherapy planning, in addition to the sparing of the parotid glands. An analysis at the University of Michigan of a validated patient-reported xerostomia questionnaire demonstrated that xerostomia improved significantly over time, in tandem with the increase in saliva production.[82] Two years following irradiation, xerostomia reported by patients receiving parotid sparing bilateral neck radiation was only slightly worse than in patients receiving unilateral neck radiotherapy. Investigators at UCSF also reported an improvement to mild or no xerostomia during the second year after IMRT for nasopharyngeal cancer.[58] Small randomized studies of IMRT versus conventional RT have been reported for nasopharyngeal cancer. Kam et al. showed an advantage of IMRT in terms of improvement of salivary flow rates, but not in xerostomia symptoms.[60] Pow et al. demonstrated significant improvement of both salivary flow rates and xerostomia-related quality of life in patients with nasopharyngeal cancer randomized to IMRT compared with those randomized to conventional RT.[61] The differences between the two studies may be related to the validity of the instruments used to measure patient-reported xerostomia. It is apparent from all of these studies that the partial sparing of the salivary glands, made possible by IMRT, achieves tangible gains both in the retention of the salivary production and in the symptoms of xerostomia. A European randomized study in various head and neck cancer sites comparing IMRT, which spared the contralateral parotid glands, to conventional RT found that observer-rated xerostomia and salivary output were significantly better in the IMRT arm. Patient-reported xerostomia was also significantly better. However, during the first posttherapy year the difference in patient-reported xerostomia between the two arms was very small.[83]

Another issue in the efforts to reduce xerostomia by IMRT is the importance of the submandibular glands. These glands lie anterior to the level II lymph node targets in the neck and produce (together with the minor salivary glands in the oral cavity) a substantial amount of mucin, which is important in lubricating the mucosa and providing a sense of hydration. Commonly, it is difficult to spare a substantial amount of these glands while treating both sides of the neck (which is required for all advanced head and neck cancer), resulting in no measurable salivary output from most of these glands after radiation.[75] Canadian investigators who moved one submandibular gland to the submental space, away from the radiotherapy fields, reported impressive reduction in xerostomia.[84] However, this technique has not yet gained broad acceptance. Efforts to spare the contralateral submandibular gland in patients in whom the contralateral neck level I is not in the target have been reported by several investigators, resulting in higher salivary output and reduced xerostomia in patients with reduced doses to these glands.[85,86] Dose–effect relationships for the submandibular glands are emerging and can guide these efforts.[87] It is important to make sure that the jugulodigastric nodes, which are important nodes lying immediately posterior to the submandibular glands, will not be underdosed if the contralateral level II is judged to be at risk.

An additional potential functional gain from IMRT over conventional RT includes reduced long-term dysphagia. For example, IMRT strategies which spare the pharyngeal constrictor muscles, as well as the glottis and supraglottic larynx, have been helpful in reducing the risk of long-term dysphagia and aspiration.[88] Sparing the pharyngeal constrictors is made easier by realizing that the lateral retropharyngeal nodes, but not the medial ones, are at risk in head and neck cancer.[89] Clinical assessment of the clinical effect of these efforts demonstrated significant dose–response relationships for these swallowing/aspiration structures, which may serve as a basis for related optimization cost functions and motivate the efforts to reduce the doses to these structures as much as possible.[89,90]

***Investigational Tumor Imaging and "Dose Painting."*** Although glucose metabolism measured by FDG-PET is the functional modality most often used to aid in target delineation, researchers are developing and testing new agents to image hypoxia, protein synthesis, DNA synthesis, and receptor expression. Hypoxia is a predictor for poor local control and the second most developed area in PET imaging.[91] $^{18}$F-misonidazole (F-MISO) is a freely diffusible tracer, which binds to intracellular molecules under oxygen concentration <10 mm Hg such that 2 hours after injection, the tracer only remains in hypoxic viable cells. Static scans can identify areas of hypoxia, whereas dynamic scans can identify areas of poor blood flow.[92] Another compound, Cu-diacetyl-bis ($N^4$-methylthiosemicarbazone [Cu-ATSM]), is reduced in low oxygen conditions and is similarly trapped within viable hypoxic cells.[91] The correlation of uptake of these tracers and local control in head and neck cancer is currently being studied. Other types of tracers are being developed to image DNA synthesis through thymidine incorporation ($^{18}$F-fluorothymidine [FLT]), angiogenesis through $\alpha_v\beta_3$ receptor expression ($^{18}$F-Galacto-RGD), and EGFR expression in the head and neck.[93,94] In addition to helping to define the tumor, some of these new PET tracers may yield additional useful information about tumor subvolumes, which may not respond well to current therapies and should be targeted for intensification of treatment.

The terms *dose painting* and *dose sculpting* refer to customizing radiation plans to deliver nonuniform doses to different subvolumes within the tumor.[95] Whereas dose uniformity has traditionally been favored, it is possible that a benefit may be gained from intensifying the doses in certain volumes within traditional anatomic borders. By incorporating metabolic, functional, and phenotypic biologic information into IMRT planning, we can devise a boost volume of potentially more radioresistant areas of tumor, which may benefit from a higher dose. Theoretic planning studies have demonstrated this proof of principle using Cu-ATSM and F-MISO to increase the dose to hypoxic volumes

(c) 2014 Wolters Kluwer. All Rights Reserved.

within GTVs.[96,97] However, the clinical utility of these plans have not yet been determined. This issue seems to be much more complex than was originally thought. For example, the hypoxic subvolumes within tumors change during the course of therapy,[98] reducing the potential utility of pretherapy planning of hypoxia-driven "dose painting." It is possible that this utility is higher for imaging nearer the completion of therapy.[94] Using FDG-PET during therapy may be another method to evaluate tumor subvolumes, which retain PET activity and may be less responsive to radiotherapy.[99–101] Whether boosting these subvolumes during the rest of the treatment course to a higher dose will overcome their perceived resistance is not yet known.

## PROTON THERAPY

Currently, all centers utilize photons, or high-energy x-rays, for their IMRT treatments. However, due to their inherent physical characteristics, protons are better able to concentrate dose inside targets and minimize dose to surrounding normal tissues. Most of the energy of a proton beam is deposited near the end of the beam path ("Bragg peak"), the location of which is determined by the energy of the beam. Therefore, the target can be included in the tissue volume receiving the high dose while little is delivered before or after the beam passes through the target, and the integral dose delivered outside the targets is lower than delivered using IMRT. This is expected to reduce the risk of secondary malignancies, which is especially important in pediatric cancer patients.[102] Using inverse planning, intensity-modulated proton therapy (IMPT) can further improve the therapeutic index of radiotherapy. Several groups, including the University of Florida, Massachusetts General Hospital, University Hospital Vienna, and the Paul Scherrer Institute in Switzerland, have published treatment planning comparisons of photon IMRT with IMPT.[103–106] Using IMPT, mean doses to OARs, the parotid glands, in particular, have been reduced by as much as 50%. However, long-term clinical treatment results are not yet available. The areas in the head and neck likely to benefit from the added conformality achievable with protons are the paranasal sinuses and nasopharynx because they are often in close proximity to the optic nerves and chiasm, as well as brain.[107] Retrospective reviews of 3D conformal proton therapy from Massachusetts General Hospital and Loma Linda University suggest maintenance of local control rates with minimal toxicity, including preservation of vision in advanced sphenoid sinus cancers.[108] As more patients are treated with protons and with IMPT, we will be able to determine whether these dosimetric improvements lead to significant clinical gains.

## NEUTRON AND CARBON ION THERAPY

In addition to protons, other particles have been used to treat head and neck cancers. Neutrons have found a niche in treatment of salivary gland tumors, after a small trial randomizing patients to photon or neutron radiotherapy demonstrated a survival benefit to neutron therapy.[109] Other ions, including helium, neon, and carbon, have been investigated over the last 50 years. Currently, carbon ion therapy shows the most promise. Compared with photons, carbon ions have the conformality advantage of protons, with the additional advantage of a greater relative biologic efficacy (RBE): a smaller dose of carbon ions is required to achieve the same biologic effect as a reference dose of photons. This is due to a higher linear energy transfer, which theoretically causes more irreparable DNA damage, is more effective on hypoxic cells, and is less subject to variation in radiosensitivity with cell cycle. Currently, there are three centers worldwide that are able to treat with this modality. Initial results in adenoid cystic carcinoma, unresectable head and neck sarcoma, and locally advanced SCC of the head and neck are promising and demonstrate excellent local control rates with low toxicities.[110,111] However, long-term results are not yet available.

## IMAGING-GUIDED RADIOTHERAPY

The term *IGRT* relates to patient and tumor imaging using electronic portal imaging devices (EPIDs) or CT before each fraction or every few fractions of therapy to ensure tracking of the tumor by the treatment beams. In cancer of the head and neck, where breathing-related motion is nonconsequential, IGRT aims at two main goals: (a) minimizing setup uncertainties and enabling reduction of the PTV margins and (b) assessing anatomic changes in tumor and critical tissue during the course of therapy.

### Reduction of Setup Uncertainties

To reduce setup uncertainty, many groups have advocated daily imaging, with patient position correction if the displacement from the original plan exceeds a threshold value.[112,113] The systematic error can typically be observed and corrected after few initial daily imaging, following which it is only required to correct the small random errors. This can be done by imaging once weekly, if the PTV margins are set at 5 to 6 mm; however, more frequent imaging is required if PTV margins are smaller (see details in "The Planning Tumor Volumes" above). Using 2D EPIDs for this end, relying on orthogonal view of the bony anatomy before treatment in comparison with the bony anatomy observed at the planning CT may be sufficient. Using CT for this purpose may achieve a marginal benefit, allowing corrections of patient rotation (which is not efficiently detected by 2D imaging). However, lacking breathing-associated movements, it is questionable whether CT is required for head and neck cancer. At the University of Michigan, daily online imaging and setup correction before each treatment fraction has reduced the setup error to $1 \pm 1$ mm, enabling a reduction in PTV margins to 3 mm.

### Tracking Anatomic Changes during Therapy

During the 6- to 7-week course of radiotherapy, many anatomic changes can occur. As dose distributions achieved using IMRT have steep gradients, and PTV "safety" margins are becoming smaller, it is especially important to understand the consequences of anatomic changes during therapy on the dose to both targets and normal tissues. In definitive cases, the primary tumor and/or nodes can shrink, whereas in postoperative cases, inflammation and edema can resolve. Additionally, weight loss, a common consequence of acute treatment toxicity, can lead to muscle wasting and shifting of both normal tissue and tumor positions. Barker et al. recently conducted a detailed study of such anatomic changes during radiotherapy for head and neck cancer.[114] The primary tumors and nodes were noted to shrink at a median rate of 1.8% of the initial volume per treatment day, such that on the last day of treatment, the median overall volume loss was close to 70%. The tumor center of mass changed as well: while the median displacement of the GTVs was small (3.3 mm), it varied widely and was 17.3 mm in one case. The parotids moved medially during treatment such that the median displacement at the end of therapy was 3.1 mm, with a range of 0 to 9.9 mm, and the volume of the parotid glands decreased by a median of 28% by the end of treatment. These changes were highly correlated with patient weight loss and reflect significant changes in the position and size of both the gross tumor and OARs during therapy. Similar findings have recently been reported by additional

(c) 2014 Wolters Kluwer. All Rights Reserved.

investigators.[115,116] Taken together, these studies indicate that the mean dose to the parotid glands increases during radiotherapy as they move medially toward high-dose regions. Because parotid dose and resulting xerostomia have a significant impact on quality of life, several replanning studies have been undertaken to specifically address parotid sparing. By replanning half way through treatment, the volume of the parotids receiving 26 Gy or more was decreased by 15% to 20%.[115,116] However, significant change in parotid volumes and doses is only observed in a minority of patients who lose substantial weight, while on average the change is quite small. Although comparative objective salivary function tests and quality of life studies have not been performed to determine whether replanning results in clinical benefit, compared with no replanning, it seems that replanning at some point during treatment may be reasonable for patients who lose substantial weight or who have bulky tumors which shrink rapidly. However, it is unclear when and how often this should be performed. Strategies are being developed to deform treatment plans in near real time to account for differences in anatomy rather than replan the entire case.[117] This method closely approximates full IMRT replanning in a small fraction of the time required for full planning. Few replanning series showed improvements in parotid gland doses in the range of few percentage points, while target coverage is in general retained throughout treatment, such that the related benefit of replanning is marginal.[118,119] Also, current data suggest that for most patients, replanning is not likely to be beneficial more than once at midtherapy, and only few patients are likely to benefit from replanning twice during therapy. This topic is a subject of research performed in many institutions, and it is likely that significant additional related information will be available in the very near future.

***New Technologies to Deliver Highly Conformal Radiotherapy.*** While IMRT is usually delivered using multileaf collimators, new technologic innovations have provided some improvements in several aspects of the dose delivery, usually with some trade-offs, compared to the multileaf IMRT.

1. Tomotherapy delivers treatment through continually rotating around the patient in a slice-by-slice manner in combination with integrated image-guided abilities. In principle, the patient is treated continuously during the rotation of the radiotherapy source, practically increasing substantially the number of beams compared with the beams utilized by MLC-based IMRT. As expected, this substantially higher number of beams increased dose conformality and target dose homogeneity, allowing better sparing of critical tissues, at the expense of higher tissue volumes receiving low-to-moderate doses. However, the apparent dosimetric improvement, which is reported in studies which compare tomotherapy with IMRT, may not be enough to translate into clinically meaningful benefits.[120]
2. VMAT delivers modulated radiation in one or two arcs.[121] The main advantage is a marked reduction in overall treatment time, which increases the comfort of the immobilized patient, is expected to reduce intrafraction setup uncertainties, and has obvious benefits for a busy clinics. Planning exercises show that VMAT, if planned by experienced planners, can achieve similar dosimetric results as IMRT, especially if two arcs are used.[121] It delivers less monitor units and produces similar delivery accuracy compared with IMRT. However, VMAT planning time is longer, and it requires much more data for 3D dose storage and computing resources, which may interfere with adaptive replanning (if desired) during therapy.
3. Robotic radiosurgery, using Cyberknifec or other commercial systems, has been used for stereotactic hypofractionated RT in cranial and extracranial sites. Its main benefits are very sharp fall-off of doses and its ability to track respiration-related moving targets in the chest and abdomen. In the head and neck, few publications in recent years have suggested its use for reirradiation of recurrent tumors. Treatments are delivered as hypofractinated, high dose per fraction programs (typically 5 Gy or more), twice weekly to a total of 30 to 40 Gy. Clinical results published thus far using this method suggest that local tumor control is not superior to that expected after standard fractionated RT, while severe toxicity rate is high and is likely underdocumented given the short follow-up in these series.[122] Specifically, the rate of reported carotid blowout seems to be higher following stereotactic RT compared with standard fractionated RT.[123] At this time, the use of robotic radiosurgery for recurrent head and neck cancer, or for any other indication in head and neck cancer patients, is not recommended.

## Intraoperative Radiation Therapy

Intraoperative radiation therapy (IORT) is a novel approach to delivering high doses of radiation directly into a tumor bed, at the time of surgical resection. The intraoperative setting allows displacement of skin and other normal organs and permits the radiation oncologist to deliver radiation to very limited tissue volumes, encompassing the tumor bed with minimal normal tissue. The role of IORT in head and neck cancer has been recently reviewed.[124] Its major application has been in the management of recurrent disease in previously irradiated patients, or in patients who have developed a second primary cancer in a bed of prior treatment. Treatment can be delivered using either electron beam techniques or using high dose rate remote afterloading (HDR-IORT) in a shielded operating room. Often IORT is part of a strategic plan that includes postoperative external beam RT, in an effort to comprehensively re-irradiate a patient.[125] Free-flap reconstruction is an important complement to the surgical resection and IORT, both aiding the wound healing, and providing a fresh blood supply.[126] This allows additional external beam radiation to be added safely. Nowadays, with multidisciplinary approaches to salvage therapy, including surgical resection, IORT, flap reconstruction plus addition external beam RT, and biologic/chemotherapy, 2-year survival rates have been reported in 60%[125] of a patient population that was previously without good therapeutic options.

CHAPTER 6

F. Christopher Holsinger

# New Approaches: Robotics and Endoscopic Head and Neck Surgery

## INTRODUCTION

Minimally invasive and endoscopic head and neck surgery[1] (eHNS) represents the natural evolution of the surgical disciplines within the multidisciplinary treatment paradigm. Yet, for years, head and neck surgery was virtually synonymous with "radical" transfacial and/or transcervical procedures. Although there were "conservation" or organ-preservation procedures in the larynx, such as the vertical partial laryngectomy or the open supraglottic laryngectomy, (Chapter 18), operative indications were often too narrow for surgery to play a significant role in treatment. Thus, multidisciplinary care for head and neck cancers gradually shifted toward a radiation-based approach. Multidisciplinary care was virtually synonymous with nonsurgical therapy.

However, an evolution in our understanding of transoral anatomy, the advent of computer-assisted surgery, and a host of new technologies has ushered in a new era for the head and neck surgeon. For tumors of the upper aerodigestive tract, especially the larynx and oropharynx, eHNS has naturally developed around transoral exposure, using either transoral laser microsurgery (TLM) or transoral robotic surgery (TORS) or a combination of the two (Table 6.1). With greater understanding of these minimally invasive approaches, surgeons have now begun to apply eHNS techniques to the neck systematically. Finally, using transaxillary and retroauricular approaches, surgeons have demonstrated the feasibility of operating on the neck for both thyroid and parathyroid surgery and even lymphadenectomy through small cervical incisions with video-assistance or through small inconspicuous incisions located some distance from the primary tumor site, hidden in the folds of the axillary or behind the ear.

Here, we review these developments, focusing on rationale, anatomy, and technical aspects, as well as indications and limitations of minimally invasive and eHNS. The term "eHNS" is preferred, since every approach described below from robotic surgery to TLM or minimally invasive video-assisted thyroid surgery (MIVAT) utilize an endoscope to provide unparalleled access and visualization of head and neck surgical anatomy. More importantly, eHNS is independent of a particular technology or medical device industry, and focuses on surgical technique and its evolution, unfettered by the bonds of commercial affiliations and sponsorship.

## TRANSORAL LASER MICROSURGERY

### Laser Physics and Choice of Technology

eHNS was born in 1972 within the field of laryngology using transoral exposure for the resection of benign and early limited cancers by Strong and Jako.[2] Since then, the technique of TLM has emerged as a standard of care for early laryngeal cancer (Chapter 18b) and also an important surgical approach for selected tumors of the oropharynx, supraglottis, and hypopharynx. TLM is performed via direct laryngoscopy, with an operating microscope, microsurgical instruments, and the surgical carbon dioxide ($CO_2$) (Fig. 6-1), pulsed potassium titanyl phosphate (KTP), or thulium laser.

Since a surgical laser serves as a scalpel, the surgeon must understand this tool and have a firm grasp of laser physics and the thermal and mechanical aspect unique to a particular laser's soft-tissue interactions. In TLM, the laser is used to cut, not to ablate or to simply cauterize tumors, delivering energy in the form of light directly to target tissue. Light energy is absorbed directly without mechanical or electrical trauma, but when absorbed by soft tissue is transformed into heat, producing a photothermolysis. As more laser energy is absorbed by a particular

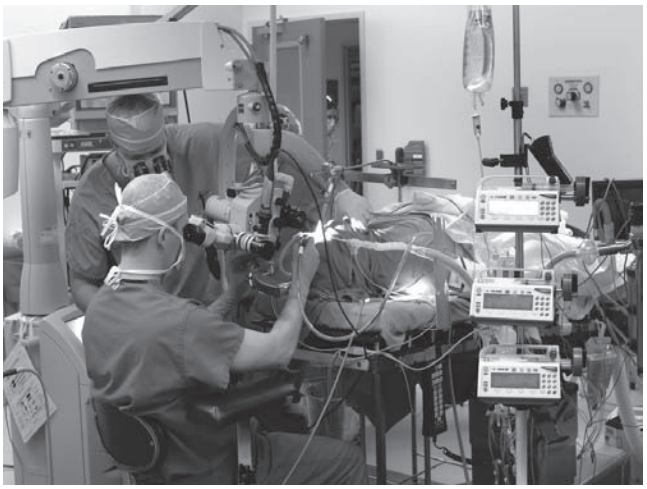

**FIGURE 6-1.** Intraoperative photograph demonstrating the technique of transoral laser microsurgery. A laryngoscope is fixed to a bedside stand and an operating microscope provides 4x to 10x magnification. A bedside assistant is seen providing external compression which assists the operating surgeon by providing exposure and countertraction to optimize the resection.

tissue, the laser's chromophore, covalent bonds are released and tissue is vaporized, usually at the boiling point. The physics of the $CO_2$ laser make it ideally suited for head and neck surgical applications. Water, as the primary component of most cells in the human body, serves as an efficient chromophore for light energy from the $CO_2$ laser, due to its frequency of 10,600 nm. As the cells absorb the light energy from the laser, the cells' temperature rises quickly and at 100°C the cells vaporize. This soft-tissue interaction allows the surgeon to cut and coagulate tissue without electrocautery, thus minimizing collateral damage to adjacent neurovascular, mucosal, and muscular structures.

If laser beam is not efficiently delivered, tissues are burned, not completely vaporized. Inefficiently denatured protein appears to the surgeon as carbon debris, or "char," which further interferes with the surgeon's visualization and obstructs the efficient delivery of laser energy to the target tissue resulting in greater subablative heat build-up. Using a pulsed laser is an important way to avoid thermal injury: that is, turning the laser on and off in microsecond bursts. In this pulsed mode, thermal relaxation time is reduced and target tissues can dissipate heat before char develops. Also, thermal injury can be diminished by reducing exposure time. That is, using a "repeat-delay" setting, a pulsed laser can be turned on every 0.1 to 0.3 seconds, further reducing thermal damage during TLM.

In addition to these general considerations, the long wavelength of the $CO_2$ laser carries with it some limitations. The beam itself is invisible. Thus, a visible and parallel **beam** of light from a **Helium–Neon** laser (wavelength of 656 nm) is used to identify the invisible 250 $\mu$m "spot" generated by the $CO_2$ laser. A mirror micromanipulator is connected to a microscope, and the laser beam can then be directed with a small surgical joystick. For many patients with tumors throughout the laryngopharynx, direct "line-of-sight" exposure is achieved, whether by direct transoral exposure to the oral cavity, tonsil, and palate or via endoscope for the deeper oropharynx, larynx, and hypopharynx. However, this line of sight restriction may limit the "working space" of the laser within which the surgeon can work and proves problematic as tumour size increases or patient anatomy restricts line-of-sight delivery. The Omni Guide System (Omni Guide, Inc., Cambridge, Massachusetts) introduced the first widely commercially available fiber-optic $CO_2$ laser.[3] With a fiber, the surgeon can wield and direct the fiber-optic laser almost as a scalpel. In so doing, the $CO_2$ laser can be used "around-corners" and into the difficult recesses of the head and neck, thus overcoming some of the limitations associated with line-of-sight exposure.[4] The flexibility of the $CO_2$ laser fiber delivery system permits either hand-held operation or even mounting to a specialized robotic manipulator. Yet, these hollow-core fibers can be fragile and fail when handled too aggressively or bent at extreme angles. Other teams are at work to deliver $CO_2$ laser energy through glass fibers that might provide greater durability.[5]

Further technical refinement for the $CO_2$ laser was first presented by Remacle et al.[6] with the introduction of the scanning robotic micromanipulator. The surgeon can use this robotically crafted, pulsed laser beam in several different shapes and spot sizes ranging from 0.4 to 5 mm, using a computer-assisted algorithm. These settings allow the surgeon a great deal of precision to customize the laser–soft tissue interaction, resulting in greater finesse, especially for instance when operating on lesions of the true vocal cord. Furthermore, the surgeon can choose from several patterns or cutting shapes, instead of just a 250 $\mu$m spot. Using this "digital acublade" on varying pulsed modes, Remacle et al.[6] showed significant reduction in thermal injury zone to 12.5 $\mu$m and increased operative precision, when compared to the traditional "dot-by-dot" joystick micromanipulator approach.

Finally, thulium-based fiber-optic lasers[7] have similar properties to $CO_2$ lasers and demonstrate promise for benign laryngeal and tracheal disease, as well as, for cancer. The 2,013-nm wave length of this laser allows its energy to be delivered by a small caliber glass fiber, yet it retains water as a chromophore. This laser appears to offer a smooth vaporization pattern and excellent hemostasis, similar to that realized with the pulsed KTP laser,[8] but with less risk of deep tissue penetration.

## Technique and Its Role in the Multidisciplinary Paradigm

Independent of the novel and emerging technologies in TLM, head and neck surgeons now routinely employ this transoral endoscopic approach for tumors of the upper aerodigestive tract. Traditionally, these techniques fell under the purview of laryngologists. Steiner and Ambrosch[9] first paved the way for broader use and greater acceptance of TLM through head and neck oncologic surgery. First and foremost, the laser is used as a precise endoscopic scalpel, to cut and to coagulate, not to ablate or cauterize. Furthermore, TLM, as espoused by Steiner and Ambrosch, challenged widely held belief in Halsted's fundamental surgical principle of en bloc resection.[10] With TLM, as a tumor is transected, precise visualization under the operating microscope reveals the full depth of tumor. By understanding this third dimension of the resection, the surgeon can optimize margin of resection. Oncologic outcomes from TLM are discussed in further detail in Chapter 18b, but by conserving the maximum amount of normal mucosa, crucial structures are preserved and function is optimized. Preservation of laryngopharyngeal function is accomplished through maintenance of at least one valve of the larynx for airway protection, swallowing, and native voice.[11] In fact, the promise of TLM and endoscopic head and neck surgical approaches to larynx cancer and that of other sites within the upper aerodigestive tract is this: patients who undergo these procedures, especially for T1-2 tumors, tend to fare remarkably better than was expected when these techniques were first introduced. Transoral endoscopic resection preserves the laryngeal

cartilaginous and musculature framework in the neck. The end-terminal branches of the superior laryngeal nerve (Fig. 6-2) are preserved providing rapid return of laryngopharyngeal sensation and thus swallowing function. In an unradiated patient, the repeated and constant use and soft-tissue remodeling appears to restore anatomy to its near normal state, with a surprising degree of associated normal function. For instance, a surgical defect for a T1 verrucuous carcinoma, that requires a deep resection of the mucosa and even a portion of the vocal ligament, heals over time without significant deformity and good vocal outcomes (Fig. 6-3). For larger tumors of the larynx, with a more complex defect, from glottic larynx through the ventricle and into the false cord, the same postoperative healing appears to restore normal function (Fig. 6-4). Ultimately, the human body's remarkable restorative capacity lies at the heart of the opportunity and potential for eHNS within the multidisciplinary paradigm.

# TRANSORAL ROBOTIC APPROACHES

## Robotic Technology and Its Application in eHNS

Although the term "robot" dates back to a 1921 play *Rossum's Universal Robot*[12] by a Czech playwright,[12] the widespread use of robotics in surgery has debuted only in the last decade. In 2007, "robotic surgery" was defined as any "surgical procedure or technology that adds a computer technology–enhanced device to the interaction between a surgeon and a patient during a surgical operation and assumes some degree of control heretofore completely reserved for the surgeon."[13]

At present, there is only a single commercially available surgical robot. While the da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, CA) is widely used to facilitate laparoscopic minimally invasive surgery in urological, abdominopelvic, thoracic, and cardiac surgery, its use for "transoral otolaryngology" procedures was approved by the FDA in December 2009.[14] The da Vinci is not a singular "robot" but rather a surgical system in three parts or, to be more precise, three surgical carts. At the operating room table, surgical instruments are deployed from a **"patient-side" cart** and are safely placed by the surgeon within the patient's body under direct and/or endoscopic guidance. A binocular 8.5- or 12-mm endoscope with dual 0- or 30-degree optics is used to visualize target anatomy. The three-dimensional surgical anatomy is then recreated using the "vision" cart, where computer processing links the camera's image and the real-world spatial relationships of the instruments in a virtual environment. The surgeon, sitting at a **remote console cart** (Fig. 6-5) can then operate within this virtual three-dimensional environment using "master-controllers" (Fig. 6-6) that control and direct movements of the robotic instruments. These master controllers bear a remarkable similarity to joysticks and other hand-held devices employed in video games and other virtual reality simulators. The surgeon has an unprecedented perspective on the surgical anatomy as well as the ability to operate with 540 degree of wristed instrumentation and at either 0- or 30-degree angle. Furthermore, motion scaling increases precision and reduces the larger hand movements required by humans while eliminating tremor and fatigue. This surgical system permits the surgeon to interact with surgical anatomy with a novel perspective, around corners, in otherwise accessable places, and in ways that would not otherwise be possible. In other words, robotic surgery represents a fundamental advance in the art and science of surgery. For the first time, the surgeon and his hands are physically separate from the patient (Fig. 6-7). Real surgery is performed in a virtual environment. With further technological refinement and innovation, as stereoscopic cameras and instruments become smaller and more miniature, the limitations in what can be achieved will become even fewer.

The first transoral robotic head and neck procedure was performed by McLeod and Melder[15] in 2003 at the Walter Reed Army Medical Center. Using a slotted and custom-modified Lindholm laryngoscope, the authors resected a vallecular cyst with the first-generation "standard" da Vinci robotic system. Their report was finally published in 2005; that same year, Hockstein et al. first demonstrated the feasibility of transoral robotics for more extensive laryngopharyngeal surgery. "Hockstein's leap" was to place robotic arms through oral and oropharyngeal retractors, rather than traditional laryngoscopes, to more reliably facilitate surgery and thus significantly reduce external collisions.[16,17] Using standard tubed laryngoscopes, this team documented limited mobility of the robotic instruments (either 8 or

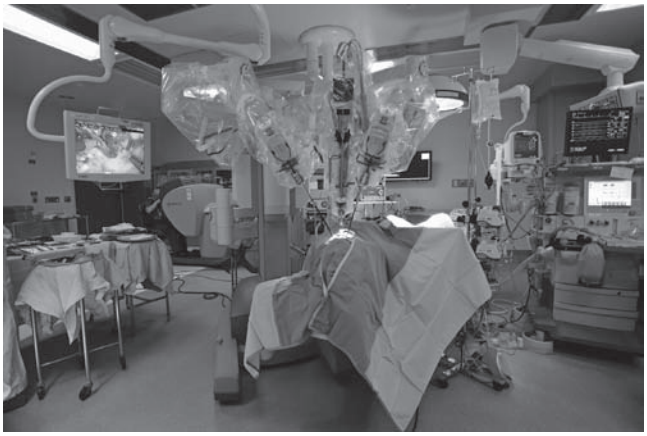

**FIGURE 6-7.** This intraoperative photograph demonstrates the relationships between the patient (foreground; covered in drapes), the patient-side robotic surgical cart, delivering the instruments into the oropharynx, and the remote surgical console **(back left)** where the surgeon operates. Robotic surgery incorporates real surgical maneuvers performed in a virtual environment.

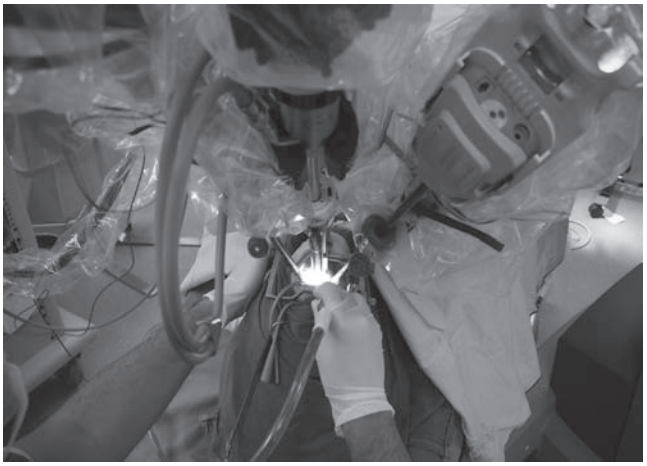

**FIGURE 6-8.** The Feyh-Kastenbauer retractor (Olympus) shown here provides several axes of exposure and retraction, first distracting the mandible from the maxilla. In addition, different "blade" can be inserted providing varying soft-tissue retraction. Finally, the blade can be angled to provide additional exposure and angulation during transoral endoscopic head and neck surgery.

5 mm) as well as the stereo-endoscopic camera. In fact, using this configuration, movement of the robotic arms tended to move the laryngoscope significantly, which suddenly and unpredictably changed visualization—a limitation that precluded safe simulated surgical procedures, even in a mannequin model. However, when the McIvor oropharyngoscope was utilized, instrument collisions were reduced or eliminated entirely in the oropharynx and was still possibly in both the hypopharynx and supraglottis. Difficulty in accessing the glottic larynx persisted using the da Vinci System.

Thus, the term "transoral robotic surgery" was proposed and a series of papers reported on robotic resection of oropharyngeal carcinoma (OPC) in the tongue base[18] and tonsil.[19] In TORS, three of the four da Vinci robotic arms are placed through the mouth using standard retractors such as the McIvor, Crowe-Davis, or Dingman oral retractor. Tumors of the tonsil (without glossopharyngeal sulcus extension) and soft palate are nicely exposed with these retractors. O'Malley reported on the superiority of the Feyh-Kastenbauer over standard oral/oropharyngeal retractors, such as the Dingman and Crowe-Davis,[18] especially for tongue-base carcinomas (Fig. 6-8). Once exposure is achieved, the surgeon introduces the binocular camera and on its side two instruments, using 5- or 8-mm dimensions. Typically, monopolar electrocautery is used for cutting and coagulation by means of a 5-mm spatulated cautery device (Fig. 6-9). While the hemostasis achieved with the spatula is excellent, the thermal burn associated 5-mm instrument may sacrifice excess normal tissue. For this reason, the $CO_2$[5,20,21] (Fig. 6-10A) has been used to increase the precision of mucosal incisions and to reduce collateral thermal damage. A 5-French introducer (Fig. 6-10B) has been developed to deliver a Thulium laser[22] through a robotic arm. A variety of tissue forceps, with teeth for gently grasping (Fig. 6-11), provide the ability for fine dissection as well as traction and counter-traction.

TORS simultaneously introduces two new aspects to traditional surgical techniques for many surgeons: transoral endoscopic surgery and robotics. Yet despite its novelty, several centers adopted the technique, which was associated with a clear learning curve and much of which surrounded, gaining initial transoral exposure and access. Genden[23] showed a precipitous decline in the setup time from over an hour to only 20 minutes, in his first series of 20 cases. Lawson[24] found a similar learning curve in a series of 24 patients from Mont-Godinne in Belgium. Setup time was 24 ± 14 minutes (range 10–60 minutes), with mean surgical time of 67 ± 46 minutes (range 12–180 minutes). Moore[25] found that operative times were significantly longer in the first 10 cases, then rapidly declining to an average of 71 minutes. Many of the initial surgeons who published earlier experience in TORS also had extensive published expertise in conventional transoral[26–28] or TLM,[24] suggesting that facility

**FIGURE 6-9.** A 5-mm spatulated cautery tip is the work-horse for transoral robotic surgery. Using the "cut" setting minimizes mucosal char when compared to "coagulate" mode.

with transoral exposure and surgery might reduce these learning curves and possibly complications.

## TORS for Oropharyngeal Tumors: Surgical Technique

***Transoral Robotic Oropharyngectomy.*** Understanding the transoral surgical anatomy of the lateral oropharynx, which was well described prior to TORS, is likely paramount for adequate hemostasis and good outcomes.

**FIGURE 6-11.** A 5-mm Maryland forceps provides soft-tissue handling during the initial mucosal incisions. This instrument is well suited for tonsillar and soft-palatal tumors. For tongue-base and larger tumors, the Cadiere or ProGrasp forceps with larger open jaws provide better traction on surrounding normal tissues.

Transoral robotic oropharyngectomy is performed under general endotracheal anaesthesia. After adequate oropharyngeal exposure is obtained, the surgeon first palpates the tonsillar fossa, to confirm that the tumor and surrounding tonsillar fossa is mobile. Preoperative trismus (suggesting medial pterygoid [MP] involvement) and/or hypomobility or fixation of the tonsil is a clear contraindication to transoral surgery. An incision is made through the mucosa overlying submucosal raphé between the superior constrictor and buccinator muscles. Cuts are made superiorly through the intermaxillary mucosa and inferiorly through the glossotonsillar fold, and if need be, some of the posterior floor of mouth. The tumor and attached lateral oropharynx is then retracted medially, which opens a fascial plane just deep to the superior constrictor, from the cranial to caudal aspect of the lateral oropharyngeal resection (Fig. 6-12). The MP muscle can then be identified as the specimen is retracted laterally (Fig. 6-13). The surgeon can use the precise visualization of robotics to identify the parapharyngeal fat, which covers the plane of the internal carotid artery, which is located more posterolaterally. Depending on the location of the tumor, the anterior tonsillar pillar is then transected both above at the soft palatal margin and below at its junction with the tongue base, glossotonsillar fold, and posterior floor of the mouth. These maneuvers release the surgical specimen from the lateral oropharyngeal wall, both above and below, which then allow the surgeon to separate the specimen from its deep attachments from the parapharyngeal space (PPS). Located more cephalad, the stylopharyngeus muscle is divided from its attachment to the undersurface of the superior constrictor. Usually, a branch of the ascending pharyngeal artery and vein is found here and is ligated using a surgical clip for adequate long-term hemostasis. More caudally, the styloglossus muscle is identified and transected. Often a branch of the glossopharyngeal nerve is found between these two muscle bellies, as well as branches from the facial vascular system. Finally, a medial incision is made in the posterior oropharyngeal completing the resection. Most often, the surgical defect is left to heal by secondary intention.

***Transoral Robotic Resection of the Tongue Base.*** After the patient's tongue base is exposed with an FK retractor, a horizontal tongue-base incision is made just posterior to the circumvallate papillae, extending from the posterior- most aspect of the floor of the mouth, through the lateral-most aspect of the base of tongue

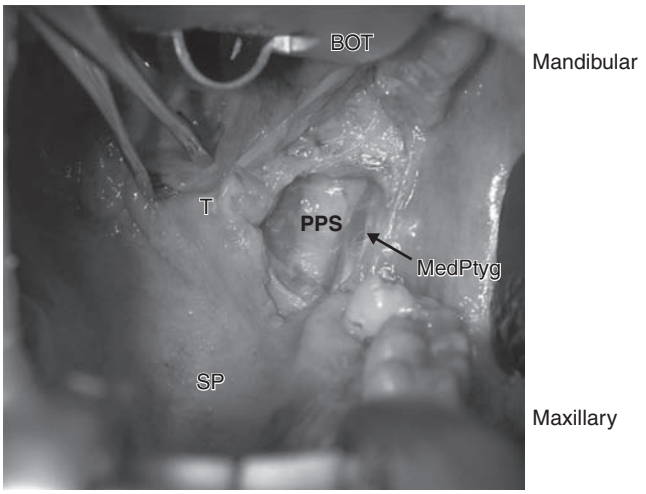

**FIGURE 6-13.** For orientation, the mandibular and maxillary dentition are labeled to the right. The base of tongue is shown above and the soft palate below. A submuscular plane of dissection deep to the superior constrictor is developed as the ipsilateral tonsil (T) is gently grasped with tenaculum and pulled medially. The right medial pterygoid muscle can then be identified as the specimen is retracted laterally. Then, the parapharyngeal space can be safely exposed without significant risk of vascular injury. Small venules from the ascending pharyngeal and dorsal facial vascular system must be clipped and precisely controlled to prevent hemorrhage on postoperative days 7 to 10.

(BOT) to nearly the midline (depending on tumor location and size). A sagittal incision is then made down into the substance of the tongue. This serves as our medial margin. From the lateral aspect of the incision, in the floor of mouth, an incision is made along the anterior tonsillar pillar and down through the remnant tonsillar fossa or superior margin into the glossopharyngeal sulcus, all the way to the posterior oropharyngeal wall. Returning to the substance of the tongue base, the muscle of the substance of the tongue is divided from lateral to medial, essentially aiming toward the hyoid bone. During every pass of the electrocautery spatula tip, tissue is retracted more posteriorly, to optimize the amount of tissue that is resected. This minimizes the chance for a positive deep margin. Once the hyoid is found (or an adequate cuff of muscle margin is obtained), an incision is made into the vallecula. From the previous sagittal incision in the midline, a deep plane of dissection then connects the medial aspect of resection toward the lateral oropharyngeal wall. This is done to safely approach and avoid injury to the hypoglossal nerve and lingual artery. Branches of the superior laryngeal system can be identified in the pharyngoepiglottic fold and then, a sagittal incision to the midline of the tongue connects all the way down to the base of the vallecula. The final incision follows through the base of the vallecula, thus avoiding thermal trauma to the epiglottis.

## Oncologic Outcomes and Functional Outcomes for TORS

The University of Pennsylvania's first extensive report on the role of TORS came in 2007. Weinstein performed "radical tonsillectomy" via TORS in 27 patients with previously untreated invasive squamous cell carcinoma of the tonsillar region, staged T1-3 N0-2, without free-flap reconstruction. A careful reading of the paper clarifies that a transoral lateral oropharyngectomy was actually performed; the term "radical tonsillectomy" is inadequate. This technique had been initially described in French by Huet[29] with wide mucosal margins and an underlying deep muscular margin of the superior constrictor muscle.[26] Nonetheless, with this novel use of robotics, negative margins were achieved in 25 of 27 patients (93%), which compared favorably with conventional technique.[27] Complications were limited to a single case of postoperative mucosal bleeding, delirium tremens, unplanned tracheotomy for temporary exacerbation of sleep apnea, and hypernasality and two cases of moderate trismus. Postoperative adjuvant therapy was required for most patients: 89% had radiation, and at least a third of these also had chemotherapy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Yet, at the completion of the study, 96% (26/27) were swallowing without the use of a gastrostomy. That same year, Weinstein reported on the University of Pennsylvania's TORS experience for the treatment of 3 patients with supraglottic laryngeal cancer as well.[30] Two patients had close or positive margins, but subsequent re-resection at the time of the initial surgery revealed no microscopic residual disease. One of these three patients had chemoradiation afterward for multiple metastatic lymph nodes found during staged neck dissection.

Adverse events following TORS appear to be limited. Most patients complain of a week or two of postoperative odynophagia and most return to normal swallowing within 30 days. Moore et al. reported a prospective study from Mayo with 45 patients treated with TORS and found that no patients required long-term feeding tubes nor tracheostomy.[25] However, for patients with advanced T stage 3 to 4 or location outside the oropharynx, functional outcomes following TORS may be associated with a higher risk for enterogastric feeding and poor swallowing outcomes.[31] This study from the University of Alabama–Birmingham showed that initially most patients resumed an oral diet before leaving the hospital (69%) and 83% within 2 weeks. However, longer term at a year, age >60 ($p = 0.017$), advanced T-stage classification ($p = 0.009$), and tumors within the larynx had higher rates of swallowing dysfunction using the MD Anderson Dysphagia Inventory (MDADI).[32] Assessment of functional outcomes using other quality-of-life instruments, including the Performance Status Scale (PSS) for Patients with Head and Neck Cancer,[33] showed similar results. For 38 patients treated with TORS and postoperative adjuvant therapy, PSS Eating and Diet domains demonstrated significant decreases occurred at 6 months, returning to postoperative baseline at 12 months.[34] This finding correlated with a decline in the SF-8 Global Health (QualityMetric Inc., Lincoln, RI) domain at 6 months, returning to normal at 1 year. Surprisingly, in this series of patients with oropharynx cancer, declines in the PSS Speech domain were seen at both endpoints, 6 and 12 months. Patient who had TORS only had rapid return of function on all indices and maintained this recovery.

In the largest functional outcomes study, Hurtuk et al.[35] reported on the TORS experience at The Ohio State University with 64 previously untreated patients: 57 patients had malignant tumors and 7 benign. The same decline from baseline in the speech, eating, aesthetic, social, and overall QOL domains was documented immediately after treatment. One year following treatment, the health-related quality-of-life (HRQOL) scores in the aesthetic, social, and overall QOL domains recovered. However, patients who underwent adjuvant radiation therapy or chemotherapy and radiation therapy had lower postoperative scores in the eating, social, and overall QOL domains ($p < 0.05$). Sinclair et al. found that postoperative chemotherapy was associated with reliance upon gastrostomy for longer than 3 months.[36]

In 2012, an extensive experience with TORS was published,[37] describing results from a US multicenter study on the feasibility, safety, and surgical margins for 177 patients undergoing TORS.[38] There was no intraoperative mortality or death in the immediate postoperative period. Postoperative hemorrhage following transoral surgery is always a concern.[39] In this series, there were no cases of catastrophic hemorrhage or emergent airway compromise: average blood loss was 83 mL and no patients required transfusion. A similar study in France[40] found higher rates of postoperative hemorrhage and reported two deaths, but nearly 65% of the patients had TORS for tumors of the supraglottic larynx, epilarynx,[41] or hypopharynx. These data suggest that robotics using the da Vinci Surgical System is best suited for tumors of the oropharynx.

Results are now emerging from several long-term experiences. Mayo Clinic recently presented a series of 66 patients with previously untreated squamous cell carcinoma (SCC) of the tonsil or the tongue base with a minimum follow-up of 24 months. The rate of gastrostomy dependence for nutrition was 4.5% and a single patient had tracheotomy. Local control and regional control at 3 years were estimated at 97.0% and 94.0%, respectively. Disease-specific and recurrence-free survival were 95.1% and 92.4% at 2 years, respectively.[42]

Furthermore, in contrast to the literature, outcomes following TORS may be independent of human papillomavirus (HPV) status. At the University of Pennsylvania,[43] 50 patients with OPC undergoing TORS as primary therapy had HPV status evaluated by real-time quantitative polymerase chain reaction (AttoSense HPV) for E6 proto-oncogenes for high-risk HPV. Thirty-seven patients were HPV positive (74.0%) with 34 of them (91.9%) being serotype-16. There was no difference in the ability to achieve negative margins: 92.3% for the HPV-negative cohort and 94.6% for the HPV-positive cohort. Neither group had local recurrence, but a single regional and distant recurrence was found in the HPV-negative cohort and two distant recurrences in the HPV-positive group. There were no statistically significant differences in survival between the two cohorts (overall survival, disease-specific survival, disease-free survival). In a follow-up paper, also from the University of Pennsylvania, Quon[44] evaluated the role of p16 immunohistochemistry (IHC) as well as polymerase chain reaction (PCR) for high-risk HPV subtypes to determine any association with HPV and oncologic outcomes. There was good concordance between p16 IHC and PCR, with p16 and HPV positivity in 73% and 74% of patients, respectively. Only a single local-regional relapse was seen in both p16-positive and p16-negative groups, and there were no differences in disease-free and overall survival differences. However, in both of these studies, HPV-negative patients represented a minority of the patients under evaluation. With this skewed population (with a favorable overall outcome in HPV-positive patients), further study is required to determine whether successful upfront treatment with TORS is truly independent of HPV status.

## Role of Robotic Surgery within the Multidisciplinary H&N Treatment Paradigm

While the safety and feasibility of TORS appears to be gaining acceptance, its role within the multidisciplinary paradigm is less certain. In many of the initial reports, well over half of patients undergoing TORS received some form of postoperative adjuvant therapy: radiation therapy with or without chemotherapy, ranging from 63% to 89%. Since the rate of positive margins in these series was low, the most common indication was neck disease. Skeptics suggest that TORS results in overtreatment, since most of the tumors amenable to TORS would be effectively treated with upfront chemoradiation.[45] Advocates, though, point to the superb functional results seen in these experiences, despite triple-modality therapy. In fact, in the largest published series to date, in which 89 patients had upfront surgical treatment with TORS, 63% received postoperative radiation therapy, with 49% of these patients also receiving concurrent chemoradiation.[46] Progression-free survival at 2 years was 86.5%, and no patient required a feeding tube for nutrition. In the multicenter trial, in patients undergoing TORS without previous therapy, the percutaneous endoscopic gastrostomy (PEG)-dependency rate was 5.0%.[37] Advocates interpret this and other series favorably and suggest the hypothesis of "deintensification."

That is, OPC patients treated upfront with TORS, even while needing postoperative chemoradiation, have similar oncologic outcomes, but do quite well functionally with "triple-modality" therapy because the overall dose to the pharynx is diminished.[47]

(c) 2014 Wolters Kluwer. All Rights Reserved.

This hypothesis will require further testing: ideally in the setting of a prospective clinical trial.

In the meantime, the changing epidemiology of oropharyngeal cancer will likely lead to a greater role for eHNS in the management of this disease. Reports from the United States[48,49] and abroad[50] have documented the precipitous rise in the incidence of OPC in individuals younger than typically expected for "traditional" head and neck cancer patients.[51] In a prospective case-control study, D'souza and Gillison[52] demonstrated an association between HPV and OPC, as well as the role of increasing oral sexual partners. This is explored in more detail in Chapter 12. Using the Surveillance, Epidemiology, and End Results (SEER) repository, Chaturvedi reported that the incidence of HPV-positive oropharyngeal cancers increased by 225% from 1988 to 2004.[49]

Fortunately, these tumors tend to respond favorably to standard organ-preservation approaches. In RTOG 0129, Ang et al. highlighted the significant impact HPV status has on the treatment of OPC,[53] after adjusting for demographics, T-stage, N-stage, smoking, and patients with HPV-positive. OPC had a 58% reduction in the risk of death and a 51% reduction in risk of progression or death. While these response rates are encouraging, young OPC survivors have the potential to live decades with the sequelae of their disease. Hutcheson et al.[54] have recently drawn attention to the long-term chronic severe dysphagia that may develop or progress years after radiation-based therapy for OPC. Given the potential long-term sequelae of radiation[54] in a rapidly enlarging population[49] of young patients with OPC, eHNS must play a greater role in their management.

## FUTURE DIRECTIONS: THE NECK AND BEYOND

A convergence of new techniques available in minimally invasive thyroid surgery[55,56] and the capabilities of the da Vinci Surgical System has ushered in a new era of opportunity in the neck for the endoscopic head and neck surgeon.[57] Minimally invasive endo-robotic and/or endoscopic neck surgery had been performed in human cadaver models.[58] Werner et al. demonstrated the feasibility of endoscopic sentinel lymph node biopsy for squamous carcinoma.[59] However, recent reports of robotic neck dissection for differentiated thyroid cancer from the Republic of South Korea have suggested the feasibility of routine endoscopic neck dissection for head and neck cancer.[60] Chung and colleagues performed robotic neck dissection via incisions in the axilla on 33 patients with lateral neck metastases from a differentiated papillary thyroid cancer. These patients had robot-assisted thyroidectomy and modified radical neck dissection using a gasless, transaxillary approach, yielding, on average, 6 nodes from the central compartment and 28 nodes in the lateral compartment. Koh et al. have demonstrated a similar technique for clinically N0 patients with oral tongue cancer, also using a robotic approach, but with transaxillary and retroauricular incisions.

Endoscopic approaches to the neck and the innovative techniques of robotic surgery may not have reached their full potential just yet. As access to robotic systems increases and as smaller robotic platforms are developed, TORS and robotic neck dissection may serve as a stepping stone to more complex operations of the neck, including tracheoesophageal resection and reconstruction, laryngeal framework surgery, and skull base surgery. Through the years, the radical neck dissection, as described by Crile in 1906,[61] has progressively been replaced by functional and selective neck dissections without compromising oncologic outcome. A similar thoughtful and clinical trial driven effort is required here, as well.

## SUMMARY

eHNS represents the natural evolution for the field of head and neck surgery. For tumors of the glottic larynx, TLM remains the gold standard. TORS has emerged as a safe, feasible, and effective approach for tumors of the oropharynx and selected tumors of the supraglottic larynx (Table 6.1). In the ensuing years, with robotic surgery and laser technology as a common platform, we foresee the development and widespread use of several new and innovative procedures for head and neck surgery, via transoral, retroauricular, and transaxillary approaches.

CHAPTER 7

Jonas A. de Souza, Ezra E. W. Cohen, and Everett E. Vokes

# Targeted Agents in Squamous Cell Carcinoma of the Head and Neck

## INTRODUCTION

Squamous cell carcinoma of the head and neck (SCCHN) is a heterogeneous disease of cancers located in different anatomic subsites and made up of diverse molecular biology. As our understanding of the molecular biology of the disease evolves, so do therapy options. This chapter will further describe the main mechanisms of disease, important pathways, and newer agents under investigation in SCCHN.

Over the last several years, epidemiologic studies have revealed that HPV-related oropharynx cancers represent a distinct disease entity based on clinical and molecular characteristics. HPV-related SCCHN is primarily driven by silencing of critical tumor suppressor genes by viral proteins and will be discussed in detail in Chapter 13. Several other oncogenes and tumor suppressors are dysregulated in non-HPV SCCHN and, for the first time, comprehensive exome sequencing data are available to catalogue these changes.[1,2] Some important pathways are described in Figure 7-1. The full impact of these alterations on tumorigenesis, prognosis, and therapeutics has yet to be realized, but generalizations can be made regarding which pathways are most frequently disrupted in SCCHN.

### Epidermal Growth Factor Receptor and Its Ligands

Epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase that is almost universally expressed in SCCHN. It contains an extracellular ligand-binding domain, a hydrophobic transmembrane segment, and an intracellular tyrosine kinase domain that is autophosphorylated upon activation. The primary ligands in SCCHN appear to be amphiregulin and transforming growth factor alpha (TGF-$\alpha$), which induce homo- or hetero-dimerization with other receptors.[3] EGFR activation has been linked with proliferation, invasion, angiogenesis, and metastasis. Moreover, increased EGFR expression has been associated with worse outcome in patients treated with surgery, radiotherapy, or chemotherapy.[4–6]

EGFR expression is primarily driven by gene amplification or polysomy, which together are observed in 40% to 50% of SCCHN.[7] Increased EGFR expression appears even in preneoplastic lesions, and preclinical studies have demonstrated a reversal of SCCHN formation upon inhibition of EGFR.[8] Therefore, EGFR has been a rationale target in SCCHN although protein expression, gene copy number, or ligand expression have not been reliable predictive parameters in patients treated with EGFR inhibitors.[9]

### PI3K/AKT Pathway

The PI3K/AKT/mTOR pathway has been implicated in many cancers, and activation of this pathway contributes to formation and progression of SCCHN as well as resistance to chemotherapy and radiation. Constitutive AKT activation has been associated with amplification of the gene encoding the p110$\alpha$ catalytic subunit of PI3K (*PIK3CA*) or *AKT2*; activating mutations in *PIK3CA* or *AKT1*; and *PTEN* loss. In studies of SCCHN tumor specimens, *PIK3CA*, *AKT2*, or *PTEN* alterations were found in 30% to 50%.[10–12]

### *p53*

The *p53* gene product is a pleiotropic protein that is the most commonly mutated gene in SCCHN (50%–60%).[1,2] Functionally, *p53* is involved in the regulation of diverse cellular processes including cell cycle, apoptosis, autophagy, DNA repair, and metabolism. Mutations generally render the gene nonfunctional and provide growth advantage to cancer cells. Specific *p53* mutations have been linked with poor outcome in SCCHN and likely render tumors more resistant to therapy.[13] Interestingly, *p53* mutations are almost exclusively associated with HPV negative, tobacco-related SCCHN.[14]

### Cyclin D1

Entry into S phase of the cell cycle is dependent on phosphorylation of pRb by cyclin D1–cyclin-dependent kinase (CDK)-4, cyclin D1–CDK6 and cyclin E–CDK2 complexes. This leads to release of inhibition of key transcription factors that activate genes required for cell-cycle progression. Cyclin D1 itself is tightly regulated through transcriptional control (e.g., Myc), protein degradation (e.g., GSK3$\beta$), or inhibition of its partner CDKs by CDK inhibitors (e.g., p16). However, when cyclin D1 is amplified, which is detected in approximately 30% of SCCHN,[15–18] physiologic controls can be overridden driving rapid proliferation and tumor growth. Cyclin D1 amplification has been associated with early carcinogenesis and resistance to therapy including cisplatin, EGFR targeting agents, and other small molecule kinase inhibitors.

With these important pathways in mind, an extensive list of agents has been developed and grouped in the following sections by their mechanism of action.

## EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS

Cetuximab, a recombinant chimeric anti-EGFR monoclonal antibody, was the first drug approved by the FDA for SCCHN since cisplatin, and it remains the only targeted therapy to have an indication and be routinely used in clinical practice for this disease. It inhibits activation of the receptor tyrosine kinase in addition to inducing antibody-dependent cellular cytotoxicity.[19] Cetuximab is approved in combination with radiation therapy for locally advanced disease, in combination with platinum-based chemotherapy and 5-fluorouracil (5-FU) for the first-line treatment of recurrent/metastatic disease, and as a single agent for R/M disease after failure of platinum-based chemotherapy.

Vermorken et al.[20] investigated cetuximab monotherapy in a phase II trial enrolling 103 patients with R/M SCCHN who failed to respond to platinum-based therapy. Patients were allowed to receive platinum plus cetuximab as salvage treatment upon disease progression. The best overall response rate—the primary endpoint of the trial—was 13% (95% confidence interval [CI], 7%–21%) with no complete responses seen. Of the 53 patients (51%) who received platinum plus cetuximab at progression, no responses were seen. Two phase II trials[21,22] further tested the addition of cetuximab to cisplatin in patients who were refractory to platinum-based combination chemotherapy. In the first trial,[21] the addition of cetuximab to platinum chemotherapy, the latter administered at the same dose and schedule at which progressive disease (PD1) was documented, produced an overall response rate of 10% in 96 patients, compatible to single agent cetuximab and likely only exposing patients to added cisplatin toxicities. The second trial[22] enrolled 132 patients to receive two 3-week cycles with cisplatin/paclitaxel or cisplatin/5-FU. Patients ($n$ = 30) with a complete or partial response continued standard therapy and cetuximab was given with cisplatin to those with stable disease (SD), PD1 and progressive disease within 90 days after platinum-based therapy (PD2). In total, 9 out of 51 patients who had SD after the first 2 cycles, 5 out of 25 patients who had progressed after 2 cycles of chemotherapy (PD1), and 3 of 54 patients who had progressed beyond 2 cycles up to 90 days (PD2) achieved an objective response, with median duration of response of 4.2, 4.1, and 7.4 months for the PD1, PD2, and SD groups, respectively, with median overall survival times of 6.1, 4.3, and 11.7 months. The lessons learned from these early trials were twofold: (a) cetuximab in combination with these agents was safe and tolerable at full doses of the respective cytotoxic agents; (b) the response rates of cetuximab as a single agent in platinum-refractory patients-suggest that its activity can be attributed mostly to the addition of cetuximab and that the monoclonal agent alone may achieve the same results. These trials led to a phase III trial in the first-line treatment for R/M SCCHN, conducted by the Eastern Cooperative Oncology Group (E5397).[23] In a placebo-controlled randomized phase III trial of cisplatin (100 mg/m$^2$ on day 1 every 4 weeks) with or without cetuximab (400 mg/m$^2$) loading dose on week 1 followed by 250 mg/m$^2$ weekly, a total of 117 patients with SCCHN were randomized. The patients had newly diagnosed metastatic disease or locoregional recurrence/persistence after initial locoregional therapy. A significant improvement in the objective response rate was

(c) 2014 Wolters Kluwer. All Rights Reserved.

observed for the cetuximab plus cisplatin patient group, with 22.66% versus 9.3% ($p = 0.03$). Although the trial did not have the power to show significant differences in survival endpoints, the cisplatin-cetuximab arm had longer progression-free survival (4.2 vs. 2.7 months, hazard ratio [HR] for progression of 0.78; 95% CI, 0.54–1.12) and a trend for a longer median overall survival (9.2 vs. 8.0 months, $p = 0.21$).

The definite trial was the Erbitux in First-Line Treatment of Recurrent or Metastatic Head and Neck Cancer (EXTREME), which confirmed the benefit of adding cetuximab to standard chemotherapy as a first-line treatment in the R/M setting.[24] In total, 442 patients with R/M SCCHN, who were not candidates to local therapy and had not received systemic therapy in this disease setting, were randomized to treatment with either cetuximab plus platinum-based chemotherapy (cisplatin or carboplatin plus 5-FU) or platinum-based chemotherapy alone. Patients received cetuximab at a loading dose of 400 mg/m$^2$ followed by 250 mg/m$^2$ weekly until progression or unacceptable toxicity and either carboplatin (AUC, 5; Day 1) or cisplatin (100 mg/m$^2$ intravenously; Day 1) plus 5-FU (1,000 mg/m$^2$ intravenously; Days 1–4) every 3 weeks for a maximum of 6 cycles or the same dose and schedules of platinum plus 5-FU without cetuximab. Crossover of patients after disease progression was not allowed. The primary endpoint was OS with secondary endpoints of PFS, best overall response, disease control (complete response + partial response + stable disease), time to treatment failure, duration of response, and safety. The most common primary site in both arms was oropharynx (36% in cetuximab arm, 31% in chemotherapy alone arm).

The addition of cetuximab to platinum-based chemotherapy with fluorouracil (platinum–fluorouracil) significantly prolonged the median overall survival from 7.4 months in the chemotherapy-alone group to 10.1 months in the group that received chemotherapy plus cetuximab (HR for death, 0.80; 95% CI, 0.64–0.99; $p = 0.04$). The addition of cetuximab further prolonged the median progression-free survival time from 3.3 to 5.6 months (HR for progression, 0.54; 95% CI, 0.43–0.67; $p < 0.001$). The addition of cetuximab improved the response rate from 20% with chemotherapy alone to 36% with chemotherapy plus cetuximab ($p < 0.001$), although the duration of response did not differ significantly (4.7 months in chemotherapy arm, 5.6 months with cetuximab).

These clinical benefits were achieved with no changes in quality of life associated with the addition of cetuximab to chemotherapy.[25] Of the 219 patients receiving cetuximab, 9% had grade 3 skin reactions and 3% had grade 3 or 4 infusion-related reactions. Patients in the cetuximab arm also had significantly more hypomagnesemia ($p = 0.05$) and sepsis ($p = 0.02$). Six patients in the cetuximab arm had grade 3 or 4 infusion reactions compared with none in the chemotherapy alone group. There were 10 treatment-related deaths, 3 on the cetuximab and 7 in the chemotherapy-alone arm, although there were no cetuximab-related deaths. In a subset analysis, there was a greater benefit for patients below 65 years of age, those with better performance status, and those who received cisplatin (as three quarters of study participants did, and also compatible with data that suggest that carboplatin is not as effective as high-dose cisplatin.[26] Based upon these data, cetuximab is approved for first-line use in combination with platinum-based chemotherapy in both Europe and the United States, and a triplet regimen consisting of platinum (preferably cisplatin), 5-FU and cetuximab should be strongly considered in symptomatic patients with a good performance status.

In the locally advanced setting, cetuximab is approved in combination with radiotherapy based on a multinational trial in which 424 patients with oropharynx, hypopharynx, or larynx locally advanced tumors were randomly assigned to radiotherapy with or without concurrent weekly cetuximab.[27] Cetuximab was initiated 1 week before radiotherapy with a loading dose of 400 mg per square meter, followed by 250 mg per square meter weekly throughout radiotherapy.

Median overall survival of patients treated with cetuximab and radiotherapy was 49.0 (95% CI, 32.8–69.5) versus 29.3 (95% CI, 20.6–41.4) months in the radiotherapy-alone group (hazard ratio [HR] 0.73; 95% CI, 0.56–0.95; $p = 0.018$). Five-year overall survival was 45.6% in the cetuximab-plus-radiotherapy group and 36.4% in the radiotherapy-alone group. The addition of cetuximab to radiotherapy was associated with similar rates of grade 3 or 4 toxic effects in both groups. The incidence of acneiform rash and related hypersensitivity reaction was significantly higher in the combination cetuximab–radiotherapy group than in the group receiving radiotherapy alone. Rash and nail changes appeared to be the most common side effects associated with cetuximab. A further unplanned and underpowered subset analysis-showed that this benefit was limited to patients below the age of 65 and with a Karnofsky performance score (KPS) 90 to 100, and those with oropharyngeal cancer, findings that have to be confirmed.

Further, the interpretation of this trial is challenging since chemotherapy was not part of the study, making it difficult to assess whether the combination of cetuximab and radiotherapy was as effective as concurrent chemoradiotherapy. RTOG 0522 further enrolled 940 patients with locally advanced squamous cell carcinoma of the oropharynx, hypopharynx, or larynx to answer this question.[28] Preliminary results from the clinical trial RTOG 0522 did not show benefits of concurrent cisplatin (100 mg/m$^2$ on days 1 and 22) plus accelerated radiotherapy (70 Gy in 42 fractions over 6 weeks) with cetuximab when compared to concurrent treatment without cetuximab. With a median follow-up of 2.4 years, neither was there any improvement in progression-free survival, the primary endpoint of the trial, nor was there a statistically significant improvement in overall survival (83% vs. 80%, HR 0.87, 95% CI, 0.66–1.15). The final analysis of this trial is eagerly awaited.

Other monoclonal EGFR receptor inhibitors have also been investigated. Panitumumab is a fully humanized IgG2 monoclonal antibody with high affinity to the extracellular domain of EGFR,[29] currently approved for use in metastatic colorectal cancer. Because of its structure (fully human antibody), infusion-related reactions are minimal. After promising early phase trials,[30] a trial similar in design to the EXTREME trial was performed. The SPECTRUM trial[31] assessed the addition of panitumumab to cisplatin and 5-FU chemotherapy had clinical activity with a significant increase in PFS and response rate, but failed to demonstrate a survival benefit. With median PFS of 5.8 months for patients in the panitumumab arm and 4.6 months for patients in the chemotherapy-alone arm (HR = 0.78; 95% CI, 0.66–0.92; $p = 0.004$), and overall response rate of 36% in the panitumumab arm, compared to 25% for patients who received only chemotherapy (descriptive $p = 0.007$), the median overall survival was 11.1 months in the panitumumab arm, compared to 9.0 months in the chemotherapy-alone arm (HR = 0.87; 95% CI, 0.73–1.05; $p = 0.14$). In a subsequently planned subanalysis, outcomes were analyzed by tumor HPV status. Of the 657 patients enrolled in the trial, 443 (67%) were evaluable for HPV testing by central review. There were 83 (22%) HPV-positive tumors and 294 (78%) HPV-negative tumors. In patients with HPV-negative disease, the addition of panitumumab was associated with significantly improved OS (11.7 vs. 8.6 months; HR = 0.73; 95% CI, 0.58–0.93; $p = 0.01$) and PFS (6.0 vs. 5.1 months; $p = 0.001$).[32] However, this result has yet to be confirmed in further studies, given the lack of data that define HPV as a prognostic factor in R/M SCCHN or predictive factor regarding anti-EGFR therapy, as well as limitations in this analysis,

(c) 2014 Wolters Kluwer. All Rights Reserved.

including its retrospective nature and missing HPV status in 35% of patients. Furthermore, similar findings were not seen in the phase II randomized CONCERT I trial of chemoradiotherapy with or without panitumumab in patients with unresected, locally advanced SCCHN.[33] In this trial, compared with the cisplatin and radiation with regard to PFS and OS, there was a trend favoring concurrent cisplatin and radiation without panitumumab, with the addition of panitumumab increasing the HR of death to 1.63 ($p = 0.1223$).

Zalutumumab, previously known as HuMax-EGFr, is a completely human IgG1 monoclonal antibody against human EGFR that also triggers Fc-mediated antibody-dependent cellular toxicity. Following a phase I/II study that included 28 patients with R/M SCCHN after failure to conventional treatments showed promising activity,[34,35] an open-label phase III study was conducted. A total of 286 patients with SCCHN who were regarded as incurable by standard therapy and had PD1 within 6 months of platinum-based therapy were randomized in a 2:1 ratio to receive zalutumumab plus best supportive care (191 patients) or best supportive care with optional methotrexate (95 patients). Zalutumumab was dose-escalated to achieve a grade 2 rash. Patients in the best supportive care arm had the option to receive weekly methotrexate up to 50 mg/m$^2$/week. Eligible patients were allowed up to two prior chemotherapy regimens in addition to treatment with platinum. There was a statistically nonsignificant increase in overall survival with zalutumumab compared with best supportive care (6.7 vs. 5.2 months; HR = 0.77; 95% CI, 0.57–1.05). The percentage of patients surviving at 12 months was longer with zalutumumab (22% vs. 12%). Zalutumumab significantly prolonged PFS from 8.4 weeks in the control group to 9.9 weeks (HR for progression or death, 0.63; 95% CI, 0.47–0.84; $p = 0.0012$). Response rate for zalutumumab was 6% including two complete responses. Grade 3 to 4 infection, hypomagnesemia, and cardiac events occurred more frequently in the zalutumumab group than in the control group. Given that methotrexate was utilized by 78% of patients in the control arm and that poststudy chemotherapy drugs other than methotrexate were given earlier and more frequently in the control group, the study essentially compared zalutumumab with an active treatment arm.

Small-molecule EGFR tyrosine kinase inhibitors have also been investigated in SCCHN. The most studied agents are erlotinib and gefitinib. Several trials assessed the single agent activity of gefitinib, an anilinoquinazoline reversible EGFR inhibitor that has been shown to be effective as a single agent in SCCHN cell lines and tumor xenografts as well as a radiosensitizer agent. Its promising early results have not translated into a survival benefit in a randomized trial. In the R/M setting, a randomized phase III trial of gefitinib versus standard methotrexate including 486 patients.[36] Patients were stratified by whether they had received prior platinum-based chemotherapy (group A) or were too ill to receive such treatment (group B). Patients in each group were randomized to three treatment arms: oral gefitinib (250 or 500 mg daily) or intravenous methotrexate (40 mg/m$^2$ weekly with dose escalation to 60 mg/m$^2$ weekly) until disease progression. The overall response rates were 2.7%, 7.6%, and 3.9% in the gefitinib (250 and 500 mg) and methotrexate arms, respectively. The median overall survival was similar in the three treatment groups: 5.6, 6.0, and 6.7 months in the gefitinib (250 and 500 mg) and methotrexate arms, respectively. However, patients who received gefitinib experienced higher rates of tumor-related hemorrhage than those who received methotrexate, and gefitinib was associated with skin rash in 29% to 39% of patients and with diarrhea in 26% to 39%. When combined with conventional chemotherapy, also in the R/M setting, a phase III randomized trial of docetaxel plus placebo or docetaxel plus gefitinib 250 mg orally until disease progression was also reported.[37] Although there was a statistically significant difference in time to progression from 2 months with docetaxel/placebo to 3.5 months with docetaxel/gefitinib ($p = 0.03$), there was no increased overall survival.

In the locally advanced setting, gefitinib was further incorporated into the chemoradiotherapy regimen in 67 patients.[7] Two cycles of induction therapy with carboplatin and paclitaxel followed by FHX (5-FU, hydroxyurea, and radiotherapy on days 1 through 5 every 2 weeks for 5 cycles) and concomitant gefitinib 250 mg daily were administered, and gefitinib was continued for 2 years after the start of chemoradiotherapy. Grade 3 and 4 toxicities included mucositis (76% grade 3, 10% grade 4), dermatitis (29% grade 3, 3% grade 4), and diarrhea (1% grade 3, 0% grade 4). The majority of patients ($n = 62$) received maintenance gefitinib, and the median number of weeks on gefitinib was 95. The estimated overall 2-year survival was 83%, with PFS of 77%. Disease-specific survival at 2 years was 86%. The overall clinical response rate was 91%. These data further suggested a potential role for EGFR inhibition in combination with standard chemoradiotherapy regimens. Furthermore, maintenance gefitinib was feasible and this finding may support future chemopreventive strategies with EGFR-inhibitors.

Erlotinib is an orally available, potent, reversible, and selective inhibitor of the EGFR tyrosine kinase. In a large phase II trial including 150 patients receiving erlotinib 150 mg daily,[38] an overall response of 4.3%, median OS of 6.0 months, and median PFS was 9.6 weeks were noted. Given these results, one can conclude that erlotinib as a single agent is marginally cytoreductive in this patient population. When combined with cisplatin in a phase I/II trial, erlotinib 100 mg daily and cisplatin 75 mg/m$^2$ every 21 days[39] showed a response rate of 21%, with one complete response, eight partial responses, and disease stabilization in 21 patients (49%; 95% CI, 33%–65%). Median progression-free survival was 3.3 months (95% CI, 2.7–4.8 months), and median overall survival was 7.9 months (95% CI, 5.6–9.5).

Another single arm phase II study assessed 60 previously untreated patients with stage III or IV locally advanced SCCHN (60% with oropharynx tumors).[40] Patients received induction chemotherapy with 6 weeks of paclitaxel, carboplatin, infusional 5-FU, and bevacizumab; followed by concurrent chemoradiotherapy that included weekly paclitaxel, bevacizumab, and erlotinib. Radiation therapy began on day 1, with 1.8-Gy single daily doses, Monday through Friday, to a total dose of 68.4 Gy. Paclitaxel 50 mg/m$^2$ was administered by 1-hour intravenous infusion on day 1 and weekly for six consecutive doses. Bevacizumab 15 mg/kg, intravenous infusion, was administered on days 1 and 22. Erlotinib 150 mg daily began concurrently with radiation therapy and continued daily during the 7-week course of radiation. At 2 and 3 years, the estimated progression-free survival rates were 83% and 71%, respectively, whereas the 2- and 3-year overall survival rates were 90% and 82%, respectively. The investigators reported significant toxicities, with treatment breaks in 72% of patients, treatment noncompletion in 18%, two treatment-related deaths, and one myocardial infarction. In addition, 46 patients (76%) required enteral or parenteral nutrition during treatment. There are currently several clinical trials in progress assessing erlotinib for head and neck cancer. An interesting use of this agent has been in the chemoprevention setting. A clinical trial assessing erlotinib versus placebo as chemopreventive agents in a patient at high risk of developing SCCHN has finished accrual.

Lapatinib is an oral, small-molecule, reversible inhibitor of both EGFR and ErbB2. In a phase II trial in R/M SCCHN, oral lapatinib 1,500 mg daily was given to two groups of patients, those with and without previous exposure to an EGFR inhibitor.[41] In all the evaluable patients, no objective responses were observed in either cohort, and lapatinib appeared to have no activity in this disease setting. In an intent-to-treat analysis, SD was observed in 37% of patients without prior exposure, and 20%

(c) 2014 Wolters Kluwer. All Rights Reserved.

of those who had previously received an EGFR inhibitor. Thus, lapatinib appeared to have little clinical activity as a single agent in patients with SCCHN who were EGFR inhibitor naive or who had refractory disease. In the locally advanced setting, a phase II study including 107 therapy-naive patients were randomized (2:1) to receive 1,500 mg of oral lapatinib or placebo.[42] During the short duration (14 days) of lapatinib treatment, there was a statistically significant reduction in mean tumor cell proliferation index in patients who had received lapatinib compared to the placebo arm (−6% vs. −1.7%, respectively, $p = 0.030$), and 17% had a complete or partial response, compared with no responders on the placebo arm. A further randomized phase II trial comparing lapatinib (1,500 mg/day) or placebo with concurrent chemoradiotherapy followed by maintenance therapy with lapatinib or placebo in unresected LAHNC[43] showed a complete response rate at 6 months postchemoradiotherapy of 53% with lapatinib versus 36% with placebo. Furthermore, a phase III study (NCT00424255) is in progress to assess the benefit of lapatinib (1,500 mg) or placebo once-daily with radiotherapy and cisplatin for 7 weeks in high-risk SCCHN patients.

Other agents able to simultaneously inhibit cooperative signaling, such as EGFR and ERBB2, have been developed. Afatinib or BIBW292, an anilinoquinazoline derivative, is a highly selective, irreversible inhibitor of EGFR/HER1 and ERBB2. The open-label, phase II trial randomized 124 patients (median age 58.0 years, 87.1% male) to afatinib 50 mg/day, or weekly cetuximab 400 mg/m$^2$ loading dose followed by 250 mg/m$^2$/week until disease progression or treatment-related adverse events (AEs) (stage 1), at which point they could opt to cross over treatment arms (stage 2). Following stage 1, mean tumor shrinkage, the primary end point, was comparable for afatinib and cetuximab by independent central review. Objective response rate was 8.1% for afatinib and 9.7% for cetuximab ($p = 0.78$) and median progression-free survival was 13 weeks and 15 weeks ($p = 0.99$). The most common treatment-related AEs were diarrhea, 78.7% for afatinib versus 20.2% for cetuximab, and rash/acne, 78.7% versus 76.6%, respectively.

Preliminary results of a phase II study of afatinib versus cetuximab in 124 patients with platinum-refractory R/M SCCHN showed that following stage 1, mean tumor shrinkage, the primary end point, was comparable for afatinib and cetuximab, −16.6% versus −10.1% by independent central review ($p = 0.30$). Objective response rate was 8.1% for afatinib and 9.7% for cetuximab ($p = 0.78$) and median progression-free survival was 13 and 15 weeks ($p = 0.99$). Median PFS was 16 versus 10 weeks for afatinib versus cetuximab, respectively. In stage 1, most common treatment-related AEs were diarrhea, 78.7% for afatinib versus 20.2% for cetuximab, and rash/acne, 78.7% versus 76.6%,-respectively. For Stage 2, in which 68 patients crossed over arms (32 from afatinib and 36 from cetuximab), disease control rate was 33.3% (afatinib as second treatment) versus 18.8% (cetuximab second); duration of disease control was 17.3 versus 16.6 weeks. In the afatinib and cetuximab arms, 29.5% and 3.3% of patients had AEs leading to dose reduction, and 37.7% and 16.7% leading to discontinuation. Giving these promising results, a phase III trial of afatinib versus methotrexate in patients with platinum-refractory R/M SCCHN (NCT01345682) is planned, and a phase III trial of afatinib versus placebo as adjuvant therapy after chemoradiotherapy in patients with unresected locoregional SCCHN (NCT01345669) is recruiting participants.

Dacomitinib or PF-00299804 is an irreversible TKI of HER1, ERBB2, and HER4 which has demonstrated single-agent activity in a phase II trial of 69 patients as a first-line treatment in the R/M SCCHN, reporting an objective response rate (ORR) of 12.7%, median progression-free survival of 12.1 weeks and median overall survival of 35.9 weeks.[45] The most common grade 3 events were (3% of patients) diarrhea, fatigue, dermatitis acneiform, and hand–foot skin reaction.

In summary, EGFR inhibition has been a landmark in SCCHN, monotherapy has had limited success, mainly with cetuximab, and several inhibitors are still under development. Moving forward, two issues become of paramount importance in further developing this class in SCCHN. Given that virtually all SCCHN cases express EGFR, the first challenge lies in a better understanding of mechanisms of resistance to EGFR inhibitors. Secondly, simultaneous inhibition of other pathways, such as detailed later in this chapter, has been actively investigated and may further inhibit the molecular crosstalk between pathways.

## Insulin Growth Factor Receptor Pathway

The insulin-like growth factor system is composed mainly of the circulating ligands, insulin-like growth factor I (IGF-I), IGF-II, insulin, multiple receptors, and their binding proteins. Both preclinical research and clinical investigations have implicated the IGF-1R and its ligands in the development and progression of human epithelial tumors.[46] It has been shown that IGF-1R expression is increased in SCCHN compared to normal mucosal epithelia[47,48] and that IGF-1R signaling significantly promotes S-phase transition in a phosphoinositide-3-kinase/AKT and mitogen-activated protein kinase-dependent of human head and neck cancer cell lines.[47] It has also been shown that erlotinib and gefitinib induce heterodimerization of EGFR/IGF-1R, resulting in the activation of IGF-1R and induction of AKT/mTOR-mediated synthesis of survivin protein,[49,50] suggesting that targeting both IGF-1R and EGFR may be an effective approach. A recent case report also suggested that AMG-479, an IGFR-I receptor inhibitor, may have sensitized a previously cetuximab resistant tumor to further cetuximab therapy, as shown by its gene expression profile.[51] However, a study of CP-751,871 as monotherapy in R/M SCCHN was terminated due to lack of efficacy. A study of IMC-A12 with or without cetuximab in R/M SCCHN finished accrual and results are awaited.

## Hepatocyte Growth Factor and the c-Met (HGF/Met) Pathway

The receptor tyrosine kinase c-Met and its only known ligand, hepatocyte growth factor (HGF), also known as scatter factor, have become promising targets for new therapies. c-Met and HGF have normal physiological functions in regulating the embryonic development of a variety of organs.[52,53] Upon HGF binding, c-Met autophosphorylates and activates downstream several pathways including RAS-RAF-ERK, phosphatidylinositol 3-kinase-AKT-mTOR, and the signal transducer and activator of transcription (STAT) 3 pathway.[54–56] The Ras-mitogen-activated protein kinase (MAPK) signaling cascade, which operates as downstream effectors for the activated MET receptor, particularly, plays an essential role in cancer cell invasion by inducing epithelial-to-mesenchymal transition as a result of loss of intracellular adhesion by cadherins.[55] Small molecule tyrosine kinase inhibitors as well as antagonistic antibodies to either HGF or c-Met are currently being evaluated in phase I and/or phase II clinical trials for patients with advanced cancers, including SCCHN[57–59] PF-02341066 is an orally available selective Met competitor that has been shown to inhibit tumor cell growth *in vitro* and *in vivo*.[58,60] In a preclinical model, invasion of SCCHN cells induced by HGF derived from tumor-associated fibroblasts was completely blocked by a HGF-neutralizing antibody.[61] Further work by Seiwert et al.[62] showed that Met inhibition by PF-02341066 in SCCHN tumors disrupted Met signaling, cell viability, motility/migration *in vitro*, and tumor angiogenesis *in vivo*. Further, inhibition-of PI3K/AKT

(c) 2014 Wolters Kluwer. All Rights Reserved.

and MAPK by blocking either EGFR or c-Met may be overcome by activation of the other pathway, which may advocate for dual EGFR and c-met targeting. Thus, the combination of PF2341066 with the EGFR inhibitor gefitinib was assessed in SCCHN cell lines and the expression levels of EGFR and c-Met further determined by Western analysis and correlated with antitumor responses.[63] The inhibition of both pathways resulted in maximum antitumorigenic effects compared with single-agent therapy both *in vitro* and in a preclinical xenograft model. Inhibition of cell growth was also observed when combining a Met inhibitor with cisplatin or erlotinib, and synergy was hypothesized to be related to EGFR-3 signaling.

## Ras/Raf/MEK/ERK Pathway

An important downstream pathway of the EGFR family is via the Ras/Raf/MEK/ERK pathway. Although mutations in *ras* or *BRAF* genes are rare, with only approximately 3.5% of patients with locally advanced SCCHN presenting K-Ras codon 12 mutations,[64] members of the *ras* family are overexpressed in SCCHN[65–69] and *in vitro* evidence suggests that the level of K-Ras expression is a determinant of proliferation of SCCHN cell lines.[65] Thus, the EGFR-Ras-Raf-MEK-ERK signaling pathway in SCCHN is an attractive therapeutic target. Further, when coupled with the high levels of VEGF observed in EGFR-inhibitor resistant tumors and as the upregulation of VEGF levels by EGFR activation, agents that simultaneously inhibit the Ras-Raf-MEK-ERK and vascular factors are very promising.[70,71] The further combination of erlotinib and bevacizumab, a recombinant monoclonal antibody to the VEGF is described further in this chapter.[72]

Among the multikinase inhibitors, sorafenib is a multiple tyrosine kinase inhibitor, targeting VEGFR-2 and 3, platelet-derived growth factor receptor (PDGFR)-$\beta$, c-Kit, and RET, as well as inhibiting downstream Raf kinase isoforms (wild-type Raf-1, and B-Raf and mutant b-raf V600E).[73] A phase II Southwest Oncology Group trial assessed sorafenib as a single agent in 44 chemotherapy naive patients with R/M SCCHN.[74] With a median overall survival of 9 months (95% CI, 7–14 months) and progression free survival of 4 months (95% CI, 2–4 months), one patient (2%) had a confirmed and two had unconfirmed partial responses.

Another agent, sunitinib, was assessed in other two phase II studies in R/M SCCHN, also with disappointing results in several trials.[75,76] In the largest phase II trial, 38 patients with SCCHN having evidence of PD1 were treated with sunitinib 37.5 mg/day monotherapy given continuously until progression or unacceptable toxicity. A partial response was observed in only one patient and SD in 18, and disease progression in 19.[77] In summary, sorafenib and sunitinib have shown poor activity as single agents in R/M SCCHN, and caution should be exercised when embarking on trials of these agents in this disease.

## Mammalian Target of Rapamycin (mTOR) Inhibitors

The mTOR is a conserved serine/threonine protein kinase, belonging to the phosphatidylinositol kinase-related kinase (PIKK) family. The phosphoinositide 3-kinase (PI3K)/protein kinase B (AKT)/mTOR pathway has been implicated in proliferation, survival, angiogenesis, invasion, and metastasis of several cancers including SCCHN. Dysregulation of the PI3K/AKT/mTOR pathway occurs frequently in SCCHN and has been linked with poor outcome. Furthermore, AKT activation, PI3K accumulation, and PTEN down-regulation detected in SCCHN could reflect the early biochemical effects of tobacco components such as nicotine.[78,79] Rapamycin is an FDA-approved macrolide antibiotic derived from the bacteria *Streptococcus hygroscopicus*, commonly used as an immunosuppressant. To illustrate the importance of this pathway, the combination of enzaustarin, an AKT inhibitor, with rapamycin has been shown to have efficacy in cell lines and cause tumor shrinkage *in vivo*.[80] The rapamycin analogues temsirolimus (CCI-779), everolimus (RAD-001), and deforolimus (AP-23573) have been developed as cancer drugs. Temsirolimus is an ester of rapamycin that is available as an intravenous or oral formulation. *In vivo* studies using a mouse model demonstrated that even at the lowest possible dose, temsirolimus inhibited 70% of growth in SCCHN cell lines by 7 days and 80% by 21 days.[81] Everolimus is an oral mTOR inhibitor that is approved in Europe as an immunosuppressive agent for solid organ transplantation. Nine patients with SCCHN received escalating doses of everolimus in combination with cisplatin in a phase I trial, with one partial response.[82] A third mTOR inhibitor, ridaforolimus, can be delivered orally or intravenously. In a phase I study with deforolimus and capecitabine, 1 patient with advanced SCCHN was reported to have SD for $>4$ months.[83]

# TUMOR VASCULATURE

Angiogenesis, the process of forming new blood vessels to support growth in both normal and tumor tissues, is a hallmark of tumor progression. Vascular endothelial growth factor A (VEGF-A) is the best known agent that induce angiogenesis, belonging to the platelet-derived growth factor (PDGF) superfamily, which also includes VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor (PlGF). Several cytokines are produced in SCCHN that induce angiogenesis.[84,85] VEGF expression is regulated by hypoxia-inducible factor-1$\alpha$ (HIF-1$\alpha$) dependent and independent mechanisms involving PI3-K and AKT. HIF-1$\alpha$ levels rise rapidly under hypoxic conditions and induce the transcription of multiple genes including VEGF, endothelin-1, and c-Met.[86] The vascular growth factor receptor (VGFR) tyrosine kinases VGFR-1, VGFR-2, and VGFR-3 also play an important role, and VEGFR-2 is the most important one through which VEGF exerts its vascular permeabilizing effects on endothelial cell.[4] In SCCHN, a meta-analysis of 12 studies including 1,002 patients affected by cancer of oral cavity (70.8% of patients), pharynx (15.2%), and larynx (14%), VEGF expression detected by immunohistochemistry was evaluated, and its positivity was associated with a 1.88-higher risk of death at 2 years.[87] In addition, resistance to EGFR inhibitors in preclinical models has been associated with upregulation of VEGF.[71]

The humanized recombinant monoclonal antibody to the VEGF bevacizumab has been the most studied antiangiogenic agent and several studies have been performed. The combination of bevacizumab and an EGFR inhibitor has been initially assessed in a phase I/II in R/M SCCHN.[72] The phase I study was designed to determine the maximum tolerated dose of bevacizumab when associated to erlotinib: erlotinib was given at dosage of 150 mg/daily, while bevacizumab was administered in escalating dose cohorts. In the phase II portion, 48 patients were assessed for response, the best observed response included complete or partial response in 7 patients (15%; 95% CI, 6–28) and SD in 15 patients. Four patients achieved a complete response with duration of response that lasted up to 17 months in one patient. The median overall survival was 7.1 months (95% CI, 5.7–9.0), with 15 patients surviving 1 year, and the median progression-free survival time was 4.1 months (2.8–4.4). The most common toxic effects of any grade were rash and diarrhea (41 and 16 of 48 patients, respectively). Three patients had serious bleeding events of grade 3 or higher, one of which was fatal, ascertained at autopsy to be laryngeal in origin, but not at a site of active disease. In an exploratory analysis, high phosphorylated

(c) 2014 Wolters Kluwer. All Rights Reserved.

VEGFR2/VEGFR2 and endothelial cells phosphorylated EGFR/EGFR ratios in baseline tumor specimen identified patients with the greatest probability of response to erlotinib and bevacizumab. Another trial evaluating bevacizumab and cetuximab revealed a partial response in 5 (20%) and SD in 14 (56%) of 25 evaluable patients.[88,89] In these two studies, patients were allowed up to one prior regimen for their R/M disease. When bevacizumab was combined with the antifolate pemetrexed in previously untreated R/M disease in a phase II trial, an interim analysis showed an overall response of 36%.[90] In 22 evaluable patients, 3 (14%) had complete response, 5 had (23%) partial response, and 13 (59%) SD. Two deaths were reported, one from sepsis in a neutropenic febrile patient and another from tracheal bleeding in a previously reirradiated area triggered by suctioning. Three hemorrhagic events were reported.

In the locally advanced setting, Seiwert et al.[91] performed a phase 1 study where bevacizumab was added to fluorouracil and hydroxyurea-based chemoradiotherapy (BFHX) in patients with relapsed previously irradiated SCCHN or with poor prognosis of newly diagnosed disease. Forty-three patients were treated: 29 patients (67.4%) were previously irradiated, while 14 patients (32.6%) were newly diagnosed. Dose-limiting toxicities were reached at level 3 (bevacizumab 5 mg/kg, FU 800 mg/m$^2$, HU 1,000 mg), with two grade 3 transaminase elevations and one grade 4 neutropenia, attributed to the combination of chemotherapy with bevacizumab. For level 4, chemotherapy doses were reduced (FU 600 mg/m$^2$, HU 500 mg), and bevacizumab escalation continued to 10 mg/kg. After chemotherapy dose de-escalation (level 4) no neutropenia occurred. The adverse events probably related to bevacizumab were grade 3 hypertension in 3 patients, 1 allergic rash reaction, 2 deep vein thrombosis, 1 stroke, and 2 fatal hemorrhages. The median OS of the patients enrolled was 10.7 months. Patients with no prior radiation had a significantly longer OS (40.1 months) than those with prior radiotherapy (9.2 months). Further, with the hypothesis that BFHX with twice-daily radiotherapy would be adequate for T4N0-1 and provide locoregional control rates similar to historical controls, a randomized phase 2 study of FHX with or without bevacizumab was performed.[92] This study was closed early due to an increased locoregional failure rate in the experimental (BFHX) arm, with all four locoregional progression cases occurring in T4 tumors randomized to BFHX. Two-year survival was 89% for those treated with FHX and 58% (95% CI, 33%–78%) treated with BFHX. Two patients receiving BFHX died during therapy, and one died shortly after therapy. No catastrophic bleeding events were seen. Further, the addition of bevacizumab to FHX required dose reductions on both 5-FU and hydroxyurea compared with standard FHX. The reduced doses of cytotoxic chemotherapy in the FHX plus bevacizumab regimen could be determinant with regard to the increased incidence of locoregional failure, although the small sample size (26 patients) in the phase 2 study precludes definitive conclusions. Alternatively, there is a possibility that the combination of bevacizumab with FHX decreased the efficacy of the regimen, given that prior FHX regimens including a third systemic agent demonstrated that T4 tumors had locoregional control rates of 71% to 75%.[93,94]

The combination of an EGFR inhibitor with bevacizumab has also been reported in the locally advanced setting.[95] In a single arm, nonrandomized study in newly diagnosed patients with stage III/IV, patients received a 2-week regimen consisting of bevacizumab 10 mg/kg and/or erlotinib 100 mg daily, followed by both agents with concurrent cisplatin and twice daily radiotherapy. Twenty-nine patients were enrolled on study, with 27 completing therapy. Common grade III toxicities were mucositis ($n$ = 14), dysphagia ($n$ = 8), dehydration ($n$ = 7), osteoradionecrosis ($n$ = 3), and soft tissue necrosis ($n$ = 2). Median follow-up was 46 months in survivors, with 3-year locoregional control and distant metastasis-free survival rates of 85% and 93%. Three-year estimated progression-free survival, disease-specific survival, and overall survival rates were 82%, 89%, and 86%, respectively.

Bevacizumab has also been added to the widely common regimen consisting of concurrent high-dose cisplatin and definitive intensity-modulated radiation therapy (IMRT) in patients with stage III through IV SCCHN.[96] Forty-two previously untreated patients (39 patients with oropharyngeal carcinoma and 3 with laryngeal carcinoma) were treated with IMRT (70 grays) with concurrent cisplatin (50 mg/m$^2$ on days 1, 2, 22, 23, 43, and 44) and bevacizumab (15 mg/kg on days 1, 22, and 43). Human papillomavirus (HPV) status was determined by *in situ* hybridization (HPV positive, 16 patients; HPV negative, 14 patients, unknown HPV status, 12 patients). The most common grade ≥3 adverse events were lymphopenia (100% of patients), mucositis (86% of patients), throat pain (74% of patients), and neutropenia (43% of patients). There were two treatment-related deaths, including 1 sudden death and 1 death from aspiration pneumonia. With a median follow-up of approximately 31.8 months (range, <3–51 months), the 2-year PFS rate was 75.9% (95% CI, 63.9%–90.1%), and the 2-year OS rate was 88% (95% CI, 78.6%–98.4%).

Vandetanib (ZD6474) has shown potent, selective activity against VEGF receptor-2 and has activity against EGFR and rearranged during transfection (RET) tyrosine kinases. Vandetanib has been shown to reduce invasion of SCCHN cell lines, where its antitumor effects seemed to be exerted via its EGFR inhibitory.[97] In cisplatin and radiation-resistant SCCHN cell lines, treatment with vandetanib, cisplatin, and radiation alone or in combination *in vitro* and *in vivo* showed that vandetanib plus cisplatin radiosensitized SCCHN cells *in vitro* and *in vivo*.[98] Further, the combination treatment with vandetanib, cisplatin, and radiation was superior to the rest of treatments (including the double combinations) in antitumoral effects, prolonging survival, decreasing cervical lymph node metastases *in vivo*. Clinical trials assessing vandetanib as monotherapy and in combination with chemotherapy are in progress. An interesting hypothesis currently being tested in a randomized placebo-controlled phase II study is that vandetanib will inhibit angiogenesis in preneoplatic tissues compared to placebo as a chemopreventive agent. Patients at high risk for oral squamous cell carcinoma are currently being enrolled in this trial.

In summary, the addition of angiogenesis inhibitors has been feasible in most studies, and encouraging efficacy has been found in comparison with historical controls. However, this comparison may prove difficult in view of the higher incidence of HPV-positive oropharyngeal tumors with a more favorable prognosis present in current studies. Thus, the potential benefit of these drugs, mainly bevacizumab, as either a radio or chemosensitizer is still unknown. Active ongoing research has been done in identifying predictive biomarkers, such as functional imaging techniques, which may allow the selection of patients who may benefit from this approach.

## PARP-Inhibitors: the Chemo/Radiosensitizers

With respect to chemotherapy and radiotherapy modifiers, a promising new area investigation is the use of poly (ADP-ribose) polymerases (PARP) inhibitors (PARPi) to improve both cytotoxic modalities. PARP is involved in several forms of DNA repair including single and double strand break (DSB) repair as well as base excision repair. PARP-1 is the principal isoform involved in the cellular process,[99] whereas PARP-2 and other PARP members constitute the residual activities (10%) when PARP-1 is inhibited. The concept of "synthetic lethality" is applied when targeting

(c) 2014 Wolters Kluwer. All Rights Reserved.

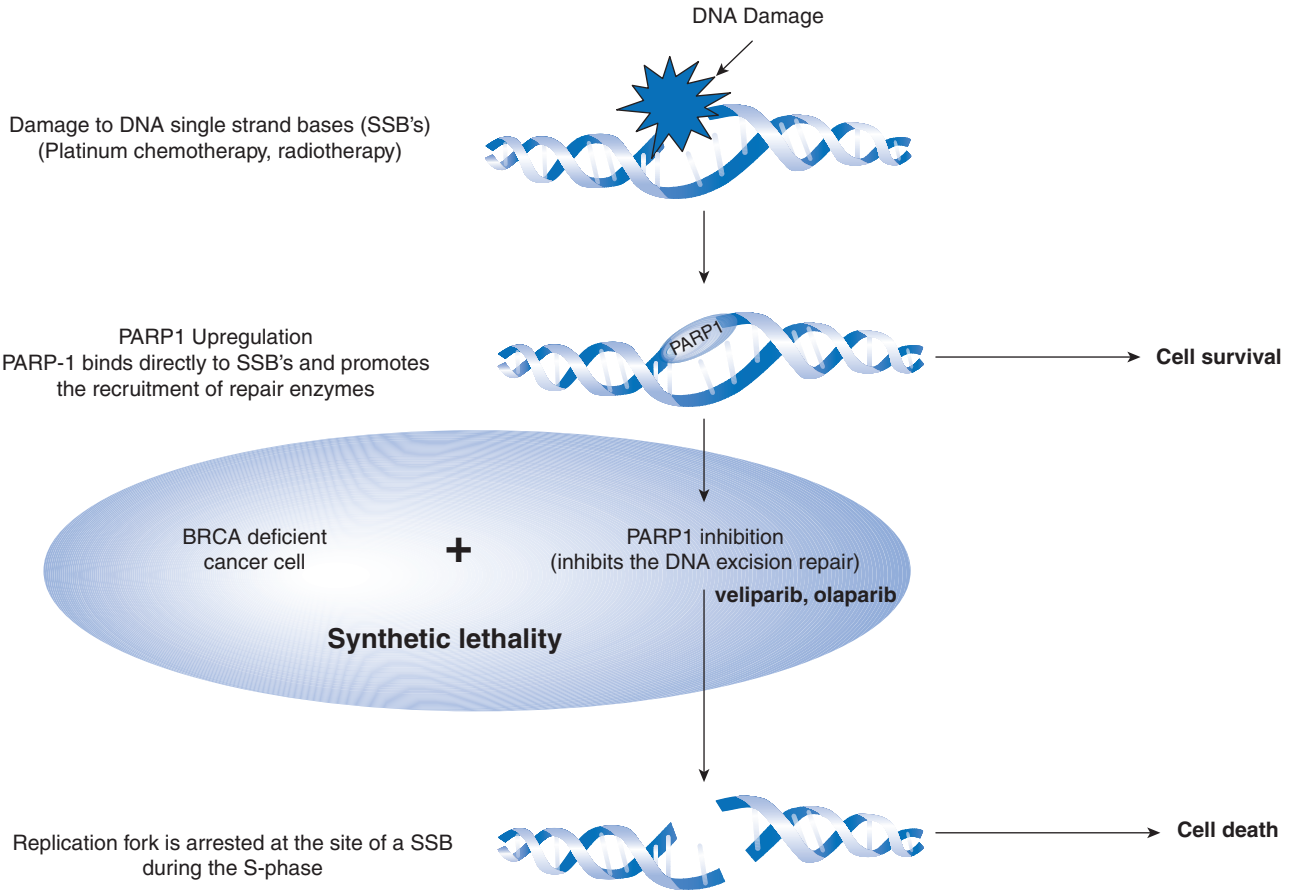

**FIGURE 7-2.** Schematic illustration of synthetic lethality. Synthetic lethality consists of killing cells with a specific DNA repair defect by inhibiting a second DNA repair pathway. In normal replicating cells, double-strand breaks are repaired by the homologous recombination (HR) pathway. BRCA1 or 2 are necessary for the HR pathway to function. The inhibition of a second DNA repair mechanism through PARP inhibitors would promote cell death.

cells with a specific DNA repair defect by inhibiting a second DNA repair pathway, as shown in Figure 7-2. In other words, targeting one of the mechanisms cancer cells use to escape the toxic effect of chemoradiotherapy by altering the ability of cancer cells to activate PARP-related repair can improve cytotoxic effects. This concept has become an important model for the use of PARPi in breast and ovarian cancer patients. Patients defective in BRAC1 and BRAC2 mediated homologous repair are proposed to be sensitive to PARPi which block the nonhomologous repair pathway. Further, in addition to BRCA-1 and -2 proteins, RAD51, RAD54, DSS1, RPA1, NBS1, ATR, ATM, CHK1, CHK2, FANCD2, FANCA, and FANCC have been related to increased sensitivity to PARP inhibition through defective DNA damage repair.[100]

Pre-clinical data have been recently obtained for this class of agents in SCCHN. In one study, the inhibition of DNA repair by the PARP inhibitor GPI-15427 induced significant sensitization to radiotherapy in a xenograft mouse model of SCCHN.[101] Another recent study showed that cetuximab enhances cytotoxicity with ABT-888 in SCCHN cells.[102] This increased cytotoxicity was achieved by cetuximab-mediated reduction of nonhomologous end-joining (NHEJ)- and homologous recombination (HR)-mediated DNA DSB repair, the consequent persistence of DNA damage, and further activation of the intrinsic apoptotic pathway. Several clinical trials are assessing the use of PARPi in combination with radiotherapy. Finally, the effects of olaparib and radiation were assessed in the BRCA1/BRCA2 wild-type SCCHN cell lines, and both radiation and olaparib alone induced DNA damage, and the combination of olaparib and radiation significantly enhanced this response.[103] Several trials with this class of agents in SCCHN are expected in the near future.

## CONCLUSION

In the era of personalized medicine, patients with recurrent/metastatic SCCHN not amenable to curative treatment still have a dismal prognosis with a median survival of around 8 to 10 months. Those patients with locally advanced disease often receive treatments with life-long, lasting toxicities. At the same time, the increased understanding of the biology of cancer and the availability of new technologies, such as microarrays, proteomics, and novel imaging, has allowed the identification of several molecular targets for cancer drug development, with the promise of increasing survival endpoints with more acceptable toxicities. However, the overwhelming number of new drugs and the nonlinear interactions and multiple redundant feedback loops occurring among the key targets in signaling pathways emphasize the challenges to this field. This is exemplified by the fact

(c) 2014 Wolters Kluwer. All Rights Reserved.

that despite all the agents discussed in this chapter, cetuximab is the only FDA-approved targeted therapy for use in SCCHN.

The way forward inevitably lies on two fronts: the successful development of predictive biomarkers and the reassessment of endpoints in clinical trials. The discovery and development of predictive biomarkers, linking drug discovery to predictors of efficacy early during the agent's research and development phase, would allow these therapies to be used in the subpopulations of patients most likely to benefit from them. For example, a promising technique is mass spectrometry-based proteomics. Chung and colleagues[104] looked at 108 pretreatment serum or plasma of recurrent/metastatic SCCHN tumor samples of patients treated with gefitinib, erlotinib/bevacizumab, or cetuximab. These patients were categorized into good or bad prognosis groups using a MALDI-MS algorithm validated in non–small cell lung cancer. The classification algorithm generated predicted OS benefit in two cohorts: (a) Patients in the good prognosis group having significantly longer OS time compared to the patients in the poor prognosis group: gefitinib-treated patients ($p = 0.007$; HR, 0.41; 95% CI, 0.22–0.79); and erlotinib/bevacizumab treated patients ($p = 0.02$; HR, 0.20; 95% CI, 0.05–0.78). The OS of the cetuximab-treated cohort showed a trend toward statistical significance ($p = 0.06$; HR, 0.26; 95% CI, 0.06–1.06). Beyond identifying patients who may benefit from these therapies, one may argue that identifying the patients who will not benefit from these therapies is equally, if not more, important. Finally, particularly important in individuals with a disease whose cure comes at a high personal and financial cost, as long-term survival becomes more frequent in SCCHN, these agents must also be evaluated from the patient's quality-of-life and financial perspective, and these outcomes should be increasingly incorporated in clinical trials.

and Cathy L. Lazarus

# Multidisciplinary Reconstruction of the Head and Neck: General Principles

As the management of head and neck cancer has evolved over the last decade, so too has the reconstruction of defects created by ablative surgery. Because of the level of confidence in transferring tissue of various types, thickness, and dimensions to achieve the desired goal, the overall level of sophistication has increased in the various subsites that are restored. As head and neck reconstructive techniques have evolved from the era of pedicled flaps to that of free tissue transfers, the focus has become less of simply covering a defect or "closing a hole" but rather addressing the multifactorial problems of restoring a region to a level of form and function that best replicates the predisease state.

The last two decades have been dominated by the application of microvascular surgery to the head and neck; the early emphasis was on discovering new donor sites for hard and soft tissue and later on a more detailed understanding of the recipient site required to select the best reconstructive technique. Just as head and neck cancer demands a multidisciplinary approach that tailors the treatment of the disease, so too does the reconstructive component in which there is a need for several disciplines working in a collaborative manner. The reconstructive/rehabilitative team should include a reconstructive surgeon, an oral and maxillofacial surgeon, an oral and maxillofacial prosthodontist, an oculoplastic surgeon, and a speech pathologist. Preoperative assessment of each patient by the appropriate disciplines helps ensure that all considerations are taken into account before embarking on the implementation of the reconstructive plan. A careful assessment of the tumor and a prediction of the anticipated three-dimensional defect will help the team anticipate the need for hard and soft tissue as well as prosthodontic rehabilitation. The reconstructive team must determine the goal for each individual patient, which is a balance determined by the components of the defect, the biology of the disease, the comorbidities and motivation of the patient, the wound-healing properties of the recipient site determined by exposure to prior therapy, the patient's nutritional status, and their continued usage of alcohol and tobacco. The goals, therefore, may vary for different patients faced with the same subsite defect because of these variables. If bone is to be a part of the reconstruction, then determination of the method of fixation must be established to ensure flap stability until bony union has occurred. In pediatric patients, there are special considerations related to the impact of bone harvest on the donor site. In addition, there is often a preoperative plan to remove fixation hardware in the early postoperative period, so that growth of the maxillofacial skeleton can continue unencumbered by rigid framework. Meticulous execution of the reconstructive plan must be followed by the appropriate rehabilitative therapy to maximize the recovery of function. The reconstructive team must be dynamic in its approach so that unforeseen circumstances that arise can be addressed during surgery. A positive surgical margin, for example, can substantially alter the reconstructive plan; a larger flap or even one from a different donor site may be required to accomplish the desired goal. Outcome measures specific to each subsite should be critically evaluated to determine the level of functional recovery. The monitoring and evaluation of function that results from reconstructive efforts are essential to the continued progress of these sophisticated and essential techniques. The continued refinement of approaches and the determination of the optimal reconstructive strategies depend on it. Centers vary their approach based on the collective experience and professional expertise within their respective institution, ideally based on this process of critical assessment of the outcome of their reconstructive approach.

The classification of defects is a critical undertaking that allows the reconstructive team to organize its approach to a particular subsite and to communicate, predict, and evaluate functional outcomes. Just as cancer staging provides a common lexicon for treating physicians that leads to therapy selection, prognostication, therapeutic outcomes, and to grouping of similar patients for outcomes analysis, defect classification does the same in head and neck reconstruction. The staging systems that are used to define cancers in particular subsites of the head and neck do not allow sufficient definition of the defect to permit accurate treatment planning. The size of an oral cancer and whether it has invaded mandible or maxilla determines the T stage for that cancer, but it does not provide the necessary ingredients for an accurate selection of the optimal reconstructive technique. This is determined by predicting what soft tissues and how much bone is to be removed. By estimating this, a more meaningful determination of what tissues must be harvested to restore form and function. Cancers of similar dimensions arising in the tongue and the buccal mucosa may lead to similar oncologic staging, but create very different demands for the reconstructive endeavor. Similarly, invasion of bone of the hard palate and the mandible may lead to a comparable T4 oncologic stage, but very different needs and strategies for functional reconstruction/rehabilitation. Moreover, different portions of the mandible and the presence of dentition will lead to very different reconstructive considerations that must be accounted for in the classification of that defect, none of which is addressed in the tumor staging.

(c) 2014 Wolters Kluwer. All Rights Reserved.

The desirability of using prosthetic restoration, whether it be for dental, auricular, nasal, ocular, or facial restoration, must be determined in the early stages of treatment planning and must be communicated to the patient in a very thoughtful discussion in which they are allowed to articulate their concerns regarding the use of prosthetics versus native tissue to achieve the final goal. Although the restoration of dentition with a conventional denture or more favorably with an implant-supported prosthesis is very well accepted, patients, more often than not, have very strong feelings regarding the application of a prosthetic solution, instead of their own tissues, for restoration of a part or all of the ear, nose, or face. In the past, the concern about loss of retention of the prosthesis to the facial tissues often led to less favorable patient satisfaction. This has largely been overcome by the application of osseointegration and fixation to achieve prosthetic stability and retention. However, there remains a significant bias by patients regarding the use of a prosthetic nose or ear that may lead them to select reconstruction, albeit with the acceptance of a less favorable aesthetic result. It is imperative that the reconstructive team embarks on very frank discussions with the patient and his or her family regarding the availability of a skilled prosthodontist and a skilled reconstructive surgeon with experience in restoring the particular defect at issue. Patients with devastating defects must be provided realistic counsel and perhaps offered alternative centers to undergo treatment. If implants are to be placed to achieve the desired outcome, then consideration must be given to the volume and quality of the underlying bone, the quality of the overlying soft tissue, and the timing of implant placement with respect to the institution of adjuvant radiation. Radiation alters the process of osseointegration and, therefore, compromises the overall success of the implants. Discussion of implant placement and radiation will be provided later in the chapter.

Although much of the emphasis in contemporary head and reconstruction surgery is placed on achieving an optimal restoration, the ability to shorten the recovery from ablative/reconstructive surgery has significant implications for the outcome of the cancer treatment. It is therefore essential for the reconstructive team to outline a restorative strategy that achieves a suitable "packaging" of the entire surgical treatment and recovery in an appropriate time period. The achievement of these goals depends, of course, on the performance of these reconstructive efforts by experienced teams of experts who are able to accomplish this in a predictable and reproducible manner.

The debate of whether it is more appropriate to perform a delayed or primary reconstruction has been waged over the past several decades as primary reconstruction has emerged as a highly predictable and reliable technique. The notion that a delay in reconstruction helps to make patients appreciate more fully the delayed reconstructive efforts may be valid in select subsites such as the nose and the auricle. More often than not, however, such an approach leads to inferior reconstructive results for mandible and maxilla, where primary reconstruction offers superior outcomes. The use of surveillance imaging performed in a sequential manner during the posttreatment period provides a useful method of monitoring the reconstructive site once the bone has been placed to restore the defect. Granted, the hardware that is used to achieve rigid fixation somewhat distorts, and therefore compromises the images, but despite these associated problems the value of improved function and dental rehabilitation that can be achieved by primary reconstruction far outweighs the drawbacks. Specific functional outcome studies for each of these two subsites will be discussed in detail later in the chapter.

In addition to the variables specific to the patient, the selection of donor sites for both hard and soft tissues will be influenced greatly by the experience level of the reconstructive team. The adage that "simple is better" continues to have relevance in reconstructive decision making, that is to say, the concept of starting with simple and moving to complex methods should be considered for each reconstructive challenge. Although selection of a *simpler* technique may utilize a less demanding procedure, it is imperative that all aspects of that procedure be anticipated and understood. A good example of that planning discipline is the decision-making process for reconstructing the floor of mouth. Although it may be tempting to use a split-thickness skin graft for the sake of expediency, the surgeon and the patient must understand the implications of failure of "graft take" on the mobility of the tongue and the architecture of the oral cavity. It must be understood that if an untoward outcome such as loss of a graft should occur, then wound contracture will result in a compromised functional result that can only be partially corrected by further reconstructive efforts.

There are a number of regional flaps that continue to play an important role in the management of patients with head and neck cancer. Certain donor sites, such as the forehead were commonly used as a source of flaps for head and neck reconstruction in the 1960s, but are rarely utilized in contemporary reconstruction. There does, however, remain an important role for the pectoralis major flap, the deltopectoral flap, the trapezius flap(s), and the latissimus dorsi flap. Additionally, there are newer regional sources of soft tissue such as the submental flap, the temporalis and temporoparietal flaps, and the posterior scalping flap. The role of regional flaps serving as carriers for vascularized bone has largely been eliminated due to the emergence of flaps harvested from the fibula, the scapula, the iliac bone, and the radius, which are all much more reliable donor sites for the restoration of the maxillomandibular skeleton.

In the contemporary era of head and neck cancer management, there are certain subsites such as the oropharynx and the laryngopharynx in which ablative surgery is usually reserved for the salvage setting or for less common types of neoplasms such as those arising from the minor salivary glands. There are centers where primary surgery, whether endoscopic, robotic, or open, is applied. It is safe to say, however, that for both the oropharynx and the laryngopharynx, the role of surgery is usually relegated to failures of primary radiation with or without chemotherapy. There are special considerations when performing reconstruction in a patient who has severely compromised tissues as a result of extensive prior treatment. An increased likelihood of wound breakdown and salivary fistula must be accounted for in the reconstructive strategy, and every effort to prevent these sequelae should be instituted. This usually includes the importation of healthy muscle to provide coverage of the carotid artery as well as the microvascular pedicle if a free flap has been transferred; this muscle may come with the free-flap donor site or may require a second donor site, often the pectoralis major muscle flap (Fig. 8-1). There are additional issues related to the availability of recipient vessels in patients who have undergone extensive prior surgery that often makes the conventional recipient vessels unsuitable for use in a microvascular transfer. Knowledge and experience in harvesting recipient vessels, such as the thoracoacromial vessels or the internal mammary artery and vein, are sometimes required to achieve a successful reconstructive result.[1,2]

In keeping with the organization of much of this book, this chapter has been organized according to the various subsites of the head and neck. In each subsite discussion, the major considerations for reconstruction and the defect classification scheme that the authors feel best defines the extent of the reconstructive problem will be presented. In addition, functional outcomes studies, when available, will be reviewed to help understand the impact of the reconstructive techniques on the functional recovery of the patient. A section covering various topics in maxillofacial prosthodontics will be presented to complete a comprehensive

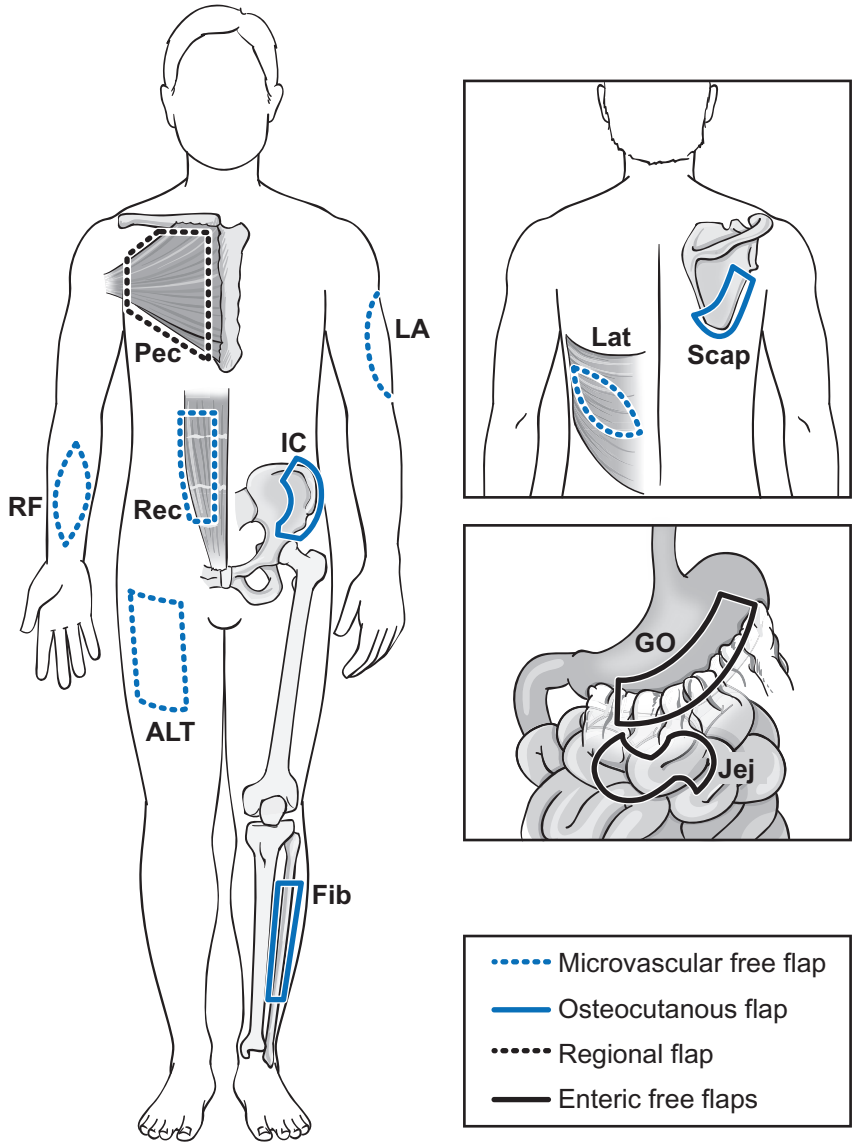

**FIGURE 8-1**. Types of regional and free microvascular, osteocutaneous, and enteric flaps. (See color insert.)

discussion of contemporary head and neck reconstruction/rehabilitation. Unfortunately, the constraints on the length of this chapter do not permit every subsite to be presented. The authors have selected the most common subsites and the topics in which new data are available since the publication of the prior edition of this text.

## ORAL CAVITY RECONSTRUCTION

### Tongue

From the perspective of oral function, the tongue is undoubtedly the most important structure within the oral cavity and its substance and mobility should be preserved whenever possible. Under all but the most extraordinary circumstances, the tongue should not be utilized as a source of mucosa for reconstruction of defects of the oral cavity. In contemporary head and neck cancer management, the oral cavity and therefore cancers of the mobile tongue, the floor of mouth, the gingiva, the palate, and the buccal mucosa are most frequently managed by primary surgery. Although in most centers the treatment of base of tongue squamous cell cancers is by radiation, with or without chemotherapy, there are circumstances in which salvage surgery and treatment of nonsquamous cancers requires the resection and reconstruction of the tongue base. Usually the latter resections include portions of the oropharynx and occasionally the supraglottic larynx. Extirpation of mobile tongue and floor of mouth cancers can be done very effectively and in a manner that preserves oral function. The decision as to whether the mandible should be included in the resection, in the form of a marginal or segmental resection, is discussed in detail in Chapter 16.

### Classification of Glossectomy Defects

Several years ago, the authors' team established a defect classification scheme for glossectomy defects that was designed to assist with the communication between clinicians, to assist with treatment planning, and to allow clinicians to determine the prognosis for functional recovery based on the extent of the tongue removed and the integrity of the innervation to the remaining tongue.[3] At that time, the tongue was divided into mobile and base of tongue defects and further subdivided into quarters to help quantify the extent of the resection. The status of

(c) 2014 Wolters Kluwer. All Rights Reserved.

the motor (hypoglossal) and the sensory (lingual) nerve supply to the tongue was also included in that scheme.

One of the premises of any reconstructive scheme is that the subdivisions are reflective of the contemporary techniques that are available for reconstruction. Toward that end, the authors have since modified the classification scheme to better reflect the reconstructive approach currently in use.

The separation of the tongue base and the mobile tongue has been retained, and the authors have further subdivided the mobile tongue into the following defects: minimal glossectomy defects that do not involve the floor of mouth, minimal glossectomy defects that do involve the floor of mouth, subtotal glossectomy defects that preserve a portion of the mobile tongue that has intact muscle and an intact nerve supply, and total mobile tongue defects. The total mobile tongue defect is further subdivided into those with an intact mandible and defects that are associated with a segmental mandibulectomy. The base of tongue is divided into three categories of minimal glossectomy, subtotal glossectomy, and total base of tongue resection. Finally the total glossectomy defect is subdivided between those that have an intact mandible and those that are combined with a segmental mandibulectomy.[4]

## Goals of Reconstruction of the Tongue

The fundamental goals of reconstruction of the tongue are to restore the patient's ability to swallow without aspiration and to form words with the greatest possible clarity. Conversational speech both in person and by telephone can be accomplished with a level of effectiveness that permits the patient to resume his or her premorbid quality of life (QOL). There are important components that assist toward that end. Retention of tongue mobility is critical to success and when there is a portion of the tongue that retains a motor supply, then the goal is to restore the missing part with redundant tissue so as to prevent tethering of the tongue to the inner table of the mandible or to the floor of mouth. Restoration of sensation is also an important goal in surgery and assists in giving the patient valuable feedback as to the location of food particles in the oral cavity. With this capability, the patient is better able to move those particles between the occlusal plane for mastication and propel them posteriorly to initiate the pharyngeal phase of deglutition. One of the key goals of restoring larger glossectomy defects is to match the neotongue to the volume of the oral cavity and the pharyngeal chamber. Therefore, any loss of movement can be compensated for by the restoration of volume that preserves the ability of the tongue to contact the palate and the walls of the pharynx, respectively.

## Reconstructive Options

Restoration of mobile tongue defects depends greatly on the amount of the tongue that is resected and whether the floor of mouth mucosa has been preserved. The major consideration noted earlier is related to the preservation of movement and the restoration of volume, which becomes a more significant concern when the size of the defect increases and when the anticipated loss of mobility of the tongue is greater. For minimal glossectomy defects that do not involve the floor of mouth, primary closure provides a simple and effective means of restoring function. However, for minimal glossectomy defects that include the floor of mouth, there is a need to introduce thin pliable tissue to prevent tethering that would otherwise occur with primary closure to the gingival tissue. The workhorse reconstruction for that purpose is the radial forearm free flap that usually provides the thinnest available tissue and which provides excellent lining for the oral cavity (Fig. 8-1). This donor site has a well-defined sensory distribution and large sensory nerves (the medial and the lateral antebrachial cutaneous nerves) that are easily incorporated in the harvest of tissue from the volar surface of the forearm.[5]

As mobile tongue defects increase in size, the need for more tissue is balanced by the integrity of the motor nerve supply and the amount of muscle in the tongue remnant. Through the incorporation of de-epithelialized segments of the forearm soft tissue, bulk can be added to the reconstruction by placing that vascularized subcutaneous tissue under the skin which is used to reline the tongue and the floor of mouth.[3] Alternative donor sites such as the lateral arm flap and the anterolateral thigh (ALT) flap (Fig. 8-1) provide an opportunity to transfer skin with more subcutaneous tissue than is usually present in the radial forearm donor site.

After resection of the total mobile tongue and a segment of the mandible, the reconstruction of the oral cavity requires two separate but integrated strategies for replacing the bone and the soft tissue. In this type of reconstruction, the goal is to match the volume of the neotongue with the volume of the oral cavity. Alternatively, a palatal prosthesis can be used but that involves coverage of the intact palate and the loss of a valuable source of sensate mucosa. One approach that the authors have adopted is the transfer of an iliac crest free flap (Fig. 8-1) with the associated skin paddle and placing that bone in a horizontal orientation so that it serves as a platform for support of the soft tissue. Although this is opposite the usual orientation of the iliac bone (placing it vertically for restoration of the mandibular alveolus), the technique provides valuable support of the neotongue reconstruction with a rigid platform that helps to prevent caudal migration of the soft tissue. Therefore, long-term contact between the neotongue and the palate is achieved.[6]

For total mobile tongue resections with an intact mandible, the technique that the authors employ is to transfer a large soft tissue flap that is inset in a manner that places the soft tissue above the occlusal plane. Achieving long-term stability of that reconstruction, so that gravity does not lead to a decrease in the height of the neotongue, requires a number of intraoperative maneuvers that simulate the strategy noted earlier whereby the goal is to maintain contact of this static reconstruction with the palate. One such maneuver was noted earlier where the introduction of supplemental soft tissue under the skin provides added bulk that is preserved due to the fact that it is vascularized tissue. In addition, suturing the supplemental tissue to drill holes in the lower border of the mandible helps to form a platform to support the overlying neotongue. The authors described the use of a rectus abdominus flap (Fig. 8-1) where the anterior rectus sheath is sutured to the lower border of the mandible and thereby all of the soft tissue above that fascial layer is supported. The muscle component that the authors anticipate will atrophy is below the fascia and does not contribute to the anticipated bulk.[6]

The reconstruction of the base of tongue is very similar to that of the mobile tongue with respect to the goal of achieving primary closure when possible and the introduction of increased bulk to match the volume of the pharyngeal chamber. In the salvage setting, the performance of surgery in this region involves more liberal indications for introducing vascularized tissue to aid the wound-healing process that usually has been substantially compromised by radiation therapy. These defects often involve adjacent anatomic structures, such as the pharyngeal walls and the soft palate (SP), all of which must be addressed at the same time. Primary closure of smaller pharyngeal defects with native tissue helps narrow the caliber of the chamber that places less of a demand on the base of tongue. The restoration of this region has greater functional implications for the patient with respect to safe and effective swallowing. The more efficient the swallowing, the less likely the patient is to aspirate, which when significant can lead to dependence on alternative routes of enteral alimentation such as a gastrostomy tube.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Although the restoration of a dynamic component of the tongue is a laudable goal, to achieve this in a way that actually provides functional neotongue movement that contributes to swallowing and articulation is very challenging. Movement alone, or demonstration of electromyographic (EMG) activity in transferred muscle that is reinnervated through the hypoglossal nerve (HG), does not constitute appropriate tongue reanimation. It is critical that comparative studies with patients having comparable tongue defects be functionally evaluated following static reconstructions, described earlier, and dynamic reconstructions involving the transfer of reinnervated muscle. To date, such studies have not been conducted.

As a means of helping to overcome the loss of activity of the hyomandibular muscle complex, the authors have found laryngeal suspension to be a very useful maneuver following base of tongue or total tongue resection. By statically positioning the larynx in a more cephalad and more anterior position, the larynx is placed in a more favorable functional position for avoiding and/or minimizing aspiration.

## Functional Outcomes of Tongue Reconstruction

Very little meaningful outcomes research has been done comparing the results of various reconstructive techniques for the specific defects that are mentioned in this discussion. Owing to the lack of sufficient patient volume in any one institution, there are no comparative institutional studies that will help the surgeon decide between various reconstructive options.

These authors have been examining outcomes following tongue resection with and without reconstruction (lateral and anterior resections). To date, oral outcome variables of tongue strength, tongue and jaw range of motion (ROM), and saliva production have not been extensively assessed in this population, nor have they been correlated with performance status on speech and swallowing and patient-rated QOL. Results in a cohort of 28 patients have shown only moderate reductions in lingual strength (mean = 35 kPa) as compared to healthy individuals. Jaw ROM was within normal limits (mean = 40 mm) and tongue ROM was a mean of 82% of normal (utilizing a converted scale). Oral outcome variables of tongue strength, tongue ROM, and degree of jaw opening were found to significantly correlate with all three functional domains of the Performance Status Scale (PSS),[7,8] including Normalcy of Diet, Eating in Public, and Understandability of Speech.[9] Improved functioning on these oral outcome variables were associated with a more normal diet, greater ability to eat in public and improved understandability of speech.[9]

When examining oral outcome variables with patient-rated QOL, tongue strength, jaw opening, and saliva weight were significantly correlated with QOL outcomes for swallowing on the EAT-10,[10] the MD Anderson Dysphagia Inventory (MDADI),[11] and speech (the Speech Handicap Index).[12] Those patients scoring higher on tongue strength, jaw opening, and saliva weight found their QOL to be improved for both speech and swallowing.

Objective performance status on the PSS significantly correlated with patient-rated QOL on all three QOL scales, with improved QOL correlating with a more normal diet and higher Eating in Public scores (i.e., more likely to eat out in public). Interestingly, no significant differences were found by surgical reconstruction type (i.e., free flap vs. primary closure) for PSS score or QOL score, since the primary closure group demonstrated smaller surgical defects and one might anticipate better performance in this group. However, tongue strength scores were significantly higher for the primary closure group, likely due to a greater amount of native tongue muscle.

When examining the effects of postoperative radiotherapy ± chemotherapy across tumor site and reconstruction type, those patients who underwent surgery >12 months from time of assessment and who underwent radiotherapy ± chemotherapy demonstrated significantly lower tongue strength scores than those seen in the surgery-only group. This is not surprising, since tongue strength has been found to be reduced in patients having undergone chemoradiotherapy for oral and oropharyngeal tumors.[13]

Oral outcome variables described previously have also been found to correlate with performance status on PSS and patient-rated QOL in patients having undergone microvascular free-flap reconstruction only, including the lateral tongue, the anterior tongue, and the total tongue sites.[14] Tongue strength was highest in the lateral tongue resection group, as assessed with the Iowa Oral Performance Instrument (IOPI). This device measures tongue force, with placement of an air-filled bulb on the tongue and instruction to press upward with maximum pressure on the bulb against the palate.[15] Three of five total glossectomy patients could perform a similar flap-resistance task and performed surprisingly well, demonstrating 46% of the mean strength seen in lateral tongue patients. No significant differences in Understandability of Speech were observed between groups. Total glossectomy patients scored 75% understandable speech, which was a better outcome than expected for this group of patients.

When examining overall QOL functioning in these three surgical groups utilizing the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire, Head and Neck Module (EORTC H&N35)[16] significant correlations with the oral outcome variables were found for the Swallowing and Sticky Saliva domains, with greater jaw opening correlating with better Swallowing scores, and reduced jaw ROM and less saliva weight correlating with poorer Sticky Saliva scores.[14] Patient-rated EORTC domains of Swallowing and Speech both correlated significantly with performance status domains of Normalcy of Diet and Understandability of Speech. Thus, patient-rated QOL correlated well with functional outcomes related to diet and speech.

It is clear that surgical resection and reconstruction affect functional outcomes after surgery. The amount of native tongue, degree of lingual mobility and strength, jaw ROM, and saliva weight after oral cancer surgery play a key role in speech and swallowing performance as well as overall QOL. As can be seen from these data, overall functioning across oral tumor site and reconstruction type can be quite high. In addition, patient perception of function correlates well with measured functional outcomes. Data on oral outcome measures in larger groups of patients should help predict functional outcomes and QOL after definitive resection and reconstruction for tongue cancer.

There are very little data concerning the role of sensation in producing a functional advantage for tongue reconstruction. However, Loewen and colleagues[17] found similar sensation ability in patients who underwent oral cavity sensate flaps as compared to healthy individuals. Specifically, these authors found improvement in light touch and two-point discrimination on the tongue. They also found improvement in swallow functioning, with improved oral transit times and improved bolus clearance through the oral cavity, as well as increased diet options when comparing these patients to similar patients cited in the literature. The recovery of sensation after surgery remains somewhat controversial. Boyd et al.[5] reported that some patients with nonsensate flaps placed into the oral cavity experience recovery of sensory feedback, presumably through the growth of sensory nerves from the perimeter and/or the depth of the wound into which the flap is being placed. This provides the most compelling information available on this topic.

In patients destined to undergo a substantial glossectomy, the surgeon must address fundamental questions relating to laryngeal function; specifically, whether he or she will be able to regain function with this organ in place or whether a functional laryngectomy should be performed at the time of primary

(c) 2014 Wolters Kluwer. All Rights Reserved.

surgery to prevent aspiration. The prediction as to whether a patient will be able to swallow is often difficult and that uncertainty is heightened due to the nature of deglutition, which is multifactorial. When the disease mandates the removal of the larynx to obtain clear margins, the decision is easier. When the disease requires the removal of the supraglottic larynx, then protection of the airway is certainly compromised and the likelihood of safe deglutition is diminished. During the era when partial laryngeal surgery was performed as the mainstay of therapy, the effectiveness of the extended supraglottic laryngectomy in which a portion of the base of tongue was removed was well documented. However, the patient's comorbid conditions, especially chronic lung disease and the amount of tongue that is to be removed certainly impact the likelihood of success. The irreversibility of a total laryngectomy usually leads us to avoid performing it in the primary setting, and often the procedure is reserved for the secondary setting after a period of adaptation and intensive therapy with an experienced speech pathologist. If the patient demonstrates an inability to protect the airway, then a functional laryngectomy can be performed in a secondary setting.

## OROMANDIBULAR RECONSTRUCTION

Success in oromandibular reconstruction is no longer measured simply by achieving a bone restoration of the segmental mandibular defect, but rather by the ability to restore not only the form but also the function of the oral cavity. A great deal of effort has gone into the detailed three-dimensional analysis of composite defects and into selecting the best reconstructive option that will provide both the optimal soft and hard tissue to restore the given defect. In the past, the major emphasis was on the restoration of the bony defect, but with the highly predictable nature of microvascular transfer of composite flaps, the realization that functional recovery was largely dictated by the movement of the tongue, the emphasis shifted to the soft tissue restoration as well as the restoration of functional dentition. One of the most important considerations is the effect of the soft tissue flaps on the form and function of the tongue and the floor of mouth. After a partial glossectomy, the unpreventable sequelae are related to the loss of the intrinsic tongue musculature and the neurologic supply. Preservation or restoration of sulcular anatomy is important for oral competence, tongue mobility, and denture stability. Additional requirements in soft tissue reconstruction may involve the buccal mucosa, the SP, and the pharynx. Lastly, patients with composite defects involving bone, mucosa, and skin require external coverage as well.

### Defect Classification System

A clear definition of the reconstructive options begins with a careful definition of the extent and nature of the defect using a practical classification that will direct the restorative effort. The shortcomings of the previously used classification schemes did not fully take into account the intricate, composite nature of the defects. Furthermore, the resulting neurologic deficit and its impact on the restoration of reasonable function was also largely ignored. The authors felt the need for a more encompassing, yet simple, classification system and in 1991 introduced a new oromandibular classification system to define the physiologic and aesthetic impact caused by the ablative procedure and the challenges that would be faced by the reconstructive surgeon in achieving the optimal functional restoration of the patient.[3] It should be emphasized that although the structure of the mandible is not that difficult to duplicate, the removal of various portions of the mandible leads to disruption of various muscular attachments and, in addition, the components of the temporomandibular joint, both of which impact the function of the reconstructed lower jaw. This system was also designed to aid in the selection of the composite free tissue transfer that would provide the best combination of soft tissue and bone components to restore a given defect.

On the basis of the functional impact from resection of the mandibular condyle, lateral defects are divided into three zones: the condyle, ramus, and body (Fig. 8-2). The rationale for subdividing body and ramus defects is based on the functional impact that will result from the disturbance of the masticator muscle sling. Body defects are defined as the tooth-bearing segment that extends from an area just posterior to the canine tooth to the junction between the horizontal and vertical rami of the mandible (anterior to the attachment of the masticator muscle sling). Finally, ramus defects encompass the entire vertical ramus to the level of the subcondylar region. Symphyseal defects are more challenging to restore due in part to the shape of the bone but also the loss of support of the tongue that is produced when the suprahyoid and extrinsic tongue musculature are completely detached. Contouring of the bone flap to restore the symphyseal anatomy can be quite challenging, requiring multiple osteotomies which adds to the complexity of the reconstruction. Since the initial description of this classification scheme, the authors added the superscript M to denote a marginal resection of the mandible. The classification system also describes the associated soft tissue defects as mucosal defects of the oral cavity, defects of the tongue, and defects of the overlying skin.

Finally, the authors also felt the need to include both sensory and motor nerve deficits that result from the particular ablative procedure. These include deficits of the inferior alveolar, the lingual, the hypoglossal, and the facial nerves.

### Goals of Oromandibular Reconstruction

With the major emphasis being placed on the quality of functional restoration, the following goals have been identified:

1. Reestablishment of mandibular continuity with a bone-containing flap that will reasonably match the height and shape of the resected segment and will form a firm union at the interface with the native mandible
2. Reestablishment of the normal position of the condyles as well as normal occlusal relationships for prosthetic restoration and near-normal mandibular range of motion

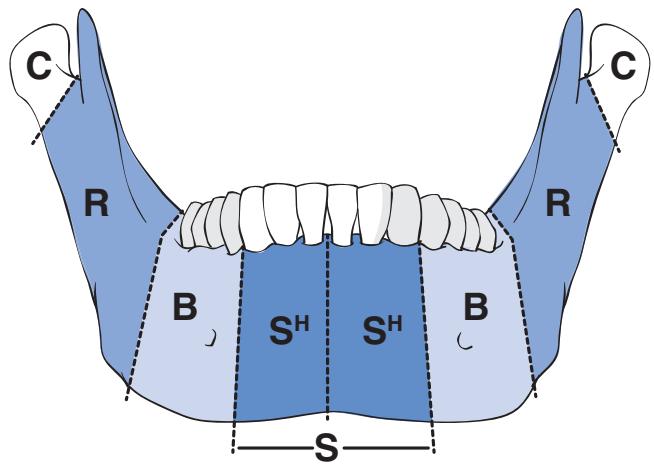

**FIGURE 8-2.** Classification of segmental bony defects of mandible.

(c) 2014 Wolters Kluwer. All Rights Reserved.

3. Restoration of a functional perioral muscular sphincter to ensure oral competence
4. Restoration of sensation to the lips and oral soft tissues by the use of sensate flaps and nerve grafts when indicated
5. Preservation of tongue motion and restoration of tongue volume as outlined earlier
6. Restoration with a functional dental prosthesis.

## Techniques of Oromandibular Reconstruction

The donor sites available for harvesting vascularized bone-containing free flaps (VBFFs) have provided a menu of choices based on the particular qualities of the different soft tissue regions; therefore, a more critical selection of the ideal type of soft tissue for reconstruction is possible. When dealing with more complex defects, there is often no single flap that provides the ideal tissues to restore all of the missing parts. One of the key provisions is that an adequate amount of bone is supplied for the placement of endosteal fixtures to support a dental prosthesis, thereby restoring the occlusion. It is, however, the soft tissues of the flaps that will frequently determine the ultimate success of the reconstruction and hence soft tissue evaluation plays an important role in the selection of the donor flap.

Four donor sites are routinely used for oromandibular reconstruction: the fibula, the scapula, the iliac crest, and the forearm (Fig. 8-1). Each donor site has advantages and disadvantages related to the amount and quality of the bone and soft tissue needed, the caliber and length of the vascular pedicle, the donor-site morbidity, and, on a practical level, the necessary intraoperative positioning of the patient that will allow for a simultaneous two-team approach.

The fibula osteocutaneous free flap is supplied by the peroneal artery and venae commitantes. It provides bone of sufficient length (up to 25 cm) for reconstruction of subtotal segmental mandibular defects.[18] The height of the fibula is significantly less than that of the normal mandible, making it more ideally suited for the reconstruction of the vertical ramus (including the condyle) as well as the mandibular arch in edentulous patients with a moderate degree of mandibular atrophy. When the defect lies within the tooth-bearing arch in dentate and edentulous nonatrophic patients, the height discrepancy between the reconstructed segment and native mandible must be addressed at the time of prosthetic restoration by the use of an implant supported mesostructure for a fixed denture prosthesis or an implant-assisted removable prosthesis. The skin paddle that can be harvested on the basis of septocutaneous perforators can be used to reline mucosal defects. There is usually a need to perform soft tissue debulking at the time of implant uncovering, owing to the thickness of the subcutaneous tissues and the fact that it is hair bearing. When used externally, the color match can be problematic. Finally, the distance of the donor site from the head and neck facilitates a simultaneous, two-team surgical approach.

The scapular system of flaps offers the widest array of soft tissue components, which accompany the 10 to 12 cm of bone that can be harvested from the lateral scapular border in an adult.[19] The scapular and parascapular cutaneous flaps can be harvested, both of which are based on the circumflex scapular branches of the subscapular vessels. The angular branch of the subscapular vascular system supplies the tip of the scapula, allowing an independent vascularized segment of bone to be harvested. Inclusion of the latissimus dorsi and the serratus anterior muscles can also be accomplished and adds to the versatility of the composite flaps that can be harvested. The main advantages of this donor site are the number and mobility of the soft tissue components relative to the bone, which are supplied by independent vascular pedicles of the subscapular system. The disadvantages of this donor site relate to the variable bone stock that can be harvested from the scapula, which is often inadequate for the placement of dental implants, as well as the need for intraoperative repositioning of the patient into a lateral decubitus position, which makes a simultaneous two-team approach difficult, if not impossible.[20]

The iliac crest osteocutaneous flap is supplied by the deep circumflex iliac artery (DCIA) and vein, branches of the external iliac artery and vein.[21] The vascular pedicle provides both an endosteal and periosteal supply to the iliac bone. The stock of bone that can be harvested is ideal for mandibular reconstruction, and the natural curvature of the ilium often assists in restoring the contour of the ipsilateral hemimandible.[22] The skin overlying the crest is supplied by perforators that traverse the three muscle layers of the abdominal wall. One of the major limitations of this flap, when used in oromandibular reconstruction, is related to the skin paddle, which is often too bulky for use within the oral cavity. In addition, the skin has a relatively fixed relationship to the bone sometimes making it very difficult to restore the complex three-dimensional anatomy required to restore the composite defects. The addition of the internal oblique muscle based on the ascending branch of the DCIA greatly increases the versatility of this donor site.[23] The thin pliable muscle, which undergoes atrophy after denervation, is ideally suited to restore gingival and mucosal defects over the neomandible. In such cases, the skin paddle is used for the restoration of cutaneous defects or simply as an external monitor of the circulation to the flap. A simultaneous two-team approach is possible. The major disadvantages of this donor site are the early gait disturbances and the potential for development of a ventral hernia. This can, to some extent, be avoided through meticulous closure of the donor site and the use of a mesh to augment the repair of the abdominal wall musculature.

The radial forearm free flap, which is based on the radial artery and the cephalic vein, provides thin sensate, pliable skin that can be transferred as an osteocutaneous flap. A segment of radius up to 8 to 10 cm and approximately 40% of its circumference can be transferred with the skin.[24] The bone is of limited dimensions for structural and functional reconstruction of the mandible. The thin, pliable soft tissue component of this flap is ideal for use in relining the floor of mouth, the tongue, and the posterolateral pharyngeal wall defects. This makes the use of this flap ideal in a small subset of patients who have a very limited posterolateral segmental mandibular defects along with a significant soft tissue defect. In these patients, the missing mandibular segment is usually located beyond the dentate segment and, therefore, the inability to place implants is less important. The most significant complication associated with this flap is the overall 25% incidence of pathologic fracture of the remaining radius, an occurrence that can lead to a significant impairment in hand function.[25] Fixation of the graft can also be problematic because it requires some stripping of the periosteum in the area of screw placement. This invariably leads to a decrease in the blood supply to the bone, which is periosteal in nature. These issues, coupled with the limited bone stock, has led to the infrequent use of this donor site for reconstruction of mandibular defects.

## Prosthodontic Management of the Mandibulectomy Defect

The major goals for prosthodontic treatment in this group of patients are to advance and optimize speech and swallowing functions while restoring form to dentoalveolar structures. The incorporation of prosthodontic care into initial treatment planning for surgical reconstruction of the mandibulectomy patient can shorten overall treatment time for functional recovery and improve the QOL. One of the main goals of primary mandibular reconstruction is to functionally rehabilitate the patient by

(c) 2014 Wolters Kluwer. All Rights Reserved.

restoring occlusal relationships and a denture-bearing surface. Conventional prosthodontic treatment uses the remaining dental arch to stabilize a removable partial denture over a bone-containing free-flap reconstruction to replace lost dentition. The condition of the dentition and periodontium is important for successful prosthodontic restoration. If there is no remaining dentition for clasp stabilization and retention, the edentulous patient will have a nonfunctional dental restoration. Compromised neuromuscular control resulting from a segmental mandibulectomy and related soft tissue deficits of the floor of mouth and/or the tongue can lead to the inability to tolerate a tissue-borne prosthesis and limit functional recovery. Osseointegration of dental implants in this patient population has a large impact on the ability to predictably restore them with stable dentures.

Mandibular prostheses supported by osseointegrated implants have a high rate of success and improved level of patient function and satisfaction by stabilizing occlusal contacts against the maxillary dentition and aiding in the restoration of symmetry and projection of the mouth. These objectives can be achieved with either a fixed or a removable implant-assisted prosthesis. When restoring the dentoalveolar complex with a removable implant overdenture, it is necessary to place a minimum of two fixtures in the symphyseal region. These fixtures can later be connected with a cast metal bar framework. Corresponding attachments are incorporated into the denture base to provide retention and stability of the prosthesis. A removable implant overdenture employs the attached mucosal base for additional tissue support to the prosthesis.

In cases in which the remaining arch is edentulous, and in which a lateral mandibular reconstruction is performed, the surgeon should place the implants in the anterior native mandible. This is an ideal location for fixture placement in patients undergoing a lateral jaw resection for a posterior alveolar, lateral tongue/floor of mouth, or tonsilar primary tumor because this area is usually spared from the radiation.

Fixed implant-assisted prostheses require multiple implants for support of the restoration. A minimum of four or five implants should be placed with the greatest anterior–posterior spread to minimize the cantilever effect of the posterior extension of the prosthesis beyond the most distal fixture. The posterior placement of the distal implant on the contralateral side is limited by the position of the mental foramen. Care must be taken to identify this landmark and avoid injury to the mental nerve.

The authors have adopted the approach of placing dental implants at the time of primary oromandibular reconstruction regardless of whether the patient has already been treated with radiation therapy or is scheduled to do so in the postoperative period. Following primary implant placement, the restorative team must allow a minimum of 12 to 16 weeks of undisturbed healing to achieve the most favorable level of success for osseointegration. When radiation is given after the reconstruction and primary implant placement, the fixtures are uncovered once the soft tissue reaction to radiation has subsided. This usually occurs approximately 6 months after placement. The uncovered implants may require soft tissue modifications such as vestibuloplasty or debulking procedures before definitive rehabilitation. The approach that the authors have developed allows the functional restoration of the patients within a period of approximately 7 to 8 months after their ablative/reconstructive procedure. Therefore, QOL can be expeditiously restored and patients are able to reintegrate into social interactions.

In the primary setting, once the bone flap is fixed to the reconstruction plate and the anastomosis to the recipient vessels is completed, fixture placement is then performed. Access to the new ridge is ideal when the cheek flap is elevated and the oral soft tissue retracted. The number and the layout of fixtures will depend on the size and location of the defect, the bone flap, and the type of prosthetic restoration that is planned for the patient. As noted earlier, the segmental defect reconstructed with a fibula free flap presents certain challenges for successful prosthodontic rehabilitation. To restore the facial outline form, the fibula free flap must be placed at the inferior border of the mandible. This can result in a significant height difference from the occlusal plane of the native dentition to the tissue base of the fibula. If implants are placed into the fibula, this height discrepancy can potentially produce unfavorable lever forces on the implants. One strategy that can alleviate these forces is to use the remaining dental arch to connect and stabilize a removable implant overdenture prosthesis.

The height difference between the native mandible and VBFFs also becomes a consideration for fixed implant prosthetic restorations. A shorter distance from the neoalveolus to the occlusal surface can be achieved more easily when using the iliac crest compared to the fibula. In so doing, there will be less nonvertical forces placed on the implants. In the authors' experience, whether the iliac crest or the fibula is used for the surgical reconstruction, the distance can be overcome by prosthetic design. The bicortical stabilization of the implant placed into the fibular bone adds to the stability of the implant and permits the use of prosthetic and implant framework designs to compensate for height differences between the fibula and the occlusal plane (Fig. 8-3A,B).

For hemimandibulectomy defects in the dentate individual, restoration of the dentition with a fixed implant–borne denture provides the best prosthetic option for the patient. The authors' preference for achieving a functional rehabilitation is to provide the patient with a fixed implant prosthodontic restoration whenever possible. The psychosocial impact of reconstruction and rehabilitation can be minimized with a fixed osseointegrated prosthesis. Oral hygiene and maintenance do not have to be compromised, which eliminates the need for removal and insertion as daily reminders of disease and treatment.

Implant placement in the primary setting also takes advantage of the vascular bed for osseointegration before adjunctive radiotherapy and serves to circumvent the use of hyperbaric oxygen (HBO). The fabrication of an interim tissue-borne removable prosthesis for partially dentate patients who have to undergo mandibulectomy can help to advance function during the osseointegration phase of treatment. An interim prosthesis can also be utilized as a surgical stent at stage II implant surgery for vestibuloplasty and/or debulking procedures. Split-thickness skin grafts can mimic attached mucosal surfaces and minimize peri-implant soft tissue complications. These strategies can lead to favorable outcomes for the patient who has to undergo reconstructed mandibulectomy, but require a high level of preoperative planning and a coordinated effort by the reconstructive team.[26,27]

Another treatment strategy for implant rehabilitation after free-flap reconstruction of maxillo-mandibular defects involves the use of computer-assisted planning and the ability to provide immediate provisional restorations with careful patient selection. Computer-assisted implant rehabilitation of reconstructed maxillo-mandibular defects can achieve superior results to provide fixed dental prostheses (Fig. 8-4A–D). The authors have examined 28 consecutive patients treated with computer-assisted implant rehabilitation.[28] All of the patients were reconstructed with vascularized bone-containing free flaps from the fibula, iliac crest, and scapular donor sites. One-hundred twenty-two implants were planned and 116 were subsequently placed, of which 102 implants (87.9%) achieved osseointegration. Ninety-nine implants were used for prosthetic restorations for an 85.4% success rate. Thirteen of 28 patients received immediate or early fixed restorations at stage I implant surgery. Fifty-six implants were placed into these 13 patients, of which 50 (89.3%) achieved osseointegration and were used for definitive prosthodontic rehabilitation in the immediate load group. Twelve of 13 patients

The facial position of the implants can also be negotiated with this design.

in the immediate load group went on to receive a fixed dental restoration. Twenty-five of the 28 patients in the study received fixed dental prostheses after implant rehabilitation.

Definitive restoration of the occlusal surfaces helps to enable the patient to achieve functional mastication, an important, but only a single parameter in the overall swallowing process. The ability of the remaining tongue or the reconstructed tongue to retrieve food particles and present the bolus to the occlusal surfaces, initiating the first phase of swallowing is extremely important in the restoration of function. Other parameters that impact the quality of the functional recovery include lip and cheek competence, the degree of disruption of the neurosensory feedback that effects the determination of the location and size of the food particles within the oral cavity, and the effects of adjuvant therapy on decreasing salivary flow and causing fibrosis of the swallowing muscles.

## PALATOMAXILLARY RECONSTRUCTION

The use of microvascular free-flap reconstructive techniques in the midface region for restoration of palatomaxillary defects is a relatively new application of some of the same strategies that were employed in restoring oromandibular defects. The collective experience in reconstructing the palatomaxillary complex, rather than relying on prosthetic restoration, is much smaller than the experience with oromandibular reconstruction due to the fewer number of maxillary cancers and also because of the relatively recent interest in this form of rehabilitation for these defects.

There are inherent differences between palatal and segmental defects of the mandible that have also contributed to the relatively later use of VBFFs for their rehabilitation. Most importantly, the remaining maxilla will not shift following removal of a portion of the palate, and the use of palatal prosthetics has provided a means for dental restoration at the same time that obturation of the defect is accomplished. Owing to the lack of movement of the remaining maxilla after performing an ablative procedure, the use of soft tissue flaps may play a limited role, which is quite different from the situation in reconstruction of segmental mandibular defects in which soft tissue flaps result in a shift of the remaining mandible. The immobility of the palatomaxillary complex means that the success of its reconstruction will not require a restoration of dynamic activity and therefore the overall restoration is judged on the basis of the quality of the static reconstruction. Finally, the lack of involvement of the tongue in most palatomaxillary resections translates into a much higher expectation for functional recovery than in oromandibular resections where the tongue is often involved leading to challenges in speech and swallowing.

### Classification of Palatomaxillary Defects

The authors' approach to designing a classification scheme for palatomaxillary defects was very different than for any other subsite in the head and neck.[29] Owing to the reasonable degree of success and the ability to restore dentition with an obturator, the authors elected to consider the essential biomechanical properties that lead to success and failure in obturation. As will be discussed later, the features of a palatomaxillary defect that contribute to prosthetic retention and stability include the midline palatal shelf and the scar band that forms at the interface between the skin-grafted maxillectomy cavity and the buccal mucosa. The prosthodontist capitalizes on these anatomic retention spots in the design of a palatal obturator. The obliteration of those structures by the introduction of a flap has implications for the success of restoring dentition to the upper arch. In addition to the midline palatal shelf and the scar band, the remaining maxillary dentition plays a very important role in prosthetic success. In particular, the canine and the molar teeth are particularly important structures due to the superior root form that is capitalized on by the prosthodontist with the use of clasps on those teeth that assist in prosthetic retention.

In 2001, the authors introduced a palatomaxillary defect classification scheme that has been slightly modified in the authors' current utilization.[30] The horizontal component of the defect was classified on the basis of the biomechanical principles noted earlier. The vertical component of the defect was classified on the basis of the extent of disruption of the orbital support and anterior projection of the cheek (Fig. 8-5).[30]

The authors classified central defects of the palate that do not involve the alveolus as **class 1a**. Those defects that involve the posterior alveolus, but do not lead to loss of the ipsilateral canine tooth were labeled as **1b**. Defects that involve up to one half of the palate and, in particular, that lead to removal of both

the canine and the molar teeth on one side, are designated as **class 2**. Such defects include the traditional hemimaxillectomy defect. In addition, horizontal defects of the palate that involve one half of the anteroposterior dimension of the palate and include the removal of both canines or both molars are also designated as **Class 2** defects.

**Class 3** defects include subtotal and total defects of the palate. **Class 4** defects were added after the 2001 publication and reflect those defects that involve the suprastructure of the palatomaxillary complex while preserving the native palate. In an effort to indicate the vertical components of a palatomaxillary defect, the superscripts f, z, o, i, and s were added to indicate that the resection included the orbital floor and inferior orbital rim, the zygomatic body, an orbital exenteration, exposure of the intracranial contents, and the overlying skin.[29]

## Goals of Palatomaxillary Reconstruction

It is imperative that the reconstructive surgeon realizes that the time-honored standard for palatomaxillary restoration is the

use of a palatal obturator, which eliminates the communication between the oral cavity and the sinonasal cavities as well as providing teeth to the maxilla. It is therefore imperative that the utilization of reconstructive options to be described in the sections which follow achieve those goals as well as others to be outlined. Support of the globe to prevent orbital dystopia is imperative in those defects that extend vertically to include the orbital floor and rim. In addition, symmetry of the midface region must be achieved. The avoidance of epiphora and ectropion must also be accomplished. Finally, functional mastication, velopharyngeal competence, and the avoidance of trismus are also important goals of the reconstruction.

## Reconstructive Approach

The basic principle of the classification scheme described earlier is that there are "horizontal and vertical" components to each defect that the surgeon must consider in the decision as to how best to restore an optimal functional and aesthetic result. In addition to the defect-related factors, there are also a number of patient-related and disease-related factors that must be considered, which include the biologic behavior of the disease, whether the disease is being treated for the first time or represents salvage therapy, the exposure to prior radiation therapy, the status of the remaining dentition, the status of the remaining bone stock in the palate, the presence of comorbid conditions, and the motivation of the patient to undergo a more involved surgical procedure. Preoperative discussions should be carried out between the patient, the reconstructive surgeon, and the prosthodontist to provide a clear understanding of the merits of each restorative approach.

After ablative surgery of the palatomaxillary complex, the continued monitoring of the cavity remains a topic of much debate. The authors believe that serial follow-up scans provide an effective surveillance for recurrence of disease. There are certain diseases such as mucosal melanoma and recurrent ameloblastomas, where the ability to visualize the mucosa lining the cavity is as important as the presence of nodularity on a scan. It is imperative for the surgeon to ensure, through very detailed conversations, that the patient fully understands the issues of surveillance and the prognosis for prosthetic success to make the most informed decision on whether to restore a defect with a prosthesis or a reconstructive technique that eliminates the palatal opening. The region of the orbital rim, the orbital floor, and the zygomatic body, however, must be reconstructed because a palatal prosthesis will not address those components of the defect. In defects that warrant open cavity surveillance, however, there may be a need to reconstruct the superior aspect of the defect while addressing the palatal opening with a prosthesis.

In general, the authors' approach to class 1a and 1b defects is to either use a prosthesis or a soft tissue flap. Class 2 defects can be managed either with a prosthesis or the transfer of a vascularized bone containing flap. Class 3 defects have such a poor outlook for long-term prosthetic success that the authors routinely reconstruct with vascularized bone. Class 4 defects require soft tissue and hard tissue replacement.

As noted in the discussion earlier, the horizontal component of the defect is fundamentally based on the size and location of the palatal opening and the presence of favorable dentition to assist in the retention of a palatal obturator prosthesis. For class 1a and b defects, the smaller size of the defect and the presence of one molar and two canine teeth permit the use of soft tissue reconstructions while not compromising the ability to restore dentition to the maxilla. In the event that any of those teeth is not present, then the use of implants can help stabilize the prosthesis, provided that the alveolar bone is adequate for successful osseointegration. In these defects, the authors have employed either a palatal island flap or a radial forearm flap depending on the size of the palatal opening.[30–32] When the transposition of the remaining palate, which is based on one greater palatine vascular pedicle, is sufficient to provide coverage, a palatal island flap is the method of choice. Alternatively, when the defect is too large and the remaining palatal mucosa will not comfortably provide closure, a radial forearm flap is employed and the vascular pedicle delivered to the recipient vessels in the submandibular triangle. One other contraindication to employing the palatal island flap is the exposure to radiation of this region, a circumstance that predisposes to the development of osteoradionecrosis because of the denuding of the palatal bone.

(c) 2014 Wolters Kluwer. All Rights Reserved.

In class 2 defects, in addition to the increased size of the defect, the loss of the ipsilateral canine and molar dentition makes the use of bony reconstruction important if the surgeon decides to avoid using a prosthetic obturator. The placement of a soft tissue flap into this defect leads to an unfavorable environment for dental restoration due to the loss of essential stabilizing properties in the defect. For class 2 defects that include only the horizontal component, the authors utilize the fibular flap to restore the bone of this region thereby gaining the ability to accommodate implants that are critical to a functional rehabilitation. In defects that extend vertically to include the zygoma and orbital rim and floor, the authors favor utilizing the iliac crest internal oblique flap, as originally described and later modified.[33] This flap transfers a significant volume of bone with sufficient height to restore the vertical components of the defect, including the inferior orbital rim. The iliac bone is placed in a vertical orientation to restore the maxillary alveolus, while the midportion of the palate is replaced with the internal oblique muscle that is transposed through the defect and used to reline the lateral wall of the nose.[34] The internal oblique muscle undergoes denervation atrophy and contours to the palatal vault, and within a very short time, it remucosalizes. One final aspect to the restoration of the vertical component of the defect is the use of onlay bone grafts to restore the anterior projection of the zygomatic body to achieve symmetry in this portion of the midface.

When bone is introduced into the midface region for palatomaxillary restoration, it has been the authors' practice to perform a coronoidectomy to increase the posterior space for placement of the bone and at the same time reducing the risk of trismus due to impingement of the maxillary bone on the anterior ramus.

Class 3 defects are highly unfavorable for prosthetic restoration due to the larger size of the defect and the loss of key retaining properties. The cantilever forces and resulting fulcrum line of the prosthesis place significant stress on the remaining dentition when class assembles are placed onto those teeth. The stress on the dentition is compounded by the detrimental effects of radiation. Restoration of the alveolus is usually best accomplished with a fibular flap, but sealing of the sinonasal cavity is often difficult in these situations and the authors most often employ a bipaddled radial forearm flap that places either skin or fascia on the superior and the oral surfaces of the defect, and the fibular bone in between. Bone-to-bone contact posteriorly and anterior support of the nose are critical for success.

Class 4 defects of the palatomaxillary complex are best restored through a combination of techniques that include the incorporation of either regional soft tissue flaps such as the temporoparietal fascial flap or the temporalis muscle flap in combination with either free bone or an alloplast to achieve support for the globe and projection of the midface region. If skin is removed, then options for facial skin replacement must be considered. This will be more fully discussed in the section on reconstruction of parotidectomy defects.

## Prosthodontic Management of the Palatomaxillary Defect

Maxillary obturators can be fabricated so as to restore speech and swallowing. With larger defects in the palate, however, the prognosis for functional recovery utilizing prosthetic rehabilitation is less. These patients have lower speech intelligibility and tend to avoid social events.[35]

Surgical separation of the oral cavity from the sinonasal cavities is potentially better than artificial closure with a prosthetic obturator. A soft tissue flap can provide absolute closure of the palatomaxillary defect but it may hinder the restoration of a functioning dentition due to the elimination of some of the important properties of the defect that assist the prosthodontist in achieving retention and stability with a palatal obturator. The loss of the midline palatal shelf and the obliteration of the scar band that forms at the interface between the skin graft and the mucosa are critical factors that are exploited by the prosthodontist. Alternatively, the placement of a fasciocutaneous free flap creates a smooth, spongy, and highly compliant surface that provides neither support nor retention and can potentially hinder the stability of the prosthesis in large maxillary defects.

With restoration of the dental arch and maintenance of a stable base as goals, it is apparent that the use of fasciocutaneous free flaps are not ideal for all but the more limited palatal defects. If optimal functional rehabilitation is to be achieved when soft tissue is employed for surgical reconstruction, an adequate remaining palate and dental arch is needed to derive support, stability, and retention for a removable denture.

If surgical reconstruction is anticipated, soft tissue free flaps should be reserved for defects in which the remaining palate and dentition are sufficient for prosthodontic rehabilitation (class 1b). The remaining dentition, arch length, and palatal surface determine whether a removable partial denture provides stability of the prosthesis over the defect through direct retainers and a palatal connector. The superior root form of the canine tooth as a terminal abutment closest to the defect and clasping of molar teeth will promote prosthetic stability as well. Implants in the native maxilla may be necessary to overcome a compromised dentition or edentulism leading to either a fixed or removable implant-assisted restoration (Fig. 8-6A–D).

Total and bilateral maxillectomy defects are more difficult to restore with prosthetic obturators and are more likely to have side effects that can compromise the QOL for the patient. Large maxillectomy defects involving the hemipalate, total maxilla, or bilateral maxillae are more challenging to restore function (class 2 and 3). As a defect increases in size and the remaining palate and dental arch decreases, a VBFF is preferred over a soft tissue free flap. Osseointegration and prosthodontic rehabilitation can restore the dentoalveolar structures and occlusion to optimize speech and swallowing functions. An implant supported fixed dental prosthesis is the authors' preference for restoring patient function in this complex reconstructive approach.

## Functional Outcomes

In the past, a major criticism of oromandibular reconstructions was directed at the time required to perform a primary oromandibular restoration and the limited success in achieving functional dental rehabilitation. The use of root form endosteal titanium fixtures and advances in the field of dental implantology over the last three decades have had a dramatic impact on the functional rehabilitation following oromandibular reconstruction in patients with oral cancer. As stated earlier, the use of dental implants to provide stable anchorage of a denture has been extremely effective. In addition, the predictability has increased dramatically whereas the length of time of performing these reconstructions in the primary setting has diminished with increased experience of busy head and neck surgical teams. Outcome studies that the authors and others have performed on patients following palatomaxillary and mandibular reconstruction were very encouraging in terms of functional outcomes and long-term success.[36] When the authors specifically looked at bite force and masticatory efficiency in a small subset of patients who had undergone a hemimandibulectomy/primary reconstruction with an iliac crest free flap and primary fixture placement, the results were comparable to those of a subset of noncancer

(c) 2014 Wolters Kluwer. All Rights Reserved.

patients from the prosthetic clinic who had their missing dentition restored by either implant-supported or implant-assisted prostheses. This is a remarkable finding because the noncancer patients were not subjected to the effects of a surgical procedure that disrupted the muscular attachments of the mandible and resulted in significant scarring of the perimandibular tissues. Furthermore, they also did not have the effects of neurosensory loss and radiation therapy associated with the mandibular resection and adjuvant radiotherapy. When the authors compared patients with smaller palatomaxillary defects (Class 1a and 1b) reconstructed with soft tissue–only flaps with a similar number of age- and defect-matched nonreconstructed patients who were using tissue-borne obturators, it was found that although there was no statistically significant difference in the chewing performance, there was a significant difference in the QOL of these patients as measured by patient comfort, social interaction, and convenience.[32] Speech was also vastly improved in the reconstructed patient. As the defects became larger to involve a significant portion of the midface skeleton, the advantage of immediate reconstruction with bone-containing free flaps became more obvious. Reconstructed patients demonstrated a trend toward improved masticatory function, speech, and comfort.[36] The composite bone flaps easily achieved the separation of the sinonasal cavities from the oral cavity. These flaps also provided a bony platform for the placement of titanium fixtures for the retention of the prosthesis as well as support of the globe and projection of the midface (malar projection). Nevertheless, these results must be viewed in the context of the significant complexity of oral function. Adequate restoration of the occlusal surfaces enables the patient to incise and grind a food bolus, which is only one parameter in this complex process. Additional factors include the amount and function of the remaining tongue, the SP, and the pharyngeal structures, the disruption of the neurosensory feedback that allows the determination of the location and size of the food particles within the oral cavity, and, last but not least, the effect of the surgery and radiation therapy on swallowing.

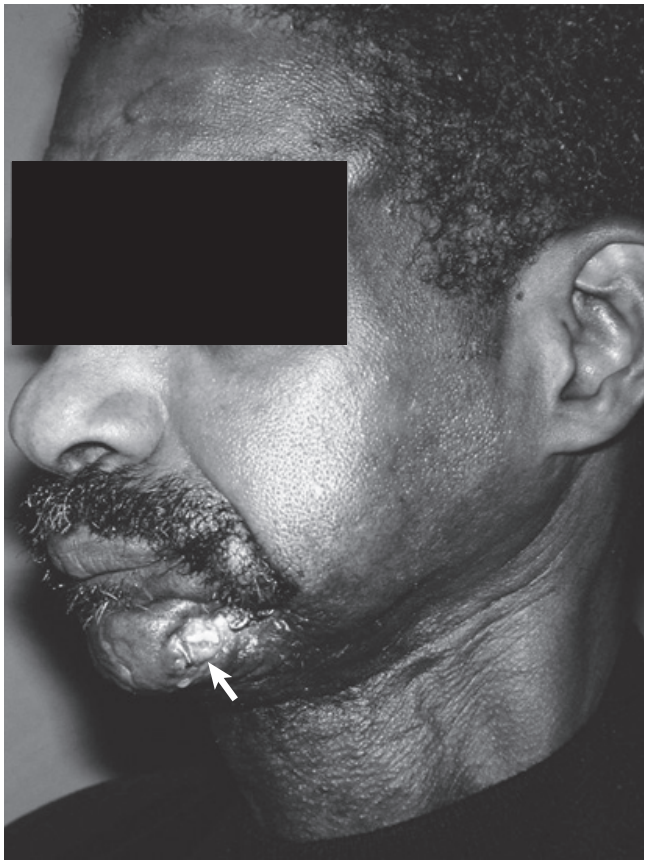

**FIGURE 8-7.** Facial view of patient with cutaneous fistula *(arrow)* due to stage III osteoradionecrosis of the mandible.

## OSTEORADIONECROSIS

Osteoradionecrosis (ORN) can be a devastating complication of radiation therapy. It affects mandibular bone more frequently than any other bone in the head and neck.[37] It can occur as a result of primary or adjuvant radiation therapy and has been reported to occur following either external beam radiation treatment or brachytherapy.[38] The standard of care for patients presenting with advanced osteoradionecrosis, pathologic fracture, fistula, and full-thickness involvement of bone (Figs. 8-7, 8-8A,B, 8-9, 8-10A) is a segmental mandibulectomy with a free osteocutaneous flap reconstruction. Preservation of the inferior alveolar nerve can be accomplished with this procedure (Fig. 8-10B). Reconstruction after surgical replacement of all nonvital bone can be accomplished with a variety of hard tissue free flaps, all of which were previously described (Fig. 8-10C–F). We have examined the impact of ORN surgery on functional outcomes.[39] In a group of 31 patients who underwent ORN surgery, 57% reported improved overall QOL, as reported on a 5-point scale. Performance on objective functional outcome domains of the Performance Status Scale[7] including Normalcy of Diet, Eating in Public, and Understandability of Speech significantly correlated with patient-rated swallowing, speech, and overall head and neck QOL (Table 8.1). For those patients reporting no improvement in QOL after ORN surgery, deficits in speech and swallowing were a result of prior and long-standing postradiotherapy changes and would not have been addressed with ORN surgery. Thus, despite removal of nonvital hard and soft tissue and restoration of mandibular continuity with vascularized bone, functional outcomes as well as QOL may remain impaired due to other chronic problems associated with high-dose radiotherapy to the head and neck.

## OROPHARYNX

The oropharynx is defined as the region of the upper aerodigestive tract (UADT), which is bounded by the nasopharynx superiorly, oral cavity anteriorly, and hypopharynx inferiorly. Conventionally, the oropharynx is subdivided into the posterior pharyngeal (PP) wall, the lateral pharyngeal (LP) walls, the SP, and the base of tongue. Each of these anatomic locations within the oropharynx represents a unique reconstructive challenge. The objective of oropharyngeal reconstruction is the restoration of deglutition, respiration, and speech production. This is accomplished by using contemporary reconstructive techniques to maintain the caliber of the chamber and the function of the velopharyngeal sphincter through the restoration of lining, bulk, and sensation.

To date, there is no universally accepted classification scheme of defects of the oropharynx. The classification system that the authors have developed, and the one that is used in this chapter, is based on the individual regions of the oropharynx and it attempts to categorize the extent of the ablative defect created as well as the functional impairment (Table 8.2). Most

oropharyngeal ablation defects involve multiple subsites within the oropharynx.

When faced with an oropharyngeal defect, the reconstructive surgeon is confronted with a major challenge of restoring function to this highly complex region. Choosing the appropriate method requires careful consideration of the subsites involved. Sensory reinnervation of the flaps is preferred whenever possible. Smaller defects (LP1, PP1, PT1, and SP1) can be closed primarily, left to granulate, or covered by a split-thickness skin graft. Larger defects usually require a reconstruction that involves a combination of local flap, regional, and free tissue transfers. Together, the base of tongue and the walls of the pharyngeal chamber together constitute the muscular tube through which air, food, and liquids must pass in a coordinated manner. During swallowing, the pharyngeal walls contract, the SP elevates, and the base of tongue acts as a plunger to move the food bolus into the esophageal inlet. Together these structures act to form a dynamic conduit. If a partial resection of the pharyngeal walls is performed, the remaining pharynx and tongue can compensate for the loss of a dynamic portion of the pharynx. When an ablation defect is small and isolated (LP1, PP1, PT1, and SP1), it is best to use local tissue that maintains the integrity and dynamic activity of this muscular tube. If the defect is large, however, iatrogenic pharyngeal stenosis can occur following primary closure. This results in a suboptimal swallowing outcome. Transferring soft tissue from a regional or distant site helps to prevent pharyngeal stenosis but results in an adynamic area within the oropharynx. When the defect involves multiple subsites within the oropharynx, a smaller pharyngeal chamber may actually enhance the functional outcome of the reconstruction by improving the contact between the base of tongue, the SP, and the pharyngeal walls. With this in mind, the reconstructive surgeon must be conscious of the size and the design of the new pharyngeal chamber; if the diameter is too large or too small, the swallowing outcome will be less than optimal.

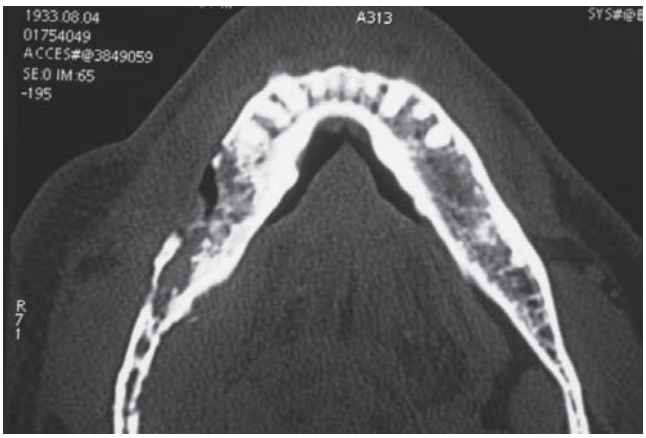

**FIGURE 8-9.** CT scan of mandible showing osteolysis due to osteoradionecrosis.

The base of tongue plays an extremely important role in deglutition because it is responsible for pharyngeal closure during the oral phase of swallowing and is the main driving force of the bolus through the pharyngeal phase. It is imperative that the reconstruction restores adequate bulk and lining apart from ensuring continued mobility of the remaining base of tongue. This will allow the newly reconstructed base of tongue to continue to act as a valve during the oral phase of swallowing and a plunger during the pharyngeal phase. Fasciocutaneous flaps, such as the radial forearm free flap, are excellent for use in base of tongue reconstruction.

The SP is a critical component of the velopharyngeal sphincter and is responsible for proper speech, articulation, and resonance. In the past, velopharyngeal incompetence after a palatal resection was often treated with the use of a palatal prosthesis. Recently, the need to utilize a palatal prosthesis after an SP resection has been reduced because of the advances in SP reconstruction.

Small SP defects can often be compensated for by the remaining pharynx and the base of tongue, providing for excellent functional outcomes by avoiding velopharyngeal incompetence. Small lateral SP defects can be closed primarily or by local advancement flaps. Larger lateral defects often require more complex reconstructions such as a superior constrictor advancement flap combined with a radial forearm flap.[2,40] This technique is effective for resections of up to one half of the SP (SP2). The goal of this reconstruction is to restore the velopharyngeal sphincter to a smaller caliber in an attempt to minimize nasal escape of air and nasal regurgitation of liquids and foods. As the size of the SP defect increases (SP3), a more elaborate reconstruction is necessary. The folded radial forearm free flap has been a workhorse

reconstruction for large SP defects (SP3). The flap is folded on itself to provide epithelium on both nasal and oral surfaces so as to limit the contracture expected by allowing mucosalization of the nasal surface.[41]

Commonly, velopharyngeal insufficiency is a major problem with this reconstruction. In an attempt to minimize this problem, an adhesion of the folded free flap to the PP wall is created, leaving only a small unilateral port. The remaining velopharyngeal sphincter should be closed to an opening of no more than 10 $mm^2$.[42] This has become the technique of choice for SP3 defects.

## Functional Outcomes

The goal of treatment of oropharyngeal lesions is to achieve the best possible disease control while minimizing morbidity. The oropharynx is a part of the UADT where a less-than-optimal reconstruction can dramatically affect a patient's ability to speak and swallow. Seikaly et al. examined 27 consecutive patients who underwent oropharyngeal tumor ablation and reconstruction with radial forearm free flaps.[42] The defects produced by the tumor ablation involved multiple subsites within the oropharynx, including the pharyngeal walls, the SP, and the base of tongue.

**TABLE 8.1 Correlation of Functional Outcomes Utilizing the Performance Status Scale and % Oral Nutrition with Patient-rated Quality-of-life Questionnaires, Including Eating Assessment Tool (EAT-10) and Speech Handicap Index (SHI)**

| | Performance Status Scale | | | |
|---|---|---|---|---|
| **Patient-perceived QOL** | **Normalcy of Diet** | **Eating in Public** | **Understandability of Speech** | **% Oral Nutrition** |
| EAT-10 | –0.79 | –0.72 | –0.65 | –0.76 |
| Speech Handicap Index (SHI) | –0.75 | –0.65 | –0.89 | –0.62 |

The results of this study suggested that the radial forearm free flap is an excellent choice for reconstruction of this particular area.[3] These patients achieved excellent speech and swallowing function. Sinha et al.[43] examined the use of the folded radial forearm free flap in 16 patients for reconstruction of SP and pharyngeal defects. This study examined speech intelligibility, resumption of diet, ability to be decannulated, and postoperative complications. Similar to the results of Seikaly et al.,[42] these authors concluded that the radial forearm free flap provided excellent functional outcomes for SP and pharyngeal reconstruction. Reiger et al.[44] published their functional outcomes for surgical reconstruction of tumors located at the base of tongue in 36 patients. In this series, a resection of 50% or greater of the base of tongue was performed and all defects were reconstructed using a radial forearm free flap followed by postoperative radiation therapy. The results of this report proved that highly functional speech and swallowing is possible after surgical resection and reconstruction of a large portion of the base of tongue.

## HYPOPHARYNX

The restoration of function and avoidance of complications following a hypopharyngectomy is often a significant challenge for the reconstructive surgeon. Classically, a hypopharyngectomy implies resection of a portion or the entirety of the pharynx, with or without resection of the larynx and the cervical esophagus. Reconstruction of the hypopharynx has historically been performed with local flaps as a multistaged procedure, which often led to prolonged hospitalizations and high rates of complications, such as flap loss, fistulae, and strictures. With the advent of microvascular surgery, the reconstruction of the hypopharynx and the pharyngoesophageal segment have evolved into single-stage procedures with vastly improved functional outcomes.

The hypopharynx is a tubed structure that acts as a conduit for the transport of food, liquids, and air, and although it may seem functionally quite simple, it is a dynamic organ endowed with intricate sensory feedback mechanisms that allows food and fluids to be transported posteriorly into the esophageal inlet while air passes anteriorly into the larynx. Tumor ablation can disrupt the function of this structure resulting in temporary or permanent chronic aspiration and dysphagia. The primary goal of the surgeon is to restore the swallowing mechanism in such a way that it provides the ability to maintain nutrition by mouth and to safely manage secretions. The probability of achieving this goal can be vastly different depending on whether the hypopharyngectomy includes a total laryngectomy or not. In the setting of a total laryngectomy, the reconstructive surgeon is charged with restoring the tubed conduit in sufficient caliber to allow for adequate swallowing and tracheoesophageal speech, which is less complex than performing a hypopharyngeal reconstruction in the setting of an intact larynx. In the latter scenario, the challenge is to perform a reconstruction of the pharyngoesophagus with sufficient caliber so that the patient can properly coordinate swallowing to prevent aspiration.

Surgical defects of the hypopharynx can range from small areas that can be closed primarily to very large and complex defects that require free tissue transfers with significant surface area. Each defect requires a different reconstructive approach to adequately restore form and function. In an effort to simplify surgical planning and decision making, the authors have created a defect classification system that is a modification of the one developed by Disa et al.[45] (Table 8.3).

The reconstructive requirement for each type of hypopharyngeal defect is distinct. Noncircumferential defects (type I) are those in which a portion of the native mucosa is retained. In these situations, the reconstruction requires patching the defect while limiting disruption of the native tissues to preserve as much function as possible. Reconstruction of circumferential defects (type II) requires that the entire circumference of the pharynx be restored to allow for unimpeded passage of food and liquid into the esophagus, although this leaves the patient with an adynamic segment. The patient relies mainly on the base of tongue to propel the food bolus into the reconstructed segment. Once in the neopharynx, gravity helps to propel the bolus into the esophagus.

Contemporary reconstruction of circumferential and noncircumferential defects can be accomplished by using either fasciocutaneous or enteric free flaps. The most commonly used fasciocutaneous donor sites are the radial forearm and the ALT. The most common enteric flaps are jejunum and the gastro-omental free flaps. Additionally, one must consider the pectoralis major pedicled flap in the reconstructive algorithm. This regional flap provides a reliable skin paddle for reconstruction of a pharyngeal defect, which requires a patch, but it is usually too thick to consider tubing into a circumferential skin-lined tube for restoration of type II defects.

Although there is a significant debate over which donor site provides the optimal reconstruction for a particular hypopharyngeal defect, each patient represents a unique reconstructive challenge. Type I defects retain a native pharyngeal strip allowing for a noncircumferential closure. These defects require a reconstruction that reconstitutes the tubular structure of the pharynx with a sufficient luminal diameter to prevent pharyngeal stenosis. This defect is most commonly approached with a patch-like reconstruction utilizing either a radial forearm free flap or a pectoralis major pedicled flap. Type II defects involve circumferential defects of the pharynx; therefore, a complete reconstruction of the pharynx must be performed. In this setting, a tubed radial forearm or ALT free flap can be utilized. Additionally, enteric flaps such as the jejeunal free flap or the gastro-omental free flap can be utilized thereby achieving a restoration with a mucosal-lined

**TABLE 8.2 Oropharynx Ablative Defect Classification System**

| Classification | Definition |
|---|---|
| **Soft palate (SP)** | |
| SP0 | No SP defect |
| SP1 | Minimal defect (<¼) treated by primary closure or healing by secondary intention and unlikely to result in velopharyngeal incompetence (comparable to uvulopalatopharyngoplasty) |
| SP2 | <½ the SP (not including the uvula) |
| SP3 | >½ the SP (including the uvula) |
| **Lateral pharyngeal (LP) wall** | |
| LP0 | No or minimal lateral wall defect |
| LP1 | Involving one LP wall |
| LP2 | Involving both LP walls |
| **Posterior pharyngeal (PP) wall** | |
| PP0 | No or minimal posterior wall defect |
| PP1 | <½ of the PP wall. Implies adequate remaining posterior wall soft tissue to elevate and attach to remaining SP (SP1 or SP2 defect) for closure of the nasopharyngeal side of the defect |
| PP2 | >½ of the PP wall. Inadequate tissue for reapproximation to existing soft tissue |
| **Posterior tongue (PT)** | |
| PT0 | No PT defect |
| PT1 | Minimal defects involving <¼ of the base of tongue, which can either be closed primarily (these defects do not require significant additional bulk for adequate closure) |
| PT2 | Defects involving >¼ of the base of tongue, but less than a total posterior glossectomy (these defects usually require additional tissue to reconstruct lining and bulk) |
| PT3 | Total posterior glossectomy |
| **Hypoglossal (HG)** | |
| HG0 | Both HGs are present and intact |
| HG1 | One HG is not functioning |
| HG2 | Both HGs are not functional |
| **Lingual nerve (LN)** | |
| LN0 | Both LNs are intact |
| LN1 | One LN not functional |

segment of tissue. Type III defects are extensive, noncircumferential longitudinal deficiencies involving multiple anatomic levels above the clavicles. These defects are often best approached with a large soft tissue flap such as the ALT, the radial forearm, or a rectus abdominus flap. A rectus free flap can be harvested with a large skin paddle to restore the pharyngeal lining in conjunction with the rectus abdominus muscle, which can provide the soft tissue coverage for an irradiated neck. Type IV defects extend into the thoracic esophagus and are best approached with a total esophagectomy and a gastric pull-up procedure.

## Functional Outcomes

In recent years, the ALT has been frequently utilized for pharyngoesophageal reconstruction. Lewin et al.[46] published the results of their functional outcomes analysis, comparing circumferential pharyngoesophageal reconstruction using the jejunum with the ALT free flap. They reported that the ALT has similar complication rates but shorter intensive care unit (ICU) and hospital stays as well as better speech and swallowing.[46] Yu, Robb, and colleagues also published their results which showed that the ALT flap offers comparable complication rates, but superior speech and swallowing functions, minimal donor site morbidity, a more rapid recovery, and a shorter hospital stay.[47,48]

The radial forearm fasciocutaneous flap has been highly utilized in both partial and circumferential pharyngoesophagectomy defects and has been found to be extremely useful and reliable with respect to speech and swallowing functions. Varvares et al. found that of the 20 consecutive patients reconstructed with the radial forearm, 85% were able to achieve oral alimentation.[49]

**TABLE 8.3 Hypopharynx Defect Classification System**

| Classification | Definition |
|---|---|
| Type 0 | Small defects amenable to primary closure |
| Type I | Defects that retain a pharyngeal strip so that a noncircumferential closure can be achieved |
| Type II | Defects that require a circumferential closure |
| Type III | Defects that are extensive, noncircumferential longitudinal deficiencies involving multiple anatomic levels above the clavicles |
| Type IV | Defects that extend below the clavicles, into the mediastinum |

## SALVAGE SURGERY

### Salvage Total Laryngectomy

Early-stage (T1, T2) squamous cell carcinoma of the larynx is treated equally effectively with external beam radiation therapy or surgery (transoral or open). Voice quality is generally perceived to be better following radiation therapy.[50,51] For this reason, surgery is often held in reserve for use as a salvage treatment. After primary radiation therapy, the failure rates for T1 disease range between 5% and 10% and slightly higher for T2. It is therefore evident that a certain number of patients with even early-stage laryngeal cancer will ultimately require some form of salvage surgery for persistent or recurrent disease.

Prior external beam radiation therapy has been identified in several studies as a significant risk factor for the development of pharyngocutaneous fistula formation following a laryngectomy.[52–54] Salvage laryngectomy in the setting of prior chemoradiation therapy has been associated with high rates of wound complications ranging from 59% to 77%.[55,56] Additionally, the more damaging effects of chemotherapy and radiation therapy on the wound-healing properties of tissue have been well established.[57,58] For these reasons, many reconstructive surgeons have developed techniques designed to minimize postoperative complications in the salvage setting—techniques that bring healthy, well-vascularized, nonirradiated tissue to the area.

Free and pedicled flaps have been utilized to repair laryngectomy defects when insufficient tissue is available for a primary closure of the pharynx. Withrow et al.[59] recently reported their use of free tissue transfer for reconstruction of a laryngectomy defect in the salvage setting. They compared the rate of pharyngocutaneous fistula, stricture formation, length of hospitalization, and feeding tube dependence between the standard total laryngectomy group and the free-flap reconstruction group. The free-flap group had a lower rate of fistula (18%) compared to the primary closure group (50%). They also had a lower rate of stricture formation (19% vs. 25%) and feeding tube dependence (23% vs. 45%). The authors concluded that planned reconstruction of posttreatment defects with vascularized tissue is the optimal means of reconstruction and is associated with a lower complication rate and may improve long-term outcomes.

Fung et al.[60] published a study in which free flaps were either used to reinforce the pharyngeal suture line in the salvage laryngectomy setting or the free flap was integrated into the neopharynx. The authors described the inset of the free flap with tacking sutures placed in the prevertebral fascia on both sides of the primarily closed pharynx. The patients who underwent free-flap reinforcement were then compared with those in RTOG-91-11, and it was found that the overall rate of pharyngocutaneous fistulas did not differ (29% vs. 30%),[60] but the patients who had undergone the free-flap procedure were treatable with local wound care in the outpatient setting as opposed to requiring major surgical intervention. This led Fung et al. to summarize that the free flap had converted major wound complications to minor wound complications.[60]

The trend seems to be clear that the use of soft tissue flaps as a source of healthy, well-vascularized tissue either in the pedicled or regional form has a beneficial effect in the salvage laryngectomy setting. The issue of which donor site is ideal is highly dependent on the performance and nutritional status, age and body habits of the patients, and the size requirement of the skin paddle. The most commonly used regional flap is the pectoralis major flap. The commonly used free flaps are the radial forearm, the ALT, and the latissimus flaps. Less commonly, enteric flaps such as jejunum or the gastro-omental free flap can be utilized but these surgical options subject the patient to significantly more morbidity associated with a laparotomy.

## MANAGEMENT OF PHARYNGOESOPHAGEAL STENOSIS

Pharyngoesophageal stenosis is a devastating complication following the use of chemoradiation for primary treatment of UADT malignancies. Unfortunately, despite an intact larynx, pharyngoesophageal stenosis can result from this treatment leaving a patient unable to take oral nutrition, as well as unable to tolerate his or her own secretions, and tracheostomy dependent. The tendency for the formation of UADT stenosis may often lead to futile attempts to address this problem through dilation, laser laryngopharyngoscopy, and open surgical procedures due to the damage done to the mucosal lining and the observation that further manipulation may lead to further stenoses that are often worse with each intervention.

The presumed etiology for the development of pharyngoesophageal stenosis following radiotherapy is likely to be multifactorial. Contributing factors may include a combination of long-term nasogastric tube placement and/or chronic gastroesophageal reflux.[61] Perhaps a larger problem is that severe radiation mucositis results in stenosis during healing, which may be exacerbated by using alternative routes for enteral nutrition, placing the cervical esophagus at rest, and thereby allowing denuded surfaces to collapse against each other. In addition, as hypopharyngeal or cervical esophageal tumors respond to treatment, significant portions of the mucosa are eliminated and must then heal by secondary intention.[62] Chemotherapy sensitizes tissues to the effects of radiation, resulting in a greater incidence of both acute toxicity and late complications.[63]

Once identified, pharyngoesophageal stenosis can be managed in a variety of ways as alluded to earlier, but one must consider a number of factors when determining the optimal course of treatment. The authors have developed a new defect classification scheme for defining the key variables leading to posttreatment pharyngoesophageal stenosis.[64]

In this new defect classification system, the degree of pharyngoesophageal narrowing is defined according to the location and completeness of the obstruction, as well as whether the larynx was partially or fully intact, the length of the stenotic segment, and whether prior attempts at dilation led to perforation.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Surgery usually includes interposition of a skin-lined or mucosal-lined flap to widen the site of stenosis. If the stenotic segment is complete and long, a circumferential resection may be required and a segment of neopharynx must be created. The commonly employed soft tissue flaps are the free jejunal and gastro-omental transfer, radial forearm free flap, and ALT flap. If the region of stenosis extends into the thoracic esophagus, a gastric pull-up is the procedure of choice. Additionally, if the patient has an intact larynx, one must consider whether the stenotic or obstructed segment can be successfully increased in caliber with a flap reconstruction while preserving laryngeal function. If this is not technically feasible, one must give strong consideration to performing a total laryngectomy at the time of the pharyngoesophageal reconstruction. The recommendation to perform a larynx-sparing augmentation of the pharyngeal in patients in whom the intent was to preserve the larynx must be given extensive counseling so that they are well informed as to the possibility that reestablishment of an adequate conduit may not translate into a resumption of safe swallowing. As a result of radiation damage, there are multiple sites of injury that impact normal deglutition, which may be impossible to overcome. Unfortunately, it is not possible to assess the likelihood of recovery of function in patients before opening up the narrowed or obstructed segment. Patients must be advised that there may be a need for a functional laryngectomy if the altered protection of the airway is insufficient despite an open pharyngoesophageal segment. These authors have found improved functioning of voice, secretion management, and diet intake following PE reconstruction surgery in those patients with an intact larynx, those with laryngectomy, and those converted to total laryngectomy due to the severity of stenosis.[64] However, a small subset of patients did not improve in swallow functioning, despite a patent reconstructed segment, due to prior pharyngeal phase dysphagia resulting from radiotherapy.[64]

## CONCLUSION

As the range of reconstructive options has increased, so too has the level of sophistication in addressing defects in the various subsites of the head and neck. The degree of detail that is reflected in the classification schemes outlined in this chapter is a direct reflection of that phenomenon. The extent to which the next generation of surgeons will restore patients afflicted with these diseases and these reconstructive problems will undoubtedly continue to evolve with an even greater attention to detail.

Although there are few studies that prove the direct correlation between advances in reconstruction and survival, there is little doubt that the ability to offer ablative surgery to such patients as shown in Figure 8-7, would not have been considered two to three decades ago. The safety of such a procedure is a product of the level of sophistication in imaging, surgical approach, and the ability to provide safe and reliable reconstruction in a previously irradiated setting. Hanasono et al.[65] found equivalent survival rates and improved local control rates in patients with oral cavity cancers treated prior to the introduction of free tissue transfer surgery versus those treated with microvascular free tissue surgery, despite higher T stage in the microvascular surgery group. In addition, fistula rates and tracheostomy dependence rates were lower in the microvascular surgery group.[65]

QOL and functional outcome studies are greatly needed to allow those involved in the treatment of patients with head and neck cancer to fully understand the impact of their treatment and thereby choose the appropriate therapeutic option. Pooling of patients from multiple institutions will likely be required to accrue sufficient numbers in order to generate meaningful data.

James C. Lemon, and Mark S. Chambers

# Dental Oncology and Maxillofacial Prosthetics

In caring for head and neck cancer patients, most treatment centers use a team approach. By doing this, each involved discipline (e.g., surgery, radiotherapy, dental oncology, chemotherapy, and speech pathology) determines its role for an enhanced treatment outcome. Rehabilitation of function, aesthetics, and prevention of infection should be a major concern before treatment and following the elimination of disease in the patient with head and neck cancer. Patients with head and neck cancer should be referred to an oncologic dentist or maxillofacial prosthodontist during their initial medical workup for evaluation of their oral and dental health. The results of this evaluation can then be integrated into the primary treatment plan. Early dental intervention can optimize outcome and decrease morbidities such as radiation-induced osteoradionecrosis and chemotherapy-induced systemic infection. Early intervention and planning can also allow surgically removed anatomic structures, such as the maxilla, to be immediately replaced with a prosthesis during the primary ablative procedure.[1,2]

## ORAL AND DENTAL ANATOMY

Surgeons, radiation oncologists, and medical oncologists, who treat patients with head and neck cancer, should be familiar with oral and dental anatomy so that they can accurately communicate with their dental colleagues. Adult teeth are routinely used as landmarks to document the location of tumors of the jaws and to plan intraoral resections and prosthetic procedures before and after surgery. A commonly used scheme for this purpose is the universal numbering system, which is used in the United States to identify the position and type of adult teeth. In this system, adult teeth are numbered sequentially from 1 to 32 (in both the maxilla and the mandible), starting with the right maxillary third molar and proceeding around the arch to the left third molar, down to the left mandibular third molar, and then around the mandibular arch to the right third molar. Missing or impacted teeth are counted in this system.[3] The FDI World Dental Federation Notation (International) is used elsewhere in the world. This system divides the mouth into four quadrants: (a) maxillary right quadrant; (b) maxillary left quadrant; (c) mandibular left quadrant; and (d) mandibular right quadrant. The teeth in each quadrant are then numbered from 1 (central incisor) to 8 (third molar).

The retained, nondiseased anatomic structures of the maxilla and mandible are important for retention and support of prostheses used in rehabilitation of patients with head and neck cancer. In the maxilla, the tissues important for the support and retention of prostheses are the maxillary tuberosity, alveolar ridge, and hard palate. In the mandible, the major supporting structures are the alveolar ridge, retromolar pad, and buccal shelf. Sound and periodontally healthy teeth in both arches are very important in retention and support of prostheses. Conservation of the supporting tissue, without compromising oncologic principles used in the eradication of disease, should be a goal of the surgeon and medical oncologist.[4,5]

## ORAL AND DENTAL EVALUATION

Throughout treatment and follow-up care, the surgeon, radiation oncologist, and medical oncologist should be able to recognize oral pathology secondary to poor dental status, for example, advanced periodontal disease, gross dental caries, tissue irritation secondary to poorly fitting prostheses, and poor oral hygiene. Plaque and calculus formation on teeth is an indication of poor oral hygiene. Preliminary findings of the initial medical examination should be noted. Patients require a pretreatment evaluation by an oncologic dentist, who should do a thorough radiographic and oral/dental examination and make impressions of dental and facial structures as appropriate. Panoramic, periapical, bitewing, and occlusal radiographs can be diagnostic and are inexpensive and easily obtained in the dental office (Fig. 9-1).[6] Stone casts obtained from impressions of the maxilla, mandible, and facial structures can be useful in treatment planning, surgical prosthesis fabrication, and posttreatment rehabilitation. Compromised teeth with a poor prognosis should be extracted before irradiation or chemotherapy (Fig. 9-2). This may require general anesthesia or intravenous sedation with local anesthesia depending on the difficulty of dental surgery and the patient's mental and physical status. Performing dental surgical procedures at the time of the primary ablative procedure will reduce any delay before starting adjunctive treatments such as radiotherapy or chemotherapy. However, appropriate healing time is recommended prior to beginning chemotherapy or radiotherapy. Eliminating sites of infection decreases the chances of osteoradionecrosis in patients who undergo radiotherapy and infectious episodes in patients who receive chemotherapy.[7]

For the first year after cancer therapy, patient follow-up by the oncologic dentist is vital. Patients treated with radiotherapy to the head and neck may experience dry mouth (xerostomia) and a subsequent increase in oral or dental problems such as infection, periodontal disease, and dental caries. All members of the treatment team should understand the importance of fluoride

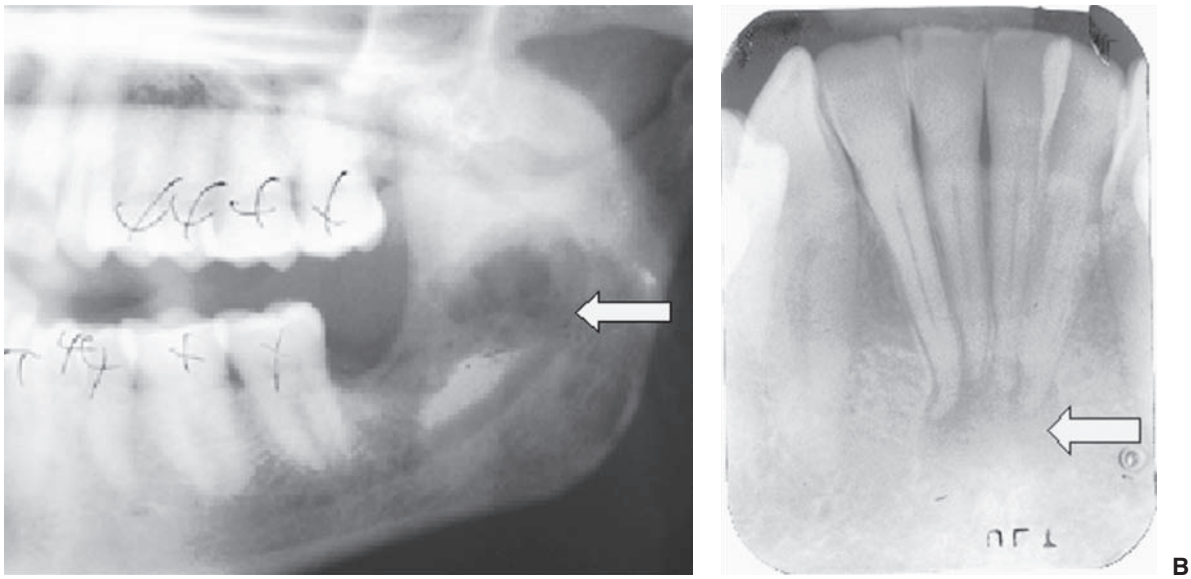

**FIGURE 9-1.** Radiographs obtained in the dental office are relatively inexpensive, easily obtained, and can be diagnostic. The panoramic radiograph **(A)** shows a cancer in the ramus of the mandible. A periapical radiograph **(B)** shows an abscess associated with the anterior mandibular teeth in a patient with lymphoma.

and at each follow-up appointment should encourage the patient to use daily fluoride therapy.[8–10] In many instances, patients can be referred back to their general dentist for routine dental care after the initial posttreatment period.

In summary, a thorough primary, oral, and dental evaluation by an oncologic dentist documents the oral and dental pathology and allows for appropriate intervention before cancer treatment is started. The results of the oral/dental evaluation enable the treatment team to inform the patient about rehabilitation, reduce or eliminate the sites of potential infection, and reveal important information that will be useful during treatment and rehabilitation. To ensure an appropriate level of continued oral care, a dentist should be included as a member of the treatment team.[11]

**FIGURE 9-2.** Patient with poor oral hygiene and periodontal disease will need multiple dental extractions before chemotherapy or radiation therapy. This can be done at the primary ablative procedure or at a separate procedure under local, intravenous, or general anesthesia.

## INTRAORAL PROSTHETIC REHABILITATION

Three phases of prosthetic rehabilitation exist in most cases: surgical, interim, and definitive. Each phase may span several months to 1 year or more, depending on the size and location of the tumor and on the type of treatment required. Initially, surgical and interim prostheses may require frequent follow-up appointments and adjustments. Patients who undergo surgery that involves the maxilla and sinus may experience nasal regurgitation of food and liquids from the mouth into the nose. During and following treatment, meticulous oral and dental hygiene is important as a life-long therapy. Physical therapy may also be necessary to maintain oral opening and prevent trismus.

### Maxilla

Malignant and benign tumors involving the maxillary sinus, hard palate, and upper alveolus often require surgical resection with an infrastructure maxillectomy procedure. The resultant surgical defect is an oral–nasal and/or oral–antral communication, which may cause substantial postoperative speech and swallowing problems. These defects often require prosthetic obturation. Surgical considerations that may improve prosthetic rehabilitation of patients who receive a maxillectomy are described in detail in the following text. In a dentate patient, the head and neck surgeon should make the alveolar osteotomy through the socket of an extracted tooth to preserve bone support around the terminal tooth. In cases in which cuts are made between teeth, both teeth may be lost. The palatal osteotomy should conserve as much of the supporting tissue as possible, for example, premaxilla, tuberosity, and alveolar ridge, consistent with oncologic principles. If possible, a split-thickness skin graft (STSG) should be placed in the maxillary defect. A well-placed STSG reduces postoperative secretions, facilitates oral hygiene, provides a sound tissue base for a prosthesis, and creates a scar band for greater retention of the prosthesis. The palatal mucosa, if it is not affected by disease, can be retained and used to line the midline portion of the palatal cut. This tissue is extremely resistant to the abrasive forces of the prosthesis.

(c) 2014 Wolters Kluwer. All Rights Reserved.

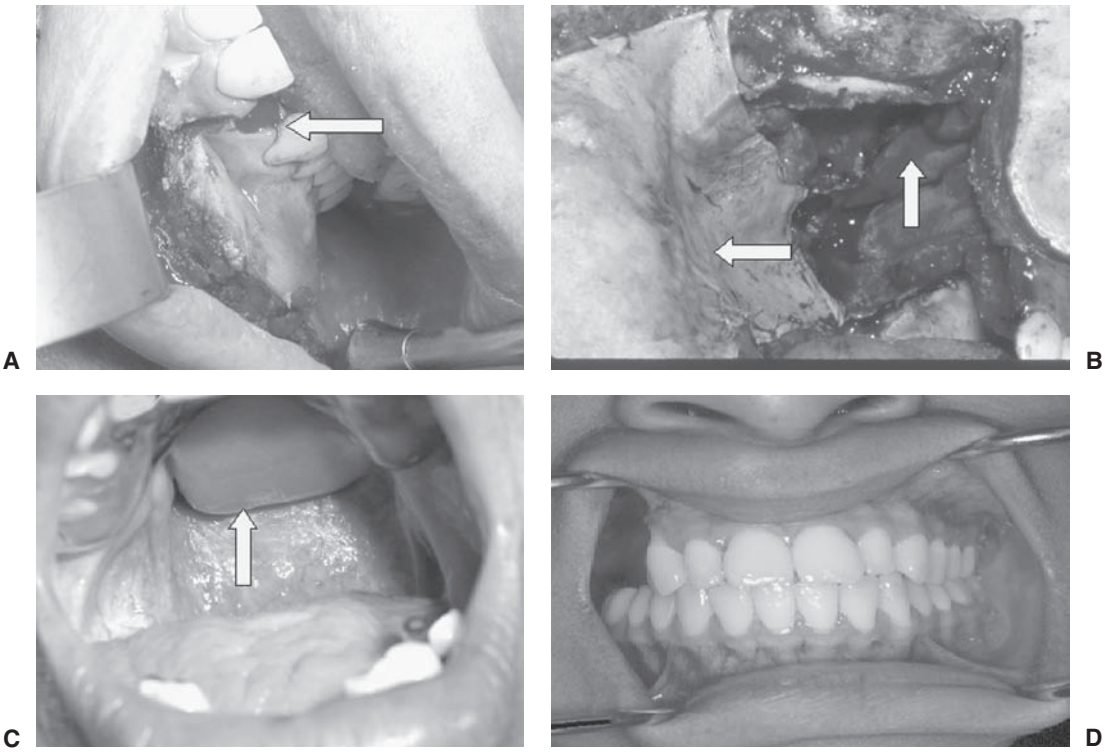

**FIGURE 9-3.** Important surgical considerations in maxillectomy. **A:** Make alveolar cuts through extraction socket in dentate patients. **B:** Remove inferior and middle turbinates and place split-thickness skin graft. **C:** Remove total soft palate to improve prosthesis function. **D:** Perform intraoral resection and spare premaxilla when possible.

The inferior and middle turbinates should be removed to allow extension of the prosthesis into the defect area and will ensure a good prosthetic seal. Mandibular molar teeth on the side of the maxillectomy should be considered for extraction if the opposing maxilla and teeth are resected. These teeth can pose a hygiene problem and are essentially nonfunctional after a posterior maxillectomy. This problem is particularly significant when the resection extends inferiorly in the buccal mucosa. When possible, the maxillectomy should be performed intraorally, thereby eliminating the facial incision and resulting disfigurement (Fig. 9-3).[12]

A surgical obturator prosthesis placed at the time of the ablative procedure reestablishes the palatal contour, restoring speech and swallowing function. This prosthesis also supports the surgical packing and skin graft in position. The surgical obturator can be ligated to the remaining teeth with a 24-G ligature wire or retained with a bone screw in the edentulous patient. The surgical obturator prosthesis may allow the patient to speak and swallow almost immediately after surgery and, in turn, may obviate the need for a nasogastric tube (Fig. 9-4). The prosthesis maintains proper lip and cheek support during initial healing and therefore increases resistance to the contracture and subsequent facial deformity or scar tissue. Patients scheduled for maxillectomy should be referred to an oncologic dentist (presurgical) during their initial oncologic evaluation to ensure adequate time for fabrication of this prosthesis.[13]

An interim obturator prosthesis is placed immediately after the surgical obturator and packing are removed, usually 5 to 8 days postsurgery. The interim obturator prosthesis has an extension that obturates the oral nasal/antral defect. This extension is created with a soft, moldable denture tissue conditioning

**FIGURE 9-4.** Surgical obturator prosthesis retained by interdental wiring negates the use of a nasogastric tube and fixates the split-thickness skin graft reconstruction during initial healing. It also provides postoperative aesthetics and supports the cheek and lips, which resist facial contracture. This prosthesis is removed along with the packing in 5 to 7 days.

(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 9-5.** Interim obturator prosthesis is placed after removal of the surgical obturator prosthesis. This prosthesis must be followed closely and modified to accommodate healing. It is usually worn for 3 to 6 months until the surgical defect stabilizes.

material, and is modified as necessary to accommodate healing during the initial healing phase (Fig. 9-5). A minimum of five to ten appointments may be needed to adjust and modify the prosthesis during this distinct phase of rehabilitation.[14]

A definitive obturator prosthesis is made after the surgical defect has stabilized, approximately 6 months after the surgery. This prosthesis allows for enhanced aesthetics and function. The average lifespan of the definitive obturator prosthesis is 3 to 5 years, and close follow-up with adjustments is important to ensure continued accurate fit and comfort (Fig. 9-6).[15]

**FIGURE 9-6.** Definitive obturator prosthesis in place. This prosthesis maximizes function and aesthetics.

Microvascular free-flap surgical reconstruction of the maxilla in patients treated with a maxillectomy is becoming increasingly common. In some cases the use of free flaps may be an excellent alternative to the prosthetic obturator prosthesis, whereas in others this option may not offer acceptable aesthetic or functional results. Older adults, mentally challenged individuals, and those who have lost the dexterity to place and remove a prosthesis should be considered for free-flap reconstruction. Prosthetic rehabilitation after free-flap reconstruction may be difficult due to bulkiness and mobility of the flap. Patients who demand a functional and aesthetic restoration after reconstruction with a free flap should be referred to a maxillofacial prosthodontist before the procedure so that information concerning rehabilitation can be considered before the procedure.[16]

## Soft Palate

When the soft palate is involved in the surgical procedure, the surgeon must consider whether the remaining soft palate will be useful in prosthetic rehabilitation. In most cases, any remaining soft palate that is nonfunctional should be completely removed. Removal of the soft palate allows easy access to the pharynx for fabrication of the pharyngeal obturator prosthesis. Occasionally, a thin strip of soft palate can be vitally important for prosthesis retention in patients with limited supporting tissue (teeth, hard palate), such as when a bilateral total maxillectomy has been completed (Fig. 9-7).[17] In cases where the resection of the soft palate is anticipated, an intraoperative dental consultation may be indicated. Primary radiation treatment of the soft palate may cause muscle fibrosis leading to incompetency of the soft palate. In this situation, prosthetic rehabilitation may be impossible because of poor access to the oropharynx. In some cases, surgical removal of the soft palate may be required before prosthetic rehabilitation. Prosthetic rehabilitation may not restore the pretreatment speech and swallowing function because of radiation-induced fibrosis and limited movement of the muscles of the pharyngeal walls. These muscles are important in compensating for the missing soft palate by contacting the pharyngeal obturator during speech and swallowing.[18]

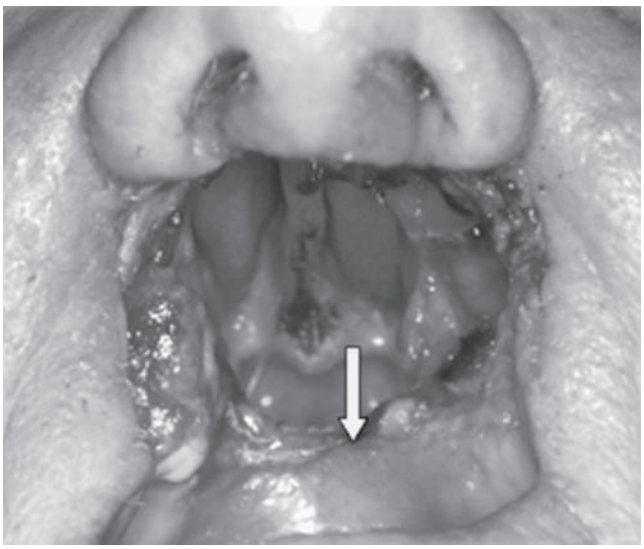

**FIGURE 9-7.** Midface resection with total bilateral maxillectomy. Soft palate (*arrow*) is retained for retention and support of obturator prosthesis.

(c) 2014 Wolters Kluwer. All Rights Reserved.

## Mandible

Patients requiring a mandibulectomy may need surgical stents to assist the surgeon in realignment of the residual mandible before reconstruction. These stents are custom-made and require preoperative fabrication. Reconstruction plates are medical devices used during the resection and reconstruction of mandibles. The reconstruction plate holds the remnants of the mandible/condyle in its preresected position and attaches to the bony segments of the microvascular flap. This optimizes appropriate mandibular contours and function. These plates must be precisely bent onto the preresected mandible, attached with reconstruction screws, and then removed prior to the resection. Reattachment in the same position later with the microvascular flap ensures accuracy. Intermaxillary fixation with arch bars may also aid in realignment and stabilizing the mandible during reconstruction.[19] The maxillary teeth opposite the mandibular reconstruction may need to be extracted to prevent trauma to bone and soft tissue flaps. In cases in which reconstruction is not being considered for a patient who has received a mandibulectomy, removal of the remnant condyle and ramus on the affected side prevents migration of these structures medially toward the maxilla. Such migration can make prosthetic rehabilitation more difficult and add more frustration to the patient.[20]

In general, soft tissue coverage of the mandible when free flaps are used does not provide adequate supporting tissue for prosthetic rehabilitation (Fig. 9-8). Vestibuloplasty is a surgical procedure designed to restore alveolar ridge support by reducing the attachment of muscles to the buccal, labial, and lingual aspects of the jaw and thinning the existing tissue, such as flaps used in the initial reconstruction. STSGs are important because they provide a sound tissue base for a prosthesis and can also be used to separate the floor of the mouth from the buccal mucosa (Fig. 9-9).[21] When the tongue is sutured to the buccal or labial mucosa, prosthetic rehabilitation is limited if not impossible. As with the maxilla, conservation of the supporting tissue in the mandible, consistent with removal of disease, is important. Dental implants can be placed in the nonirradiated native or reconstructed mandible and may be critical to the stability and retention of the mandible prosthesis. Maxillary and mandibular resection dentures can be fabricated for patients who do not receive reconstructive surgery after mandibulectomy.

## Tongue

Speech and swallowing dysfunction are common problems in patients following glossectomy. Tumors of the oral cavity often involve contiguous structures and resections within the floor of the mouth and are likely to involve the tongue and muscle attachments, or innervation. The ultimate treatment goal is maximum restoration of speech and swallowing, which may require the combination of soft tissue and prosthetic reconstruction.

Palatal augmentation prostheses are removable palatal prostheses that reshape the hard palate to improve contact between the residual tongue and the palate during speech and swallowing (Fig. 9-10). These prostheses improve speech and swallowing function due to impaired tongue mobility as a result of surgery, trauma, or neurologic/motor deficits. Resection sites that are most likely to affect oral components of speech and swallowing are the oral tongue, anterior or posterior mandible, floor of the mouth, and base of the tongue.[22]

The greatest improvement in function with palatal augmentation prostheses results when movement of the residual tongue tissue is retained. Replacing lost tissue bulk with soft tissue may obliterate some of the space that cannot be controlled by the limited range of motion of the tongue. Patients with the greatest movement of the residual tongue benefit the most from the augmentation

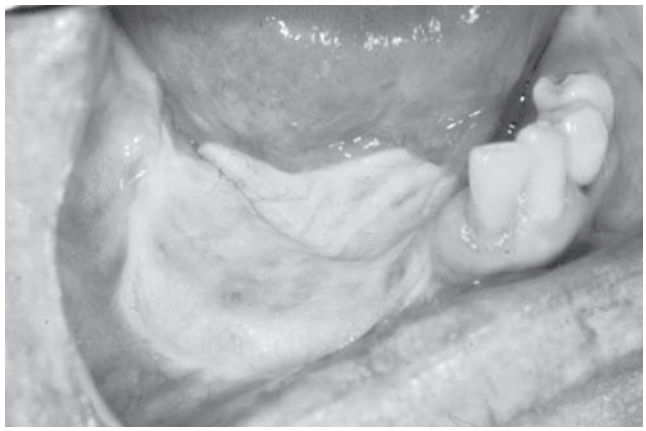

**FIGURE 9-9.** Fibula reconstruction of mandible with split-thickness skin graft vestibuloplasty and dental implant placement. Patient is now ready for prosthetic rehabilitation.

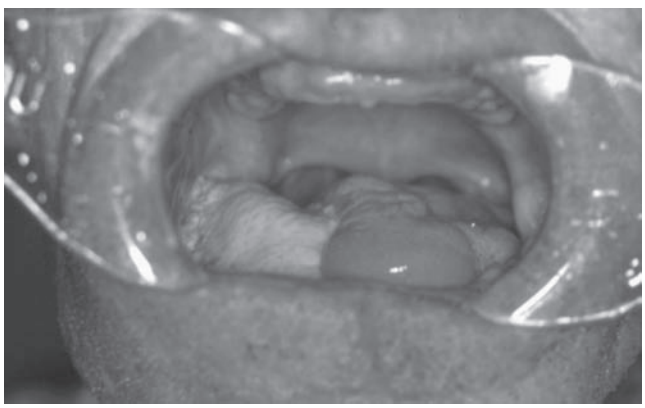

**FIGURE 9-8.** Fibula reconstruction of mandible with skin paddle is reconstructing floor of mouth and covering mandible. This skin paddle is movable, thick, and not satisfactory for prosthesis support.

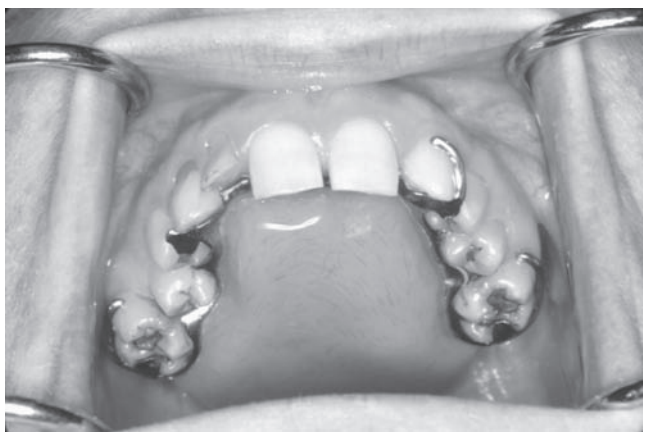

**FIGURE 9-10.** Patient with total glossectomy reconstructed with free flap and palatal augmentation prosthesis. Prosthesis functions against free flap and improves speech and swallowing.

(c) 2014 Wolters Kluwer. All Rights Reserved.

prosthesis, and patients with a mobile tongue tip have the best function. The use of thinner microvascular flaps for closure of the surgical site allows the residual innervated portion of the tongue to function with minimal impairment of movement. The palatal augmentation prosthesis offers rehabilitation advantages for patients with impaired function of the tongue.

## Oral Hygiene Procedures

Oral hygiene is one of the most important aspects of postoperative care. Initially, the surgical defect should be irrigated with an irrigation system, that is, bulb or syringe irrigation or power-spray units. After initial healing, a power-spray unit such as Water Pik (Teledyne Dental, Buffalo, NY) can be used by the patient. The patient should be instructed in the proper use of the lavage system. Initially after surgery, the patient should rinse three times a day with a saline solution made by adding one teaspoon of salt and one teaspoon of sodium bicarbonate to 16 oz of water. The irrigation system must provide enough pressure to ensure that the rinse reaches all parts of the surgical defect. Routine dental hygiene, that is, tooth brushing and flossing should be started as soon as possible. Patients are usually apprehensive about resuming the brushing and flossing of teeth because of concerns that doing so may harm the surgical site. However, if healing proceeds normally, using a power-spray system (low setting) beginning 4 weeks after surgery should not pose a problem. During the fourth week of healing, a 1:1 dilution of 3% hydrogen peroxide in water can be added to the oral hygiene routine. A sponge-tipped applicator (e.g., Oral-Swab, Crystal Lake, IL) may be used to clean the skin graft portion of the defect. After the surgical site has been cleaned, the entire oral cavity including the teeth, the tongue, the cheek, and the remaining hard palate is cleaned.[13,23]

## Physical Therapy

Conventional oral physiotherapy (i.e., mouth opening exercises) should be performed during and after radiation treatment, especially if the pterygoid regions are included in the radiation treatment fields.[24] If a restricted mouth opening is noted following surgery, tongue blades stacked on each other can be inserted between the posterior teeth until maximum opening is obtained. The blades are held in place for several minutes to allow the forming scar tissue to stretch, and then another tongue blade is added until a pain threshold is reached.

Various passive and active commercial devices to aid in mouth opening are available. Two such devices are the Therabite mouth opener (Atos Medical, Milwaukee, WI) and the Dynasplint (Dynasplint Systems Inc., Severna Park, MD). These devices open the mouth vertically with a manual separation of the jaws or a prolonged stretch (Fig. 9-11). Each of these devices is customized to the patient and has advantages and disadvantages. Users of these devices must follow manufacturers and physical therapy guidelines and ensure that teeth do not incur orthodontic tooth movement or damage. The edentulous patient can use his or her fingers, placing them between the maxillary and the mandibular ridges, to pry open the mouth. The exercises can be combined with extraoral palpation and stretching of the cheek and upper lip to keep the tissue as pliable as possible. During the first 4 weeks, the patient should be instructed to do these stretching exercises three or four times a day (15 minutes each session). In addition, a trained physical therapist can institute more advanced means of physical therapy, such as electrotherapy, ultrasound therapy, and isometric exercises. Daily mouth opening measurements should be recorded to help both the clinician and the patient measure progress resulting from these exercises, that is, rulers or calipers measuring vertical dimension between the maxillary and the mandibular incisors or ridges. In many cases, these physiotherapy techniques should be continued for at least 1 year. If a patient has a sudden loss of mouth opening, the dentist should immediately suspect and rule out recurrence of disease or infection.[25]

# OSSEOINTEGRATED DENTAL IMPLANTS

Osseointegrated implants have been used widely in dental rehabilitation since the 1980s. However, indiscriminate placement of these implants can decrease their effectiveness and increase the cost of rehabilitation dramatically. In patients with a normal mandible and maxilla, the success rate of osseointegration is between 90% and 95%.[26] However, in patients with a reconstructed mandible, the success rate may be lower, depending on

**FIGURE 9-11.** Physical therapy is a very important aspect in the care of the patient who has undergone head and neck surgery. This figure illustrates tongue blades and the Therabite mouth opener (Atos Medical, Milwaukee, WI), which help maintain oral opening during initial healing along with facial massage and stretching.

(c) 2014 Wolters Kluwer. All Rights Reserved.

the quantity and quality of the recipient bone. Careful planning is required before an implant is placed in any patient.

Implants may be the only means by which some maxillofacial prostheses can be retained, particularly those placed over osteocutaneous flaps. Patients who have undergone a free fibula tissue transfer placed using microvascular techniques make excellent recipients of implants. The fibula's bicortical configuration and vertical height are ideal for endosteal implant placement. Vertical height of the fibula averages 15.2 mm, which is ideal for the standard-sized implant.[27] The number, positioning, and spacing between implants is critical in prosthesis fabrication. These details are best dealt with after reconstructive surgery, in a separate procedure, when a surgical stent made by the dentist responsible for rehabilitation can help guide the surgeon in the exact alignment and positioning of the implants. The information needed to obtain proper fit and positioning of prostheses can be determined only by postoperative evaluations. Some implant systems require two-staged surgical procedures, whereas others require only one stage. The type of implant used should be the choice and responsibility of the dentist responsible for the prosthetic rehabilitation of the patient (Fig. 9-12).[28] Patients requiring postoperative radiation may not be candidates for implants if placed in the volumes of tissue radiated. This subject is discussed later in the chapter in the section "Care of Patients with Head and Neck Cancer Treated with Radiation."

## EXTRAORAL IMPLANTS

In the beginning of 1993, one extraoral implant system had been approved by the U.S. Food and Drug Administration (FDA); however, more have been approved since then and are currently available. Like many of their intraoral counterparts, extraoral implants are placed in two stages; however, the extraoral implants should heal unloaded for 4 to 6 months to allow adequate time for integration. Extraoral implants can be of great benefit for retention and stability of facial prostheses when correctly placed, but do not always guarantee a successful prosthesis.[29] Other retention systems available for facial prostheses are adhesives and tapes. Undercuts in the defect, if properly prepared, can also be used to retain prostheses. When contact between intraoral and extraoral defects results from surgery, the facial portion of the prosthesis can be retained through its attachment to an intraoral component.

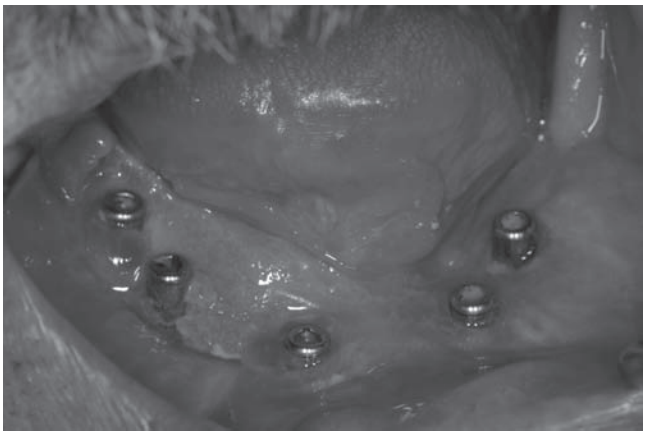

**FIGURE 9-12.** Patient reconstructed with fibula graft and dental implants. Number and position of implants are determined by dentist responsible for rehabilitation.

## RAPID PROTOTYPING

Rapid prototyping is an automated construction of objects with three-dimensional printers, stereolithography machines, or laser sintering devices that are useful in dental implantation. The first rapid prototyping techniques were developed in the 1980s and were used to fabricate prototypes of tools and parts.[30] Currently, it is used in the biologic sciences to create dimensionally accurate models of anatomic structures. Computed tomography and magnetic resonance imaging can be used to transform medical images into resin replicas of skeletal anatomy. A three-dimensional model of an ablated site in the head and neck region can be used in preoperative planning or surgical stent fabrication or to create a template for implant placement. In addition, rapid prototyping provides an accurate spatial reference during surgery (Fig. 9-13).[30,31]

## FACIAL PROSTHETICS

In general, a successful facial prosthesis is aesthetically pleasing, retentive, and tissue compatible. In addition, a prosthesis should be simple in design so that the patient can place and remove it easily. Materials used in constructing facial prostheses should be easy to clean, color stable, resistant to bacterial and fungal growth, durable, and well tolerated by tissues. The two materials that meet these criteria most fully are methylmethacrylate (plastic) and medical-grade silicones. Extraoral prostheses may be combined with intraoral prostheses to enhance retention and aesthetics.

### General Rehabilitative Principles for Ablative and Reconstructive Surgery Involving Facial Structures

***General Principles.*** Numerous general surgical principles can be applied to placement of prostheses at all facial sites. Although basic, these principles are extremely important in ensuring the success of facial prostheses:

- Smooth and round off all bony margins at the conclusion of the ablative procedure.

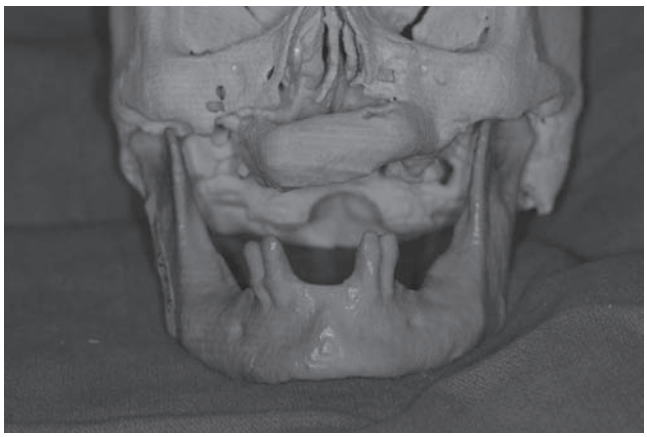

**FIGURE 9-13.** Rapid prototyping model used to plan reconstruction of maxillary defect. This model shows the fibula reconstruction of the maxilla and will be used to plan implant placement necessary for prosthetic rehabilitation.

(c) 2014 Wolters Kluwer. All Rights Reserved.

- Place an STSG on any exposed bone or periosteum that is not covered with free tissue or a pedicle flap.
- Remove unsupported tissue tags.
- Take replacement tissues from areas that best match the tissues surrounding the recipient bed.
- When using free tissue transfer flaps or pedicle flaps to repair the surgical defect, take care not to overbulk the surgical site in a patient for whom a prosthesis is planned.

***Orbit.*** When the orbital contents are removed in conjunction with a maxillary resection, reconstruction of the infraorbital rim improves the facial contour and enhances the prosthetic rehabilitation. This reconstruction can be accomplished by using a microvascular reconstruction with bone. If the bony structures of the orbit are left intact, an STSG can be placed in the defect, thereby allowing a prosthesis contact with the tissue at the depth of the defect (Fig. 9-14). Care must be exercised in placing the STSG so that the normal position of the eyebrow is maintained. Alternatively, microvascular reconstruction can be used to obliterate the defect entirely.

***Nose.*** Patients who undergo partial or total rhinectomy can be adequately rehabilitated using a removable prosthesis. An STSG should be placed in the defect to stabilize the borders of the defect and to maintain a normal lip position. For patients undergoing total rhinectomy, it is especially important that the inferior border of the nasal defect be fixated and that a dam at the inferior border of the defect be created. If the defect cannot be skin grafted, the surgeon should consider positioning the mucocutaneous junction as far posteriorly into the defect as possible. This measure will fixate the border and help form a dam. If possible, the nasal spine should be spared and the mucosa of the septum covered with a skin graft.

***Ear.*** The superior rim and tragus should be spared if possible (Fig. 9-15). If supported by cartilage, the superior rim can be used to support eyewear. The tragus can be used to hide anterior margins to improve aesthetics. The STSG can tolerate tissue adhesives used to retain facial prostheses and will also improve hygiene.[32]

***Midface.*** To enhance prosthetic rehabilitation at midface sites, several special considerations must be made before and during the reconstructive procedure.[29] During the ablative procedure, the surgical team should conserve as much of the maxilla and associated structures as possible. Respiratory mucosa should be removed from the remaining vomer, nasal floor, and sinuses, and a STSG should be placed.[21] The STSG will allow extension of the removable facial prosthesis into these areas if this extension later becomes necessary and will stop secretions from the replaced respiratory mucosa (crusting), thereby improving overall hygiene.[33]

A free-flap reconstruction with bone can be placed to improve the retention and support of the facial prosthesis. Sufficient space for this purpose is critical because if the graft is placed too far anteriorly, the aesthetics of the facial prosthesis can be diminished. If the reconstruction infringes on this space, placement of the prosthesis may be impossible. In this case, another surgical procedure to reposition the graft would be needed before prosthesis fabrication. The free-graft reconstruction should be done after irradiation if implants are indicated. Once bone is irradiated, its capacity for implant placement and subsequent osseointegration is severely diminished or lost because its osteogenic potential and microvascularity are decreased.[34]

## CARE OF PATIENTS WITH HEAD AND NECK CANCER TREATED WITH RADIATION

The clinical use of radiation is a complex process involving many professionals and a variety of interrelated functions. The aim of radiation therapy is to deliver a precisely measured dose of radiation to a defined target volume, thereby eradicating the tumor while causing minimal damage to surrounding healthy tissue.[35] More than 80% of patients diagnosed with advanced head and neck cancer receive a course of radiation therapy as a component of their treatment.

### Radiation Stents

The use of conformal radiotherapy treatment helps to minimize radiation dose to the adjacent normal oral structures. Despite this, side effects to the adjacent tissues continue to be common. Radiation stents can be fabricated by the dental oncologist under the direction of the radiation oncologist. These intraoral devices can position oral tissues into or away from the radiation treatment fields and help to immobilize the oral cavity structures

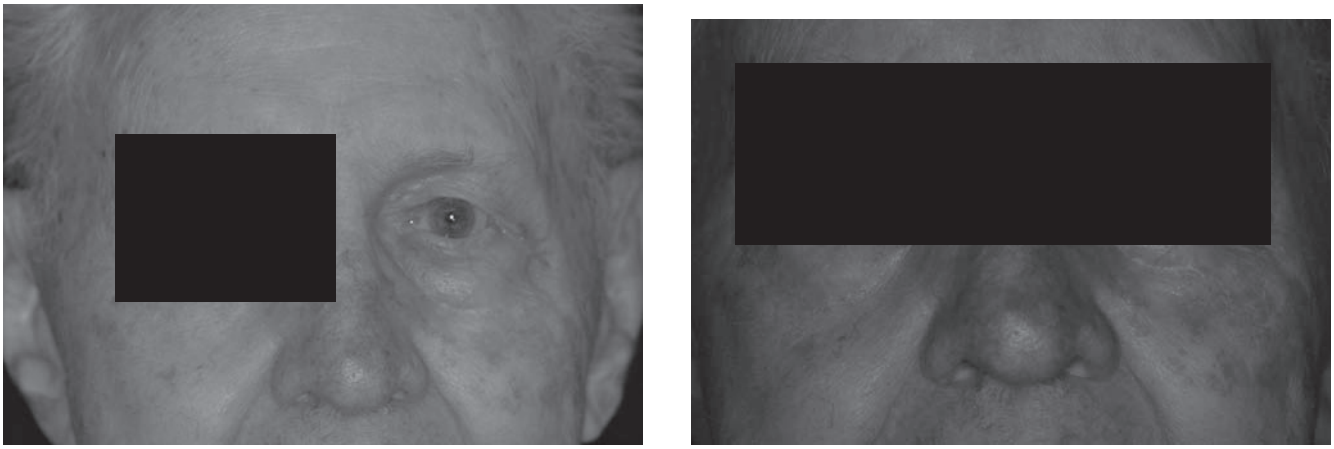

**FIGURE 9-14.** This figure illustrates an excellent split-thickness skin graft (STSG) reconstruction of an orbital defect and rehabilitation with an orbital prosthesis. If the bony structures of the orbit are left intact, an STSG should be placed in the defect. This allows placement of an orbital prosthesis that contacts the tissue at the depth of the defect. Implants placed into the lateral orbital rim help to retain and position the prosthesis.

**FIGURE 9-15.** Nasal defect that represents basic principles for surgical preparation of facial defects. A split-thickness skin graft reconstruction that stabilizes the borders of the defect and no tissue tags is shown. The superior rim and tragus should be spared if possible when dealing with ear defects.

during each daily treatment.[36] Two common stents are the mouth opening/tongue depressing (MOTD) stent, and the unilateral stent. The MOTD stent separates the maxilla and the mandible by approximately 2 cm. and depresses the tongue into the floor of the mouth. This stent spares the mandible and tongue if the maxillary sinus/nasal cavity structure is being radiated. Conversely, the MOTD stent spares the maxillary sinus/nasal cavity structures if the tongue, mandible, or neck is being radiated. The unilateral stent is utilized during radiotherapy treatment of lateralized malignancies, that is, parotid, buccal mucosa, tonsil, retromolar trigone. This stent positions the tongue to the unaffected side, and positions the maxilla and the mandible in the same position during each treatment (Fig. 9-16).

## Oral Complications

A healthy oral status before radiation therapy reduces the risk for complications from therapeutic administration of ionizing radiation to the head and neck. These complications can be categorized as either acute (e.g., mucositis, infectious stomatitis, alteration of taste or smell acuity, dermatitis, pain, inflammation, and difficulty swallowing) or chronic (e.g., xerostomia, caries, abnormal development, fibrosis, trismus, photosensitivity, osteoradionecrosis, and pain).[37–39] The severity of treatment-induced morbidity depends on multiple factors such as the radiation dose, energy source, volume of tissue treated, pretreatment performance status, and pretreatment periodontal condition.[40] The volume of tissue irradiated is susceptible to dermatitis and mucositis, which are often accompanied by salivary gland hypofunction, dysgeusia, dysphagia, odynophagia, hypovascularity of soft and hard tissues, fibrosis, or trismus.[37,40,41] Widespread oral melanotic hyperpigmentation and hypopigmentation have been reported. Developmental abnormalities of the dentition and jaws may occur in children undergoing head and neck radiation therapy.[42–45] In patients of all ages, altered tissues within the volume of tissue irradiated are highly susceptible to infectious processes, especially with fungal organisms, such as *Candida albicans* or other species; bacterial infections, especially with *Streptococci* and *Staphylococci*; and viral infections, especially with herpes simplex virus (Fig. 9-16).[46,47] Resistant strains can further pose a significant challenge to patients and clinicians.

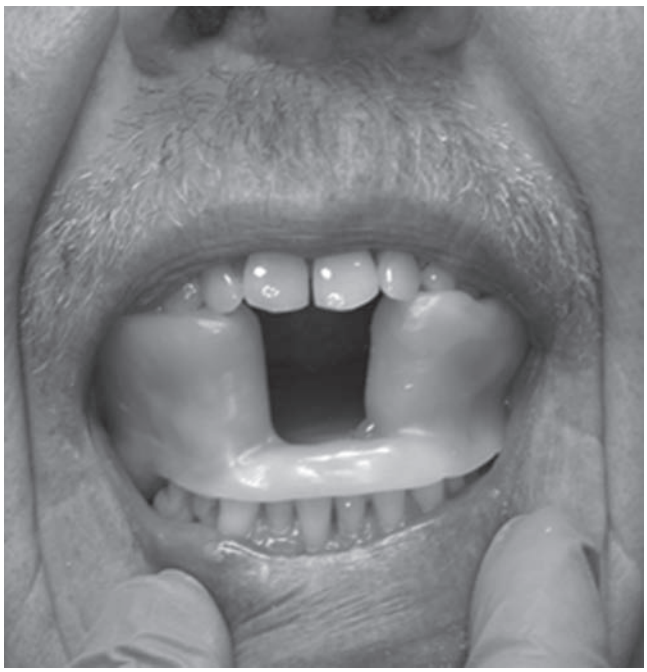

**FIGURE 9-16.** Mouth opening/tongue depressing radiation stent (wax pattern) positioned intraorally. This patient is being treated for a base of tongue malignancy. The stent positions the maxilla away for the radiation field and immobilizes the oral tissues during each radiation treatment.

**FIGURE 9-17.** Oral candidiasis in a patient undergoing external beam radiation therapy for a base of tongue primary carcinoma.

**FIGURE 9-18.** Radiation-induced mucositis in a patient receiving treatment for a squamous cell carcinoma of the oral tongue with metastatic disease in the cervical region.

## Mucositis

Oral mucositis generally occurs 5 to 7 days after initiation of external beam radiation therapy (Fig. 9-17). Oral mucosal changes depend on the fractionation, energy source, total dose of radiation, and oral and dental status.[40] When an electron beam is used with high-energy photon beams in the treatment of deep lesions, the mucosal reactions on the side of the entering beam may consist of patchy or confluent exudate, whereas the contralateral side may show only erythema. During the course of radiation therapy, the mucosa becomes thin as a result of direct cell death and the sloughing off of rapidly replicating epithelial cells.[48]

Eliminating all secondary sources of irritation such as alcohol, smoking, and coarse products that can further dehydrate oral tissues can decrease the severity of oral mucositis. Hot foods, alcohol- or phenol-containing mouth rinses, and sodium[49] should be avoided. Treatment of mucositis typically consists of palliative pain-reduction therapy. Physicians have advocated several agents for topical use, including benzydamine hydrochloride, allopurinol, sucralfate suspension, kamillosan, povidone-iodine, antacids, sodium bicarbonate, local anesthetic agents (such as lidocaine hydrochloride), chlorhexidine gluconate, oral suspension of prostaglandin E2, and aloe vera with the active ingredient acemannan.[49–53] Unfortunately, very few clinical trials have examined these substances, and the results have shown only moderate clinical efficacy.[54,55] Good oral hygiene is essential for improving oral comfort and reducing the risk for oral contamination. Bacterial, fungal, and viral infections can occur as superinfections with mucositis, but are less likely to induce septicemia in patients undergoing radiation therapy than in patients receiving chemotherapy.[37] Patients receiving a concurrent regimen of radiation therapy and chemotherapy may be at a greater risk for infectious mucositis than patients treated with either therapy alone. With fungal infections, such as oral candidiasis, the pathogenesis can be invasive, refractory to treatment, and potentially septic.[46] Candidiasis can manifest as pseudomembranous, hyperplastic, or atrophic (erythematous) oral lesions.[46] The sites most frequently affected are the tongue, buccal mucosa, hard or soft palate, or the commissurae labiorum oris (i.e., angular cheilitis) (Fig. 9-18). Treatment consists of such topical antifungal agents as nystatin oral suspension or clotrimazole troches, depending on the degree of xerostomia.[46,56,57]

To avoid oral infections and to reduce the mucositis that may arise from radiation therapy, patients must frequently rinse the oral cavity to reduce oral microorganisms and to maintain mucosal hydration. Such oral lavage can be performed by rinsing with a solution of one teaspoon of sodium bicarbonate dissolved in 12 oz water several times each day to alkalinize the oral cavity and to keep the oral and oropharyngeal tissues moist. Mouth rinses, saliva substitutes, and gustatory stimulants are frequently abandoned by patients treated with head and neck radiation therapy because the effect is short-lived or not effective.[37] Such patients should be encouraged to increase water intake, decrease acidic and carbonated beverage intake, and decrease sodium intake.

## Osteoradionecrosis

Radiation can permanently destroy cellular elements of bone and therefore limit the potential for wound maintenance and the ability to heal after infection or trauma (e.g., dental extraction and alveoloplasty).[58,59] The risk for complications following trauma or oral surgical procedures in an irradiated field can be highly significant, depending on a predetermined threshold of irradiation, and result in osteoradionecrosis (Fig. 9-19).[40] For these reasons,

**FIGURE 9-19.** Patient undergoing radiation therapy to the oral cavity with angular cheilitis in the bilateral commissures and a candidal infection on the lower labial tissues.

(c) 2014 Wolters Kluwer. All Rights Reserved.

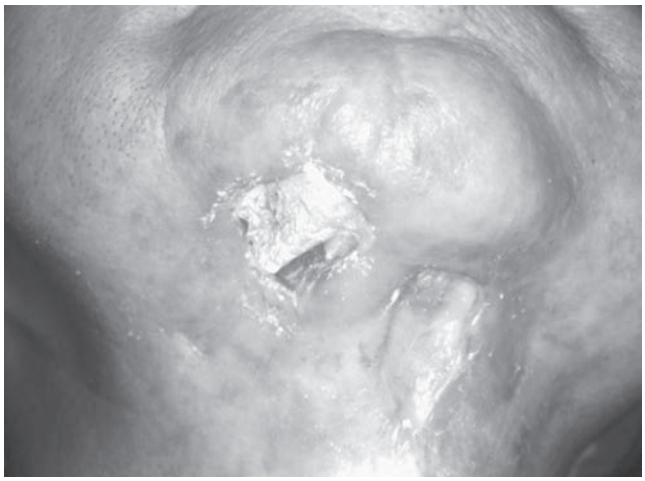

**FIGURE 9-20.** Osteoradionecrosis in the anterior mandible secondary to trauma from a motor vehicle accident. The mandible and upper cervical region were in the radiated field.

elective oral surgical procedures such as extractions or soft tissue surgery are contraindicated within an irradiated field owing to hypovascularity, hypocellularity, and hypoxia (Fig. 9-20).[37] Nonsurgical dental procedures that can safely be performed include routine restorative procedures, oral prophylaxis, radiography, and endodontic and prosthodontic procedures.

If oral surgical intervention is required after radiation therapy, the clinician should discuss the volume of tissue irradiated and specific treatment parameters with the treating radiation therapist and should request a copy of the simulation or port films and treatment summary. Preoperative hyperbaric oxygen therapy may increase the potential of wound healing while minimizing the risk for osteoradionecrosis by promoting angiogenesis and osteogenesis (Fig. 9-21). Hyperbaric oxygen therapy must be used as an adjunct to debridement (sequestrectomy), wound care, parenteral antibiotics (as dictated by bone culture results), and composite bone and muscle grafts by free tissue transfer (subject to the availability of the requisite microvascular skills).[60,61] Antibiotics are chosen on the basis of macrodilution or microdilution sensitivity testing.

Hyperbaric oxygen therapy is time-consuming and expensive and must be performed in an accredited wound care center. However, compared with a postradiation surgical treatment consisting of radical debridement and reconstruction, hyperbaric oxygen treatment can be cost-effective. Hyperbaric oxygen may also preclude the need for jaw amputation, large resection, or microvascular surgery. The Marx protocol, consisting of 20 preoperative hyperbaric oxygen treatments followed by 10 postoperative treatments, is the standard treatment regimen.[60,62] Optimal oral health must be maintained during and after radiation therapy. However, to avoid soft tissue injury during the postradiation healing period, patients must curtail all but the most basic oral hygiene procedures (i.e., brushing, flossing, and fluoride therapy). Following initial recovery from radiation effects, nonsurgical periodontal therapy, usually with prophylactic antibiotic coverage, is appropriate for treatment of the periodontium within the radiation field. It is important to detect and treat dental caries or traumatic dental injury that could lead to disease. If postradiation extractions are necessary, hyperbaric oxygen therapy, along with a specific oral care regimen, is indicated to augment wound healing.[60] In such cases, tissues should be managed gently, and antibiotic coverage is required. Local anesthetics containing epinephrine should be avoided, when possible, to prevent further vascular constriction.[63] The literature has reported successful placement of endosseous implants in irradiated fields, with a pretreatment regimen of hyperbaric oxygen (Fig. 9-22).[64,65] In contrast, osteoradionecrosis has been initiated by such elective surgical intervention.[65,66]

**FIGURE 9-21.** Osteoradionecrosis in the posterior maxilla secondary to a tooth extraction. This patient has radiation-induced hypovascularity in the bilateral maxillae secondary to irradiation of the soft palate and tonsil.

## Caries

Dental caries is a common morbid sequela in patients with head and neck cancer treated with radiation therapy.[67] Irradiation of major salivary glands leads to qualitative and quantitative changes in salivary secretions, reducing the buffering capacity of saliva.[68] The result is a cariogenic environment, particularly in patients who ingest a diet high in carbohydrates or sucrose (Fig. 9-23). Susceptibility to caries is not limited to the dentition within the

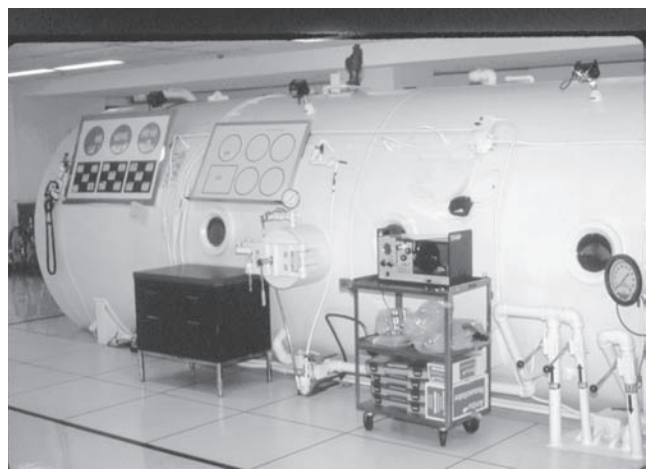

**FIGURE 9-22.** A multiplace hyperbaric chamber. Patients will undergo hyperbaric oxygen treatment using the Marx protocol (90 minutes of treatment, breathing 100% oxygen at 2.2 to 2.5 atmosphere absolute); 20 to 30 preoperative treatments are followed by 10 to 20 postoperative treatments.

By torque evaluation and clinical/radiographic assessment, the implants are considered osseointegrated without evidence of necrosis.

volume of tissue irradiated; it extends to the entire dentition. Patients who have undergone irradiation should be treated with a specific prophylactic regimen consisting of flossing, brushing, and fluoride therapy. Fluoride treatment consists of a daily application of 0.4% stannous fluoride or 1.1% sodium fluoride.[37,40,68] In adults with xerostomia, fluoride leaches out of the enamel within 24 hours; therefore, the fluoride regimen must be performed daily to ensure optimal protection. The most efficient method of fluoride application is to use a custom-made polypropylene fluoride carrier that completely covers, and extends slightly beyond, the tooth surface (Fig. 9-24).[40] Patients load the carriers with fluoride gel and place them onto the dentition daily for 10 minutes. Patients who receive low doses of radiation and are expected to have a slight degree of xerostomia can use a toothbrush to apply the fluoride gel.[69] A daily fluoride program can decrease postradiation dentinal hypersensitivity; remineralize cavitated enamel matrices; and, more importantly, inhibit caries-forming organisms.[37,40] Patients are encouraged to floss their teeth daily, followed by tooth brushing, sodium bicarbonate rinse, and the fluoride treatment.

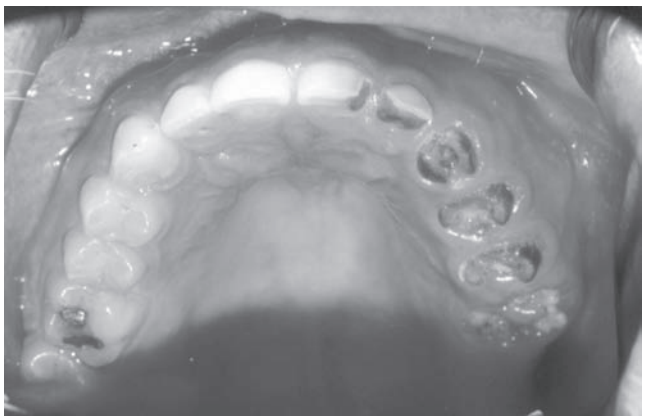

**FIGURE 9-24.** Radiation-induced caries in a patient who has received unilateral external beam radiation treatment for a parotid gland tumor with cervical nodal involvement.

## Xerostomia

Sialagogue therapy, such as with cholinergic agonists (e.g., pilocarpine hydrochloride), has been shown to provide clinically significant relief of symptoms of postradiation xerostomia.[70,71] Other rinses reported to decrease oral discomfort related to xerostomia or mucositis contain cytokines, aloe vera derivatives, or antibiotics. When administered intravenously, during radiation therapy, amifostine, a free radical scavenger, has been shown to diminish toxic effects of irradiation on salivary glands.

If these guidelines are followed, healthy oral tissues can be maintained following radiation therapy. Achievement of this goal depends on the patient's cooperation and compliance, which should be verified by clinicians at follow-up appointments.

# CARE OF PATIENTS WITH HEAD AND NECK CANCER TREATED WITH CHEMOTHERAPY

Most patients with cancer receive chemotherapy as a single- or multiple-drug regimen, either alone or in combination with other therapies.[72,73] The duration of treatment ranges from several months to years, depending on how long the therapy remains effective or how long the patient can tolerate it. Because chemotherapeutic agents damage mitotically active normal tissue cells or multiplying tumor cells, chemotherapy often induces toxicity in the hematopoietic cells, skin, and aerodigestive tract.[38,72] Such toxicity may cause treatment-induced complications in the oral cavity, especially if myelosuppression has occurred. Many of the sequelae of chemotherapy are similar to those induced by radiation therapy, but are sometimes more episodic depending on the dosing schedule or chemotherapeutic agents administered.

## Oral Complications

Acute oral conditions detected during the evaluation of the oral and dental status of patients with cancer must be treated before chemotherapy if the patient's health or hematologic values permit or when the opportunity arises between treatment cycles and when an appropriate performance status has been established. Chronic problems should not go unattended but should be treated strategically as the patient continues with chemotherapy.[38] Through appropriate coordination, acute problems can be treated promptly. If left untreated, chronic conditions may become acute at a time when the patient's physical well-being or hematologic parameters will not allow oral treatment intervention.

## Oral/Dental Treatment

During oncologic chemotherapy, the treatment plan for patients with cancer should be simple, practical, and functional in relation to the patient's oral or dental health and should not be in the realm of cosmetic dentistry, fixed prosthodontics, or advanced periodontal therapy.[38] Dental specialists face an almost overwhelming temptation to give aesthetic possibilities undue consideration while not recognizing the difficulty patients face in coping with their cancer diagnosis and undergoing drug therapies that have serious side effects.[37–39]

The dentoalveolar complex should be thoroughly evaluated for microbial reservoirs or sanctuaries (e.g., plaque, calculus, or periodontal pockets), and these infectious foci should be eliminated before the start of chemotherapy (Fig. 9-25).[74] A diminished periodontal status presents a risk for infection. Clinically, however, the risk for infection depends on multiple interacting factors such as oral hygiene, immunomyelosuppressive status,

(c) 2014 Wolters Kluwer. All Rights Reserved.

**FIGURE 9-25.** Fluoride carrier filled with 0.4% stannous fluoride and in position over maxillary and mandibular dentition.

**FIGURE 9-26.** Heavy calculus and plaque on dentition providing a sanctuary for microbial and fungal activity.

chemotherapeutic agents used, prophylactic or therapeutic antimicrobial agents used, and the degree of periodontal pathology.

To minimize the risks for periodontal infection, it is important to develop simple and practical guidelines for maintaining periodontal health and for diagnosing, preventing, and treating periodontal infections during therapy.[37,74] Patients with cancer should make regular dental visits for overall dental assessment. Patients receiving chemotherapy can undergo a dental cleaning provided that they meet the following hematologic conditions: first, an absolute neutrophil count of approximately 1,000 per $mm^3$, a level at which the risk for developing an infection is minimal; and second, a platelet count >50,000 per $mm^3$ with a normal coagulation profile.[75] The administration of prophylactic antibiotics is essential in combating induced bacteremia, immunocompromised status, and potential hypofunction of the white blood cells introduced by chemotherapy. The American Heart Association recommends a viable antibiotic regimen for subacute bacterial endocarditis prophylaxis before periodontal procedures. The second dose should be given 6 to 8 hours after the loading dose.[76]

Patients with an uninfected dentition and good periodontal health do not pose a diagnostic treatment challenge, nor do patients with advanced periodontal disease that mandates immediate surgical intervention. However, patients with increased loss of attachment with furcation involvement or periodontal pocket formation with furcation involvement pose a treatment dilemma, particularly for those taking bisphosphonates who are at risk to develop osteonecrosis of the jaws.[38] Patients in whom the soft tissue parallels the bone loss and in whom pocket depth is normal can be treated with regular periodontal care and maintenance. Extraction should be considered only for patients with pathologic mobility of dentition or with a fulminant periapical abscess.[37] Patients with moderate to advanced periodontal disease present a greater challenge and would, under usual circumstances, receive instructions for infection prophylaxis and dental hygiene, as well as surgical correction. However, the feasibility of such comprehensive therapy during chemotherapy can be limited by several factors including performance status, type of malignant disease, cycling of chemotherapy, and hematologic competence. The clinician should strive to provide a thorough scaling and encourage maintenance through exceptional plaque control (i.e., brushing, flossing, and use of chlorhexidine gluconate).[37–39,77] To reduce the risk for sepsis, extractions should be considered for patients with any exacerbated acute periodontal infection, except for those who have had dosing with bisphosphonate therapy. This oral surgical correction should be performed at the appropriate time in the treatment cycle or when the patient's cancer is in complete remission (Fig. 9-26). If chemotherapy is on hold, periodontal surgery could be considered, provided that the hematologic status is appropriate. The oncologic dentist must discuss with the treating medical oncologist the patient's oral status, treatment plan, and contraindications to surgical intervention, as well as the appropriate timing of oral treatment intervention.[37–39,72]

Brushing and flossing of the teeth should continue to be the standard of dental care for patients who routinely brush and floss. However, as in the general population, many patients with cancer either do not floss or floss only infrequently. Therefore, clinicians may either instruct patients to floss or may stress brushing techniques only. In most cases, patient factors and limited time parameters do not permit the patient to become proficient in flossing techniques.[37] Patients who floss regularly are instructed to modify the flossing technique in certain clinical situations. First, patients are instructed to floss gently when the lining of the oral cavity starts to become sensitive to thermal changes or food substances because sensitivity indicates mucosal thinning due to suppressive effects of chemotherapy on the normally proliferative epithelium.[49] Second, patients are instructed to floss only to the gingiva when the platelet count decreases to <50,000 per $mm^3$. This technique removes most of the debris from this area.[38]

In controlling plaque accumulation, it is important to minimize the risk for gingival inflammation, the oral bacterial load, and the potential for infection. Along with routine brushing and flossing, rinsing with chlorhexidine gluconate should be initiated when patients begin chemotherapy. Such rinsing is an adjunct to ideal oral-periodontal care and can also be used when indications arise, such as oral mucosal changes secondary to chemotherapy and subsequent increased soft tissue sensitivity.[37,38,77] Patients undergoing chemotherapy should be encouraged to rinse with a dilute saline and sodium bicarbonate solution (5%) to reduce adherent mucoid debris on oral soft tissues, lubricate oral mucosal and oropharyngeal tissues, and elevate the pH of oral fluids.[39] Patients experiencing nausea and anorexia should be encouraged to rinse with the sodium bicarbonate and saline solution several times throughout the day to reduce oral acidity and minimize the mucosal insult.

Another challenge that patients with cancer face in oral care is the risk for local infection or septicemia associated with dental

(c) 2014 Wolters Kluwer. All Rights Reserved.

implants. If an implant with its restorative component poses a risk for infection in patients under normal circumstances, this risk will be intensified during chemotherapy. Interventional antibiotics and aggressive hygiene have limited ability to control infection caused by a poorly integrated endosseous implant, whereas a well-integrated implant should not pose problems if its integrity is maintained with effective dental hygiene practices.[78,79]

Appropriate evaluation of the oral cavity and correction of existing oral and dental pathology can minimize, and in some cases eliminate, treatment-limiting toxicities such as mucositis, oral infections, and bleeding that necessitate chemotherapy dose reduction or termination.[72]

## Mucositis

A diagnosis of oral mucositis or oral mucosal barrier injury should be reserved for oral tissue changes that are the direct cytotoxic effects of chemotherapy. The most common acute complication of chemotherapy, mucositis, has a specific and defined mechanism of progression: mucosal erythema progresses to oral sensitivity and then to mucosal denudation (Fig. 9-27).[49,54] All other factors must be ruled out before a condition is diagnosed as mucositis because an incorrect diagnosis of mucositis could cause unnecessary delay, reduction in the dose, or complete discontinuance of effective chemotherapy.[38] Incorrect mucosal assessment can also lead to improper care and treatment and thereby to the persistence of this mucosal pathology. This problem can be further compounded by superinfection, pain, decreased nutritional intake, bleeding, or a focus for sepsis, effects that increase the treatment morbidity, costs, length of hospital stay, need for additional antibiotic therapy, and need for parenteral nutritional support.

Chemotherapeutic agents known to produce mucositis are antimetabolites, antibiotics, and alkylating and vinca alkaloids.[49,80] In cases of appropriately diagnosed mucositis, the emergence of mucosal toxicity would be expected to coincide with the administration of the chemotherapy. However, mucosal herpes simplex virus infections occurring early in the chemotherapy cycle can mimic mucositis. Failure to collect diagnostic cultures with each mucosal reaction can lead to a misdiagnosis of mucositis, in which case the infection would go untreated.[81] Culturing at this early stage of therapy is essential for differentiating mucositis from infectious stomatitis that can be caused by a bacterial, fungal, or viral agent and that is usually associated with low hematologic values (Fig. 9-28).[37–39] Oral mucosal infectious agents must be correctly identified and treated, because the loss of mucosal integrity creates a portal of entry for systemic infection in immunocompromised patients.[82]

**FIGURE 9-27.** Postextraction site with an organized clot in a patient with pancytopenia undergoing myelosuppressive chemotherapy. This patient is at the nadir and should have had no oral surgical intervention until the recovery phase of therapy with hematologic stability. Patient required random donor platelets with antibiotic therapy and a surgical debridement.

**FIGURE 9-28.** Chemotherapy-induced oral mucositis (World Health Organization grade III).

Chemotherapy-induced pancytopenia, combined with mucositis, can lead to oral infection and bleeding events. Patients may also have severe thrombocytopenia (platelets <20,000 per $mm^3$) and neutropenia (neutrophils <500 per $mm^3$) despite having normal-appearing oral mucosa. Serious complications, such as hemorrhagic diathesis or sepsis, can occur if hematologic parameters are not considered in the treatment of the oral cavity. Therefore, clinicians should conduct a benefit-versus-risk analysis of the intended therapy and should thoroughly assess the hematologic values before each treatment intervention. Treatment guidelines based on such assessments have been established.

# BISPHOSPHONATE OSTEONECROSIS

The use of the bisphosphonates both injectable and oral has been associated with mandibular and maxillary osteonecrosis. A substantial number of these cases have been associated with dental procedures such as tooth extraction. The product labels for bisphosphonates were updated in 2004 to include precautions about osteonecrosis of the jaw. Patients with concomitant risk factors such as cancer, chemotherapy, corticosteroids, and poor oral hygiene should undergo a dental examination and preventive dentistry before bisphosphonate treatment. Clinically, bisphosphonate-induced osteonecrosis is indistinguishable from radiation-induced osteonecrosis.

The American Dental Association endorses the 2004 Expert Panel Consensus recommendations (convened by Novartis Pharmaceuticals Corporation) for planning dental interventions in patients with bisphosphonate-induced osteonecrosis. Patients should be educated on maintaining oral hygiene to reduce the risk of infection. Dentists should check and adjust removable dentures to avoid soft tissue injury. Routine dental cleaning should be performed with care not to inflict soft tissue injury. Dental infections should be managed nonsurgically (when possible). Endodontic therapy is preferable to extractions. When necessary, coronal amputation preceded by root canal therapy may be used to avoid the need for extraction.[83,84]

## Diet

Although generally unrecognized, diet profoundly influences the stability of the oral tissues and can cause mucosal problems when a patient is undergoing cancer therapy.[37] During the myelosuppressive phase of therapy or when the mucosa is thinned owing to chemotherapy, the diet should consist of nontraumatizing, soft foods that cannot puncture, abrade, or otherwise damage the vulnerable mucosal epithelium. Hard or abrasive food items can lead to increased pain, infection, or bleeding episodes.

All patients receiving chemotherapy are at risk for oral complications, and some patients are at a greater risk than others, depending primarily on the type of malignancy and the aggressiveness of the cancer treatment. Patents with hematologic malignancies (e.g., leukemia and lymphoma) have a greater risk than patients with solid tumors (e.g., breast cancer, lung cancer, and sarcomas), because the protective elements that maintain bodily homeostasis are part of the malignant process of hematologic malignancies.[72] Additional aggressive therapy that is given cyclically or that allows hematologic recovery before the start of the next cycle further increases the risk for oral complications in these patient populations.

## Viral and Bacterial Infection

Viral reactivity may lead to severe oral or disseminated infections during periods of myeloimmunosuppression. In particular, herpes simplex virus infections are often associated with severe, painful, and prolonged ulcerations atypical of those found in immunocompetent hosts (Fig. 9-29).[37–39,81] Suspected herpes simplex virus lesions should be treated with antiviral agents, such as acyclovir, administered orally or intravenously and managed as described previously for patients who receive radiation therapy. The diagnosis should be established using viral cultures, direct immunofluorescence or other rapid diagnostic tests, and histologic examination (Fig. 9-30).[81,85] Bacterial infections following chemotherapy can cause localized mucosal lesions, sialoadenitis, periodontal abscesses, pericoronitis, or acute necrotizing ulcerative gingivitis.[38] Because systemic infection is a serious complication in patients with neutropenia, constant vigilance must be maintained to prevent or manage oral infections of any type. Because antileukemic therapy is designed to achieve myelosuppression, this risk may be higher among patients with leukemia than among those with solid tumors.[37] Oral infections should be treated with selected antibiotic combinations (broad-spectrum antibiotics), including an agent effective against anaerobic gram-negative bacilli such as *Pseudomonas*, *Klebsiella*, or enterobacteria, which are often found in the oral cavity of immunocompromised individuals.[37–39] Oral microbial culture testing should be done to ensure antibiotic sensitivity and resistance selection and to assist in identification of the causative organisms.

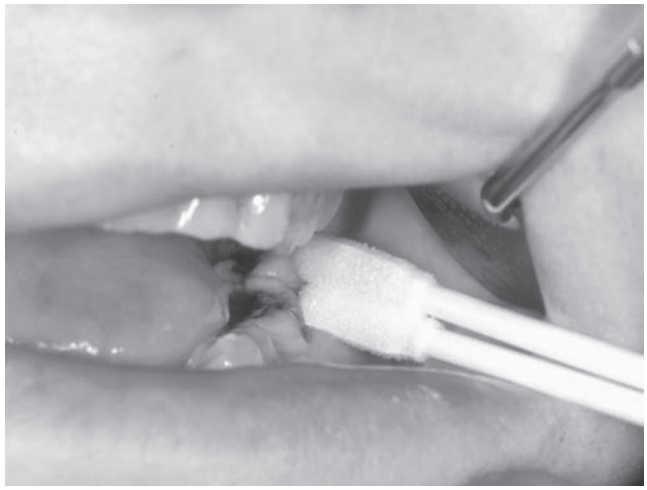

**FIGURE 9-29.** Culturing of an oral bacterial infection.

**FIGURE 9-30.** Culture-positive herpes simplex virus on the mandibular gingiva tissue. Patient placed on an antiviral regimen. Herpes simplex virus is an often overlooked and underdiagnosed oral condition.

# PREMALIGNANT ORAL LESIONS

The oral cavity is continually exposed to a variety of physical, biologic, and chemical carcinogens that can lead to the development of premalignant oral lesions. The reaction of the oral mucosa to these carcinogens is determined by the patient's age, sex, health, and genetic predisposition as well as the duration and intensity of the exposure. Tobacco and alcohol are considered the major etiologic factors in the initiation of premalignant oral lesions. The mean age of onset of premalignant oral lesions is 55.7 years.[86]

Premalignant oral lesions are the most common chronic lesions of the oral cavity. If not diagnosed and treated early, these lesions can progress to malignancy. The anatomic location of premalignant oral lesions is important in assessing their risk for malignant transformation. Lesions of the tongue, gingiva, and floor of the mouth are at a higher risk for transformation than are lesions located in the palate, buccal mucosa, and lips. The transformation of an epithelial premalignant oral lesion to a carcinoma is an extremely complex biologic multistep and nonsynchronous process. Various exogenous and endogenous factors enhance or impede malignant transformation, either directly or indirectly. New research has only recently begun to address these issues. The two epithelial lesions of the oral cavity at the highest risk of malignant transformation are leukoplakia, which presents as a chronic white plaque, and erythroplakia, which presents as a red, somewhat roughened area. In some cases, leukoplakia and erythroplakia occur together, creating a mottled- or speckled-appearing lesion. These lesions can be found anywhere in the oral cavity and cannot be removed by rubbing or scraping. They must be excluded from other clinically similar appearing lesions and do not typically respond to the resolution of known etiologic, traumatic, or inflammatory factors. Leukoplakia and erythroplakia can occur at any site along the aerodigestive tract but are most likely to be initially diagnosed in the oral cavity because of the accessibility of this area.

Clinicians must be well acquainted with other oral lesions that are clinically similar in appearance to leukoplakia and erythroplakia, such as lichen planus, erosive lichen planus, white sponge nevus, hairy leukoplakia, *C. albicans*, linea alba, leukoedema, and frictional keratosis. Lichen planus, a chronic inflammatory disease, can also present with the clinical characteristics as leukoplakia or erythroplakia. The erosive form of this disease can be painful and interfere with normal oral function. The results of some studies indicate a higher rate of malignant transformation in lichen planus; other studies suggest that the malignant transformation rates are similar to those of other nonpremalignant lesions.

Because most premalignant oral lesions are asymptomatic, they are usually detected during an oral examination by trained professionals. The diagnosis is best determined by soft tissue incisional biopsy, with pathologic interpretation by a pathologist familiar with oral pathologic characteristics. One of the most widely used biopsy techniques is the punch biopsy that is performed using a circular knife with variable diameters. The biopsy can easily be performed in an office setting under minor local anesthesia and in most instances requires no sutures. If necessary, more than one biopsy sample can be obtained from the same lesion. A biopsy is mandatory when a lesion of the oral cavity is not associated with a reversible cause. If a lesion is found to be cancerous, the patient should be referred to an oncologist.

Current treatment modalities for premalignant lesions include surgical excision (knife or electrocautery), laser ablation, and cryotherapy.[86] Localized, relatively small premalignant oral lesions in high-risk areas such as the lateral border of the tongue, floor of the mouth, soft palate, and retromolar triangle can be excised by conventional surgery or electrocautery. Lasers have also been used effectively in the treatment of these lesions. Many different types of lasers and delivery systems are being used and tested. However, recurrence of these lesions is common, even after excision because the entire epithelial surface of the aerodigestive tract has been exposed to the same factors that caused the premalignant oral lesion, a phenomenon termed *field carcinogenesis*. No premalignant oral lesion should be considered cured unless there has been no recurrence after treatment or resolution of the lesion for a minimum of 3 years.[87,88,89]

Chemoprevention is a relatively new investigational approach that addresses field cancerization by reversing the premalignant process, thereby returning the affected tissue to a state of normal maturation and function.[88,89] Multiple randomized trials have been conducted in chemoprevention, and many have had positive results, yielding a tremendous interest in this approach to cancer treatment. Retinoids are the most studied class of compounds in chemoprevention.[85–98]

CHAPTER 10

Diane Serra, Bridget Bennett, Elise Carper, Alice Fox, and Seth Resnick

# Interdisciplinary Symptom Management

## INTRODUCTION

In head and neck cancer patients, complex care issues exist that are best addressed by an interdisciplinary approach. Disabilities that can result during and after treatment affect eating, swallowing, speech, and daily social contact, all of which can severely affect a patient's overall quality of life (QOL). Physical, social, and psychological well-being are greatly affected by the potential disfigurement and dysfunction resulting from disease and its treatment.[1]

Several modalities of treatment of head and neck cancer are well established. Radiation therapy, surgery, chemotherapy, and various combinations of these three therapeutic modalities all comprise today's optimal treatment.[2,3] Investigative treatment methods include biological therapy, immunotherapy, and gene therapy. The treatment regimen for a specific patient depends on tumor site, stage, histology, and other factors. Treatment is composed of a single-modality or a combined approach. Each treatment method entails both general symptom management and specific care related to its distinctive side effects.

This chapter presents guidelines for interdisciplinary symptom management for patients receiving treatment for cancers of the head and neck. We begin with a discussion of what constitutes interdisciplinary care, drawing in part on the experience of collaboration at an urban Cancer Center, a center of excellence in head and neck cancer. A discussion of fatigue, a common and troubling symptom, is followed by a section on nutrition. Pain assessment and management, including algorithms to assist in treatment, skin care, and the management of mucositis follow. We have included discussion of psychiatric conditions, psychosocial assessment, the incorporation of integrative medicine in oncology as well as issues of survivorship. Finally, we have included a section on the integration of palliative care within oncology practice, with evidence to suggest this as a best practice model.

## INTERDISCIPLINARY SYMPTOM MANAGEMENT

Comprehensive symptom management that anticipates patient needs helps patients and their families participate in care, complete all treatments without interruption as recommended by their health care team, and adjust to changes in function and appearance brought about by cancer and its treatment.[3] Providing comprehensive symptom management to head and neck cancer patients is uniquely challenging, but is critical to successful treatment outcomes.

The identification of potential problems, as well as individual strengths, should be made at the time of initial contact with patients. These may include physical, psychological, spiritual, practical, social, and cultural issues. A review of information regarding cancer diagnosis, plan of care, treatment-related side effects, and their management may be presented by several providers, before treatment actually begins. Identifying factors which may affect patient learning (e.g., educational level, language barrier, and unfamiliarity with the medical system) can be identified and addressed proactively.

Multimodal treatment for head and neck cancer requires coordination from each member of the interdisciplinary team, especially when care is provided across several ambulatory sites (e.g., radiation oncology and chemotherapy sites) as well as inpatient settings. At the Continuum Cancer Centers of New York, a video conference connecting three physical sites is held weekly.[4] The goal of this conference is to maximize the communication and coordination between providers, by reviewing each head and neck cancer patient's progress through treatment. Disciplines represented include advance practice nurses from radiation oncology, ambulatory and inpatient medical oncology nurses, an integrative oncology nurse, social workers, nutritionists, speech and swallowing specialists, and palliative care specialists. The presence of significant physical symptoms, psychosocial distress, and unusual family circumstances which may impact care are discussed.

In addition to this conference, an interdisciplinary team from three sites, consisting of psychiatrists, social workers, nutritionists, palliative care specialist, and patient advocate collaborates weekly. Individual patients are discussed, as well as sharing of resources and expertise. The time spent on this interdisciplinary communication and collaboration improves patient care, reassures patients that providers are communicating with each other, and assures safe transitions in level of care, especially between inpatient and outpatient settings.

### Fatigue

Fatigue is a common state in patients with head and neck cancer. Although its mechanism of development is undoubtedly multifactorial, it is thought that a variety of circumstances, such as growth of the cancer itself, chemotherapy, radiation therapy,

(c) 2014 Wolters Kluwer. All Rights Reserved.

compromised nutrition, physical "deconditioning," altered sleep patterns, hormonal changes, anemia, worry, and fear all contribute to a feeling of overwhelming tiredness or exhaustion that interferes with QOL and daily functioning.[5] Although being "tired" is part of the human condition, its intensity is often greatly amplified when the fatigue is induced by cancer or its treatment.

The underlying mechanism causing fatigue is receiving greater attention as survivors of head and neck cancer live longer and experience more intensive multimodal treatments. It has been proposed that fatigue is the result of the production of proteins by actively growing cancer cells. These cytokines or cell proteins may be responsible for fatigue as well as weight loss; both important nonspecific constitutional symptoms that guide clinicians' judgment about a patient's response to treatment or underlying disease progression.[6]

Attempts to successfully address fatigue can help sustain the QOL experienced by patients and their families. A variety of pharmacologic and nonpharmacologic interventions may alleviate patients' fatigue or restore a patient's sense of control over their symptoms and environment. Several factors may contribute to fatigue in the head and neck cancer patient. These include physical decondition, sleep, hormonal changes, and anemia, which are elaborated below, along with nutritional factors as well as mood and anxiety which are addressed in subsequent sections.

### Physical Deconditioning

Energy conservation, a balance between physical (and mental) activity and rest may be both protective and restorative in the midst of, or after multimodal treatment for, head and neck cancer. Patients who overextend themselves describe compensatory periods of rest in the following days. Counterintuitively, an optimal amount of physical activity helps maintain energy rather than deplete it. Self-directed home-based programs or those tailored to patient needs include flexibility training or yoga.[7] Referral to a physical medicine and rehabilitation specialist can help customize a plan for recovery. Special emphasis on the flexibility of the neck and jaw can lead to fewer long-term consequences.

### Sleep Regulation

Too much sleep, too little sleep, or poor-quality sleep can account for a component of the fatigue experienced by head and neck cancer patients.[8] Pain and difficulty clearing oral secretions commonly interrupt sleep in head and neck cancer patients. Patients may even avoid sleep for fear of aspirating. Elevation of the head of the bed, or sleeping in a recliner may alleviate this component. Restorative sleep is an important component of the healing process.

### Hormonal Changes

Hypothyroidism is a well-known sequela of radiation therapy to the head and neck area and needs to be monitored in long-term survivors. Patients whose treatment is limited to surgery to the thyroid or parathyroid similarly need periodic monitoring and adjustment of thyroid replacement. The systemic influence of other hormonal changes, particularly testosterone in men and estrogen in women, may play a significant role in overall energy reserves that are depleted by cancer and its treatment.

### Anemia

The contribution of anemia to fatigue and its potential correction with erythropoietin-$\alpha$ has elevated anemia from a rarely considered state to its current prominence. Guidelines for the correction of anemia to physiologic levels are changing with greater use and outcomes evaluation in head and neck cancer survivors. Iron supplementation is often unnecessary and ineffective to correct fatigue. Correction of anemia may help improve QOL by allowing patients to remain active and functional.[9] Until recently, supplementation of endogenous erythropoietin had been thought to optimize outcomes, especially in QOL, but Henke found that patients with advanced head and neck cancer (T3, T4, or nodal involvement) who received 300 U/kg of erythropoietin-$\alpha$ with 60 to 70 Gy had achieved loco-regional control correlated negatively with the expression of erythropoietin receptors.[10]

### Depression

Low energy is a symptom of depression. A full psychiatric assessment of a patient with fatigue is an important facet of adequately addressing the symptom which may derive from or contribute to an underlying mood disturbance which is commonly experienced in head and neck cancer patients (please refer to Psychiatric Considerations section).

## NUTRITION

The head and neck cancer patient is particularly challenged within the greater cancer population when it comes to sustaining adequate nutrition. This is due in part to the physical location of the cancer itself and its proximity to the mouth and entire upper digestive tract. The long list of potential nutritional problems starts with the head and neck and works its way through the digestive tract for this patient population, who should be closely monitored for symptoms arising throughout treatment. Following a diagnosis, surgical interventions, radiation, and chemotherapy courses can and do have immediate and lasting impact on one's ability to take food and liquids orally.[11] Ongoing consultation with an oncology dietitian/nutritionist is essential in guiding patients throughout treatment and beyond.

### Screening and Assessment of Nutritional Status

Patients may or may not present with preexisting weight loss and/or malnutrition. Some patients enter into treatment reportedly asymptomatic. Others present with diminished ability to eat "normally" due to pain, dysphagia, or oral intake issues due to tumor location or previous surgery. Similarly, some patients will already have a percutaneous endoscopic gastrostomy (PEG) tube in place to facilitate adequate nutrition where a compromised oral route exists.

Patients initiating a treatment regimen of chemotherapy, radiation therapy, or a combination of both require screening and a comprehensive nutritional assessment as early as possible, ideally prior to the start of treatment. Clinicians can assist in screening a patients general nutritional status during an initial consult by noting the following and referring for nutrition intervention and follow-up as indicated:

Screening

- Age and visual exam
- Diagnosis, preexisting disease (i.e., diabetes), s/p head and neck surgery
- Weight/height—Underweight/obese/body mass index (BMI)
- Weight history—Usual body weight/weight change
- Oral symptoms: Ability to eat, dentition, dysphagia, mucositis, odynophagia, etc.
- GI symptoms: Nausea, vomiting, diarrhea, constipation, PEG
- Appetite and intakes (food recall for adequacy of calories/protein/fluids/nutrients)

(c) 2014 Wolters Kluwer. All Rights Reserved.

- Social support: Ability to shop/purchase/cook and store foods
- Lab values

It is common for patients to express a significant loss of appetite and even aversion to foods, thereby making it challenging to maintain adequate nutrition. Nutrition intervention and counseling can help the patient maintain an optimal weight, facilitate tolerance and healing from treatment, minimize symptoms, maintain or improve QOL, and decrease morbidity.

## Nutritional Needs

During a baseline (or initial) nutrition assessment, the dietitian/nutritionist estimates the patients nutritional needs and provides guidance and specific written information to the patient and their family and/or caregivers. At the minimum, the precachectic patient requires adequate calories and protein to facilitate weight maintenance and healing. Encouraging the patient to continue eating their preferred foods is stressed; however, adjusting food intakes to meet an individual's increased nutritional needs must also be a consideration. Undergoing chemotherapy and radiation treatment increases the bodies need for calories (kcal), protein, and fluids.[12] General guidelines are as follows:

- Patient remain on a regular, nutrient rich, weight-maintaining diet
- Caloric needs: 30 to 40 kcal/kg body weight
- Initiate meal replacement drinks BID in addition to regular meals (see Supplementation section)
- Protein needs: 1.3 to 2.0 g/kg body weight
- Fluid needs: Usually 1 cc per kcal; however, will be dependent on chemotherapy regimen, hydration status, and lab values.
- Modified food texture/composition based on symptom management and specific patient needs (i.e., soft, moist food, nonacidic, liquid diet)
- Enable patient access to foods (i.e., financial assistance, enteral food ordering)

It is worth briefly noting the myriad of symptoms that comprise cancer cachexia in this section about estimating nutritional needs. Cachexia involves metabolic abnormalities and inflammatory processes beyond what is seen in starvation, for example, the loss of lean body mass and production of cytokines. The addition of calories alone will not reverse the loss of weight and muscle mass in the cachectic patient. Clinicians are challenged in recognizing those patients at risk based on their symptoms. Researchers are seeking a consensus that defines cachexia[13] to facilitate best practice for its treatment,[14] and a variety of pharmacological treatments are being explored for efficacy.

## Nutritional Supplements

For patients undergoing chemotherapy and radiation to the head and neck, symptoms can appear gradually and worsen as treatment progresses. Clearly, this will affect the type and texture of food and liquids that can be consumed orally. It is critical to emphasize the additional intake of high-calorie, high-protein food and fluids prior to becoming symptomatic (see recommendations above). Early intervention with nutritional supplementation can reduce the chance of inferior outcome in patients at high risk for weight loss.[15]

Most cancer centers have a multitude of commercial meal replacement drinks at their disposal to provide to patients as samples, such as Ensure, Boost, Orgain, and the like. Most standard supplements have between 250 and 375 calories and between 9 and 15 g of protein per 8-oz can or box. Patients should be encouraged to test different brands and flavors for tolerance and palatability. If a supplement is too dense, it can be thinned with liquid or blended into a milkshake. Patients may augment their diet with supplements between meals or as meal replacement when solid foods are too difficult to consume. Ready-to-drink supplements are convenient to use if a patient has a long travel time to treatment as they do not require refrigeration prior to opening. They are also useful for patients lacking the energy to shop and/or prepare foods at home. Most grocery stores carry generic meal replacement drinks as well as a variety of prepared juice blends or protein-based drinks, which can contain as many calories and protein as commercial supplements.

## PEG Tube

Some head and neck patients may require a PEG tube during the course of their care (Fig. 10-1). This may be due to an extensive surgery or a compromised or unsafe oral route. The purpose of the PEG is to facilitate provision of adequate liquid food (enteral food) and fluid to the patients GI tract when oral ability is compromised, contraindicated, or significantly diminished. It is a clinical decision to determine whether a patient may require a PEG emergently during the treatment course or if it should be placed prophylactically based on the anticipation of significant

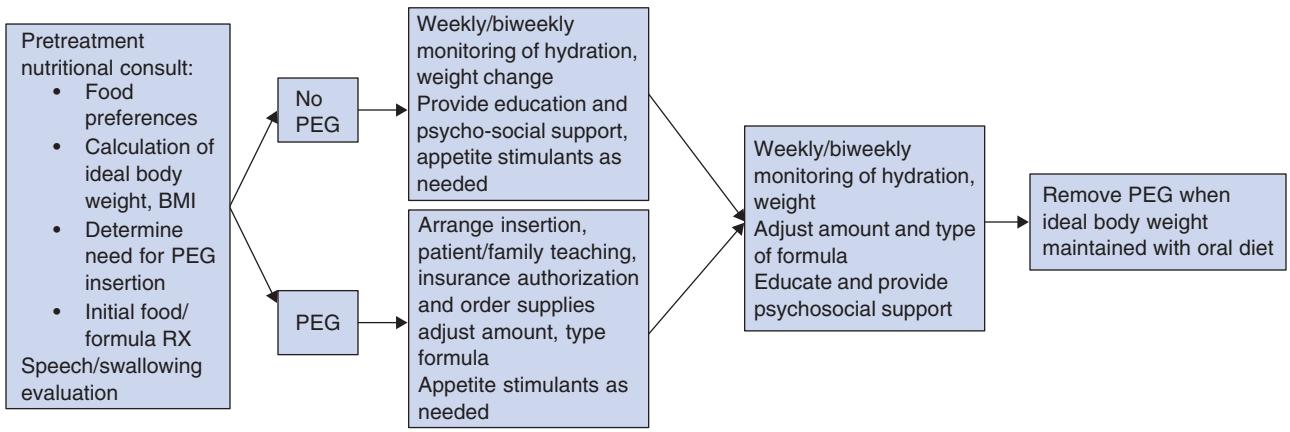

**FIGURE 10-1.** Nutrition assessment and intervention algorithm. BMI, body mass index; PEG, percutaneous endoscopic gastrostomies.

(c) 2014 Wolters Kluwer. All Rights Reserved.

toxicities. More research is necessary to inform physician behavior on whether prophylactic PEG tube placement is warranted in the treatment of head and neck cancer.[16] In any event, the PEG is a valuable tool for maintaining nutrition in patients whose symptoms prevent adequate oral intakes, thus risking significant weight loss. Such a group of patients requires specialized care from their health care team in regard to nutritional support. It is standard to initiate a bolus feeding with a 1.0 to 1.5 kcal/cc enteral formula that contains fiber. Formula selection is tailored to medical history (i.e., diabetes), and patients should be closely monitored for tolerance and appropriate usage. Method of feeding and formula can be modified as needed based on tolerance. PEG feeding frequency should increase as oral intakes diminish; however, oral intake of tolerated foods is encouraged to continue as long as the swallowing ability is safe.

### Counseling and Education

Nutrition education is an extremely helpful means for patients and their family to actively participate in their own care. Ongoing counseling throughout treatment enables clinicians to address issues as they arise. In oncology centers without an oncology dietitian on staff, patients should be screened and receive general nutrition advice from RNs and/or other clinicians. Simple handouts with age and education-level appropriate ideas for high-calorie/high-protein, soft, nonacidic food and liquids can be provided. Patients should be made aware of the normal symptoms they may experience and provided with the tools to minimize them, such as the appropriate diet modifications and/or medications. A combined approach of medications for symptom management and nutritional counseling is utilized.

If patient face-time is limited, develop a resource handout that lists recipes, cookbooks, and websites that are specific to optimizing nutrition through head and neck cancer treatment.

## PAIN ASSESSMENT AND MANAGEMENT

Pain is a significant problem that affects 50% to 80% of patients with cancer and disturbs overall QOL.[17] Yet cancer pain can be effectively managed in up to 90% of patients by following certain guidelines of pain management.[18] Pain in the head and neck patient can be disease-related or treatment-related or a combination of both.[17,19,20] Nearly all patients who receive radiation therapy to the head and neck experience pain at some point during treatment.[19,20] It is important to institute analgesics early in treatment in order to maximize patient comfort.

The assessment of pain should not only include the descriptive dimensions of the pain (location, intensity, quality, temporal features of onset and daily fluctuations, and aggravating and alleviating factors), but assessment of cause and effect on functioning. Once a cause has been identified, disease-modifying treatments may be offered, for example, the use of radiation for bony metastases. A description of burning or shooting pain, for example, can guide treatment toward use of adjuvant medications for neuropathic pain. A thorough initial pain assessment is important to ascertain past use of analgesics and effectiveness as the treatment of opioid-tolerant patients is significantly different than opioid-naive patients.[21]

Awareness of psychosocial aspects of the experience of pain is an important component of assessment: What is the meaning of pain for this patient and family? What cultural, religious, or spiritual dimensions are influencing perception of pain and attitudes toward treatment?[18] For minority patients with pain, significant barriers to effective pain management may exist, including beliefs about stoicism and difficulties communicating with physicians and other health care providers.[22] The ongoing assessment and management of pain includes the psychosocial impact of pain on the patient and family, quality and nature of distress, and the assessment of psychiatric comorbidities, for example, anxiety and depression, as well as history of substance abuse.

Pain management for patients with head and neck cancer should follow established guidelines, based on the original principles elucidated by the World Health Organization (WHO) and the Agency for Health Care Policy and Research (AHCPR).[19,23] These are briefly reviewed in Figure 10-2. Small doses of opioids, for example, morphine or oxycodone, available in either pill or liquid form, may often safely and effectively be used for the treatment of moderate pain.

Evaluation of pain should be part of every assessment as a standard of care.[24] The goal of pain management is to provide sustained comfort with few side effects and in this way to maximize patients' QOL. The treatment of cancer pain commonly includes the use of opioid analgesics, but other categories of treatment may also be included; for example, nonopioid analgesics and other adjuvant medications as well as interventional therapies, neurostimulation, and integrative medicine approaches.[24] The use of nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., naproxen or celecoxib) must be done cautiously due to safety concerns of gastrointestinal and cardiovascular risks.

Frequent reassessment of the analgesic regimen is important to evaluate efficacy and tolerability. Titration of current medications, rotation to other opioids, and/or addition of adjuvant medications may be required, especially if pain has nociceptive and neuropathic components.[18] For more severe and prolonged pain and for patients with history of substance-use disorders, methadone may be used. It is a long-acting opiate that can treat both the incident and neuropathic components of cancer pain. Methadone has a long half-life averaging about 24 hours, can be dosed in 6-to-8-hour intervals, and compared with other opiates is relatively inexpensive. Due to lack of active metabolites, it may be preferable in the setting of renal impairment.[24] In view of its prolonged half-life, as well as individual variation, familiarity with prescribing is essential, as full effects of the medication may be delayed for days and up to a week or more. Patient and family education is essential to reinforce the idea that methadone is not only for maintenance but also for withdrawal from heroin.

### Nonopioid Analgesics

Drugs used to treat the neuropathic component of pain are often part of the analgesic regimen, as nerve involvement is common in cancer pain and treatments. The use of gabapentinoids (gabapentin or pregabalin), glucocorticoids, such as prednisone or dexamethasone, as well as bisphosphonates for bone pain has been well studied.[24]

Patients may have inadequate pain relief due to lack of knowledge, fear of narcotic dependency, fear of acknowledging disease progression, or poor clinical management.[25] Lack of adherence to medication regimens has been studied, with evidence suggesting that around-the-clock (ATC) dosing is more frequently adhered to than as-needed (PRN) and that patients are not always prescribed ATC medications, according to practice guidelines.[26] They may also have comorbid conditions that exacerbate cancer pain. These issues need to be considered in order to achieve maximum patient comfort.

Postoperative pain is initially controlled with parenteral narcotics, administered by continuous intravenous route, patient-controlled analgesia (PCA), or by subcutaneous injection, converted to an oral analgesic via the nasogastric tube or by mouth. For patients who have been treated with opioid analgesics prior to surgery, informing the acute pain management team prior to surgery is important, as these patients may need more than usual amounts of postoperative analgesics. Mild pain should be treated by acetaminophen-based

(c) 2014 Wolters Kluwer. All Rights Reserved.

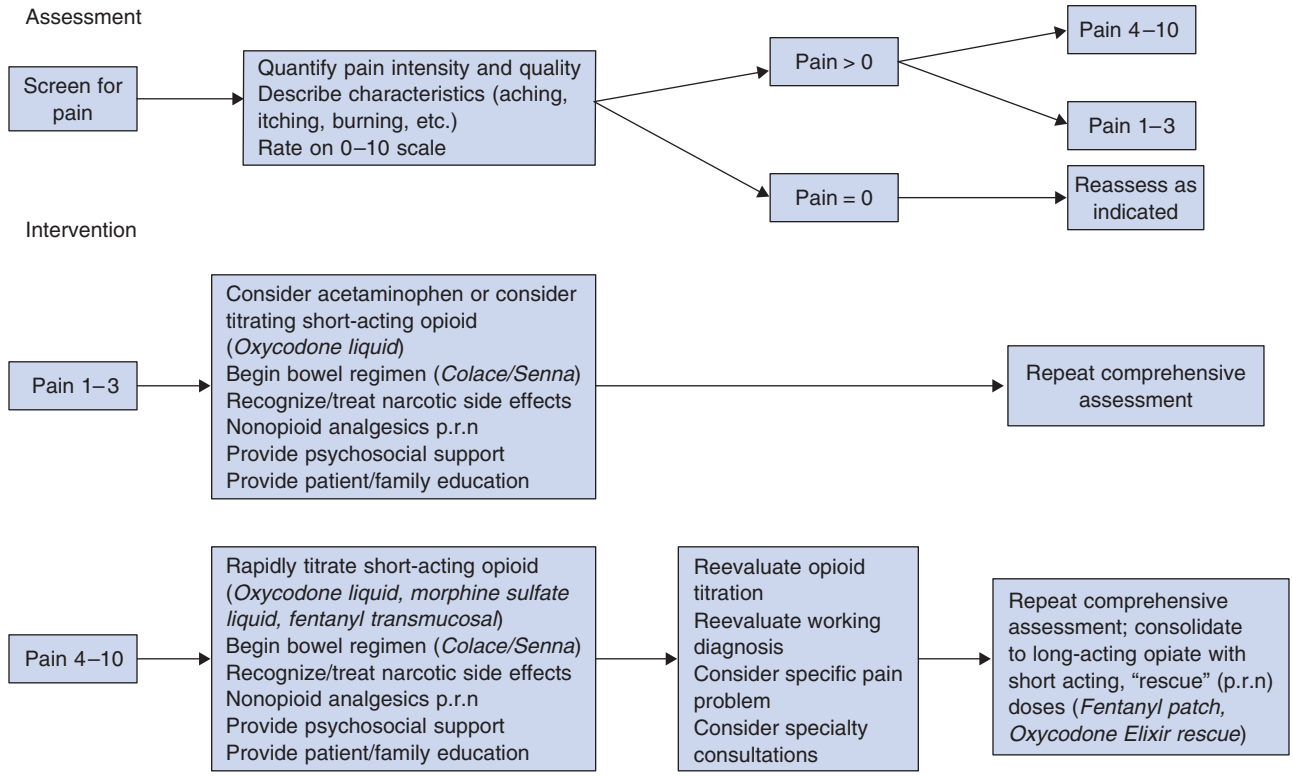

**FIGURE 10-2.** Acute pain assessment and intervention algorithm.

products, rather than aspirin or nonsteroidal anti-inflammatory medications, which can reduce platelet aggregation and impede healing or optimal cosmesis.

Moderate levels of pain can be initially managed with codeine-based analgesics,[27] or combinations of acetaminophen and opioids in small doses. Severe pain should be treated with regimens that include opioids (morphine, oxycodone, oxymorphone, or fentanyl-based regimen). With any class of opiates, analgesics with a short half-life should be prescribed based on their period of effectiveness, usually every 3 hours to establish needs, then converted to longer acting preparations orally or parenterally. Longer acting opioids are usually given every 8 to 12 hours, depending on patient response.

Because taking oral medications can be difficult during treatment of head and neck cancers, the transdermal fentanyl patch may be a good choice; however, this is not advised as initial therapy. Patients should begin with short-acting preparations to assess appropriate requirement and tolerance. Typical doses for the transdermal fentanyl patch range from 12 to 100 mcg per hour, but may be titrated up to 200 to 300 mcg per hour. A new patch is applied to clean, dry skin every 3 days; patients are given instructions on how to apply new patches, cautioned about dangers regarding extreme heat (e.g., sun exposure, fever), which can create irregular dose absorption, and educated about slow onset of action.

## Drugs for Breakthrough Pain

Often as regimens are being titrated, or due to the episodic nature of the pain, short-acting drugs are required in between the longer acting opioids. This can be either single-agent formulations, such as morphine, oxycodone, hydromorphone, or combinations with opioids and nonopioid. Fentanyl formulations, which are absorbed quickly, are now available in the form of lozenges, buccal tablets and patches, sublingual tablets, and nasal spray.[24] Regular breakthrough doses signal a need for higher doses of the long-acting preparation, unless the cause is expected to resolve quickly. The dose of the short-acting drug is generally roughly 5% to 15% of the total daily dose, though recommendations are to begin with the lowest dose of fentanyl preparations, as the effects of these medications may not be proportional to the fixed-dose scheduling.[18,24]

Assessment and treatment of severe and refractory pain may require continuous narcotic intravenous infusion delivered through a subcutaneous peripheral site or centrally through an indwelling central venous catheter. A patient-controlled analgesia (PCA) pump is commonly used, most often in hospital settings, because it delivers maintenance ("basal" rate) of analgesia plus a patient-controlled "rescue" dose for breakthrough pain. Morphine, hydromorphone, fentanyl, and methadone are common drugs used for PCA infusion. This method is used frequently for patients with end-stage disease.

Neural blockade approaches and implant therapies encompass a varied group of medications. Neurosurgical pain control for refractory pain and neuropathic pain in specific areas, for example, the brachial plexus, or for cancer-related facial pain may be effective, using chemical or radiofrequency neurolysis.[28]

With any opiate, care must be given to monitor constipation and sedation, as well as mouth dryness or urinary retention, which may require change in dose, preparation, or delivery route. When initiating any narcotic analgesic, patients are instructed to increase fluid intake by at least 1 L per day and to use a docusate-based stool softener liberally and daily to prevent constipation, often with addition of a laxative. Patients who can take medications by mouth should be instructed to take the medication with food or a supplement to minimize potential nausea.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Education of patients and family regarding pain management is important.[27] As health care has changed and patient care has shifted more to the outpatient area and to patients' homes, knowledge of how to manage pain must be provided to caregivers. Mode of action, expected side effects of pain medications, and implementation of a bowel regimen are important aspects of patient and caregiver teaching. Written and verbal instructions and information should be given.

## Risk Assessment and Addiction Issues

A routine barrier to adequate analgesic treatment is the fear that opiates of any class when used for cancer pain from illness or treatment will become addictive. Patients with a preexisting dependence or substance abuse themselves are the most vulnerable patients, and their management should respect both this predisposition and their need for adequate analgesia.[29] Ironically, patients who have been dependent on opiates, barbiturates, or benzodiazepines in the past likely will need higher than expected doses for pain relief. Such a contradictory pattern mandates good communication and very clear dosage parameters. This involves a minority of patients who are overrepresented among those with head and neck cancers who have a higher incidence of substance abuse. For the majority of patients without substance abuse histories, fears of addiction may interfere with using adequate amounts of analgesics. Reassuring patients that tolerance to a drug is not a sign of drug addiction is very important. Educating medical professionals about the important distinctions between drug tolerance, dependence, and addiction is also important as misconceptions about these terms and their meaning may be barriers to optimum prescribing of the most effective analgesic regimen.

For patients at risk for ongoing substance abuse, referrals to and collaboration with addiction specialists may be a necessary and important part of treatment. The use of additional methadone for pain management in patients who are already enrolled in methadone maintenance treatment programs for heroin addiction may be safer than using other opioids. Other risk assessment strategies may be employed, for example, dispensing smaller quantities with frequent monitoring and screening of urine for prescribed and nonprescribed drugs.

## Residual Pain

Neuropathic pain throughout the face, especially throughout the ear and the mandible, serves as a constant reminder of their cancer to a minority of patients who have undergone multimodal treatment. Often mechanical in origin with resulting nerve compression or irritation, these symptoms are treated with custom-designed oral appliances, exercises, or anticonvulsants. Patients benefit from ongoing assessment with speech and swallow specialists for exercises to maximize function in the face of more chronic, residual pain.

Tricyclic antidepressants and anticonvulsants have been shown to be effective in neuropathic pain syndromes and are a reasonable alternative depending on comorbidities.[30] Duloxetine, a serotonin reuptake inhibitor antidepressant, has been approved for use in diabetic peripheral neuropathy and may be helpful in cancer or chemotherapy-related neuropathic syndromes as well.[30,31] Regular evaluations by a dentist or oral surgeon is often indicated to rule out persistent or recurrent cancer.

# SKIN CARE

Managing skin reactions of patients undergoing therapy is crucial in minimizing patient discomfort and pain. Preventing breaks in treatment which may affect treatment outcomes for patients with head and neck cancer is another reason skin care management is so important. Though there is a paucity of evidence-based literature regarding care of the skin, some principles of skin assessment and management are clearly appropriate.

A radiation skin reaction is an expected, normal, and temporary side effect of radiation therapy. It is also the most frequently experienced side effect of radiation therapy, affecting between 87% and 90% of all patients receiving radiation.[32] The reaction is caused by the effect of radiation on the normal process of epidermal cell turnover. The mitotic ability of stem cells within the basal layer of epidermis is damaged by ionizing radiation. This decreases repopulation of cells which are then more rapidly shed.[33] This causes a thinning of cornified cells at the skin surface, making the skin more vulnerable to further radiation damage. An inflammatory response leads to release of serotonin and histamine and resulting edema. Increased blood flow to the injured tissues leads to erythema. Melanin rises to the surface of the skin, causing the characteristic darkening of the radiated skin.[33,34] Alopecia is common as the hair follicles are affected and is permanent after 5 to 6 weeks of treatment.[34]

Standards of care for managing radiation-induced skin reactions are based primarily on clinical judgment and expert clinician preferences. Randomized clinical trials are few and far between and have not demonstrated strong evidence for any particular skin care regimen.[33,34] Development of standards for skin care, based on what evidence is available, is strongly encouraged.

Assessing patients' skin before radiation begins is an important first step in skin care management. This involves evaluating patients' individual risk of skin breakdown during treatment, due to both patient-related and treatment-related factors (Table 10.1). The entrance and exit portals should be evaluated for obvious

breaks in skin integrity. Skin folds, lips, and ear lobes are at increased risk of breakdown, as is the thin, sensitive skin of the eyelids.

The acute reaction begins 2 to 3 weeks after starting radiation and continues 3 to 4 weeks after completion of therapy.[32,33] The effect of the radiation on the skin is cumulative and progresses from mild erythema through hyperpigmentation to dry desquamation (dryness, pruritis) and moist desquamation. Moist desquamation, in which loss of the epidermis leads to open, weeping skin, can occur in skin fold areas (ear lobes) and at the point where two treatment fields overlap. Moist desquamation places patients at risk for infection and fluid losses and can cause significant anxiety and discomfort.[33,34] Severe moist desquamation can lead to a treatment break, which may affect the overall effectiveness of radiation treatment.[35]

Providing clear, comprehensive patient education on skin care measure to minimize pain, decrease incidence of skin breakdown, and decrease infection is vital.[32,34] As most skin care measures are done by patients, it is important to obtain their active involvement. Detailed verbal and written instructions for skin care during treatment should be provided to patients. This should begin with a review of what patients may expect, a rough timeline of when each phase of the reaction will most likely appear, and the interventions for each phase. Changes in appearance in each phase as well as information on possible discomfort and pruritis should be described. Reassurance that any discomfort will be addressed promptly is also important.[32]

As previously stated, the evidence for skin care management is sparse and conflicting, without clearly proven "best practices." However, those skin care measures which *are* generally agreed upon are described in Table 10.2. Cleansing the skin within treatment fields involves washing the skin gently with warm water, using only mild soaps (e.g., Dove unscented or Basis soaps), and rinsing well before gently patting the skin dry.[36] A gentle shampoo (e.g., a baby shampoo) is also recommended.[37]

Moisturizing skin within the treatment field using a hydrophilic moisturizer (e.g., Aquaphorâ, Eucerinâ, aloe vera gels) is also generally recommended.[32,33,34,37] Patients should apply moisturizer two to three times per day (depending on risk of breakdown of specific tissue), being careful to wash any residual moisturizer off the skin before treatment. On any day on which treatment is not given (weekends, holidays), moisturizer should be applied after washing in the morning and again at bedtime. Patients should be instructed to prevent irritation of radiated skin by avoiding physical irritants (e.g., tight fitting clothing and shaving), chemical irritants (e.g., perfumes, cosmetics,

**TABLE 10.2 Skin Care Guidelines for Patients**

Skin that receives radiation therapy needs special care. Although a skin reaction is expected and temporary, it can sometimes be uncomfortable. The following tips address how you can help yourself (and your skin) during your course of therapy. These are only guidelines, and if you have any questions or concerns, you should speak with your nurse or physician.

**General skin care instructions**

Wash skin in the treatment field with a mild soap; Dove for sensitive skin or Basis is preferred.

Apply Aquaphor ointment to the skin immediately after each treatment and at bedtime. On weekends, holidays, or any day in which you do not receive radiation therapy, apply the ointment in the morning and at night.

Your skin should be free of any ointment during the treatment. If necessary, wash your skin immediately before each treatment.

Do not apply any other skin cream, makeup, after-shave, or cologne to the area being treated. If you are uncertain about this, please speak with a nurse.

Avoid constrictive clothing, starched collars, tight ties, and other irritants to the skin during your course of radiation therapy.

Always use a sunscreen, SPF-45, when in the sun for >10 min, and wear a face-shading hat when possible.

**Dry desquamation (flaky, itchy skin)**

Increase frequency of moisturizer, and decrease use of soap.

Cornstarch may be used on shoulders and back. Do not use in moist skin folds.

Topical 0.5% hydrocortisone cream applied with Aquaphor twice daily may reduce itching.

Benadryl 25–50 mg may help at bedtime but will increase oral dryness.

**Moist desquamation (moist, blistered skin)**

Goals are to prevent infection, reduce pain, and prevent treatment breaks.

Keep skin clean but minimize use of soap and water when possible.

Air-dry after washing. Fanning may feel cooling.

Continue with use of moisturizer unless directed to stop use. You may add frequent soothing and cooling applications of refrigerated, alcohol-free aloe vera gel throughout the day.

Silvadene ointment may be prescribed. Use as directed by your team.

You may be given nonstick dressings to cover the affected area to prevent clothing from sticking.

If you are uncomfortable, ask your team for medication to reduce discomfort.

Remember, a skin reaction is expected, temporary, and reversible. Skin commonly takes 2–3 wk to fully recover.

If you have a fever, or notice foul-smelling discharge or increased discomfort, speak with your medical team immediately.

(c) 2014 Wolters Kluwer. All Rights Reserved.

deodorants, and moisturizers other than those recommended), extreme heat or cold, and prolonged, direct sun exposure.[32–34]

Though study patients were women receiving breast irradiation, a recent prospective, double-blinded, placebo-controlled study was done to compare effectiveness of three different skin care products versus placebo in reducing the incidence of radiation-induced skin reactions.[38] Products evaluated included Aquaphor ointment, Biafine RE cream, RadiaCare gel, and a sterile water mist—the placebo. Despite a more-than-adequate sample size and well-executed blinding of researchers, the study revealed no product to be more effective than a sterile water mist in preventing skin reactions.[38] The study did support the evidence that patients prefer using some type of product (ointment, cream, or gel) to water.

Several RCTs of the efficacy of aloe vera gel[39–41] have revealed no statistically significant advantage of aloe vera over routine skin care. Biafine has not been shown to provide a statistically significant advantage over cheaper, more available products,[42] and in a more recent study comparing Biafine with calendula (marigold extract) crème, Biafine was found to be less effective.[43]

Calendula and hyaluronic acid may be somewhat effective in reducing the incidence of radiodermatitis,[44] but more studies are needed to support this. Interestingly, a study done by Wells[45] demonstrated no statistical differences in skin reaction of patients using aqueous creams, sucralfate creams, hydrogels, versus no cream/gel at all. Statistically, increased skin reactions were seen in smokers, patients getting chemotherapy, and patients getting bolus treatments (additional therapy to a specific area).

During radiation therapy, patients' skin is assessed for the degree of skin discomfort, presence of scaling or pruritis, tissue breakdown, or moist desquamation. Patients receiving concomitant chemotherapy, cranial radiation, or nasopharynx radiation may note peeling of the scalp, pruritus, and alopecia. Such patients are instructed to use a mild shampoo and to frequently apply the recommended moisturizer to the scalp.[46] Any signs and symptoms of skin infection (fever, increased pain, purulent, or foul-smelling discharge) should be evaluated promptly, drainage should be cultured if present, and antibiotics should be prescribed.[32,33,46] Skin care continues after radiation therapy has completed. This includes assessment of skin reaction resolution, reinforcement of the need for lifelong prevention of further skin injury by use of sun block (sun protection factor [SPF]–45), and the avoidance of extreme heat or cold to skin in the treated area.

Long-term effects of radiation therapy on skin are noted months or years after completion of radiation therapy and may include thinning of epithelium (with increased risk of skin injury), telangectasia, loss of sweat and sebaceous glandular function, and hyperpigmentation or hypopigmentation. These effects are difficult to predict and are often more related to individual patient characteristics than to radiation dose or technique.[47]

# MUCOSITIS MANAGEMENT

As described throughout this text, treatment of head and neck cancers has evolved to more aggressive therapies with improved outcomes.[48] The incidence of mucositis in patients receiving head and neck cancers is 80%.[48] Mucositis is an expected side effect of radiation therapy to the head and neck. Grade 3 and 4 mucositis causes severe pain, dysphagia, and weight loss due to inability to eat. Mucositis often leads to psychological distress, isolation, fear, depression, and overall decrease in QOL.[49] Profound weight loss and pain may lead to treatment modifications with possible negative implications on treatment efficacy, though research is urgently needed to properly quantify this.[35,48]

A basic understanding of normal oral mucosa is crucial to understanding the changes present with mucositis.[50,51] The oral mucosa overlies connective tissue and bone and consists of squamous cell epithelium. The dorsal tongue is specialized mucosa as it contains the sensory nerves responsible for taste. Masticatory mucosa lines the gums and the hard palate. It is tough and is keratinized, which differs from thinner, nonkeratinized mucosal lining. It covers the inside lips, cheeks, soft palate, and underside of the tongue. As the cells on the surface slough off, they are replaced by new cells generated by the stem cells directly above the submucosa, which contains the blood and nerve supply for the cells. This turnover takes approximately 2 weeks for the lining mucosa and slightly longer for the masticatory mucosa.

## Pathophysiology of Mucositis

The pathophysiology of mucositis is the subject of much recent research and is defined today as a multiphased process.[50,51] The first or "initiation phase" begins immediately following a tissue insult such as mucosal exposure to radiation therapy or chemotherapy. During the initiation phase, the epithelial cells DNA is damaged and ultimately leads to cell death. Two to 3 days later, the "upregulation and message generation phase" begins. During this phase, biological switches such as nuclear factor-$\kappa$B (NF-$\kappa$B) are turned on. These factors upregulate genes which then generate increased amounts of cytokines. During phase II, the radiation and chemotherapy may also directly affect cells by increasing the rate of apoptosis of mucosal cells. As a result of these processes, the mucosa begins to thin, redden, and become painful.[50]

During phase III, or "amplification and signaling phase," direct damage to the oral tissues continue, mainly, below the level of the mucosa. TNF-$\alpha$ activates NF-$\kappa$B and other cytokines which cause more proinflammatory changes with increased activation of TNF-$\alpha$. Thus, a feedback loop is formed. This results in the fourth phase of the mucositis process, "tissue ulceration." This phase is clinically obvious, with ulcers frequently extending downward to the submucosa from the epithelium. Pseudomembranes may cover the lesions or they may be open with exposure of nerve endings and increased pain. Bacteria often colonize the ulcerations, and in neutropenic patients, infections requiring hospitalization may occur.[50,51] From initiation to ulcer formation takes 10 to 15 days. The fifth and final "healing phase" begins 14 to 21 days after mucosal assault. The epithelial cells near the ulcer move to gradually fill in new tissue, and normal flora of the oral cavity is restored. Unfortunately, the layers beneath the surface do not ever fully recover and are vulnerable to further injury as the radiation continues or chemotherapy is readministered.

Assessment of each patients' risk of severe mucositis begins at consultation, when both patient-related and treatment-related factors are evaluated.[52] A list of risk factors is provided in Table 10.3. Reducing risk factors when possible can reduce mucositis severity during treatment.[53] For example, patients who are malnourished and underweight at consultation should have a feeding tube placed and intensive weight-gaining support prior to initiating treatment. Evaluating each individual's risk early allows timely interventions and pinpoints patients needing intensive support.

## Mucositis Assessment

The need for consistent assessment and documentation of mucositis is obvious for both clinical practice and reporting of research outcomes. The assessment tool should be precise, objective, validated, and reproducible as well as sensitive to the subjective components of mucositis.[53] A review of existing oral mucositis measurement tools by Steve Sonis and colleagues[54] demonstrated variability among those used most often. The NCI-CTC, WHO,

Reduced-volume salivary tissue, impaired function of saliva

**Treatment factors**

Concomitant chemotherapy

Chemotherapy agent (5-fluorouracil [FU], methotrexate, and etoposide cause increased mucositis)

Chemotherapy dose (high-dose regimens lead to higher rate and degree of mucositis)

Radiation dose, duration of treatment, and site of treatment

More sensitive—pharyngeal wall, soft palate, tonsillar pillars, buccal mucosa, lateral tongue, and floor of mouth

Less sensitive—hard palate, gingival ridge, and vocal cords

Surgical procedures resulting in altered anatomy (transplanted tissue responds to radiation as it would in original body site)

Metallic dental work or surgical plates will increase "scatter" radiation to proximal mucosa

*Source:* Modified by Carper E. Department of Radiation Oncology, Continuum Cancer Centers of New York, 2007, with permission.

**TABLE 10.4 Patient Self-Care Regimen for Oral Hygiene**

Rinse your mouth and gargle 4–6 times a day before and after meals. Use the following solution:

1 qt water

1 tsp salt

1 tsp baking soda

Use a soft toothbrush or toothette and mild toothpaste (e.g., Biotene, or Arm and Hammer baking soda toothpaste) after every meal and at bedtime. Be sure to clean your dental appliance or dentures at this time.

Continue flossing gently if this is your habit. If you do not normally floss, do not begin flossing during radiation therapy.

Avoid any mouthwashes containing alcohol.

Use a lip moisturizer frequently. Be sure to remove before your treatment!

Wear your fluoride trays (without fluoride during your treatments if ordered by your team).

Use a humidifier or vaporizer in the bedroom. Warm and cool mists are equally effective; the water comes to room temperature by the time it reaches you. Whichever "steamer" you choose, it should be cleaned *daily* and filled with *fresh* water. Position it to direct the spray toward your head. This humidifies secretions that thicken during radiation.

Avoid any oral irritants: spicy foods, scratchy-textured foods (pretzels), *any* type of smoke, and *all* alcohol.

Try to minimize talking by creating a "phone call tree" (updating one to two people a day and asking them to pass on this information to others you designate). Talking can be painful and exhausting.

*Source:* Developed by Carper E. Department of Radiation Oncology, Continuum Cancer Centers of New York, 2002, with permission.

and RTOG scales are commonly used in the clinical arena and in reporting research. These tools combine assessment and measurement of symptoms (pain), signs (erythema), and functional changes (inability to eat solid foods) in order to grade mucositis, with grade 1 being mild mucositis, grade 2 being moderate, grade 3 being severe, grade 4 being life-threatening, and grade 5 being death. Whatever tool is chosen, a systematic assessment and documentation of mucositis should be done with each patient encounter. Interventions are then made based upon grade, individual patient characteristics, and comorbidities.[53–55]

## Mucositis during Radiation Therapy

Mucositis usually begins about 2 weeks after starting radiation therapy and continues with symptoms for 4 to 5 weeks after completion. Mucositis results in several tissue effects such as redness, swelling, tenderness, pain, difficulty swallowing, and hoarseness. These symptoms resolve once the acute mucosal affects have healed.[55]

Evidence-based guidelines for care of patients at risk for mucositis and for treating mucositis are scarce.[12,56] Minimal research has been done to determine the most effective oral care regimen for patients. Studies have demonstrated, however, that a systematic, consistent mouth care regimen is needed throughout radiation.[56,57] Care focuses on promoting patients' oral hygiene to minimize risk of infection, providing measures to treat infection should it occur, and increasing patients' comfort. Patients are taught a self-care regimen that includes the key elements listed in Table 10.4, which is individualized as needed.

Patients are instructed to reduce irritation of mucous membranes during treatment by avoiding chemical irritants such as tobacco, alcohol, commercial mouthwash, spices (e.g., pepper, chili powder, horseradish, curry powder), and citrus fruits and juices (e.g., orange, lemon, lime, grapefruit, pineapple, and tomatoes). Physical irritants to be avoided include the extremes of hot or cold foods, hard or coarse foods (e.g., toast, crackers, raw vegetables, potato chips, pretzels), and ill-fitting dentures. Dietary changes to cool foods and fluids (e.g., ice pops, ice cubes, ice cream, sherbet, and yogurt), a pureed or liquid diet, and increased use of nutritional supplements will be helpful during the course of radiation.[51,56,57]

## A Spray and a Weigh . . . Every Day

As treatment strategies have escalated in intensity, so should symptom management efforts. A daily spray of normal saline, delivered under low pressure, along with weighing patients daily helps maximize support of patients receiving intensive treatment for cancers of the head and neck. The spray cleanses the mouth, liquefies mucus, and provides comfort to patients. During this spray, a gentle flow of saline is directed to all surfaces of the oral

(c) 2014 Wolters Kluwer. All Rights Reserved.

cavity and oropharynx. This continues until the patient's mouth is clean and moist. Patients with oral cavity, oropharynx, and nasopharynx cancers may benefit most from this regimen, as the extent of irradiated mucous membranes can be quite extensive.

An additional benefit of the daily oral spray is that it provides an opportunity for an assessment of the patient's physical, nutritional, psychosocial status, and a determination of any pain management or dental needs. This also provides a perfect opportunity to reinforce the recommended self-care regimen which enhances patient learning.[57,58] In addition, the oral cavity is inspected for signs of infection. *Candida albicans,* evidenced by white patches, is the most common cause of infection in patients receiving head and neck radiation.[13] If patients develop *Candida* infection, an appropriate antifungal medication (such as fluconazole) should be prescribed.

## Prevention of Mucositis-Related Treatment Break

Patients with moderate to severe mucositis need intensive symptomatic support. They are at high risk for malnutrition, weakness, or pain to a degree that may necessitate a treatment break, with a resultant possible decrease in treatment effectiveness. Early identification and management of mucositis is critical. Intensive nutritional support, early placement of a PEG, and heavy reliance on supplements is often necessary and common, especially for patients receiving concomitant therapies. Usually a combination of both systemic pain medications and local anesthetics are utilized throughout the treatment course, with timely titration of medication and an appropriate bowel regimen employed.[59,60] For an example of a pain medication regimen used for patients receiving radiation therapy, see Table 10.5.

## Local Analgesia

Topical anesthetics for relief of mouth and throat pain may be indicated. This is especially true for patients receiving radiotherapy. Patients need careful instruction on how, where, and when to apply topical medications. A solution composed of equal parts of 2% viscous lidocaine (Xylocaine), diphenhydramine (Benadryl), and aluminum hydroxide–magnesium hydroxide–simethicone (such as Mylanta or Maalox) often is helpful in relieving generalized mouth and throat pain. Patients are instructed to swish 10 to 15 mL of this solution in their mouths for 30 to 60 seconds, to gargle, then to spit out the solution (oral fields) or swallow (hypopharynx, tongue, and larynx fields). This short-acting anesthetic should be taken before meals, at bedtime, and as needed up to eight times in a 24-hour period. Overuse could cause cardiac arrhythmia.

Ulcerations and discrete areas of inflammation, such as scatter-related (from dental fillings) lateral tongue lesions, are often very painful. An ointment containing benzocaine, which may be obtained without prescription, may be helpful in providing a protective film over the area to promote healing and provide near-immediate acute relief of pain. Patients are instructed to apply the ointment directly to the inflamed area by using a cotton-tipped applicator or their fingers. Again, patients must be cautioned not to overuse this cardiac stimulant.

When radiation therapy is complete, reinforcement of self-care measures that promote oral comfort and adequate nutrition is essential. Often, mucositis escalates for 1 to 2 weeks after completion of radiation. Typically, resolution of mucositis is complete within 6 to 8 weeks, and patients begin to resume normal activities of speaking and eating. Patients are informed that prolonged use or stress of the voice may lead to hoarseness even months after treatment, and they are encouraged to avoid smoke and fumes. A slow and gradual increase in texture

**TABLE 10.5 Sample Medication Regimen for Mucositis**

| Weeks 1–2 of treatment | | Weeks 3–7 of treatment and for 4–8 wk following completion of radiation therapy |
|---|---|---|
| Topical anesthetic (Orobase with Benzocaine, viscous Xylocaine 2% jelly) | | Actiq transmucosal "lollipop," 200–600 μg, q 3–4 h prn, *or* |
| Acetominophen 650–1,000 mg, ibuprofen 400–600 mg, q 4–6 h prn | | Oxocodone elixir, 20 mg/mL, 0.25–0.5 mL, q 3–4 h, prn, *plus* |
| Magic mouthwash–*dilute* formula swish/gargle/expectorate prn, no dose limits | | Fentanyl patch, 25–100 mcg, q 72 h |
| 1,000 mL | Normal saline for irrigation | Bowel regimen: |
| | $NaHCO_3$ | Colace, two capsules/liquid equivalent, t.i.d. |
| | Benadryl liquid | |
| | Viscous xylocaine 2% | Senakot, 2–4 tablets/liquid equivalent, qhs, prn |
| Or | | |
| Magic mouthwash–*full strength* formula | | |
| Use before meals, q hs, up to 8x/day maximum | | Fleet oil-retention enema, wait 4–6 h, then regular Fleet enema, q 3 d as needed or |
| 300 mL | 100 mL Mylanta | |
| | 100 mL Benadryl Liquid | |
| | 100 mL Viscous Xylocaine 2% | Glycerin suppository, wait 4 h, then Ducolax suppository |

of foods (from liquid to soft to regular) and the cautious addition of seasoned foods is advised. Pain medications and stool softeners are tapered and discontinued as soon as possible.

## Mucositis—Pharmacologic Interventions

Shih and colleagues presented a thorough review of treatments currently used for mucositis caused by radiation and chemoradiation treatment.[47] As previously described, daily rinses of a mixture of water and salt (± sodium bicarbonate) are commonly used due to their cleansing and soothing abilities. Systemic narcotics afford relief from pain. Other medications recently studied for ability to minimize mucositis are categorized in one of four types: antimicrobial, coating, anti-inflammatory, or cytokine-like.[47]

The only intervention with enough evidence for practice recommendation is use of a bland rinse as previously described. Most agents commonly used for treatment of mucositis lack the clinical trial support for treatment recommendation and are described as "effectiveness not established."[47]

This category includes antimicrobial agents and Benzydamine HCl (BZD), a nonsteroidal agent with analgesic, antimicrobial, anti-inflammatory, and anesthetic properties, which work by inhibiting growth of bacteria for the possible result of less bacterial and fungal infections.[47] Not yet approved for use in this country, BZD is commonly used in Europe. Only six studies utilizing randomization and placebo control have been reported thus far in the literature. Results are mixed and are based on a limited numbers of subjects. A recent trial comparing efficacy of BZD and chlorhexidine for preventing and treating mucositis revealed no significant difference.[56,61]

Sucralfate oral suspension has been shown to significantly diminish gastric ulceration and is the coating agent most studied for efficacy in minimizing radiation mucositis. Early studies showed a trend toward decreased mucositis in patients who used sucralfate. However, out of eight randomized clinical trials, only one showed a reduction of mucositis in patients using sucralfate solution.[62] A newer coating product is Gelclair. Gelclair is a concentrated oral gel. It is rinsed and gargled in the mouth for as long as possible to maximize coating of all oral tissues. It forms a protective barrier that reduces pain by soothing tissues. It is used three times daily or as needed.[63] Early studies are promising, but larger, randomized, placebo-controlled studies are needed to establish efficacy.

Exciting, emerging research is being conducted with historically defined nutritional agents. One such agent is glutamine, an amino acid rich in nitrogen believed to be important in cancer cachexia.[64] Savarese and colleagues[65] describe the biology and metabolism of glutamine and then describe possible therapeutic used of glutamine in preventing radiation-induced mucositis. In their small, randomized trial of only 17 patients, those given glutamine swishes reported less objective and subjective signs and symptoms of grade 3 or worse mucositis.[65]

Other agents under investigation include GM-CSF, silver nitrate, topical morphine, and corticosteroids. Studies using less traditional agents are underway such as capsaicin in the form of a pepper candy, chamomile, vitamins, and other antioxidents. Cryotherapy in the form of ice chips and popsicles is being evaluated for radiation-induced mucositis, and honey is also being studied as an oral bacterial modulator.[51]

Palifermin or keratinocyte growth factor (KGF) is another agent under investigation. KGF works by stimulating growth of cells at the surface of the mouth and repairs damage done to the mucous membranes by chemotherapy or radiation therapy. It has proven effect in transplant patients.[25] Studies are ongoing for its efficacy in minimizing radiation-induced mucositis.

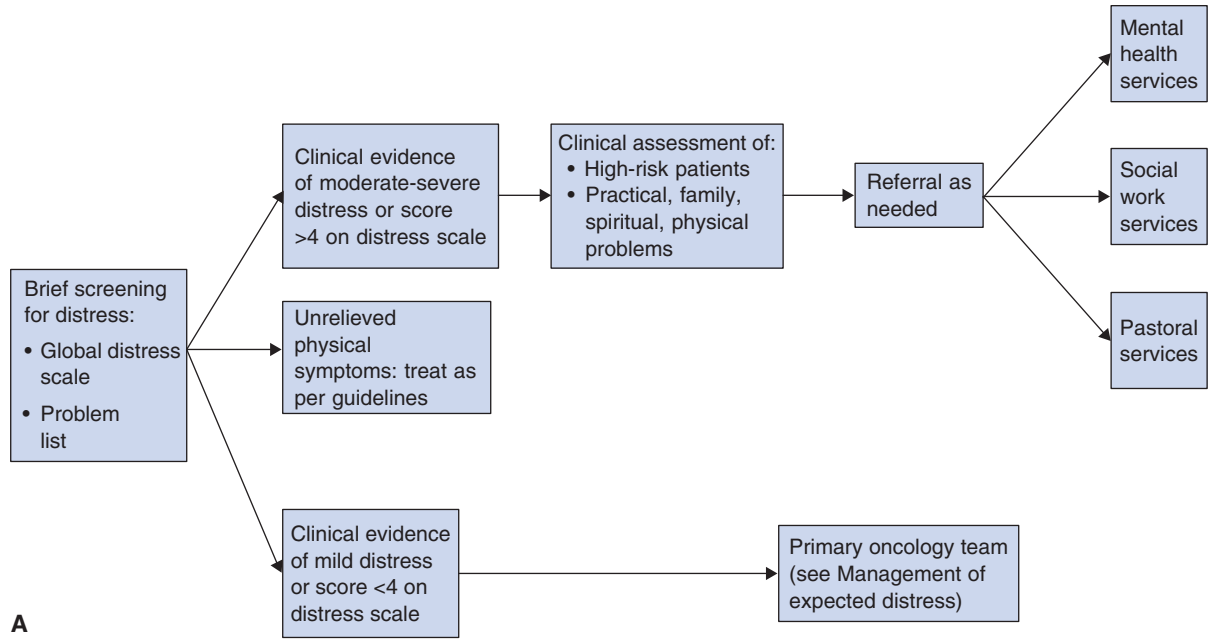
# PSYCHIATRIC CONSIDERATIONS

The head and neck cancer population is prone to the general psychosocial challenges that most cancer patients face in adjusting to their illness Fig. 10-3. The disease and its treatment pose psychological distress through interruption to routine daily activity, disturbance in lifestyle, and impairment that prevents engaging in usual interests. Such disruption can lead further delay in functional rehabilitation. Relationships may suffer as patients are faced with a changed role involving increased dependence on those who serve as caregivers, further complicated by its being imposed rather than willfully chosen. Symptoms related to the disease such as fatigue and loss of appetite (anorexia), cause disability, as do other side effects stemming from treatment including radiation therapy. Social issues, not the least of which are financial concerns, are encountered when stricken by the practical losses sustained. Difficulties are encountered over the course of the illness when facing complicated decisions regarding treatment, the overall challenge of resuming self-care activities after its completion, and uncertainty about disease progression. Spiritual needs may be faced when confronting mortality with the threat of death.

Disturbance in psychosocial functioning and psychological distress are reported by many head and neck cancer patients, with the main symptoms being worry, anxiety, fatigue, depression, and mood disturbance.[66]

## General Cancer-related Psychosocial Issues Applied to Head and Neck

Head and neck cancer patients have the highest rate of suicide, depression, and anxiety among cancer patients.[67,68]



Depression and anxiety may arise from impairment experienced by side effects of treatment for head and neck cancer.[69] A major challenge in treating cancer is preserving form and function while pursuing oncologic control. "Organ preservation" is a particularly important consideration for treatment of all head and neck cancers even as it varies based on subsite because crucial functions, including but not limited to speech and swallowing, are often at risk.[70] Effects of the cancer and its treatment on these functions may be as significant as the cancer itself in impacting QOL.

Pain is a very common and emotionally distressing occurrence in patients with head and neck cancer and, if it is not a presenting symptom, frequently results from treatment which often includes a lengthy course of radiation therapy. By the midpoint of radiation treatment, for head and neck cancer, it has been found in one study that all patients experience pain which, furthermore, can persist in some for up to 6 to 12 months. The experience of pain, particularly of such long-lasting nature, is complex, involving psychological responses through direct interaction across emotional, cognitive, and behavioral dimensions.

## Head and Neck Cancer–specific Issues

Head and neck cancer introduces unique psychosocial challenges and adaptive demands. Behavioral and lifestyle factors play an important role in the etiology of head and neck cancer. As such, patients who develop head and neck cancer may have a high prevalence of preexisting psychosocial issues. Individuals with tobacco dependence are at high risk for developing squamous cell carcinoma of the head and neck, as tobacco use is linked to approximately 85% of cases. The established link between alcohol use disorders, as well as cigarette smoking, and the development of head and neck cancers[71] presents an additional complicating factor and challenge to patients in this population possibly needing to deal with addiction issues and self-blame

along with anxiety, depression, pain, and other physical symptoms directly related to their cancer. Increased number of sexual partners and engaging in promiscuous sexual activity or risky and unsafe sexual practices are tied to a variety of psychosocial issues and psychiatric conditions and associated with head and neck cancer as sexual activity and the number of sexual partners have been associated with human papillomavirus (HPV) and with squamous cell carcinoma of both the oral cavity and the oropharynx. While HPV-associated cancers tend to have an overall better response to treatment and prognosis compared to head and neck cancers in general for a variety of hypothetical reasons, including the psychosocial profiles of such individuals as well as the otherwise relatively robust medical condition of the individuals afflicted given their relatively young age, this latter factor

yields a host of psychosocial concerns related to suffering serious illness in youth.

Head and neck cancer is considered to be highly traumatic and, stemming from this, yields profound psychological morbidity.[66] This patient population faces a unique set of obstacles including disfigurement and functional impairment. As a result, head and neck cancer has an enormous impact on the QOL of patients.[69] The tumor and the consequences of its treatment can significantly impact one or more of the several important functions that the oral cavity, oropharynx, nasopharynx, larynx, and hypopharynx normally serve. Alteration of functions, including mastication, speech, taste, swallowing, salivation, and oral sensation, as well as negative view of body image can be devastating to patients.[66,72] Head and neck cancer patients are prone to treatment-related side effects, which make their care complex.[67] Despite regimens of concurrent radiation and chemotherapy and targeted-radiation delivery using intensity-modulated radiation therapy and other advances to reduce collateral damage to normal surrounding tissue while maximizing dosage delivered to the tumor volume, side effects from the treatments, particularly radiation, can be life altering. These often include, but are not limited to, pain that may become chronic in nature, including oral pain and pain when swallowing (odynophagia); difficulty swallowing (dysphagia) from fibrosis of subcutaneous tissues; and, occasionally, stricture formation. Other feeding problems associated with difficulty eating, drinking, and chewing that may be related include impaired jaw opening (trismus), possible substantial and permanent dry mouth (xerostomia) resulting from reduced saliva production, and taste distortion (dysgeusia), which may be diminished (hypogeusia) or, rarely, lost (ageusia). These can lead to long-term feeding-/gastrostomy-tube dependence. Alterations in patterns of breathing and speech (dysphonia) such as hoarseness, diminished production (hypophonia), or, rarely, loss of voice (aphonia), may result from airway problems or from radiation-related fibrosis or edema. Other problems include earache (otalgia), mouth sores, and the general problems of hair loss, nausea, and fatigue, as well as skin rash or changes, and problems related to sexual adjustment. All of these problems can become more intense with continual treatments.[73,74] Dysfunction or loss of the sense of smell is not commonly reported, and tinnitus or disturbance in hearing is not reviewed prominently in the literature. Depression and anxiety often experienced by head and neck cancer patients can result from these treatment-related side effects.

Head and neck cancer also differs from some other cancers in that both the tumor and side effects of treatment, such as skin reactions or surgical grafts, are often visible, and, as such, can greatly affect body image.[74] Additionally, undesirable cosmetic outcomes can occur from chronic tracheostomy dependence, face and neck incisions, and whole-organ extirpation (i.e., eyes, nose, larynx, tongue, and mandible). Changes to body image as a result of the cancer and disfiguring treatment can give rise to diminished self-esteem and sexual functioning.[66,75] Facial disfigurement can lead to shame and social avoidance that compromises QOL. The ability to socialize can also become significantly challenged with marked impairment in eating and speaking. Patients often need to stop working during treatment, presenting

(c) 2014 Wolters Kluwer. All Rights Reserved.

an additional financial burden to themselves and their families. When head and neck cancer patients require tracheostomy and/or feeding tubes, their daily functioning is impacted by having to adjust to this markedly altered and challenging way of living. Despite the numerous side effects associated with these cancers, there is limited research on the psychological and psychosocial implications of head and neck cancer.[69]

## Eating and Drinking

Head and neck cancer and side effects from its treatment including dysgeusia, xerostomia, dysphagia, odynophagia, oral pain, and trismus cause a decreased ability to eat by mouth or in a manner comfortable in typical social settings. Forced change in diets to meet nutritional needs in the context of change in tolerability of foods, often entail blended or bland foods or supplements, and problems with oral intake may present hazardous nutritional deficits requiring bypassed feeding through gastrostomy tubes, presenting a substantial challenge to patients within a basic element of lifestyle and social interaction. Patients may feel uncomfortable, awkward, or embarrassed in these settings, as a result of self-consciousness about their eating, which has become mechanically compromised as a result of difficulty with jaw opening, abnormal anatomy of the oral cavity, or altered and decreased sensation of mouth structures, and, once taken for granted as effortless, is now a cumbersome and onerous task. Patients often experience altered taste sensation which, compounded by dry mouth and hyposalivation, reduces the enjoyment formerly associated with eating and drinking. Patients may remove themselves from the family meal, yielding increased isolation that risks exacerbating mood symptoms and a sense of despair at a time when they are most in need of social contact and support. These impairments in behavior so essential to livelihood and survival often represent a substantial loss to the patient on physical, psychological, and social levels. Persistent encouragement and support from friends and family is helpful in dealing with these difficulties. Patients may emerge with a new appreciation for such basic elements of life.

## Speech

In a similar vein, verbal communication obviously plays an important part in one's day-to-day functioning. As such, a profound physical loss is understandably difficult to face emotionally when surgical treatment of head and neck cancer leads to vocal alteration. If speech is maintained but distorted, the ability to engage in routine conversation may still be dramatically impacted. The diminished capacity to accurately convey emotions through voice tone may be experienced as exceedingly frustrating to the patient. The vocal deficit may only affect special circumstances such as speaking before an audience or singing, but may nonetheless be markedly impairing. In the case of total laryngectomy, speech can be produced though artificial means, and communication may still be achieved in other ways and through alternative or assistive devices, as simple as a laptop computer, though the adjustment curve is quite steep. Positive predictive factors in speech rehabilitation include age, marital status or the presence of an external support system, and engagement in problem-solving behavior.[69] Understanding and patience are needed to assist the patient in addressing this difficulty.[69] If presented with the scenario, choosing between the latter two vital functions is obviously a very grave process.

## Sexual Adjustment

Due to concerns about body image and facial disfigurement as well as odor, sexual functioning can become a major issue for head and neck cancer patients and their partners or spouses. These problems may interact with additional factors affecting sexuality in head and neck cancer, including alcohol abuse, aging, depression, and anxiety. Interest in sexual activity may decline or the pleasure derived from it may be markedly diminished. Abatement or complete termination of sexual relationship is a common occurrence in couples in which a member has head and neck cancer. This issue can itself become parasitic to a relationship in need of healing from strains to which it was exposed in going through cancer treatment. This issue is of particular vulnerability because the tendency to suffer in silence without seeking help is reinforced by feelings of shame that may already be present. It is especially important for health care providers to prompt patients about this issue, and at an early stage, because, in doing so, it is presented as an appropriate and acceptable topic to discuss and an issue that the team is willing to address, thereby providing helpful reassurance.[69]

## Disfigurement

Facial disfigurement, mainly from surgery, is not only considered to be among the most disturbing stressors associated with head and neck cancers, but also possibly the most poorly addressed. Head and neck cancers are difficult to conceal as the location of the tumors are in visually prominent areas of the body. Impairment in important functions of the face such as emotional expression, reflecting animation, as well as verbal communication presents challenges with its distortion. The face is also essential to the sense of self and to interpersonal interaction and relationships, so it is not surprising that research has confirmed that disfigurement is associated with negative effects on mood,[76] self-image, and romantic, family, and other relationships.[77] These can be greater in marital partners than patients.[78] Even small alterations in one's appearance can have a major adverse impact on one's body image and self-esteem.[75] Just maintaining privacy about one's diagnosis is often impossible. However, both individual characteristics and the social environment may moderate the effect of disfigurement following head and neck surgery. Social support, particularly among women surgically treated for head and neck cancer,[79] and social self-efficacy[80]—the belief that one can exercise control over the reactions and openness of other people—may moderate and buffer the psychosocial impact of disfigurement.

The process of adjustment to facial disfigurement is extremely difficult from a psychological perspective.[81] Prior to even dealing with the fear of facial disfigurement, the head and neck cancer patient initially confronts and must cope with the possibility of imminent and premature death encountered by many cancer patients. Dealing with these existential issues may be particularly intense for those with head and neck cancer because facial disfigurement is so visually evident, acting as a frequent reminder of the pathology that the patient is repeatedly forced to face directly. At first overshadowed by these other challenges, adjusting to facial disfigurement eventually comes to the fore. Facial appearance is a central feature of physical attractiveness, which is highly emphasized in various domains of social status, in addition to its role in reflecting animation, intellect, and emotion, and serving as a means of communication with others. The difficult task of coming to terms with one's facial disfigurement involves recognizing and accepting that people will respond differently to the individual. Through the process of body image reintegration, occurring gradually over time, the patient learns to accept and compensate for anatomic alterations.[82] It seems important for a patient to begin to establish a revised self-image, as such, before attempting to fully resume social activities such as employment. Encountering relatives and friends poses special concerns for some patients. The immediate family frequently provides an

(c) 2014 Wolters Kluwer. All Rights Reserved.

important support system, usually reacting with compassion. Reactions from others in the patient's life may be variable, and conflicting responses may impact the patient's coping process. Patients who experience facial disfigurement may find the medical setting frustrating, especially when encountering visit delays, scheduling difficulties, or perceived lack of empathy from staff. Continuity of care and continuous exchange of information among team members may assist in the recovery process. Factors affecting reintegration of body image in head and neck cancer patients include age, sex, marital status, previous body image acceptance, the extent of structural and functional loss, extent of disfigurement, state and trait anxiety (experienced at a particular interval and as a stable factor over time, respectively), previous emotional stability, capacity for self-care, and self-acceptance in social situations.[69]

## Addiction

Head and neck cancer patients may often express feelings of guilt or self-blame due to perceived culpability and responsibility for their illness from having engaged in unhealthy behaviors that may have caused their malignancy, such as smoking or drinking alcohol which may figure to varying degrees in their history.

Less than 20% of patients who smoked prior to their diagnosis quit afterward, and relapse rates are high.[83] One study found that more than one quarter of the larynx cancer patients continued to smoke after treatment.[66] Another study found that approximately 35% of head and neck cancer patients continued to smoke or consume alcohol following surgical removal or radiation of the primary tumor. Managing addiction in patients with cancer can be time consuming, labor intensive, and challenging.[84] Furthermore, patients who continue to use tobacco or alcohol following treatment for head and neck cancers are at a greater risk for cancer recurrence and mortality.[66,71,85] Studies have found that continued smoking among patients with head and neck cancer has greatly increased the risk of recurrence compared to nonsmokers and doubled the risk compared with patients who stopped smoking.[66] Abusing alcohol or smoking is also one method patients may use to cope with their illness. It has been suggested that patients may use smoking as a means of reducing pain and self-medicating. Nicotine is known to have analgesic properties, which may impact cancer patients' willingness to quit smoking without reassurance that their pain will be managed.[83]

Alcoholism often develops or recurs as a consequence of severe psychological stress, chronic medical conditions, or terminal illness.[86] Cancer patients have numerous barriers to smoking cessation including heavy nicotine dependence, urgency of cessation, fatalistic attitudes about cessation benefits, cancer-related psychological distress and treatment factors, and presence of smokers in their social networks.[87] The high prevalence and clinical implications of continued substance use highlights the importance of psychosocial interventions for head and neck cancer patients. Furthermore, the IOM report recommended behavioral interventions such as smoking cessation programs to address patients' psychosocial needs.[88]

## Treatment

Normalizing the experience, providing education, and the proper services at treatment centers can help reduce distress, depression, and anxiety prevalent in head and neck cancer patients. Referral to substance abuse programs is essential for those patients whose recidivism may predispose to a recurrence, apart from the effects on general health.

Patients' natural fears about mortality, difficulties swallowing, breathing, or eating may progress to disabling depression or anxiety requiring formal treatment. A psychosocial intervention (education, individual, or group counseling) and judicious use of anxiolytics or antidepressants can be pivotal in patients' adjustment to cancer, adherence to full treatment schedules without missed appointments for radiation, chemotherapy or surgery, and improvements in QOL.[89] Anxiolytics such as lorazepam, so commonly used as antiemetics, can be more regularly dosed, or benzodiazepines, with a longer half-life (such as clonazepam), can be substituted for ease in dosing. Selective serotonin receptor antagonist antidepressants have minimal drying effects, better suited for patients with thickened secretions or xerostomia. Agents such as fluoxetine, sertraline, citalopram, or escitalopram lack significant sedation that can compound cancer-induced fatigue. Patients with insomnia or agitation may welcome the addition of a more sedating serotonin reuptake inhibitor such as paroxetine or venlafaxine at bedtime.

Long-term group and short-term psychoeducational programs have been shown to be effective in improving QOL for head and neck cancer patients.[90] Additionally, individual psychotherapy incorporating a variety of standard approaches may be beneficial, including psychoeducation to provide information about the disease and its treatment in a therapeutic context addressing ways to manage these challenges, cognitive-behavioral strategies to attend to maladaptive coping response that compromise psychological well-being, and supportive-expressive techniques useful particularly for symptoms of depression and anxiety.[65]

***Psychosocial Distress Assessment.*** Presently, the understanding of the emotional effects of cancer and its treatment on the patient and family and the role of psychosocial support is better integrated with surgery, chemotherapy, and radiation treatment for cancer. Also, symptom management is adapted from the palliative care and hospice world and modified for use in curative as well as palliative care of head and neck patients. In recognition of the need for such integration, the National Comprehensive Cancer Network (NCCN) has established Distress Management Guidelines in tandem with its site-specific guidelines[91] (see Fig. 10-3).

Distress has been defined as a multifactorial unpleasant emotional experience of a psychological (cognitive, behavioral, emotional), social, and/or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms, and its treatment. Distress extends along a continuum, ranging from common normal feelings of vulnerability, sadness, and fears to problems that can become disabling, such as depression, anxiety, panic, social isolation, and existential and spiritual crisis.

Distress should be recognized, monitored, documented, and treated promptly at all stages of cancer. All patients should be screened for distress at their initial visit, at appropriate intervals, and as clinically indicated, especially with changes in disease status. Screening should identify the level and nature of the distress, using an instrument with qualitative and quantitative measures. An example of the distress thermometer used at Continuum Cancer Centers is in Figure 10-3.[92] A similar distress thermometer has been validated in the ambulatory setting.[93]

The most commonly endorsed items: pain, fatigue, worry, sadness,[94] and eating should be managed using best practices adapted from the NCCN Clinical Practice Guidelines. Patients, families, and treatment teams should be informed that management of distress is an integral part of total medical care and provided with appropriate information about symptom management and psychosocial services available in the treatment center and the community. Quality of distress management should be included in institutional continuous quality improvement (CQI) projects.

Specific to head and neck cancer, fatigue and pain are likely to spike at predictable times as treatment progresses and varying with the timing of the surgical intervention or chemotherapy

(c) 2014 Wolters Kluwer. All Rights Reserved.

schedule for patients receiving combined treatment. As treatment ends, patients may be relieved, reflected in lower distress levels, or frightened of an immediate recurrence, causing an increase in distress scores. Effective symptom management and patient education may actually maintain distress ratings lower than would be anticipated as the symptoms are optimally managed, and patients and families know what to expect.

## INTEGRATIVE ONCOLOGY

There is an emerging recognition for the importance of integrative medicine in cancer care. Integrative oncology is a practice that combines the strengths of traditional allopathic Western medicine with the best approaches of complementary and alternative medicine (CAM).[89] It brings additional dimensions to patient care, increasing overall QOL through the use of supportive therapies coordinated with conventional therapies already integral to clinical care. CAM practices are focused on addressing the needs of body, mind, and spirit or, more specifically, the entire psychosocial experience of a cancer occurrence and its treatment rather than simply addressing the physical aspect of cancer.[89] By addressing these additional facets of patient care, integrative oncology can effectively make use of unconventional treatment modalities and approaches that are nonsurgical and nonpharmaceutical but have known efficacy.

Defining exactly what components comprise a complementary intervention varies widely between clinicians, treatment centers, and the public.[89] Using a wide definition, patients use integrative modalities without even realizing it. These include dietary changes (vitamins at usual or mega-doses, herbs, and supplements), mind–body techniques (massage, chiropractic adjustment, energy healing, biofeedback, acupuncture), relaxation techniques (guided imagery, hypnosis), psychosocial support (individual counseling, professionally led support groups, self-help groups), and spirituality (prayer, spiritual healing).[89,95] Recommendations for complementary and alternative therapies are provided in Table 10.6.

Complementary integrative oncology programs are already a core part of many major cancer centers for patients undergoing allopathic cancer treatment and include dietary education, counseling, and prayer.[96] Such programs also provide selective encouragement and discouragement of potential treatment modalities.[97] As early as 1998, a survey of 117 of the 125 US medical schools indicated more than half offered courses in CAM topics, either as required or elective classes. At that time, however, there was lack of standardization and quality in the content, format, and core requirements of CAM courses.[97,98] Currently, more programs that focus on lessening chemo and radiation treatment side effects and decreasing pain and the need for postoperation medication have been incorporated into pre-op teaching curriculums intended to prepare patients for surgery. One such program, The Bravewell Collaborative, offers a distance-learning fellowship at the University of Arizona Center for Integrative Medicine in a 1,000-hour training program to readdress patient care for preventative and individualized practice. At New York's Beth Israel Medical Center Residency Program in Urban Family Practice, family medicine residence are required a 1-month block rotation in CAM training and practice, receiving 20 hours

**TABLE 10.6 Grading Recommendation for Complementary or Alternative Therapies**

| Grade | Recommendations | Benefit vs. Risk | Strength of Evidence | Implication |
|---|---|---|---|---|
| 1A | Strong recommendation, high-quality evidence | Benefits clearly outweigh risk and burdens, or vice versa | RCTs without important limitations or overwhelming evidence from observational studies | Strong recommendation, can apply to most patients in most circumstances without reservation |
| 1B | Strong recommendation, moderate-quality evidence | Benefits clearly outweigh risk and burdens, or vice versa | RCTs with important limitations (inconsistent results, methodological flaws, indirect, or imprecise) or exceptionally strong evidence from observational studies | |
| 1C | Strong recommendation, low- or very low-quality evidence | Benefits clearly outweigh risk and burdens, or vice versa | Observational studies or case series | Strong recommendation may change when higher-quality evidence is available |
| 2A | Weak recommendation, high-quality evidence | Benefits closely balanced with risk and burden | RCTs without important limitations or overwhelming evidence from observational studies | Weak recommendation; best action may differ depending on circumstances or patients' or societal values |
| 2B | Weak recommendation, moderate-quality evidence | Benefits closely balanced with risk and burden | RCTs with important limitations (inconsistent results, methodological flaws, indirect, or imprecise) or exceptionally strong evidence from observational studies | |
| 2C | Weak recommendation, low- or very low-quality evidence | Uncertainty in estimates of benefits, risk, and burden; may be closely balanced | Observational studies or case series | Very weak recommendations; other alternatives may be equally reasonable |

per week of didactic/experiential education in herbal medicine, hypnotherapy/mind–body medicine, nutritional medicine, and osteopathic manipulation (see listed resources).

Demonstrating a wider understanding and acceptance of treatment options may alleviate the routine occurrence of adverse interactions or reduced efficacy between traditional and complementary therapies, as a large majority of patients often do not disclose their involvement in complementary therapies to physicians for fear of receiving a disapproving response.[96] Estimations of patients' use of complementary therapies range from 10% to >60% depending on applied definitions; a Data Monitor 2002 Survey indicated 80% of cancer patients utilized CAM, many as complementary to traditional treatment.[96] It is therefore imperative to discuss and monitor CAM usage; to encourage treatments that have proven effective as well as to discourage treatments that may be unsafe or that show little evidence of success. The recommendations by the Society of Integrative Oncology, a multidisciplinary panel of professionals who provide a forum for discussion and peer review of evidence-based research and treatment modalities, are to evaluate alternative medicine options based on evidence provided by credible information sources (see attached resources list), thereby avoiding discouraging patients from potentially helpful intervention modalities.[96]

## Mind–Body Techniques: Hypnosis/Guided Imagery/Yoga

With regard to fatigue, pain, and emotional distress, studies suggest that complementary techniques such as guided imagery and yoga have beneficial effects and can improve function and overall survival in cancer patients. A meta-analysis of 116 studies demonstrated "that mind–body therapies reduced anxiety, depression, and mood disturbance in cancer patients and assisted them in their coping skills."[96]

Psycho-neuroimmunological theories suggest that psychological response to guided imagery may down-regulate the hypothalamic-pituitary axis, resulting in reduced stress response and increased state of well-being.[99] Cognitive theory suggests that changing negative thought patterns leads to a reduction in the autonomic nervous system's arousal. Pickett et al. (1982) hypothesized that the effect of guided imagery may be due to its action as a coping mechanism, giving an individual a greater sense of control and empowerment when dealing with a difficult situation.[99] The use of progressive muscle relaxation reduces psychological distress and improves cancer patients' ability to cope with their disease.[100]

In a postoperative study on same-day surgical procedures, patients who listened to guided imagery compact disks reported less pain and decreased anxiety levels than patients who did not receive this therapy method. In ambulatory surgery, guided imagery led to significantly reduced preoperative anxiety, which can result in less postoperative and pain and earlier discharge times.[101]

The use of an "optimal healing environment"[102] was studied by implementation of the Urban Zen Initiative at Beth Israel Medical Center in New York City, in which physical space was remodeled, nursing staff received specialized training in complementary therapies, and yoga therapists were available for one-on-one sessions with patients. Results indicated significantly lower levels of tension, depression, fatigue, and mood disturbance after implementation, as well as a greater rate of improvement and lowered medication costs per patient.[102] The practices of mind–body techniques are recommended as supportive modalities in reducing anxiety and pain.

Hypnosis is defined as a state of restful alertness in which a person has a level of focused concentration. An independent panel convened by the National Institute of Health found that it may be helpful for treating chronic pain issues when used with standard medical care. Hypnosis proved helpful in the reduction of pain and distress during medical procedures in children with cancer, in addition to effectively reducing fear and anxiety.[103] A growing body of research has evaluated the effectiveness of behavioral interventions on QOL for cancer patients. Hypnosis has been applied to chronic pain conditions including those from cancer.[104] However, most of the studies are related to intervention with breast cancer and not head and neck patients.

## Psychosocial Techniques: Music/Pet

Clinical studies have shown that the use of music applied within a therapeutic context provide a myriad of benefits for cancer patients managing pain. Music therapy can be provided in both individual settings, such as during simulation and radiation therapy, as well as in group sessions, including waiting areas and chemotherapy suites. Music therapy leads to reduced nausea, emesis, and illness-related anxiety. Additionally, patients have reported increased comfort and less fatigue, tension, and decreased procedural and treatment-based stress, such as in radiation and chemotherapy.[105–107]

A growing body of evidence points toward positive interactions with companion animals and visitations by therapy dogs. Animal contact has been shown to lower blood pressure, reduce anxiety, decrease depression, and reduce pain perception in children.[108–112] Therefore, therapy is generally assessed for QOL issues for patients undergoing treatment and suffering from general distress and pain management. Beth Israel Medical Center in New York, Taussig Cancer Center of the Cleveland Clinic, and Denver Children's Hospital, all have ongoing visiting dog program or animal-assisted therapy, though data have yet to be collected for review.

## Symptom Management: Anxiety/Pain/Fatigue

Complementary therapies such as acupuncture, mind–body techniques, and massage therapy can help when conventional treatment does not bring satisfactory relief or causes undesirable side effects. Acupuncture is a treatment modality originating from China, involving insertion of sterile needles along established meridians in the body to allow flow or energy, known as qi.[96] The manual stimulation of each point by rotation, thrust, and lifting motions achieve feelings of heaviness or tingling at the point of insertion, indicating that the site has been correctly stimulated.[95] Acupuncture's contribution to cancer pain management has been studied as complementary rather than alternative modality, but has demonstrated proven effectiveness in randomized controlled trials testing for pain reduction.[96,113]

For head and neck cancer patients, xerostomia is a common side effect that has successfully been alleviated by acupuncture, a low-cost therapy with minimal side effects. Studies conducted in 2009 demonstrated a lasting response of higher salivary flow rates, and that, when given alongside radiation therapy for head and neck cancer, acupuncture reduced the debilitating effect of xerostomia and provided an acute benefit for chronic pain.[96,113] Saliva flow rates were significantly greater in a group of patients who received acupuncture concurrently while treated compared to a control group beginning just 3 weeks into radiotherapy and persisting through a 1- and 6-month follow-up. Several uncontrolled studies have indicated that acupuncture also helped with other cancer-related symptoms such as chronic pain, hot flashes, and fatigue.[96,114]

## Energy-Based Therapies

Therapeutic touch, reiki, qigong, and tai chi are energy-based therapies. For therapeutic touch and reiki, biofield energies are used in the form of healing intent or life energy, which are conducted into patients for the purpose of unblocking energy centers and increasing self-healing abilities.[96,97,115] In an *in situ*

(c) 2014 Wolters Kluwer. All Rights Reserved.

cell-based RCT to verify the efficacy of therapeutic touch, fibroblasts, tenocytes, and osteoblasts in culture were twice-weekly treated by therapeutic touch, resulting in significantly stimulated cell proliferation compared to control and sham/placebo treatment arms.[115] In RCT studies conducted on 189 cancer patients receiving chemotherapy, however, both Reiki and placebo therapies were statistically significant in raising comfort and well-being of patients postinfusion, with no adverse results.[116] Conclusions from the trial indicated that the presence of an "RN providing one-on-one support during chemotherapy was influential in raising comfort and well-being levels, with or with an attempted healing energy field".[116] Some nurses practice therapeutic touch and Reiki therapy, with many professional nursing organizations available that offer training and certification programs. Qigong and Tai chi are energy-based practices of individual daily exercises and awareness of breath, providing the patient comfort through self-induced treatment.[96]

### Supplementation: Herbs and Botanicals

The concurrent use of dietary supplements, herbs, and other botanicals while undergoing chemotherapy, radiotherapy, or surgical treatments pose the greatest hazard as the most number of adverse interactions occur between this method of CAM and conventional medicine. As an example, patients who use the commonly available herbal supplement St. John's wort while receiving a taxane risk unexpected toxicities.[117] However, such supplementation may prove beneficial: In a 2000 study, oral glutamine demonstrated potentially significant reductions in the duration and severity of objective oral mucositis during radiotherapy, with a study dose of 2 g/30 mL liquid swished and swallowed four times a day.[118]

## INTEGRATION OF PALLIATIVE CARE WITHIN ONCOLOGY PRACTICE

Palliative care is an interdisciplinary approach that focuses on the care of patients with serious or life-threatening illness. The focus is on comprehensive symptom management, as well as attention to the psychosocial aspects of illness (psychological, social, emotional, spiritual dimensions) which contribute to the experience of suffering. For cancer patients, palliative care should be an integral part of the treatment from the time of diagnosis and not reserved for the time when all disease-modifying treatments have been exhausted. Recent studies have shown that involvement of palliative care specialists earlier in the course of serious and life-threatening disease can be beneficial not only in supporting patients through treatments, but even in prolonging survival, despite less frequent use of aggressive end-of-life care.[119]

The goal of palliative care to be delivered concurrently with all modalities of treatment is part of practice guidelines established in 2001.[120] The goals set forth in these guidelines are to enhance the QOL for patients and their families through optimizing function and assisting with decision making. Palliative care interventions are intended to address the multidimensional aspects of suffering, to assist in developing coping strategies, to facilitate communication with oncologists and other medical professionals, to support decision making, and to facilitate the often difficult conversations regarding advance directives and goals of care. Recommendations are that palliative care should be integrated in a seamless manner with other aspects of care.

In particular, referrals to palliative care specialists should be considered for patients with advanced disease, where progression of symptoms is likely and treatments are aimed at palliation; for patients with multiple symptoms or symptoms of unclear etiology; for patients with complex pain not controlled on current regimen; for patients with advanced or recurrent disease, regardless of current symptoms; for patients with high levels of distress; or when decision making is complex.

A model of concurrent care, in which palliative care specialists are colocated within a cancer center, is ideal for several reasons.[121] Patients undergoing cancer treatments are already burdened by multiple appointments and time spent in radiation and chemotherapy treatment sessions. It may be very difficult to schedule additional appointments for assessment by palliative care specialists. The presence of a palliative care team within a cancer center allows optimum support for patients, assisting them during cancer treatments. This allows oncologists to focus primarily on the management of cancer. The interdisciplinary team provides ongoing dialogue and assessments to maximize comfort, clarify patient and family priorities, minimize need for emergency room visits, and decrease patient and family distress during treatments.

The integration of palliative care specialists in oncology practice eases the clinical burden on oncologists.[122] Conversations about physical and emotional symptoms are time-consuming and collaboration with interdisciplinary team requires coordination and continuity. Patients may need help in interpreting clinical information and, frequently, the goals of care change during course of treatment. Palliative care specialists who work within an oncology practice form relationships with oncologists, nurses, social workers, dietitians, and chaplains. This facilitates the smooth flow of clinical information, especially when patients' care moves between inpatient and outpatient settings.

Improving linkages between palliative care and oncology practice can limit the burden of suffering in patients with progressive cancer. The two goals of actively treating the disease and managing symptoms may be best achieved using an "integrated model." Currently, referrals to palliative care occur late in the course of disease, within 30 to 60 days before death.[122] Early referral to palliative care can improve symptom management, provide psychosocial support throughout the continuum of the disease, and assist with transitions of care, when disease-modifying therapies are no longer effective, no longer tolerable, or no longer desired. Evidence suggests that early referral to palliative care can improve the QOL of patients with advanced disease as well as relieve family stress.[122] When patients are referred to palliative care teams early in the course of treatment, it allows time to form relationships with palliative care team members, who remain involved in their care as their disease progresses. Time spent in this relationship can ease the transition to hospice care if and when this is desired and appropriate.

In addition to improving patients' QOL, early involvement of palliative care teams facilitates patients' participation in their plan of care, without having to choose between usual care and hospice.[123] The cost savings of such an approach has been studied in clinical trials, with evidence suggesting cost savings of more than US$4,800 per patient.[123] Additional randomized trials of various palliative care initiatives and interventions have confirmed the improvement in symptom control, QOL, and satisfaction with care for patients and their family caregivers.[124]

Encouraging conversations between palliative care specialists, oncologists, patients, and their families about the continued benefits of ongoing treatments, in the face of progressive disease, highlighting both personal choice and functional status is a priority in providing supportive care to patients and their families during and after treatment.

### Survivorship

A report from the Institute of Medicine in 2005, "From Cancer Patient to Cancer Survivor: Lost in Transition," describes cancer survivorship as a distinct phase of the cancer trajectory and

(c) 2014 Wolters Kluwer. All Rights Reserved.

suggests that a strategy is needed for the ongoing clinical care of cancer survivors. The IOM report recommended that, after completing primary treatment for cancer, patients be given a summary of their treatment and a comprehensive plan for follow-up, including the long-term effects of cancer and its treatment, as well as the identification of psychosocial support resources in their communities. It should include guidance on follow-up care, prevention, and health maintenance.[125]

According to the organization Support for People with Oral and Head and Neck Cancer, Inc. (SPOHNC), there are presently more than 500,000 survivors of oral and head and neck cancer living in the United States. In addition, 58,000 people in the United States will be diagnosed with this disease this year.[126] SPOHNC is recognized by the American Cancer Society, the National Cancer Institute, and many medical centers and health care professionals as an organization dedicated to meeting the needs of oral and head and neck cancer patients. New guidelines and standards of care have been updated for 2012 which widen the scope of practice. Recent publications focuses on patient-centered needs.[126]

The mnemonic LEARN is a recovery plan for patients and families to better organize information and tasks as a new cancer survivor, starting at time of diagnosis through a period of "disease-free survivorship or recurrence/relapse."[126] It focuses on information that can be learned from "providers about a particular clinical course, with an emphasis on five basic tasks"[126]:

L—**Living**—Focus regularly on an aspect of living outside of the treatment with a broader life perspective.
E—**Education**—Learning as much as fits your style about one's cancer and its treatment to expedite recovery.
A—**Activity**—Physical activity to the extent able during and after treatment minimizes deconditioning afterward.
R—**Rest**—Using periods of rest and energy conservation to optimize energy during and after treatment.
N—**Nutrition**—Good nutrition paired with the limitations of treatment to maintain lean body mass, energy, and healing.

CHAPTER 11

Jan S. Lewin and
Katherine A. Hutcheson

# Evaluation and Rehabilitation of Speech, Voice, and Swallowing Functions After Treatment of Head and Neck Cancer

"Few other cancers demonstrate the need for anticipatory treatment and rehabilitation to the magnitude required in the management of head and neck cancer."

—Myers, Barofsky, and Yates, 1986.[1]

Head and neck cancer often results in significant functional changes including alterations in or loss of human voice, disruptions in speech production, and deterioration of swallowing ability. These problems can occur as the result of the disease as well as the primary treatment, whether surgery, radiation therapy (RT), or both. Adjuvant treatments that include RT generally increase functional deficits. A thorough understanding of the functional effects associated with the given treatment modality or combination of modalities is essential and must be conveyed adequately to the patient as the patient's choice of treatment modality and their compliance with therapy often depend on functional restoration. A multidisciplinary team approach and ongoing communication among clinicians is critical to successful rehabilitation and optimal speech, voice, and swallowing outcomes.

Experience has shown that patients with head and neck cancer express similar concerns and functional goals. What seems to be most important to patients is to avoid a stoma, to speak with laryngeal voice, to eat and drink by mouth, and to avoid the use of adaptive equipment for either speech or swallowing. In a multicenter study, speaking abilities ranked as the primary contributor to psychosocial outcomes and quality of life after treatment for head and neck cancer followed by swallowing function.[2]

## OVERVIEW OF SPEECH AND SWALLOWING IMPAIRMENTS

Speech, voice, and swallowing are highly complex processes that depend on a series of precisely coordinated biomechanical events and physiologic interactions of the oral, pharyngeal, and laryngeal anatomy. Oropharyngeal anatomy and movement are the key determinants of speech intelligibility, vocal resonance, and swallowing competency. Therefore, any alteration in structure or physiology, such as those that result from head and neck cancer, will ultimately affect aerodigestive tract functioning.

## EVALUATION OF SPEECH, VOICE, AND SWALLOWING

### Pretreatment Evaluation

Rehabilitation, more specifically its planning, should begin at the time of diagnosis with patient counseling and a thorough baseline evaluation provided by a speech pathologist who is an expert in the management of functional disorders associated with head and neck malignancies. For many patients, the need for speech and swallowing treatment is unexpected and, therefore, difficult for the patient to accept. Fears and misconceptions associated with cancer treatment and its outcomes are often alleviated by providing realistic expectations for recovery and discussing the rehabilitative options that are available to the patient for functional restoration. Subsequent understanding and acceptance often leads to better follow through with the cancer treatment and rehabilitation.

Pretreatment evaluation establishes a baseline of speech and swallowing ability for appropriate treatment planning and posttreatment comparison. The plan for posttreatment rehabilitation, which should be based on both clinical and objective measures of examination, will depend on the site of the disease and the type of cancer treatment selected.

### Swallowing Evaluation

The act of swallowing includes the oral preparatory, oral, pharyngeal, and esophageal stages. The oropharyngeal swallow consists of the first three stages only, which include all events occurring from the lips to the upper esophageal sphincter (UES). It is the oropharyngeal swallow that is most often affected by head and neck cancer.

Speech pathologists evaluate and treat oropharyngeal swallowing disorders. Unlike esophageal swallowing problems, disorders of the oral preparatory, oral, and pharyngeal stages of the swallow can be treated with functional interventions such as changes in posture and exercises that strengthen and increase the range of motion of muscles involved in the act of swallowing.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Gastroenterologists generally manage esophageal causes of dysphagia, such as esophageal stricture, for which the main treatment is dilation.

Oral tongue control and strength are important to ensure efficient movement during mastication and posterior propulsion of foods and liquids to the pharynx. Regardless of the type of cancer treatment, surgical or nonsurgical, the primary correlates of pharyngeal swallowing proficiency are tongue base retraction, pharyngeal contraction, and laryngeal elevation and anterior excursion.[3] Tongue base retraction and pharyngeal contraction act as the driving force to move the food through the pharynx, whereas hyolaryngeal excursion is essential to open the cricopharyngeus and deflect the epiglottis downward for airway protection. The ability of the true vocal folds (TVFs) to completely close is important but not essential to airway protection and functional swallowing. For example, patients with unilateral TVF paralysis often compensate for glottic incompetency by using other mechanisms of airway closure to safely swallow without aspirating; therefore, safe swallowing is not solely dependent on TVF closure. Thus, procedures that augment the TVFs to improve airway closure and reestablish subglottic pressure may help swallowing but may not always prevent aspiration if the dysphagia etiology includes more than impaired glottic closure. Therefore, the results from objective instrumental examinations should clearly define the etiology of the aspiration to help guide rehabilitation and avoid the use of techniques, surgical or otherwise, that are not indicated or useful in remediating the dysphagia.

The assessment of swallowing competency relies on comprehensive examination including patient interview, clinical observation, and physiologic findings from instrumental examinations. The *clinical or bedside swallowing examination* allows observation of important events in the oral stage of swallowing, including labial and lingual control, adequate clearance of food from the oral cavity after the swallow, and oral sensitivity. However, the clinical swallowing evaluation is not reliable to diagnose pharyngeal swallowing disorders because clinicians must infer problems that occur during the pharyngeal stage. Despite this limitation, the examiner can detect signs and symptoms suggestive of pharyngeal swallowing problems. A well-trained clinician synthesizes overt as well as subtle observations from the clinical or bedside examination and uses this knowledge to make recommendations including the need for further objective swallowing assessments.

The need for objective, instrumental swallowing evaluation in patients with head and neck cancer cannot be overemphasized. Instrumental evaluation is essential because swallowing physiology cannot be reliably inferred from subjective patient reports.[4] For example, patients may report no problems swallowing when in fact, they are actually silently, without coughing or exhibiting any other indication, aspirating what they swallow. In studies of patients with advanced laryngeal cancer, aspiration has been reported as high as 36% in unselected samples with rates up to 82% in patients who complain of dysphagia. More concerning are the data that show between 36% and 80% of patients who aspirate do so silently.[5–7] In fact, as many as 60% of patients with head and neck cancer have speech and/or swallowing impairments but may not fully perceive them.[8]

The most widely used instrumental swallowing evaluations are the modified barium swallow (MBS) study and the fiberoptic endoscopic evaluation of swallowing (FEES). The choice of either test usually depends on the type of swallowing problem and the ability of the patient to undergo a radiologic procedure. In any case, an instrumental examination, MBS, and/or FEES should be used for any patient with head and neck cancer and/or who is at risk for swallowing problems or aspiration.

The MBS study is generally most preferred for assessing the oropharyngeal swallow. It allows the examiner to radiographically assess all three stages of the oropharyngeal swallow, from the point at which the food is placed in the mouth to the time it enters the cervical esophagus. The MBS study is performed jointly by a speech pathologist and a radiologist. The swallowing assessment should include the use of radiopaque liquids, pastes, and solids because swallowing physiology will vary according to the consistency and amount of food. This is in contrast to the traditional barium swallow study or esophagram, the primary purpose of which is to evaluate the structural integrity of the esophagus and identify aspiration while a large liquid bolus is continuously swallowed. The barium esophagram is not the evaluation of choice for examining oropharyngeal swallowing physiology as the results do not provide the information necessary to differentially diagnose oropharyngeal swallowing disorders and the causes of aspiration. In contrast, the primary purpose of the MBS study is to obtain information that is essential to understanding oropharyngeal swallowing physiology. An additional benefit of the MBS examination is the ability to immediately assess the usefulness of selected compensatory swallowing strategies to relieve the dysphagia. Therapeutic recommendations are made on the basis of the physiologic findings shown on the MBS study. Figure 11-1 shows the normal oropharyngeal anatomy viewed laterally on an MBS study. Figure 11-2 shows a normal swallow viewed laterally on an MBS, and Figure 11-3 shows an abnormal swallow with aspiration.

Alternatively, FEES uses a flexible endoscope placed transnasally to examine the pharyngeal swallow while providing direct visualization of laryngeal anatomy. The main advantages of FEES are that it does not expose the patient to radiation and that it can be easily performed as a clinical procedure for patients who cannot tolerate or are not candidates for the MBS study. FEES has been shown to be equivalent to the MBS study in its ability to detect aspiration.[9] It is a particularly excellent examination for patients who have larynx cancer because it provides the best view of glottic competency, including airway protection and vocal fold mobility. Unlike the MBS study, FEES can be paired with sensory testing to help determine laryngeal sensitivity.[10]

The primary disadvantages of FEES are its inability to visualize the oral preparatory and oral phases of the swallow and the period of "white-out" that occurs at the onset of the pharyngeal stage of swallowing that obscures visualization during peak of

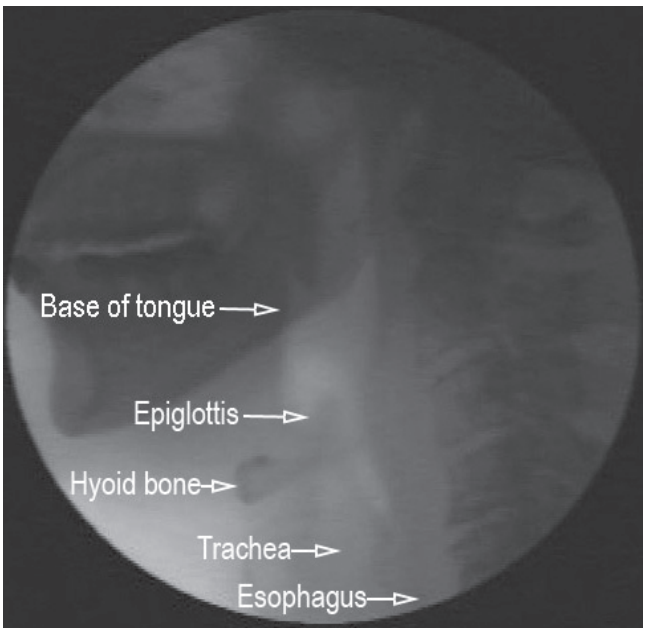

**FIGURE 11-1.** Normal anatomy.

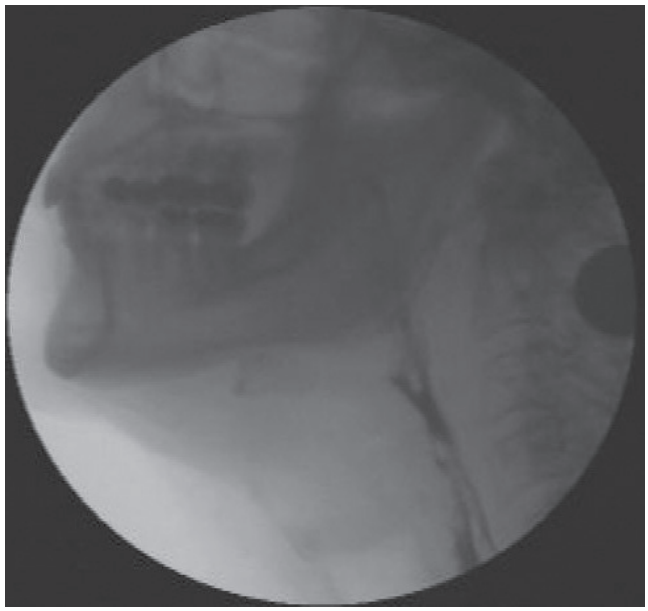

**FIGURE 11-2.** Normal airway closure during the swallow with food passage through the esophagus.

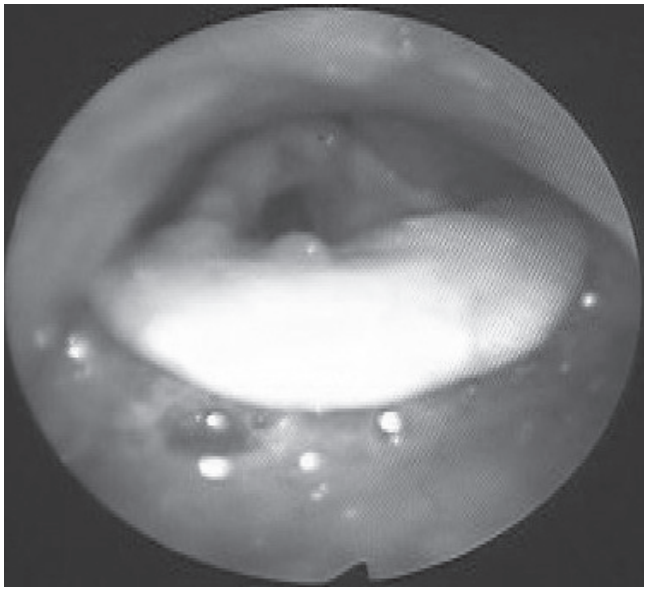

**FIGURE 11-4.** Fiberoptic endoscopic evaluation of swallowing (FEES) with food residue in the pharynx and on the laryngeal surface of the epiglottis after the swallow.

deglutition. Therefore, because all oral phase disorders as well as some pharyngeal disorders of swallowing must be inferred, the usefulness of FEES is more limited in patients with tumors of the oral cavity and oropharynx. However, like the MBS study, FEES provides critical feedback regarding the effectiveness of swallowing compensations and strategies. FEES is also useful in its ability to provide the patient with immediate biofeedback and visualization during therapy sessions. Figure 11-4 demonstrates FEES with food residue in the pharynx after the swallow has occurred.

## Voice Evaluation

Voice evaluation should assess the perceptual, vibratory, acoustic, and aerodynamic parameters of voice production.

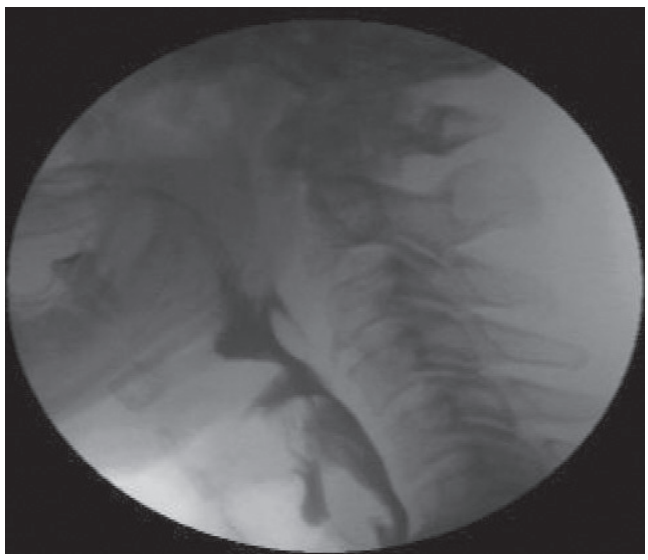

**FIGURE 11-3.** Aspiration into the trachea during the swallow.

A comprehensive evaluation should at a minimum include assessment of the fundamental frequency of sound production, the ability to vary pitch and intensity, phonatory duration, and properties of airflow, air pressure, and glottal resistance.

Laryngeal videostroboscopy provides a critical assessment of patients with head and neck cancer and vocal abnormalities. Videostroboscopic assessment employs the use of an endoscope that uses a straight and pulsed light source to assess vocal fold movement and vibration. Like FEES, videostroboscopy can be performed as an office procedure. This examination provides valuable information regarding vocal fold vibration as well as an immediate and magnified image of the presence or absence of laryngeal pathology that is often undetectable using standard methods of indirect laryngoscopy. The clinician can observe patterns of TVF approximation, symmetry and regularity of motion, and the presence of mucosal wave that will be affected by laryngeal disease and its treatment. Videostroboscopy is an essential component of the physical examination of patients with head and neck cancer and provides a permanent record for documentation and comparison of laryngeal functioning over the course of treatment. Videostroboscopic results are illustrated in Figures 11-5, 11-6, and 11-7.

## Speech Evaluation

Speech evaluation generally encompasses the administration of a combination of perceptual measures of articulation and speech intelligibility that include examination of the rate of speech, articulatory precision, and intelligibility in single words, phrases, and conversation. Formal test batteries that have been standardized on targeted populations provide an objective appraisal of speech production that can be used for comparison over time. A combination of formal and perceptual measures of speech production and a physical examination of the structures of the oral cavity and their patterns of movement are the most useful tools for differentially diagnosing speech disorders and planning effective treatment.

The findings from a thorough speech assessment are also critical to other members of the multidisciplinary rehabilitation

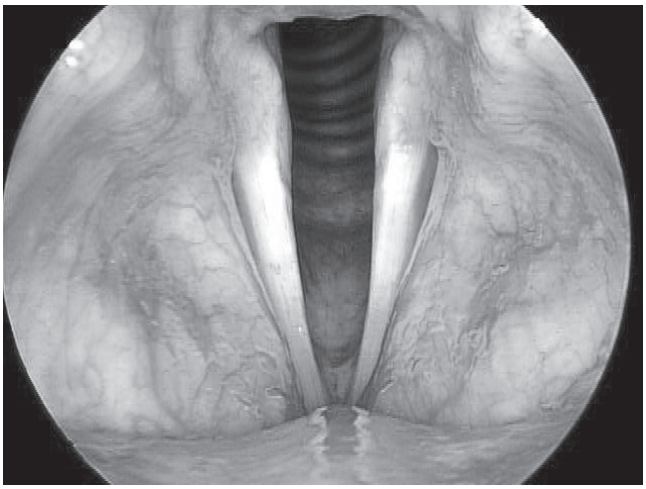

**FIGURE 11-5.** Vocal fold abduction.

**FIGURE 11-6.** Open for vibration.

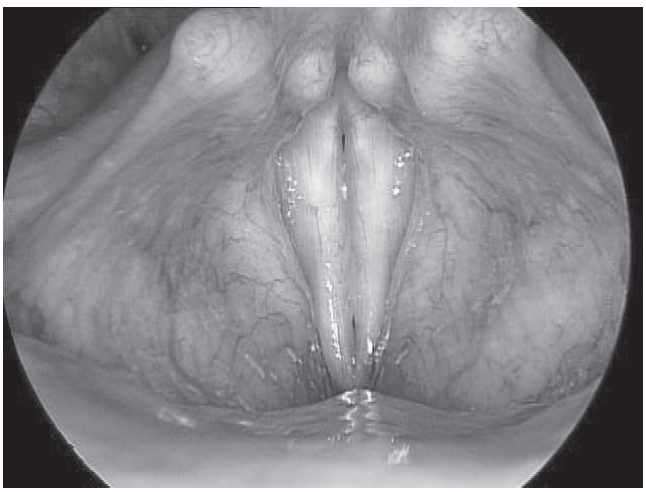

**FIGURE 11-7.** Fully adducted.

team. Information regarding articulation and vocal resonance assists maxillofacial prosthodontists in determining candidacy for and manufacturing of palatal augmentation prostheses, obturators, and lifts for patients with defects of the oral cavity and soft palate. Additionally, information regarding speech articulation and intelligibility helps plastic surgeons select reconstructive procedures and techniques that will optimize cosmetic and functional outcomes.

## REHABILITATION AFTER SURGICAL RESECTION

Any surgery that resects critical structures of the upper aerodigestive tract and disrupts oropharyngeal physiology will result in problems with both speech and swallowing. The functional disability that occurs after head and neck surgery is usually proportional to the volume and site of resection. The correlates of dysfunction depend on the site of lesion and include oral tongue mobility, base of tongue retraction, pharyngeal motility, glottic closure, and laryngeal excursion.[3] The rehabilitative focus varies depending on the type of surgery and reconstruction. For example, patients who undergo glossectomy will require both speech and swallowing rehabilitation to improve speech intelligibility and facilitate the return to oral alimentation. Alternatively, the focus of rehabilitation after total laryngectomy is usually to restore voice or sound production.

### After Oral Cavity Resection

The size and location of the tumor, extent of surgery, and type of reconstruction greatly impact functional outcomes after oral cavity resection. Because the tongue is a fundamental structure to both speech and swallowing, the degree of dysfunction often correlates with the extent and location of tongue resection. Studies have shown that resections of the tongue base and anterior tongue are associated with significant functional deficits.[8] Despite the importance of the oral tongue, data clearly show that the tongue base remains the most essential lingual region for normal swallowing.[3] Even after a total resection of the oral tongue, a patient can learn to swallow safely as long as the base of the tongue is preserved and continues to function.

Reconstructive procedures for oral cavity defects are often challenging because they require sufficient tissue to preserve function while avoiding overcorrection with tissue bulk that obstructs adequate speech and swallowing. Reconstructions of the oral cavity should aim to preserve mobility, shape, and volume of remaining structures and prevent pooling of secretions and food. Resections of the oral cavity that preserve sensorimotor innervation in combination with reconstructions that allow residual tongue mobility generally result in better speech and swallowing function. The degree of functional impairment often depends on the quality rather than the extent of the reconstruction; experience has shown that some patients who have undergone total glossectomy swallow better than patients who have undergone partial resections that use bulky flap reconstructions or those that tether the tongue.

In addition to the importance of the tongue during the oral phase of swallowing, the tongue plays a critical role during the pharyngeal phase of swallowing. Oral cavity resections may impact oral transit and control and consequently affect the ability to elicit a safe pharyngeal swallow. There is an increased risk for aspiration as resections of the oral cavity become larger and more extensive and interfere with oropharyngeal physiology. In particular, patients whose surgeries affect the suprahyoid musculature may aspirate because of the disruption to the elevation and anterior tilting action of the larynx, which is needed to protect

(c) 2014 Wolters Kluwer. All Rights Reserved.

the airway during swallowing. Thus, the ability to spare adjacent musculature, such as the suprahyoid elevators, is an attractive feature of transoral endoscopic surgical approaches.

In addition to swallowing, resections that affect critical structures and physiology of the oral cavity will also affect speech production and intelligibility. The severity of speech and swallowing dysfunction usually parallel each other. The mechanisms for articulatory compensations may include exaggeration of remaining labial, jaw, dental, pharyngeal, and laryngeal movements. Surgical alterations of the tongue and oral cavity can also change the characteristics of vocal tract resonance such as pitch, nasality, and vocal quality by changing the shape and vibrating properties of the vocal tract.

Most patients are able to achieve understandable speech and some degree of oral nutrition after adequate postoperative healing and rehabilitation. A recent systematic review suggests that speech remains largely intelligible (sentence level: 92% to 98% intelligibility) for a majority of surgically treated patients with advanced-stage oral cancer, including those with involvement of the tongue. However, deviant speech characteristics such as abnormal articulation were reported in most cases despite intelligible speech ratings.[11]

After oral cavity resections, a variety of rehabilitative techniques are used to maximize speech and swallowing function that may include targeted exercise regimens, articulatory compensations, postural adjustments, swallowing maneuvers, or the use of adaptive equipment. The selection of the appropriate intervention should be based on a thorough examination of functional deficits. Again, multidisciplinary interaction and communication cannot be overemphasized. This is particularly true for patients who require palatal prostheses after oral cavity resections that include the hard palate and/or tongue. For these defects, the speech pathologist and maxillofacial prosthodontist work together to fabricate a prosthesis that is tailored to the patient's individual needs.

Hard palate resections that result in oronasal fistulas are usually addressed at the time of surgery with a prosthetic obturator. However, patients who also require partial resection of the soft palate cannot be easily obturated due to the dynamic nature of the residual soft palate and are therefore more difficult to rehabilitate than patients who have undergone total soft palate resection. As is the case for patients with hard palate resections, our experience shows that patients who have undergone total soft palate resection and who are adequately obturated usually speak and swallow without difficulty.

When there is minimal lingual range of motion, or when 50% or more of the tongue is resected, a palatal augmentation prosthesis is generally designed to lower the palatal vault so that the remaining native or reconstructed tongue can contact the prosthesis. Generally, palatal prostheses are more useful for speech than they are for swallowing except in cases in which the prosthesis fills a defect in which food may collect.

## After Total Laryngectomy

Total laryngectomy results in a variety of functional changes; however, the most debilitating is the loss of verbal speech production. Verbal communication is restored using three major approaches: (a) the artificial larynx or electrolarynx, (b) esophageal speech production, and (c) surgical prosthetic voice restoration, the most common of which is tracheoesophageal (TE) voice restoration. However, not all approaches are appropriate for every laryngectomized individual because not every patient is capable of or interested in all methods of restoration. The alaryngeal method of choice is a patient-specific decision and should never be made solely by the physician, family, or speech pathologist. However, clinician experience with the specific alaryngeal voice alternative will play a large part in the patient's overall success in acquiring alaryngeal speech production. Given the current state of rehabilitation, no patient should be without some method of functional speech restoration after total laryngectomy. Figure 11-8 illustrates anatomy before and after total laryngectomy.

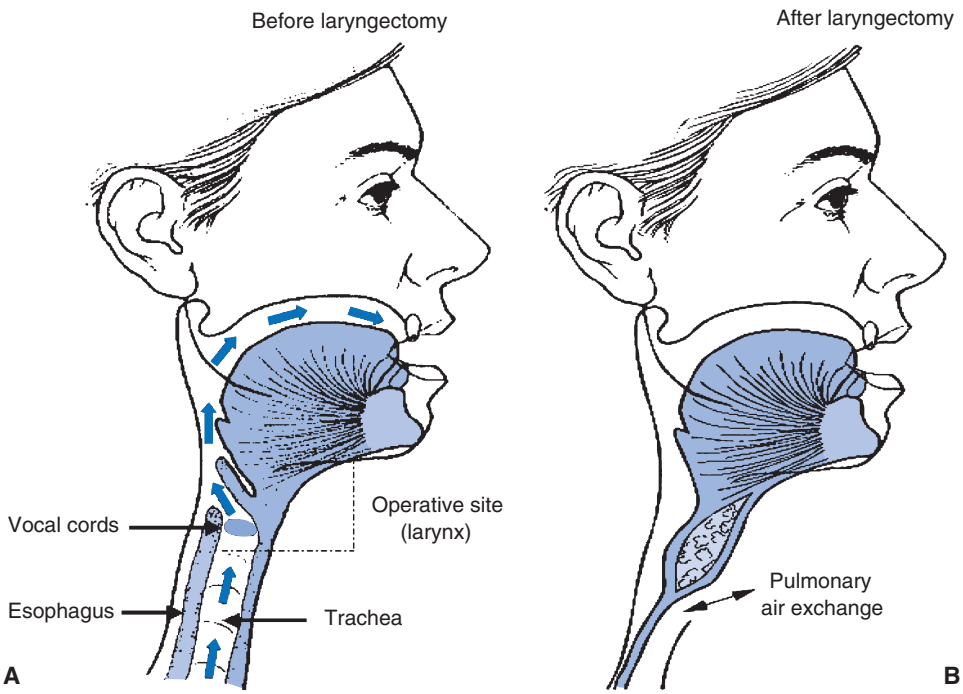

**FIGURE 11-8. A:** Before laryngectomy. **B:** After laryngectomy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

## Electrolarynx

The electrolarynx, or artificial larynx, as shown in Figure 11-9 A and B provides an external, mechanical sound source that is placed against the neck or intraorally for speech production after laryngectomy. All laryngectomized individuals should be encouraged to learn to use an artificial larynx because it provides a simple means of immediate verbal communication and requires little maintenance. Use of the electrolarynx does not interfere with subsequent development of esophageal or TE speech. The electrolarynx is often the first alternative an individual uses to communicate during the immediate recovery period after laryngectomy. In the long term, the electrolarynx can serve as a backup method of communication for individuals who acquire other forms of alaryngeal speech production. It also becomes the alternative of choice for patients who are not interested in or who are unable to learn or use esophageal or TE speech. Despite the advances in alaryngeal voice restoration, particularly surgical prosthetic alternatives, the electrolarynx remains the most commonly used method of alaryngeal communication worldwide.[12]

## Esophageal Speech

Historically, esophageal speech production was the alternative of choice for alaryngeal speech rehabilitation. Esophageal speech depends on the transfer of air from the oral cavity into the esophagus for vibration of the pharyngoesophageal walls to provide a sound source for speech production. Although esophageal speech production provides the advantage of oral communication without the use of mechanical or prosthetic devices, it is rarely the method of choice for alaryngeal communication after total laryngectomy in current practice. Conservative estimates suggest that it takes 4 to 12 months of consistent therapy and daily practice to learn this method, and <30% of patients actually acquire functional esophageal speech production.[13] In addition, studies have found that the quality of esophageal speech is reduced in comparison to TE speech.[14] For these reasons along with the lack of good esophageal speakers and clinicians who can reliably teach esophageal speech production, alaryngeal communication using esophageal speech has become much less common and is generally preferred for select patients only. Patients who are not surgical candidates for TE voice restoration but have viable sound production of the pharyngoesophagus, and do not wish to use an artificial larynx for primary communication, should be considered candidates for esophageal speech. Figure 11-10 illustrates the method of esophageal speech production.

## Tracheoesophageal Voice Restoration

TE voice restoration remains the gold standard for alaryngeal speech production after total laryngectomy because it provides the highest quality of alaryngeal voice and patient satisfaction.[12] The method depends on the surgical creation of a small hole or fistula in the TE wall, commonly referred to as the *tracheoesophageal puncture* (TEP). A unidirectional valved prosthesis is placed to maintain the TEP. The valve of the prosthesis remains closed to protect the airway during swallowing and opens to divert pulmonary air across the pharyngoesophageal mucosa for phonation when the tracheostoma is occluded. The resulting sound is shaped into words by articulatory movements of the structures of the oral cavity. The tracheostoma can be manually

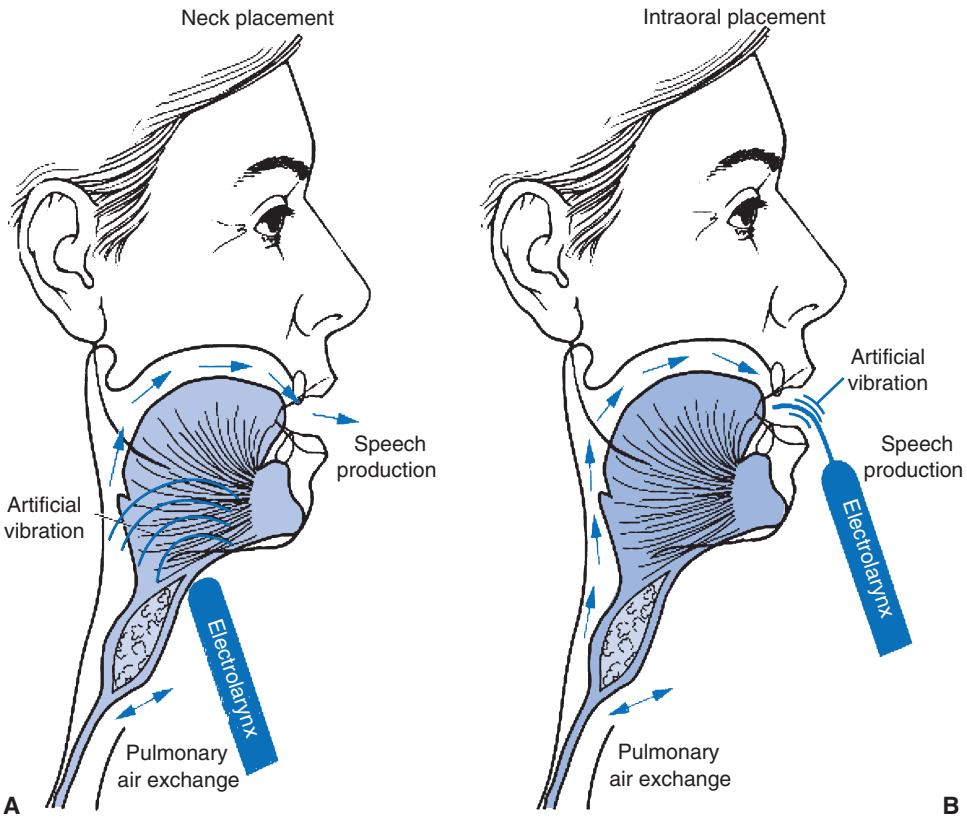

**FIGURE 11-9.** Artificial larynx (electrolarynx).

(c) 2014 Wolters Kluwer. All Rights Reserved.

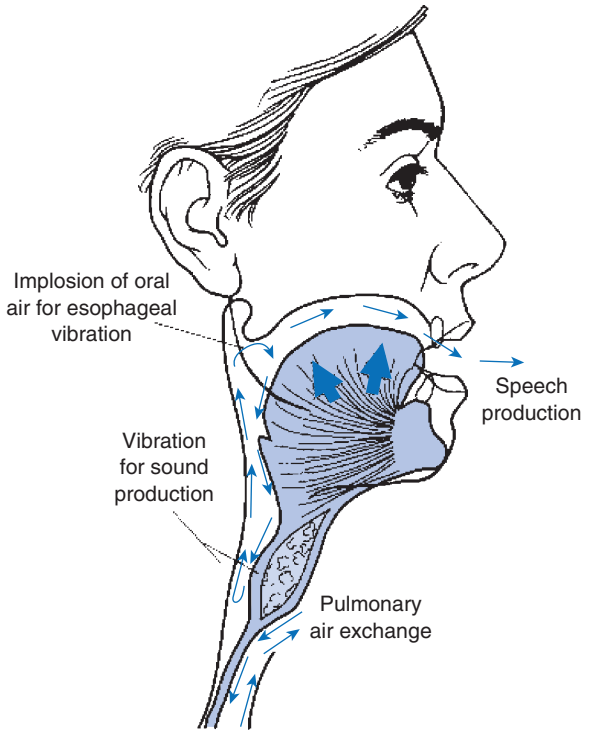

**FIGURE 11-10.** Esophageal speech.

occluded by the patient or automatically occluded by means of a hands-free valve to shunt air into the pharyngoesophagus for sound production. TE voice restoration and methods of stomal occlusion are shown in Figure 11-11.

TE voice restoration has been associated with the highest patient satisfaction because it offers the advantage of a rapid return to more natural-sounding verbal speech production. TE voice production is frequently documented as the alaryngeal speech alternative most comparable to normal laryngeal speech in quality, fluency, and ease of production. Superior vocal quality, phonatory duration, and vocal intensity have been found in comparisons of TE voice production to other alaryngeal speech alternatives.[14]

The TEP can be performed as a primary procedure at the time of the total laryngectomy, or secondarily after the patient has fully healed from surgery. Data have shown that TE voice restoration outcomes are comparable whether the procedure is performed primarily or secondarily[13–15]; however, the choice of timing is generally dependent on patient characteristics along with physician preference and experience. TEP was first introduced as a secondary procedure.[16] Primary puncture then became the treatment of choice for most patients because surgical experience and clinical data demonstrated no significant occurrence of complications associated with the procedure nor difference in the ultimate quality of TE speech production. One of the most compelling arguments for primary puncture remains the psychological advantage of an early return to oral speech production. However, as cancer treatments have evolved and become more aggressive, often combining radiation and chemotherapy with more complex surgical reconstructions, patient selection has become even more

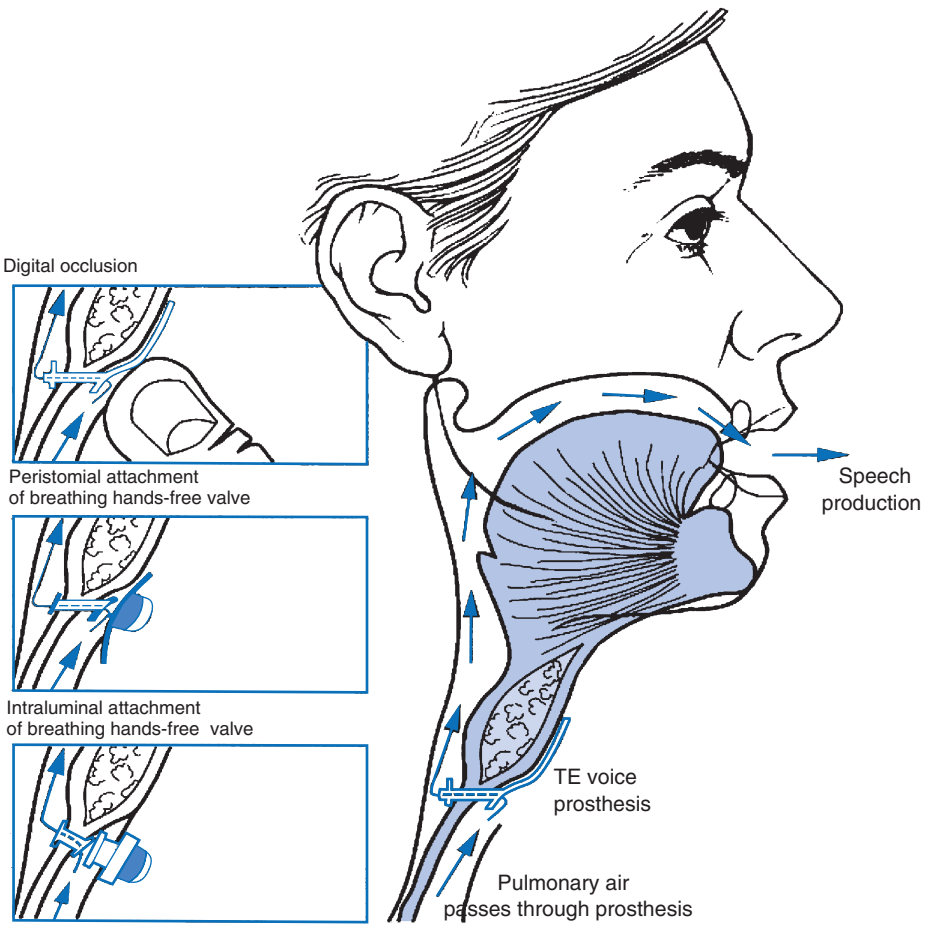

**FIGURE 11-11.** Tracheoesophageal (TE) speech.

**TABLE 11.1 Considerations for the Timing of the Tracheoesophageal Puncture (TEP)**

| Primary TEP | Secondary TEP | No TEP |
|---|---|---|
| Standard laryngectomy | Complicated medical history | Marked cognitive impairment |
| Motivated patient | Extended surgeries | Severe substance abuse |
| Compliance | "At-risk" patients | Poor compliance[a] |
| Independence and support | Limited readiness and independence | Limited rehabilitative access[a] |
| Rehabilitative access | | No support[a] |

[a]In combination, these three factors are felt to be a poor indicator for tracheoesophageal speech success.

important. The universal application of primary or secondary puncture is no longer appropriate, nor is it the best procedure for all patients. Our experience suggests that the use and timing of TEP depend on existing patient characteristics and medical factors. These indicators are outlined in Table 11.1.

## General Considerations for Alaryngeal Voice Rehabilitation

The choice of alaryngeal speech method centers on the evaluation of the patient's psychological factors, treatment history, and comorbidities along with his/her motivation for TE voice restoration. In general, age alone is not predictive of rehabilitative success. The artificial larynx may be preferred in older and more sedentary patients, but some of the best TE speakers are those in their 70s and 80s. Alternatively, the traditional method of esophageal speech production is often the best choice for children, adolescents, and young adults, who will readily learn to incorporate this method of communication as their own over their lifespan. Despite the popularity of TE voice restoration, the method relies on the use and maintenance of prosthetic devices. Thus, TE speech production brings added attention to anatomic and physiologic changes in young patients that only serves to further differentiate them from their peers.

Probably the single most important characteristic of the patient that influences the choice of alaryngeal speech method is cognitive or mental status. An impaired mental status may prevent acquisition of alaryngeal speech despite adequate physical capability. For example, although a viable vibratory segment is the key determinant of successful esophageal and TE voice production, a patient with severe cognitive dysfunction will not be able to learn the technique of esophageal speech or manage a TE voice prosthesis. Hence, high levels of motivation and the presence of necessary anatomy are not sufficient without adequate cognitive functioning. Even the use of the artificial larynx is dependent on learned behavior. Patients with extreme cognitive impairment may find the use of standard communication board systems most effective for daily routine needs.

Patients with head and neck cancer often present with a variety of comorbidities that may impact the choice of alaryngeal speech alternative and rehabilitative success. Patients who have pulmonary diseases, such as emphysema or chronic obstructive pulmonary disease (COPD), often find it more difficult to achieve TE voice production. Their reduced lung capacity inhibits the ability to clear secretions from the airway and provide adequate pulmonary support for speech production. Likewise, pulmonary disease may impede the coordination and control of air transfer for esophageal speech production. In addition, degenerative conditions such as arthritis, neuromuscular disorders, or visual and hearing impairments may require modifications to the standard manner of execution of the particular method of alaryngeal speech production, but they do not prevent the acquisition of alaryngeal speech. For instance, an individual with poor manual dexterity, who is unable to occlude the stoma for TE speech production, may be a successful TE speaker by using a hands-free valve. Potential barriers to TE speech success should be thoroughly communicated to the patient to ensure realistic expectations for recovery because the presence of comorbid conditions may complicate the rehabilitative process and affect the final speech outcome.

Persistent or recurrent cancer in the head and neck region may also affect the choice of alaryngeal speech communication. The presence of a tumor may increase the likelihood of complications, particularly in patients who are TE speakers. In general, however, persistent or recurrent disease has little effect on the use of an artificial larynx unless the structures and movements of the oral cavity or neck are involved.

Although radiation is not a contraindication to any method of alaryngeal speech production, the initiation of alaryngeal speech therapy may need to be delayed when the effects of radiation are significant. During RT, patients often experience transient difficulties in producing alaryngeal voice or speech, and inflammatory reactions around the stoma and stomal stenosis are not uncommon. The magnitude of the effect varies from patient to patient, but in general, radiation affects tissue elasticity, viscosity, vascularization, and healing ability. In severe cases, extensive fibrosis, necrosis, and poor wound healing may limit the choices for alaryngeal voice restoration. Additionally, radiation-induced edema may interfere with accurate preoperative assessment and prediction of postoperative TE speech fluency. We generally recommend that evaluation for TEP be delayed 4 to 6 weeks after the completion of RT to allow the effects of edema to subside. Patients who have been heavily irradiated and demonstrate severe tissue changes are at risk for significant complications and may be better suited for secondary TEP.

One of the most challenging complications to manage after TE voice restoration is enlargement of the TEP and therefore this complication has become a focus of recent studies. An enlarged TEP significantly increases the risk of aspiration pneumonia resulting from leakage of liquids, saliva, or food around the TE voice prosthesis into the airway.[17] Although recent studies report the incidence of enlarged puncture between 8% and 18%, the individual risk of enlarged TEP is influenced by specific clinical factors.[18,19] A diagnosis of loco-regional recurrence or distant metastasis after laryngectomy, postoperative stricture, and advanced nodal staging have been identified as independent risk factors for TEP enlargement. In addition, extended resection requiring pharyngeal reconstruction, postoperative radiotherapy,

(c) 2014 Wolters Kluwer. All Rights Reserved.

and preoperative nutritional deficiencies portend a higher risk of TEP enlargement.[18] Although a number of methods have been proposed to control aspiration from an enlarged TEP,[19] there is general consensus that conservative nonsurgical methods are preferred over surgical reconstructions that permanently close the TEP. Prospective data suggest that customization of the TE voice prosthesis achieves immediate relief of aspiration in >75% of cases. The immediate success of prosthetic customization is attractive in a clinical setting, but promising long-term success rates of 80% are also reported.[20]

Finally, patients who require pharyngeal reconstruction show a higher rate of morbidity, elevated risk of complications, and less optimal recovery of voice and swallowing functions. Pharyngeal reconstruction is used after extended resections that create a pharyngoesophageal defect or in salvage total laryngectomy cases after chemoradiation failure to decrease the risk of pharyngocutaneous fistula. A variety of reconstructive choices are available. The two primary options for circumferential defects include tubed fasciocutaneous flaps and alimentary tract organ transposition. Alternatively, partial pharyngeal defects may be reconstructed using fasciocutaneous "patch" flaps. Numerous studies have demonstrated the feasibility of TE voice restoration after pharyngeal reconstruction, but the choice of reconstruction has been shown to affect TE voice and swallowing outcomes. Circumferential pharyngoesophageal defects that are reconstructed with a tubed anterolateral thigh flap are associated with higher rates of TE speech fluency, routine use of TE voice, and oral alimentation compared with those using jejunal interposition.[21]

## REHABILITATION AFTER ORGAN PRESERVATION

Organ preservation, either surgical or nonsurgical, is now a primary consideration when treating head and neck cancer. As organ-sparing treatments have evolved and improved, a greater focus on preservation of speech and swallowing function and quality of life has emerged. Data have shown that even those treatments that are designed specifically for organ preservation, such as RT, chemotherapy, and partial surgical resections, alone or in combination, frequently result in marked functional sequelae.[22] Clearly, anatomic preservation does not always ensure preservation of speech or swallowing function. For patients with larynx cancer, the ability to eat, swallow, and speak intelligibly after total laryngectomy may be preferred to feeding tubes, gestures, and writing when anatomic preservation of the larynx fails to preserve function.

Again, it is important to discuss realistic expectations for speech and swallowing recovery after organ-sparing procedures. Despite the often-subtle changes in vocal quality, speech is generally adequately intelligible unless significant alterations in the structures and physiology of the oral cavity have occurred. Unlike speech, however, swallowing function is at a greater risk for impairment, and outcomes vary greatly depending on the site of disease and the type of organ preservation regimen chosen. For example, a unilateral pharyngeal wall tumor treated with radiotherapy will have very different swallowing outcomes compared with those following treatment of a posterior pharyngeal wall tumor that crosses midline and is treated with a combined regimen of radiation and chemotherapy. In some cases, patients return to oral nutrition and regular diets after treatment, whereas others remain gastrostomy tube dependent for the remainder of their lives. We are only beginning to understand the impact of organ preservation techniques on long-term speech and swallowing function in patients treated for head and neck cancer.

### After Nonsurgical Organ Preservation

Nonsurgical organ preservation alternatives primarily include regimens of RT, combined chemoradiotherapy (CRT), and experimental chemotherapy protocols. Targeted molecular therapy is offered with increasing frequency in organ-sparing protocols, and promising functional data are emerging following use of these regimens.[23] The effects of RT or CRT produce immediate as well as long-term alterations in speech, voice, and swallowing that may increase in severity even years after the completion of radiation treatment. The magnitude of the effects from RT or CRT varies among patients but the majority experience some degree of speech and swallowing impairment.[22,23] RT may adversely affect speech production, intelligibility, and vocal quality resulting in slurred speech, problems with articulation, and changes in sound quality.

In general, however, RT has a greater and more persistent effect on swallowing than it does on speech, yet dysphagia and aspiration remain underreported and underappreciated consequences of RT and CRT despite this finding.[22] The true extent of this toxicity is unknown; however, it has been estimated that up to 50% of survivors of advanced head and neck cancer have dysphagia.[4] Studies report aspiration rates between 30% and 62% after RT or CRT, and silent aspiration is observed in at least one-third of aspirators after CRT.[5] Radiation-induced dysphagia most commonly results from oropharyngeal fibrosis, cranial neuropathy, and sensory alterations associated with acute and chronic tissue changes. The extent of dysfunction varies with the total dose, schedule, and duration of RT, as well as the extent of the radiation field. Recent investigations have identified associations between swallowing outcomes and dose-volume distributions to key structures including the pharyngeal musculature, supraglottic larynx, esophageal inlet, and oral cavity. Several investigators have identified key organs at risk (OARs) and are developing dose-limiting treatments that use intensity-modulated radiation therapy (IMRT) to reduce normal tissue damage and preserve function. However, the ability of these treatment regimens to improve long-term function, generally >5 years, through dysphagia-specific dose constraints continues to be investigated.[24] Additionally, data from clinical and population-based studies suggest that chemotherapy exacerbates the effects of RT on dysphagia,[25] particularly when delivered concurrently with radiotherapy. Again, the long-term effects remain unknown.

Acute tissue edema and erythema during RT or CRT may result in swallowing dysfunction by reducing mastication and slowing the movement of food through the oral cavity. When the impairment is severe, aspiration may occur. Acute swallowing impairments generally resolve as edema and mucositis improve, but it is not uncommon for dysphagia to persist or occur months or years after the completion of RT or CRT. We are just beginning to appreciate the devastating effects to swallowing as long-term head and neck cancer survivors treated with regimens of radiation 5 to 10 years ago return complaining of increasing difficulty maintaining oral nutrition and an inability to swallow their own saliva. Instrumental examinations in cases of late dysphagia after RT or CRT are characterized by significantly impaired range of motion of the laryngopharynx leading to profound pharyngeal residue and a tendency for silent aspiration.[26] Unfortunately, the exact combination of risk factors that result in long-term dysphagia are unknown; therefore, any patient with or at risk for dysphagia should be evaluated by an experienced speech pathologist.

Although current knowledge limits our ability to identify those patients who are likely to develop long-term dysphagia after radiation treatment, several risk factors have been reported. Investigators have shown that the site of the primary tumor and T stage impacts the type and severity of dysphagia after definitive RT

(c) 2014 Wolters Kluwer. All Rights Reserved.

or CRT. Of all patients with head and neck tumors, swallowing dysfunction is most pronounced in patients with oropharyngeal, supraglottic, laryngeal, and hypopharyngeal tumors, but overall, patients with hypopharyngeal tumors have the greatest degree of swallowing impairment.[27] Patients who have difficulty swallowing before treatment are also at higher risk for chronic dysphagia and permanent feeding tube dependency.[5] Likewise, prolonged intervals of nothing per oral (NPO) >2 weeks during RT or CRT are associated with poorer swallowing outcomes.[4] Therefore, patients should be encouraged to swallow throughout the course of RT or CRT as much as possible, and even brief NPO intervals should be avoided.[22]

Head and neck cancer patients commonly require nutritional support during RT or CRT due to mucositis and other acute toxicities of therapy. However, there is a lack of consensus about clinical practices concerning enteral nutrition during RT or CRT.[28,29] Although studies demonstrate that prophylactic or early placement of feeding tubes decrease acute weight loss and treatment interruptions, data also suggest that many prophylactic PEG tubes may be placed unnecessarily, resulting in undue patient burden and expense. In addition, the unnecessary placement of feeding tubes puts patients at significant risk for long-term g-tube dependence and swallowing dysfunction. A recent survey found that almost half of patients who had a prophylactic PEG tube prior to RT or CRT had limited use of the tube. Other reports suggest that between 30% and 60% of patients may be able to maintain oral nutrition during RT or CRT and avoid unnecessary feeding tube placement.[29–31] Data demonstrate an important association between function and long-term swallowing deterioration and g-tube placement. Based on a study of 474 patients with oropharyngeal cancer, 62% required the use of a g-tube during the 5-year study period. In addition, patients who presented with baseline swallowing dysfunction were more likely to need a g-tube for nutrition. Additionally, comparisons from observational studies have also reported a higher incidence of severe dysphagia and esophageal stricture, lower swallowing-related quality of life, and longer duration of feeding tube dependence in patients who received gastrostomy tubes prophylactically.[31]

Investigators are now focusing on the benefit of targeted swallowing therapy to prevent long-term swallowing dysfunction after radiation therapy alone or in combination with regimens of chemotherapy. Early data regarding patient adherence to appropriately selected swallowing exercises show that patients who reported exercise adherence were less likely to undergo gastrostomy tube placement compared with those who did not report adherence (RR = 24.0, $p < 0.001$).[31] It is therefore not surprising that the current emphasis of treatment for patients with radiation-induced dysphagia has shifted from rehabilitation to prevention. Nonsurgical organ preservation treatment regimens should include targeted swallowing intervention based on the findings of instrumental examinations that aim for maximal swallowing recovery quickly. Studies have shown that any delay in swallowing intervention may prevent maximal functional recovery due to the cumulative effects of RT. Fibrosis, once present, becomes nearly impossible to reverse, and therefore early concentrated intervention is critical. Data reinforce the importance of daily exercise that targets the strap musculature, pharyngeal constrictor complex, and the base of the tongue during radiation therapy. These same data show improved swallowing outcomes after the completion of radiation therapy. Preventive swallowing exercises have been associated with superior swallowing-related quality-of-life scores, better base of tongue retraction and epiglottic inversion, preservation of postradiotherapy muscle mass of critical swallowing musculature, and shorter duration of gastrostomy tube dependence after RT or CRT.[31–33] Therefore, timely therapeutic regimens of swallowing exercises designed to strengthen musculature and maintain range of motion cannot be overemphasized as they may provide the best prevention of long-term swallowing dysfunction in patients who have received RT or CRT for head and neck cancer.

## After Surgical Organ Preservation

Along with improvements in nonsurgical organ preservation techniques, new surgical techniques that include endoscopic laser and robotic procedures have shown dramatic evolution in their ability to surgically preserve the organ and its function. This is particularly true for cancers of the larynx, in which surgical organ preservation conserves the airway and allows for laryngeal speech production without a permanent tracheostoma. The options for surgical preservation of the larynx include transoral laser microsurgery (TLMS) and conservation surgeries. Historically, cordectomy, supraglottic laryngectomy, and vertical partial laryngectomy have been the most common examples of open conservation surgeries. However, the disadvantage of open surgical conservation procedures has been the significant disruption to the adjacent suprahyoid musculature that is critical to swallowing function. The supracricoid partial laryngectomy (SCPL) provides an alternative for patients who might otherwise require a total laryngectomy. Most recently, transoral robotic surgery (TORS) is used as a conservation surgery for frontline management, most commonly for pharyngeal cancers as an alternative to definitive radiotherapy-based regimens. These data along with prospective comparisons are forthcoming, but preliminary small studies suggest satisfactory functional outcomes after TORS and TLMS as frontline treatment for a variety of disease sites.[34]

The choice of any surgical organ-sparing procedure requires appropriate patient selection to achieve successful recovery and optimal functional outcomes. This remains true for patients with advanced as well as early disease. When the probability of patient survival remains equal regardless of the treatment alternative, surgical or nonsurgical, as is the case for patients with early glottic cancers, the choice of treatment then centers around long-term functional outcomes. Hence, thorough evaluation and patient selection is critical for both survival and optimal quality of life.

Depending on the choice of surgery, patients must often be able to tolerate the effects of aspiration that result from a severely compromised glottic or supraglottic sphincter. Rehabilitative intervention should begin with preoperative examination to establish baseline function. The choice of instrumental evaluation (FEES or MBS study) depends on the type of conservation laryngeal surgery. Studies have shown that levels of pretreatment functioning are frequently predictive of postoperative rehabilitative potential. The findings from postoperative instrumental swallowing examination should be used to guide the rehabilitative course of swallowing recovery because of the high risk for a sensate aspiration. Experience has shown that patients' readiness to begin oral intake following organ preservation surgeries varies. Recommendations regarding the initiation of oral intake and the types and quantities of food the patient will best tolerate are based on objective swallowing data with the final goal of swallowing rehabilitation to advance the patient to the least restrictive diet they are able to tolerate.[35]

# CONCLUSION

Rehabilitation of patients with head and neck cancer is a multidisciplinary team effort that must include a speech pathologist who is an expert in evaluating and managing patients with head and neck malignancies. Rehabilitation should start early to maximize the functional restoration of speech and swallowing. Future research will identify the critical determinants to help clinicians

(c) 2014 Wolters Kluwer. All Rights Reserved.

predict long-term functional outcomes in patients treated for head and neck cancer. In the meantime, patients who are at risk for speech and/or swallowing problems must be properly evaluated before treatment begins so that appropriate rehabilitative interventions can be initiated to prevent long-term functional deterioration.

CHAPTER 12

K. Kian Ang and Erich M. Sturgis

# Human Papillomavirus–associated Head and Neck Carcinoma

## INTRODUCTION

Worldwide, head and neck squamous cell carcinoma (HNSCC) accounts for a relatively small percentage of all cancers, with notable exceptions of high nasopharyngeal cancer incidence in Southeastern China and Southeastern Asia and high oral cavity cancer incidence in Melanesia and South-Central Asia.[1] More than 600,000 people were diagnosed with HNSCC worldwide in 2008.[2] In the United States, HNSCC accounted for only 3% (about 53,000) of all new cancer cases and only 2% (approximately 12,000) of all cancer deaths in 2010.[3] HNSCC affects men 2 to 4 times more commonly than women.

Intensive laboratory and clinical investigations conducted during the past few decades along with technological advances have significantly improved our knowledge of the biology of HNSCC and led to the establishment of new multimodality treatment regimens, improved surgical and radiation therapy methods, and refined management strategies for HNSCC originating at different subsites to optimize tumor control while preserving organs and physiologic functions. As these research efforts have been evolving, the epidemiology and demographics of HNSCC have been changing, particularly during the past decade, mainly because of the appearance and increasing incidence of human papillomavirus (HPV)–related carcinoma.

In this chapter, we address the changing demographics of HNSCC, its diagnosis, and the clinical behavior of HPV-associated oropharyngeal carcinoma, focusing on studies devoted to assessing the discovery of prognostic and predictive biomarkers. Rather than providing an exhaustive review, we chose to present pertinent data to illustrate important discoveries relevant to clinical practice. We also discuss briefly the current research strategies aimed at changing treatment paradigms so as to reduce morbidity while preserving high tumor control rates through well-coordinated clinical trials.

## CHANGING EPIDEMIOLOGY OF HEAD AND NECK CANCER

### Decline in Tobacco Use and Smoking-related HNSCC

As presented by Giovino in an overview paper and illustrated in Figure 12-1A,[4] smoking of manufactured cigarettes accounted for 1% of all tobacco consumed in the United States in the 1880s but this form of use increased progressively to about 80% by 1950, when overall annual tobacco consumption peaked at about 13 lb per person. As evidence mounted regarding the association between tobacco use and lung cancer, cardiovascular disease, and other illnesses, and with the Surgeon General's warning about the hazards of cigarette smoking, its use diminished consistently since the mid-1960s and dropped to 3.7 lb annually per capita by 2006.[4,5] More than half of men and one-third of women in the United States smoked in 1965 but less than a quarter of men and less than one-fifth of women smoked in 2006.[4]

HNSCC is one of several cancers that are strongly associated with tobacco use.[6] As might be expected for diseases with a long initiation phase associated with chronic tobacco exposure, the primary public health goal of reducing cancer incidence by smoking cessation did not begin to occur until the late 1980s.[5] Cancer statistics data available at the Surveillance, Epidemiology, and End Results (SEER) website (http://www.seer.cancer.gov/faststats) indeed reveal a steady decrease in the age-adjusted incidence rates of carcinoma of the larynx, the floor of mouth, the gingiva, and most other oral cavity sites since early 1980s Figure 12-1B.[7] In contrast, however, the age-adjusted incidence rates of carcinoma of the tongue, the tonsil, and other pharyngeal regions have not decreased over the years and, in contradiction to expectations, even began to increase since approximately the turn of the millennium. These complex trends in oropharyngeal cancer incidence are consistent with the decline of one carcinogenic exposure (smoking) but the emergence of another unrelated etiologic exposure during the same period.

Significant site admixture occurs in the annual U.S. "Cancer Statistics" overview, where all subsites of pharyngeal cancer are listed as a single site, "pharynx" (including not only oropharyngeal cancers but also hypopharyngeal and nasopharyngeal cancers) and where base of tongue (lingual tonsil or oropharyngeal tongue) cancers are often listed collectively with oral (mobile or oral cavity) tongue cancers as the generic site "tongue."[3] More thorough analysis, however, revealed that the age-adjusted incidence of oropharyngeal carcinoma is rising dramatically (about 5% annually) in the United States while that of oral cavity cancer is diminishing (approximately 2% annually).[8] Furthermore, the increase in oropharyngeal cancer incidence seems to be primarily represented by middle-aged (40–59-year-old) white men.[8] These contrasting changes in trends suggest that exposures to other carcinogens are emerging in the pathogenesis of HNSCC. As summarized below, an increasing body of data now demonstrates

(c) 2014 Wolters Kluwer. All Rights Reserved.

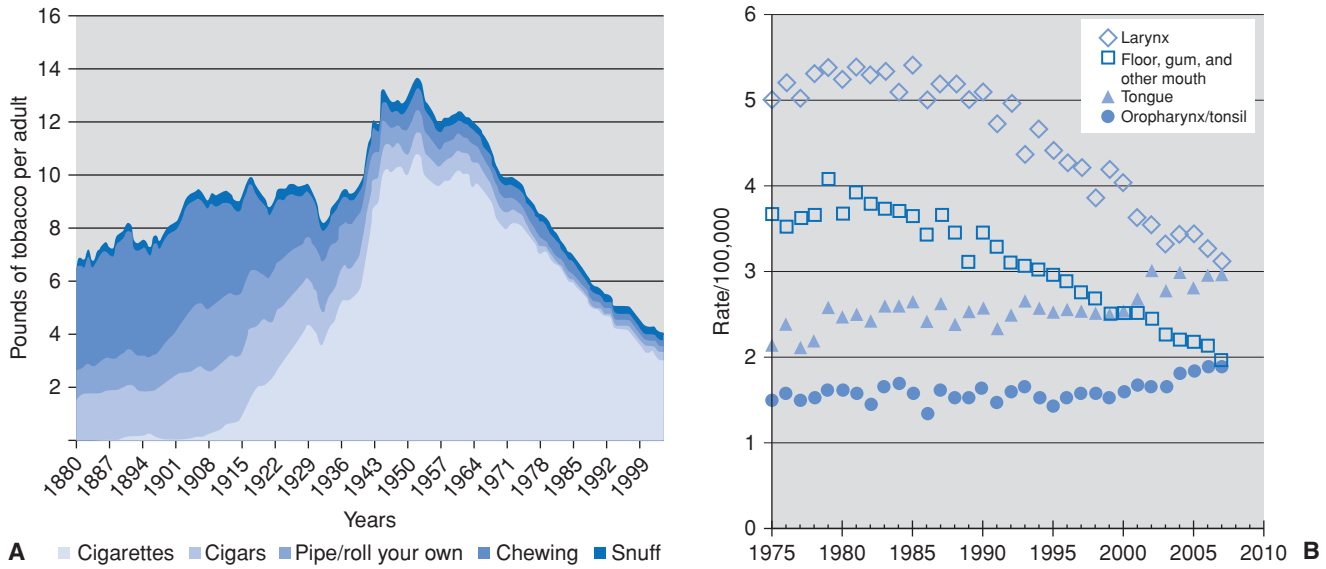

**FIGURE 12-1.** **A:** Trends in per capita consumption of various tobacco products in the United States, 1880 to 2004[4]; reproduced with permission. **B:** Age-adjusted SEER incidence rates for laryngeal cancers, floor of mouth/gingival/other mouth cancer, tongue cancers, and oropharyngeal cancers in the United States. (See color insert)

that HPV is the main contributor to the changing demographics and epidemiologic trends of HNSCC. In fact, U.S. and Swedish subsets from population-based registries have demonstrated that over time an increasing proportion of oropharyngeal cancers are HPV positive.[9–12]

## Emergence of HPV-Associated Oropharyngeal Carcinoma

The role of some types of HPV, most notably HPV-16 and HPV-18, in the pathogenesis of cancer of the uterine cervix has been recognized for more than two decades (reviewed by zur Hausen[13,14]). It is now accepted that carcinogenic effects are mediated mainly through two high-risk HPV oncoproteins, E6 and E7, which inactivate the *TP53* (also referred to as *p53*) and retinoblastoma (also referred to as *Rb*) tumor suppressor gene products, respectively,[15,16] and thereby disrupt cell-cycle regulatory pathways.

More recently, several lines of evidence have established the potential of HPVs to induce HNSCC, specifically oropharyngeal cancer. In reviewing epidemiological and experimental evidence, Franceschi et al.[17] showed that at least a proportion of cancers of the upper aerodigestive tract harbor relatively high copy numbers of HPV-DNA and transcripts of viral E6/E7 genes, and a clonal association with HPV has been demonstrated in these tumors. A case-control study showed that the presence of HPV DNA in the oral cavity was associated with a higher risk of oral cancer, independent of alcohol and tobacco consumption, with an odds ratio of 3.7 (95% confidence interval [CI], 1.5–9.3). Notably, however, this study suffered from site admixture of oral cavity and oropharyngeal cancers.[18] Another study revealed that after adjustment for cotinine levels, the odds ratio for HNSCC in subjects who were seropositive for HPV-16 was 2.2 (95% CI, 1.4–3.4) with no increase in risk observed for other HPV types.[19] Remarkably, the odds ratio for oropharyngeal cancer specifically was >14.

A systematic review and meta-analysis revealed that HPV-associated HNSCC is located mainly in the oropharynx and that HPV-16 accounts for the vast majority of these carcinomas.[20,21] The prevalence of HPV in oropharyngeal carcinomas has increased steadily in Western countries. Cohorts of patients mainly from the 1990s had prevalence rates of ≤50% whereas more recent series reported rates in the 70% to 80% range.[8,10,11,20–24] Chaturvedi et al.[8] found in analyzing SEER data that the incidence of all oropharyngeal carcinomas increased significantly between 1973 and 2004, with an annual percentage increase of 0.8 during that time. In a review of tumors from three registries within the SEER, Chaturvedi et al. found HPV prevalence rates increasing over time and were able to estimate that the incidence of HPV-associated oropharyngeal cancer has been increasing over the past two decades, while the incidence of HPV-negative oropharyngeal cancers has declined by approximately half, similar to incidence trends for oral cavity and laryngeal cancer.[12] The authors go on to estimate that the number of HPV-positive oropharyngeal cancers will surpass the number of cervical cancers in 2020.[12]

Interestingly, across the oropharyngeal subsites, the incidence of base of tongue and tonsil carcinomas increased most significantly during this period (with annual incremental rates of 1.3% and 0.6%, respectively) whereas that of pharyngeal wall cancers was stable. In contrast, the incidence of HNSCC originating at anatomical sites unrelated to HPV infection (oral cavity) declined significantly between 1973 and 2004 at a yearly rate of –1.9%. Consequently, the proportion of HNSCC that originated from oropharynx has increased from 18% in 1973 to 31% in 2004. The same phenomenon has been observed in other Western countries such as Sweden.[25]

# HUMAN PAPILLOMAVIRUS

## Characteristics of HPV

HPV is a double-stranded DNA virus that infects human epithelia. The >100 existing genotypes are broadly classified as high-risk or low-risk based upon their oncogenic capabilities.[14,26]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Low-risk types (such as HPV-6 and HPV-11) are associated with both cutaneous and mucosal papillomas, whereas high-risk types (such as HPV-16, HPV-18, HPV-31, and HPV-33) can induce squamous cell carcinomas and are thus termed "oncogenic."[14,26,27] The structure is that of circular viral DNA (approximately 8,000 base pairs) surrounded by viral capsid proteins arranged in a capsule. The approximately 80 genes in the HPV genome are referred to as early (E) or late (L) based upon when during the cell differentiation process they are transcribed and the remaining long control region made up of transcriptional regulators. The early proteins are expressed typically in the basal layer of the epithelia (early in the viral life cycle) and are responsible for gene regulation and replication, whereas the late proteins expressed in more differentiated layers make up the viral capsule,[14,26,27] as described below.

HPV infects the basal layer of the epithelium through breaks in the stratified (differentiated) layers of the epithelium. How and why these breaks in the epithelium occur differs according to the site of infection. HPV affinity for the basal epithelium of different anatomic sites is, in theory, due to variations in the mechanisms and frequency of access to the basal layer as well as tissue-specific differences in the extracellular matrix and cell surface receptors (principally integrins) at each anatomic site.[26] Endocytosis brings the virus into the cell, and subsequently the viral DNA persists as an episome (circular form) in the nucleus.[26–28] At this point, the episome relies upon the host cellular machinery to replicate along with the host DNA. As the host cell differentiates and moves progressively to the superficial layers, the replicated viral DNA is packaged within viral capsids produced during expression of the late genes. The virus is subsequently released as the superficial epithelial layers are desquamated.

## Viral-Mediated Carcinogenesis

The E6 and E7 proteins seem to be critical to the oncogenic potential of HPV because these proteins have the ability to inhibit important tumor suppressor pathways (reviewed by Allen et al.).[26] The principal effect of the E6 protein is the binding and enhanced degradation of the *p53* protein, thus allowing unregulated cell proliferation. Other *p53*-independent effects seem to include effects on telomerase. The E7 protein inactivates another tumor suppressor pathway (the Rb pathway) by binding to Rb proteins, thereby allowing release of the transcription factor E2F and subsequent cell proliferation. E7 also seems to have Rb-independent effects by enhancing the transcriptional activity of E2F through direct binding to E2F-DNA complexes as well as by facilitating HPV avoidance of host immune defenses. Although both E6 and E7 are produced by high-risk (oncogenic) and low-risk HPV, differences in the binding affinities with tumor suppressor proteins among HPV genotypes may account for the observed difference in oncogenic potential.[29]

Most adults have been exposed to HPV, with >80% of women and 60% of men having had a genital infection in their lifetimes.[29,30] Lifetime prevalence rates for oral HPV infection are not known, but point prevalence estimates are generally in the 5% to 10% range[31] and seem to increase with age and to be higher in men than in women.[32] In the largest study to date (>5,500 individuals), oral HPV prevalence, determined by oral rinse and gargle sampling, demonstrated that HPV-62 (followed by types 55, 84, 72, 89, 61, and 6) were the most common low-risk HPV types and HPV-16 (followed by type 66 and less commonly types 51, 39, 56, 52, 59, and 18) were the most common high-risk types.[32] In multivariate analyses, these oral infections were associated with older age, male sex, cigarette smoking, and lifetime number of sexual partners (oral sex partners, vaginal sex partners, and any sex partners).[32] Most of these infections are cleared,[29] and in terms of relative numbers few new cases of cervical, other anogenital, or oropharyngeal cancer are diagnosed annually (<40,000).[3]

Incorporation of the viral genome into the host genome (rather than remaining in the episomal form) may be a critical step in carcinogenesis.[29] Viral DNA insertion tends to occur at certain risk sites (fragile sites) of the host genome, and changes in the viral genome with insertion (particularly interruption of the E2 gene) affect E6 and E7 oncoprotein expression levels.[33] Each step raises important prevention opportunities: the possibility of determining who (by genetic variations) is at risk of HPV-associated cancers among those exposed as well as which viral genotypes are the most oncogenic.

Gillison et al. generated evidence in support of the causal relationship between HPV infection and a subset of HNSCC.[34] This group of investigators assayed tumor specimens from 253 patients with newly diagnosed or recurrent HNSCC for the presence of the HPV genome by polymerase chain reaction (PCR), Southern blot hybridization, and *in situ* hybridization; they also sequenced the viral E6 coding region to confirm the presence of tumor-specific viral isolates as well as sequencing exons 5 to 9 of the *TP53* gene from 166 tumors. HPV was detected in 62 (25%) of 253 cases. HPV-16 was identified in 90% of the HPV-positive tumors and was localized within the nuclei of cancer cells in preinvasive, invasive, and lymph node disease. Southern blot hybridization patterns were consistent with viral integration. As compared with HPV-negative oropharyngeal cancers, HPV-positive oropharyngeal cancers were less likely to have *TP53* mutations. On the basis of available evidence, the International Agency for Research on Cancer concluded in 2007 that HPV type 16 is a cause of oropharyngeal carcinoma (Monograph Volume 90, 2007, which can be accessed from the following website: http://monographs.iarc.fr).

A more recent study compared 28 HPV-16-associated (determined by HPV-specific PCR and fluorescence *in situ* hybridization [FISH] analysis and positive *p16* immunostaining) and 32 HPV-unrelated oropharyngeal carcinomas by comparative genomic hybridization to identify differences in chromosomal and genetic profiles.[35] This work showed that HPV-negative tumors had (a) higher numbers of chromosomal alterations ($p = 0.03$) and amplifications ($p = 0.039$); (b) more losses at 3p ($p = 0.002$), 5q ($p = 0.03$), 9p ($p < 0.001$), 15q ($p = 0.02$), and 18q ($p = 0.004$) and gains/amplifications at 11q13 ($p = 0.001$); and (c) less often 16q losses ($p = 0.02$) and Xp gains ($p = 0.03$). Interestingly, 16q loss, predominantly identified in HPV-related oropharyngeal carcinoma, was a strong determinant of better overall survival ($p = 0.008$) and disease-free survival ($p = 0.01$) and none of those patients had a tumor recurrence.

# DIAGNOSIS AND CLINICAL FEATURES OF HPV-ASSOCIATED OROPHARYNGEAL CARCINOMA

## Histology

No uniform terminology has existed until recently for reporting HPV-associated oropharyngeal carcinoma. Histologically, HPV-associated oropharyngeal carcinomas have been misinterpreted as poorly differentiated carcinomas based on the immature appearance of tumor cells or often described as "basaloid" carcinoma based on the lobular growth of cells with hyperchromatic nuclei and a high nuclear-to-cytoplasmic ratio. A recent study showed that the "basaloid" subtype consists of a mixed group of HPV-positive and HPV-negative carcinomas with very different behaviors.[36] The presence of HPV denotes a subset of basaloid squamous carcinoma with a more indolent behavior.[36] Therefore,

(c) 2014 Wolters Kluwer. All Rights Reserved.

the recommendation was made to classify this subset of tumors as *nonkeratinizing squamous cell carcinoma* to avoid confusion and to routinely test all carcinomas arising in the oropharynx for the presence of HPV, as described below.

## Methods of HPV Detection

Methods of HPV detection have evolved substantially since a connection between HPV and cancer of the uterine cervix was postulated in the 1980s. Currently available methods include detection of serum antibody against several HPV epitopes, type-specific and consensus (broad spectrum) PCR assays, real-time PCR (RT-PCR) to quantify viral load, type-specific DNA *in situ* hybridization, and immunohistochemical detection of surrogate markers, particularly a known biomarker of HPV E7 oncoprotein function, the cyclin-dependent kinase inhibitor p16 protein. As recommended at the 2008 meeting of the task force of the National Cancer Institute's head and neck steering committee, the choice of HPV assay depends on how the information obtained is to be used.[37] In short, HPV serology and PCR-based methods have been used mostly for studying the natural history of HPV infection. A weakness of the nonquantitative PCR-based assay is that it cannot distinguish oncogenic virus from biologically irrelevant (trancriptionally inactive) virus. These methods are being refined, and more sophisticated forms may become available for clinical use.

*In situ* hybridization (ISH) and immunohistochemical (IHC) assays are now widely used for characterizing oropharyngeal carcinoma, and each has strengths and limitations. The presence of punctate hybridization signals within the nuclei of tumor cells is seen only after the HPV DNA has been integrated into the host genome and is thus more biologically relevant.[38] The introduction of various signal amplification steps has significantly improved the sensitivity of this technique, even to the point of viral detection down to one viral copy per cell.[38] Recent advances also make ISH more practical and cost-effective for everyday use in most diagnostic laboratories that routinely process formalin-fixed and paraffin-embedded (FFPE) tissue blocks. For example, the development of nonfluorescent chromogens now allows display of DNA hybridization using conventional light microscopy, and adaptation of ISH to FFPE tissues has made this technique compatible with standard tissue-processing procedures and amenable to retrospective analysis of archival tissue blocks.[37] A type-specific probe is very sensitive for detecting the presence of HPV-16, and a consensus ISH probe can detect 15 HPV types.

Because of its simplicity and ease of interpretation (almost a binomial distribution of staining), the *p16* IHC assay has been advocated as a reliable surrogate marker of HPV-associated oropharyngeal carcinoma.[39,40] Direct comparison of *p16* IHC assay and HPV-16 ISH for relatively large series of HNSCCs reveals a discordance rate of up to 25%. The discrepancies mostly consist of carcinomas that are negative by HPV-16 ISH but are positive by *p16*. In about half of discrepant cases, *p16* expression is attributed to the presence of some other HPV types, as confirmed by wide-spectrum ISH. When E6/E7 mRNA levels were used as a standard of biologically relevant HPV infection, positive *p16* was found to be 100% sensitive but only about 80% specific.[41] The remaining discordance between HPV ISH and *p16* IHC likely reflects the imperfection of *p16* as a surrogate marker, as it is also expressed in basaloid carcinomas that are not related to HPV infection (e.g., carcinomas of the breast, lung, and skin).[37] Overexpression of *p16* could result from perturbations, such as mutational inactivation of the pRB pathway through other mechanisms and perhaps altered methylation or mutation of the *p16* gene.[42] Overexpression of *p16* by IHC has also been documented in HPV-negative nasopharyngeal carcinomas.[43]

Standardization of assay methods is urgently needed so that reproducible results can be obtained from and compared among diagnostic laboratories. A logical and practical HPV detection strategy is also required to improve consistency in daily clinical practice. An algorithm proposed by Westra at a National Cancer Institute State of the Science Meeting that took place in November 2008[37] combines the sensitivity and simplicity of *p16* IHC with the specificity of HPV ISH. IHC for *p16* is recommended as a good first-line assay for eliminating HPV-negative cases from any additional analysis. HPV-16 ISH can be run concurrently with *p16* IHC or as a second-line assay after a positive *p16* result. Given a specificity approaching 100%, a positive HPV-16 ISH reduces the numbers of false-positive cases by *p16* staining alone. A *p16*-positive/HPV-16-negative result identifies a subset of tumors that qualify for rigorous third-line analysis for other oncogenic HPV types by using a consensus ISH probe that detects 15 other HPV types. This strategy can accurately establish the HPV status of the vast majority of oropharyngeal carcinomas while minimizing the expenditure of resources by limiting the cases requiring multiple assays.

## Clinical Features of HPV-Associated Oropharyngeal Carcinoma

HPV-positive oropharyngeal cancers tend to occur in either the tonsils or the tongue base rather than in other oropharyngeal subsites. Numerous case series have established that HPV-positive oropharyngeal cancers have unique demographic, behavioral, and clinical characteristics. A case-control analysis showed a strong association between lifetime sexual behavior and marijuana use for HPV-associated carcinomas, whereas strong trends were observed between consumption of alcohol and tobacco, poor oral hygiene, and HPV-negative cancers.[44]

Most patients with HPV-positive oropharyngeal carcinoma are middle-aged white men, often with higher socioeconomic status, who consume no or relatively low amounts of tobacco or alcohol.[23,44–46] As a group, patients with HPV-positive oropharyngeal carcinoma tend to have higher numbers of sexual partners, and in particular, more oral sex partners.[44,46–48] Though oral mucosal HPV infection is generally thought to be sexually transmitted,[32,49] the reason why HPV-related oropharyngeal carcinoma predominantly affects men is not well understood. Possibly, higher HPV viral loads in infected cervical tissues than in penile tissues might result in a higher viral exposure dose and thus increase the probability of contracting HPV infection when performing oral sex on a woman.[50]

Differences have also been noted in the TNM distribution at the time of diagnosis between HPV-positive and HPV-negative carcinomas. However, published data are not entirely consistent, and the magnitude of these differences varies among series. This discrepancy likely results, to some extent, from the heterogeneous composition of the study population in terms of the primary tumor sites, particularly whether laryngeal cancer was included, and other eligibility criteria for various prospective trials, which limit the generalizability of their results to the oropharyngeal cancer population at large.

Two clinical trials have reported findings from patients with carcinoma at various head and neck sites. The prospective Eastern Cooperative Oncology Group phase II induction chemotherapy trial (protocol ECOG 2399), for example, enrolled patients with stage III or IV squamous carcinoma of the oropharynx or the larynx; tumor specimens were available for assays from 96 patients. More HPV-positive carcinomas were found to have been in earlier T categories (T2, 58% vs. 33%; T3–4, 42% vs. 67%) but in more advanced N categories (N2–3, 66% vs. 50%) compared with HPV-negative tumors.[51] The Danish Head and Neck Cancer

(c) 2014 Wolters Kluwer. All Rights Reserved.

Group trials (DAHANCA 6&7) enrolled patients with stage I to IV carcinoma of the larynx, pharynx, or oral cavity and found no significant difference between *p16*-positive and *p16*-negative tumors in terms of T category, although *p16*-positive tumors were more likely to have had nodal involvement than *p16*-negative tumors (81 of 179 [45%] vs. 192 of 615 [31%]; $p = 0.001$).[52]

Three clinical trials with large number of patients with oropharyngeal carcinoma had similar patterns of distribution by T and N categories. In the series of 323 patients enrolled in a Radiation Therapy Oncology Group (RTOG 0129) phase III trial,[53] HPV-positive carcinomas were on average smaller at diagnosis (T2 34.5% vs. 23.9%; T3 40.8% vs. 36.8%; T4 24.8% vs. 39.3%; $p = 0.006$) compared with HPV-negative tumors, but no significant difference was found in the distribution by N category between the two groups (N0 7.3% vs. 7.7%; N1 10.7% vs. 20.5%; N2 71.4% vs. 64.2%; N3 10.7% vs. 7.7%; $p = 0.46$). Notably, however, patients with T1–2 N0–1 disease were not eligible for this trial. Findings from the TAX-324 series of 111 patients were similar to those from the RTOG series, that is, the incidence of T1–2 tumors was higher for HPV-positive carcinomas than for HPV-negative tumors (49% vs. 20%; $p = 0.001$) but no significant differences were found in nodal status or N category between the two groups.[54] In the Trans Tasman Radiation Oncology Group (TROG) trial of 185 cases, however, patients with *p16*-positive carcinomas had less advanced T category (T1–2 37% vs. 15%; $p = 0.001$) but more advanced N category (N2–3 86% vs. 65%; $p = 0.001$).[55]

Taken together, these findings show that HPV-positive oropharyngeal carcinomas are generally diagnosed at an earlier T category than are HPV-negative tumors. Findings on the extent of nodal involvement at diagnosis are less consistent among series but a trend seems evident toward HPV-positive oropharyngeal carcinomas presenting at more advanced N categories. Of clinical interest is that involved lymph nodes from HPV-positive carcinoma often appear cystic on imaging.[56] This feature is now recognized as a trait of HPV-associated carcinomas, particularly those originating from the tonsil or base of tongue and, therefore, is considered an indication for diagnostic tonsillectomy and multiple base of tongue biopsies when a clinical workup, including examination under anesthesia, fails to detect the primary tumor.

As outlined above, HPV-associated oropharyngeal cancers, as described chiefly in single-institution case series or clinical trials with specific entry criteria, have distinctive demographic, behavioral, and clinical characteristics. Population-level trends in oropharyngeal cancer mirror these characteristics and support HPV as the cause of the national increase in the incidence of oropharyngeal cancer, which is greatest among middle-aged white men.[8] Although many behavioral researchers have suggested that the prevalence of oral sex has risen over the past three decades, reliable data on such national trends are lacking. However, it is clear that smoking prevalence has dropped over this period and, as expected, the incidence of tobacco-associated neoplasms have subsequently declined.[5,8,57–59] National trends also reveal a rising proportion of cancers of the tongue and tonsil presenting as higher-grade tumors, but this is not the case for tumors at other sites.[60] In addition, several groups using population-based registries have described dramatic increases in HPV-positive oropharyngeal cancer among archived tumor specimens over time.[9,10,12,24,61]

## TREATMENT OUTCOMES OF HPV-ASSOCIATED HEAD AND NECK CARCINOMA

### Case-Control Series

Several single-institution retrospective series published about a decade ago suggested that the prognosis for patients with HPV-positive oropharyngeal carcinomas was much better than for those with HPV-negative tumors (Table 12.1). Most of these early series used PCR-based methods to detect the presence of HPV.

Mellin et al., for example, assayed pretreatment biopsy specimen from 60 patients with primary tonsillar carcinomas, treated with radiotherapy alone (45%) or radiation and surgery (55%), for the presence of HPV DNA and also for HPV type with PCR.[62] HPV-16 was detected in 26 (43%) of the cancers, including one double infection with both HPV-16 and HPV-33. Patients with HPV-positive tonsillar cancer had a lower risk of relapse within 3 years after diagnosis than did HPV-negative patients (odds ratio [OR], 4.2; $p = 0.025$). Furthermore, cause-specific survival was significantly ($p = 0.047$) better in patients with HPV-positive tonsillar carcinomas: 5-year survival rates were 53.5% for patients with HPV-positive tumors and 31.5% for those with HPV-negative tumors. The better outcome for patients with HPV-positive tonsillar cancer was independent of TNM classification, nodal status, gender, and age.

Gillison and colleagues tested tumor tissues from 253 patients with newly diagnosed or recurrent HNSCC of the oral cavity, the oropharynx, the hypopharynx, the larynx, or the nasopharynx for the presence of the HPV genome by PCR-based assays, Southern blot hybridization, and ISH.[34] Most patients were treated with surgery with postoperative radiotherapy (49%) and the remainder with surgery alone (17%), radiotherapy alone (25%), or other modalities. HPV was detected in 62 (25%) of the

**Table 12.1 Treatment Outcome by Tumor HPV Status from Single-institution Retrospective Series**

253 cases, and HPV-16 was identified in 90% of the HPV-positive tumors. After adjustment for some known prognostic variables such as the presence of lymph node disease, heavy alcohol consumption, and age older than 60 years, the reduction in risk of death from cancer for all patients with HPV-positive tumors was 59% compared with HPV-negative HNSCC patients (hazard ratio [HR], 0.41; 95% CI, 0.20–0.88; $p = 0.02$), and those with HPV-positive tumors may have had better overall survival as well (HR, 0.60; 95% CI, 0.35–1.0; $p = 0.07$).

Schwartz and colleagues identified through the Cancer Surveillance System (a participant in the SEER program) 254 patients who had received surgery, radiotherapy, or both for primary cancer of the oral cavity, tonsil, or other oropharyngeal sites and who had provided tumor specimens for assays.[63] They tested tumor HPV-16 status by PCR for the presence of the *L1* and *E6* regions and compared the results with treatment outcome. Forty tumors (15.7%) tested positive for HPV-16, and 22 (8.7%) for other HPV types. Patients with HPV-16-positive tumors had significantly lower all-cause mortality (HR estimates, 0.34; 95% CI, 0.14–0.83) and disease-specific mortality (HR, 0.17; 95% CI, 0.04–0.76) than did those with HPV-16-negative patients after adjustment for age, disease stage, treatment, smoking, alcohol use, education, and comorbid diseases. Although not statistically significant ($p = 0.355$), the interaction term for radiation and HPV-16 in the models suggested that HPV-16 positivity was associated with better survival among patients receiving radiotherapy (HR, 0.29; 95% CI, 0.11–0.77) whereas little association was noted among those who did not receive radiation therapy (HR, 0.84; 95% CI, 0.11–6.65).

Similarly, Lindel et al. analyzed biopsy samples from 99 patients with oropharyngeal carcinomas treated with radiation alone (72 patients) or radiation combined with chemotherapy (27 patients) by multiplex PCR for the presence of the L1 open reading frame and *E2* gene.[64] They found 14 tumors to be HPV-positive (11 HPV-16, 1 HPV-33, 1 HPV-35, and 1 HPV-45). Patients with HPV-positive tumors had significantly better local control and overall survival rates. In multivariate analysis, HPV positivity remained associated with a lower risk of local failure (risk ratio [RR], 0.31; $p = 0.048$). Of interest is that four of 11 HPV-16-positive tumors had a disrupted *E2* gene and only tumors with a disrupted *E2* gene manifested local treatment failure.

Weinberger et al. compared *p16* expression by IHC with treatment outcome for 123 patients with primary or recurrent oropharyngeal carcinoma treated with radiotherapy alone (73 patients), surgery with postoperative radiotherapy (44 patients), or other regimens.[40] Good-quality assays were obtained for 120 tumors, of which 24 (20%) were scored as positive for *p16* expression. This study showed that *p16* overexpression was associated with lower 5-year local recurrence rates (11% vs. 53%) and higher rates of 5-year disease-free survival (62% vs. 19%) and overall survival (60% vs. 21%). In multivariate analysis, *p16* expression status remained an independent prognostic factor for local recurrence, disease-free survival, and overall survival.

A meta-analysis of the relationship between HPV status and overall survival and disease-free survival revealed that patients with HPV-positive HNSCC had a lower risk of dying (meta-HR, 0.85; 95% CI, 0.7–1.0) and a lower risk of recurrence (meta HR, 0.62; 95% CI, 0.5–0.8) than HPV-negative HNSCC patients.[65] In addition, tumor site–specific analyses showed that patients with HPV-positive oropharyngeal carcinoma had a 28% reduction in risk of death (meta HR, 0.72; 95% CI, 0.5–1.0) compared with patients with HPV-negative oropharyngeal tumors. Similar observations were made for disease-free survival (meta HR, 0.51; 95% CI, 0.4–0.7). No difference was found in overall survival between patients with HPV-positive or -negative nonoropharyngeal cancer, which supports the notion that the effect of HPV is limited to oropharyngeal cancer and its presence may not be relevant to the etiology or clinical behavior of nonoropharyngeal cancers.

Although these early series have the usual weaknesses of relatively small sample sizes with significant heterogeneity of tumor subsites, disease stage, and treatment administered, confounding by known prognostic variables, assay methods, and so on, the consistency of the findings was rather remarkable and thus provided the impetus for studies using annotated samples of patients enrolled in prospective studies, particularly large phase III trials, as described below.

## Cooperative Group Trial Series

Based on the encouraging findings from early small retrospective series, several subsequent studies were undertaken using annotated archived tumor specimens from well-characterized patients enrolled in phase II and III trials and receiving specific protocol treatment regimens (Table 12.2).

***ECOG 2399 trial.*** Fakhry and associates analyzed samples from patients enrolled in this ECOG phase II trial testing the nonsurgical management of clinical stage III or IV squamous cell carcinoma of the oropharynx or the larynx.[51] Of the 111 patients

enrolled, tumor specimens were available for correlative analysis from 96 patients, most of whom were white men, often with fewer than 20 pack-years of cigarette consumption. Treatment consisted of induction chemotherapy with two cycles of carboplatin and paclitaxel followed by weekly paclitaxel concurrent with standard-fractionation radiotherapy (70 Gy in 35 fractions over 7 weeks). Tumor specimens were evaluated by HPV ISH and *p16* IHC. HPV ISH was positive in 38 (40%) of 96 tumor specimens (36 were positive for HPV-16 and one each for types 33 and 35). Sufficient specimens were available for IHC assay in 36 of the 38 HPV-positive tumors, and all of those 36 samples showed high *p16* expression. Comparisons with clinical outcome data showed that the response rate to induction chemotherapy was higher for HPV-positive carcinomas than for HPV-negative tumors (82% vs. 55%; $p = 0.01$). More importantly, compared with patients with HPV-negative tumors, those with HPV-positive carcinomas had a better 2-year overall survival rate (95% vs. 62%; $p = 0.005$) and, after adjustment for age, disease stage, and ECOG performance status, a lower risk of tumor progression (HR, 0.27; 95% CI, 0.10–0.75; $p = 0.01$). When the analysis was restricted to the subgroup with oropharyngeal tumors, patients with HPV-positive carcinoma had lower risks of both death (HR, 0.39; 95% CI, 0.15–1.05; $p = 0.06$) and tumor progression (HR, 0.38; 95% CI, 0.12–1.15; $p = 0.09$) than patients with HPV-negative tumors after adjustment for ECOG performance status. As the investigators pointed out, sample size constraints limited the number of variables that could be included in the multivariate adjustment. Consequently, larger confirmatory studies were recommended to provide definitive evidence that tumor HPV status is an independent prognostic determinant of survival among patients with oropharyngeal cancer.

***RTOG 0129 Trial.*** Ang et al. undertook a study using tumor specimens from patients in a large phase III trial of HNSCC to assess the demographics and the independent prognostic significance of HPV-related oropharyngeal carcinomas.[53] In that trial, eligible patients with pathologically confirmed, stage III or IV squamous cell carcinoma of the oropharynx, the larynx, the hypopharynx, or the oral cavity without distant metastases were randomly assigned to receive high-dose cisplatin (100 mg/m$^2$) concurrently with either accelerated fractionation (by means of concomitant boost regimen [the experimental arm]) or standard fractionation radiotherapy (the control arm). A total of 721 patients meeting the protocol criteria were enrolled, of whom 433 (60%) had oropharyngeal carcinoma. Tumor samples of sufficient quality were available for marker assays from 323 (75%) of the 433 patients. Tumor specimens were evaluated for HPV-16 DNA by ISH and for *p16* expression by IHC assays. HPV-16-negative tumors were further evaluated for 12 additional oncogenic HPV types (18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). No significant differences in baseline characteristics, overall survival, or progression-free survival were detected between patients with or without available tumor specimens, and the two treatment groups were balanced with regard to tumor HPV status, which suggests that no systematic biases were present. After a median follow-up time of 4.8 years (range 0.3–6.5 years), the 3-year overall survival rate was not significantly different in the accelerated fractionation or the standard fractionation groups (70.3% vs. 64.3%; $p = 0.18$). Therefore, data for all patients with oropharyngeal carcinoma were combined to analyze the association between tumor *p16* status and treatment outcomes. In a Kaplan-Meier analysis, patients with *p16*-positive oropharyngeal carcinoma had better survival outcomes than patients with *p16*-negative oropharyngeal tumors (Table 12.2). The corresponding 3-year rates of overall survival were 83.6% and 51.3% ($p < 0.001$), and the 3-year rates of progression-free survival were 74.4% and 38.4% ($p < 0.001$). An analysis of patterns of relapse revealed a significantly lower 3-year rate of local-regional relapse among patients with HPV-positive oropharyngeal carcinoma (13.6% vs. 35.1%; $p < 0.001$), but an apparent difference in 3-year rates of distant metastasis was not significantly different (8.7% vs. 14.6%; $p < 0.23$). The cumulative incidence of second primary tumors was significantly lower among patients with HPV-positive tumors (5.9% vs. 14.6%; $p = 0.02$), largely because of lower prevalence of smoking-related second cancers in that group.

In the multivariate analysis, age, race, performance status, tumor stage, nodal status, and number of pack-years of tobacco smoking were also significant determinants of overall survival and progression-free survival. Comparing the unadjusted hazard ratios for *p16*-positive versus *p16*-negative tumor status with the corresponding adjusted hazard ratios led to estimates that these factors accounted for a relative difference of approximately 9% in the rates of overall survival and progression-free survival between patients with *p16*-positive versus those with *p16*-negative oropharyngeal squamous cell carcinoma. After this adjustment, patients with *p16*-positive tumors still had a 67% reduction in the risk of death compared with patients with HPV-negative tumors (HR, 0.33; 95% CI, 0.21–0.53; $p < 0.001$) and a 58% reduction in the risk of relapse or death (HR, 0.42; 95% CI, 0.28–0.64; $p < 0.001$) (Table 12.2).

***TROG 02.02 Trial.*** Richin and colleagues studied the prognostic significance of *p16* expression in patients with oropharyngeal carcinoma enrolled in a large phase III trial of the Trans Tasman Radiation Oncology Group (TROG).[55] This protocol randomly assigned patients with previously untreated stage III or IV squamous cell carcinoma of the oral cavity, the oropharynx, the hypopharynx, or the larynx to receive radiotherapy (70 Gy in 7 weeks) with cisplatin (100 mg/m$^2$, on day 1 of weeks 1, 4, and 7) or radiotherapy (70 Gy in 7 weeks) plus tirapazamine (290 mg/m$^2$, on day 1 of weeks 1, 4, and 7 and 160 mg/m$^2$ three times per week in weeks 2 and 3) and cisplatin (75 mg/m$^2$, given 1 hour after tirapazamine on day 1 of weeks 1, 4, and 7). A total of 861 patients were enrolled, of whom 465 (54%) had oropharyngeal cancer. Tumor specimens from 185 patients with oropharyngeal carcinoma who received at least 60 Gy of radiation were available for assay, and overall 106 (57%) of these samples tested positive for *p16* expression. A caveat of this study is that the clinical features of patients with slides available for assay differed from those of patients without available slides in that those with available slides had better performance status, lower T category, and higher hemoglobin levels and were less likely to be current smokers.

Overall survival was better in the *p16*-positive group than in the *p16*-negative group, with 2-year survival rates of 91% and 74% (HR, 0.36; 95% CI, 0.17–0.74; $p = 0.004$) (Table 12.2). Failure-free survival was also better in the *p16*-positive group, with corresponding 2-year rates of 87% and 72% (HR, 0.39; 95% CI, 0.20–0.74; $p = 0.003$). On multivariate analysis, *p16* was a significant prognostic factor (HR, 0.45; 95% CI, 0.21–0.96; $p = 0.04$). Analysis according to treatment regimen showed that the 2-year overall survival rates in the cisplatin group were 89% for *p16*-positive patients and 68% for *p16*-negative patients (HR, 0.34; 95% CI, 0.14–0.86; $p = 0.021$). The corresponding 2-year overall survival rates in the tirapazamine group were 94% and 80% (HR, 0.36; 95% CI, 0.11–1.18; $p = 0.094$). The test for interaction between *p16* and treatment group was not statistically significant ($p = 0.95$). However, a trend was evident for improved local-regional control with the tirapazamine regimen for the *p16*-negative patients.

HPV ISH analysis of 102 of the *p16*-positive tumors showed that 58 (57%) of these tumors were ISH-negative. However, additional assay with PCR demonstrated the presence of HPV in

(c) 2014 Wolters Kluwer. All Rights Reserved.

44 (76%) of those 58 tumors, suggesting that some commercially available HPV ISH assay kits may have lower sensitivity than others.

***TAX-324 Trial.*** Posner and colleagues assessed the prognostic significance of *p16* expression in patients with oropharyngeal carcinoma enrolled in a phase III trial.[54] This protocol randomly assigned patients with previously untreated stage III or IV squamous cell carcinoma of the oral cavity, the oropharynx, the hypopharynx, or the larynx to receive induction chemotherapy with three cycles, given every 3 weeks, of docetaxel (75 mg/$^2$) plus cisplatin (100 mg/m$^2$) and fluorouracil (1,000 mg/m$^2$ for 4 days) (TPF) or three cycles of cisplatin and fluorouracil at the same doses (PF) followed by radiotherapy (70–74 Gy in 7–7.5 weeks) with concurrent weekly carboplatin (area under the curve of 1.5). Of the 501 patients enrolled, 264 (53%) had oropharyngeal cancer. Tumor specimens from 111 patients with oropharyngeal carcinoma were subjected to HPV-16–specific E6 and E7 viral oncoprotein PCR, and 56 (50%) tested positive. No obvious differences were apparent in the clinical features of patients with or without available specimens for assay. At the time of analysis, at a median follow-up time of >80 months, 79% of patients with HPV-positive oropharyngeal carcinoma were alive and their progression-free survival rate was 73% compared with 31% alive and 29% alive without progression with HPV-negative oropharyngeal carcinoma ($p = 0.0001$). HPV-positive oropharyngeal carcinoma was associated with an 80% reduction in mortality (HR, 0.2; 95% CI, 0.10–0.38; $p < 0.0001$). Analysis of the pattern of failure showed a significantly lower local-regional failure rate (13% vs. 42%, $p = 0.0006$) for patients with HPV-positive tumors, but the rates of distant failure, which were low in both subgroups (5% and 11%), were not significantly different. Comparison of the effects of treatment with TPF or PF in patients with HPV-positive or HPV-negative oropharyngeal carcinoma revealed no statistical differences between the regimens, but the sample size for this subgroup analysis was small.

***DAHANCA Trials.*** In this study, Lassen and colleagues correlated *p16* expression with the outcome of patients enrolled in two phase III trials of the Danish Head and Neck Cancer Group (DAHANCA 6&7).[52] These protocols randomized 1,476 patients with primary invasive (stage I–IV) carcinoma of the larynx, the pharynx, or the oral cavity to receive radiation in 2-Gy fractions, given either in 5 fractions (control) or 6 fractions (experimental) per week to total doses of 66 to 68 Gy. Patients with pharyngeal or oral cavity tumors also received the hypoxic cell radiosensitizer nimorazole (1,200 mg/m$^2$). Tumor specimens were available from 794 (54%) patients for *p16* assay, of which 179 (23%) were positive. The proportion of *p16*-positive carcinomas differed significantly ($p = 0.001$) according to primary tumor site: 83 (42%) of 200 oropharyngeal carcinomas, 71 (16%) of 428 laryngeal tumors, 12 (16%) of 74 other pharyngeal cancers, and 13 (14%) of 92 oral cavity neoplasms.

Patients with *p16*-expressing tumors had significantly better local-regional tumor control (HR, 0.66; 95% CI, 0.49–0.88; $p = 0.004$), disease-specific survival (HR, 0.58; 95% CI, 0.41–0.81; 5-year estimates 78% vs. 64%; $p = 0.001$), and overall survival (HR, 0.62; 95% CI, 0.49–0.78; 5-year estimates 62% vs. 47%, $p < 0.0001$). The significantly higher probability of local-regional control obtained with accelerated fractionation was found to apply to both *p16*-positive tumors (HR, 0.58; 95% CI, 0.35–0.99; $p = 0.05$) and *p16*-negative tumors (HR, 0.77; 95% CI, 0.60–0.98; $p = 0.04$). In the group with *p16*-positive tumors, disease-specific survival was significantly improved with the accelerated regimen (HR, 0.47; 95% CI, 0.25–0.89) but no significant overall survival benefit could be demonstrated (HR, 0.78; 95% CI, 0.51–1.19). In the *p16*-negative group, neither disease-specific survival (HR, 0.86; 95% CI, 0.66–1.31; $p = 0.28$) nor overall survival (HR, 1.02; 95% CI, 0.84–1.25; $p = 0.8$) was significantly improved by accelerated radiotherapy.

In the multivariable analysis using risk of local-regional failure as the endpoint, low T category, no lymph node involvement, good performance status, positive *p16* status, and treatment with accelerated fractionation were independent factors of good prognosis. Subgroup analysis showed that for local-regional tumor control, accelerated fractionation remained of independent prognostic significance in both *p16*-positive (HR, 0.56; 95% CI, 0.33–0.96) and *p16*-negative tumors (HR, 0.88; 95% CI, 0.67–1.15). For cancer-specific death, the accelerated regimen was independently associated with better outcome for the *p16*-positive group (HR, 0.43; 95% CI, 0.22–0.82), but not for the *p16*-negative group (HR, 0.86; 95% CI, 0.66–1.31). In terms of overall survival, the accelerated regimen had no significant benefit, with HRs of 0.68 (95% CI, 0.44–1.04) for the *p16*-positive group and 1.05 (95% CI, 0.87–1.29) for the *p16*-negative group. Moreover, no interaction between *p16* status and fractionation regimen could be demonstrated ($p = 0.40$).

## HPV *In Situ* Hybridization versus *p16* Immunohistochemistry

Weinberger and colleagues undertook a combined analysis of *p16* expression by IHC analysis and HPV-16 DNA viral load by RT-PCR in a retrospective series of 107 patients with primary or recurrent oropharyngeal carcinoma treated with radiotherapy with or without surgery.[40] The final analysis included 77 patients with tumors for which data on both HPV-16 and *p16* expression were available. These investigators found that the discriminatory power for local recurrence, disease-free survival, and overall survival increased dramatically when patients were segregated into three classes, that is, low *p16* and HPV-16-negative (Class I, $n = 30$), low *p16* but HPV-16-positive (Class II, $n = 29$), and high *p16* and HPV16-positive (Class III, $n = 18$). In multivariate analysis, no significant difference was found between patients in Class II and Class I. However, patients in Class III had significantly lower risk of death (HR, 0.19; $p = 0.013$) and risk of relapse or death (HR, 0.20; $p = 0.005$) than did patients in Class I. The inclusion of patients with recurrent disease and the heterogeneity in therapies administered may have confounded the results. The absence of tumors that were *p16*-positive but HPV-16-negative was surprising and inconsistent with findings of other series, as described below. These investigators further characterized the expression levels of 13 downstream proteins by using tissue microarray slides containing specimens from 77 patients by AQUA quantitative fluorescent immunohistochemistry and found that relative to Class II (HPV+/*p16*–, referred to as HPV-inactive) tumors, Class III (HPV+/*p16*+, labeled HPV-active) carcinomas had a significantly higher expression of β-catenin and a trend for higher expression of epidermal growth factor receptor (EGFR) and vascular endothelial growth factor receptor (VEGFR).[66] Findings on potential correlations between HPV/*p16* and EGFR, however, were not consistent with the findings of other series (see below).

The large sample size and the uniformity of treatment in the RTOG 0129 series made it possible to assess the relative strength of HPV ISH vis-à-vis *p16* IHC as a prognostic marker.[53] The presence of HPV DNA was strongly associated with *p16* expression. Of the 315 tumors tested with both assays, 192 (61%) were positive and 92 (30%) were negative for both HPV ISH and *p16* IHC; 22 tumors (7%) were HPV ISH–negative but *p16*-positive, and only 7 tumors (2%) were HPV ISH–positive

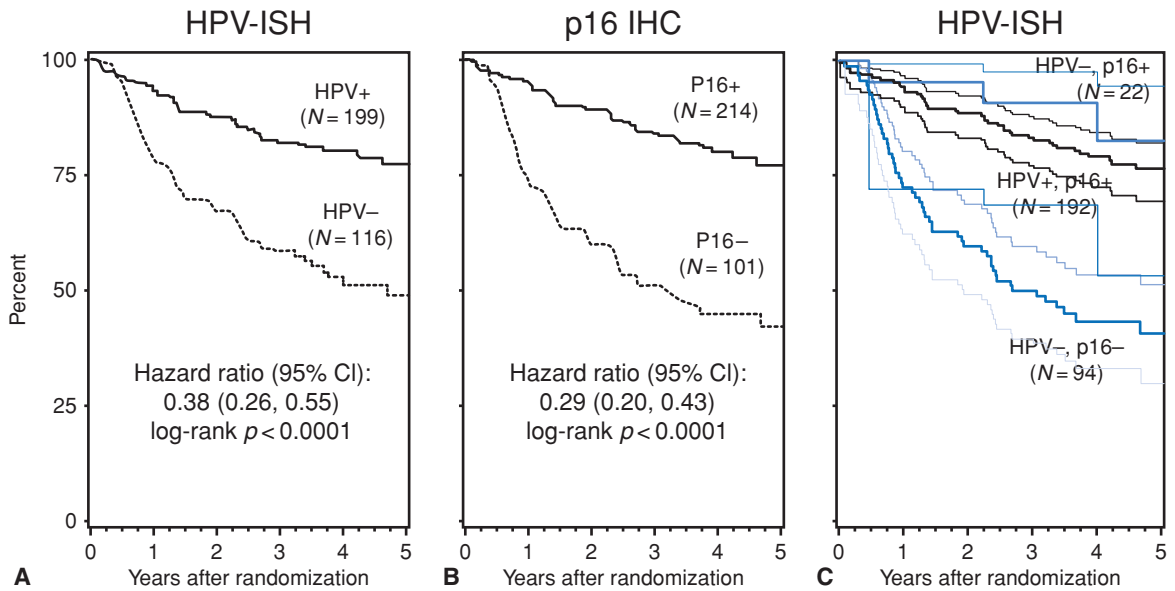

**FIGURE 12-2.** Kaplan–Meier estimates of survival of study patients with oropharyngeal carcinoma according to the results of HPV status by in situ hybridization assay **(A)**, p16 immunohistochemical staining **(B)**, or the combination of both assays **(C)**.

*Source:* Modified from Ang KK, Harris J, Wheeler R, et al. Human papillomavirus (HPV) and survival of patients with oropharynx cancer *N Engl J Med.* 2010;363:24–35, with permission.

but *p16*-negative. Results of analyses using *p16* expression as a stratification factor were consistent with those based on HPV status. However, the difference between *p16*-positive versus *p16*-negative groups seemed to be slightly more pronounced in these analyses (Fig. 12-2A, B), with HR for death of 0.29 (95% CI, 0.20–0.43) and HR for progression-free survival of 0.33 (95% CI, 0.24–0.46). The corresponding HRs after adjustment for other prognostic factors were 0.33 (95% CI, 0.21–0.53) and 0.42 (95% CI, 0.28–0.64), respectively. Notably, the Kaplan-Meier survival curve for the 22 patients with tumors that were HPV ISH–negative but *p16*-positive was similar to the survival curve for patients with tumors positive by both HPV ISH and *p16* (Fig. 12-2C).

Assay methods have varied among series, and available data are still conflicting in terms of the proportion of tumors that are HPV-positive but *p16*-negative or vice versa. To formulate a rationale for routine clinical application, further studies are needed to resolve whether *p16* IHC is a better marker than the more cumbersome HPV ISH or whether having both assays would be useful for a more refined stratification of oropharyngeal cancer behavior. Only thorough studies using annotated specimens of patients enrolled in prospective trials with stringent quality assurance can provide clearer answers to these questions.

## HPV or *p16* Expression as a Strong Independent Prognostic Marker

The field of biomarker research is still evolving. The distinction between prognostic and predictive biomarkers has not been widely appreciated until recently. Therefore, these terms have been used rather loosely and interchangeably. Figure 12-3 illustrates the concept and definition of the different classes of markers. The rates and extent of separation among the curves will vary with the disease type and stage and the efficacy of therapy, but the general principles and the relative ranking are applicable. In panel A, marker X represents a *prognostic* marker for an aggressive tumor, the presence of which is associated with poorer survival rate after both treatment (Rx) 1 and 2, although Rx 2 is more effective than Rx 1. Marker Y (panel B), on the other hand, exemplifies a *predictive* marker for response to Rx 2. Its presence is associated with better survival after Rx 2 (solid red curve). Panel C illustrates that some markers could have both prognostic and predictive value. For example, the absence of Marker Z is associated with better prognosis (solid and dotted black curves vs. dotted purple curve). However, because this marker also predicts response to Rx 2, its presence is associated with better outcome after Rx 2 (solid purple curve) relative to Z+ after Rx 1 (dotted purple curve) and Z– after Rx 2 (solid black curve).

Figure 12-3 also shows that carefully designed clinical trials incorporating patient stratification according to biomarkers and randomly assigning patients to receive distinct therapy modalities are needed to yield a conclusive answer as to whether a marker (such as HPV ISH or *p16* IHC) is prognostic, predictive, both, or neither. Because reported clinical trials were designed before the knowledge of the emergence and the distinct nature of HPV-associated oropharyngeal carcinoma, none of the phase III trials completed to date has incorporated prospective marker assessment. Therefore, the predictive nature of HPV ISH or *p16* IHC cannot be properly assessed at this time.

The available data, however, show firmly that HPV positivity or *p16* expression is a strong prognostic biomarker for oropharyngeal carcinoma. Their presence is associated with better tumor control and survival outcomes after radiotherapy alone,[52] concurrent radiation and cisplatin,[53,55] and platinum- and taxane-based induction chemotherapy.[51,54] For example, the multivariable analysis of the RTOG data showed that HPV status was the strongest prognostic determinant.[53] The HR of HPV status (negative vs. positive) for death from all causes was 2.44 (95% CI, 1.75–3.41; $p < 0.001$). In contrast, the HRs by T and N categories were 1.85 (95% CI, 1.46–2.34; $p < 0.001$) and 1.68 (95% CI, 1.33–2.14; $p < 0.001$), respectively.

## INTERACTION BETWEEN HPV STATUS AND OTHER MOLECULAR CHANGES

### Tobacco Smoking

Although cigarette smoking has been well documented as being an important and independent prognostic factor for outcome in patients with HNSCC,[67] the interaction between smoking and HPV status on clinical outcomes was less well known. The large sample size of the RTOG 0129 series and the systematic data collection in this trial allows assessment of the interaction between tumor HPV status and smoking.[53] Of the 206 patients with HPV-positive oropharyngeal carcinoma, 59 (29%) were never-smokers and 110 (53%) were former smokers. The corresponding numbers for the 117 patients with HPV-negative oropharyngeal tumor were 14 (12%) never-smokers and 54 (46%) former smokers. The median numbers of pack-years of tobacco smoking were 12.2 (range 0–152) for the HPV-positive subgroup and 36.5 (range 0–96) for the HPV-negative subgroup.

Further analysis identified tobacco smoking to be independently associated with overall survival and progression-free survival both in the subgroup of patients with oropharyngeal carcinoma and in the entire study population. The risks of death and cancer relapse or death increased significantly by 1% for each additional pack-year of tobacco smoking, and the magnitude of the tobacco effect was similar for patients with HPV-associated oropharyngeal carcinoma (HR, 1.01; 95% CI, 1.00–1.02) and for those with HPV-negative cancer (HR, 1.01; 95% CI, 1.00–1.03).

Recursive partitioning analysis was undertaken in an attempt to stratify patients into distinct risk classes. In this analysis, the *p16* status of the tumor came out as the strongest determinant of overall survival, followed by the number of pack-years of tobacco smoking (≤ 10 vs. >10) and then N category (N0–N2a vs. N2b–N3), for *p16*-positive tumors or T category (T2–3 vs. T4), for *p16*-negative tumors (Fig. 12-4A). With this method, patients with oropharyngeal squamous-cell carcinoma could be separated into low-, intermediate-, and high-risk classes with 3-year overall survival rates of 93.5%, 67.0%, and 41.6%; corresponding 3-year local-regional control rates were 90.4%, 80.9%, and 57.3%.

Compared with the low-risk group, patients in the intermediate-risk class had a 4.06-fold (95% CI, 2.22–7.43) higher risk of dying, and those in the high-risk class had an 8.75-fold (95% CI, 4.89–15.66) higher risk of dying (Fig. 12-4B). Interestingly, patients with *p16*-positive tumors were at low risk, except for smokers with N2b to N3 disease, which moved them to the intermediate-risk class; patients with *p16*-negative tumors were at high risk except for nonsmokers with T2 or T3 tumors, which shifted them to the intermediate-risk class.

These findings strongly suggest that tobacco smoking induces additional molecular alternations in HPV-associated oropharyngeal carcinomas that alter their biological behavior and response to therapy. It is hoped that further studies will identify these "driver" molecular alterations and how to target them to improve treatment outcome.

### *TP53* Mutation

Licitra and colleagues conducted a combined analysis of the presence of integrated HPV-16 and HPV-18 DNA (by RT-PCR) and *TP53* mutation in 90 patients with HNSCC who underwent surgical resection with or without postoperative radiotherapy. These investigators found that patients with tumors that were

*Source:* Modified from Ang KK, Harris J, Wheeler R, et al. Human papillomavirus (HPV) and survival of patients with oropharynx cancer. *N Engl J Med.* 2010;363:24–35, with permission.

HPV-positive and *p53* wild-type had a 5-year overall survival rate of 79%. In contrast, patients with tumors that were HPV-negative and had wild-type *p53* or tumors that harbored *p53* mutations (mostly nonsense or missense mutations) regardless of HPV status had a 5-year overall survival rate of only 46%.

## EGFR Protein Expression or Gene Copy Number

Hong and colleagues analyzed 266 patients with biopsy-proven oropharyngeal carcinoma who underwent curative treatment (information on the regimens used was not presented) at hospitals in Sydney for the presence of HPV DNA along with expression of *p16* and EGFR.[68] The presence of HPV DNA in tumors was assayed by an E6-based multiplex tandem-PCR method that simultaneously detects and identifies 21 HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 70, 73, 82, 53, 6, 11, and 26), and tumor expression of *p16* and EGFR was assessed by semiquantitative IHC assay. Overall, 99 (37%) of 266 tumors were HPV-positive (91 of which were positive for HPV-16) and 217 (87%) of 249 tumors were EGFR-positive. EGFR expression differed significantly ($p = 0.005$) by HPV status: 78% of HPV-positive tumors were positive for EGFR as opposed to 93% of HPV-negative cancer. In multivariable analyses, after adjustment for age, year of diagnosis, gender, tumor grade, T and N category, primary site within the oropharynx, and treatment modality, patients with HPV-positive cancers were found to be at significantly lower risks of local-regional failure (HR, 0.33; 95% CI, 0.17–0.61; $p = 0.003$), of an event (HR, 0.33; 95% CI, 0.20–0.52), or of death from any cause (HR, 0.37; 95% CI, 0.21–0.62) relative to those with HPV-negative cancers. After the same adjustments, patients with EGFR-positive carcinomas were found to have significantly higher risks of local-regional failure than those with EGFR-negative cancers (HR, 5.16; 95% CI, 1.52–32.29; $p = 0.006$), but the associations were weaker between EGFR and event-free survival (HR, 1.71; 95% CI, 0.86–3.78; $p = 0.13$) and EGFR and overall survival (HR, 2.48; 95% CI, 1.04–7.33; $p = 0.039$).

In another multivariate analysis of the effects of the combination of EGFR and HPV on outcomes, the best outcomes, after adjustment for age, year of diagnosis, gender, tumor grade, T category, N category, primary site within the oropharynx, and treatment modality, were seen in patients with HPV-positive/EGFR-negative cancers and the worst in those with HPV-negative/ EGFR-positive cancers. Relative to patients with HPV-positive/EGFR-negative cancers, those with HPV-negative/EGFR-positive cancers had an adjusted 13-fold increased risk of local-regional failure (HR, 12.79; 95% CI, 1.70–96.26), an almost fourfold increased risk of an event (HR, 3.89; 95% CI, 1.61–9.37), and a more than fourfold increased risk of death from all causes (HR, 4.49; 95% CI, 1.34–15.03). That the HRs for EGFR were substantially greater in HPV-negative than HPV-positive cancers suggests that the impact of EGFR expression on outcome was limited to patients with HPV-negative cancers. However, the authors pointed out that the evidence for this proposition is rather weak because only 7% of HPV-negative patients were also EGFR-negative. Consequently, this result is based on a small sample (11 patients) with a limited number of events.

Young et al. investigated the relationships between *p16* expression, *EGFR* gene copy number, and EGFR protein expression in patients with oropharyngeal carcinoma enrolled in three successive clinical trials at the Peter MacCallum Cancer Centre in Melbourne.[69] *EGFR* gene copy number was assayed by FISH and EGFR protein expression by IHC staining. The study patients received radiotherapy plus concurrent cisplatin plus tirapazamine (phase I), cisplatin with tirapazamine or fluorouracil (phase II), or cisplatin with or without tirapazamine (phase III). This study showed that *p16* expression and *EGFR* FISH positivity (defined as either high polysomy or gene amplification) were almost mutually exclusive, as only 2 (1.6%) of 126 tumors were found to be positive for both markers. No evidence was found for an independent effect of *EGFR* FISH positivity on outcome for patients with oropharyngeal carcinoma. However, *p16* was predictive of both failure-free survival (HR, 0.30; 95% CI, 0.15–0.58; $p < 0.001$) and overall survival (HR, 0.29; 95% CI, 0.13–0.62; $p = 0.001$) independent of *EGFR* FISH. Unfortunately, assays for both *p16* and EGFR protein expression were available from only 64 oropharyngeal carcinomas. Again, *p16* was found to be significantly related to failure-free survival (HR, 0.33; 95% CI, 0.14–0.78; $p = 0.023$) and overall survival (HR, 0.36; 95% CI, 0.15–0.88; $p = 0.037$). Interestingly, however, of 10 patients who were scored as EGFR-negative, 8 were *p16*-positive, and no deaths or events were recorded for these patients for the duration of the follow-up period.

## Combinations of Various Markers

Kumar and colleagues examined pretreatment biopsy samples from 50 patients with oropharyngeal carcinoma for the expression of *p16*, EGFR, *p53*, Bcl-xL, and *TP53* mutation.[70] Patients in this study received one cycle of induction chemotherapy with cisplatin (100 mg/m$^2$ for 1 day) or carboplatin (AUC 6) and fluorouracil (1,000 mg/m$^2$/d for 5 days), and responders received a combination of chemotherapy with radiation but nonresponders received surgery and radiation. This study showed that *p16* expression was significantly associated with HPV copy number ($p < 0.0001$), younger age ($p = 0.002$), response to induction chemotherapy ($p = 0.008$), receipt of chemoradiation therapy ($p = 0.009$), overall survival ($p = 0.001$), and disease-specific survival ($p = 0.003$). EGFR expression intensity was also associated with poorer response to induction chemotherapy ($p = 0.01$), marginally poorer response to chemoradiation therapy ($p = 0.055$), and poorer overall survival ($p = 0.001$) and disease-specific survival ($p = 0.002$). As single markers, neither *p53* expression nor Bcl-xL expression was significantly associated with treatment response or survival outcomes. *TP53* mutations (all missense, all overexpressed) were found in 6 (14.3%) of 42 tumors but were not associated with treatment response or survival.

Multimarker analysis showed inverse correlation between HPV titer or *p16* expression and EGFR expression. The combination of higher HPV titer and lower EGFR intensity was associated with better overall survival and disease-specific survival, as was high *p16* combined with low EGFR. The effect of EGFR remained after adjusting for *p16* on overall survival ($p = 0.03$) and disease-specific survival ($p = 0.04$). The prognostic value for *p53* depended on Bcl-xL expression status; patients with low *p53* and low Bcl-xL expression had better overall and disease-specific survival than did those with other permutations.

Further analysis showed that the poorer prognostic profile of lower HPV titer and higher EGFR intensity ($p = 0.001$ for overall survival; $p = 0.0002$ for disease-specific survival), lower *p16* and higher EGFR intensity ($p = 0.001$ for overall survival; $p = 0.002$ for disease-specific survival), and low *p53* and high Bcl-xL ($p = 0.003$ for overall survival; $p = 0.0001$ for disease-specific survival) was maintained after adjustment for age, gender, T category, N category, smoking status, and primary tumor site. Although Karnofsky performance status influenced overall survival, it was not significant in the multivariate analysis after other variables were considered.

Al-Swiahb et al. studied the effects of HPV genome and expression of *p16*, *p53*, and EGFR on survival in 220 patients with oropharyngeal carcinoma treated with surgical resection followed by adjuvant therapy, primary radiotherapy, or concurrent chemoradiotherapy at Chang Gung Memorial Hospital in Taiwan.[71] The proportion of patients receiving each type of therapy was not clearly spelled out. The HPV genome was assayed by a PCR-based method and ISH of tumor tissues from paraffin blocks, and *p16*, *p53*, and EGFR was assayed by IHC staining. Notably, 160 (73%) of these 220 patients had a history of chewing betel nut. In univariate analysis, 5-year survival rates were found to be better for patients with tumors that were positive for HPV (59.4% vs. 31.2%; $p = 0.008$), positive for *p16* (54.7% vs. 32.2%; $p = 0.04$), negative for EGFR (60.8% vs. 32.7%; $p = 0.01$), or low for *p53* expression (62.3% vs. 31.4%; $p = 0.01$). A high correlation was noted, however, between these variables: HPV-positive tumors were significantly more likely to express *p16* and were inversely associated with EGFR and *p53* expression ($p < 0.001$ for overall comparison). A Cox proportional hazards regression analysis revealed that HPV status ($p = 0.02$) and T category ($p < 0.001$) were the only independent factors associated with cumulative 5-year overall survival in this cohort.

## Current Status of Biomarker Discovery

Taken together, the findings from the studies summarized above show that HPV-associated oropharyngeal carcinoma has a distinct behavior but that the presence of other molecular changes such as mutations in *TP53*, upregulation of EGFR expression, or other alterations can change the biology of HPV-related carcinomas in ways that make them less responsive to currently available therapy modalities. Because the assay methods used were not standardized and because these series were generally small and highly heterogeneous in terms of patient composition and therapy administered, the results have not always been consistent. Consequently, the magnitude and relative contribution of these molecular changes on outcome are uncertain. Further systematic studies using well-characterized cohorts of patients are necessary to yield clinically useful data.

# ONGOING CLINICAL TRIALS

The recognition that patients with HPV-associated oropharyngeal carcinoma have excellent long-term survival and that the standard multimodality therapy options combining radiation with chemotherapy, with or without surgery, can induce rather severe persistent difficulties with swallowing, aspiration, and other morbidities have motivated many investigators to study less-intensive treatment combinations aimed at reducing long-lasting morbidity without compromising tumor control or survival. Many trials designed specifically for patients with HPV-positive oropharyngeal carcinoma also incorporate modern precision radiation planning and delivery techniques (e.g., intensity-modulated radiation therapy) to minimize the radiation dose delivered to critical normal tissues such as parotid glands, pharyngeal constrictors, and esophageal inlet. A comprehensive review of regimens being tested in ongoing clinical trials and those to be launched in the near future is beyond the scope of this chapter. Briefly, two cooperative group trials are ongoing in the United States. The ECOG phase II protocol E1308 is designed to assess induction paclitaxel, cisplatin, and cetuximab followed by 54 Gy of radiation with concurrent cetuximab for patients who had a clinical and radiographic complete response of the primary tumor, or 69.3 Gy with concurrent cetuximab for those who had a less than complete response of the primary tumor. The RTOG phase III trial (protocol 1016) was launched to formally compare 70 Gy of radiation in 35 fractions over 6 weeks with concurrent cisplatin versus the same radiation regimen with concurrent cetuximab. The study was designed to accrue 700 patients with *p16*-positive oropharyngeal cancer to test the hypothesis that the tumor control endpoint of the cetuximab arm is not inferior to that in the cisplatin arm but that the toxicity profile is more favorable. This trial will also prospectively collect smoking data to confirm and quantify the extent of detriment of cigarette smoking in patients with HPV-associated oropharyngeal cancer and also includes quality-of-life and patient-reported outcome assessments.

Additional cooperative group trials are being designed for the inclusion of transoral robotic or endoscopic surgical resection, both as a means to de-intensify therapy in HPV-associated oropharyngeal cancer (ECOG trial in development) and to intensify therapy for HPV-negative oropharyngeal cancer (RTOG trial in development).

# PROPHYLACTIC HPV VACCINATION

The findings within case series and clinical trials as well as national epidemiologic trends support the assertion that the United States is experiencing an epidemic of HPV-associated

(c) 2014 Wolters Kluwer. All Rights Reserved.

oropharyngeal cancer, in direct opposition to declining incidence of tobacco-associated cancers. Two FDA-approved vaccines are presently available. HPV4 (Gardasil™), produced by Merck, provides protection against oncogenic HPV types 16 and 18 as well as types 6 and 11 that cause genital warts. HPV2 (Cervarix™), produced by Glaxo Smith Klein, provides protection against oncogenic HPV types 16 and 18. These vaccines are of similar design, both being basically simulated type-specific virus capsids almost identical to the native virus but empty of DNA. Large clinical trials have demonstrated that these vaccines are effective in preventing type-specific HPV-related premalignant lesions and cancers in women. Unfortunately, even though these vaccines would likely prevent cancer induced by HPV-16 and HPV-18, including oropharyngeal carcinoma, they have not received widespread acceptance. The vaccination rates in the United States remain low (only 32% of 13- to 17-year-old girls received the recommended 3-dose coverage)[72] in spite of the recommendation of the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) to routinely vaccinate girls aged 11 to 12 and for girls/women aged 13 to 26 who have not been previously vaccinated.[73] Large clinical trials have also demonstrated the effectiveness of vaccinating men for the prevention of genital warts and anal dysplasia. Although cost analyses thus far have failed to support vaccination of boys for specific prevention of cancer in men,[74] analyses conducted to date have not adequately accounted for the costs (both monetary and quality-of-life lost) of HPV-associated cancers (especially oropharyngeal cancers) in men.[75] This is particularly concerning given recent estimates that oropharyngeal cancers are becoming more numerous than cervical cancers and that HPV-associated oropharyngeal cancers are estimated to become more numerous than all cervical cancers before the end of the decade.[12]

The CDC recently recommended routine HPV vaccination of boys age 11 to 12 and for boys/men aged 13 to 21 who have not been previously vaccinated. Because the current vaccination rates in girls are so low, this CDC recommendation was made principally to advance population ("herd") immunity to prevent cervical infection and subsequent premalignant lesions and cancers rather than preventing HPV-related cancers in men.[76] Evidence is already emerging to support the concept of herd immunity. Lower rates of HPV-associated genital warts have been observed in both young females (59% decline) and heterosexual males (28% decrease) in Australia, where high vaccination rates for girls (65%) against multiple HPV types have been achieved.[77] Ongoing clinical trials are investigating the next generation of HPV vaccines, which will protect against even more HPV types.

## THERAPEUTIC STARTEGIES TARGETING HPV OR HPV-ENCODED ONCOPROTEINS

The proteins encoded by the HPV genome provide unique targets for therapy of HPV-associated cancers, which in theory would avoid toxicity for normal human tissues that lack these proteins. Immune-based approaches targeting these oncoproteins have shown initial success in the treatment of genital premalignant lesions[78,79] and are already being tested in clinical trials in patients diagnosed with HPV-associated oropharyngeal cancer. The safety of and response to the MAGE-A3/HPV-16 vaccine for recurrent, progressive, or metastatic oropharyngeal cancer is being explored at the University of Maryland. A phase I trial of recombinant *Listeria monocytogenes* HPV-16 vaccine (REALISTIC trial) as an adjunct to standard definitive therapy is being conducted at three centers (Liverpool, Royal Marsden, and Cardiff) in the United Kingdom. This Listeria vaccine was shown to be safe in a phase I study of 15 patients with previously treated recurrent, metastatic, or refractory cervical carcinoma, among whom 8 patients had stable disease.[80]

Therapeutic DNA-based vaccine approaches are also being explored in clinical trials (reviewed by Monie et al.[81]). The central safety concern regarding the oncogenic potential of administering E6 and E7 DNA is addressed by using altered E6 and E7 sequences that disrupt the normal transforming potential of the transcribed protein. At present, five phase I clinical trials are underway with this therapeutic HPV DNA vaccine approach, mostly for patients with high-grade cervical intraepithelial neoplasia. Patients with oropharyngeal cancer are included in one such study and in another study that also includes a boost using a recombinant vaccinia virus encoding HPV-16 and HPV-18 E6 and E7 antigens.[81]

Because the E6 and E7 oncoproteins are constitutively expressed by HPV-associated cancers and as a consequence inhibit apoptotic mechanisms through the *p53* and Rb pathways, therapies that directly target these proteins and eliminate their functions could have both direct therapeutic effects and improving the sensitivity of tumors to radiation and chemotherapy.[82,83] At present, such E6- and E7-specific targeting remain in the preclinical stage. Several targeted agents that might improve the sensitivity of HPV-associated cancers to radiation of chemotherapy are being tested. For instance, although HPV data were not available, a secondary analysis of a phase III trial of radiation alone versus radiation with concurrent cetuximab for head and neck cancers[84] showed that improved survival resulting from adding cetuximab to radiotherapy was observed principally in subgroups having demographic profiles consistent with HPV-positive tumors. Although such interpretations are speculative, RTOG 1016 is currently addressing whether concurrent cetuximab shows the same efficacy as concurrent cisplatin in enhancing the radiosensitivity of HPV-associated oropharyngeal cancers. Other cooperative group trials for both cervical cancer and oropharyngeal cancer will ultimately identify and determine the effectiveness of agents that directly or indirectly target HPV oncoproteins.

## SUMMARY AND CONCLUDING REMARKS

The decline in tobacco consumption coupled with changing sexual behavior has altered the demographics of HNSCC, particularly in industrialized countries. The most striking change is the emergence of HPV-associated oropharyngeal carcinoma that affects predominantly middle-aged white men having higher socioeconomic status and having no or relatively low smoking history. Given the widespread nature of HPV infection, why HPV-associated carcinoma affects predominantly men is not well understood. The prevalence of HPV-associated oropharyngeal carcinoma is expected to increase further during the next two decades. How and to what extent HPV vaccination, which is being increasingly adopted for girls and now for boys, will affect the prevalence of HPV-associated oropharyngeal carcinoma remains to be determined.

HPV-positive oropharyngeal carcinoma is now widely recognized as a distinct head and neck cancer entity. At diagnosis, HPV-positive primary carcinomas are on average smaller than their HPV-negative counterparts. Although the data on N classification are less consistent, nodal disease seems to be slightly more extensive in HPV-positive oropharyngeal carcinoma at diagnosis. The discrepancy in the literature data can be ascribed in part to the selection of specific stages included in clinical trials as well as the use of various methods, each with strengths and weaknesses, for diagnosing HPV-positive tumors, as summarized in Tables 12.1 and 12.2. Whether *p16* IHC staining is a better surrogate assay than ISH has not been clearly resolved. The advantages of the *p16* assay are its simplicity, nonspecificity

(c) 2014 Wolters Kluwer. All Rights Reserved.

for HPV type, and reflection of functional downstream effects of HPV DNA integration; but *p16* is not a flawless surrogate. Assay standardization to improve interlaboratory reproducibility is needed in the near future, both for day-to-day patient care and for proper patient stratification or selection for prospective trials but, unfortunately, funding for such efforts has been difficult to obtain.

Clear evidence now exists that, relative to HPV-negative oropharyngeal cancer, HPV-associated oropharyngeal carcinoma responds better to current standard treatment modalities including radiation therapy alone, surgery with or without adjuvant radiotherapy, or combinations of radiation with chemotherapy, given concurrently or as an induction regimen. Consequently, patients with HPV-positive oropharyngeal carcinoma as a group have much better prognosis than those with HPV-unrelated carcinoma of the oropharynx or other head and neck subsites. The better long-term overall survival and progression-free survival rates of patients with HPV-positive carcinomas result predominantly from improved local tumor control and, to a lesser extent, from lower incidence of second primary tumors. The difference in the rate of distant metastasis is small. Unfortunately, no validated predictive biomarkers have been discovered for the rational selection of specific therapy for patients with HPV-positive carcinoma.

An increasing body of data suggest that smoking and additional molecular deregulations, such as *TP53* mutation and high EGFR expression, can increase the resistance of HPV-positive carcinoma to therapy. However, the underlying mechanisms, the magnitude of the effects, and how to overcome them to improve outcome have yet to be elucidated. Until many scientific issues are resolved, there is no scientific basis for altering the treatment for patients with HPV-positive carcinoma outside of well-monitored clinical trials. The current frontline standard treatment for patients with stages I to II (T1–2N0) HPV-positive oropharyngeal carcinoma is single-modality treatment with either radiotherapy or surgery. Several options are available for those with locally advanced disease (T3–4 or N2–3). One such option is surgery followed by adjuvant radiotherapy with or without concurrent cisplatin depending on surgical pathologic findings.[85–87] Nonsurgical choices, established through phase III trials and adopted in many centers, are radiation with concurrent platinum-based chemotherapy,[88–91] radiation plus cetuximab,[84,92] and induction chemotherapy with TPF followed by radiation with or without concurrent carboplatin.[93,94] Because these regimens have not been compared head-to-head, there is no validated strategy for choosing among them for individual patients. The choice depends thus mostly on the preferences and expertise of the multidisciplinary oncology team. Although many phase II studies have yielded interesting results with various regimens, these results need to be validated in randomized trials. Whether aggressive multimodality therapy can be spared for patients with low-volume stages III to IV disease, for example, T1–2 and N1–2a or N2b with small level II nodes, is unclear at the present time, as radiation alone might suffice for at least some of patients in this category.[95]

Given that patients with HPV-associated carcinoma have an excellent prognosis and that standard multimodality therapy options combining radiation with chemotherapy can induce rather severe long-term morbidities, much interest is devoted to launching clinical trials designed specifically for patients with HPV-positive oropharyngeal carcinoma. Two cooperative group trials are ongoing in the United States: the ECOG phase II protocol (E1308) assesses induction chemotherapy followed by reduced-dose radiation with concurrent cetuximab for patients who had a clinical and radiographic complete response of the primary tumor; and the RTOG phase III trial (protocol 1016) addresses 70 Gy of radiation with concurrent cisplatin or with concurrent cetuximab. Given the excellent survival outcome of patients with HPV-associated oropharyngeal cancer, it will take many years for these prospective trials to mature. Hopefully, the joint efforts of many investigators will answer some important scientific questions related to HPV-associated oropharyngeal carcinoma and contribute to defining the best management strategies for patients with various stages of HPV-associated carcinoma.

The presence of viral DNA and oncoproteins provides unique targets for therapy. The safety of and response to therapeutic empty capsid or altered HPV DNA vaccines are being investigated in clinical trials. Other therapeutic approaches targeting viral oncoproteins are being addressed in preclinical models. It will likely take many years to sort out the potential value of these novel therapeutic strategies.

CHAPTER 13

Pierre Saintigny, William N. William Jr., Waun Ki Hong, and Scott M. Lippman

# Chemoprevention

## INCIDENCE AND PREVALENCE OF HEAD AND NECK CANCERS

A majority of head and neck cancers arise in the mucosa of the upper aerodigestive tract and are squamous cell in origin. Most of the literature in head and neck premalignancy and chemoprevention has focused on head and neck squamous cell carcinoma (HNSCC) from the oral cavity. The worldwide incidence of head and neck cancer exceeds half a million cases annually, ranking it as the fifth most common cancer worldwide.[1] Males are more affected than females. The incidence is high in some regions of Europe, Hong Kong, India, and Brazil and among African Americans in the Unites States. Oral cavity squamous cell carcinomas (OSCC) are more common in India, and pharyngeal and/or laryngeal cancers are more common in other populations.[2] In the United States, 52,000 Americans develop head and neck cancer annually and 11,500 die from the disease.[3] We see three main reasons that should encourage the scientific community and stakeholders to invest in the prevention of HNSCC: (a) HNSCC are second only to lung cancer as the most common smoking-related cancer; (b) the treatment often results in substantial morbidity; and (c) compared to other tumor types, the mutational etiology is diverse, and HNSCC have few targetable mutations according to most recent reports.[4,5] These facts further emphasize the need to improve our prevention strategies.

## RISK FACTORS ASSOCIATED WITH HEAD AND NECK CANCERS

The primary risk factors associated with HNSCC cancer include tobacco use and alcohol consumption.[2] The increased risk of HNSCC is ranging from a 5- to 25-fold in cigarette smokers compared to nonsmokers, with a dose–response relationship.[6,7] Alcohol consumption independently increases the risk of cancer in the upper aerodigestive tract.[6,8–10] The increased risk of HNSCC due to alcohol is dose dependent with a relative risk (RR) of 5 to 6 with alcohol intake >50 g/day versus <10 g/day.[9–11] Alcohol and tobacco have a synergistic effect on the risk of developing HNSCC.[6,7,9,11–13] Betel nut chewing, which is widespread in certain regions of Asia, is an independent risk factor for the development of HNSCC[14–17] and has synergistic effects with tobacco and alcohol.

Epidemiologic and molecular evidence has established a causal role for human papillomavirus (HPV), primarily type 16, 18, and 33, in the recent increase in oropharyngeal squamous cell carcinoma (SCC). Those tumors are typically seen in younger patients, never smoker and drinker.[18] Patients infected with the human immunodeficiency virus (HIV) have an increased RR of 2 to 3 to develop HNSCC.[19] Nasopharyngeal carcinoma is a relatively rare malignancy in most populations except in southern China and is associated with Epstein-Barr virus (EBV). Epstein-Barr virus is also the primary etiologic agent for oral hairy leukoplakia, although the relationship of oral hairy leukoplakia with SCC is unclear.[20–23]

Constitutional genetic alteration may contribute to an increase in risk of head and neck cancer, and these factors may interact with other known risk factors. They will be developed in the Prevention and Risk Assessment section of this chapter.

## FIELD CANCERIZATION

The concept of field cancerization refers to the effects of chronic exposure to smoking and alcohol in patients with or without cancer, with progressive onset of molecular alterations in initially histologically and clinically normal epithelia. It was first used by Slaughter et al. in a study of more than 700 HNSCC from the oral cavity and pharynx.[24] The observation of the authors was that the grossly normal epithelium adjacent to the invasive carcinoma frequently demonstrated dysplasia or carcinoma *in situ*. The mucosa of the upper aerodigestive tract was described as "condemned" by the authors, reflecting repetitive damage of the entire mucosal field by carcinogens. Later, the concept of field cancerization was supported by the identification of similar genetic alterations in matched dysplastic and malignant lesions from the oral cavity.[25] This observation provided some evidence that dysplasias were precursor lesions and that the lateral migration of genetically altered cells through the oral mucosa can form multiple lesions, a phenomenon called *clonal cancerization*.[26] In other cases, genetic alterations found in dysplastic lesions were not found in matched cancer. This observation provided some evidence that multifocal disease can arise from the development of several genetically altered clones from different initiating events. Finally, the frequent development of synchronous or metachronous second or multiple primaries in the head and neck and/or the lung also supports the concept of field cancerization.[27] The second tumors may be clonally similar to or distinct from the primary tumor.[28]

The use of molecular markers has validated the concept of field cancerization. A recent study has investigated whether oral

(c) 2014 Wolters Kluwer. All Rights Reserved.

epithelium may be used as a surrogate tissue for assessing tobacco-induced molecular alterations in the lungs by studying the methylation status of CDKN2A and FHIT in oral and bronchial brushes specimens from smokers enrolled in a chemoprevention trial.[29] A dose–response relationship between the number of sites methylated in the lung and the presence of oral methylation was observed for CDKN2A. Others have demonstrated that the concomitant methylation of three or more genes in the sputum is associated with a 6.5-fold increased risk for lung cancer.[30] Recent studies have reported consistent global gene expression changes in response to cigarette smoke throughout the respiratory tract, including the bronchus, the nose, and the mouth.[31] Consistent results were obtained with proteomic and gene expression profiling.[32,33]

## MULTISTEP CARCINOGENESIS

Vogelstein et al. was the first to propose a multistep pathogenesis for colorectal cancer, in which at least four mutations in oncogenes and tumor suppressor genes being necessary for malignant transformation.[34] These genetic events result in stepwise advances including initiation, promotion, and progression leading to the development of invasive carcinoma. Later, Califano et al. proposed a "Vogelgram" for HNSCC, which linked histologic changes to specific molecular alterations.[35] They proposed that the accumulation of genetic events, rather than a specific sequence, drives the transformation of squamous mucosa of the head and neck. They evaluated global gene expression changes between malignant lesions (M), premalignant lesions (PM), distant, and histopathologically normal mucosa from patients with premalignant or malignant lesions (MN), and normal mucosa from the upper aerodigestive tract of patients with noncancer diagnoses (N). They observed a consistent separation between the N, PM, and M groups, with a closer association between the PM and M groups. They conclude that the majority of alterations occurs before the development of malignancy.[36]

Histologically, changes occur from normal to hyperkeratosis, hyperplasia, mild, moderate, and severe dysplasia and then carcinoma *in situ* before becoming invasive carcinoma. Molecular alterations in epithelial cells precede histological changes. These histological alterations or clinical lesions can be unifocal, or multifocal and represent clonally independent premalignant lesions that may or may not transform into invasive carcinoma. Clinically, mucosa may appear normal, or demonstrate various aspects such as leukoplakia, erythroplakia, leukoerythroplakia, lichen planus, or subcutaneous fibrosis.[37]

The concept of multistep carcinogenesis has several limitations. The first one is practical: the histological classification is subject to a high interobserver variation.[38] Second, it has been challenged by the fact that preneoplastic lesions can regress as well as progress to higher grade lesions, either spontaneously or by avoiding further carcinogenic exposure, or by using a chemopreventive agent to reverse or inhibit carcinogenic progression.[37] It is unknown whether specific alterations are necessary and sufficient to make the progression irreversible. Finally, it does not fit the group of never-smoker-never-drinker that represents 10% to 15% of patients with HNSCC more commonly seen in young women with oral tongue cancer, elderly women with gingival/buccal cancer, or young to middle-aged men with oropharyngeal cancer positive for HPV.[39] In this population, the identification of new driving mutations may support the concept of nonlinear progression proposed recently in lifetime never smokers with lung adenocarcinoma harboring epidermal growth factor receptor (EGFR) mutations.[40]

## MOLECULAR ALTERATIONS IN PREMALIGNANCY AND INVASIVE SCC

Hallmarks of cancer as described by Hanahan et al. include sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, activating invasion and metastasis, reprogramming of energy metabolism, and evading the immune system. Genome instability, epigenetic changes, and tumor microenvironment are underlying and fostering these hallmarks.[41] Head and neck squamous premalignant lesions and HNSCC have been shown to harbor many of these hallmarks. With respect to chemoprevention, those molecular alterations are important as they may represent biomarkers to help identify patients at high risk to develop invasive SCC; they may also represent potential therapeutic targets for rationally based chemopreventive intervention. An approach has recently been proposed to drug development in the chemoprevention setting, called *reverse migration*, which is taking advantage of our experience in the treatment of advanced cancer to bring agents, biomarkers, and study designs into the prevention setting.[42]

### Genomic Changes

HNSCC have complex karyotypes, with the most common change being tetraploidization, and an average of 15 aberrations including deletions, translocations, isochromosomes, and less frequently amplifications.[43] Losses of genomic material are more frequent than gains and affect 3p, 9p, 21q, 5q, 13q, 18q, and 8p.[44] Chromosomal gains affect 3q, 8q, 9q, 20q, 7p, 11q13, and 5p. Tumor suppressor genes or oncogenes have been associated with some of those alterations.[34] Loss of 3p is the most frequent genomic loss and involves FHIT and RASSF1A. Other examples are losses of 9p21 (*CDKN2A*) and 17p13 (*TP53*). Specific sites of loss of heterozygocity (LOH) have been associated with a risk to develop HNSCC in patients with oral leukoplakias (OLs).[45] They are discussed in the Prevention and Risk Assessment section of this chapter. Gain in 3q is among the most frequent gain and includes *TP63*, an epithelial developmental gene, and *PIK3CA*. Other examples are gains in 7p (*EGFR*), 8q (*MYC* oncogene), and 11q13 (*CCND1*). Dysplasias and carcinoma *in situ* have fewer imbalances compared with OSCC (3.2 vs. 11.9).[46] An increasing trend of microsatellite instability, which reflects a reduced DNA repair capacity by mismatch repair proteins, has also been reported in hyperplasia (6%), dysplasia (15%), and HNSCC (30%).[47] The "Vogelgram" proposed by Califano et al. for HNSCC is the following[35] : The loss of 9p, leading to inactivation of *CDKN2A*, is a very early event and found in 70% of HNSCC[48]; it is frequently followed by the loss of 3p (*FHIT*, *RASSF1*) and 17p (*TP53*) in transition to dysplasia.[49]

Two important studies published recently provided new information on the mutational landscape of HNSCC using whole exome-sequencing technology.[4,5] Far fewer genes were found to be mutated per tumor in HPV-associated tumors (5/tumor) compared to HPV-negative ones (20/tumor), independent of smoking status. More mutations were identified in tumors from patients with a smoking history (22/tumor) as compared with those from never smokers (10/tumor). Among smokers, tumors with the highest fraction of G > T transversions showed a trend toward increase in overall mutation rates. Interestingly, several outliers were observed in tumors from never smokers with low fraction of G > T transversions but very high mutation rates, including mutations in some DNA repair genes, which may explain this paradox. Most frequent somatic mutations were found in *TP53*, *NOTCH1*, *CDKN2A*, *PIK3CA*, and *HRAS* were seen in 47% to 62%, 14% to 15%, 9% to 12%, 6% to 8%, and 4% to

(c) 2014 Wolters Kluwer. All Rights Reserved.

5% of patients, respectively. The most frequently mutated genes were often affected by copy number alterations. LOH of *NOTCH1* were observed in tumors with mutations in the same genes, and most *NOTCH1* mutations were predicting truncated mutations or deleting critical functional residues. These observations support its role as a tumor suppressor gene in HNSCC. Less frequent mutations included *PTEN*, *MLL2*, *TP63*, *EZH2*, *NOTCH3*, *NOTCH2*, *DICER1*, and *RB1*. A significant proportion of mutated genes are involved in epidermal development and squamous differentiation. Similar studies using next-generation sequencing technology remain to be done to characterize premalignant lesions.

The specific case of *TP53* tumor suppressor gene is interesting. The gene encodes a nuclear protein with transcription factor activity that is a necessary component of the G1-S transition checkpoint, thereby contributing to cell cycle control, DNA repair and synthesis, and genomic integrity.[50,51] The wild-type p53 protein can induce either programmed cell death or growth arrest at the G1 phase of the cell cycle. *TP53* inactivation is nearly universal in HNSCC, although the mechanism of loss of function depends on the etiology: inactivating *TP53* mutations are identified in 78% of the HPV-negative tumors that are usually associated with an alcohol and smoking history; in the setting of HPV infection, *TP53* gene is typically none mutated but p53 is inactivated by binding to the E6 viral protein.[5,52,53] *TP53* mutation and binding to other proteins can lead to overexpression of p53 protein that is reported in 19% of adjacent normal mucosa, 29% of hyperplastic lesions, 46% of dysplastic lesions, and 58% of HNSCC. Increase in p53 expression has been associated with increased genomic instability.[54] The timing of p53 inactivation remains controversial, with some reports demonstrating aberrant expression in premalignant lesions, but the majority suggesting mutation only late in tumor evolution.[35,55–57]

## Epigenomic Changes

The inactivation of individual tumor suppressor genes such as *CDKN2A*, *CDH1*, *DAPK1*, *RASSF1*, *RAR*-β, *DCC*, *MGMT*, *NDRG2*, and *DLEC1* by promoter DNA methylation has been reported in HNSCC.[58–61] Using high-throughput DNA promoter methylation profiles, it has been shown that the overall pattern of epigenetic alteration can significantly distinguish tumor from normal head and neck epithelial tissues more effectively than specific gene methylation events. Tobacco smoking and alcohol exposures are associated with specific DNA methylation profiles.[58] Another important feature of malignant tumors is global hypomethylation, which is measured by the degree of methylation of repetitive sequences across the genome such as *LINE1*, and has been associated with genome instability. Poage et al. found that global methylation was different according to tumor site and *LINE1* methylation was associated with HPV16 E6 serology. The authors identified a distinct subset of CpG loci with significant hypermethylation associated with *LINE1* hypomethylation.[62] Few studies have looked at methylation levels of individual genes in preneoplastic lesion. *RAR*-β– silencing by methylation has been shown to be an early event in HNSCC carcinogenesis; 66% of the HNSCC showed hypermethylation of *RAR*-β versus 53% of OLs and 27% in adjacent normal tissue.[63] *CDKN2A* methylation was never detected in normal individuals, but in 5% of leukoplakia with hyperplasia, 18% of leukoplakia with mild dysplasia, 10% of leukoplakia with moderate dysplasia, 22% of leukoplakia with moderate dysplasia, and in 50% or more of OSCC.[64] In patients with betel-quid chewing in Sri Lanka, a high frequency of hypermethylation of p14, p15, and p16 was detected in precancerous lesions, although no hypermethylation was found in normal epithelium.[65]

## EGFR, PI3K/AKT/mTOR, and MET Pathways

All three pathways represent potential targets for chemoprevention, although only EGFR pathway has been studied in premalignant lesions. EGFR activation by its ligand transforming growth factor–alpha (TGF$\alpha$), activates STAT3 which increases proliferation, suppresses apoptosis, and decrease differentiation. EGFR and TGF$\alpha$ are upregulated in HNSCC, constituting an autocrine activation loop.[66–73] EGFRvIII, a variant detected in 42% of HNSCC, is associated with increased proliferation *in vitro* and *in vivo* and with decreased apoptosis in response to cisplatin and cetuximab.[74] High EGFR expression and high EGFR gene copy number have been associated with poor survival in patients with HNSCC.[56,68,75] Cetuximab, an anti-EGFR antibody, is now approved in the treatment of locally or regionally advanced HNSCC or as a single agent for the treatment of patients with recurrent or metastatic disease for whom prior platinum-based therapy has failed.[76,77] EGFR is overexpressed in malignant, premalignant, and normal-appearing tissues from HNSCC patients. EGFR expression increases progressively with increasing degree of dysplasia and is markedly elevated in more than 90% HNSCC.[67,68] We have reported that increased EGFR gene copy number in OLs was frequent and associated with an increased risk of developing OSCC.[78] Erlotinib has been shown to decrease the incidence of OSCC in a chemically induced mouse model.[79] The use of EGFR tyrosine kinase inhibitor (TKI) in the chemoprevention setting is discussed below.

PI3K/AKT/mTOR pathway has been shown to be activated in approximately 50% of HNSCC.[80–82] Mechanisms of this activation include activation of upstream tyrosine kinase receptors (EGFR, IGF-1R…), frequent amplification of *PIK3CA* (3q26) that is associated with poor prognosis, *PI3KCA* activating mutations that have been reported in up to 10% of the cases, and *PTEN* downregulation in rare cases.

MET pathway activation has been recently reported in HNSCC. Knowles et al. have shown that 80% of HNSCC express MET, its ligand HGF, or both.[83] Seiwert et al. have shown that 84% of HNSCC samples showed MET overexpression and 45% HGF overexpression.[84] MET gene copy number was increased in a significant proportion of HNSCC cell lines and tumors. The rate of MET tyrosine kinase domain mutations was 3% and the rate of non-TK domain mutations was 9%. MET inhibition was associated with decreased proliferation, migration and motility, and angiogenesis and with a greater-than-additive inhibition of cell growth in combination with cisplatin or erlotinib. The functional role of TK domain mutations in HNSCC remains to be determined.

## Cyclooxygenase-2

At least two isoenzymes, COX1 and COX2, have been described. COX1 is constitutively expressed in most tissues, while COX2 is inducible. COX2 has been shown to be frequently overexpressed in oral dysplasias and HNSCC.[85–90] COX catalyzes the synthesis of prostaglandins from arachidonic acid. Levels of prostaglandin E2 (PGE2) are elevated in HNSCC as well and correlate with poor survival.[91] COX2 inhibitors have shown to decrease proliferation and induce apoptosis in both *in vitro* and *in vivo*.[92] *In vitro*, PGE2 causes dose-dependent stimulation of cellular growth of the nontumorigenic MSK-Leuk1 oral epithelial cell line, thus providing further evidence for a possible role COX and prostaglandins in oral carcinogenesis.[93] Using immortalized oral epithelial cells and HNSCC cell lines, Abrahao et al. have shown that COX2 overexpression in cancer and inflammatory cells induce PGE2 production in the tumor microenvironment that promotes HNSCC cell growth in an autocrine and paracrine fashion.[94] COX2 has been shown to be upregulated by Snails that

(c) 2014 Wolters Kluwer. All Rights Reserved.

impedes terminal differentiation, invasion, and inflammation in oral keratinocytes.[95] COX inhibition has been shown to prevent premalignant lesions in preclinical and clinical studies, especially as it pertains to colonic polyps.[96] In murine models of oral carcinogenesis, COX2 inhibitors were found to have chemopreventive effects.[97–99]

## Transforming Growth Factor–Beta Signaling Pathway

Transforming growth factor–beta (TGF$\beta$) is a key regulator of epithelial homeostasis, immune function, and angiogenesis. TGF$\beta$ signaling dysregulation is common in HNSCC.[34] Defective TGF$\beta$ signaling in epithelial cells increases proliferation reduces apoptosis and increases genomic instability. The compensatory increase in TGF$\beta$ production by tumor epithelial cells further promotes tumor growth and metastases by increasing angiogenesis and inflammation in tumor stromal cells.[100] RAS mutations are rare in HNSCC in the Western countries, although its overexpression is common. Lu et al. have shown that combining TGF$\beta$RII loss with KRAS or HRAS overexpression in a murine model resulted in HNSCC tumor formation. Neither alteration alone resulted in a malignant phenotype.[101]

## Retinoid Receptors

Retinoids are naturally occurring and synthetic vitamin A (retinol) metabolites and analogues. Retinoids are involved in many physiologic processes including cell differentiation that they promote, proliferation, and apoptosis that they decrease. Two families of retinoid receptors have been characterized: RAR and RXR. RAR is endogenously activated by all-trans-retinoic acid and 9-cis-retinoic acid; RXR is endogenously activated by 9-cis retinoic acid only. 13-cis-retinoic acid (13cRA) is readily converted to all-trans-retinoic acid, which in turn primarily regulates gene transcription through RAR. The "retinoid axis" also includes repressors and coactivators that form interacting complexes that ultimately define regulation of genes and cellular function.[102] Cattle that are vitamin A deficient develop tumors of the aerodigestive tract and lung at a relatively high frequency.[103] Loss of nuclear RAR$\beta$ is an early event observed in premalignant dysplastic lesions.[104] This has triggered evaluation of retinoids in chemoprevention trial that is discussed below.

## Cell Cycle

Cell cycle regulation in HNSCC is altered through various mechanisms that are not exclusive to each other. One includes activation of *CCND1* and *MYC* oncogene that are often amplified and/or overexpressed.[105] *MYC* overexpression has been associated with poor survival of patients with HNSCC.[106] Other mechanisms involve inactivation of *TP53* and inactivation of the p16/p14 ARF locus, both being frequent in HNSCC.[107] Both the inactivation of *CDKN2A* and overexpression of *CCND1* increases CDK4/6 activity and RB phosphorylation that in turn promotes cell proliferation.[108,109] Soni et al. studied the expression of *CDKN2A*, *CCND1*, and *pRB* using immunohistochemistry in normal-appearing oral mucosa, hyperplastic, and dysplastic lesions and in HNSCC.[110] Alterations in all three genes were demonstrated in 11% hyperplastic and dysplastic lesions and in 18% of HNSCC. Loss of *CDKN2A* was the earliest event, loss of *pRB* was associated with the transition hyperplasia to dysplasia, and *CCND1* or *p53* overexpression was associated with the transition to HNSCC. Finally, a *CCND1* polymorphism, thought to alter cyclin D1 expression, has been associated with HNSCC risk, tumor grade, tumor recurrence, and survival.[111–115]

## Telomerase

Reactivation of telomerase is a common feature of malignant tumors. Using a telomerase rapid amplification protocol (TRAP) assay, Patel et al. identified telomerase activation in 78% to 82% of HNSCC, 55% to 85% of premalignant lesions, and 39% to 53% of adjacent normal-appearing tissue.[116,117] A higher telomere length was associated with a poor survival.[117] Thus, reactivation of telomerase appears to be an early molecular alteration. Interestingly, telomerase activity in peripheral blood mononuclear cells was correlated with higher T and N stages and was an independent predictor of survival.[118]

## Angiogenesis

Angiogenesis contribution to HNSCC progression has been studied. Angiogenesis is required for the tumor growth and the metastatic spread. The majority of HNSCC overexpress the vascular endothelial growth factor (VEGF) or the VEGF-2 and VEGF-3 receptors.[119,120] A meta-analysis involving 1,002 patients showed that VEGF tumor overexpression evaluated by immunohistochemistry was associated with a decreased survival.[121] The role of angiogenesis in progression of premalignant lesions has been recently outlined using a chemically induced mouse model and will be discussed below.[122]

## HPV-Related HNSCC

HPV-related HNSCC usually arise in the oropharynx (tonsillar crypts), they are infiltrated by lymphocytes, do not undergo significant keratinization, have basaloid morphology, affect younger individuals, and are usually stage Tx or T1–2 with early and large lymph node involvement with better outcome compared to HPV-negative HNSCC.[18] After HPV integrates its DNA within the host nucleus, it overexpresses oncoproteins E6 and E7. E6 induces *p53* degradation, and E7 binds and inactivates *RB*.[123] HPV-related HNSCC have also been shown to have a unique transcriptional profile for both mRNA and miRNAs, as well as a unique DNA methylation profile.[62,124,125] The genomic profile is also different as almost all HPV-associated tumors express wild-type *TP53* and *CDKN2A* and have a lower rate of mutations as opposed to HPV-negative HNSCC.[4,5] This would suggest that HPV infection is an early event in head and neck squamous cell carcinogenesis. With regard to the prevention setting, they are not associated with dysplasia of surface epithelium which makes early detection challenging.[126] HPV positivity in normal adjacent tissues is considered a rare occurrence. In a recent study of 200 normal tonsils, the prevalence of HPV16 and 18 was found to be zero. Although there appears to be some link between HPV and OL, evidence supporting a causal role of HPV in oral squamous cell tumorigenesis is not convincing. The exact anatomical site is not always reported with the risk to include both oral cavity and oropharynx SCCs. The detection of HPV virus does not necessarily mean HPV integration in the host genome and E6/E7 oncoproteins activation. HPV serotypes are not available in all the studies and not all HPVs are oncogenic. Finally, the magnitude of association consistent with an infectious etiology is only achieved for SCC of the oropharynx.[127–131]

# PRECLINICAL MODELS OF HEAD AND NECK SQUAMOUS TUMORIGENESIS

Few *in vitro* models are available to study head and neck tumorigenesis.[132] MSKLeuk1 and MSKLeuk1s are immortal and nontumorigenic and established from a nonsmoking patient with

(c) 2014 Wolters Kluwer. All Rights Reserved.

moderately dysplastic leukoplakia of the oral cavity adjacent to a SCC of the tongue.[133] Normal oral mucosa-9 (NOM9) cell lines were established from histologically normal buccal mucosa of a patient with tongue cancer. NOM9/TK was immortalized by overexpressing the telomerase (T) and CDK4 (K). NOM9/TKp53 was made from NOM9/TK using shRNA against *p53*. They are nontumorigenic human oral keratinocytes (HOKs).[134] HOK-16A and HOK-16B are primary HOKs transformed by transfection with recombinant HPV-16 DNA; they are immortal but not tumorigenic.[135] HaCaT is a human keratinocyte cell line. It was created from histologically normal adult body skin obtained from the distant periphery of a melanoma and is spontaneously transformed, immortalized, but is not tumorigenic and noninvasive *in vivo*.[136,137]

Premalignant cell lines being nontumorigenic, subcutaneous xenograft and orthotopic models do not allow modeling of the premalignant process. Carcinogen-induced and transgenic murine models have been developed for that purpose. Several transgenic mouse models of OSCC have been described. Caulin et al. created a transgenic mouse with inducible $KRAS^{G12D}$ activated oncogene driven by either keratin (K) 5 (expressed in the basal epithelium of the tongue and forestomach) or K14 (expressed mainly in the basal layer of the oral mucosa and tongue) promoter.[138] They observed formation of squamous papilloma of the oral cavity and subsequently found that activation of the endogenous *p53* gain-of-function mutation $TP53^{R172H}$, but not the deletion of *TP53*, cooperates with oncogenic *KRAS* and promotes progression to invasive carcinoma in few cases.[139] Using a similar approach, Vitale-Cross et al. reported various degrees of dysplasia, as well as invasive SCC in the skin, the oral mucosa and the tongue, the esophagus, the forestomach, and the uterine cervix.[140] Raimondi et al. crossed an inducible $KRAS^{G12D}$ oncogene-driven model with *TP53* conditional knockout mice, resulting in OSCC within 2 weeks.[141] Moral et al. created a mice displaying constitutive Akt activity under the control of K14 promoter (myrAkt).[142] The myrAkt mice developed oral premalignant lesions, few of them progressing into invasive SCC. When myrAkt were crossed with mice bearing *TP53* loss, the mouse developed OSCC with metastatic spreading to regional lymph nodes, activation of *NFKB* and *STAT3*, and decreased TGF$\beta$IIR expression and increased number of putative tumor stem cells.

Several methods have been used to induce OSCC in animals using carcinogenic agents. A technique developed by Salley et al. used a polycyclic hydrocarbon 9,10 dimethy-1,2 benzanthracene (DMBA) to paint the buccal surface of the cheek pouch of hamsters.[143] Lin et al. refined the technique by promotional painting with arecaidine, allowing increasing tumor incidence up to 100%.[144] Others have utilized painting with 4-nitroquinoline 1-oxide (4NQO) or 12-O-tetradecanoylphorbol-13-acetate after initial exposure to DMBA.[145] Tumors produced this way have been shown to overexpress EGFR, TGF$\alpha$, RAS, and p53 protein,[146–149] and mutations of *TP53* and *HRAS* have been reported.[122]

The 4NQO model utilizes the chronic administration of 4NQO to rodents. 4NQO is added to the drinking water of rodents and induces SCC of the palate, the tongue, the esophagus, and the stomach. The development of fully malignant SCC is preceded by increasing grades of hyperplasia and dysplasias that mimics the development of oral cancer in human.[150] Disadvantages are that the reliable development of tumors requires the administration of 4NQO over 2 to 3 months, and the detection of premalignant lesions or early SCC within the oral cavity can be difficult. Hasina et al. recently characterized the optimal dosage and timing of 4NQO treatment and established a timeline for the reproducible development of lesions showing hyperkeratosis, dysplasia, and HNSCC.[122] Interestingly, they observed increased microvessel density and VEGF expression in hyperkeratotic lesions, providing evidence that the initiation of the angiogenic phenotype occurred before the dysplasia. Inhibition of angiogenesis significantly decreased the overall incidence of OSCC.[122] Using the same model, they reported that ZD6474, a dual inhibitor of EGFR and VEGFR2, reduced the incidence of OSCC.[151] Interestingly, OSCC from ZD6474-treated mice exhibited features of epithelial-to-mesenchymal transition suggesting that this could be a mechanism of resistance to the drug. Erlotinib, an EGFR TKI, has also been shown to decrease the incidence of dysplasia and OSCC compared to the control.[79] Bexarotene failed to show any preventive effect on the incidence of OSCC induced by 4NQO.[152]

## PREVENTION AND RISK ASSESSMENT

Primary prevention of HNSCC refers to the prevention of cancer by avoiding known carcinogens.[153,154] Secondary cancer prevention refers to the treatment of preneoplastic lesions to halt progression to invasive cancer. Tertiary cancer prevention is preventing second primary cancers in patients have been cured with surgery and/or radiation therapy. This is particularly important for patients treated with HNSCC due to the "field cancerization."[27] Primary, secondary, and tertiary prevention approaches should all be considered to decrease the incidence of HNSCC. Four groups of individuals or patients with increasing risks of developing HNSCC can be defined: individuals with tobacco and/or smoking history and normal appearing mucosa, patients with a potentially malignant lesion, and patients that have been treated for HNSCC and at risk for recurrent disease and second primary tumor. In each case, individualized cancer risk assessment is a key element.

### Tobacco Smoking and Alcohol Drinking Cessation

Quitting tobacco smoking and alcohol reduces the risk of developing HNSCC. The International Head and Neck Cancer Epidemiology (INHANCE) consortium reported that a benefit for smoking cessation was realized in a short period of time with a significant 30% lower risk for HNSCC observed after stopping smoking for >1 to 4 years. The risk of HNSCC dropped to that of never smokers after having quit for 20 or more years. The cessation of alcohol drinking was associated with a reversal of HNSCC risk after quitting for 20 or more years.[155]

### Early Diagnosis

Diagnostic delay is a recognized challenge in the population of patients diagnosed with HNSCC, especially in the case of OSCC, and is often categorized as patient delay, accessibility to health care system, and health care provider delay.[156] A recent meta-analysis has shown that diagnostic delay is a risk factor for tumor growth.[157] Diagnostic delays have also been related to survival in some recent studies.[158] Therefore, public awareness of early symptoms as well as health care providers' education should allow early detection, increase cure rates, and decrease treatment-related morbidity.[156]

Recommendations regarding screening for OSCC have been recently published.[159] Screening by means of examination can detect potentially malignant and malignant lesions.[160] However, clinical features alone cannot reliably distinguish between malignant and benign lesions and the clinician cannot accurately predict the risk of malignant transformation on the basis of routine biopsy.[161–163] Only one randomized clinical trial has evaluated the effect of screening by means of visual and tactile examination on oral cancer mortality in India.[164] Between 1996 and 2004, of the 96,517 eligible participants in

(c) 2014 Wolters Kluwer. All Rights Reserved.

the intervention group, 87,655 (91%) were screened at least once, 53,312 (55%) twice, and 29,102 (30%) three times. Of the 5,145 individuals who screened positive, 3,218 (63%) only complied with referral. In the control group, 95,356 eligible participants received standard care. Mortality rate ratio was significantly decreased only in tobacco or alcohol users.[159] The applicability of these findings in Western countries remains to be demonstrated. The only recommendation is the need for the clinicians to remain alert for signs of potential malignancy when performing a routine visual and tactile examination in dental patients, especially when they have a history of smoking and heavy alcohol use.[159] Another recommendation is to develop screening tests in high-risk population in countries with low prevalence of potentially malignant and malignant oral lesions as the United States.

## Posttreatment Follow-up

Regular posttreatment follow-up is essential in patients after potentially curative treatment of HNSCC. The evidence documenting a survival benefit in this population is poor. The recommendations from the National Comprehensive Cancer Network (http://www.nccn.org) emphasize early detection of a second primary cancer in the head and neck or lung and detection and management of treatment-related complications. A major goal should also include smoking and alcohol cessation. In patients with a smoking history of ≥20 pack years, low-dose helical CT scanning of the lung can be discussed for screening of a second primary tumor in the lung.

## Biomarkers of Risk for Head and Neck Cancer

Molecular epidemiologic studies have identified genetic polymorphisms associated with the risk of HNSCC. Most of studied genes are related to single nucleotide polymorphisms (SNPs) in metabolic genes, cell cycle control, and alcohol metabolism.[165] Among these, significant associations were reported for glutathione S-transferase Mu 1 (*GSTM1*), glutathione S-transferase theta-1 (*GSTT1*), human microsomal epoxide hydrolase 1 (*EPHX1*) genes, *TP53*, aldehyde dehydrogenase 2 (*ALDH2*), and alcohol dehydrogenase variant genes (*ADH1B, ADH7*, and *ADH1C*). Recent genome-wide association studies (GWAS) have identified variants in the nicotinic acetylcholine receptor associated with nicotine dependence and lung cancer risk.[166–168] Interestingly, one variant was shown to be associated with the risk of HNSCC and esophagus cancer in women but not in men.[169] This finding was replicated in the INHANCE consortium cohorts.[170] A particular situation is Fanconi anemia that represents a well-identified population at higher risk of developing HNSCC as well as myelodysplastic syndrome and acute myelocytic leukemia.[171–173] In those patients, HNSCC arise at an earlier age and in the absence of other risk factors (tobacco, alcohol).

Wu X et al. recently genotyped 150 early-stage HNSCC patients with and 300 matched patients without second primary tumor/recurrence from a prospectively conducted randomized trial and assessed the association of these SNPs with risk of SPT/recurrence.[174] Using a custom chip containing a comprehensive panel of 9,645 SNPs representing 998 cancer-related genes, they identified six chromosomal SNPs and seven mitochondrial SNPs significantly associated with risk of second primary tumor/recurrence after adjustment for multiple comparisons. A strong gene-dosage effect was observed when these SNPs were combined. This study underscores the importance of incorporating germline genetic variation data with clinical and risk factor data in constructing prediction models for clinical outcomes but will require further validation in independent cohort of patients.

## Biomarkers of Risk for Oral Cancer

The term *potentially malignant disorder* (PMD) was recommended to refer to precancer as it conveys that not all disorders may transform into cancer.[37,38,161,175] PMDs include OL, erythroplakia, palatal lesions in reverse smokers, oral submucous fibrosis, actinic keratosis, lichen planus, and other rare diseases.

Most of the studies developing biomarkers of risk to develop HNSCC have included patients with OL, the most frequent PMD.[37] Clinical factors associated with malignant transformation of OL are female gender, long duration of leukoplakia and older patients, never smokers, size >200 $mm^2$, nonhomogeneous type, lateral and ventral tongue, floor of mouth, and retromolar/soft palate sites.[161] However, the presence of dysplasia is often the criterion that influences clinical management of OLs. The challenges are that OL without dysplasia may still progress to cancer, that a high inter- and intra-observer discordance rate has been reported in the evaluation of dysplasia, that the degree of dysplasia has not always been associated with increased cancer risk, and that OL may be reversible even when dysplasia is identified, irrespective of environmental factors.[38] Three classifications have been proposed to describe the degree of dysplasia.[176–178] To increase the likelihood of agreement between pathologists, a two-class classification has been recently proposed (no/questionable/mild: low-risk and moderate/severe: high-risk) that will need to be evaluated prospectively.[38] Liu et al. studied the usefulness of the binary system of grading dysplasia by reviewing retrospectively 218 Chinese cases of OL with a median follow-up period of 5.3 years.[179] High-risk OL had a hazard ratio of 4.6 (95% CI, 2.36–8.84) to develop OSCC and was an independent risk factor of transformation. The risk was particularly high during the first 2 to 3 years of follow-up.

The natural history of OL remains poorly understood.[161] OL can remain many years without changing, can regress spontaneously or after cessation of tobacco or alcohol, and can transform to invasive SCC. The reported rate of malignant transformation has been low in community-based studies in developing countries (0.06% per year) and higher in observational studies in Western countries involving patients followed in hospital-based academic centers (1%–5% per year). Majority of the studies in the United States found a rate of malignant transformation between 17% and 24% during periods of up to 30 years.[180–182]

No consensus is available for the treatment of OL.[175] Removal of the lesion remains the predominant method of treatment, although no randomized controlled trials have been done to test whether the excision versus observation decreases the risk of recurrence or the risk of malignant transformation.[183] Several studies have shown tobacco cessation was associated with decreased incidence and resolution of OLs.[184–186] Although it is tempting to believe that alcohol and/or tobacco cessation is associated with a decreased risk of malignant transformation, no evidence is available. Patient follow-up strategies are discussed elsewhere but have not been prospectively evaluated.[175] A clinician survey has indicated follow-up regimens of 6 monthly for lesions without dysplasia, 3 monthly for mild/moderate dysplasia, and monthly for severe dysplasia/carcinoma *in situ*.[183,187] The degree of dysplasia and the anatomical site were the two factors influencing the follow-up schema.

Inconsistencies in the value of clinical and pathological factors to predict the risk of malignant transformation of OL led to the development of biomarkers. Challenges are that OL has a low prevalence at least in Western countries, there are often not biopsied, and the rate of malignant transformation per year is generally low, which requires long follow-up periods in both retrospective and prospective cohorts to be able to drive any conclusion.[187] Chemoprevention studies with retinoids allowed unique prospective collections of biospecimens that led to biomarker development.[188]

(c) 2014 Wolters Kluwer. All Rights Reserved.

The most robust and validated one are LOH discovered by Mao et al. in 1996.[45] OL harboring LOH at 3p14 and/or 9p21 were associated with a risk of invasive cancer of 37%, compared with only 6% in lesions without LOH at 3p14 and/or 9p21. These findings were subsequently validated by larger retrospective studies from two independent groups.[189–191] OLs at former cancer sites with LOH at 3p and/or 9p were associated with a higher risk of development of invasive cancer (72% at 5 years) compared with leukoplakias without LOH (6% at 5 years).[192] The presence of LOH at the histologically negative margins of resection in patients with surgically treated HNSCC was a marker of risk of recurrence.[193] Lee et al. have shown that the most predictive factors of risk of cancer are the degree of dysplasia, previous cancer history, and three of the five biomarkers assessed: chromosomal polysomy, p53 protein expression, and LOH at 3p or 9p. In a multicovariate analysis, histology and the combined biomarker score of polysomy, p53, and LOH were the strongest predictors for cancer development.[182] A recent study has prospectively validated LOH profiles as risk predictors of progression in a prospective cohort of 296 patients with primary mild/moderate oral dysplasia. Authors used progression as the event outcome, including progression to severe dysplasia ($N = 17$), carcinoma *in situ* ($N = 2$), and invasive cancer ($N = 22$). High-risk lesions (3p and/or 9p LOH) had a 22.6-fold increase in risk compared with low-risk lesions (3p and/or 9p retention). Addition of another two markers (loci on 4q/17p) further improved risk prediction, with 5-year progression rates of 3.1%, 16.3%, and 63.1% for the low-, intermediate-, and high-risk lesions, respectively.[194]

In a prospective trial using 13-cis retinoic acid, IFN-alpha, and alpha-tocopherol for 12 months for patients with OL, Mao et al. reported that among patients who exhibited LOH at chromosome 9p21 in pretreatment biopsy specimens and who had completed at least 5 months of therapy, the genetic loss persisted in almost all of them, including patients who exhibited complete histologic responses.[195] In the same cohort, authors documented the reappearance of the wild-type *TP53* gene in posttreatment biopsies in patients whose pretreatment tissue samples expressed mutant *TP53*, as well as *TP53* mutations emergence during therapy in patients who did not achieve any clinical response.[196] Finally, *CCND1* overexpression was found in 50% and decreased under treatment in almost half of the cases. *CCND1* overexpression was associated with histological progression and cancer development.[197] A specific *CCND1* genotype was associated with a diminished treatment-induced decreased expression of cyclin D1, a decreased likelihood of response to the intervention, and an increased rate of progression to cancer.[197,198]

*TP63* has been involved in the stem cell biology of stratified epithelium, is a marker of SCC commonly used in clinical practice; deltaNp63 isoform has oncogenic properties.[199] Podoplanin was shown to promote invasion in different cancer types and was shown to be associated with poor prognosis in OSCC.[200] We reported that overexpression of podoplanin and deltaNp63 were prevalent in OL and associated with a higher risk to develop OSCC[199,201] using the largest prospective chemoprevention trial ($N = 162$ patients, median follow-up 7.5 years, transformation rate 24%) comparing 13-cis retinoic acid, beta-carotene plus retinyl palmitate, and retinyl palmitate in patients with OL.[201,202] We have also reported an *EGFR* increased gene copy number in 41% of OLs and have shown a strong association with the risk of developing OSCC in patients with OLs overexpressing EGFR.[78]

In the same cohort of patients, we have generated gene expression profiles of 86 OLs, including 35 from patients who developed OSCC.[33] We reported a strong association between gene expression and OSCC risk; with an 11% false discovery rate, more than 2,000 genes were associated with a high or low risk to develop OSCC ($p < 0.01$). Using multiple independent and publicly available data sets of HNSCC and normal mucosa with available gene expression profiles, we have shown that the vast majority of the genes associated with a high or low risk to develop OSCC were upregulated or downregulated in HNSCC, respectively. We have shown that a 25-gene signature improved our prediction of OSCC development over clinical and pathological biomarkers, including the degree of dysplasia and the expression of deltaNp63 and podoplanin.

Other biomarkers have been associated with the development of OSCC in patients with OL[187]: survivin, *MMP9*, activated Chk2, *CDKN2A* promoter methylation, mcm2, geminin/mcm2 and geminin/Ki67 ratios, SIBLING family of proteins, allelic index >2, DNA content, LOH at 11q, and DNA ploidy. Others have failed to show any value: p53 protein expression, cathepsin L mRNA, MMP1/2 mRNA, p73, LOH at 8p, cornulin, keratin 4 and 13, osteopontin, and promoter methylation of cyclin A1, cytoglobin, and *MGMT*.

Except for LOH, none of those biomarkers have been validated in multiple cohorts of patients. Ideally, this will have to be done prospectively. A complete characterization of genomic and epigenomic changes in the premalignant and subsequent OSCC from the same patient and their functional consequences on gene expression profiles and pathway activation would provide a unique opportunity to identify early key molecular events.

## Biomarkers of Risk for Larynx Cancer

Between 2 and 10 laryngeal dysplasia are reported per 100,000 of the population.[203] The main treatment modality is surgical excision. No evidence is available that it significantly affects the transformation rate.[204,205] A recent review of the literature has reported an overall malignant transformation rate of 14%.[204] The rate is 11% for mild/moderate dysplasia and 30% for severe dysplasia and carcinoma *in situ* with a mean time to transformation of 5.8 years. Some biomarkers have been evaluated for their ability to predict malignant transformation.[205,206] *p53* expression failed to show any predictive ability. Other markers studied are Ki67, cyclin D1 expression, cortactin, cyclin E, cyclin A, *CDC25A*, *CDC25B*, mdm2, bcl-2, p27, p21, and ST3. RRs ranged from 0.60 (95% CI, 0.10–3.75) for mdm2 to 85 (95% CI, 5.30–1,350) for cortactin with wide confidence intervals to the small number of patients in those studies. There is currently not enough evidence for using those markers to predict the transformation of dysplastic lesions.

## The Specific Case of HPV-Related HNSCC

A possible reason for the increasing incidence of HPV-related HNSCC has been temporal changes over the last decades in sexual behaviors, including younger age of sexual debut, increased number of lifetime partners, and oral sex.[207] No premalignant lesion has been reported in HPV-related oropharynx SCC.[18] Prevention of HPV-related cancers (cervical, vaginal, vulvar and anal cancers, as well as genital warts in both genders) with HPV vaccines is recommended.[208,209] Clinical trials for HPV vaccines have now followed women out to 5 to 8 years. Data show that the clinical protection remains high with time.[210] Such trials will not be able to assess directly whether HPV vaccines impacts HNSCC which are typically affecting individuals in their 50s or 60s. Longitudinal studies comparing rates of HNSCC before and after the introduction of HPV vaccines may answer this question. However, considering that the increased incidence of HPV-related HNSCC is related to changes in sexual behaviors and hoping that HPV vaccines confer long duration of clinical efficacy, it is reasonable to expect a decrease in the incidence of those tumors in the future.[207]

## CHEMOPREVENTION CLINICAL TRIALS

In this section, we will present the rationale and findings from the main chemoprevention clinical trials for HNSCC conducted to date. It should be noted that none of these studies resulted in a strategy that can be considered standard of care. However, advances in cancer risk assessment were achieved from correlative studies of clinical specimens obtained through these efforts. The results have paved the way for the development of a new generation of clinical trials, briefly discussed herein as well.

### Retinoids

Clinical trials with retinoids to prevent HNSCC focused on individuals with oral premalignant lesions (i.e., secondary prevention) or with a history or curatively treated head and neck malignancies (i.e., tertiary prevention).

***Retinoids for Oral Premalignant Lesions.*** Most of the studies using retinoids for secondary prevention focused on OL clinical and/or histological response as the primary endpoint. This approach bears several criticisms, including the fact that clinical response only marginally correlates with long-term oral cancer-free survival,[202] and the fact that molecular abnormalities in the oral mucosa may still persist despite disappearance of the lesion following the chemoprevention intervention.[195] Hence, the results of the studies must be interpreted in light of these limitations.

The first chemoprevention trials of systemic and topical vitamin A for oral premalignant lesions were conducted in the late 1950s and showed some evidence of efficacy.[211,212] In 1986, Hong et al. reported the first double-blind, placebo-controlled trial of high-dose 13cRA (1–2 mg/kg/day for 3 months) in this setting. The clinical response rate was 67% in the retinoid arm and 10% in the placebo arm ($p = 0.00002$). The rate of histologic improvement was also significantly better in the retinoid arm (54% vs. 10%, $p = 0.01$). However, toxic effects were frequent and severe, with two-thirds of the retinoid-treated patients experiencing mucocutaneous adverse events and hypertriglyceridemia; dose reductions were required in approximately 50% of patients treated with 2 mg/kg/day. Moreover, remission was short lived, and more than half of the patients experienced a relapse within 3 months of treatment cessation.[213] Stich et al. also demonstrated, in the 1980s, that 6-month treatment with vitamin A (200,000 IU/week) led to a higher complete response rate than placebo (57% vs. 3%) in tobacco/betel nut chewers.[214] Similar results were also seen in a second study of placebo versus beta-carotene versus beta-carotene plus vitamin A in individuals with a history of exposure to smokeless tobacco. The 6-month leukoplakia-remission rates were 3%, 15%, and 28%, respectively.[215] A later study also demonstrated that treatment with vitamin A or beta-carotene for 12 months produced higher response rates compared to placebo (52%, 33%, and 10%, respectively). However, as had previously been observed by Hong et al., 50% to 66% of the patients experienced a relapse after treatment discontinuation.[216]

To address the issues of toxicity with high-dose 13-cis retinoic acid and the short duration of response following the brief 3-months treatment period, Lippman et al. conducted a phase IIb maintenance trial following induction retinoid therapy.[217] In this study, patients with oral premalignant lesions were treated with 13-cis retinoic acid 1.5 mg/kg/day for 3 months (induction phase), followed by either low-dose 13-cis retinoic acid (0.5 mg/kg/day) or beta-carotene (30 mg/kg/day) for 9 months in individuals not experiencing progression of the lesion (maintenance phase). Consistent with the previous trials, 55% of the patients had a clinical response to the induction therapy (and reversal of dysplasia occurred in 43% of the responders). After the maintenance phase, 53 patients were evaluable for the primary endpoint. Further lesion response was observed in 33% of the patients receiving 13cRA and in 10% of the beta-carotene-treated patients. Severity of adverse events was lower during the maintenance phase, with a more favorable toxicity profile in the beta-carotene arm. The study underscored the importance of a longer retinoid treatment period to maintain clinical responses. However, on long-term follow-up, the incidence of *in situ* or invasive carcinoma was not different between the 13-cis retinoic acid and beta-carotene groups (23% vs. 27%, respectively).[180]

The follow-up trial to the phase IIb study by Lippman et al. was designed to prolong even more the duration of treatment with 13-cis retinoic acid. The doses were once again reduced to ameliorate the toxicity profile. This study's original treatment arms consisted of 13-cis retinoic acid (0.5 mg/kg/day for 1 year followed by 0.25 mg/kg/day orally for 2 years) versus vitamin A (retinyl palmitate 25,000 IU/day) plus beta-carotene (50 mg/day) for 3 years. The initial statistical design aimed at determining noninferiority of vitamin A plus beta-carotene compared to 13-cis retinoic acid in terms of clinical response.[202] However, during the conduct of the study, data became available as regard to the increased lung cancer incidence and mortality associated with beta-carotene in other ongoing chemoprevention studies.[218,219] As a result, the experimental arm was modified to vitamin A single agent. The final analysis of the trial demonstrated that patients receiving 13cRA more frequently experienced grade 2 or higher toxicities. Vitamin A single agent was associated with a lower 3-month clinical response rate (20%) compared to beta-carotene plus vitamin A (32.5%) and 13cRA (48.1%). Noninferiority could not be determined between the control and experimental arm(s). More importantly, the 5-year oral cancer-free survival was similar across the treatment groups (78%–84%), and clinical response at 3 months was only marginally correlated with long-term oral cancer-free survival. This was one of the largest and longest term studies in oral premalignant lesions ever conducted and demonstrated that 13-cis retinoic acid is not well tolerated even at lower doses and that a treatment that can prevent oral invasive cancer long-term is yet to be developed. The study also questions the use of clinical response as a valid endpoint in trials of oral premalignant lesions.

Synthetic retinoids have also been studied for secondary HNSCC prevention. Fenretinide is the agent that has been more extensively evaluated in this setting. Potential advantages of fenretinide over 13cRA include a more favorable toxicity profile and enhanced activity due to both RAR/RXR-receptor dependent (i.e., cell differentiation at lower doses) and independent (i.e., cell apoptosis at higher doses) effects.[220–223] In a 4-month placebo-controlled study, Han et al. observed significant activity of fenretinide in reversing oral premalignant lesions.[224] In a randomized study including 170 patients with resected oral premalignant lesions, Chiesa et al. demonstrated that, compared to observation, treatment with fenretinide 200 mg/day for 12 months was associated with a significant reduction in the risk of relapse 19 months after randomization. The drug was well tolerated. Unfortunately, the trial had to be stopped prematurely due to slow accrual, and a confirmatory study has not been done.[225] Fenretinide was also evaluated in individuals with retinoid-resistant OL. In a single-arm, phase II study, the response rate at 3 months was 34%, partial in all cases, often short lived, and correlated with previous response to retinoids.[226] In a follow-up study using higher doses of fenretinide (900 mg/m$^2$ /day) in the same setting, no significant clinical activity was seen (20% response rate only), prompting a planned discontinuation of the trial due to futility.[227]

***Retinoids to Prevent Second Primary Tumors.*** In 1990, Hong et al. reported the results a randomized trial of 13cRA (50–100 mg/m$^2$ /day) versus placebo for 12 months in patients with stage I to IV

(c) 2014 Wolters Kluwer. All Rights Reserved.

HNSCC who completed definitive therapy. The major endpoints of this study were disease recurrence and incidence of second primary tumors. Retinoid treatment was not associated with a reduction in local, regional or distant recurrence, or overall survival, but after a median follow-up of 32 months, patients in the retinoid arm had a lower incidence of second primary tumors compared to placebo.[228] The difference remained significant, albeit smaller, after long-term follow-up.[229] Again, retinoid therapy was associated with significant toxicities, and only two-thirds of the patients completed the full 12 months of treatment. In follow-up to this study, a large, multicenter, phase III, placebo-controlled trial of 13cRA 30 mg/day for 3 years was launched, enrolling 1,190 patients with stage I or II HNSCCs who completed definitive treatment. Unfortunately, this study failed to confirm the results originally reported by Hong et al. There were no differences in the rate of second primary tumors, local, regional or distant recurrence, or overall survival between the arms.[230] Recently, the association between SNPs and outcome has been studied in 450 patients included in this trial.[231] Patients carrying the common genotype of rs3118570 in *RXRA* were at a 3.33-fold increased risk and represented more than 70% of the study population. Interestingly, this locus also identified individuals who received benefit from chemoprevention with a significant 38% reduced risk (95% CI, 0.43–0.90). This study suggests that a pharmacogenetic approach could help select patients for 13-cRA chemoprevention.

The Northern California Oncology Group (NCOG) and the Eastern Cooperative Oncology Group (ECOG) conducted a phase III study with 13cRA (0.15 mg/kg/day) versus placebo for 2 years in 189 patients with stage I or II who completed surgery and/or radiation therapy. There were no differences in the rate of second primary tumors between the treatment arms.[232]

Meanwhile, the second-generation retinoid etretinate was evaluated in France in patients with early stage SCCs of the head and neck in the adjuvant setting. In this randomized study, 316 patients received placebo or the retinoid (50 mg/day for 1 month followed by 25 mg/day for 23 months). At 41 months of follow-up, second primary tumors developed at a similar frequency in the two treatment arms (24% for placebo, and 38% for etretinate). There were no differences in overall survival or recurrence.[233]

The largest study to prevent second primary aerodigestive tumors was conducted by the European Organization of Research and Treatment of Cancer (EORTC). The trial titled European Study on Chemoprevention with Vitamin A and N-Acetylcysteine (EUROSCAN) randomized 2,592 patients with treated lung (40%) or head and neck (60%) malignancies to receive no intervention, retinyl palmitate (300,000 IU/day for 1 year followed by 150,000 IU for 2 year), N-acetylcysteine (600 mg/day), or both in a two-by-two factorial design. It was based on the previous experience by Pastorino et al. showing a longer time to development of second primary tumors within the carcinogen-exposed field in patients with stage I non–small cell lung cancer treated for 12 months with retinyl-palmitate versus placebo.[234] Unfortunately, the EUROSCAN failed to show a benefit from either n-acetylcystein or retinyl palmitate in terms of survival, event-free survival or second primary tumor rates.[235]

Beta-carotene was evaluated for prevention of second primary HNSCC in two phase III studies. Mayne et al. randomized 264 patients with early stage head and neck cancers after completion of definitive treatment to receive placebo versus beta-carotene 50 mg/day. The study was terminated early due to slow accrual. After a median follow-up of 51 months, no differences were seen in time to second primary tumors and/or recurrences, or overall survival.[236] Bairati et al. randomized 540 patients with stage I or II HNSCC treated with radiation therapy to receive alpha-tocopherol (400 IU/day) plus beta-carotene (30 mg/day) versus placebo for 3 years.[237] After enrollment of 156 patients, beta-carotene supplementation was discontinued given the increased risk of lung cancers observed in other ongoing chemoprevention studies.[218,219] The remaining of the patients received alpha-tocopherol or placebo. After a median follow-up of 52 months, there was a higher rate of second primary cancers during the alpha-tocopherol supplementation period, but a lower rate after supplementation was discontinued. After 8 years of follow-up, the proportion of patients free of second primary tumors was similar between the groups.[237]

Taken together, the aforementioned studies do not support the use retinoids for tertiary prevention of head and neck cancers.

## Cyclooxygenase (COX) Inhibitors

Mulshine et al. randomized 57 patients with oral premalignant lesions to receive placebo or a 0.1% oral rinse solution of the pan COX inhibitor ketorolac for 30 days. The primary and secondary endpoints of the study were clinical and histological response, respectively. The placebo group had a high rate of clinical response (32%), and there were no significant differences in either of the endpoints between the groups. The authors concluded that the topical form of delivery of the drug may not be optimal for tissue penetration, thus explaining the lack of clinical activity.[238]

Papadimitrakopoulou et al. conducted a pilot, randomized study of the COX2 selective inhibitor celecoxib in individuals with oral premalignant lesions. Patients were treated with placebo, celecoxib 100 mg twice daily or 200 mg twice daily for 12 weeks during the blinded phase of the study. Six additional patients received celecoxib 400 mg twice daily on an open-label extension phase. Celecoxib was well tolerated, but there were no differences in the response rates between the groups. Interestingly, patients with higher baseline COX2 mRNA expression had an increased risk of disease progression within 3 months.[239]

Taken together, the two aforementioned COX inhibitor chemoprevention trials do not support the use of these agents for management of oral premalignant lesions. The cardiovascular toxicities associated with COX2 inhibitors observed on chemoprevention studies of colonic polyps [240] have decreased the enthusiasm for further evaluation of these drugs for HNSCC prevention.

## Green Tea Polyphenols

The polyphenol (–)-epigallocatevhin-3-gallate (EGCG) is the most abundant antioxidant present in green tea extract. Multiple signaling pathways are modulated by EGCG, including inhibition of activation of receptor tyrosine kinases (such as EGFR, insulin-like growth factor receptor, VEGF), their downstream pathways (including Akt, ERK, and STAT 3), inhibition of NF-kappa-B (a transcription factor involved in inflammation, immunity, and carcinogenesis), activation of the *p53* pathway and its downstream targets *p21*, *p27*, and *Bax*, as well as stimulation of *p73*. The combined effects of EGCG may, potentially, ultimately lead to apoptosis, cell cycle arrest, growth inhibition, antiangiogenesis, and inhibition of metastasis (reviewed in detail by Kim et al.).[241]

Clinical trials with green tea extracts for cancer prevention and treatment have been completed. These studies have used different preparations of green tea extracts, which contain varying amounts of EGCG and other potentially active ingredients. Therefore, results from these studies should be interpreted carefully and may not be extrapolated to ingestion of usual amounts of green tea in nonpharmacological formulations.

Li et al. reported the first placebo-controlled, randomized study of green tea in 59 patients with oral premalignant lesions. Patients assigned to the experimental arm received 760 mg of mixed tea capsules orally four times per day and 10% of mixed tea ointment topically (EGCG content not known). There was a favorable clinical response rate in the experimental arm (37.9%) compared to placebo (10%).[242]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Recently, Tsao et al. conducted a placebo-controlled, phase II study of three different doses of green tea extract for 12 weeks in 41 patients with oral premalignant lesions. Each 350 mg green tea extract capsule contained 13.2% of EGCG. The dose levels were 500 mg/m$^2$ versus 750 versus 1,000 mg/m$^2$ three times per day. The higher doses of the drug were associated with insomnia/nervousness. The response rates in the two higher-dose arms combined (58.8%) were significantly better than in the 500 mg/m$^2$ arm (36.4%), and placebo (18.2%), suggesting a dose–response effect. There was also a trend toward improvement in histology. There were no differences in oral cancer-free survival. Biomarkers associated with response included baseline stromal VEGF expression, and downregulation of cyclin D1 expression and stromal VEGF receptor after treatment. Interestingly, nonresponding lesions had up-regulation of the latter biomarkers, indicating that the efficacy of the drug could be mediated by a reduction in angiogenic stimuli. This study supports the evaluation of green tea extracts in longer-term trials.[243] Different formulations of green tea extracts[244] and combination with other agents (e.g., EGFR inhibitors)[245] are being developed.

## *p53*-targeted Agents

Attempts at restoring *p53* function in premalignant lesions or targeting *p53* mutant premalignant cells have been described. ONYX-015 is an attenuated adenovirus cytotoxic to cells with dysfunctional *p53*-dependant signaling pathways. Rudin et al. enrolled 22 patients with dysplatic lesions of the oral mucosa in a study of three different schedules of a mouthwash of ONYX-015. Histologic resolution of dysplasia occurred in 37% of the patients, but the majority of the responses were short lived. Lesions that had histologic regression had a decrease in *p53* expression levels by immunohistochemistry over time, but baseline *p53* expression did not predict for response to ONYX-015. Two out of three lesions had confirmed viral replication.[246]

Li et al. evaluated the effects of multipoint intraepithelial injections of a recombinant human adenovirus-*p53* in 22 patients with dysplastic OL. This adenovirus is replication-incompetent, with an E1 gene region replaced by an expression cassette containing human wild-type *p53* cDNA. After treatment, 100% of the lesions demonstrated a positive staining for p53 protein expression, mainly located in the basal and spinous layer of the epithelium. Likewise, p21 protein expression was increased post treatment in 19 of the 22 case; bcl-2 protein expression significantly decreased post treatment. After 24 months of follow-up, 22.7% of the patients had a complete response, 50% of the patients had a 20% to 70% reduction in the size of the leukoplakia lesions, 18.2% had stable lesions, and 9.1% developed invasive cancer.[247]

While the results of the aforementioned clinical trials provide proof of principle of the potential role for targeting *p53* in oral premalignant lesions, the greatest limitation of the studies is the mode of delivery of the agents. As previously discussed, field cancerization is an important aspect of head and neck carcinogenesis, and strategies using topical or local therapies may not address the remaining of the mucosa at risk, thus possibly diminishing the potential for long-term prevention of aerodigestive tract cancers more broadly.

## Thiazolidinediones

Peroxisome activator receptor–gamma (PPAR$\gamma$) is activated by natural or synthetic ligands. Following binding of the ligand to the receptor, PPAR$\gamma$ heterodimerize with RXR and the complex binds to response elements of target genes and regulate their transcription. PPAR$\gamma$ activity may also be regulated by sumoylation and phosphorylation. PPAR$\gamma$ agonists have been shown to promote terminal differentiation, inhibition of proliferation, and stimulation of apoptosis in cancer cell lines *in vitro*. In preclinical animal models, the thiazolidinediones pioglitazone[248] or troglitazone[249] decreased the tongue carcinoma multiplicity and incidence, respectively, compared to placebo. Diabetic patients treated with thiazolidinediones had a reduced incidence of lung[250] and head and neck[251] cancers in retrospective epidemiologic studies, when compared to diabetic patients receiving alternative oral hypoglycemic agents. In a randomized, placebo-controlled, phase II study including 43 patients with OL, treatment with pioglitazone daily for 3 months led to a higher clinical and/or histological response rate compared to placebo (68% vs. 0%, respectively).[252] This trial formed the basis for a larger, ongoing, multicenter, phase IIb study of pioglitazone versus placebo in patients with oral premalignant lesions.

## EGFR Inhibitors

Because of the lack of significant progress with retinoid-based chemoprevention strategies in the last three decades, associated with the parallel development of effective and well-tolerated targeted drugs for treatment of invasive disease, several clinical trials have been launched to assess the efficacy of these agents on early stages of cancer/premalignancy. Within the context of the recently proposed paradigm termed *reverse migration*,[42] EGFR inhibitors are nearly ideal drugs to be evaluated in the setting of oral premalignant lesions, given the efficacy of cetuximab-based therapies in locally advanced and metastatic disease.[253] Chemoprevention clinical studies with the EGFR monoclonal antibody cetuximab or the EGFR TKI erlotinib were launched, even before preclinical data were obtained to support their use.

In 2006, the erlotinib prevention of oral cancer (EPOC) study was activated. In this trial, patients with oral premalignant lesions (with or without a prior history of OSCC) are first evaluated for the presence of LOH at 3p, 9p, and other key chromosomal sites. As previously discussed, this molecular abnormality is associated with a substantial risk of subsequent invasive cancer.[45,189,192] All patients are followed for development of OSCC, but only the molecularly defined high-risk patients are randomized to receive placebo or erlotinib 150 mg orally daily for 1 year. Definitions of high risk includes LOH at 3p and/or 9p in patients with a prior history of oral cancer, and LOH at 3p14 and/or 9p21 plus an additional chromosomal site in patients without a prior history of oral cancer. After treatment discontinuation, patients are followed for at least 2 more years. Unlike most previous studies in oral premalignant lesions, the primary endpoint of this trial is incidence of OSCC. EPOC is an example of more efficient clinical trial designs for cancer prevention. Because it focuses on a high-risk population, it allows for a smaller trial ($N = 150$ total patients), yet with sufficient power to detect a possible effect of erlotinib in inhibiting the development of invasive cancer, a clinically more meaningful endpoint than clinical or histological response of the oral premalignant lesions.[254]

The planned accrual for EPOC includes 100 LOH positive patients with a history of prior oral cancer, and 50 LOH positive patients without a history of oral cancer. According to previous retrospective studies discussed above,[189,192] 65% of the patients with oral premalignant lesion/LOH associated with curatively treated oral cancer are expected to develop oral cancer in 3 years, and 35% of the LOH positive patients without a prior history of oral cancer are expected to develop oral cancer in 3 years. It is estimated that erlotinib will reduce the incidence of oral cancer in the two cohorts by 40%, corresponding to a hazard ratio of 0.47. With this design, the study has 85% power with a two-sided 5% type I error rate. Several correlative studies are built into the study as well, including evaluation of biomarkers at baseline and in 3- and 12-month tissue biopsies that

(c) 2014 Wolters Kluwer. All Rights Reserved.

will shed light on the biology of these high-risk lesions and may assist in developing predictive markers of response, as well as additional markers of cancer risk. After screening approximately 400 patients in five different institutions in the United States, EPOC has completed accrual, and final data are eagerly awaited. Results of other smaller studies using cetuximab, and erlotinib plus celecoxib for head and neck cancer prevention are also yet to be presented.

## CONCLUSIONS

Significant advances in HNSCC chemoprevention field have been achieved over the past decades. There is now a better understanding of molecular and phenotypic determinants of the tumorigenic process, and risk models are currently being refined to predict development of oral cancer. This will certainly allow for an improvement in chemoprevention strategies in the future. Studies with retinoids, COX inhibitors, green tea extracts, *p53*-targeted agents, and thiazolidinediones have not resulted in the development of an intervention that can be standardly used for head and neck cancer prevention, but they set the stage for a model of translational science that will hopefully accelerate drug development in this setting. According to recent sequencing efforts of HNSCC, the mutational etiology is diverse, and most importantly with regard to chemoprevention, HNSCC have few targetable mutations, further emphasizing the need to improve prevention strategies.[4,5] A complete genetic and epigenomic characterization of preneoplastic lesions and subsequent SCC will allow a comprehensive characterization of the dynamic changes occurring during early cancer development. Using a systems biology approach to integrate multidimensional high-throughput molecular profiles as well as preclinical models should allow the identification of pathways driving carcinogenesis and potentially targetable. We are entering a new era of chemoprevention clinical research, employing novel trial designs and agents, focusing on molecularly defined high-risk cohorts, and supported by improved preclinical models. This will hopefully lead to effective strategies to reduce the incidence, morbidity, and mortality from head and neck cancers in the near future.

CHAPTER 14

# Management of the Neck

## PART A:
## General Principles and Management

Kenneth S. Hu, Adam S. Jacobson, Mark S. Persky, and Louis B. Harrison

### INTRODUCTION

Successful management of the neck is a prerequisite for the cure of most head and neck squamous cell carcinomas (HNSCC). Tumor spread to the regional nodes signals the transformation of the primary tumor to a more malignant phenotype with the ability to not only invade lymphatics but also spread hematogenously. Indeed, the clinical involvement of the regional node decreases the chance for cure by at least one-half.[1] Even in a clinically negative neck, surgical data have demonstrated high rates of occult nodal involvement for the majority of head and neck primary sites. Usually, such regional spread occurs in a predictable, progressive pattern depending on the mucosal site of origin, local richness of lymphatics, proximity to midline, and tumor stage. Thus, in a clinically negative neck, the first echelon nodes and levels of potentially involved nodal stations are evaluated and risk of involvement assessed before a decision is rendered regarding selective management. For clinically node-positive patients, more comprehensive, intensive treatment is required that addresses the greater tumor burden and larger areas of potential spread. How the neck is managed usually follows the manner in which the primary site is addressed. Single modality therapy, either surgery or radiation, is used to manage early stage primary tumors and regional lymphatics at risk for harboring occult disease, whereas multidisciplinary approaches are required for advanced primary tumors. Although surgery was traditionally considered the mainstay of treatment of the primary site and neck, decades of randomized trials have established radiation therapy as an effective alternative. In that regard, advances in organ preservation therapies have resulted from the integration of concurrent chemotherapy with radiation[2–6] altered fractionated radiation therapy,[7–10] introduction of new chemotherapeutic/biologic agents,[11] use of induction chemotherapy,[12,13] better understanding of the role of functional imaging improved treatment techniques such as intensity-modulated radiation therapy (IMRT)[14,15] as well as advances in molecular profiling, especially with regard to the human papilloma virus and epidermal growth factor receptor. Recent improvements in transoral robotic techniques have renewed primary surgical approaches for multiple sites (oropharynx and hypopharynx). In this regard, a neck dissection is usually performed in a staged manner, which has emphasized risk-adapted adjuvant treatment based on pathologic factors.

The purpose of this chapter will be to discuss the role of surgery and radiation therapy in the elective, adjuvant, and definitive management of the neck. Additionally, this chapter will discuss the use of imaging to assess oncologic response and to discuss evolving concepts which may better tailor treatment of regional disease. The management of regional metastatic disease from nasopharyngeal cancer will be discussed in a separate chapter.

### CERVICAL LYMPH NODE LEVELS

The Committee for Head and Neck Surgery and Oncology of the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS) first published the guidelines for anatomic boundaries of the various cervical levels in 1991,[16] which were modified and updated in 2002.[17] These guidelines were all based on the original level designations that were created at Memorial Sloan Kettering Cancer Center to refer to the particular topographical location on the neck under which a consistent pattern of lymph nodes existed (Fig. 14-1).

### NECK STAGING

It is clear that metastases to cervical lymph nodes has a profound impact on the prognosis of a patient. The current staging system is based on a consensus between the European UICC and American Joint Cancer Committees. This system utilizes the

clinical features of nodal size, number, and laterality. It does not integrate imaging features suggestive of extranodal extension, which is well known to adversely affect prognosis. Table 14.1 describes the N staging.

Patients staged as Nx have regional lymph nodes that cannot be assessed. N0 patients have no identifiable regional nodal metastasis. N1 patients have a single nodal metastasis, ipsilateral to the primary tumor site, and ≤3 cm in greatest dimension. Patients staged as N2a have a metastasis to a single ipsilateral node, which is >3 cm but <6 cm in greatest dimension. Patients staged as N2b have metastasis to multiple ipsilateral lymph nodes and none are >6 cm in greatest dimension. Patients staged as N2c have metastatic disease in bilateral or contralateral lymph nodes; none are >6 cm in greatest dimension. Patients staged as N3 disease have a lymph node or conglomerate of lymph nodes >6 cm in dimension.

|---|---|---|---|
| N0 | No involved node | No involved node | No involved node |
| N1 | Single ipsilateral node <3 cm | Single ipsilateral <3 cm | Single ipsilateral <3 cm |
| N2 | 1. Single ipsilateral node >3 cm, <6 cm<br>2. Multiple ipsilateral <6 cm | 1. Single ipsilateral >3 cm, <6 cm<br>2. Multiple ipsilateral >3 cm, <6 cm | 1. Single ipsilateral >3 cm, <6 cm<br>2. Multiple ipsilateral <6 cm<br>3. Bilateral or contralateral <6 cm |
| N3 | | 1. Ipsilateral node(s) >6 cm<br>2. Bilateral<br>3. Contralateral only | Node >6 cm |

## NECK DISSECTION TERMINOLOGY

*Radical neck dissection:* Radical neck dissection involves removal of lymph node levels I to V, including the submandibular gland, tail of the parotid gland, sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve (Fig. 14-2).

*Modified radical neck dissection (MRND):* MRND involves removal of lymph nodes from levels I to V (as in the radical neck dissection) but with preservation of at least one of the nonlymphatic structures (i.e., sternocleidomastoid muscle, spinal accessory nerve, and/or internal jugular vein).Modifications to the radical neck dissection include the following: (a) Type I: The spinal accessory nerve is preserved; (b) Type II: The spinal accessory nerve and the internal jugular vein are preserved; (c) Type III: The spinal accessory nerve, the internal jugular vein, and the sernocleidomastoid muscle are preserved.

*Extended radical neck dissection:* Extended radical neck dissection refers to removal of additional lymph node levels or groups and/or nonlymphatic structures (i.e., muscle, blood vessels, nerves) not normally removed with a radical neck dissection. Examples of additional lymph node groups include superior mediastinal, parapharyngeal, retropharyngeal, periparotid, postauricular, suboccipital, and buccinator. Examples of other nonlympahtic structures are the external carotid artery, hypoglossal and vagus nerves, and other neural, osseous, cutaneous, muscular, or vascular structures that are potentially involved with tumor.

*Selective neck dissection (SND):* SND refers to preservation of one or more lymph node levels and sparing all vital structures (sernocleidomastoid muscle, internal jugular vein, spinal accessory nerve). There are several variations of the SND, which have been given specific names (i.e., lateral, supraomohyoid, extended supraomohyoid, posterior, and central) (Fig. 14-3A–C).

*Super selective neck dissection:* Super selective neck dissection involves complete removal of all fibrofatty tissue contents, including lymph nodes, along the defined boundaries of one or two contiguous neck levels.[18]

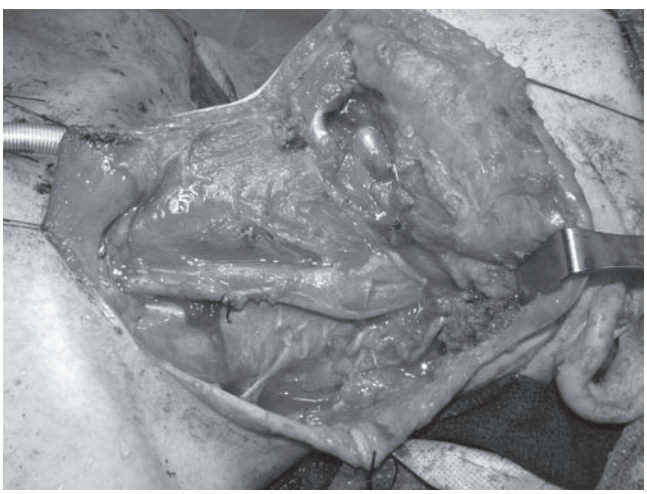

**FIGURE 14-2.** Removal of lymph node levels I to V.

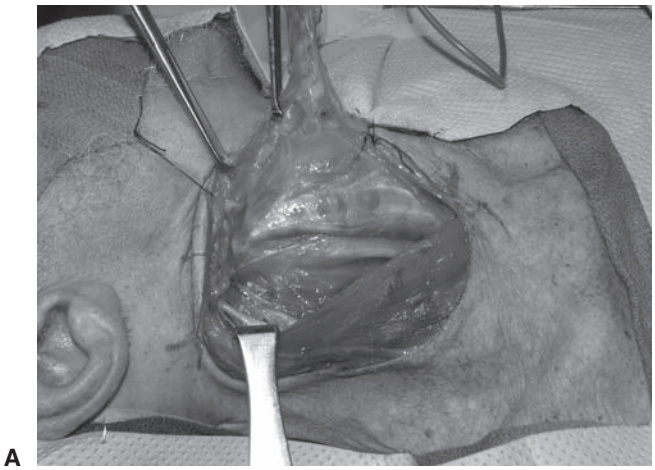
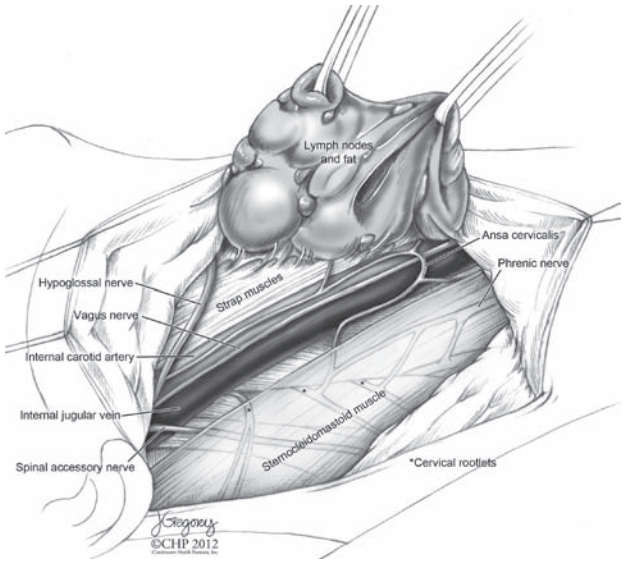


The super selective neck dissection has been pioneered by Robbins et al. who have utilized the super selective neck dissection in patients with advanced head and neck cancer that have been treated with primary chemoradiation and have residual pathologic lymphadenopathy limited to a single lymph node level.[18,19] It is believed that by minimizing the surgical field, soft tissue fibrosis is reduced and its impact on swallowing, mastication, and range of motion of the neck are minimized.

## THE EVOLUTION OF THE NECK DISSECTION



Surgeons of the early 19th century were aware that cancers of the head and neck metastasized to cervical lymph nodes; they often regarded this as a sign of incurability.[20] It was believed that the cervical metastases needed to be removed with the primary tumor, in order for the patient to have any chance of survival. In 1888, Jawdynski published the first description of an en bloc neck dissection, which was later popularized by George W. Crile, who published a systematic approach to the neck dissection in 1906.[21] In this procedure, all lymphatic tissue between the superficial and deep cervical fascial layers of the lateral neck were removed en bloc, including the sternocleidomastoid muscle, internal jugular vein, tail of the parotid gland, submandibular gland, and spinal accessory nerve.

In 1951, Hayes Martin and colleagues published their experience with 1,450 cases of neck dissections.[22] This paper helped to define the technique, as well as gain acceptance within the surgical community. In 1952, Suarez published his modifications of the classical radical neck dissection, which he called the "functional neck dissection." The goal of the functional neck dissection was to reduce morbidity while preserving the oncologic efficacy of the classic radical neck dissection. The modifications made by Suarez were preservation of the sternocleidomastoid muscle, internal jugular vein, omohyoid muscle, and, whenever possible, the spinal accessory nerve. Bocca and colleagues went on to popularize the selective removal of cervical lymphatics with preservation of vital structures (i.e., sternocleidomastoid

**FIGURE 14-3.** Selective neck dissection. **A:** Selective removal of lymph node levels II, II, and IV. **B:** Illustration of selective removal of lymph node levels II, II, and IV. **C:** Neck after selective removal of lymph node levels II, II, and IV. (See color insert for Part **B**)

muscle, spinal accessory nerve, internal jugular vein).[23] Preserving these structures allows for maximization of control of the regional disease with minimization of the morbidity associated with a radical neck dissection (chronic neck and shoulder pain, cosmetic deformity, facial edema, etc.).

At this point, surgeons had become adept at systematically removing cervical lymphatics, but it was not until 1972 when Robert Lindberg first recognized patterns of cervical metastases in correlation with the primary tumor location.[24] This publication revealed that there were clear and predictable patterns of spread in the cervical lymphatics from each subsite within the upper aerodigestive tract. This observation that the patterns of cervical nodal disease are dictated by the location of the primary tumor has enabled surgeons to selectively remove nodal basins at risk for metastases based on the primary site of disease. This newfound knowledge opened the doors for preservation of low-risk nodal basins, thus decreasing patient morbidity. In the 1980s, Ballantyne from M. D. Anderson Cancer Center became one of the initial proponents of the SND. In 1988, Byers et al. described the patterns of nodal metastasis among 428 patients with HNSCC.[25] In 1990, Shah reported the progression of metastatic disease in the neck in a consecutive series of 1,081 patients with primary tumors of the oral cavity, the oropharynx, the hypopharynx, and the larynx.[26] The SND is now routinely used as a staging procedure to determine the presence or lack of occult metastases (which can help in the decision to apply adjuvant radiation therapy). More recently, the SND has been utilized in N+ necks as well as in postchemoradiation planned neck dissections. The use of the SND in clinically positive necks has been gaining widespread acceptance in recent years.

## CURRENT PHILOSOPHY FOR LATERAL COMPARTMENT NECK DISSECTIONS

The contemporary approach to removing cervical lymphatics has evolved from the highly morbid radical neck dissection to the much less morbid yet effective SND. Although the pendulum has shifted to a much less aggressive extirpation of lymphatic and nonlymphatic tissues, the radical neck dissection still remains the gold standard by which all modifications to the neck dissection must be compared. The current philosophy of ablative surgeons can be distilled down to a few simple goals. The first is the removal of all clinically positive lymph nodes and all involved nonlymphatic structures. The second goal is to preserve all nonlymphatic structures, which are not diseased, to optimize functional outcomes. The third goal is removal of all lymph node levels, which are at high risk for harboring metastatic disease. With these simple but clear goals, ablative surgeons are now more thoughtful in their extirpation.

## CENTRAL COMPARTMENT NECK DISSECTION

The central compartment (level VI) is important to address when managing patients with thyroid cancer and those tumors with subglottic extension. The boundaries for the central compartment of the neck (level VI) are the carotid arteries laterally, the hyoid bone superiorly, and suprasternal notch inferiorly. The inferior border of a central compartment neck dissection is located below the sternal notch at the level of the innominate artery and brachiocephalic vein (level VII). A comprehensive central compartment neck dissection incorporates level VI and level VII lymph nodes. These lymph node echelons are most commonly associated with metastases from thyroid cancer. In papillary thyroid

(c) 2014 Wolters Kluwer. All Rights Reserved.

cancer, the incidence of central compartment metastases has been reported between 21% and 60%.[27,28] Lymph node metastases in patients with papillary thyroid cancer are associated with a higher recurrence rate.[29] There is evidence that patients 45 years of age or older with regional nodal metastases have a higher mortality rate.[30] There is also evidence that patients with clinically evident nodal disease who undergo lymphadenectomy may have a reduced rate of recurrence and mortality.[29,31,32] Therefore, there is general agreement that clinically involved lymph nodes should be removed and comprehensive central compartment neck dissection should be performed in this situation.

A prophylactic central compartment neck dissection is defined as a level VI lymph node dissection in patients with no evidence of lymph node metastases on preoperative physical examination or imaging. A prophylactic central compartment dissection remains controversial because occult metastatic disease within the central compartment of patients with papillary thyroid cancer have been reported to range between 31% and 62% and rarely become clinically relevant.[28,33,34] In most series, the rate of recurrence in the central neck for patients with a papillary thyroid cancer >1 cm that were clinically node negative and were treated with total thyroidectomy without a central compartment neck dissection is 2% to 3%.[33–36] Currently, there has been no proven benefit for a prophylactic central compartment neck dissection.

## ROLE OF CAROTID ARTERY RESECTION IN NECK DISSECTION

Direct invasion or encasement of the carotid artery may occur in cases of advanced HNSCC. Resection of the carotid artery remains controversial because of the significant morbidity and mortality which may be associated with it. The prognosis for these patients is poor with the 1-year disease-free survival (DFS) ranging from 0% to 44%.[37,38] The surgical alternatives consist of peeling the tumor off the carotid artery which may be palliative or curative, carotid resection without revascularization, and carotid resection with vascular bypass grafting. Since complete tumor removal is the most important prognostic factor in head and neck surgery, peeling the tumor of the carotid artery is not considered an oncologically sound resection.[39]

The indication for carotid resection is based on preoperative imaging such as magnetic resonance imaging (MRI) and computed tomography (CT). When studies suggest carotid involvement with no evidence of distant metastases (DM) consideration for carotid artery resection is given and a preoperative assessment is made to determine the patient's risk for cerebrovascular accident when perfusion is interrupted during this procedure. A balloon occlusion study is often performed preoperatively in order to determine the patient's ability to temporarily tolerate complete obstruction of blood flow through the carotid artery. If the patient is able to tolerate a balloon occlusion study, then they are considered a candidate for a carotid artery resection. If the patient is not able to tolerate the balloon occlusion study, then the consideration of a carotid artery resection is no longer a viable surgical alternative.

There are only a limited number of publications discussing the outcomes of a carotid artery resection during treatment for head and neck cancer. Brennan et al. reported their 10-year experience of carotid artery resection without revascularization in advanced squamous cell carcinoma of the neck.[40] Seven patients underwent elective carotid artery resection, and all seven specimens showed invasion of the carotid artery fascia on pathological exam. Cerebrovascular accident occurred in two patients and the perioperative mortality was 29%.[40] The 5 remaining patients all died of locoregional recurrence or metastatic disease within 1 year after surgery.[40] The largest series reported in the literature is by Sessa et al. with 30 procedures reported.[41] In this series, a 35% DFS rate at 2 years was reported.[41] In 2001, Katsuno et al. performed a retrospective review via a computer search of all articles published in the English literature dealing with carotid artery reconstruction for head and neck cancer from 1987 to 1998.[42] Studies of patients who underwent a carotid artery resection without a reconstruction were excluded and case reports were excluded. Only 11 articles met criteria for inclusion allowing for a total of 148 patients to be compiled in this series.[42] Major neuromorbidity was 4.7% and mortality was 6.8% and the combined major neuromorbidity and mortality were 10.1%.[42] The oncologic outcomes were surprisingly interesting. Four of 10 patients from one of the series were reported as disease free for >2 years.[43] The Sessa series reported a 35% DFS rate at 2 years.[41] Other articles also reported justifiable oncologic results.[37,44–46]

## ELECTIVE MANAGEMENT OF THE CLINICALLY N0 NECK

The basis and need for elective nodal treatment in head and neck cancer have been based largely on surgical series evaluating pathologic nodal involvement found on elective neck dissection in patients with clinically negative necks. In a consecutive series of 1,081 head and neck cancer patients undergoing radical neck dissection, the incidence of pathologic node involvement was 33% among those undergoing elective neck surgery.[47] The pathologic findings identified the nodal stations at risk by tumor site to establish the rationale for SND as the elective surgical procedure.

Several reports have summarized the risk for metastases and nodal stations at risk.[24,48–51] Some general observations from such data can be made. Regarding larynx cancers, Candela reported the Memorial Sloan Kettering Cancer Center experience in determining the patterns of cervical nodal metastases in 247 larynx cancer patients undergoing 262 radical neck dissections.[52] Seventy-eight underwent elective radical neck dissection whereas 118 underwent immediate radical dissection for clinically node-positive disease. The majority of patients ($n$ = 189) were supraglottic larynx and 58 were glottic. Pathologic nodal involvement was found in 37% undergoing elective neck dissection. It is noted that cervical nodes spread in a similar fashion whether the patients are clinically node negative or positive with predominant involvement of level II and III jugular nodes. In clinically node-negative patients, the incidence of involvement of level I and V is <5% with <10% involvement of level IV. In node-positive patients, the incidence of level IV node increases from 15% to 31% with greater involvement of levels II and III. In clinically node-positive patients, very rarely did patients present with isolated level I nodal metastases without involvement of the jugular nodes.

Similarly, Shah and Candela reported that among oropharynx or hypopharynx cancers treated with elective radical neck dissection occult metastases are found in 26% and that level I and V were involved in only 1.4%, always in association with nodal disease at level II to IV.[47,52] No skip metastases were reported. Among oropharynx patients, levels II to IV were predominantly involved, and in the hypopharynx lesions, the primary levels involved were levels II and III. In patients clinically node positive undergoing therapeutic neck dissection, the incidence of level I and V involvement increased to about 10% to 15%; however, levels II to IV were predominantly involved (Table 14.2). Level V involvement only occurred in association with nodal involvement at levels II to IV whereas the incidence isolated level I involvement without levels II to IV involvement ("skip metastasis") occurred in 0.4%. Thus, based on these studies, elective treatment of the neck in oropharynx or hypopharynx can be directed at levels II to IV.

**TABLE 14.2 Percentage Incidence and Distribution of Pathologically Involved Nodes in a Clinical Node-Positive after Therapeutic Radical Neck Dissection**

| | I | II | III | IV | V |
|---|---|---|---|---|---|
| Oropharynx $n = 165$ | 14 | 71 | 42 | 28 | 9 |
| Larynx $n = 183$ | 7 | 57 | 59 | 29 | 4 |
| Hypopharynx $n = 104$ | 10 | 76 | 73 | 46 | 11 |
| Oral cavity $n = 324$ | 46 | 43 | 33 | 15 | 3 |

*Source:* From Shah JP. Patterns of cervical lymph node metastasis from squamous carcinomas of the upper aerodigestive tract. *Am J Surg.* 1990;160(4):405–409, with permission.

Among oral cavity patients, the incidence of nodal disease was 34% on elective evaluation. The majority of metastatic nodes involved levels I to III with only 1.5% incidence of skip metastasis to level IV. Level V involvement is found in only 0.5% with occult disease simultaneously involving other levels. Among those undergoing therapeutic neck dissections, the incidence of level IV involvement increased to 20% while that at level V was 4% always restricted to lower gum or floor of mouth primary sites.

The need for elective treatment not only relates to the estimated probability of nodal involvement and usually is implemented when the risk is 20% or greater but also relates to the morbidity of such treatment as well as the adequacy of coverage. Table 14.3 demonstrates the incidence of nodal involvement of the most common head and neck cancer sites. It should be noted that such data are invaluable but do not address areas that are not addressed surgically, such as the retropharyngeal or pretracheal nodal basins.

Elective nodal treatment by radiation or surgery both offer distinct advantages as radiation may add more comprehensive nodal coverage including the contralateral neck and in regions difficult to surgically address such as the retropharyngeal nodes, inner mandibular nodal areas, and high subdigastric near the exit of the facial nerve at the mastoid process. However, surgery offers important pathologic data, which is useful prognostically, and tailors further therapy according to risk stratification. It should be noted that no randomized or comparative studies of observation versus neck dissection versus ENI have been reported, nor will likely be completed.

## Elective Surgical Treatment

Byers reported a series of patients undergoing elective treatment with SND demonstrating excellent outcomes and thus establishing this procedure as a standard of care for elective treatment.[53]

Retrospective studies point to an improvement in disease-specific survival with the addition of elective neck dissection. Piedbois et al. reported a retrospective comparative study of 233 patients with early stage oral cavity carcinoma with the primary site treated with an interstitial iridium-192 ($^{192}$Ir) implant who underwent either elective neck dissection or neck observation resulting in two cohorts of patients for analysis.[54] This resulted from a change in departmental policies minimizing the impact of potential selection biases. Neck dissection revealed metastases in 25% who then received postoperative radiotherapy. Among those observed, 17% developed a neck relapse with salvage surgery successful in 62%. Some patients were unable to undergo surgery because of unresectability of disease or poor patient performance status. The 10-year survival was 37% and 31%, respectively, with regression analysis demonstrating that neck observation was associated with an adverse risk for disease-related mortality ($p < 0.04$). Haddadin et al. reported on a retrospective analysis of 137 patients with T1 to T2 N0 oral tongue carcinomas with at least 2 years of follow-up who either received an elective neck dissection, neck observation with salvage therapeutic neck dissection, or no neck surgery at all.[55] The cohort receiving elective neck dissection had a superior 5-year cause-specific survival compared with the two other groups despite a negative bias due to a greater proportion of pathologic upstaging of the primary tumor and clinical T2 lesions.

Two randomized studies of patients with early stage oral cavity lesions failed to show a survival benefit in patients randomized to receive elective neck dissection compared to observation with salvage neck dissection if nodal disease developed. In one study, the primary site was managed with primary brachytherapy whereas in the other study the primary site was managed with radical resection.[56,57] In the Vandenbrouck study, a 49% incidence of nodal involvement was reported in electively treated patients whereas nodal disease subsequently developed in 47% in the observation group. In the observation arm, the nodal disease appeared to become more aggressive with a higher incidence of extracapsular extension (25% vs. 13%) compared to the electively treated patients and 10% of patients could not undergo therapeutic dissection. However, no survival difference could be detected between the two groups. The authors recommended observation in patients with early stage lesions who could be followed regularly. In the second study of early stage oral tongue cancers, patients undergoing hemiglossectomy and elective neck dissection showed no difference in DFS or overall survival (OS) compared to patients undergoing hemiglossectomy alone.[57] The number of patients enrolled on these trials was small and not powered to show equivalence of survival.

## Elective Nodal Irradiation

The efficacy of elective nodal irradiation (ENI) is largely based on single institutional studies demonstrating reduced neck relapse.[48,58] Fletcher established the dosimetric basis for elective nodal treatment and the need for comprehensive treatment. Delivering elective doses of 50 Gy to a clinically negative neck results in neck control in 95%.[58] At a dose of 50 Gy in 5 weeks, the incidence of neck failure was 0% whereas doses of 30 to 40 Gy were associated with regional failure in 9% to 10.5%.[58] Further support for ENI is reported by Mendenhall who reported a retrospective review of 125 patients with squamous cell carcinoma of the oral cavity, the oropharynx, the nasopharynx, the hypopharynx, and the supraglottic larynx with a clinically negative neck

(c) 2014 Wolters Kluwer. All Rights Reserved.

and control at the primary site.[48] The neck failure rate was 1.9% with ENI and 18% without ENI. Among a group of patients expected to have a <20% risk for occult nodal metastases, the neck relapse rate was 13% in patients who did not receive ENI versus 6% in patients who received ENI. Similarly, among a group of patients with an expected risk for occult nodal metastases >20%, the neck relapse rate was 31% and 5%, respectively. In a separate report, Mendenhall et al. demonstrated 100% disease control after ENI with 50 Gy in 25 fractions and 99% at a dose of 40.5 Gy in 15 fractions both given as daily fractions.[59]

Vergeer reported on a large Dutch experience evaluating the benefit of elective radiation therapy treatment of a N0 neck. Nodal irradiation was delivered to 785 N0 hemi-necks in 619 head and neck patients. Necks were clinical N0 (cN0) in 558 and pathologically N0 (pN0) in 227. About 47% of patients were oral cavity and well balanced between the two subgroups, with more larynx (22 vs. 13.6) and fewer oropharynx (25 vs. 31%) and hypopharynx (5.7% vs. 7.5%) in the pN0 subgroup. Positive margins were noted in 17.0% versus 21.5% along with greater proportion of T3/4 (77% vs. 59%) in the pN0 group. Patients were treated with a radiotherapy dose of 46 to 50 Gy. At 3 years, the regional failure for the entire cohort was 5% with a trend toward greater failure in the cN0 of 6% versus 3% in the pN0 ($p = 0.08$) and 10% in the ipsilateral neck compared to 4% in the contralateral neck ($p = 0.006$). Positive margins at the primary site increased the risk of regional failure in the ipsilateral cN0 neck to 22% but not in the contralateral cN0 neck, where it was 4%, and was significantly higher than those with close or negative margin with regional failure <1%. On multivariate analysis, the laterality (ipsilateral), positive margin status and clinically staged necks had worse regional failure.

Based on older radiation-delivery techniques, traditional ENI involves treatment of bilateral necks with generous coverage of the jugular nodes and major salivary glands with various degrees of coverage of the retropharyngeal, level I and level V nodes depending on the primary site. With the advent of IMRT, such comprehensive coverage can be duplicated or tailored much more extensively. The ability to treat lymphatic areas more discriminately has challenged radiation oncologists to integrate clinical judgment, experience, and understanding of the surgical data to adequately plan regional coverage that it is tailored appropriately for each case. There have been several excellent reviews regarding the delineation of lymph node target volumes indicated for head and neck radiation therapy.[14,15,51,60] These summaries have served as a basis for axial-based image treatment planning guidelines that is used for conformal irradiation and IMRT.[51] In general, surgical levels defined by Robbins et al. (America Academy of Otolaryngology–Head and Neck Society) are used as the basis for regional target delineation.[61] However, there are a wide variety of radiographic landmarks that have been proposed.[51,60,62,63] A transatlantic consensus has been reported for the electively treated neck as well as the clinically involved and postoperative neck. Gregoire et al. provide a summary recommendation of the nodal groups that should receive ENI in the neck without altered lymphatic flow (see Fig. 14-1; Table 14.4A).[51] These recommendations do not address specific presentations that may modulate the risk for occult metastases. It has been accepted in practice that a risk for <20% warrants at least a deliberation for ENI considering the competing issues of potential benefit and toxicities and risk for secondary HNSCC requiring further therapy.

## Elective Surgical versus Radiation Therapy Treatment

The efficacy of ENI versus elective neck dissection showed no obvious differences as reported by Barkley in a major retrospective experience of neck management in 596 patients with oropharynx, larynx, or hypopharynx carcinoma treated at MD Anderson Cancer Center.[64] Two hundred thirteen were oropharynx, 202 larynx, and 181 hypopharynx. Of these, 226 were N0 whereas 370 were node positive. Patients underwent radiation therapy ($n = 292$), surgical management ($n = 199$), or combined modality therapy ($n = 105$) of the neck. All patients had a minimum follow-up of 2 years and a median follow-up of 4 years. Among the electively treated patients, regional control was >90% regardless of the treatment approach as long as comprehensive neck treatment was implemented. However, partial treatment of the neck resulted in 15%, 35%, and 20% regional failure after radiation, surgery, or combined therapy, respectively.

# RECOMMENDATIONS REGARDING ELECTIVE TREATMENT OF COMMON HEAD AND NECK CANCER SITES

Given the significant risk for occult nodal involvement, the standard of care has evolved to electively treat such patients despite the lack of confirmatory randomized trials. Nodal coverage of levels I to III for oral cavity tumors and levels II to IV for oropharyngeal, hypopharyngeal, and laryngeal tumors are mandatory as elective treatment[24,47,52,65,66] (Table 14.4B). Elective nodal irradiation including the retropharyngeal lymph nodes is added for primary tumors involving the nasopharynx, tonsil, pharyngeal wall, and the soft palate. Bilateral ENI should be considered for tumors arising from or extending to midline structures such as the soft palate, the base of tongue, and the pharyngeal wall. Tumor sites such as the hypopharynx and the supraglottic larynx require bilateral ENI regardless of the specific tumor stage given high risk for contralateral nodal involvement. In contrast, tumor involvement of ipsilateral structures such as the parotid, the buccal mucosa, and selected tonsil cancers warrants consideration of ipsilateral ENI.[67,68] Elective nodal irradiation including level IV lymph nodes should be considered in those with tumors involving the tip of the oral tongue due direct drainage to this area that bypass the orderly contiguous progression in the anterior jugular nodes.[47,69] Involvement of the ipsilateral level V lymph nodes in node-negative oral cavity tumors is rare, occurring in <1%, and does not warrant ENI. However, with increasing involvement of levels I to III or the involvement of level IV, the risk for level V involvement increases warranting ENI. In contrast, involvement of only the true vocal cords does not warrant ENI due to the paucity of lymphatic drainage.

# IPSILATERAL NECK RADIATION IN LATERALIZED OROPHARYNX CANCER

O'Sullivan et al. reported the results of a large retrospective review which identified oropharyngeal tumors that could be spared by contralateral ENI.[67] Two hundred twenty-eight patients with tonsillar carcinomas were treated with ipsilateral radiotherapy at Princess Margaret Hospital. Eligible patients typically had T1 or T2 tumors (191 T1–2, 30 T3, 7 T4) with N0 (133 N0, 35 N1, 27 N2–3) disease. Radiation was typically delivered with wedged pair Cobalt beams and ipsilateral low anterior neck field delivering 50 Gy in 4 weeks to the primary volume. At a median follow-up of 5.7 years, the 3-year local control rate was 77%, regional control 80%, and cause-specific survival 76%. Contralateral neck failure occurred in 3% (8/228). All patients with T1 lesions or N0 neck status had 100% contralateral neck control.

Patients with a 10% or greater risk of contralateral neck failure included those with T3 lesions, lesions involving the medial one-third of the hemi-soft palate, tumors invading the middle third of the ipsilateral base of tongue, and patients with N1 disease. In the presence of ipsilateral node metastases, the risk for contralateral neck failure was 9.5%, 14%, and 21% (all crude rates) for involvement of the soft palate, the base of tongue, and both structures, respectively. However, the authors appropriately note the limitations of these observations as they included patients with uncontrolled primaries and involved a total of only eight patients with contralateral neck failures. Despite this, the report provides confidence in the selection of patients with T1 N0 tonsil carcinomas (as well as selected patients with more advanced disease) for only ipsilateral ENI. Similar observations were also reported by Jackson et al. further supporting these observations.[70]

## ELECTIVE NODAL IRRADIATION FOR MAXILLARY SINUS CANCER

Traditionally, ENI has not been routinely considered for maxillary sinus carcinomas due to the low incidence of nodal disease at presentation. However, several investigators have suggested a benefit of ENI for locally advanced N0 squamous cell carcinoma of the maxilla.[71–74] Le et al. reported a retrospective review of 97 patients with maxillary sinus carcinoma treated with primary radiotherapy or postoperative radiation at UCSF and Stanford.[73] Squamous cell histology was the most common with 60% (58/97), followed by adenoid cystic carcinoma in 20% (19/97) and undifferentiated carcinoma in 16% (16/97). Eighty-nine patients had T3–4 lesions with T2 in eight patients whereas 11% (11/97) presented clinically with nodal disease. Of these 11, one was treated with combined neck dissection and post-op radiation whereas 10 were treated with primary radiation to a median dose of 63 Gy. Of the 86 clinically node-negative patients, 25 patients received ENI (median dose 50 Gy) to the bilateral upper neck nodes. The 5-year actuarial risk for nodal relapse was 0% in patients receiving ENI and 20% for those not receiving ENI. The most common site of nodal relapse was in the ipsilateral level I and II nodal groups with a small number of regional failures in the ipsilateral parotid and upper level V nodes and no instance of failure at level III/IV or supraclavicular nodes. There was no association between primary recurrence and risk for neck failure. However, on multivariate analysis, there was significant association between neck failure and incidence of distant metastasis with higher risk after neck recurrence compared to those regional controlled (82% vs. 19%, $p = 0.02$). The influence of selection bias with regard to these results is unclear. However, it is likely to have biased against the efficacy of ENI because those patients receiving ENI were likely to have had more advanced disease. Only 1 of 10 patients with neck relapse was salvaged. Of greater significance was the observation that the 5-year actuarial risk for DM was 29% for patients with neck control and 81% for patients with neck failure. Multivariate analysis demonstrated that T stage, N stage, and regional nodal control (HR = 4.5, $p = 0.006$) independently influenced this risk. The 5-year survival was 37% and 0% for patients with neck control and neck relapse, respectively ($p = 0.3$). Late complications arising from neck irradiation occurred in 1 of 36 patients who developed ipsilateral brachial plexopathy and severe neck fibrosis. In light of the relapse pattern, the investigators concluded that ipsilateral ENI to only the upper neck (levels I and II) be considered for patients with T3 and T4 N0 squamous cell carcinoma of the maxillary sinus. Similar conclusions were reached by other investigators.[23,25]

## MANAGEMENT OF THE CLINICALLY NODE-POSITIVE NECK (N+)

Management of the clinical positive neck is controversial with a wide variety of approaches that mirrors the complexity and competing regimens established to treat the primary site. These include neck dissection followed by postoperative radiation; definitive concurrent chemoradiation, radiation, or concurrent chemoradiation followed by planned or salvage neck dissection; and induction chemotherapy followed by neck dissection before or after radiation. Refinements in the radicality of neck dissection (radical vs. modified vs. selective vs. super selective neck dissection) and the identification of patients at high risk for recurrence, development of consensus guidelines in nodal target delineation for intensity-modulated treated patients, radiation dosing, and fractionation as well as integration of chemotherapy have been issues that have been explored to maximize regional control and preserve quality of life and function. The manner in which the primary site is managed guides treatment of the neck. Thus, relevant considerations in the decision include the resectability of the primary and neck disease, the functional morbidity incurred by surgery or radiation at the primary site, and the appropriateness of the primary lesion for potential organ-preserving therapy with either radiation alone or in combination with chemotherapy. When unresectable disease exists, the use of chemoradiation strategies has largely been favored. Although the optimal chemoradiotherapy regimen for both organ preservation and unresectable disease remains to be defined, the bulk of the data favor concurrent chemoradiation whereas more recent data point to possible additional benefit of induction chemotherapy or to integration of biologic therapies. Following these therapeutic considerations for the primary lesion, the principal issue with regard to neck management has been the necessity of adjuvant postoperative radiotherapy/chemoradiation or postradiotherapy/chemoradiation neck dissection.

### Surgery and Postoperative Radiation

Surgery and postoperative radiation remains a common strategy for regional management especially for the majority of resectable oral cavity tumors and many locally advanced but resectable HNSCC such as bulky or cartilage invasive hypopharynx or larynx cancers. More recently with early and intermediate stage oropharynx cancer, transoral robotic surgery is used increasingly followed by neck dissection. Historically, radical neck dissection alone had been the mainstay of regional treatment with radical extirpation of the neck nodes and adjacent nonlymphatic structures with significant functional and cosmetic morbidity as described by Crile in 1903[75,76] and reintroduced in the 1950s by Martin.[77] However, it was well recognized that recurrence in the neck after radical neck dissection carried an ominous prognosis.[78] Large series evaluating risk factors for recurrence after neck dissection have been reported. Of these, the most consistently reported risk factor for recurrence is extracapsular extension (ECE). Snow et al. reported one of the first important large institutional experience using pathologic factors to predict risk of recurrence. In a series of 405 patients, he reported that the presence of extracapsular extension of nodal disease was the single most important predictive factor on multivariate analysis for neck recurrence and poor survival.[79] Furthermore, he noted that although there was a relationship between node diameter and fixation with ECE as >75% of nodes >3 cm and 70% with fixation had ECE, these parameters themselves were not sufficient as 20% of nodes <1 cm had ECE and 30% with nodal fixation had no ECE.[79] Carter et al. reported an extensive analysis of 250 radical neck specimens and their clinical significance.[80] Both the presence and the extent of

(c) 2014 Wolters Kluwer. All Rights Reserved.

ECE was found to be the most important factor predicting for neck relapse with a distinction between macroscopic and microscopic ECE emphasized with the former having a worse prognosis.[80] Others have verified such findings.[80–82] and reported other poor prognostic pathologic factors including lymphvascular invasion,[1] perineural invasion,[83] number of nodes involved,[79,84] as well as nodal level involved.[64,84–88] Risk factors for recurrence based on findings from primary site include most importantly the status of the resection margins[89–92] as well as the primary tumor site origin.[93,94]

Postoperative head and neck radiation therapy was pioneered by Fletcher, who laid down the principles of treatment fields and time-dose factors.[95] He demonstrated that 50 Gy offered excellent control rates as elective treatment but greater doses were needed to control high-risk disease in a postoperative setting.[90] Moreover, he reported the importance of comprehensive treatment of the entire neck and primary site either as adjuvant or as salvage for gross residual disease given that localized radiation was associated with high rates of locoregional failure including contralateral neck compared to comprehensive radiation of the primary and whole neck (locoregional failure 73% vs. 58%, respectively).[95] Thus, the majority of studies in the postoperative setting have evaluated the benefit of radiation as a locoregional treatment for indications based on high-risk features from either the primary site or neck.

Postoperative radiation (PORT) appears to benefit patients with extracapsular extension compared to resection alone. In a retrospective review of 405 patients treated at the Netherlands Cancer Institute, Bartelink et al. reported that PORT decreased recurrence and improved survival compared to surgery alone in the cohort of patients with ECE but no preoperative fixation of lymph nodes.[96] Similarly, Huang et al. reported superior survival rates in a retrospective review of a more homogeneous cohort of 125 patients with high-risk features (ECE or positive resection margin) treated with either surgery and PORT or surgery alone.[48] Factors demonstrated to independently influence survival included the use of PORT ($p = 0.0001$) and the number of lymph nodes with ECE ($p = 0.0001$).[97] Despite the use of PORT, the number of lymph nodes with ECE remained significant attesting to the adverse influence of this pathologic feature. This study is significant because the two study populations resulted from the management bias of the operating surgeons to prefer or not to prefer PORT. This clearly defined treatment choice limits the selection bias that often confounds retrospective analyses. Others have reported the locoregional benefit of PORT in patients with multiple positive nodes.[98–100]

Postoperative radiation has consistently been shown to decrease locoregional failure[53,64,85,87,101] but its impact on survival is less conclusive as some retrospective studies report a survival benefit whereas others report only an alteration in failure pattern toward distant metastasis but no survival benefit.[85,102,103] Mishra et al. reported on the randomization of 140 patients with stages III and IV (T3–T4, N0–N2B) buccal mucosa carcinoma to PORT (mean dose 60 Gy) or observation following surgical resection.[104] A significant improvement in the DFS was observed in favor of PORT (68% vs. 8%, $p < 0.005$) after a minimum follow-up of 36 months. This observation is noteworthy given the selection bias against the PORT arm that resulted from a biased randomization process due to surgeon preference, yielding a greater proportion of advanced node-positive disease in the PORT arm. Kokal et al. reported the preliminary results of a potentially underpowered randomized trial of 51 patients with stage III and IV squamous cell carcinoma arising from the oral cavity, the larynx, and the pharynx treated with surgery or surgery and adjuvant PORT (50 Gy).[105] The study excluded randomizing patients in the postoperative setting if the resection margins were positive or there was clinical evidence of nodal metastases, hence largely evaluating the role of PORT for pathologic nodal metastases. A median follow-up of 30 months was reported. No differences in locoregional control in the primary site and ipsilateral neck was observed (22% vs. 26%) in the surgery alone versus postoperative radiation group. However, fewer contralateral undissected neck recurrences (5.3% vs. 14.8%, crude rates) and fewer DM (5.3% vs. 14.8%, crude rates) were observed in favor of the cohort receiving PORT. This resulted in a nonsignificant difference in the actuarial relapse rate and 3-year OS rate (37% vs. 68%, $p = 0.16$ and 58.5% vs. 46.5%, $p = 0.31$, respectively) in favor of the irradiated group.

A matched pair analysis of patients treated at the Mayo clinic demonstrated a benefit of postoperative radiation in dissected patients.[106] Matched pair analysis was drawn from two pools of patients. One consisted of 95 consecutively treated patients undergoing neck dissection and postoperative radiation therapy (bilateral neck irradiation; median dose 56 Gy) treated from 1974 to 1990. The other cohort consisted of 284 patients treated by neck dissection only between 1970 and 1980. Patients were matched by nodal stage, age, gender, number of nodes involved >4, desmoplastic nodal pattern, which had been highly predictive for neck recurrence at this institution. A total of 56 matched pairs were compared. The relative risk (RR) for recurrence on the unilaterally dissected side, any neck recurrence, cancer-related death and death from any cause were 5.82, 4.72, 2.21, and 1.67 in the surgery alone arm compared to those receiving postoperative radiation. Although extracapsular extension was not specifically studied, the authors reported a high correlation between desmoplastic nodal pattern and ECE, suggesting the growth pattern may be a reasonable surrogate for ECE. With regard to absolute outcomes in the 95 patients receiving radiation therapy, the regional failure was 26% at a median follow-up of 4.5 years whereas the 5-year disease-specific survival and OS were 64% and 39%, respectively, consistent with other postoperative experiences. Frank et al. also reported an improvement in both OS and DFS in a retrospective comparative review of 110 patients with carcinoma of the hypopharynx treated with either surgery alone or followed by PORT.[107] Despite the presence of more advanced disease, the cohort receiving PORT was demonstrated to have a superior locoregional relapse rate (14% vs. 57%, $p < 0.0001$), DFS, and adjusted 5-year survival (48% vs. 18%, $p = 0.029$). Treatment with PORT was an independent prognostic factor in multivariate analysis for both DFS ($p = 0.0009$) and OS ($p = 0.0289$).

Several retrospective studies have reported the effectiveness of achieving neck control by nodal stage, and selected reports from large U.S. centers are illustrated in Table 14.5.[64] Conventional postoperative radiation offers excellent control in N1 patients, acceptable results in the N2 neck and suboptimal outcomes after N3 treatment. Vikram reported improved regional control after postoperative radiation in patients with one or multiple nodal stations involved and emphasized the importance of minimizing treatment delay.[101] A series of 114 patients treated with surgery and postoperative radiation were compared to historic control treated with similar surgical techniques (radical neck dissection). Seventeen percent were found to have nodal metastasis at one level whereas 66% had disease at multiple nodal levels. Patients were treated with postoperative doses of 50 to 60 Gy over 5 to 6 weeks. The crude regional failure rate among patients with positive nodal disease treated with postoperative radiation was 10%. Compared to patients treated with surgery alone, the regional failure rate after postoperative radiation was decreased whether disease was localized at a single nodal level (regional failure 16% vs. 36.5%) or if multiple levels of nodes were positive (13% vs. 72%) and also appeared better than another cohort treated with preoperative radiation to a dose of 20 Gy (regional failure 28% [single nodal level] and 37% [multiple nodal levels]). Regional

failure was greater in patients starting radiation 6 weeks postoperatively compared to those starting radiation within 6 weeks (2% vs. 15%, $p < 0.02$). This time interval of >6 weeks negatively impacted on regional control whether single-level nodal involvement (regional failure 33% vs. 0%) or multiple levels of nodes were involved (27% vs. 3%). Others have also demonstrated the importance of minimizing the total treatment package time.[108–110]

## Unilateral Postoperative Radiation Therapy in Oral Cavity Cancer

Vergeer reported the experience of treating 123 oral cavity cancer patients with lateralized tumors who underwent resection and unilateral postoperative radiation. A lateralized tumor was defined as >1 cm from midline. Patients were treated to the primary tumor bed in all cases, which included the ipsilateral neck in 90%. Tumors involved the oral cavity primarily including the gingival, the oral tongue, the floor of mouth, the buccal mucosa, and the floor of mouth in 104 patients with T1–4 and node-positive disease in 62%. The median total doses to the primary site involved nodal station, and elective nodal areas were 63 Gy, 66 Gy, and 46 to 50 Gy, electively. At a minimum follow-up of 5 years, a total of seven patients failed contralaterally with a 5-year actuarial failure rate of 8%. The risk of contralateral nodal failure rate was related to the pretreatment nodal stage ($p = 0.008$) and occurred in 1%, 12%, and 27% in patients with pN0, pN1–N2a, and pN2b, respectively. Of the seven contralateral nodal failures, five were salvaged with neck dissection. The presence of extracapsular extension was of borderline significance ($p = 0.06$) for increased risk of contralateral nodal failure (14% vs. 6%, $p = 0.081$). The benefit of unilateral radiation therapy was the low rate of morbidity. At 5 years, the incidence of cumulative RTOG chronic grade 2 to 4 xerostomia was 20%, grade 3 mucosal complications 9%, grade 3 to 4 bone complication 17%, and grade 3 to 4 fibrosis 23%.

## Special Issues Regarding a Solitary Node

In patients with a single histologically positive node without extracapsular spread, the regional recurrence rate may not warrant radiation therapy. In the study by Carter et al., where ECE is present in a solitary lymph node, the 3-year neck relapse rate was found to be 25%.[80] Where ECE is absent, Barkley et al. noted neck relapse in 5 of 47 (11%) patients with N1 disease treated with surgery alone compared with a comparable retrospective cohort of 21 patients that received PORT with no neck relapse observed.[64] Hence, neck irradiation is commonly recommended in the setting of ECE, reserving neck observation where no ECE is present and the patient is likely to remain compliant to a course of close observation. After SND without radiation, the regional recurrence rates ranges from 4% to 10% and did not appeared to be improved with the addition of radiation. However, others note the poor outcomes after recurrence in a dissected neck and favor treatment.[53,98,111–114]

For patients having undergone a local excision of a solitary node, the adequacy of radiotherapy in the management of a neck with potentially a higher burden of residual microscopic disease has been reported.[115,116] Mack et al. reported on 41 patients referred for irradiation following excision of a solitary neck metastasis with no gross residual disease.[116] The N stage was Nx ($n = 7$ patients), N1 ($n = 15$ patients), N2A ($n = 18$ patients), and N3A ($n = 1$ patient). Neck irradiation was administered with doses ranging from 5,485 cGy to 8,100 cGy (median dose, 6,675 cGy). A planned neck dissection was administered in two patients. Actuarial neck control was 95% at both 5 and 10 years. Distant metastasis was observed in 0 of 36 patients with disease controlled above the clavicles versus 3 of 5 patients with relapse above the clavicles. Hence, this report would support the efficacy of postexcision radiotherapy to the neck for most patients presenting with solitary N1 or N2A disease without an increased risk for distant metastasis. The efficacy of postexcision radiotherapy for N3A disease is unclear given the higher risk for residual microscopic disease in the neck. A neck dissection would appear to be warranted. Ellis et al. confirm that the potential adverse effects of violating the neck with an open neck biopsy, on both the probability of neck control and the risk for distant metastasis, could not be demonstrated in a regression analysis when radiotherapy was subsequently delivered to the neck.[117] In a separate report from the same institution, Parsons et al. also reported on the neck control rates following an open neck node biopsy resulting in patients with or without gross residual disease.[115] Gross residual neck disease remained in 55 patients. A neck control rate of 64% was observed when the neck treatment was predominantly with radiotherapy alone. The subsequent consistent addition of a planned neck dissection improved the neck control rates. For N1 to N2 disease, the neck control rate was 65% with irradiation alone and for N2 disease 86% with the addition of a neck dissection. For N3A disease, the neck control rate increased from 29% (2/7) to 63% (5/8) supporting the need for a neck dissection where the burden of residual microscopic disease is increased.

## HPV and Need for Completion Neck Dissection in a Violated Neck

Loyo reported on 94 patients treated at Johns Hopkins University or University of Pittsburgh who had an open cervical biopsy and managed with either completion neck dissection ($n = 53$) or chemoradiation ($n = 41$). Oropharynx comprised 84% of patients (79/94) and were HPV positive in 87% (55/63). Patients treated with neck dissection had a lower proportion of HPV negative patients (3.7% vs. 14.6%, $p = 0.009$) compared to those managed nonoperatively. Regional failure rate was similar 2/53 versus 2/41 in patients managed surgically or with radiation, respectively. There appeared to be no difference in 5-year disease-specific survival (82% vs. 85%, $p = 0.58$) or DFS (82% vs. 70%) in those managed with completion neck dissection versus nonoperative management.

## Pre- versus Postoperative Radiation Therapy

The sequencing of radiation therapy either before or after definitive resection was explored in the Radiation Therapy Oncology Group (RTOG) trial 73-03 involving 320 patients of primarily

(c) 2014 Wolters Kluwer. All Rights Reserved.

stage III/IV patients.[93] Patients with larynx or hypopharynx cancer undergoing radical surgery ($n$ = 211) were randomized to receive 50 Gy preoperatively or 60 Gy postoperatively whereas patients with oral cavity/oropharynx were randomized to three arms: pre- or postoperative radiation or a third arm of definitive radiation therapy (65–70 Gy) only. Results were reported at a median follow-up of 5 years. Of the 277 patients treated with radical resection, postoperative radiation was superior to preoperative radiation in increasing locoregional control (65% vs. 48%, $p$ = 0.04) and trended toward improved OS (38% vs. 33%, $p$ = 0.10). Among the 43 oral cavity/oropharynx treated with definitive radiation therapy, locoregional control was lower compared to those undergoing resection and pre-op or post-op radiation (38% vs. 43% vs. 52%, respectively) but not significantly different likely due to small numbers of patients. Survival was similar (33% vs. 30% vs. 36%, respectively). The rates of severe surgical or radiation complications requiring hospitalization occurred in 15% to 20% and was not significantly different. Thus, this trial appeared confirmed that postoperative radiation is the best treatment sequence for patients undergoing radical resection of the primary site.

## Dose Escalation in Postoperative Radiation

Retrospective studies have demonstrated the importance of dose escalation to overcome the greater risk for recurrence for close or positive margins.[89,90,92] The value of dose escalation with postoperative radiation was explored in a prospective, randomized trial reported by Peters stratifying 302 radically resected patients as low, intermediate, or high risk for locoregional recurrence based on an empirically derived scoring system evaluating margin status, stage, and pathologic factors.[118] Patients were randomized to four dose levels at 52.2 Gy, 57.6 Gy, 63 Gy, and 68.4 Gy to the resection bed whereas 54 Gy was delivered to nonsurgically treated areas of potential subclinical disease. Analysis of 240 patients at a median follow-up of 45 months failed to validate the scoring system but did show that ECE was the overriding risk factor for locoregional recurrence (30% vs. 19%, $p$ = 0.04). For the 110 patients with ECE, a dose of 63 Gy was superior compared to <57.6 Gy (locoregional recurrence 26% vs. 48%, respectively) but there was no further benefit at 68.4 Gy (locoregional recurrence 28%) and more complications. There did not appear to be a comparable increased risk for neck relapses (neck control: <54 Gy, 89%; 57.6 Gy, 86%; 63 Gy, 89%). For patients stratified to the high-risk group, there did not appear to be any significant benefit with regard to neck control rates (84% vs. 77%) when the 63 Gy dose level was compared with the 68.4 Gy dose level. Although these observations may reflect an underpowered analysis, it has been concluded that a dose of at least 63 Gy is warranted to postoperative sites at greatest risk. The study did show that the presence of two or more risk factors predicted a high risk for failure. These factors included the presence of a primary oral cavity site, close or positive surgical resection margins, perineural invasion, two or more metastatic lymph nodes, node diameter >3 cm, a treatment delay to PORT >6 weeks, and a Zubrod performance status of >2. Based on this trial, minimum doses of 57.6 Gy are recommended to the whole operative bed with boost to 63 Gy to areas at high risk, especially where ECE is present.

## Altered Fractionated Postoperative Radiation

The value of accelerated postoperative radiation to decrease the total treatment package time was demonstrated in a follow-up multi-institutional randomized trial reported by Ang et al.[110] Patients were stratified by risk according to the risk factors identified in the aforementioned study. Patients with no adverse pathologic factors were deemed low risk and not given PORT. Patients with one pathologic risk factor were deemed intermediate risk and treated with conventional fractionated radiation to a dose of 57.6 Gy in 6.5 weeks. Those with ECE or the presence of >2 risk factors were deemed high risk and treated with high-dose conventional radiation to 63 Gy/7 weeks or to accelerated radiation by delayed concomitant boost to 63 Gy/5 weeks. At a median follow-up of 59 months, locoregional control was excellent for low-risk patient who were observed and intermediate-risk patients (5-year actuarial LRC 90% vs. 94%, respectively). High-risk patients had a 5-year actuarial LRC and survival rate of 68% and 42%, respectively. Within this cohort, patients undergoing accelerated postoperative radiation had a nonsignificant improvement in LRC ($p$ = 0.11) and survival ($p$ = 0.08). The value of accelerated treatment was based on the ability to keep the treatment package time to 11 weeks or less as patients who were started with a 7-week conventional course of radiation within 4 weeks of surgery did as well as the accelerated radiation group. These results confirmed that in the absence of adverse pathologic factors, as studied, low-risk patients do not require PORT. In contrast, high-risk patients need a shortened treatment package time.

## Post-op Chemoradiation for High-Risk Disease

***Sequential Post-op Chemoradiation.*** The role of chemotherapy has been integrated into locoregional management due to the poor survival outcomes (30%–40%), potential for improved locoregional control from 70% to 80% and distant metastasis in 20% after standard therapies. The concept of synergistic effect of cisplatin-based chemotherapy and radiation has been reviewed.[119]

The NCI-sponsored Head and Neck Contracts Program multi-institutional phase III trial was conducted between 1978 and 1982 in 462 patients with resectable stage III/IV cancers of oral cavity/larynx/hypopharynx testing the possible benefit of either induction or adjuvant chemotherapy in patients receiving conventional postoperative radiation.[120] Patients were randomized to three arms: (a) standard resection and postoperative radiation, (b) induction cisplatin/bleomycin for one cycle followed by standard therapy, or (c) therapy as outlined in (b) followed by maintenance cisplatin chemotherapy for 6 months. Radical neck dissection was performed in node-positive patients. Radiation therapy was delivered with conventional technique to final doses of 60 to 70 Gy for any residual disease. There was no differences in postoperative surgical complications or delays in initiating radiation therapy in chemotherapy patients compared to standard therapy patients. No differences in acute or late radiation toxicities could be detected with the addition of chemotherapy. At a median follow-up of 61 months, the incidence of DM was significantly decreased in patients receiving maintenance chemotherapy (9% vs. 19% vs. 19%, $p$ = 0.025 and 0.021, respectively) compared to the standard and induction chemotherapy patients. The difference in distant metastasis was even more remarkable given that 45% randomized to the maintenance arm did not receive any chemotherapy due primarily to patient refusal, cancer recurrence, or death whereas only 9% received all six cycles. No difference in locoregional control was noted. Overall or DFS in maintenance chemotherapy patients was not statistically significantly increased compared to standard and induction arms (OS: 45% vs. 35% vs. 37%, respectively) and (DFS: 64% vs. 55% vs. 49%, respectively). However, adjuvant chemotherapy is not routinely recommended given the poor compliance and lack of evidence of survival benefit in large meta-analysis.[2–5,121]

(c) 2014 Wolters Kluwer. All Rights Reserved.

Intergroup-0034 randomized 442 patients to standard surgery and radiation therapy versus surgery followed by CDDP/5FU chemotherapy for three cycles then postoperative radiation.[121] Only patients with negative margins were entered and then stratified according to low or high risk. High-risk patients included those with close surgical margins (<5 mm), extracapsular extension or *in situ* disease at the margins. For all patients, there was no difference in locoregional control, disease-free survival, or OS. The incidence of first failure in the neck (10% vs. 5%, $p = 0.03$) and DM (23% vs. 15%, $p = 0.03$) was lower in the chemotherapy arm. However, among patients with high-risk disease, there was a suggestion that chemotherapy did decrease locoregional failure (28% vs. 34%, $p = 0.07$) and improve OS (50% vs. 39%, $p = 0.06$).[121]

***Concurrent Post-op Chemoradiation.*** Based on the Intergroup-0034 study, a high-risk group was identified that might benefit from chemotherapy. The concept of combining chemotherapy concurrent with radiation to provide synergistic benefit and spatial cooperation (radiation to cover locoregional disease and chemotherapy to address systemic micrometastasis) had been proposed and tested in multiple trials using single or polychemotherapy regimens in the definitive setting. Subsequent large meta-analyses demonstrated that the benefit of chemotherapy on survival and locoregional control was largely derived when combined concurrently. Although multiple chemotherapy regimens had been studied, the most consistent to offer a benefit was single-agent cisplatin.

Two landmark studies were organized independently in Europe (EORTC 22931) and in the United States (RTOG 95-01).[122,123] Both tested whether the addition of three cycles of high-dose cisplatin concurrent with conventionally fractionated postoperative radiation could benefit patients at high-risk for recurrence. The dose of cisplatin was 100 mg/m$^2$ every 3 weeks while the dose of radiation in the RTOG study was 60 to 66 Gy and 66 Gy in the European Organization for Research and Treatment of Cancer (EORTC) trial. Definition of high risk included extracapsular extension and positive margins in both studies; however, each study had other nonoverlapping eligibility criteria including multiple nodes in RTOG 95-01 and lymphvascular invasion, perineural invasion, stage III/IV disease, or level IV or V nodal involvement in oral cavity/oropharynx primaries in EORTC 22931. The primary endpoint in the RTOG trial was locoregional control whereas progression-free survival was the primary objective in the EORTC study. Table 14.6 compares the patient characteristics and outcomes of both trials. Oropharynx cancers comprised a greater proportion of patients (42% vs. 30%) in the RTOG study whereas the EORTC study had more hypopharynx cancer (20% vs. 10%). More N2/3 patients were entered in the RTOG study (94% vs. 57%). The incidence of ECE was similar between the two studies (RTOG: 53% vs. EORTC: 57%), but more positive margins were noted in the EORTC study (29% vs. 10%). Also, the majority of patients in the EORTC study received 66 Gy whereas only about a tenth of patients in the RTOG study did so. At a median follow-up of 60 months in the EORTC study and 46 months in the RTOG, the addition of chemotherapy improved the primary endpoints. Both studies showed about a 9% to 13% improvement in loco-regional and DFS, with no difference in incidence of distant metastasis. OS was statistically improved in the EORTC study with a 13% absolute improvement at 5 years and trended toward significance in the RTOG trial with a 9% absolute 4-year increase.

**TABLE 14.6 Comparison of Phase III Postoperative Chemoradiation versus Radiation**

OPX, oropharynx; OC, oral cavity; LX, larynx; HPX, hypopharynx; ECE, extracapsular extension; CT, chemotheraphy; RT, radiation therapy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

A pooled analysis of the two studies was reported by Bernier et al.[124] For all 750 patients, the chemoradiation group had improved locoregional control (hazard ratio [HR] = 0.581), DFS (HR = 0.772), and OS (HR = 0.776) compared to radiation-only patients. Among the 479 patients with either ECE or positive margins, the benefit of concurrent chemoradiation was even larger for all three endpoints: LRC (HR = 0.524), DFS (HR = 0.695, $p = 0.0$), and OS (HR = 0.702, $p = 0.0$). However, chemoradiation showed no benefit in RTOG patients with multiple nodes in any of the 3 endpoints and trended toward a locoregional control advantage (HR = 0.42, $p = 0.10$) and OS benefit (HR = 0.75, $p = 0.06$) in the EORTC patients who qualified based on the other criteria without ECE or positive margin. Because of the small number in the latter group of EORTC patients ($n = 101$) having a wide variety of eligibility criteria with only a trend toward improved outcomes, no definitive conclusions could be drawn about the addition of chemotherapy in patients with these criteria.

In summary, the use of PORT remains an important component in the management of locally advanced resectable HSNCC with pathologic high-risk features for relapse. Of these, the presence of nodal ECE is a dominant factor influencing the risk for regional relapse. There is persuasive retrospective and compelling level I evidence supporting the use of concurrent chemotherapy with PORT to reduce locoregional relapse and improve survival. Patients undergoing surgical resection, in which PORT is deemed to be likely, should be jointly evaluated prior to surgery to minimize treatment delay. Standard PORT remains with a daily fractionated schedule to at least one dose of 60 to 66 Gy to high-risk areas with the use of accelerated schedules or concurrent chemotherapy remaining promising but requiring further study.

## Primary Radiation Treatment of the Node-Positive Neck

The management of nodal metastases with primary radiation therapy has been recognized as an alternative treatment to surgery for small solitary nodes, but for increasing size and number of nodal metastases, surgery has been traditionally integrated due to the concern that such metastases are more radioresistant. With the emergence of more intensive chemotherapy and radiation therapy regimens to treat the majority of cancers of the pharyngolarynx, the effectiveness of primary radiation to control neck disease has been reevaluated. Fletcher recognized that nodal radiocurability was inversely related to the size of the metastases and the need to deliver higher doses to achieve radiocurability.[58] Certainly for N1 disease, primary radiation therapy alone offers excellent control, but is suboptimal for N2–3 disease. Traditionally, the combination of radiation and neck dissection has yielded the optimal regional control in the N2–3 patients. Improvements in locoregional control with the addition of concurrent chemotherapy, altered fractionated radiation and radiation techniques such as intensity modulated radiation and brachytherapy as well as improvement in imaging to detect residual disease has challenged this paradigm. Increasingly, it has been argued that a planned neck dissection may not be required in patients in whom a complete clinical response has been achieved after more intensive radiation-based regimens primarily with concurrent chemoradiation.[125] Better functional and anatomic imaging posttreatment has improved the selection of who may be spared a neck dissection.

***Radiation Therapy Alone.*** Thariat reported the MDAC experience of 880 node-positive patients who were treated with definitive radiation therapy either with conventional or accelerated radiation by delayed concomitant boost fractionation. Concurrent chemotherapy was given in 19% of patients. Nodal stage was 21% N1, 71% N2, and 6% N3. Primary sites were 77% oropharynx, 14% larynx, and 9% hypopharynx. CT was performed 4 to 8 weeks after radiotherapy. Forty-three percent (377/880) achieved a complete response (CR) and were observed. Of those with less than a CR, 53% (268/503) underwent neck dissection at median time of 9 weeks after radiotherapy. Pathologic residual disease remained in 30%. At a median follow-up of 51 months, regional failure for the entire group was 12% and among those with a CR, partial response (PR), and neck dissection, PR without neck dissection was 8%, 10%, and 24%, respectively. Isolated regional failure was 4%. Multivariate analysis showed lower risk for patients with oropharynx primary (HR 0.47, $p < 0.001$) and those with complete pathologic response (HR 0.10, $p < 0.001$), while N3 status (HR 3.97, $p < 0.001$), T3–4 tumors (HR 2.16, $p < 0.001$), those with less than a CR (HR 2.61, $p < 0.001$) were at higher risk.

In a retrospective review of 110 patients, in whom primary lesions were controlled, Mendenhall et al. demonstrated an inverse relationship between the size of the lymph node and its subsequent control rate after definitive radiation therapy.[126] For lymph nodes 1.5 to 2 cm, 2.5 to 3 cm, 3.5 to 6 cm, >7 cm, the regional control rates were 88%, 74%, 70%, and 0%, respectively. These authors also demonstrated a marked influence of treatment time and total dose for lymph nodes 2.5 to 6 cm, implying that a more accelerated schedule may be particularly important for regional control. In a follow-up retrospective review, Mendenhall et al. confirmed a high regional control rate of 92% in an updated cohort of patients with a single lymph node <3 cm treated with daily fractionated radiotherapy alone.[127] There was no apparent difference in regional control when compared with a cohort of patients treated with radiation and a planned neck dissection (91%) confirming the adequacy of radiotherapy alone for N1 disease.

The Institute Gustave Roussy reported the largest experience using definitive radiation therapy for the treatment of large nodal disease.[49,128–130] Bataini and Bernier reported on the impact of nodal regression and regional control probability on 708 node-positive oropharynx or pharyngolarynx cancers treated with definitive radiation therapy with doses >55 Gy (two-thirds received >70 Gy) using accelerated radiation (6-week treatment duration) fractionation and cobalt shrinking field technique.[128] Measurement of maximal nodal diameter was made at the completion of radiation as well as 2, 4, and 6 months after radiation. At the completion of the radiotherapy, one-third (247/759) of metastatic nodes had demonstrated a CR. With further follow-up, 72% (546/759), 77% (586/759), and 79% (597/759) of lymph nodes had demonstrated a CR at 2, 4, and 6 months, respectively. The mean time to CR for lymph nodes <3 cm, 3 to 6 cm, and >6 cm was 40, 51, and 62 days, respectively. The probability of obtaining a nodal CR was dependent on initial maximal nodal diameter. At 2 months, 83% of nodes <3 cm, 63% of nodes 3 to 6 cm and 45% of nodes >6 cm achieved a CR. By 6 months, the CR rates were 90%, 80%, and 55%, respectively. However, if a CR had been attained, the risk for regional failure rate was 8%, independent of the initial nodal size. Regional control for all patients with lymph nodes <3 cm, 3 to 6 cm, and >6 cm was 90%, 85%, and approximately 75%, respectively. A dose–response relationship was observed with a dose of 65 Gy, 70 to 75 Gy, and 75 Gy recommended for lymph nodes <3 cm, 3 to 6 cm, and >6 cm, respectively.[129] If residual disease persisted at 4 and 6 months, the chance for regional failure was 50% and 75%, respectively. The chance for obtaining CR was associated with site of tumor origin. The probability of complete nodal response at the end of radiation was worse for the 239 pharyngolarynx patients compared to the 469 oropharynx patients (22% vs. 40%, $p < 0.0001$). The estimated rate of regional control was 90% in nodes <3 cm with 65 Gy, 85% nodes 3 to 6 cm treated with 70 to 75 Gy and 75% for nodes >6 cm treated with 75 Gy. With regard to DFS, nodal size >6 cm, involvement of mid- or lower jugular nodes, or

(c) 2014 Wolters Kluwer. All Rights Reserved.

involvement of posterior cervical nodes with upper jugular nodes fixation of a single node prognosed a worse DFS. Moderate to severe complications were reported in 9% of patients (crude) with 3% of patients with complications related to neck irradiation.[129] The majority of these complications were noted to be cervical fibrosis associated with entrapment and paralysis of the hypoglossal nerve.[129] Others also reported >RTOG grade 2 fibrosis in 22% of patients treated with definitive radiation[94] and caution treatment of nodes extending into the low neck due to the risk for brachial plexopathy and severe fibrosis.[131]

An analysis by Prada Gomez et al. is relevant in providing insight into the factors influencing the radiocurability of lymph nodes describing selection criteria for patients requiring a neck dissection.[132] They reported a multivariate analysis for regional control rates in a large cohort of 313 patients treated predominantly with daily fractionated radiotherapy. A wide range of dose was delivered between 50 and 80 Gy. Significant independent factors included lymph node response to radiation ($p = 0.0000$), lymph node size ($p = 0.0000$), radiotherapy dose ($p = 0.0037$), control of the primary lesion ($p = 0.0015$), and treatment of recurrent nodal metastases following prior definitive surgery ($p = 0.0286$). With the primary controlled, regional control for lymph nodes <3 cm and for nodes >3 cm was 89% and 32%, respectively.

Bartelink demonstrated that the regression rate of nodal metastases during radiation was prognostic in a cohort of 27 patients treated to 70 Gy in 7 weeks using bi-dimensional measurements of index lymph nodes.[133] Only 1 of 12 patients with a fast regression rate (defined by a nodal volume halving time of 20 days during radiation therapy) developed a neck recurrence. In contrast, neck recurrence was significantly greater (7 of 15 patients) with a slower regression rate. Furthermore, the prognostic distinction could be made as early as day 28 after the start of the radiotherapy. In a larger study of 233 patients with nodal disease treated with primary radiation therapy, Bartelink et al. also demonstrated that persistent disease at 6 weeks post radiation corresponds with an increased risk for regional recurrence. Large nodal diameter, fixation, and multiple nodes were the main risk factors for persistent disease.[134]

***Altered Fractionated Radiation.*** The value of altered fractionated radiation has been demonstrated to improve locoregional control in stage III/IV head and neck cancers.[7–10] Altered fractionation regimens proven to increase locoregional control compared to conventional fractionation include hyperfractionated radiation which allows dose escalation typically to 77 to 80 Gy, accelerated radiation by delayed concomitant boost which attempts to overcome on treatment tumor repopulation as well as the DAHANCA regimen of six conventional treatments per week.[9] Furthermore, of these regimens, meta-analysis further show an apparent survival benefit from hyperfractionated radiation.[10]

Peters reported on 100 node-positive oropharyngeal carcinoma patients treated with accelerated radiation by delayed concomitant boost technique.[131] Seventy-five had definitive radiation therapy to the nodal region with 13 having residual disease requiring neck dissection whereas the other 62 had CR and were observed. The probability of achieving a CR after definitive radiotherapy was inversely related to maximal diameter of the involved node, as 12/13 patients with residual disease had tumor >3 cm. However, as reported by Bataini,[130] if a CR was achieved, the initial maximal nodal diameter did not impact on regional control (87% if initial tumor diameter was <3 cm vs. 85% if tumor diameter was >3 cm). The other 25 patients underwent excisional biopsy ($n = 8$) and neck dissection ($n = 17$) prior to radiotherapy. N stage for all patients were as follows: N1, $n = 35$; N2a, $n = 20$; N2b, $n = 18$; N2c, $n = 13$; and N3, $n = 14$. Radiation dose to gross disease was 72 Gy, and six patients received induction cisplatin and 5FU. At a median follow-up of 39 months, regional control was 87% (13/100). Among the 62 who attained a CR after definitive radiation therapy, the crude regional failure was 11% (7/62) and isolated regional failure in 5% (3/62). In the subgroup of complete responders, there was no difference in regional control between lymph nodes <3 cm and those >3 cm. Neck failure was greater in nodes >3 cm demonstrating an incomplete response. For the 13 patients achieving less than a CR and proceeding to resection, the regional failure was 0%. Among the 25 patients treated with neck surgery initially prior to radiotherapy, the regional failure was 24% (6/25). Regional failure was higher in patients who also had local failure versus those who had primary local control (33% [5/15] vs. 9% [8/85], respectively). Surgical salvage was attempted in 7 of 13 patients with regional failure and successful in one. With regard to toxicity, RTOG grade >3 fibrosis occurred in 22% of the definitively treated radiation patients and in 27% of patients treated with neck surgery and radiation. No difference was reported if surgery was added. However, if the initial nodal size was >6 cm, the risk of severe fibrosis was 40% versus 24% if the initial nodal diameter was 3 to 6 cm.

Parsons et al. reported the impact of the hyperfractionated radiotherapy studied on regional control rates censoring for primary failures due to the possibility of reseeding.[135] In this retrospective review, a small subgroup of patients with advanced neck disease (based on the 1983 American Joint Committee on Cancer system) did not receive a planned neck dissection as per specific departmental policies. For patients with solitary large nodal metastases (N2A and N3A) treated with radiation and a neck dissection (17 patients) or definitive hyperfractionated radiotherapy (9 patients), the 5-year actuarial regional control rate was 74% versus 41% ($p = 0.036$), respectively. The proportion of patients with N2A and N3A was noted to be virtually identical between these two patient cohorts. Similar observations were noted when comparing patients with multiple advanced neck nodes (N2B and N3B) with 5-year actuarial regional control rates of 85% (39 patients) and 68% (43 patients) ($p = 0.03$) for patients treated with a planned neck dissection or definitive radiotherapy, respectively. Wound complications in patients undergoing neck dissection occurred in 6/58 patients consisting of wound separation, flap necrosis. No carotid rupture or fatal complications were noted. The authors noted reservations regarding the use of high-dose definitive radiotherapy for large-volume N2 to N3 neck disease due to inferior regional control rates and increased neck fibrosis with increased surgical wound complications.

In summary, treatment of N2–3 disease with altered fractionated radiation therapy results in CR rates of 65% to 80%, with regional failure in 10% to 20% despite CR. Neck dissection was performed in 20% to 35% who achieved less than a CR after patients received full-dose radiation therapy. The incidence of complications from definitive radiation therapy appeared to be increased fibrosis especially for large nodes as well as increased wound complications if neck dissection is required for persistent disease. For patients attaining a CR, it remains unclear if a neck dissection can further reduce the risk for regional relapse, and the risk for surgical complications may offset any additional benefit that may exist.[136] Several investigators have advocated salvage neck dissections based on nodal response to definitive radiotherapy.[125,131] Daily fractionated radiotherapy to definitive doses appears sufficient for nodal masses <3 cm. When considering primary regional irradiation for bulky nodal disease, it is important to select patients in whom the primary lesion has a high probability of control to definitive irradiation. It is important to balance this strategy with the increased neck fibrosis that is particularly problematic when irradiating large neck volumes and in critical locations where entrapment and paralysis of the brachial plexus and CN XII may be of concern.

## Radiation Therapy with Planned Neck Dissection

Multiple series have consistently reported efficacy of a planned neck dissection for advanced neck disease treated in conjunction with moderate doses of radiation therapy.[137–144] In general, high regional control rates have been reported with high rates of positive pathologic neck specimens suggesting therapeutic benefit. Typically, positive neck specimens have been seen in 30% to 50% of cases. One of the earliest reports, using low-dose preoperative radiation therapy (20 Gy), to decrease neck recurrence was reported by Strong.[85,145] However, this was shown to be ineffective by Ogura and this low-dose approach has largely been abandoned.[146] MacComb and Fletcher[147] introduced the concept of moderate doses of radiotherapy combined with a planned neck dissection that was further supported by Barkley et al.[64] This combined modality approach further evolved to treat N2 and N3 disease.

Several groups have reported excellent regional control outcomes after conventional doses of preoperative radiation therapy followed by planned neck dissection. Mendenhall et al.[127] reported that the addition of a neck dissection appeared to increase the regional control rate in patients with multiple nodes. These investigators also demonstrated that the risk for post–neck dissection wound complications was increased when maximum subcutaneous doses >60 Gy were delivered (17% vs. 6%) with a suggestion that most of the increased complications occurred when the neck dissection was performed >6 weeks after radiotherapy (29% vs. 14%). Further analysis noted a dose-dependent relationship for neck dissection wound complications for doses 45 to 90 Gy.[148] Currently, 60 Gy is delivered to nodal metastases with a planned neck dissection.

Lee et al. reported on a cohort of 58 patients with base of tongue carcinoma treated uniformly with 60 Gy delivered to palpable nodal disease followed by a planned neck dissection for all patients with N1 to N3 neck disease.[137] All patients had base of tongue cancers with N1 disease in 24, N2 in 25, and N3 in 7. As a brachytherapy implant was used to boost the primary, the use of a neck dissection was incorporated during the general anesthesia required for the implant. Pathologic residual disease was noted in 30%. At a median follow-up of 36 months, 5-year actuarial regional control rate of 96% was observed. In contrast, an actuarial regional control rate of 86% was noted in a cohort of patients treated with radiotherapy alone to the neck before the institutional policy of planned neck dissections was employed. All patients undergoing planned neck dissection were controlled while 1 of 7 who had a CR after induction chemotherapy recurred after radiation without neck dissection. It is also noteworthy that a clinical CR (cCR) lacked sufficient predictive power for a pathologic CR. Discordant results were observed with not only patients with cCRs demonstrating persistent pathologic disease but also patients with clinical PRs having a negative pathologic specimen. Hence, the authors concluded that despite the potential of overtreatment in possibly 70% of treated patients, systematic planned neck dissection was recommended given the favorable therapeutic ratio. Other comparable retrospective series reporting the results of comparable strategies in the treatment of base of tongue carcinomas have demonstrated high regional control rates.[149–151]

The University of Florida has advocated the use of planned neck dissection after external beam radiotherapy (EBRT) especially for patients with N2–3 neck disease.[152] In comparing 5-year neck control of 196 treated with radiation alone compared to 144 heminecks treated with combined surgery plus neck dissection, patients with N2b or N3 disease had better regional control with neck dissection added (regional failure 9% vs. 30% for N2b, $p < 0.01$; 31% vs. 67% for N3, $p < 0.01$) but not patients with N2a disease (regional failure 32% vs. 21%, $p = 0.6$). The authors recommended tailoring of preoperative dosing depending on size and location of node as well as fixation. Thus, 50 Gy was advised for mobile nodes 3 to 4 cm, 60 Gy for nodes up to 5 to 6 cm and fixed nodes while 70 to 75 Gy was recommended for nodes 7 to 8 cm.

## Neck Dissection Prior to Radiation Therapy

Byers et al. have reported on the results of initial neck dissection prior to a definitive course of radiotherapy to the primary site that included postoperative neck radiotherapy.[153] Typically, this strategy was undertaken to minimize the overall treatment time for early primary lesions with advanced resectable unilateral nodal disease where a general anesthetic was thought to be required for dental extractions with the advantage of avoiding a second anesthetic. These investigators demonstrated that the success of this strategy necessitated meticulous attention and skill to minimize any delay >2 weeks to start radiotherapy. In patients with a delay >14 days, OS was decreased (82% vs. 38%, $p = 0.010$). More than half (20/35) experienced such treatment delay for unclear reasons. The regional failure rates were not reported with this approach. Smeele reported on 35 patients with N2–3 neck disease who underwent neck dissection then definitive radiation therapy to the primary site. The mean interval between neck dissection and radiation therapy was 35 days. Overall locoregional control was 43% at 2 years with regional failure in 20% (7/35). Disease-specific survival was 49% at 2 years.

Although the sequencing of a planned neck dissection after definitive radiotherapy is not without disadvantages, the use of an up-front neck dissection does not appear to provide any significant benefit, and this strategy poses the potential for altered lymphatics and a necessity to irradiate the surgical scar and drainage sites with increased irradiated normal tissues.

## Primary Chemoradiation

Given the success of organ-preservation approaches, definitive chemoradiation for the node-positive neck has become increasingly popular with neck dissection either as a planned procedure or reserved for salvage of persistent/recurrent disease. For N2–3 disease, the integration of planned neck dissection was thought to yield optimal regional control. However, with intensive regimens of concurrent chemoradiation as well as induction chemotherapy, high rates of CR can be confirmed with anatomic and functional imaging. With careful surveillance, regional control comparable to patients treated with planned neck dissection after chemoradiation. Patients who are found to have residual pathologic residual disease on neck dissection after chemoradiation have worse survival, locoregional, and particular higher risk for distant metastasis. However, the benefit of additional therapy remains to be established in this setting.

## Planned Neck Dissection after Concurrent CT/RT

Following paradigms combining radiation followed by neck dissection especially for N2/3 disease, numerous series have reported excellent regional control for N2/3 patients treated with concurrent chemoradiation with planned neck dissection.[130,133–140] The bulk of the data are derived from single institution series with some data from randomized studies. In the majority of these series, planned neck dissection after initial definitive treatment to the primary site results in regional control rates of 93% to 99%, with pathological residual disease of 20% to 40% (Table 14.7).

Stenson et al. reported on 69 of 237 patients treated with concurrent chemoradiation undergoing a planned neck dissection for N2 or N3 neck disease or for residual adenopathy.[154] SND was performed in >82% of patients with radical or modified radical in the rest. Of the 63 patients evaluable radiographically

after chemoradiation, 48% had a CR (30/63). Pathologic residual disease persisted in 35% of the neck specimens (N2: 36%, N3: 50%, $p = 0.09$). No significant relationship could be detected between radiologic CR or PR with residual microscopic disease. The negative predictive value (NPV) of a radiographic CR was 0.77 (23/30) and the positive predictive value (PPV) of a radiographic PR was 0.39 (13/33). At a median follow-up of 30 months, the regional failure was 1.4% (1/69).

In a follow-up report with more patients, Argiris reported on 131 N2/3 patients treated with concurrent chemoradiation consisting of hyperfractionated radiation using 5FU/hydroxyurea on an alternate-week schedule with radiotherapy plus cisplatin or paclitaxel.[155] Thirty-nine were observed and compared to 92 N2/3 patients treated similarly who underwent neck dissection. The decision to proceed with neck dissection was based on institutional bias in this multicenter study. At a median follow-up of 4.6 years, the actuarial 5-year regional failure rate was 18% in those patients observed versus 1% in those undergoing neck dissection ($p = 0.0007$). Among the 30 patients who had a CR and were observed, the actuarial regional failure rate was 8%. Evaluating all patients having achieved a CR ($n = 92$), the addition of neck dissection did not improve OS (53% vs. 49%, $p = 0.95$) or regional failure (2% vs. 8%, $p = 0.21$). Among the 34 patients having a PR, the addition of a neck dissection did improve survival (68% vs. 12%, $p = 0.0003$) and decreased regional failure (0% vs. 74%, $p = 0.0002$). Among the 104 N2 patients, the addition of a neck dissection decreased regional failure (2% vs. 18%, $p = 0.004$) with no statistically significant improvement in 5-year OS (59% vs. 45%, $p = 0.19$) compared to those observed without neck dissection. Similarly, among the 27 N3 patients, the addition of neck dissection decreased regional failure (0% vs. 14%, $p = 0.09$) with no obvious statistically significant improvement in OS (55% vs. 29%, $p = 0.10$). However, there was a progression-free survival in N3 patients after neck dissection (79% vs. 36%, $p = 0.04$) but not for N2 patients (72% vs. 70%, $p = 0.78$). Based on these findings, the authors conclude that neck dissection may be omitted in N2 patients attaining a cCR but should be planned for N3 patients.[155]

Lavertu et al. reported on the comparative results of neck management resulting from a randomized trial of concurrent cisplatin and 5FU (two cycles) and conventionally fractionated radiotherapy versus conventional radiotherapy alone.[156] Treatment response was assessed at both the primary and the neck after 50 to 55 Gy, with nonresponders (<50% response) and those with disease progression, proceeding to surgery. Otherwise, radiotherapy continued to 65 to 72 Gy followed by a planned neck dissection after evaluation at 4 to 6 weeks for residual disease or for N2 and N3 disease regardless of the response. The addition of chemotherapy was observed to increase the cCR rates in the neck compared with treatment with radiotherapy alone. Among N2–3 patient, the CR rate was 64% (30/47). Thirty-five patients with N2–3 neck disease had neck dissection (18 with a cCR and 17 with less than a CR) whereas 12 were observed after achieving a CR. Regional failure occurred in 3% (1/35). In comparison, 25% of 12 patients ($n = 3$) who were observed after achieving a CR in the neck recurred regionally. None of these latter three were salvageable. Despite observing no significant differences in survival for a planned neck dissection (which likely reflected an underpowered analysis), these investigators advocate a planned neck dissection for N2 and N3 disease irrespective of treatment response and for persistent adenopathy.

A follow-up study was reported from the Cleveland Clinic of 109 N2/3 patients treated with concurrent 5 Fluorouracil/Cisplatin (5FU-CDDP) with either conventional or hyperfractionated radiation.[157] Sixty percent (65/109) achieved a cCR. The probability of attaining a cCR was dependent on maximal node diameter (cCR: diameter <3 cm: 76% [19/25] vs. diameter >3 cm 55% [46/84], $p = 0.06$) as well as N stage (cCR: N2 66% [53/80] vs. 41% N3 [12/29], $p = 0.019$). Among patients who underwent neck dissection (32 with cCR and 44 with <cCR), the regional failure was 6.5% compared to 12% (4/33) who were observed after attaining a cCR. The clinical status of the neck had an NPV of 0.75 and

(c) 2014 Wolters Kluwer. All Rights Reserved.

PPV of 0.39. The authors conclude that the clinical status is not a useful tool to determine in which patients to omit SND.

Brizel reported a survival advantage in patients undergoing neck dissection based on 108 patients treated with hyperfractionated radiation and concurrent cisplatin/5FU.[158] Sixty-five underwent planned MRND whereas 43 were observed. Thirty patients had N1 disease whereas 78 were N2–3. Patients were assessed for clinical response by physical exam and CT scan. Of the 13 N1 patients undergoing neck dissection, 12 had a cCR prior to surgery whereas one had less than a CR. For these patients, the NPV was 92% after CR and PPV of residual nodal mass of 100%. Among N2–3 patients, 16 had a CR and were observed, 10 had progressive disease outside of the neck and did not proceed to neck surgery, and 52 proceeded to neck dissection. The NPV for CR and PPV for residual nodal abnormality for N2–3 patients was 74% and 44%, respectively. At a median follow-up of 4 years, patients with N2–3 neck and complete CR who underwent neck dissection had better 4-year DFS (75% vs. 52%, $p = 0.08$), lower regional failure (2% vs. 19%), fewer distant metastasis (10% vs. 31%), and increased OS (77% vs. 50%, $p = 0.04$) compared to N2–3 patients with CR who were observed. Neck dissection showed no survival benefit in N1 patients. The authors hypothesize that the survival benefit of neck dissection in N2/3 patients may be related to a smaller proportion of patients failing regionally (2% vs. 19%) and distantly (10% vs. 31%) in those patients undergoing neck dissection. Serious morbidity attributable to ND occurred in none of the N1 patients and 8% of the N2–3 patients including two with wound dehiscence and two with vagal nerve injury. Brizel reported accuracy of 60% between clinical response and pathologic findings in 52 patients treated with chemoradiation followed by planned neck dissection.

***Planned Neck Dissection after CT/RT for N3 Neck.*** Smyth reported on the University of North Carolina experience for 100 patients with N3 neck disease evaluated retrospectively treated over a 20-year period from 1989 to 2009.[158a] Tumor sites included oropharynx in 53 patients, hypopharynx or larynx in 22 patients, and oral cavity in 8 patients. Seventy-six patients received definitive chemoradiation versus 24 undergoing up-front resection. Patients were well balanced with regard to age, sex, and nodal size whereas chemoradiation patients had a greater proportion of T3/4 disease (54% vs. 25%). Reflecting the changing practice patterns toward definitive chemoradiation, surgically treated patients had longer follow-up (9.5 vs. 1.6 years). Twenty-two percent had evidence of unresectable disease characterized by carotid encasement or invasion of the deep muscles and treated with chemoradiation. Patients treated with primary resection were compared to those treated with primary chemoradiation, and those treated with definitive resection appeared to have a better OS (5-year 68% vs. 32%) and DFS (64% vs. 32%). If unresectable patients were excluded, a trend toward survival benefit was maintained with surgery ($p = 0.07$ for OS and $p = 0.08$ for DFS). Patients with nonoropharyngeal primary cancers ($n = 46$) appeared to have a survival benefit with definitive neck dissection over chemoradiation (5-year OS 58% vs. 15%, $p = 0.02$ and 5-year DFS 58% vs. 10%, $p = 0.01$) but no statistical difference was seen among oropharyngeal carcinomas (5-year OS 80% vs. 46%, $p = 0.3$ and 5-year DFS 70 vs. 49%, $p = 0.5$).

Of the 76 patients treated with chemoradiation, 30% ($n = 22$) attained a CR, 53% ($n = 40$) had a PR, whereas 8% had stable disease and 8% had unknown outcome. Neck failure occurred in 4% (1/24) of dissected neck and 9% (4/44) of nondissected necks.

Postchemoradiation neck dissection did not change survival in patients with N3 disease. The authors recommended resection for nonoropharyngeal primary sites.

Based on these results, planned neck dissection after chemoradiation has also been advocated for regionally advanced neck disease given consistently excellent regional control as well as the low probability of successful salvage (14%–22%) of subsequent neck relapses.[126,131] However, opponents of such a systematic approach for N2/3 patients claims that neck dissection adds morbidity with marginal gain in regional control or survival especially since nearly two-thirds will have pathologically negative specimens.[125,136,139,143]

## Salvage Neck Dissection for PR after Chemoradiation for N3

Igidbashian reported on 70 N3 patients treated with concurrent chemoradiation with imaging at 6 to 8 weeks to evaluate patients for salvage neck dissection for a PR. CT criteria of CR was derived from their larger experience for node-positive patients, nodal response >90% shrinkage and/or nodes <1 cm. Eighty percent of patients had oropharynx primary sites. Overall, the CR rate was 37% (26/70) and these patients were observed except for two who underwent neck dissection. Of the 63% ($n = 44$) of patients with PR, 31 underwent neck dissection whereas 13 were unable to proceed to neck dissection due to disease progression ($n = 7$) or on treatment mortality ($n = 2$) or patient refusal ($n = 4$). At a median follow-up of 3.5 years, N3 patient observed after CR to chemoradiation had worse DFS compared to those who had a PR followed by salvage neck dissection (2-year DFS 63% vs. 85%, $p = 0.04$) because of higher rate of distant metastasis (33% vs. 7%, $p = 0.06$). OS at 2 years was not significantly worse (63% vs. 79%, $p = 0.26$).

## Extent of Neck Dissection after Chemoradiation

SND after chemoradiation represents the standard of care when integrated as a planned procedure typically within 6 to 8 weeks after chemoradiation. Compared to radical neck dissection, similar excellent regional control and lower morbidity are attained with SND even with bulky N2 or N3 disease. In only about one-third of patients undergoing planned neck dissection will residual viable pathologic nodal disease be found.

Multiple publications have shown that an SND after chemoradiation is adequate allowing lower wound complications and shoulder dysfunction with sparing of the spinal accessory nerve. Boyd showed that a low level of persistent nodal disease in level I and V existed in 28 patients treated with comprehensive neck dissection with only one patient with disease at level V, suggesting a level II to IV resection is adequate. Robbins suggest that radiation therapy is adequate to control disease in noninvolved nodal stations.[159] Multiple institutions have shown high rates of regional control after SND.[154,160,161]

## Super Selective Neck Dissection after PR with CT Evidence of One Nodal Station

Given that SND yields less wound complications and shoulder dysfunction, efforts to limit morbidity even further have brought into question whether even more targeted surgery at greatest risk for residual disease can further decrease morbidity without sacrificing regional control. Specifically, sparing levels IV and V are of particular interest. Inoue reported better functional outcomes and decreased pain when levels IV and V are not included in the neck dissection.[162]

Robbins' advocated the use of a super selective neck dissection confined to two nodal levels if residual lymphadenopathy is found on imaging at only one nodal level. He reported on 177 patients treated with concurrent chemoradiation using intra-arterial cisplatin. Tumor sites were as follows: oropharynx, 46%; hypopharynx, 22%; larynx, 15%; and oral cavity, 11%. Response

(c) 2014 Wolters Kluwer. All Rights Reserved.

was evaluated by CT of the neck, 6 weeks after treatment. CR in the neck was noted in 50%. Among the 89 patients with PR, 73 had evidence of residual adenopathy in one neck level. Of these 73 patients, 54 patients underwent 57 neck dissection whereas 19 were unable to proceed to neck dissection due to unresectable local disease ($n = 6$), distant metastasis ($n = 4$), death ($n = 3$), or noncompliance ($n = 3$). The majority had SND encompassing at least three nodal levels. Prior to treatment, 29 heminecks were deemed by CT imaging to have disease at one nodal level, 23 at two nodal levels, 4 at three nodal levels, and 1 at four nodal levels. Fifty-two of 54 had disease involving one level at the nodal stations predicted on the posttreatment neck CT whereas 2 patients had disease beyond the predicted nodal level with 1 at a contiguous nodal level and 1 at a noncontiguous nodal level. Thus, of the 54 patients with evidence of a single residual node, 53 would have disease encompassed by a super selective neck dissection of two nodal levels.[163]

Yeung also reported the benefit of using postradiation treatment CT to tailor neck dissection. CT response at 4 weeks after radiation therapy was correlated with pathologic findings on with neck dissection done at a median 7 weeks after treatment. Radiographic CR was defined as a node <1.5 cm without filling defects or calcifications. Sixty-one of 211 node-positive heminecks showed a CR at the initially involved nodal levels but underwent neck dissection with inclusion of the initially involved nodal station. Pathologic residual disease was found in 3 of 61 heminecks. When all 211 heminecks were examined by nodal level specifically, the NPV of the CT was 95% or greater for all nodal levels I to V. The authors conclude that there is a 5% risk of leaving disease behind if the initially involved nodes that have CR are left undissected.[164]

Cannady reported a retrospective single institution study of 241 N2/3 patients 329 node-positive necks treated with chemoradiation at the Cleveland Clinic. N3 comprised about 26% (63/241) of patients. Oropharynx comprised 68% of patients with 11% larynx and 12% hypopharynx. The primary site had to be in CR as an inclusion criteria. The complete clinical response was 65% (210/329) as defined by a negative physical exam and imaging with CT and/or PET after chemoradiation. Neck dissection was performed at a median of 10 weeks in 31% (65/210) of patients with complete clinical response and 81% in patients with a partial nodal response (96/119). Pathologic residual disease was found in 14% of those with a complete clinical response versus 40% in those with PR ($p < 0.01$). In analyzing the 47 necks with residual nodal disease, 72% had disease present in the originally positive node and 98% had disease at the original level or 1 distal level. Only one patient had disease beyond one distal level at level V. Regional failure occurred in 6.6% of patients (16/241) and was higher in patients with partial clinical response (9% vs. 3.4%, $p = 0.04$) and those with residual pathologic nodal disease ($p < 0.01$) as well as those with primary site recurrences ($p < 0.01$). Isolated regional failure occurred in 3.6% ($n = 10$) patients with primary site controlled and none were successfully salvaged with all dying with uncontrolled neck disease. No significant difference was noted based on neck dissection types. Distant metastasis occurred in 26% of patient with residual pathologic disease compared to 13% in those with complete pathologic response ($p < 0.05$). Neck dissection did not improve 5-year OS in those who achieved a complete clinical response compared to those who were observed (79% vs. 78%).[165]

## Role of Planned Neck Dissection for Patients with a CR to Chemoradiotherapy

There is no controversy regarding the role of a salvage neck dissection in patients who undergo primary radiation or chemoradiation and have a PR. Unquestionably, these patient require a surgical salvage whether it be a radical, modified radical, or selective neck dissection. Additionally, it is commonly accepted that a planned neck dissection is not required in low volume (N1) disease. The controversy that exists surrounds the role of a planned versus a salvage neck dissection in high volume (N2 or greater) disease who achieve a complete clinical response after radiation or chemoradiation. There are many centers worldwide that perform a planned neck dissection for N2 disease or greater regardless of the clinical response. Many feel that the high pathologic positivity rate (30%–40%) in postchemoradiation neck dissection specimens justifies a planned neck dissection regardless of the clinical response.[166,167] However, although pathologic positivity predicts for increased risk of both locoregional and distant failure, it is controversial whether patients attaining a CR after radiation or chemoradiation will have any added benefit from a neck dissection.[168]

The concept of withholding a planned neck dissection in patients who undergo a complete clinical response began in the early 1990s and has been steadily gaining momentum. In the early studies, complete regression of palpable disease was used to withhold a planned neck dissection. In these studies, regional failure was below 10%.[169–174] Posttreatment imaging has become increasingly utilized as a method to assess for PR or CR in addition to physical examination. The use of a posttreatment CT scan has become the most commonly utilized method of determining a patient's response to treatment. Retrospective studies examining locoregional failure rates range from 0% to 8%.[175–180] In 2008, Corry et al. published their study of 102 patients treated with chemoradiation for HNSCC with N2–N3 disease. They found that none of their patients who had a complete clinical response developed isolated regional recurrences and therefore concluded that a planned neck dissection was not justified in this subset of patients.[175]

More recently, with advent of more sophisticated imaging techniques such as FDG-PET/CT imaging, the role of the planned neck dissection has become even more questionable. PET-CT imaging has been shown to have an excellent and highly reliable NPV after a CR to chemoradiation.[181–185] This allows for an even higher level of comfort after a CR.

## MORBIDITY AFTER NECK DISSECTION

The main complication of a planned neck dissection is the increased risk for wound healing especially with the addition of concurrent chemotherapy. Interestingly, the data do not appear to show the risk to be unacceptably increased. Definitive doses of radiation, which are higher than the doses given when there is a plan for a staged neck dissection, appear to increase the risk for complications even more. Strategic planning to minimize the dose delivered to the neck and to ensure that the neck dissection is not unduly delayed will minimize the risk.

Davidson reported on 34 patients who underwent planned neck dissection after radiation therapy or chemoradiation.[136] Patients were treated with a mean preoperative dose of 58 Gy (50–80 Gy) and 37% ($n = 15$) patients received chemotherapy. Fifty-eight percent underwent radical neck dissection and 42% were treated with a supraomohyoid or MRND. The total complication rate was 45% with wound complications (skin necrosis, facial edema, chyle leak, seroma, nerve injury) in 24% ($n = 8$) and systemic (aspiration, urinary retention) in 21% ($n = 7$). Doses of 70 Gy or greater appeared to increase wound complications (42% vs. 14%, $p = 0.09$) and skin necrosis (33% vs. 0%, $p = 0.005$) when compared to those receiving lower doses.

Lavertu reported a comparison of 54 patients who underwent a neck dissection after radiation ($n = 30$) or chemoradiation ($n = 24$).[186] The patients had been gleaned from the phase III

(c) 2014 Wolters Kluwer. All Rights Reserved.

trial comparing radiation therapy alone versus concurrent chemoradiation. More patients in the chemoradiotherapy group were a higher neck stage (62% N2b–N3 vs. 43% N2b–N3) compared to the RT alone group. Selective, modified radical, and bilateral neck dissections were performed in 0, 15, and 4 patients, respectively, in the chemoradiation group whereas the corresponding numbers in the radiation-only group were 2, 16, and 0, respectively. Neck dissections were performed at a median of 7 to 8 weeks after radiation. Patients in the chemoradiation group had more wound complications with an increase in skin incision breakdown (33% vs. 7%). Overall, there were no major differences in overall complications (33% vs. 29%, $p = 0.68$) or major complications (0% vs. 7%) in the chemoradiation versus radiation-only group. No differences were noted in length of hospital stay, operative blood loss, or time between radiation and surgery. Thus, the addition of chemotherapy to radiation did appear to impair wound healing but not overall complications. Lavertu further reported that salvage ND performed later than 12 weeks after radiation was associated with an increased rate of major surgical complication compared with planned ND within 4 to 12 weeks (20% vs. 3.4%, $p = 0.04$) and overall complications (60% vs. 31%, $p = 0.04$).[186]

Stenson reported on the toxicity of 69 patients with node-positive disease treated with concurrent chemoradiation followed by SND ($n = 56$) or modified/radical neck dissection ($n = 13$). Two patients had N1 disease, 47 with N2, and 20 with N3 disease. CT was done usually 4 weeks after chemoradiation. Thirty patients had a radiographic CR, 33 had a PR, and 6 did not have imaging reported. Surgery was performed within 5 to 17 weeks after chemoradiation. Patients were followed for a mean of 30 months. Wound complications occurred in 10% (7/69) with four requiring surgical intervention requiring ultimate closure. Another 16% (11/69) had other complications including need for tracheotomy ($n = 7$), cranial nerve palsy ($n = 3$), and hypocalcemia ($n = 1$). No chylous fistula for flap necrosis was reported.

Ahlberg reported on 108 patients undergoing either supraomohyoid ($n = 25$) or MRND ($n = 83$) and adjuvant radiation and compared them to 98 patients treated with radiation without neck dissection. Patients were followed for 1-year prospectively to evaluate swallowing, trismus, cervical range of motion, and shoulder disability and underwent early rehabilitation. Among the 108 neck dissection patients, 75 underwent radiation followed by neck dissection and 33 received postoperative radiation. More patients in the postoperative radiation group underwent supraomahyoid dissection (16/33) compared to those treated with preoperative radiation (9/75). Patients treated with postoperative radiation had a higher incidence of swallowing disorders compared to the preoperative group (45% [15/33] vs. 20% [15/75], $p = 0.032$). The incidence of shoulder disability was 18% with no statistically significant difference between MRND and supraomohyoid (20% vs. 8%, $p = 0.23$). MRND caused reduced cervical range of motion at 2 and 12 months after surgery and decreased mouth opening at 2 months.[187]

## COMPLICATIONS BASED ON DOSE AND INTERVAL TO SURGERY

The University of Florida reviewed their experience of 205 patients treated with planned unilateral neck dissection. Radical neck dissection was performed in three-fourths (159/205). Twenty-seven wound complications occurred within 6 months of surgery. Patients receiving increasing dose to the neck trended toward a higher risk of complications while interval between radiation and surgery did not. Patients who received a total of <60 Gy had a 3% complication rate (1/34) versus 10% (15/147) in those receiving >60 Gy. The incidence by dose groups was 6% (45–60 Gy), 13% (60–75 Gy), and 17% (75–90 Gy) and trended toward significance ($p = 0.08$).[148]

Chepeha compared shoulder function in 54 patients undergoing 64 neck dissections comprised of 32 MRND with spinal accessory nerve sparing and 32 patients with SND. Patients were followed with the constant's shoulder scale and variables evaluated to predict for shoulder dysfunction included type of neck dissection, tumor stage, site, age, weight, radiation therapy, time from surgery, and handedness. Patients receiving MRND had significantly worse shoulder function and those undergoing radiotherapy trended toward worse function, but patients who were heavier did significantly better. However, Goguen reported that in 105 patients undergoing postchemoradiation neck dissection, the complication rate was related to the type of neck dissection performed rather than timing of neck dissection.

## DYSPHAGIA AFTER NECK MANAGEMENT

Dysphagia after multidisciplinary management of the neck concurrent chemoradiation is significant. Radiation dose, larynx/hypopharynx primary site, advanced age, female sex as well as neck dissection have been found to increase the risk for long-term dysphagia and risk for feeding-tube dependence. Retrospective review of 199 patients at the Cleveland clinic demonstrated that 21% of patients developed strictures requiring dilation. Risk factors associated with stricture formation included twice-a-day fractionation, primary tumor of the hypopharynx, and female gender (Lee, 2006).[187a] University of Florida reported similar risk factors for chronic feeding tube placement in 934 patients treated with definitive radiotherapy included hypopharynx, RT dose, and female sex.

Machtay reported on 230 stage III/IV patients treated with concurrent chemoradiation on three RTOG trials evaluating factors associated with severe late toxicity. A total of 479 were enrolled in the studies and 136 were excluded because of locoregional failure or death, 100 excluded because of severe laryngopharynx baseline dysfunction, and 13 were excluded because of missing data. Twenty percent (47/230) underwent posttreatment neck dissection with similar proportion regardless of primary site (oral cavity/oropharynx 22% vs. 19% of larynx/hypopharynx). Grade 3 and 4 late toxicity was common, occurring in 43% of patients. On multivariate analysis, patients with older age (OR 1.05, $p = 0.001$), neck dissection (OR 2.39, $p = 0.18$), advanced T stage (OR 3.07, $p = 0.0036$), and larynx/hypopharynx primary site (OR 4.17, $p = 0.0041$) were significant variable correlating with developing severe late toxicity. Among those undergoing neck dissection versus those not undergoing neck surgery, the crude rate of severe late toxicity was higher (55% versus 40%). The data were a retrospective analysis, and those undergoing neck dissection may have had a selection bias for worse neck disease since >50% had N2/3. Nevertheless, the author hypothesize that neck dissection could impair swallowing dysfunction because of increased fibrosis and impaired mobility of laryngopharynx.

Lango reported on 67 patients with node-positive disease treated with primary radiation or chemoradiation at Fox Chase. Thirty-four patients were observed whereas 33 had a comprehensive neck dissection at a median time of 6 weeks after treatment. The two groups were well balanced with regard to those undergoing concurrent chemoradiation, T and N stages whereas patients undergoing neck dissection were younger (56 vs. 62 years, $p = 0.011$), more likely to have a stricture present (6% vs. 1%, $p = 0.054$), and less likely to have a tonsil primary (7% vs. 17%, $p = 0.54$ with similar rates of larynx/hypopharynx primary sites 12% vs. 9%). Minimum follow-up was 24 months. On multivariate analysis, the authors reported a significant

(c) 2014 Wolters Kluwer. All Rights Reserved.

association with posttreatment neck dissection with feeding-tube dependence with an RR of 4.74 at 18 months and higher risk at 24 months (RR = 7.66). If patients with strictures were excluded from analysis, the RR for feeding-tube dependence was 5.49 at 18 months (40% vs. 2%, $p = 0.02$) and 11.28 at 2 years (40% vs. 1%, $p = 0.005$) after neck dissection. No increased risk for feeding-tube dependence was noted at 1 year with RR of 1.19 (29% vs. 24% $p = 0.658$). Other risk factors predictive for feeding-tube dependence included pretreatment weight loss ($p = 0.04$) and advanced age ($p = 0.03$).

## NECK CONTROL AFTER PRIMARY CHEMORADIATION WITHOUT PLANNED NECK DISSECTION IN NODE-POSITIVE PATIENTS

Given that pathologic CR is noted in about two-thirds of patients undergoing planned neck dissection after radiation or chemoradiation, multiple institutions have reported low rates of overall regional and isolated regional failure with observation in complete responders. Attaining imaging confirmed CR for N1 disease is high occurring in >80% while for N2 patients it is achieved in 60% to 80% and modest for N3 patients, successful in about 40% (Table 14.8). Aside from N stage, factors which improve the chance for a CR, include the use of induction and concurrent chemotherapy, higher radiotherapy dose, HPV status, and oropharyngeal primary site.

Forest reported on neck control after definitive concurrent chemoradiation in 184 patients with 13% N1, 72% N2, and 15% N3 with oropharynx in 73%, larynx 13%, and hypopharynx 6%. Patients were evaluated with CT at 6 to 8 weeks after treatment. Complete clinical radiographic response was defined as a node <1 cm with well-defined borders and no focal abnormalities (no necrosis) or nodal shrinkage >90% compared to initial CT. Salvage neck dissection was performed in patients with persistent disease at 6 to 12 weeks after treatment. Of the 184 patients, radiographic CR was 68% and the rate of CR related to the size of nodal such that nodes <3 cm, 3 to 6 cm, and >6 cm had a CR rate of 83%, 66%, and 43%, respectively. One hundred twenty-six patients attained a CR and were observed except in 3 patients who underwent neck dissection. Fifty-eight patients had a PR and 45 underwent neck dissection with 9 patients refusing surgery and 4 with disease progression. Regional failure among the 123 CR patients was 5% (6/123) and only 1 of 6 could be salvaged. Among the PR patients undergoing neck dissection, regional failure was 7% and 40% had pathologic residual nodal disease. No obvious difference was noted in regional failures between patients obtaining a CR who were observed versus patients undergoing neck dissection after a PR whether they were 3 to 6 cm (7% vs. 4%) or >6 cm (9% vs. 8%), respectively.

**TABLE 14.8 Complete Response after Chemoradiation Based on Initial N Stage**

| | Getec ($n = 103$) | Smyth ($n = 100$) | Igidbashian ($n = 70$) | Corry ($n = 102$) | Clavel ($n = 369$) |
|---|---|---|---|---|---|
| N1 | 86% | | | | 83% |
| N2a | 90% | | | | 66% |
| N2b | 50% | | | 63% (all N2) | 72% |
| N2c | 60% | | | | 80% |
| N3 | 45% | 30% | 37% | 40% | 45% |

Corry reported regional control of 102 N2–3 patients treated with definitive concurrent chemoradiation with neck dissection reserved for salvage on the Trans Tasman Radiation Oncology group Study 98-02. Oropharynx comprised the majority of patients (78/102) with hypopharynx in 15/102 and larynx 6/102. N2 constituted 82/102 and N3 20/102. CR was determined based on physical exam and CT of the neck 12 weeks after chemoradiation. The CR rate was defined as <1 cm without focal abnormalities. CR was achieved in 60/102 for all patients and was 63% of N2 and 40% for N3 disease. Median follow-up was 4.3 years. Among patients with complete nodal response, the regional failure was 8% with no isolated regional failures.[188]

Several other groups reported a low incidence of isolated failure after radiologic CR[189] and Groupe d'Étude des Tumeurs de la Tête Et du Cou (GETTEC).[190] Lambrecht evaluated 368 patients treated with definitive radiotherapy, with 37% receiving concurrent chemotherapy. At a median follow-up of 34 months, 3-year regional failure was 20%. Crude data showed that 41 patients developed neck failure (11%) of the 368 but only 11 (3%) were isolated failures. At 3 years, nodal control for N1, N2a, N2b–c and N3 patients was 84%, 83%, 70%, and 67%, respectively.

Yovino reported on 120 patients with node-positive disease treated with definitive chemoradiation to the neck. CT was performed 8 weeks after treatment with a CR defined as tumor <1.5 cm without focal necrosis. Seventy-six percent (91/120) achieved a CR. At a median follow-up of 30 months, regional failure occurred in 3% (3/90) patients with 2% isolated regional failure. Among partial responders who proceeded to neck dissection, regional failure was 4/29 patients.[189]

Dequanter reported on 28 patients with N2/3 disease treated with primary chemoradiation without planned neck dissection.[191] Patients received conventionally fractionated radiation to a dose of 65 to 70 Gy with concurrent high-dose cisplatin or induction 5FU/cisplatin. Twenty-five had a clinical and radiographic CR and were observed while 3 had residual clinical disease and underwent neck dissection. Of the 25 who were observed, 20% developed a regional recurrence at a median follow-up of 11 months with 2 of 5 also having primary recurrence. None were salvageable and all died of progressive disease. Among the three patients undergoing neck dissection, all were regionally controlled at a median follow-up of 36 months.

Grabenhauer reported on 97 patients who had cCR at the primary site after chemoradiation.[192] Forty-one refused neck dissection and 56 patients proceeded to neck dissection. However, 22% who refused neck dissection were N0 versus 3% in the patients who underwent neck surgery whereas there were 22% more N2b/2c patients in those undergoing neck dissection. Pathologic residual disease was seen in 17% undergoing neck surgery. At a median follow-up of 37 months, no difference in 5-year regional failure in those observed versus undergoing neck dissection (15% vs. 20%, respectively) or OS (42% vs. 44%).The highest neck recurrence rates in those observed were among those with multiple nodes and hypopharynx primary. Wound healing complications occurred in 10% and dysphagia requiring PEG dependence was worse in patients undergoing neck surgery versus observation (21% vs. 12%). The authors recommend neck dissection in those patients with CR at the primary site who have multiple residual nodes or a hypopharynx primary.

Lau reported on 56 N2/3 patients treated with definitive concurrent chemoradiation to the neck. N2 patients comprised 91% and 9% were N3. Oropharynx patients comprised 59% with larynx in 15%, hypopharynx in 11%, and unknown primary

(c) 2014 Wolters Kluwer. All Rights Reserved.

in 15%. CR was assessed primarily by physical exam with imaging in 31%. The CR rate was 85% (46/54). Of the eight patients with <CR, salvage neck dissection was performed in three all of which were pathologically negative whereas four patients were inoperable due to persistent disease at the primary site or developed disease distantly ($n = 1$) and one patient was medically inoperable. At a median follow-up of 35 months, regional failure for the entire group was 15%, occurring in 9% in those with a CR versus 63% in those with <CR ($p < 0.001$). Regional failure among CR patients occurred at median time of 15 months (7–24 months). OS for the entire group was 82% at 2 years whereas patients with a CR had a higher 2-year OS (92% vs. 25%, $p < 0.001$) compared with those who had <CR. Two-year survival was similar among patients who had a neck dissection versus those who did not (82% vs. 75% $p = 0.28$).

The GETTEC group reported on 103 stage III/IV node-positive patients treated with definitive chemoradiation consisting of cis- or carboplatin with or without 5FU. Sixty-nine patients had N2 disease whereas 14 had N1 and 20 with N3. Oropharynx was the most common site in 67 patients with hypopharynx primaries in 14 and oral cavity in 12.

CR was defined by disappearance of detectable disease by physical exam and CT scan done at a mean time of 3 months after chemoradiation (1–4 months) and was achieved in 61% of all patients and were 86%, 90%, 50%, 60%, and 45% for N1, N2a, N2b, N2c, and N3, respectively. Among the 39% patients achieving a PR, 70% (28/ 40) proceeded to salvage neck dissection and found to have pathologic disease in 50%. The 2-year regional failure was 18% for the entire cohort and 8%, 29%, and 42% in those patients achieving a CR, PR with salvage neck dissection or PR without surgery. At a median follow-up of 30 months, the DFS and OS were similar between those who were observed after CR or those who had PR. Although regional failure was decreased, salvage neck dissection did not appear to improve survival in patients achieving a PR but may be related to a high pathologic nodal residual disease rate in those undergoing neck dissection.

## Salvage Neck Dissection for Residual Nodes after Induction Chemotherapy

Induction chemotherapy has been employed as a strategy to select for favorable responsive tumors that may be appropriately treated with organ-preserving primary radiation. Although meta-analysis of large groups of patients have demonstrated minimal survival benefit of induction chemotherapy compared to concurrent chemoradiation, new induction trials combining a taxane with cisplatin/5FU have demonstrated promising survival benefit and have renewed interest in this form of therapy.[12,13] The benefit of the addition of neck dissection in this setting has not been reported. The evidence suggesting a benefit of withholding a neck dissection if a CR is obtained after induction chemotherapy is derived from older induction chemotherapy regimens based on cisplatin and 5FU.

Wolf reported on a subset of 46 patients with N2/3 disease randomized to the organ preservation arm on the VA Cooperative Larynx Study.[193] Patients received induction 5FU/CDDP followed by definitive radiation therapy to the primary and involved neck nodes (66–75 Gy). Among those patients undergoing organ preservation, 74% had a major response (CR in 39% [18/46] and PR in 35% [16/46]) after induction chemotherapy and then proceeded to definitive radiation therapy. Salvage neck dissection was required in 5 of 18 patients with nodal CR and 19 of 28 with nodal PR. Twelve of the 46 patients died of uncontrolled neck with a higher rate of neck failure in patients with PR than CR (53% [10/19] vs. 11% [2/18]). Patients achieving a CR had better DFS compared to those with less than a CR (67% vs. 33%, $p = 0.014$). Wolfe and Fisher recommended neck dissection after induction chemotherapy and before radiation therapy would improve survival in patients with partial nodal responses.

A subsequent study reported by this group on 39 node-positive patient undergoing early neck dissection before radiation if a less than a CR was obtained after induction chemotherapy.[194] Patients received three cycles of induction 5FU/carboplatin/leucovorin. A nodal CR was obtained in 49% of all patients (19/39) and was higher for N1 patients compared to N2–3 (80% [8/10] in N1, 39% [9/23] in N2, and 33% [2/6] in N3 patients). Fifty-one percent had less than a nodal CR and underwent neck dissection before radiation therapy whereas those with a nodal CR proceeded to radiation therapy without planned neck dissection. At a median follow-up of 26 months, patients undergoing up-front neck dissection had a regional failure of 21% compared to 15% in those achieving a CR after induction chemotherapy who were observed. Of the N3 patients with less than a CR undergoing neck dissection, regional failure was 80%. There was no difference in DFS or OS between the two groups. Thus, results appeared to favor the use of early neck dissection in patients having a PR after induction chemotherapy.

Similarly, Armstrong reported outcomes in 53 node-positive patients treated with cisplatin-based induction chemotherapy followed by radiation only or neck dissection.[195] Major response in the neck after induction chemotherapy occurred in 66% (CR in 24 and PR in 11). Of these 35 patients, 22 (17 CR, 5 PR patients) were treated with definitive radiation alone (mean dose 66 Gy), 10 patients (6 CR, 4 PR) underwent neck dissection (9 prior to radiation therapy), and 3 had no further neck therapy. More patients in the radiation-therapy-alone arm were staged as N1 compared to the neck-dissection group (41% vs. 0%, $p = 0.02$). At a median follow-up of 25 months, regional control was better in those undergoing radiation therapy than patients undergoing neck dissection plus radiotherapy (regional control of 91% vs. 70%, $p = 0.40$). Regional control was 94% (16/17) in those obtaining a CR and 80% in those having a PR (4/5). No difference in survival was observed between the definitive radiation therapy versus neck dissection group (3-year OS 43% vs. 53%, respectively). Clark reported that 23 patients with N2–3 neck disease who had a CR after induction chemotherapy followed by radiotherapy also had excellent regional control of 87% (20/23). Patients who had a PR to chemotherapy followed by definitive radiation therapy had regional control of 33% (15/40).

Leon reported on 65 patients with residual nodal disease after induction chemotherapy who underwent either neck dissection followed by definitive radiation therapy to the primary site or upfront radiation therapy followed by planned neck dissection.[196] Two hundred eleven node-positive patients received three courses of CDDP/5FU and CR was obtained in 41% and PR in 46%. The neck stage (1987AJCC) predicted response to chemotherapy as CR was noted in 54% of N1, 41% of N2, and 15% of N3 patients ($p < 0.0001$). Except for two patients, all patients achieving CR received radiation therapy alone to a dose of 65 to 70 Gy to the primary and involved nodes. Among those with less than a CR, 65 patients underwent resection and radiation therapy whereas 64 received definitive radiation therapy alone. Patients with N2–3 disease with less than a CR and undergoing resection ($n = 46$) had better regional control (70% vs. 32%, $p = 0.001$) compared to those with less than a CR treated with radiation therapy alone ($n = 38$). The addition of surgery for all N stages improved regional control in patients not achieving a CR after induction chemotherapy as follows: N1, 79% versus 65%, $p > 0.05$; N2, 80% versus 36%, $p = 0.02$; and N3, 57% versus 23%, $p = 0.05$. The timing of neck dissection either before or after radiation therapy had no impact on regional control, 73% versus 75%, respectively ($p > 0.05$).

(c) 2014 Wolters Kluwer. All Rights Reserved.

Soltys reported on 90 patients with N2/3 disease treated with induction chemotherapy followed by concurrent chemoradiation. Patients were imaged by CT or MRI after 5 weeks into radiation treatment to determine who should proceed to planned neck dissection. Patients who had nodal disease >1 cm proceeded to planned neck dissection whereas those with a CR were observed. By this criteria, 62% (56/90) attained a CR of whom 48 observed and 8 underwent neck dissection with no residual disease found. Among the 48 CR patients, 10% (5/48) failed regionally with isolated regional failure of 2% (1/48). Thirty-four patients (38%) had a PR and 30 underwent planned neck dissection whereas 4 developed progressive disease. Pathologic residual disease was found in 47% (14/30). Those with pathologic residual disease had a higher relapse rate (50% [7/14] compared to 13% [1/16]) with those with no residual disease. Among the 30 patients with PR undergoing neck dissection, the neck failure rate was 12% (4/34) with 1 isolated regional failure. Nineteen patients had N3 disease and 53% (10/19) achieved a CR and were observed with no regional failures. At a median follow-up of 5 years, the regional failure rates among patients with CR, those with PR with no residual pathologic disease and those with PR but with residual nodal disease were 10%, 7%, and 22%, respectively, but not statistically significant. Corresponding 5-year DFS was 53%, 75%, and 42% ($p = 0.04$), respectively, and 5-year OS was 68%, 81%, and 48% ($p = 0.012$), respectively. Thus, pathologic confirmed CR was associated with higher survival compared to those with a cCR. Regarding regional control, planned neck dissection of all patients would have yielded a potential benefit in only 2% (2/90).

Paccagnella reported a phase II randomized study of induction TPF × 3 cycles followed by concurrent chemoradiation versus concurrent chemoradiation alone. One hundred one stage III/IV patients were randomized with 66% N2/3 disease in the concurrent chemoradiation arm versus 64% N2/3 in the induction arm. Imaging was performed 6 to 8 weeks after chemoradiation. CR after chemoradiation was doubled in the induction arm (50% vs. 21%, $p = 0.004$). Surgery for residual neck disease was higher in the concurrent chemoradiation arm versus the induction arm (34% [18/47] vs. 10.8% [5/46], $p = 0.012$). At a median follow-up of 42 months, no difference in median OS was noted between the two groups (40 vs. 33 months, $p = 0.268$).[197]

Thus, it appears that induction chemotherapy increases CR rates in patients treated with concurrent chemoradiation and those achieving a CR may be observed. Those with less than a CR clearly benefit from a planned neck dissection. There appears to be no difference whether the neck dissection is performed before or after radiation therapy, but should be incorporated as a planned procedure rather than as salvage. Whether these data are relevant in patients achieving a PR after induction chemotherapy followed by concurrent chemoradiation is unknown.

## Role of Imaging to Confirm CR after Definitive Chemoradiation

Determining which patients have achieved a CR after definitive chemoradiation of a node-positive neck is challenging, but progress has been made using imaging to identify such patients in a timely manner so that surgical salvage may be performed without undue morbidity. Clearly, a discordance exists between physical exam and imaging with standard CT with regard to pathologic findings seen on neck dissection. False negatives after a complete clinical response is seen in 20% to 40%, whereas false positives are noted in 60% with a clinical PR.[155]

***Computed Tomography.*** Multiple investigators have proposed radiographic parameters of CT scans done 4 to 8 weeks after treatment which correlate highly with pathologic CR or high rates of long-term regional control.

The University of Florida reported the radiographic–pathologic correlation between pre–neck dissection CT scans performed at 4 weeks post radiation treatment to the pathologic findings of neck dissection in 211 patients.[198] The study cohort were culled from 550 patients who were LN positive and treated with definitive radiation to the primary site (62% oropharynx, 16% hypopharynx, and 13% larynx). One-fourth received induction or concurrent chemotherapy, and planned neck dissection was performed in 341 patients within 8 weeks of completion of radiation. Of these 341 patients, 211 had CT scans at 4 weeks available for review. The radiographic characteristics with highest predictive value for a pathologic CR were absence of node >1.5 cm and no focally abnormal node (focal lucency, focal enhancement, or focal calcification). If these conditions were satisfied, the NPV was 94%. About 29% (61/211) of patients met these criteria. Of these 61, 29 proceeded to neck dissection and showed residual disease in 6% (2/29). Regional failure was 0% in these patients. The other 32 who did not undergo neck dissection and the regional failure rate was 3%.

Greven reported on 103 patients with node-positive disease with disease as follows N1 26 whereas 77 had N2/3 (N2a, 4; N2b/c, 65; and N3, 8) patients. Concurrent chemoradiation was delivered to 58 patients whereas 45 were treated with radiation alone. Seventy-seven patients had a posttreatment CT scan at a median of 4 weeks after treatment (range 2–24 weeks) whereas 24 were observed without scan. Radiographic CR was defined as <1.5 cm without necrosis. An rCR was attained of 49 of 103 patients, 50% of N1 and 47% of N2/3 patients attained an rCR. Posttreatment neck dissection was performed in 13 of N1 patients (50%) and 29 (38%) of N2/3 patients. Patients with rCR had higher neck control compared to those with rPR (95% vs. 85%). Ten patients of 49 with rCR underwent neck dissection with residual nodal disease in 60%. However, neck control was not improved in patients with rCR undergoing neck dissection versus none (97% vs. 89%, respectively, $p = 0.24$). In contrast, among rPR patients, nodal control was higher in those patients undergoing neck dissection (94% vs. 73%, $p = 0.14$) but with no difference in DFS. No improvement in DFS was noted in patients undergoing neck dissection in either those with rCR (50% vs. 87%, $p = 0.01$) or rPR (67% vs. 62%, $p = 0.93$), respectively.

Clavel reported on the Montreal experience evaluating the role of CT scan to monitor patients after definitive chemoradiation in 369 node-positive patients with 13% N1, 72% N2, and 15% N3 and oropharynx in 77%, larynx in 10%, and hypopharynx in 5%. Concurrent chemoradiation consisted of 5FU with either carbo- or cisplatin and in about one-third IMRT was delivered. CT was performed about 6 to 8 weeks after chemoradiation. CT parameters associated with a high rate of CR was a >80% decrease in the initial nodal volume from initial CT (NPV 100) and nodal size <1.5 cm without focal heterogeneity (NPV 86%). Overall, 71% of the group achieved a CR with N1, N2a, N2b, N2c, and N3 achieving a cR in 83%, 66%, 72%, 80%, and 45%, respectively. Among the 29% ($n = 106$) who achieved a PR, neck dissection was performed in 96 patients while 10 were observed. Neck dissection was performed at about 8 to 12 weeks after CT/RT and consisted primarily of selective neck in 55% and modified radical in 27%. Pathologic nodal disease was noted in 40%. Median follow-up was 44 months. Regional failure was 9%. Patients who achieved a CR or underwent neck dissection after PR had a regional failure of 4%. Among the PR patients, neck dissection appeared to increase regional control (50%–92%), DFS (40%–78%), and OS (40%–80%). Among 16 patients failing regionally, only 2 were salvaged.

Thus, it appears that CT characteristics of nodal size <1.5 cm without focal abnormality and nodal shrinkage >80% are important early predictors of CR but it should be noted that reliance of CT will not capture all patients who are successfully controlled regionally with definitive chemoradiation.

(c) 2014 Wolters Kluwer. All Rights Reserved.

***Functional Imaging with FDG PET/CT.*** The incorporation of PET/CT imaging in the posttreatment assessment of node-positive patients treated with chemoradiation has been well established to improve clinical-pathologic concordance compared to CT such that better selection is possible for those who may avoid neck dissection[152,153,159–163] (Table 14.9). In that regard, several studies have demonstrated the critical importance of timing of the PET in relation to the end of treatment to achieve maximal accuracy.

Greven reported on 45 patients followed with serial PET scans as well as either MRI or CT at 1, 4, 12, and 24 months after radiation therapy.[199] At 1 month, 36 patients had surveillance PET of whom 25 were reported as PET negative, but 7 had subsequent positive biopsies 3 to 12 months after radiation, 6 were positive on PET and confirmed on biopsy, 5 PETs were reported as equivocal but positive on biopsy in 4. Thus, at 1 month, the NPV was 72% (18/25) whereas the PPV was 100% (6/6). At 4 months, the NPV was 100% (18/18) with a PPV of 86% (6/7). The NPV remained at 100% at 12 and 24 months post treatment. Other groups reported the NPV ranging from 97% to 100% when a PET scan is done after 3 months.[152,161] The NPV was poor when a PET/CT was done at 1 month.

Timing of the PET/CT at 2 months after chemoradiation yield conflicting data regarding its NPV. Some have shown modest NPV whereas others have demonstrated high NPV. PET/CT at 6 to 8 weeks after chemoradiation was evaluated in 31 patients. Patients were treated on the RADPLAT regimen of high-dose targeted intra-arterial cisplatin during radiation therapy. N2/3 comprised 16/31 and 16% (5/31) were N1 and oropharynx were present in 58% while oral cavity, larynx, and hypopharynx each comprised about 10%. Patients were observed if a complete clinical response was achieved. Neck dissection were performed as salvage treatment for clinically suspicious residual disease based on imaging and physical exam. Median follow-up was 24 months. For the 21 N1–3 patients, 3 patients had persistent FDG uptake with confirmation of residual disease on neck dissection and thus the PPV was 100% but due the limited sample size, the authors opted to report the PPV of 75% or greater to account for the next collected event assuming it was positive. They reported an NPV of 94%. For the primary site, the PPV was lower at 31% with similar NPV (92%). Chen also reported a high NPV when PET/CT is done at 2 months. Thirty patients with node-positive disease underwent PET/CT and contrast enhanced CT at about 7 ± 4.4 weeks (range 2–24 weeks) after treatment. Pathologic residual disease was noted in 28%. All patients were oropharynx or unknown primary and 25 were N2/3. The PPV for the neck was 36% for PET/CT but the NPV was 100%.[200]

In contrast, Gourin reported on 32 N2/3 patients treated with concurrent chemoradiation with PET/CT at 8 to 11 weeks after chemoradiation and planned neck dissection.[201] N3 comprised 6 of the 32 with oropharynx in 25/32, larynx in 5, and hypopharynx in 2. PET/CT was positive in 63% (20/32); however, pathology was positive in 31% ($n = 10$), six of whom had a positive PET and four with a negative PET, yielding a PPV of 30% (6/20) and NPV of 67% (8/12). Thus, authors conclude that PET/CT at 8 to 11 weeks is a poor predictor for patient needing neck dissection.

Similarly, Waldron reported a prospective trial to evaluate the benefit of PET/CT to predict need for neck dissection after definitive radiation therapy in 399 patients with N2–3 disease. CT and PET/CT at a mean of 9.2 weeks (8–10 weeks) following definitive RT with or without chemotherapy. Patients with residual nodes >1 cm underwent neck dissection. Sites of disease were primarily oropharynx (75%) but also oral cavity (8%), hypopharynx (8%), and unknown primary (14%). N2 disease comprised 90% and N3 10%. A total of 152 neck dissections were performed and 201 necks were observed. Three hundred twenty-five patients were followed for at least 18 months. PET/CT sensitivity was significantly lower than CT (53% vs. 94%). The regional failure rate was 4% in those who were observed. The NPV was 73% and PPV was 44%.[202]

***PET/CT 3 Months after Chemoradiation.*** Consistently, PET/CT 3 months or later after treatment yields high rates of NPV >95% and improved rates of PPV. A prospective trial correlated PET with pathologic findings in 23 patients with N2b or greater disease (70% oropharynx) treated with concurrent chemoradiation in 87% (20/23).[203] PET scans were done at a median time 13.3 weeks (6.3–26.1 weeks). Seventeen patients underwent neck dissection (1 patient bilateral) and 6 patients with residual nodes >1 cm underwent fine-needle aspiration (FNA). Pathology showed 19 negative nodes and 5 neck with residual disease. Using a maximum standardized uptake value (SUV) of 3.0 or greater as positive, 8 of 24 necks were considered positive and 16 negative. Of the 8 PET positive necks, 5 were positive and all 16 PET negative were pathologically negative. The NPV was 100% and PPV was 63%. Therefore, the group recommends PET to be done at 3 months after radiation and defined a negative PET as having an SUV <3.0.[153]

A follow-up prospective study validated the use of PET/CT to select patients who may have omission of neck dissection after definitive radiation.[204] Ninety patients with N2/3 neck disease (N2a: 12%; N2b: 43%; N2c: 31%; N3: 13%) with 71% oropharynx were evaluated using PET/CT to evaluate the need for neck dissection after definitive treatment to the involved nodes and primary site. IMRT was used to deliver 70 to 74 Gy to involved neck nodes defined as those >1 cm, exhibiting focal necrosis or having abnormal PET uptake. Cisplatin chemotherapy was given in 74 patients (73 concurrent). Sixteen patients had residual nodal

disease after treatment, of which 13 had neck dissection while 2 refused and 1 had distant metastasis. Seventy-four patients were observed without neck dissection. All had negative CT scans and 64 had negative PET scans done at 3 months. Among the observed patients, at a median follow-up of 29 months, regional failure occurred in 1 patient for a regional failure of 1% and a corresponding NPV of 98% (1/63) for PET scans at 3 months. Of the 13 patients undergoing neck dissection, 43% were pathologic positive and thus the PPV was 62%. For all 90 patients, the 3-year regional failure was 5% and local control 96%. The incidence of distant metastasis was 20% and OS was 68%.

The role of PET in the management of neck nodes was reported in 53 patients with N2a disease or greater.[205] The N staging was as follows: N2a = 3, N2b = 25, N2c = 15, N3 = 8, N2 (nasopharyngeal) = 2. All patients had CR of the primary site after treatment with definitive radiation therapy with or without chemotherapy. PET scans were done at median time of 15 weeks posttreatment (5 to 29 weeks). Seventy heminecks were evaluated with bilateral neck performed in 17 patients. No residual lymphadenopathy was noted on CT scan and negative PET were seen in 42 heminecks, and all were observed without neck dissection. Residual lymphadenopathy with positive PET was seen in seven heminecks and all were evaluated pathologically, six undergoing neck dissection and one having an FNA. Three contained residual neck disease and four pathologically negative. Residual lymphadenopathy with negative PET was noted in 21 heminecks. Neck dissection was performed in four at the discretion of the clinician. All four were pathologically negative. At a median follow-up of 26 months, no regional failure was identified nor were there any local failures. The NPV of PET was 100% and PPV 43%. The authors conclude that a patient with no residual lymphadenopathy and negative PET at 12 weeks after definitive radiation therapy warrants observation.

Rabelais reported on 52 node-positive patients managed with concurrent chemoradiation. Approximately, 62% were N2 with 27% N1, 56% were oropharynx, and 33% larynx cancers. PET/CT was done at a median time of 12 weeks after chemoradiation. Ten patients were PET/CT positive in the neck. Five were followed due to patient refusal or medically inoperable. Two of the five had residual palpable lymphadenopathy. All five were followed by serial PET/CT and became pet negative without obvious neck recurrence at 1-year follow-up. Three patients underwent neck dissection with 2 of 3 positive for residual disease. Two patients had disease documented in the neck on FNA and the other developed metastatic disease. Eleven patients had palpable lymphadenopathy at the end of treatment with 5 having PET/CT positivity and 6 negative. Among those that were PET/CT positive with palpable nodes, three were confirmed pathologically and two patients were followed by serial PET/CT without evidence of recurrence. Among the six patients that were PET/CT negative with residual nodal disease, two had neck dissection that showed no residual cancer while four were followed serially without evidence of neck recurrence. The PPV was 42% and NPV was 100%.

Loo reported on 34 N2 patients treated with induction chemotherapy followed by radiotherapy (with concurrent chemotherapy in 79%). Oropharynx comprised 82% (28/34) of patients. Patients underwent PET/CT 3 months after radiation therapy. PET/CT was positive in the neck in 1 of 34 patients, and salvage neck dissection showed no residual disease. The neck was observed if PET/CT was negative. At a median follow-up of 39 months, no regional failures were reported with five recurrence (two distant metastasis and three local failure/persistent disease).[206]

Wang reported on 44 patients treated with induction chemotherapy followed by concurrent chemoradiation. Tumor sites comprised hypopharynx in 45%, oropharynx in 39%, and larynx in 9%. PET scans without CT were performed at a minimum of 12 weeks and median 16 weeks post chemoradiation. All patients had CT scans done at 2 months post chemoradiation and residual nodal disease defined as positive if 1 cm or greater. Seventy-five percentage of patients had N2/3 disease. Neck dissection or FNA evaluation was performed in patients with residual nodal masses or FDG avid disease. Patients with CR on exam and PET were observed. Fourteen patients had residual palpable nodal disease and 9 of them were FDG avid and confirmed on pathologic evaluation whereas 5 were negative on PET and 2 were confirmed as negative on neck dissection and 3 showed no evidence of regional recurrence at 6 months. The PPV and NPV were 100% in patient with residual nodal masses. Of 30 heminecks without palpable residual nodal disease, 2 had a positive FDG scan, both of whom had neck dissection with pathologic confirmation in 1 patient; thus the PPV was 50% and NPV was 100%. For distant metastasis, the PPV was 83% and NPV was 100% whereas for the primary site the PPV was 79% and NPV was 100%. In contrast for CT scans done at 2 months, the PPV was 64% and NPV was 97%. Interpretation of the PET and CT scans were done independently.

Thus, current studies suggest that PET scan at 3 months may offer the best test to monitor patients who are observed after a cCR. The promising results of PET need confirmation at multiple centers and longer follow-up with standardization of PET guidelines. The ability of PET to select out patients at risk for distant metastasis is an important area to be addressed as even the Yao study revealed a rate of metastasis of 20%. Moreover, the role of CT to assess cCR as well as the role of limited surgery (excision of initially involved nodes vs. more extensive surgery with SND) to evaluate patients with clinical PR remain to be defined. A randomized study comparing planned neck dissection to neck dissection only in patients with a positive PET scan after chemoradiation is underway in the United Kingdom.[207]

***Value of PET beyond CT.*** Some have questioned the added value of PET over CT. Tan reported the Cleveland Clinic experience among 48 patients who underwent PET/CT or PET and CT at median 2.5 months (1.1–5.3 months) after chemoradiation (cisplatin/5FU). Ninety-three percent were node positive with 28% having N1, 50% having N2, and 15% having N3 disease with planned neck dissection in the majority of patients ($n = 27$) and salvage neck dissection in 5 patients. Pathologic residual disease was noted in 5/33 and 3/5, respectively. PET and CT were analyzed separately as well as clinical examination to determine the ability to predict for residual nodal disease. PET was called positive if any signal was detected in the node and CT was positive if nodes were >1 cm, contrast enhancing, or centrally necrotic. PET on its own was not able to predict for those with residual nodes but CT and clinical examination were able to. PET and CT, clinical exam and CT, or clinical exam and PET yielded accuracies of 87%, 79%, and 90%, respectively, with NPV of 95%, 94%, and 93%, respectively, and PPV of 20%, 25%, and 33%, respectively. In the setting of a positive CT and or clinical exam, 8 of 11 patients with residual neck disease or neck recurrence was detected. Among the three other patients with persistent or recurrent disease, only one was detected after 45 PETs were performed whereas two would have been missed. The authors question the added utility of PET scan despite such a low threshold for calling the PET positive.

The added benefit of PET over CT at 8 weeks postradiation treatment may be restricted to poor-risk patients. PET and CT was performed for 98 patients at a median time of 8 weeks (5–12 weeks), the majority of whom were nonsmoking males with stage IV oropharyngeal cancer. Seventy-eight patients received chemotherapy. Twenty-two patients underwent planned or salvage neck dissection at median time of 12 weeks after treatment. At a median follow-up of 23 months, the 2-year loco-regional

(c) 2014 Wolters Kluwer. All Rights Reserved.

control was 88%, OS 91%, and disease-specific survival 90%. For all patients, PET did not add to the accuracy of CT scan nor did it appear to improve the NPV for the primary site (96% vs. 97%, respectively) or node (96% vs. 98%, respectively) or for PPV (58% vs. 50% for the primary site and 27% vs. 23% for nodal site). However, if patients were stratified at low versus high risk for recurrence by T0–2 vs. 3–4, N0–2a vs. N2b–3), primary site (oropharynx vs. nonoropharynx), smoking (user vs. nonuser), HPV status, overall stage, PET did increase the PPV over CT alone from 38% to 75% for nodes and from 71% to 100% for the primary site. This increase in PPV appeared to be strongest in those stratified by risk by HPV status such that HPV-negative patients benefited from PET. ROC analysis showed the a threshold SUV max of 2.8 was the best predictor of failure for nodes and 6.5 for the primary site.

Ong reported on the MSKCC experience and demonstrated that the value of PET was to increase the PPV and accuracy of CT findings after chemoradiation treatment node-positive patients. PET/CT was done at a median time of 12 weeks (8–27 weeks) CT criteria for CR was defined as nodes <1 cm. Sixty-five patients with 84 node-positive necks were evaluated with N1 in 17% (14/65), N2 in 75% (49/65), and N3 in 3% (2/65). Oropharynx comprised 75% of patients (49/65) with larynx in nine and hypopharynx in seven patients. Neck dissection was performed in 17 patients based on N2–3 status, physical exam, and imaging results. Among 84 heminecks, CR by the CT component of the PET/CT was 65% (55/85) with CR by N stage as follows: N1, 93% (13/14); N2, 65% (42/65); and N3, 50% (1/2). Among the patients attaining CR, the PET was positive in 5% (3/55), one of which was a true positive. Among the 35% ($n = 29$) not attaining a CR, PET was positive in 34% (10/29). NPV with CT alone was 96%. PET decreased the false-positive rate of CT imaging from 23% to 10%. PET/CT done >12 weeks after chemoradiation had a higher PPV (67% vs. 14%) compared to those done from 8 to 12 weeks. NPV was 94% and 100% at those time periods, respectively. Accuracy increased from 77% to 95% if performed >12 weeks. The authors recommend observation for patients attaining CR by both CT and PET criteria and neck dissection in patients that were positive on both imaging modality. For patients either that are PET positive CT negative or PET negative CT positive, observation or neck dissection should be considered.[208]

## Planned Neck Dissection versus Primary Chemoradiation Alone for N2/3 Disease?

In summary, among N2–3 patients, regional control with the addition of a planned neck dissection appears to improve control by about 5% to 15% as regional failure occur in 1% to 7% (see Tables 14.6 and 14.10) while neck failure occurs in 8% to 25% in patients who achieve a CR and are observed after concurrent chemoradiation without planned neck dissection. For N2/3 patients treated with definitive concurrent chemoradiation, the regional CR rate was 40% to 80% after definitive concurrent chemoradiation regimens.[155,156,158] Thus, approximately 20% to 60% may have received definitive doses without the benefit of being spared neck dissection. Consequently, they are at risk for increased wound complications after exposure to higher doses compared to those treated with reduced dose radiation in conjunction with planned neck dissection. However, it may also be argued that definitive treatment spared 40% to 80% of patients a neck dissection and its consequent morbidity. Whether this translates into improved survival is not clear based on current data.[155,158] The dilemma highlights the importance of selecting patients with nodal disease that have a high probability of attaining CR and also the need for posttreatment evaluations that can confirm a CR or residual disease with high accuracy. Patients

**TABLE 14.10 Regional Control after Definitive Radiation or Chemoradiation for Node-Positive Disease**

| | Number of Patients | Regimen | Median Follow-up (mo) | PET | Regional Failure |
|---|---|---|---|---|---|
| **RT alone** | | | | | |
| Peters et al. (1996)[131] | 62 | Delayed concomitant boost | 39 mo | No | 11% |
| Chan et al. (2001)[250] | 80 | CF or split course accelerated RT | 4 yr (mean follow-up) | No | 20% |
| Bataini et al. (1987)[128] | | | | | |
| Node<3 cm | 467 | Accelerated RT | NS | No | 10% |
| Node 3–6 cm | 141 | Accelerated RT | | No | 15% |
| Node > 6 cm | 67 | Accelerated RT | | No | 25% |
| **CT/RT** | | | | | |
| Calais et al. (1999)[251] | 108 | Concurrent RT + 5FU/carboplatin | 35 mo | No | 19% |
| Sanguinetti et al. (1999)[252] | 43 | Alternating CT/RT 60 Gy | 16 mo | No | 44% |
| Grabenbauer et al. (2003)[192] | 41 | Alternating CT/RT | 37 mo | No | 15% |
| Argiris et al. (2004)[155] | 39 | Concurrent CT/RT | 55 mo | No | 18% |
| Dequanter et al. (2006)[191] | 25 | Induction or concurrent CT/RT | 11 mo | No | 20% |
| de Arruda et al. (2006)[253] | 50 | CDDP + IMRT | 18 mo | No | 12% |
| Porceddu et al. (2005)[205] | 39 | RT or concurrent CT/RT | 34 mo | Yes | 4% |
| Yao et al. (2004)[204] | 79 | CDDP + IMRT | 29 mo | Yes | 1% |

with N1–2 disease may be the best candidates for omission of neck dissection, whereas N3 or bulky disease extending into the low neck may best be treated with planned neck dissection.

## HPV Status and Need for Planned Neck Dissection

The University of Virginia reported their experience of 69 oropharyngeal cancer patients with node-positive disease. Nodal staging was N1 in 26%, N2a in 8.7%, N2b in 42%, N2c in 20%, and N3 in 3%. Sixty-eight percent were p16+. Patients in the p16+ group had an equal distribution of tonsil/base of tongue subsites whereas those that were p16- had more tonsil/base of tongue subsites (64% vs. 27%). HPV-positive patients had a greater incidence of contralateral nodes (28% vs. 5%, chi sq. $p$ = .09) with more advanced nodal N2c–N3 stage (32% vs. 5%) in p16-negative patients. No difference was reported in presence of radiographic extracapsular spread, overall stage, and T stage. Two-thirds of patients in both groups underwent posttreatment neck dissection. Patients in the P16+ group had chemoradiation (64% vs. 32%, $p$ = 0.01). Neck dissection was performed if N2–3, evidence of radiographic extracapsular disease was present pretreatment, or residual disease was seen on imaging post treatment. Forty-seven underwent a planned neck dissection. Among those undergoing neck dissection, pathologic residual disease was found in 18% versus 50%, $p$ = 0.02 of p16+ versus p16− patients, respectively, corresponding to an odd ratio for residual neck disease of 4.57.

Neck dissection complication rates occurred in 40% of patients and consisted of shoulder weakness, perioral weakness, wound infection/dishiscence, chyle leak, chronic pain, and seroma. No difference was noted based on p16 status. Complications resolved in all patients who underwent nonradical neck dissection. Of note, except for one, all patients with p16+ tumors with residual viable tumor were smokers/drinkers and who showed residual disease on imaging. The authors proposed an algorithm to consider neck dissection based on presence of radiographic evidence of extracapsular extension, residual disease on imaging, smoking, and alcohol status.

## Prognostic Implication of Pathologic Residual Disease on Neck Dissection After Chemoradiation

Pathologic residual disease is found in one-third of neck specimens in N2/3 patients treated with concurrent chemoradiation followed by neck dissection. Multiple reports indicate that such residual disease prognoses an adverse outcome with authors reporting various endpoints (Table 14.11). Lavertu demonstrated that patients with pathologic residual disease had worse survival compared to pathologically negative patients (50% [6/12] vs. 83% [4/23], $p$ = 0.03).[156] Stenson also reported that among the 58 patients with pathologic CR, the 3-year OS was 72% compared to 36% in 15 patients with residual neck disease ($p$ = 0.008).[154] In a separate study, Stenson reported a dose–response relationship between the incidence of pathologic residual disease and radiation dose to the neck.[209] Patients were treated on three sequential protocols in which radiation dose to gross disease was kept at 75 Gy whereas dose to the high- and low-risk areas were reduced from 60 Gy → 54 Gy → 51 Gy and 45 Gy → 39 Gy → 36 Gy, respectively. Pathologic residual disease occurred in 6%, 14%, and 33% in patients receiving the standard high, intermediate, and low doses, respectively ($p$ = 0.013). Sewall reported an increased risk for regional failure with residual neck disease. Regional failure was 13% (4/30) versus 1% (1/77) in patients with or without pathologic residual disease, respectively. Newkirk reported that in 33 patients treated with radiation ($n$ = 20) or chemoradiation ($n$ = 13) pathologic residual disease corresponded with an increased risk for local recurrence (33% vs. 0%, $p$ = 0.013) compared to those patients with a pathologic CR.[210] Pathologic residual disease status did not impact OS, distant metastasis, or regional control. No mention is made about whether the presence of residual neck disease had any different

**TABLE 14.11 Prognostic Implication of Pathologic Residual Disease on Neck Dissection after Chemoradiation**

| Author | Number of Patients | Pathologic Residual Disease (%) | Survival (pLN+ vs. pCR) | Distant Metastasis (pLN+ vs. pCR) | Regional Failure (pLN+ vs. pCR) | Local Recurrence (pLN+ vs pCR) |
|---|---|---|---|---|---|---|
| Sewall et al. (2007)[210] | 107 | 28% | | | 13% vs. 1% | |
| Hu et al. (2007)[211] | 82 | 29% | DFS: 47% vs. 85% $p$ = 0.013 | 41% vs. 11% $p$ = 0.011 | 14% vs. 4%, $p$ = 0.376 | |
| McHam et al. (2003)[157] | 76 | 33% | | | 20% vs. 0% $p$ < 0.001 | |
| Stenson et al. (2006)[209] | 73 | 21% | 3 yr OS: 36% vs. 72% $p$ = 0.008 | | | |
| Argiris et al. (2004)[155] | 61 | 31% | 5 yr PFS:62% vs. 80% $p$ = 0.11 | | | |
| Ganley[210a] | 56 | 33% | 49% vs. 93 ($p$ = 0.005) | 42% vs. 8% | 16% vs. 5% | 26% vs. 11% |
| Lavertu et al. (1997)[156] | 35 | 34% | 50% vs. 83% ($p$ = 0.03) | | | |
| Newkirk et al. (2001)[141] | 33 (39% received concurrent CT/RT) | 45% | | | | 33% vs. 0% |

prognostic implication in chemotherapy versus the nonchemotherapy treated patients.

Hu reported that the presence of residual pathologic nodal disease in a planned neck dissection predicts an increased risk for distant metastatic disease and worse DFS in 82 patients with N2/3 necks. Patients were treated with chemotherapy and a reduced dose of 60 Gy to involved nodes whereas the primary site was treated with definitive dose of 70 Gy with conventional or accelerated radiation by delayed concomitant boost.[211] Concurrent chemotherapy consisted primarily of high-dose cisplatin (100 mg/m$^2$ q 3 weeks for 2–3 cycles). A planned neck dissection was performed within 6–8 weeks upon completion of chemoradiation. Ninety-nine planned neck dissections were performed in 82 patients. The initial N stage were as follows: N2a, 5; N2b, 34; N2c, 22; and N3, 16. Pathologic residual disease was detected in 29% of neck specimens. The incidence of pathologic residual disease did not appear to correlate with initial neck stage and was as follows: N2a, 60%; N2b, 19%; N2c, 42%; and N3, 33%. Median follow-up was 2 years. For all patients, the 2-year estimate of regional failure was 4% and the incidence of 2-year DM was 11% with 2-year OS of 91%. The incidence of DM correlated with initial N stage (N2a: 0%; N2b: 7%, N2c: 28%, and N3: 42%) and the presence of pathologic residual disease (3-year DM: 11% vs. 41%, if pCR vs. pathologic residual disease). Patients with a pathologic residual disease had worse DFS than did patients with pathologic CR (3-year DFS: 47% vs. 85%, $p = 0.013$).

Ganley reported on 56 patients with node-positive disease treated with concurrent chemoradiation who underwent planned or salvage neck comprehensive neck dissection. Oropharynx comprised 71%, larynx 20%, and hypopharynx 9% with N1 11%, N2 78%, and N3 11%. Twenty-one percent had a CR. Fifty-four percent underwent resection 6 to 12 weeks after radiation whereas 39% had >12-week interval. Thirty-three percent (19/56) had pathologically confirmed viable tumor with a higher rate on partial versus complete responders (42% vs. 25%, $p = 0.1$). No correlation with pathologic residual disease and time interval between radiation and neck surgery (36%, 33%, and 25% at >12 weeks, 6–12 weeks, and <6 weeks, respectively). Patients with viable tumor had worse overall and recurrence-free survival (49% vs. 93%, $p = 0.005$ and 40% vs. 75%, $p = 0.004$, respectively). Failure occurred in 63% (12/19) of patients with residual viable tumor with regional failure in three, local failure in five, and distant failure in eight. Failure in the patient with no viable tumor was 16% (6/37) with local failure in four, regional failure in two, and distant metastasis in three.

Dagum reported on a series of 41 patients with node-positive disease undergoing organ-preservation therapy with induction cisplatin/5FU followed by concurrent chemoradiation consisting of 5FU/CDDP with radiation for organ preservation.[212] Seventy-eight percent had N2/3 disease (32/41). Patient with pathologic residual disease had worse survival with a trend toward increased regional and distant failure compared to those with no residual disease. Patients with pathologic residual disease also had worse survival compared to complete responders to chemotherapy and radiotherapy who were observed.

Consistently, the presence of pathologic residual disease predicts worse outcomes at multiple endpoints and is a likely indication of the responsiveness of the tumor to a particular chemoradiation regimen. This not only is important in close monitoring for locoregional recurrence, but also may predict the potential of the particular chemotherapy regimen to decrease distant metastasis, which is likely to occur in at least 20% to 25% of all N2/3 patients. It has been shown that as locoregional control rates improve, the dominant pattern of failure is that of distant metastasis.[213] Whether the presence of residual disease may select out a patient population for additional systemic chemotherapy or biologic treatment or close monitoring remains an area of future investigation.

## Posttreatment Surveillance Regimen

The surveillance of patients after combined chemoradiation remains controversial with respect to the timing and type of imaging modality which is used to follow these patients. It is generally accepted for the first 8 weeks after treatment, all imaging studies should be withheld to allow for resolution of inflammation and resolution of persistent disease which is in the process of regressing. It is at about the 8-to-12-week period that imaging can be performed and interpreted with some reliability. Imaging that relies on anatomic morphology such as MRI and CT scans can be performed at 8 to 12 weeks and if there is any doubt, the findings can be repeated serially at 3-month intervals. PET-CT is the imaging modality of choice because it not only examines for anatomic abnormalities but also examines for metabolic activity. The fusion of metabolic imaging with its anatomic correlate has a very high NPV making it an extremely valuable tool in surveying patients who have been treated with combined chemoradiation. The ideal timing of a baseline exam is at 12 weeks after the completion of therapy.[214] Repeat imaging is performed at 6-month intervals.

## Postoperative Chemoradiation

***Role of Neck Dissection in trans oral robotic surgery (TORS).*** One of the difficulties with treating carcinomas of the oropharynx (base of tongue, tonsil, pharynx, soft palate) is the surgical access to these areas. In the not-so-distant past, the only way to surgically access these areas was to perform a large open procedure, which often required a mandibulotomy and mandibular swing. This approach was difficult and highly morbid, and hence, as chemoradiation became increasingly more effective, it rapidly became the standard of care for treating carcinomas of this part of the head and neck. Recently, transoral robotic surgery has become an important new addition to the treatment algorithm for cancers of the oropharynx. The robotic arms and high-powered three-dimensional visualization have enabled surgeons to now access remote parts of the upper aerodigestive tract (oropharynx and hypopharynx) without the need the mandibular swings and tracheostomies.

TORS is an effective treatment approach to the primary tumor but one must also manage the cervical lymphatics. The neck can be managed concomitantly with the TORS procedure or in a staged fashion. Many surgeons are currently staging the neck dissections in an attempt to reduce the incidence of salivary fistula formation.[215] The neck dissections can then be performed 2 to 4 weeks after the TORS procedure. Recently, Moore et al. published their experience with 148 consecutive TORS procedures with synchronous neck dissection for oropharyngeal SCCa.[216] Although 42 of the 148 patients were identified as having intraoperative oropharyngeal–cervical communication, they were all managed with primary closure, local tissue advancement, fibrin glue application, and cervical drain placement. Six of the 42 (4%) patients developed a pharyngocutanous fistula, which were all managed conservatively. None of the patients experienced a delay in the initiation of adjuvant therapy. Boudreaux et al. also reported nine cases of robotic-assisted oropharyngectomy with synchronous neck dissection with no patients developing a postoperative pharyngocutaneous fistula.[217] Genden et al. reported their experience with 15 patients who underwent TORS with a concomitant neck dissection and found that 1 patient had an intraoperative communication with the neck, which was closed with a local muscle flap, and no patients developed a postoperative pharyngocutaneous fistula.[218] Although TORS is relatively new and the decision to perform the neck dissection simultaneously or in a staged fashion has not been resolved, it seems that both approaches are reasonable and neither approach significantly delays adjuvant therapy. Regardless of the timing of the neck dissection, it seems

(c) 2014 Wolters Kluwer. All Rights Reserved.

to be universally accepted by the head and neck surgery community, which is actively performing TORS, that a neck dissection should be performed for N0 and N+ necks. The information from the neck dissection specimen can be very important in deciding on the role and form of adjuvant therapy.

## Role of IMRT in the Management of the Neck

With increased ability to deliver highly conformal therapy, defining nodal levels at risk is crucial and has significant implications for long-term functional outcomes particularly swallowing and xerostomia. Conformal therapy allows sparing of parotids either by constraining dose to the superficial parotid lobe or by allowing differential coverage of nodal levels whereby the high level II/retrostyloid/junctional nodes are spared on a clinically negative contralateral neck.

With the advent of conformal therapy using IMRT, the identification of gross and nodal stations at risk for subclinical disease are crucial in designing the optimal treatment. Target delineation is challenging as the rationale for treatment is based on surgical data; however, the landmarks used are radiographic ones that do not use the exact surgical landmarks identified on neck dissection. Several groups have attempted to correlate radiographic boundaries with anatomic outlines defining the nodal stations reported by Robbins representing the American Academy of Otolaryngology (AAO).[51,60,62,63] These groups have also defined nodal stations not precisely defined by the AAO such as the retropharyngeal and supraclavicular nodes. Consensus guidelines have been achieved for necks that are to be treated electively, therapeutically, and postoperatively.[219,220]

Consensus boundaries for the clinically negative neck are delineated in Table 14.04a and Figure 14-1. The jugular nodes are defined by their relation to the internal jugular vein with the superior border in a node-negative neck defined by the posterior belly of the digastric muscle crossing the jugular vein or the inferior border of the C1 transverse process. In node-positive necks, coverage of the high jugular nodes are added, which incorporates the retrostyloid nodes above the digastric muscle and lie in the carotid space in front of the internal carotid artery/internal jugular vein up to the jugular foramen.[219] The hyoid bone, cricoids cartilage, sternocleidomastoid muscular, jugular vein, and submandibular gland represent important landmarks defining the jugular nodal stations. The trapezius muscle is critical for delineation of level V and the mandible and tongue muscles define level I nodes. The retropharyngeal nodes are divided into medial and lateral chains and are defined by the medial border of the carotid artery, the skull base, and the top of the hyoid bone.

The primary difference between node positive and node negative is coverage of the retrostyloid space cranially and the supraclavicular fossa caudally.[219] If extracapsular extension is demonstrated radiographically or pathologically, coverage of the adjacent muscles (e.g., sternocleidomastoid muscle) is included with a 1-cm margin based on pathologic data demonstrating that >95% of all extracapsular disease is encompassed within 1 cm of the involved nodal capsule[221] (see Fig. 14-1). Positive nodes at the junction of two nodal levels should include both nodal levels in the target. In the postoperative setting, the surgical bed should be included especially in the presence of extracapsular extension where tumor spillage into the tumor bed is possible. For positive nodes in the pharyngeal tumors, the retropharyngeal nodes should be included. The retropharyngeal nodes are divided into medial and lateral chains, the lateral nodes also called the nodes of Rouviere. Since the lateral retropharyngeal nodes are involved first, it is reasonable to exclude the medial retropharyngeal nodes in an attempt to partially spare the superior and middle constrictor muscles which may reduce long-term dysphagia.

Consensus guidelines regarding delineation of neck node levels have been reached for the node-negative, node-positive, and postoperative neck. In outlining tumors based on the nodal levels defined by the 2002 American Academy of Otolaryngology–Head and Neck Surgery consensus reported by Robbins et al.,[61] Som translated the anatomic boundaries to identifiable landmarks based on CT imaging.[63]

Several single-institution studies have reported outcomes in head and neck cancer treated with definitive and postoperative radiation.[14,60,222,223] Eisbruch reported the importance of covering retropharyngeal nodes to the skull base rather than to C1.[223] Thorstad reported the importance of avoidance of underdosage of nodes near the deep lobe of the parotid gland, which is intentionally dose constrained. Also, others have reported marginal recurrence at the match line and low-neck fields.[224] Levandag reported on 57 patients whose necks were treated with 3D conformal therapy using a defined CT-based neck nodal delineation system defined by the Rotterdam group.[60] Forty-six received definitive radiation to the primary site of whom 13 received definitive radiation to 15 node-positive necks and 11 underwent preoperative radiation for a node-positive neck. The group consisted of 81 node-negative necks and 26 node-positive necks. Node-positive patients were treated to 70 Gy and node-negative and preoperative node-positive neck received 46 Gy. Primary sites were primarily larynx ($n$ = 29), oropharynx ($n$ = 24), and also hypopharynx ($n$ = 7) as well as one oral cavity patient. At a median follow-up of 29 months, the regional failure rate was 8.6% (4/46) with a 3-year actuarial estimate of 10%. All four failures occurred in supraglottic larynx patients, and all occurred in contralateral initial N0 necks.

## Management of Recurrent Neck Disease

Recurrent squamous cell carcinoma in the neck is difficult to manage for multiple reasons. A complete or comprehensive removal of the nodal disease is not always possible due to extracapsular extension into vital structures such as the carotid artery or fixation to deep tissues such as the prevertebral fascia. Additionally, prior surgery and radiation therapy can result in severe fibrosis making the surgical dissection extremely difficult and often impossible to perform a definitive resection of all gross and microscopic disease. Moreover, recurrent disease to the neck is associated with a high risk for DM and treatment resistance due to prior multimodality therapy. Given the morbidity of uncontrolled regional disease, palliative treatment should be considered.

In a retrospective analysis of 139 patients with neck disease treated with prior radiotherapy at the University of Florida, Mendenhall et al. note that the majority of patients failing in the neck did not undergo an attempt for salvage due to unresectable disease at the primary site or the presence of DM.[126] In total, only nine patients underwent an attempted salvage. Although the details were not provided, of 25 patients failing in a solitary lymph node, 6 underwent attempted salvage with only 2 being successful. A follow-up study reported the outcomes on 51 patients who failed regionally after primary radiotherapy.[225] These patients represented 14% of 356 patients treated with primary radiation therapy without neck dissection. Nodal recurrence occurred at a median time of 5.4 months after radiation. One-third ($n$ = 18) were candidates for salvage treatment as the other patients were unresectable, medically unfit, or had distant metastasis. Of these, 14 underwent salvage neck dissection. Complications included soft tissue necrosis in four patients, vocal paralysis in two, separation of the flap in one, chylous fistula in one, and hemorrhage in one. One of 14 was salvaged with long-term neck control. For the entire group who were eligible for salvage surgery, the 5-year regional control was 9% and absolute survival was 10%.

(c) 2014 Wolters Kluwer. All Rights Reserved.

In an update, Liauw reported on 54 regional failures in 550 node-positive patients treated with definitive radiotherapy. Isolated regional failure occurred in 13 patients, 11 of whom had previous neck dissection and 2 without neck dissection. Nine patients underwent attempted surgical salvage with or without reirradiation therapy. Four of nine patients were successfully salvaged with one salvaged with surgery alone, one undergoing $^{125}$I brachytherapy with surgery, and one retreated to a total dose of 70 Gy. Three of nine patients experienced wound breakdown. For the entire group, the 5-year OS was 25% and regional control was 28%.

Similarly, Peters et al. describe only one of seven attempted salvage neck surgeries being successful.[131] Bernier reported on 116 patients with isolated nodal failures from a group of 1,646 patients treated with primary radiation at the Institute Curie.[129] Of these, only 14 had salvage neck dissection. Salvage was successful in only one for an overall success rate of 1% (1/116).

Despite dismal salvage rates, several retrospective series report on the efficacy of using interstitial brachytherapy implant or intraoperative radiation therapy in combination with salvage neck dissection, typically in necks previously irradiated and dissected. Often, these series mix primary and neck recurrences and treatment of nonrecurrent lesions, reflecting the heterogeneous spectrum of neck recurrence scenarios.[226–229] Despite the heterogeniety, the treatment strategy of combining salvage surgery with brachytherapy or IORT does appear afford meaningful control of neck relapses. Although no comparative studies have been reported, efficacy has been inferred based on clinical experience expecting further neck relapse within the first 1 to 2 years with the majority of patients receiving an implant showing at least a delay to progression.[228] Although a brachytherapy implant permits sufficient cytotoxic doses to be delivered at a defined volume that limits the risk for complications, the risk for wound complications may be further reduced by a planned coordinated introduction of nonirradiated tissue flaps. Both pedicle myocutaneous flaps[230] and microvascular free flaps have been described.[231] In turn, the introduction of nonirradiated skin and soft tissue further serves to minimize the risk for carotid exposure and rupture and may facilitate further external beam irradiation to be delivered. Typically, low dose rate implants used either iodine-125 ($^{125}$I) (Fig. 14-4) or $^{192}$Ir (Fig. 14-5). The former is typically used as a permanent interstitial implant with advantages of reduced radiation exposure. The latter is advantageous as it provides more generous coverage of the tumor bed, has the ability to after load providing an opportunity for dosimetric optimization, and permits sufficient wound fibrogenesis minimizing the risk for wound dehiscence.[232] In general, control rates of approximately 40% to 80% have been reported with complication rates of 20% to 50%. Hence, patient selection is particularly important for this indication.

Chen et al. reported on 24 patients with advanced recurrent HNSCC, using salvage surgery and $^{125}$I implantation delivering a minimum dose of 100 Gy to the tumor bed with a pedicle myocutaneous flap covering the carotid artery.[233] Neck failure was the sole or at least one component of the relapse in 19 patients. Local disease control was 42%. Two-year overall and cause-specific survivals were 29% and 50%, respectively, with a major complication rate of 21% and an overall complication rate of 50%. Two patients developed carotid rupture but in the presence of further neck recurrent disease.

Park et al. reported on 39 $^{125}$I implants in 35 patients with extensive recurrent HNSCC following salvage surgery with indications of either a close or positive resection margin.[234] The neck was implanted in 44% of the cases. The average dose delivered was 82.8 Gy. The 5-year local control rate, DFS, and OS were 29%, 41%, and 29%, respectively. Significant complications occurred in 36% of all cases. Major complications included flap

necrosis in 26%, fistula formation in 8%, carotid rupture in 5%, osteoradionecrosis in 3%, and death due to sepsis in 3%. Two patients experienced a carotid rupture that occurred in the context of recurrent neck disease.

Vikram et al. reported on 21 patients with recurrent HNSCC.[228] Neck implantation was the most common indication in eight patients (38%). All gross tumor could not be removed in 15 patients, whereas satisfactory margins could not be obtained in 6. In 11 patients, a temporary implant of $^{192}$Ir (median dose 48 Gy in 6 days) was used with a permanent $^{125}$I implant used in the remaining patients. The actuarial 2-year local control and survival rate was 81% and 55%, respectively. Complications developed in four patients (19%) and proved fatal in one patient.

Fee et al. reported on 29 patients with large masses attached to the carotid artery undergoing surgical resection with preservation of the artery and intraoperative $^{125}$I with an absorbable suture.[226] Nine patients with gross residual disease that was implanted were excluded from analysis with four of the nine recurring in the implanted volume. All nine patients died within 12 months. Eighteen patients (64%) were treated for recurrent neoplasms with neck masses >4 cm, having failed prior surgery or radiation. A mean dose of 163 Gy was delivered to the implant volume over 1 year for this cohort. With a minimum follow-up of 1 year, 76% of patients were disease-free in the implant volume and 62% were disease-free in the entire neck for the entire group. Mean survival was 15 months (2–50 months) in the primary group and 12 months (4–26 months) in the recurrent group. Neck recurrence occurred in 39% of those treated for recurrent disease with 22% occurring within the implant. DM occurred in 39% of those treated for recurrent disease. The overall and major complication rate was 41% and 28%, respectively. Two carotid rupture complications were noted again in the context of recurrent neck disease.

Paryani et al. reported on 38 patients with locally advanced head and neck cancer attached to the carotid artery treated with resection and $^{125}$I Vicryl suture implant.[229] Most patients had neck masses that were >6 cm without clinically evident DM. Twenty-six patients (68%) had recurrent disease. For the cohort with recurrent disease, local control within the implant volume was observed in 81%. Distant relapses were also observed in 50% of patients treated for recurrent disease. Mean survival was 9 months. The overall complication rate was 26% with most complications involving wound breakdown or flap necrosis. Once again, three patients developed a carotid rupture in the context of biopsy-proven recurrent disease.

## Intraoperative Radiation Therapy

Intraoperative radiation therapy (IORT) has recently become an important option in the treatment of recurrent head and neck cancer. IORT is delivered to the location of the tumor recurrence at the time of surgery and the surrounding vital structures are shielded or displaced during irradiation while allowing for maximal exposure of the tumor bed to the radiation. IORT can be used as standalone treatment or in conjunction with additional external beam radiation therapy. It offers the possibility for full-course reirradiation in safe and effective manner. It is most commonly delivered using electrons or with high dose rate $^{192}$Ir applicators (Fig. 14-6).[235–241]

To date, multiple single-institution retrospective series have been reported with heterogeneous patient and tumor selection criteria, the extent of surgical resection, and the volume of intraoperative irradiation limiting. Complete surgical resection with a negative microscopic margin remains the most important determinant for neck control and survival.[235,236,239] Doses ranging from 10 to 30 Gy or 7 to 20 Gy have been delivered as the sole

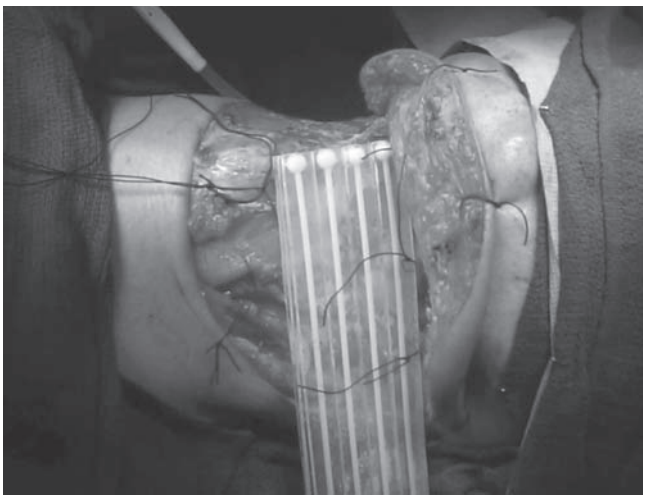

**FIGURE 14-6.** Intraoperative high-dose rate brachytherapy to the neck in a patient with recurrent neck disease following complete surgical resection.

treatment or when combined with repeat external beam radiotherapy, respectively. Complications appear to be acceptable and may include wound complications, peripheral neuropathy, osteoradionecrosis (~5%), and carotid rupture (<5%) that also appear to be related to progressive or recurrent disease. This technique is particularly attractive for several conceptual reasons: (a) high doses of radiation can be delivered with high accuracy with shielding or displacement of nearby tissue, (b) it is delivered before the onset of tumor repopulation and surgical bed hypoxia, and (c) it can be combined with a reduced dose of external beam radiation therapy. The radiobiology of large single doses of radiotherapy may be particularly advantageous in overcoming radioresistant recurrent disease.

In 2011, Zeidan et al. published their experience with 231 patients with advanced cervical nodal disease who underwent a neck dissection and IORT with electron therapy. In this report, the patients included had prior external beam radiation therapy, were at high risk for residual gross or microscopic disease within the neck, or had advanced nodal disease (N3). One hundred ninety-eight of the 231 patients presented for salvage therapy with 88% having received previous external beam radiation. A median dose of 20 Gy (range 10–25 Gy) was delivered using electrons (most commonly 5 MeV). The median cone size is 6.4 cm. Fifty patients received additional external beam radiotherapy (median dose 45 Gy). Ninety-nine patients received chemotherapy. The median follow-up was 1 year. The OS and recurrence-free survival were 26% and 49%, respectively, at 5 years. Negative prognostic factors for survival were carotid artery involvement, perineural, or dermal invasion. Complications occurred in 27% of all patients and included vascular complications in 23, pharyngocutaneous fistula in 20, wound dehiscence in 20, peripheral neuropathy in 7, and osteoradionecrosis with two flap necrosis in 8.

IORT using the high-dose rate $^{192}$Ir applicator was used in the salvage of 35 patients with isolated neck recurrences (see Fig. 14-6). The primary sites were the oropharynx (34%), the oral cavity (24%), and the larynx (21%) in the majority of cases, and 91% of patients received previous external beam radiotherapy. The major histology was squamous cell cancer (94%) and three-fourths of patients were male. Median IORT field size was 6.4 × 5.4 cm, and mean dose delivered was 13.5 Gy (range 10–17.5 Gy).

(c) 2014 Wolters Kluwer. All Rights Reserved.

Twenty-three had flap reconstructions, primarily rotational pectoral flaps (91%). More than half of the patients received (19/35) additional external beam radiation (median dose 45 Gy), and 26% received additional chemotherapy concurrent with radiation. At a mean follow-up of 20 months, the 1-year in-field control was 64% with higher rate in patients achieving negative margins (70% vs. 48%, $p = 0.44$) compared to those with microscopic positive margins. Among patients with positive margins, those receiving additional external beam radiotherapy had higher in-field control (100% vs. 44% $p = 0.035$) compared to those treated with IORT alone. In-field control translated into improved survival at 1 (100% vs. 73%, $p < 0.001$) and 2 years (100% vs. 25%, $p < 0.001$). Toxicity included one patients with vagal neuropathy and another patient with wound breakdown at 2 years.

In summary, the use of either brachytherapy or intraoperative techniques may afford a meaningful delay in the time to progression or salvage of neck relapses. Although no studies with quality-of-life end points or comparative analysis have been performed to validate the observations noted in retrospective reviews, in light of the morbidity associated with neck recurrences, its application in selected patients may be appropriate

## Future Directions

Significant improvements have been made in locoregional control with multidisciplinary treatment combining concurrent chemoradiation and surgery for patients with locoregionally advanced disease. Despite such aggressive treatment, locoregional failure or distant metastatic rates remain at 20% to 25%. Efforts to better select patients for further therapy will be important to tailor therapy appropriately. To that end, PET done at 3 months after chemoradiation appears to be promising in selecting patients who may be spared neck dissection; however, PET may not be able to predict those at risk for distant metastasis. Other imaging studies such as dynamic contrast-enhanced MRI to detect a hypoxic component may be able to detect a group of patients at higher risk for radioresistance and persistence of disease. Pathologic evaluation remains an important manner to assess risk. Limited excision of initially involved nodes may offer the best compromise between morbidity of surgery and the prognostic pathologic information gained. Biologic markers such as the epidermal growth factor may tailor therapy to determine which patients may have more aggressive disease that is radioresistant.[242] As an anti-EGFR therapy, the value of C225 in the management of the neck remains to be defined. The roles of induction and adjuvant chemotherapy are currently being reexplored as promising results have been reported with taxane-based regimens. Induction chemotherapy followed by concurrent chemoradiation may yield even higher pathologic CR rates in the neck than are obtained with current regimens, which would further select out patients likely to be cured from their head and neck cancer. Patients with residual neck disease may be candidates for further therapy. The RTOG is testing the benefit of postoperative chemotherapy within 2 weeks following surgery to minimize the delay between surgery and the onset of therapy. Integration of other biologics including antiangiogenic agents such as avastin may possibly decrease the incidence of distant metastasis. Just as modifications of neck dissection procedures has led to less radical surgery and better function, the selective delivery of radiation therapy to nodal stations at highest risk is now possible with conformal techniques such as IMRT which may better spare patients long-term morbidity.

With rapid advances occurring in genetic analysis, considerable progress has been made in the genetic deciphering of head and neck cancer. In 2005, Ferris et al. used quantitative reverse transcription polymerase chain reaction (QRT-PCR) to identify four makers that discriminated between lymph nodes harboring metastatic disease and lymph nodes which did not harbor metastatic disease.[243] The accuracy was reported to be >97%. The markers utilized in this report were pemphigus vulgaris antigen (PVA, aka desmoglein-3), squamous cell carcinoma antigen (SCCA1/2, neutral and acidic forms), parathyroid hormone–related protein (PTHrP), and tumor-associated calcium signal transducer (TACSTDI, aka epithelial cell adhesion molecule [EPCAM]). PVA was reported to discriminate between malignant and benign lymph nodes with 100% accuracy. This report suggested that it may be possible to use QRT-PCR analysis for PVA analysis to stage cervical lymph nodes in HNSCC. In 2011, Ferris et al. reported the use of this technology to perform rapid and intraoperative genetic evaluation of sentinel lymph nodes in HNSCC with QRT-PCR.[244] They reported the completion of the genetic analysis in <30 minutes.

Another approach which has been reported is to analyze the primary tumor genetic properties. It has been shown that the presence of a local recurrence can be predicted based upon the genetic expression in the primary tumor.[245] It has also been shown that the presence of a regional recurrence can be predicted based upon the genetic expression of the primary tumor.[246–248] Microarray technology has allowed for the rapid detection of multiple genetic markers in the primary tumor and the neck metastases and comparison. These studies suggest that the metastatic potential of a cancer can be deciphered from the primary tumor gene expression pattern.

A very powerful adjunct to the surgical management of the neck is the sentinel lymph node biopsy using lymphoscintigraphy. Morton et al. pioneered this technique for use in detecting the lymphatic spread of melanoma. Nuclear radiography is used to identify the primary, secondary, and tertiary lymph node basins as well as the "sentinel" lymph node within the lymph node basin. This technique provides the surgeon with the ability to try and stage the clinically occult neck. Pitman et al. of the University of Pittsburgh have explored the idea of identifying the sentinel lymph node in the primary lymph node drainage basins from known HNSCC primary neoplasms. By identifying the sentinel lymph node, the investigators were able to stage the N0 neck in a minimally invasive manner and then make recommendations for the elective neck therapy with this information. Sentinel lymph node biopsy in HNSCC is probably best considered an investigational technique—as such, it has not yet achieved the status of "standard of care" for the treatment of head and neck carcinoma patients.

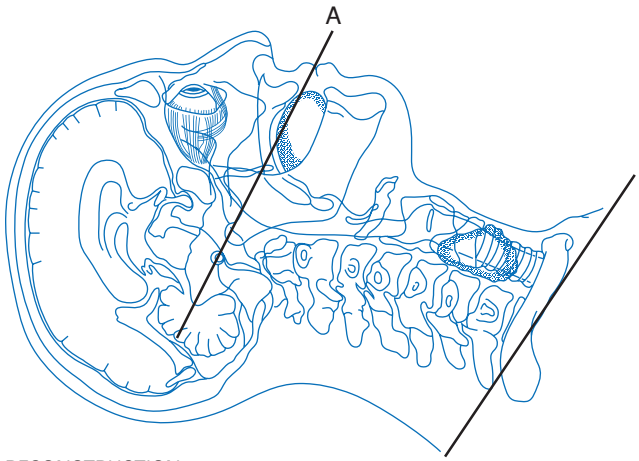
# PART B:
# Radiologic Imaging Considerations

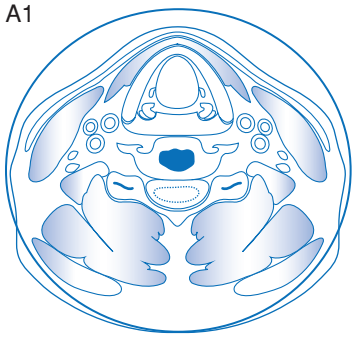


Jeffrey A. Bennett

Imaging of the neck is performed in addition to the physical exam, both as part of the initial staging of head and neck cancer and in posttreatment surveillance. It is helpful for confirmation of a clinical N0 neck, to assess nonpalpable areas of the neck such as the retropharyngeal region, and to evaluate the extent of palpable adenopathy. Prognostic information can be gained from the size of a nodal mass and the presence of extracapsular spread of tumor beyond the lymph node capsule, with associated possible invasion of muscles and vessels. Contrast-enhanced CT and contrast-enhanced MRI are the primary tools used to assess for the presence of tumor metastases in cervical lymph nodes. Ultrasound is used mostly for image-guided biopsy of a suspicious node. Suggested CT and MRI protocols are given in Figures 14-7 and 14-8.

FDG-PET can also be used to show physiological activity in lymph nodes, but its role in initial staging of head and neck cancer is still to be determined. Several studies have investigated the value of PET scanning for lymph node status in initial staging,[1–6] with a range of sensitivity from 47% to 100% and a range of specificity from 87% to 100%. Its negative predictive value is approximately 90%.[7] Its main limitation is the detection of small, < 7 mm positive nodes which is a problem given that > 40% of metastatic lymph nodes are < 7 mm in diameter.[8] Recent PET research has looked at standard uptake values (SUV) in positive lymph nodes as a prognostic factor, with one study[9] showing a higher SUV in nodes with extracapsular extension versus nodes without extracapsular extension, 11.0 versus 5.0. Higher SUV values in nodes were also shown to be predictive of distant failure at 1-year follow-up.

CT has been shown to be slightly superior to MR for the detection of metastatic deposits in lymph nodes.[8] Both CT and MRI require intravenous contrast for lymph node detection. Slice thickness should be no < 3 mm for CT and 4 mm for MRI. Multiplanar reformation of thin-section CT data can be helpful for problem solving, for example in showing a preserved fatty hilum in a folded lymph node. Criteria for calling a node positive include size, shape, enhancement pattern, and evaluation of the lymph node capsule.[10] Size, traditionally measured as the greatest diameter in the axial plane, is one feature looked at and is certainly helpful in assessing the typically uniformly enhancing lymph nodes seen in lymphoma. The availability of multiplanar reformats in CT and imaging in multiple planes with MRI allows



ACQUISITION

a better visualization of the entire lymph node. Studies have not been performed to assess the sensitivity and specificity for metastatic head and neck cancer using the greatest diameter of a lymph node in any plane or the lymph node volume, which can be obtained easily with currently available software. Shape can be helpful, as lymph nodes filled with tumor tend to become more spherical. The enhancement pattern is probably the most useful feature. Nodes positive for squamous cell cancer have internal filling defects (Figs. 14-9 and 14-10), even when they are very small.

Sometimes, lymph nodes containing cancer can become quite necrotic (Fig. 14-11). Occasionally, these cystic nodes can be mistaken for branchial cleft cysts. Since branchial cleft cysts usually present in childhood, these cystic lesions seen in older patients must be assumed to be metastatic nodes and should be biopsied. In the author's experience, these often turn out to be metastatic nodes from HPV-positive primaries (Fig. 14-12).

Extracapsular tumor spread is a feature that has prognostic implications. This finding is made when the border of the lymph node becomes indistinct and there is infiltration of the surrounding fat. This feature can result in invasion of adjacent structures such as the sternocleidomastoid muscle or carotid artery, possibly making the tumor unresectable. Carotid artery fixation is assumed

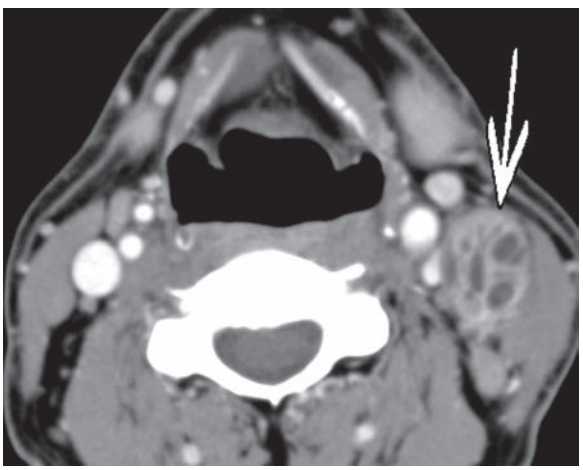

**FIGURE 14-9.** Axial CT scan with contrast shows a metastatic squamous cell carcinoma positive level III lymph node (*arrow*) showing a typical enhancement pattern of multiple filling defects.

(c) 2014 Wolters Kluwer. All Rights Reserved.

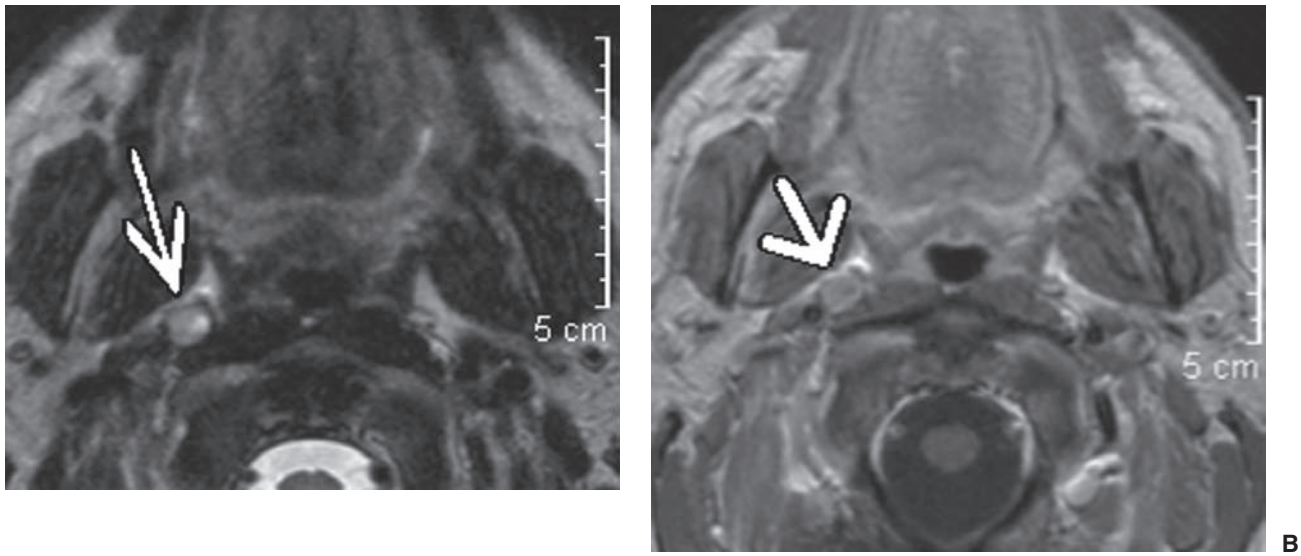

**FIGURE 14-10.** Axial T2-weighted MRI (**A**) and axial T1-weighted post gadolinium MRI (**B**) show a right retropharyngeal lymph node (*arrow*) positive for tumor in this patient with a nasal cavity primary squamous cell carcinoma. Note the high T2 signal likely representing necrosis and corresponding filling defects in its enhancement pattern.

when the tumor surrounds the carotid artery by >270 degrees (Fig. 14-13). Tumor invasion of the dermal lymphatics generally carries a poor prognosis. This is detected by skin thickening and infiltration of the subcutaneous fat (Fig. 14-14). Often focal necrotic nodules will also be present in the thickened skin.

Imaging of the neck, especially with contrast-enhanced CT, is frequently done to assess treatment response to chemoradiotherapy prior to surgery. This imaging is often performed as soon as 4 weeks post radiation. At this time point, FDG-PET would produce too many false positives from granulation tissue, and therefore CT criteria predictive of response has been generated. Labadie et al.[11] determined that a >90% reduction in the volume of a metastatic node following combined therapy compared to a pretreatment study predicted eradication of tumor within the node. Ojiri et al.[12] suggested that a neck dissection might not be necessary if the lymph nodes on the postradiation CT scan were <15 mm, free of significant internal focal low attenuation or calcification, and without imaging evidence of extracapsular spread (Fig. 14-15).

Studies have shown the value of FDG-PET when performed 3 to 4 months post radiation therapy. Two studies[13,14] showed that FDG-PET had a negative predictive value of 100% and 97% when

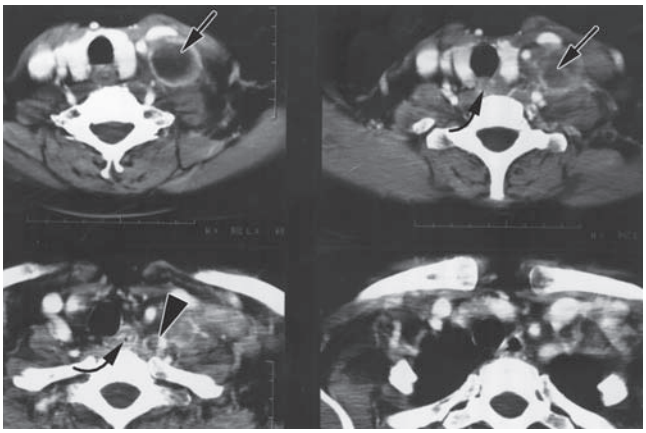

**FIGURE 14-11.** Virchow lymph node. Enhanced serial axial computed tomographic images through the lower neck. A necrotic lymph node at the left venous angle (*arrows*) and a smaller pathologic lymph node (*arrowhead*) due to a clinically occult primary squamous cancer of the esophagus (*curved arrow*) are shown.

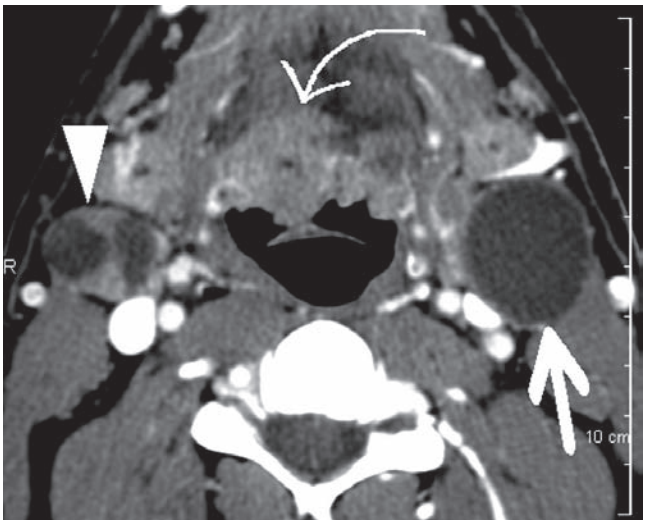

**FIGURE 14-12.** Carotid artery encasement by tumor. Axial contrast enhanced CT scan showing an almost completely cystic lymph node on the left (*arrow*) and more typically enhancing level II lymph node on the right (*arrowhead*), both positive for tumor in this patient with a primary HPV-positive tongue base squamous cell carcinoma (*curved arrow*).

(c) 2014 Wolters Kluwer. All Rights Reserved.

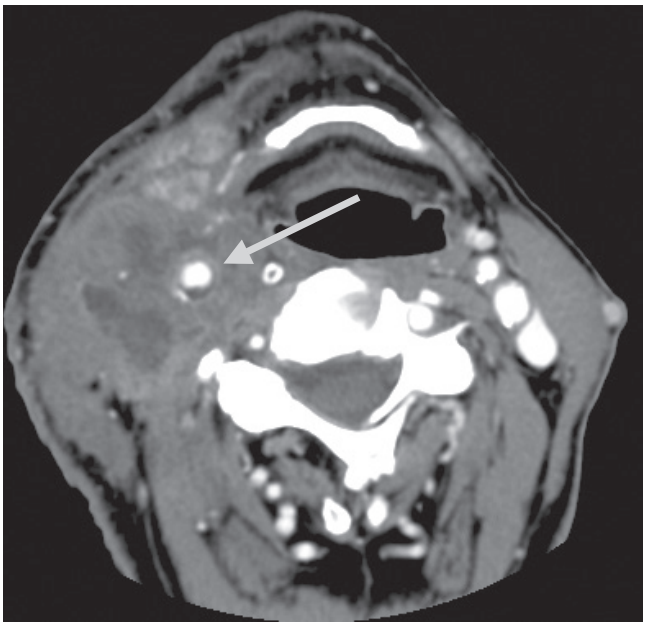

**FIGURE 14-13.** Carotid artery encasement by tumor. Axial contrast-enhanced CT shows a large tumor that completely surrounds the carotid artery indicating encasement (*arrow*). The generally agreed imaging criterion for carotid artery encasement is that the tumor must surround the carotid artery by 270 degrees. Tumors that abut or surround the carotid artery <270 degrees suggest that the tumor may be focally adherent to the carotid artery. CT, computed tomography.

performed 3 to 4 months post treatment. In most institutions, PET-CT is the preferred modality for head and neck cancer follow-up surveillance studies 4 months or greater post treatment. This is true as well for the postsurgical neck, where distortion of normal anatomy, flaps, and scarring result in challenges in interpretation

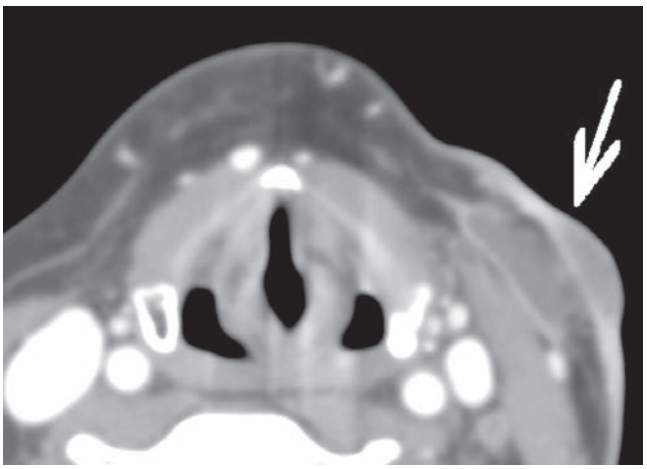

**FIGURE 14-14.** Axial contrast-enhanced CT scan showing invasion of the dermal lymphatics. Notice the skin thickening with a focal necrotic nodule located within the skin *(arrow)*. The subcuateous fat has been infiltrated with tumor.

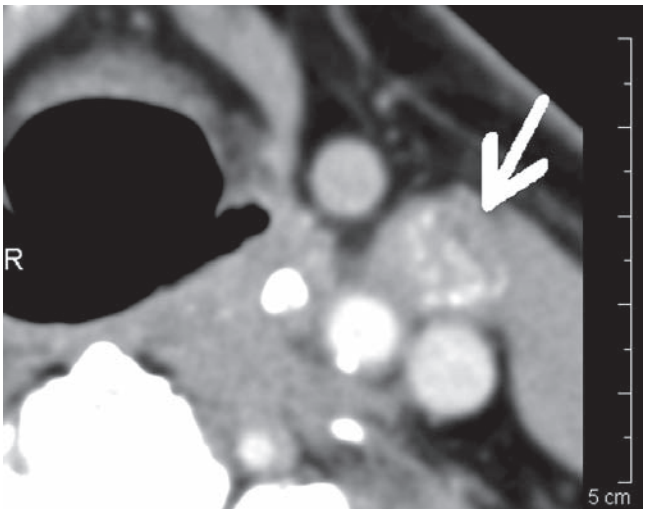

**FIGURE 14-15.** Axial contrast-enhanced CT scan obtained 4 weeks following completion of radiation therapy shows residual enhancement and calcification within a left level II lymph node (*arrow*). These imaging findings suggest the presence of residual tumor in the node and a neck dissection was recommended.

of conventional imaging studies. FDG-PET scans can be helpful to guide biopsy at sites of suspected tumor recurrence.

Diffusion-weighted MR sequences are being used more to differentiate benign from malignant neck nodes.[15] A low apparent diffusion coefficient (ADC) within a node suggests the presence of tumor compared to normal lymph nodes. Nodes that are responding to radiation therapy also have been shown to have an increasing ADC value.[16] Dynamic susceptibility-weighted contrast-enhanced MR perfusion imaging is also being studied as a promising tool to differentiate benign from malignant lymph nodes. Malignant nodes have been shown to have statistically more dynamic susceptibility contrast.[17]

## INTRODUCTION

This section describes the various types of neck dissections and their standardized descriptions, along with the indications and risks for each when applied to squamous cell carcinoma of the upper aerodigestive tract, melanoma, salivary gland malignancies, and thyroid carcinoma, respectively. Particular detail is provided for the most commonly performed neck dissections by the authors, which includes selective neck dissections (SNDs).

Neck dissection for head and neck squamous cell carcinoma is generally performed based upon (a) location of clinically evident nodal metastases and (b) the likelihood of occult metastatic disease in the various nodal levels based on primary site.[1–4] (Fig. 14-16 depicts the clinical and radiographic boundaries of

the nodal levels of the neck.[5]) Based upon these factors, the authors generalize that at a minimum, when indicated, the follow lymph node levels should be considered for neck dissection and/or radiation therapy for selected sites:

- Oral cavity: Levels I, II, III, and possibly IV (Fig. 14-17)
- Oropharynx: Levels II, III, and IV (Fig. 14-18)
- Hypopharynx: Levels II, III, and IV (Fig. 14-18)
- Larynx: Levels II, III, IV, and possibly VI

# SURGICAL TECHNIQUES

## Selective Neck Dissection (Levels I, II, III, IV)

By far, the most common neck dissection performed today is the SND, in which only the nodal levels that are clinically positive, or have a significant possibility of harboring metastatic disease for a given primary site, are removed.[6,7] The main advantage of this is a reduction in the morbidity that is associated with more extensive neck dissections.[8,9] Of course, clinical judgment should always be used, and any levels clinically involved with disease should be addressed regardless of the primary site.

In cases where surgery is the primary modality of treatment and nodal disease is clinically present, or in cases where nodal disease is clinically present after the completion of nonsurgical treatment, it is accepted that a neck dissection that includes the positive nodes should be performed. A remaining controversy exists in the management of the N0 neck and in the postchemoradiation neck mass. Each subsite deserves separate consideration of these issues, taking into consideration the tendency of that particular site to harbor occult metastatic disease.

Though the entire field of study with regard to neck dissections is deficient in the number of prospective trials that have addressed the benefits of different types of neck dissections for different levels of disease, several retrospective studies have shown a survival benefit with elective neck dissection for patients who have oral cavity disease that is staged T2–T4N0 or is ≥4 mm in thickness, especially in the subsites of the maxillary gingiva, alveolus, or hard palate,[10–15] though there have also been contrary reports.[16,17] It is well known that regional recurrences in oral cavity cancers have a dismal chance of successful salvage, however, and at present, this knowledge seems to have led many surgeons to err on the side of caution and perform SNDs on early-staged cN0 oral cavity patients.

The SND that is most commonly used for oral cavity carcinoma includes removal of levels I, II, and III (Fig. 14-17), and consideration should be given to removal of facial lymph nodes when evidence of malignancy or enlarged nodes of this region is present. Additional indications for this procedure may include lip carcinoma, submandibular gland malignancy, and melanoma of the cheek, the lips, and adjacent areas. This technique is not sufficient or indicated for oropharyngeal, laryngeal, or hypopharyngeal malignancy.

The techniques described herein will include removal of levels I, II, and III, and implies that SND is separate from primary site resection. When the neck dissection and primary site are addressed at the same time, it is important to modify the technique slightly to confirm mobilization and preservation of vital structures while removing all tumor en bloc when possible.

***Neck Incision Planning.*** The neck incision is usually marked and placed in a horizontal skin crease approximately two-finger breadths inferior to the mandible, but in a location adequate to expose the necessary lymph node levels. The neck incision is typically marked in a horizontal skin crease and may require an incision approximately 6 cm in length, although many surgeons continue to utilize an extension of the posterior aspect upward near the mastoid tip, and the anterior incision may continue across midline. The incision for most neck dissections can be limited to a horizontal incision in a skin crease, unless circumstances warrant an extension across midline, or extension of a vertical limb inferiorly for a radical neck dissection (RND), or superiorly, to include parotidectomy or extended neck dissection.

***Incision.*** The authors advocate using a 15-blade scalpel for the skin incision and electocautery for the remainder of the procedure. The skin incision should be carried through the subcutaneous tissue to expose the platysma muscle. At this point, the electrocautery is used to divide the platysma muscle in an avascular plane. The platysma is dehiscent at the anterior and posterior edge of the incision, forcing the surgeon to be aware that the external jugular vein and greater auricular nerve will be exposed deep to the subcutaneous fat overlying the sternocleidomastoid muscle (SCM). These two structures are commonly preserved and provide excellent landmarks for the posterosuperior flap elevation.

***Flap Elevation.*** Typically, double-pronged skin retractors are used by the assistant to retract the superior and inferior skin/platysma flap for elevation by the surgeon. The electrocautery is used to perform the flap elevation with adequate retraction and tension applied by the assistant. The superior flap is elevated to the level of the inferior border of the mandible, whereas the inferior flap is elevated to the level of the clavicle. Paralytic agents are avoided during this portion of the procedure to allow for identification and atraumatic dissection superiorly near the marginal mandibular branch of the facial nerve. Injury to the marginal mandibular branch of the facial nerve can cause smile asymmetry secondary to decreased innervation of the depressor anguli oris and depressor labii inferioris muscles.[18] If level I dissection is indicated, the marginal mandibular nerve is isolated, exposed, and retracted to remove level IB and lymphatics around these branches. If not, the fascia at the level of the hyoid bone or digastric muscle can be incised and mobilized to avoid injury to the marginal mandibular branch and expose the digastric muscle. Several small vessels are ligated with ligaclips, entering the skin flap during elevation, while electrocautery provides hemostasis for the other areas. During the superior flap dissection, the external jugular vein and greater auricular nerve can be dissected and isolated for preservation and form the deep extent of flap elevation.

***Approach to Lymphatic Structures.*** Once the flaps are elevated and the fascia overlying the lymph node levels to be removed is exposed, the skin is retracted with elastic self-retaining skin hook retractors in four quadrants to allow the surgeon and assistant hands-free retraction and dissection of the lymphatics. It is important to note that if nodal disease is present or involving structures, the technique will require modification to avoid entering lymph nodes or their extracapsular component, and these areas should be removed "en bloc."

***Lymphatic Dissection.*** The initial incision in the fascia is placed at the anterior border of the external jugular vein, the greater auricular nerve, and the SCM interface, and this fascia is then grasped with Allis forceps, thus providing tension and exposure to the anterior border of the SCM and levels II to IV. Using Babcock forceps on the SCM and Allis forceps on the lymphatics, the fascia and the lymphatics of levels II to IV are then freed from the anterior and deep aspect of the SCM, rounding the deep aspect of the SCM toward the deep and posterior border where cervical rootlets can then be exposed. It is crucial at this juncture to be aware that there is often a confluence of the greater auricular branch, and cervical branches 2 and 3, along with a communicating branch to the spinal accessory nerve that do not present themselves except near the posterior border of the SCM. After the skin flaps are elevated, the anterior and posterior border of the digastric muscle is exposed along with the SCM, the greater auricular nerve, the external jugular vein, and the omohyoid muscle, which are all preserved when oncologically indicated. The skin, muscles, and surrounding tissues can be retracted throughout the case with elastic self-retaining retractors. We will briefly separate the dissection of levels II, III, and IV to incorporate unique challenges of the anatomy of each level.

(c) 2014 Wolters Kluwer. All Rights Reserved.

*Level I.* See Radical Neck Dissection.

*Level II.* As the undersurface of the SCM is freed from the overlying fascia in level II, the spinal accessory nerve is identified and retracted carefully with a vein retractor. A reliable landmark for identification of the spinal accessory nerve is the presence of a vein that crosses approximately 2 mm superficial to it. Utilization of this landmark can help to avoid inadvertent spinal accessory nerve injury.[19] Iatrogenic injury to the spinal accessory nerve is repaired utilizing primary neurorrhaphy or cable grafting with the greater auricular nerve. The surrounding lymphatics are separated from the nerve and its affiliated branches to the cervical rootlets and the greater auricular nerve. If level IIB requires removal, the spinal accessory nerve is circumferentially mobilized and may be further retracted with an army-navy retractor to reach the posterior border of the SCM. At this level, no landmarks exist to specify that the junction of level IIB and VA has been reached, and thus cautery is used to dissect deeply perpendicular to the exposure to reach the floor of the neck where the splenius capitus and the levator scapulae muscles are exposed. A cranio-caudal incision in the deep fascia overlying these muscles exposes the muscle, and this fascia is then grasped with an Allis retractor, and cautery is then used to elevate the remaining lymphatic tissue anteriorly toward level IIA. At this point, the levator scapulae and the anterior scalene muscles come into view, while fascia is preserved over the anterior scalene to preserve the phrenic nerve. Visualization, palpation, and alternating anterior/posterior views are necessary to preserve and confirm the location of the spinal accessory nerve, the internal jugular vein, the internal carotid artery, and the vagus nerve. When the lymphatics are freed from the floor of the neck musculature toward the great vessels, an army-navy retractor is placed under the digastric muscle, thus exposing the internal jugular vein and possibly the external carotid artery. This "corner" of level IIA formed by the digastric muscle, the jugular vein/the carotid artery, and floor of the neck is one of the highest risk areas for jugular vein or carotid injury, and "folding" of the vein is commonly unnoticed, resulting in a small opening requiring repair. If an entry into the jugular vein or the carotid artery is present, meticulous care and exposure is indicated with suturing with a 6-0 Prolene when necessary. The lymphatics are then carefully elevated from the carotid fascia, the jugular vein, and the vagus nerve while ligating the occipital artery branch when necessary with ligaclips. Using a 15-blade scalpel, the lymphatics are freed from the adventitia of the internal jugular vein anteriorly, then diving deep between the facial vein branch and the internal jugular vein to remove this "facial pocket" and deeper bed of lymphatics of level IIA. When levels IIA and IIB are mobilized, they are removed and sent separately to pathology when oncologically sound, dividing at the inferior border of the hyoid bone.

*Level III.* Level III is performed posteriorly in a similar fashion without concern for the spinal accessory nerve. However, 2 to 3 cervical rootlets may be exposed here and preserved, while they are followed anteriorly toward the floor of the neck, staying superficial to the deep cervical fascia overlying the phrenic nerve. Dissection continues similarly to level II, toward the carotid fascia with a 15-blade scalpel used to mobilize the lymphatics from this fascia and the jugular vein, while preserving the fascia over the carotid and the vagus nerve if possible. Care is taken anteriorly in level III to preserve the superior thyroid artery and vein, the ansa hypoglossi nerve, and an occasional connection of the facial vein and the anterior jugular system. Once the omohyoid is reached, the specimen is sent to pathology.

*Level IV.* Level IV is performed in a somewhat different fashion than both levels II and III. The surgeon moves to the head of the bed, while the assistant places a large self-retaining elastic retractor under the omohyoid and the SCM or an army-navy when necessary. The surgeon uses an Allis clamp to grasp the bulky lymphatics and the electrocautery to free the lymphatics using retraction to expose the jugular vein, the transverse cervical vessels, and the thoracic duct. This lymphatic group has a more extensive quantity of fat that separates easily and can be difficult to grasp and retract. When the clavicle is reached, the lymphatics are passed off the table.At this time, irrigation is used throughout the wound, and an assessment for all vital structures is confirmed. Any bleeding is controlled with bipolar cautery. Any remaining lymphatics are removed and a drain is placed as necessary. The wound is then closed with resorbable 3-0 Vicryl undyed sutures for platysma and subcutaneous closure followed by a 5-0 Monocryl for skin closure.

Specific care is taken to avoid injury to the deep cervical fascia and the thoracic duct during the deep level IV dissection, as rates of chyle leak during neck dissection have been reported to be as high as 6%.[20] The thoracic duct enters level IV and travels anterolaterally to empty into the region before the junction of the subclavian and internal jugular veins. Meticulous dissection and a bloodless field can provide the operative surgeon with the ability to visualize this structure and ligate or avoid it as needed. After removal of the level IV lymphatics, a valsalva is provided by anesthesia to examine for any chyle in the wound. The intraoperative identification of a chyle leak requires immediate ligation and/or sealing with fibrin glue.[21]

## Radical Neck Dissection

Although rarely necessary in 2012, the RND will now be described to afford a shortened version of the modified radical neck dissection (MRND) technique, which utilizes a combination of the SND techniques and the RND techniques. A hockey stick incision is made through the skin via a natural skin crease, from the midline to the mastoid tip, allowing dissection through the subcutaneous tissue up to the superficial cervical fascia. The authors have modified the original descriptions and now avoid any inferiorly based "limb" from the horizontal incision as this "trifurcation" is often met with significant scarring, dehiscence, and poor cosmesis. Incising this fascial layer reveals the platysma, which is then incised allowing the raising of superior and inferior subplatysmal skin flaps. The skin flaps are elevated to the body of the mandible superiorly, the clavicle inferiorly, the sternohyoid medially, and the trapezius posteriorly, thereby effectively exposing the anterior and posterior cervical triangles.

The description herein will reveal an "en bloc" RND technique to highlight the difference from an SND. Thus, the only boundaries of a true RND are the mandible superiorly, the mastoid tip, the trapezius muscle, the clavicle, the strap muscles, and the contralateral anterior belly of the digastric muscle (Fig. 14-19). The deep boundaries of the RND include the muscular "floor" of the neck with preservation of the phrenic nerve, the brachial plexus, the sympathetic trunk, the carotid artery, and the vagus nerve.

We will use a "clockwise" approach to a left RND.

Dissection begins at level I by identifying the marginal branch of the facial nerve and mobilizing it superiorly to expose the mandible deep to the nerve. Monopolar cautery is then utilized to release the fibrofatty tissue of the submandibular triangle at its corner between the mandible and the anterior belly of the digastric, to include level IA and IB with the floor of mylohyoid, digastric, hypoglossal, and lingual nerves preserved. This is reflected medial to laterally until the mylohyoid muscle is appreciated, at which point an army-navy retractor is placed to elevate this muscle and gain access to the sublingual compartment. Blunt Kittner dissection is then utilized to visualize the hypoglossal

(c) 2014 Wolters Kluwer. All Rights Reserved.

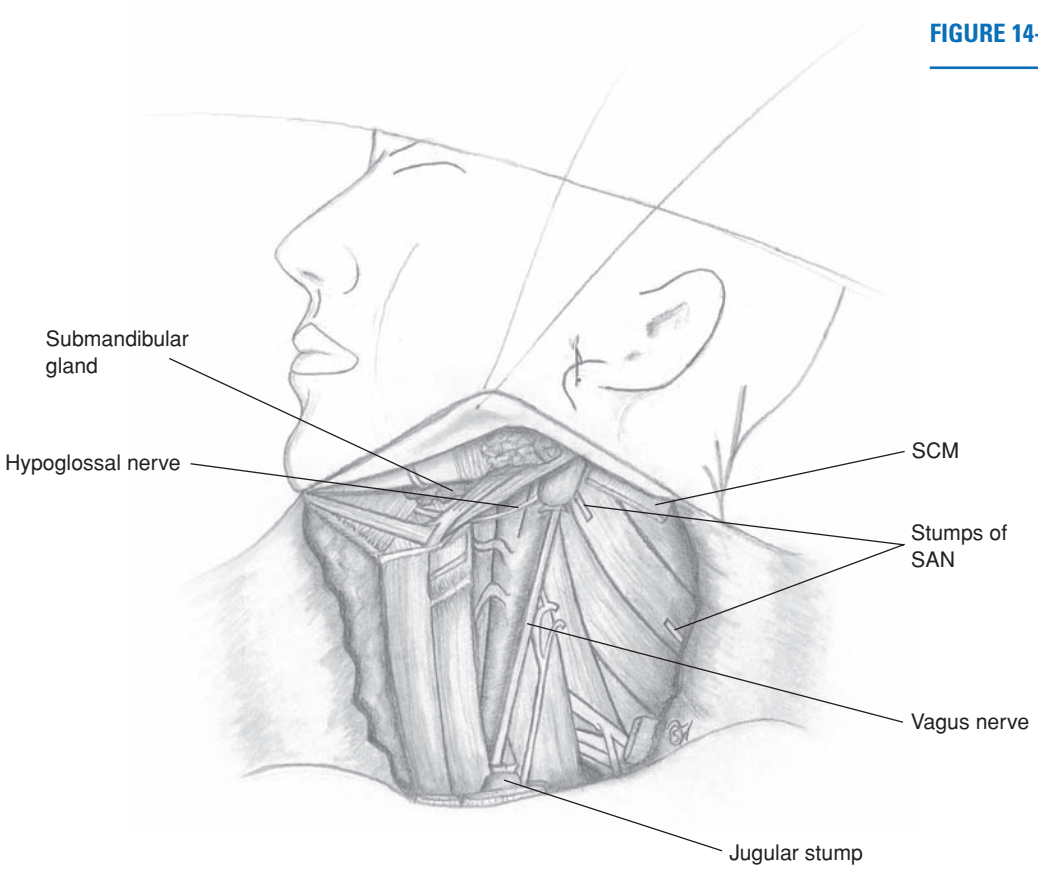

**FIGURE 14-19.** Radical neck dissection.

and lingual nerves. The submandibular duct and ganglion are identified and ligated. Following this, the facial artery is appreciated superficially as it exits the gland and crosses over the mandible. The artery is ligated as it exits the gland superficially if necessary, or preserved for microvascular anastomosis if a free tissue transfer is planned for reconstruction. The facial vein is also appreciated, and its anterior and posterior divisions noted as it passes over the submandibular gland. At this point, the specimen is reflected inferiorly, connecting it to the fascia of the digastric muscle.

Monopolar cautery is then continued with dissection through the fibrofatty tissue overlying the posterior belly of the digastric. This separates the inferior aspect of the parotid gland from the neck dissection specimen and allows dissection to proceed to the superior aspect of the SCM as it inserts onto the mastoid. The SCM is released at this superior attachment and reflected inferiorly. Blunt finger insertion deep to the released head of the SCM is utilized to develop a plane between the musculature of the posterior triangle (the splenius capitis and the levator scapula) and the overlying fibrofatty tissue. This tissue is then grasped with a series of Allis clamps and incised back to the anterior border of the trapezius. This release occurs in a posterior-superior to posterior-inferior fashion. During this turn, the spinal accessory nerve is encountered as it travels through the posterior triangle toward the trapezius muscle. It is transected and included in the specimen. After completing this turn, the specimen is reflected in a lateral to medial fashion with continued blunt finger dissection utilized to further define the muscular floor, with special attention paid to the brachial plexus as it exits between the anterior and middle scalene muscles, and the phrenic nerve, as it runs along the anterior scalene muscle. Preservation of these structures is accomplished by their direct identification. Continued lateral to medial dissection along the inferior aspect of the posterior triangle is continued, with visualization of the posterior belly of the omohyoid muscle. The transverse cervical artery and vein are also encountered and ligated for hemostasis if necessary.

The sternal and clavicular attachments of the SCM are soon encountered during this dissection, and blunt finger palpation is utilized to define its deep extent, followed by monopolar cauterization to release both ligaments. When releasing the SCM, it is important to denote the anterior belly of the omohyoid muscle deep to your dissection, in order to be sure the carotid sheath is not in danger of injury. After transecting the SCM, the omohyoid is then transected in order to gain access to the lymphatic tissue in the deep floor of the anterior cervical triangle. The circumferential "superficial" margins around the RND are now complete, and it is time to elevate the specimen from the "floor."

Beginning posteriorly at the trapezius, the lymphofatty tissue is elevated from the muscular floor posterior to anterior, and the cervical rootlets are identified in the deep neck floor and divided prior to the approach to the carotid sheath. Thus, level V is elevated and levels II, III, and IV are now being elevated from the phrenic nerve, the vagus nerve, and the carotid artery deep to the jugular vein, which is included in the specimen. At this point, the specimen is returned to its anatomic position and the carotid sheath identified deep to the transected omohyoid. It is incised, and identification of the internal jugular vein, the carotid artery, and the vagus nerve is carried out. Inferior dissection is carried out with blunt finger dissection, utilizing cold steel or cautery to open up the overlying fascia. This then proceeds superiorly, allowing the surgeon to extend deep to the posterior belly of the digastric. An army-navy retractor is utilized to retract upward the posterior belly of the digastric, thereby bringing into view the hypoglossal nerve as it runs superficial to the internal and

(c) 2014 Wolters Kluwer. All Rights Reserved.

the external carotid arteries and deep to the jugular vein. The internal jugular vein is ligated at its superior location, depending on tumor location, and the spinal accessory nerve is sacrificed as well. The inferior aspect of the internal jugular vein is also ligated, its exact location depending on tumor location. The authors typically use two separate zero silk sutures to ligate the vein, although large ligaclips and other suture techniques are acceptable.

At this point, the specimen is rotated laterally to medially and reflected off the fascia overlying the carotid artery, with care taken to preserve the cervical sympathetic chain and the vagus nerve. It is then rolled onto the fascia overlying the strap muscles and is subsequently removed in an en bloc fashion utilizing monopolar cautery.

Following this, the surgical bed is copiously irrigated and suction drains are placed. The skin flaps are returned to their anatomic positions, and interrupted 3-0 vicryl suture is utilized to reapproximate the platysma, followed by either staple or suture closure of the skin layer, depending on surgeon preference.

Care must be taken during ligation of the internal jugular vein as the vagus and the hypoglossal nerves are susceptible to iatrogenic injury during this period. During both superior and inferior ligation of the internal jugular vein, the vagus nerve must be identified within the carotid sheath, otherwise inadvertent cross-clamping of this structure may occur. Furthermore, during superior ligation of the internal jugular vein and its tributaries, identification of the hypoglossal nerve juxtaposed with the ranine plexus of veins is crucial to avoid injury to the hypoglossal nerve. In the setting of iatrogenic injury, primary neurorrhaphy or cable grafting is utilized for repair.

## Modified Radical Neck Dissection

The first described attempts to reduce the morbidity associated with RND came from Bocca et al.[22] in 1967. He described what was referred to at the time as a "functional neck dissection," which is currently referred to as a "modified radical neck dissection" (MRND). This procedure, like the RND, involves the removal of nodal levels I to V, but unlike in an RND, some or all of the nonlymphatic structures that are not involved with disease are spared.

At present, there has been a shift away from the MRND toward SNDs, even in patients with more advanced nodal disease. Though the main goal is an overall reduction in operative morbidity, an additional issue playing a role in the movement away from the MRND has been the consideration of preservation of certain lymph node groups that have low risk of metastasis. One of the more frequent discussions has been whether dissection of level V is truly necessary. Several reports have demonstrated that level V is rarely involved in the absence of the involvement of other nodal levels.[23,24] The spinal accessory nerve transverses level V, and even when the nerve is grossly spared, shoulder dysfunction can still occur due to traction or devascularization during the procedure. Thus, many surgeons consider the associated shoulder morbidity too significant to warrant level V dissection when other nodal levels are negative.

Modifications on the traditional RND are made, to include preservation of either the internal jugular vein, the spinal accessory nerve, or the SCM. The surgical approach is similar to that of the RND with the following modifications. It is important to note that if nodal disease is present or involving structures, the technique will require modification to avoid entering lymph nodes or their extracapsular component, and these areas should be removed "en bloc."

***Spinal Accessory Nerve Preservation.*** During the posterior-superior to posterior-inferior turn that is made in the posterior cervical triangle along the trapezius muscle, identification of the spinal accessory nerve is essential. This nerve is not sacrificed, but rather traced from the trapezius to the posterior border of the SCM. It is then followed through the SCM and located at its anterior aspect as it descends from the jugular foramen. At this point, the nerve is elevated out of the SCM and the dissection proceeds in traditional fashion.

***Internal Jugular Vein Preservation.*** After releasing the clavicular and sternal heads of the SCM inferiorly, the omohyoid is divided and the carotid sheath is incised. Identification of the internal jugular vein, carotid artery, and vagus nerve is carried out. The en bloc specimen is rolled laterally to medially from the posterior to anterior triangle, and the cervical rootlets are identified. The lymphatic tissue in levels II, III, and IV is rolled onto the jugular vein, where it is sharply removed utilizing a 15-blade scalpel. The common facial branch of the internal jugular vein, as well as other branches, must be effectively ligated in order to achieve hemostasis and full release of the specimen from the internal jugular vein in the modified neck dissection technique, unless a microvascular anastomosis is planned and there is no adenopathy in the vicinity.

***SCM Preservation.*** After performing the level I dissection, we traditionally proceed to release the superior attachment of the SCM to the mastoid tip. However, with SCM preservation this is not performed. The fascial layer is unwrapped off the anterior border of the SCM down to the spinal accessory nerve and the cervical rootlets. At this point, attention is then paid to defining the spinal accessory nerve as it traverses the posterior triangle. If the spinal accessory nerve is also to be preserved, it is then dissected free, and the fibrofatty tissue is reflected laterally to medially and passed under the preserved SCM and removed in continuity with the lymphatic tissue of the deep anterior triangle. If the spinal accessory nerve is to be resected, then after it is identified anterior to the SCM, it is dissected through the SCM and into the posterior triangle. After clipping it as it exits the jugular foramen, and as it innervates the SCM, it is effectively free anteriorly, and it is then included with the posterior triangle specimen and rolled under the SCM, allowing it to be removed in continuity with the lymphatic tissue of the deep anterior triangle.

## Neck Dissection in Nonsquamous Cell Head and Neck Cancers

***Melanoma.*** Melanoma is one of the more common nonsquamous cell cancers in the head and neck region. It is estimated that occult metastases are present in clinically negative neck nodes in an estimated 15% to 20% of cases and can increase to 50% with increased Breslow thickness of the primary lesion.[25] Although elective neck dissection has been used for staging purposes in these patients, the morbidity associated with the procedure is high, and no clear survival benefit has been shown.[26] Sentinel node biopsy has become a more popular way of staging neck disease than a neck dissection, or a "watch and wait" policy; however, some studies have shown that even sentinel node biopsy does not confer a survival advantage in these patients.[26] An additional drawback is that it has a high rate of false-negative results; however, a positive result is highly predictive of recurrence.[27] Studies in cutaneous melanoma of the head and neck region reveal that eradication of regional nodal metastasis does not improve overall survival, but may improve locoregional control and associated morbidity.

***Salivary Gland Cancers.*** As with other head and neck cancers, cervical nodal metastasis in minor salivary gland cancers is associated with decreased survival. A study using the data in the

(c) 2014 Wolters Kluwer. All Rights Reserved.

SEER database was conducted in 2010 with the intent of uncovering factors that may be predictive of lymph node metastasis in these patients.[28] Multivariate analysis of 2,667 cases of minor salivary gland cancer distinguished four statistically significant factors that placed patients in "high-risk" groups for the presence or development of nodal metastasis: male sex, a T stage of 3 to 4, pharynx as a primary site, and tumor histology of either high-grade adenocarcinoma or mucoepidermoid carcinoma. Thus, treatment of clinical and potential occult nodal disease in these patients is paramount.

High rates of lymph node metastasis have also been reported in certain major salivary gland cancers, with one study showing pathologically positive nodal disease in 53% of patients.[29] More recently, a study of multiple histologic types of parotid cancer demonstrated positive neck disease in 22% of patients with low-grade tumors and 49% of patients with high-grade tumors.[30] The authors concluded that a modified RND should be performed along with parotidectomy, but further trials are needed before this recommendation can be made. In general, however, neck dissection and/or radiation therapy is often indicated when high-grade major salivary gland malignancies are diagnosed.

***Thyroid Carcinoma.*** The debate over elective neck dissection in thyroid cancer patients is complex and beyond the scope of discussion for this section. A recent meta-analysis has, however, shown that when central compartment neck dissections are performed, there is no increase in permanent morbidity associated with performing the procedure along with a planned thyroidectomy.[31] The extent of lymphadenectomy is also controversial and typically includes level VI, but additional levels should be included for clinical evidence of disease in well-differentiated thyroid carcinoma and for medullary thyroid carcinoma. The level II to V techniques are well described above and, therefore, only central compartment techniques are described herein.

## Central Compartment Neck Dissection

The central compartment is made up of lymph nodes contained between the hyoid superiorly, the inominate artery inferiorly, and the carotid arteries laterally (Fig. 14-20A and B). This area is a common site for metastatic disease from the thyroid and the larynx. This compartment is further broken down into level VI (between the hyoid bone and the sternal notch) and level VII (between the sternal notch and the inominate artery).

Dissection begins by performing a transcervical incision in a natural skin crease as one typically would for a total thyroidectomy. The incision can be extended to the medial aspect of the SCM bilaterally. Superiorly and inferiorly based subplastysmal skin flaps are then elevated to the level of the hyoid superiorly and the sternum inferiorly. Dissection through the paramedian raphe enables lateral retraction of the strap muscles. Preservation or transection of these muscles can be carried out, depending on the desired level of exposure. At this point, the carotid artery is identified bilaterally and is dissected up to the level of the hyoid superiorly and the inominate artery inferiorly. Attention is then paid to removing the prelaryngeal lymph nodes between the hyoid and the thyroid. Given their scant nature, they are easily removed, yet care must be paid to identifying the superior laryngeal nerve in the process. If the thyroid gland has been removed, there is no fascial connection between the prelaryngeal nodes and the pretracheal nodes; therefore, this specimen must be passed off separately. However, if the thyroid gland is still present, the prelaryngeal nodes can be pedicled on the thyroid and removed along with the gland.

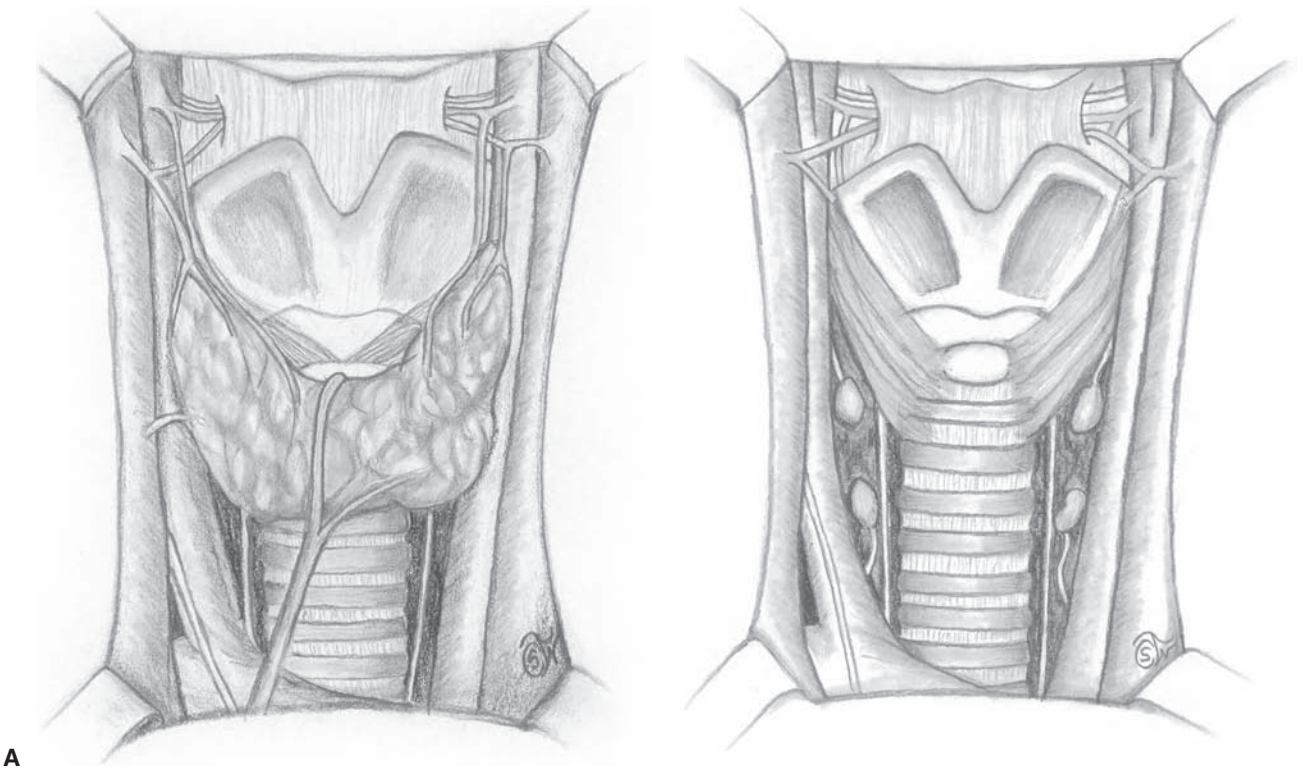

**FIGURE 14-20.** **A:** Central compartment. **B:** Central compartment after neck dissection with thyroidectomy.

(c) 2014 Wolters Kluwer. All Rights Reserved.

Attention is then turned to identifying the recurrent laryngeal nerves on either side. Both nerves are identified and skeletonized from their insertion into the cricothyroid joint down to the level of the inominate artery. The paratracheal lymph nodes are retracted laterally to medially off both nerves and pedicled on the pretracheal region. At this point, solely the pretracheal lymphatic tissue between the thyroid cartilage and the inominate artery remains. An Allis clamp can be utilized to grasp this tissue providing superior retraction. Direct visualization of the plane of the inominate artery is necessary to define your inferior extent. With both recurrent nerves directly visualized, resection of the pretracheal specimen can then occur. Identification of the inferior parathyroid glands may be carried out in the hopes of reimplantation; however, they are often resected en bloc with the specimen. As a result, identification of the superior parathyroid glands and their preservation is essential. The pretracheal specimen is resected and passed off in standard fashion. Meticulous hemostasis is necessary in level VII, given the nature of the tissue to retract into the mediastinum after retraction is released.

Following this, copious irrigation of the surgical bed is carried out and adequate suction drainage is applied. The skin incision is closed in the standard fashion.

CHAPTER 15

# Metastatic Cancer of the Neck from an Unknown Primary Site

## PART A:
## General Principles and Management

Steven S. Chang and Joseph A. Califano

### INTRODUCTION

Metastatic cervical carcinoma with an unknown primary (MCCUP) represents a small proportion of all head and neck cancers. As a head and neck surgeon, the primary goal is to utilize the many diagnostic options available to determine the site of the primary. In this chapter, we will describe a thoughtful, evidence-based, and stepwise approach to the workup of the MCCUP to search for the primary tumor. We will also address the role of surgery and radiation in the management of MCCUP. Lastly, we will discuss outcomes of treatment. The various options for workup and treatment will be summarized in an algorithmic form (Fig. 15-1).

### DEFINITION

The World Health Organization (WHO) defines carcinoma of unknown primary as the histological diagnosis of metastases without diagnosis of a primary tumor, an entity that constitutes 3% of all malignant neoplasms.[1] As a distinct subgroup, MCCUP represents 2% to 9% of all head and neck cancers.[2–6]

The entity of MCCUP was first described in 1944 by Martin and Morfit[7] as metastatic disease in lymph nodes of the neck without any evidence of a primary mucosal lesion. The definition of a neck cancer of unknown primary was carefully outlined in 1957 by Comess et al.[8] and further defined by Jesse in 1966[9] at MD Anderson Cancer Center in a series of 127 patients. In 1973,[10] the same group described treatment recommendations that consisted of treatment of the ipsilateral neck along with radiation to potential mucosal sites.

Although the histological subtype of MCCUP is most commonly squamous cell carcinoma (SCC),[11] the entity actually includes all patients with unknown primary regardless of histological subtype. Some reports have noted 50% of MCCUP to be SCC and 20% to be undifferentiated.[12] Other types of malignancies, such as adenocarcinoma and melanoma rarely occur, but have a different workup, treatment, and prognosis[13,14] and therefore are not discussed in this chapter, which is focused on SCC. With that said, there are circumstances in which certain mucoepidermoid tumors (especially tongue) present as adenopathy that cytologically resembles SCC. Although unknown primary SCC of cervical lymph nodes is by far the most common subtype of unknown primary carcinoma seen by head and neck oncologists and is the focus of this chapter, one must remember that this subgroup of patients represents <10% of all unknown primary carcinomas.[15,16] The definition of unknown may change depending on the physician and the workup performed. What is unknown to a generalist may in fact be easily discoverable with a thorough head and neck examination, and what was unknown 25 years ago may now be easily discoverable by improved radiologic imaging. In those cases in which the primary tumor is not initially obvious, >50% of lesions are discovered by physical examination, computed tomography (CT), magnetic resonance imaging (MRI), and/or panendoscopy.[17] A paper from Memorial Sloan-Kettering Cancer Center showed that >50% of patients referred for treatment of unknown primary head and neck cancer had a primary lesion identified within 2 weeks of presentation.[7] A similar study from Liverpool reports that 56% of primary lesions were identified by an otolaryngologist—head and neck surgeon in cases originally thought to be of unknown primary site.[18]

Although other head and neck cancers have increased in incidence over the last 20 years, a Danish survey reports a stable incidence of 0.34 cases/100,000/year of unknown primary cervical carcinoma. It is possible, however, that an increase in the incidence of unknown primary carcinoma has been masked by improvements in detection of the primary lesion.

### OVERALL STRATEGY FOR DISCOVERY OF SITE OF PRIMARY ORIGIN

A critical component to management of MCCUP includes the search for the site of an occult primary tumor. The importance of this exercise cannot be overestimated, as different primary sites

(c) 2014 Wolters Kluwer. All Rights Reserved.

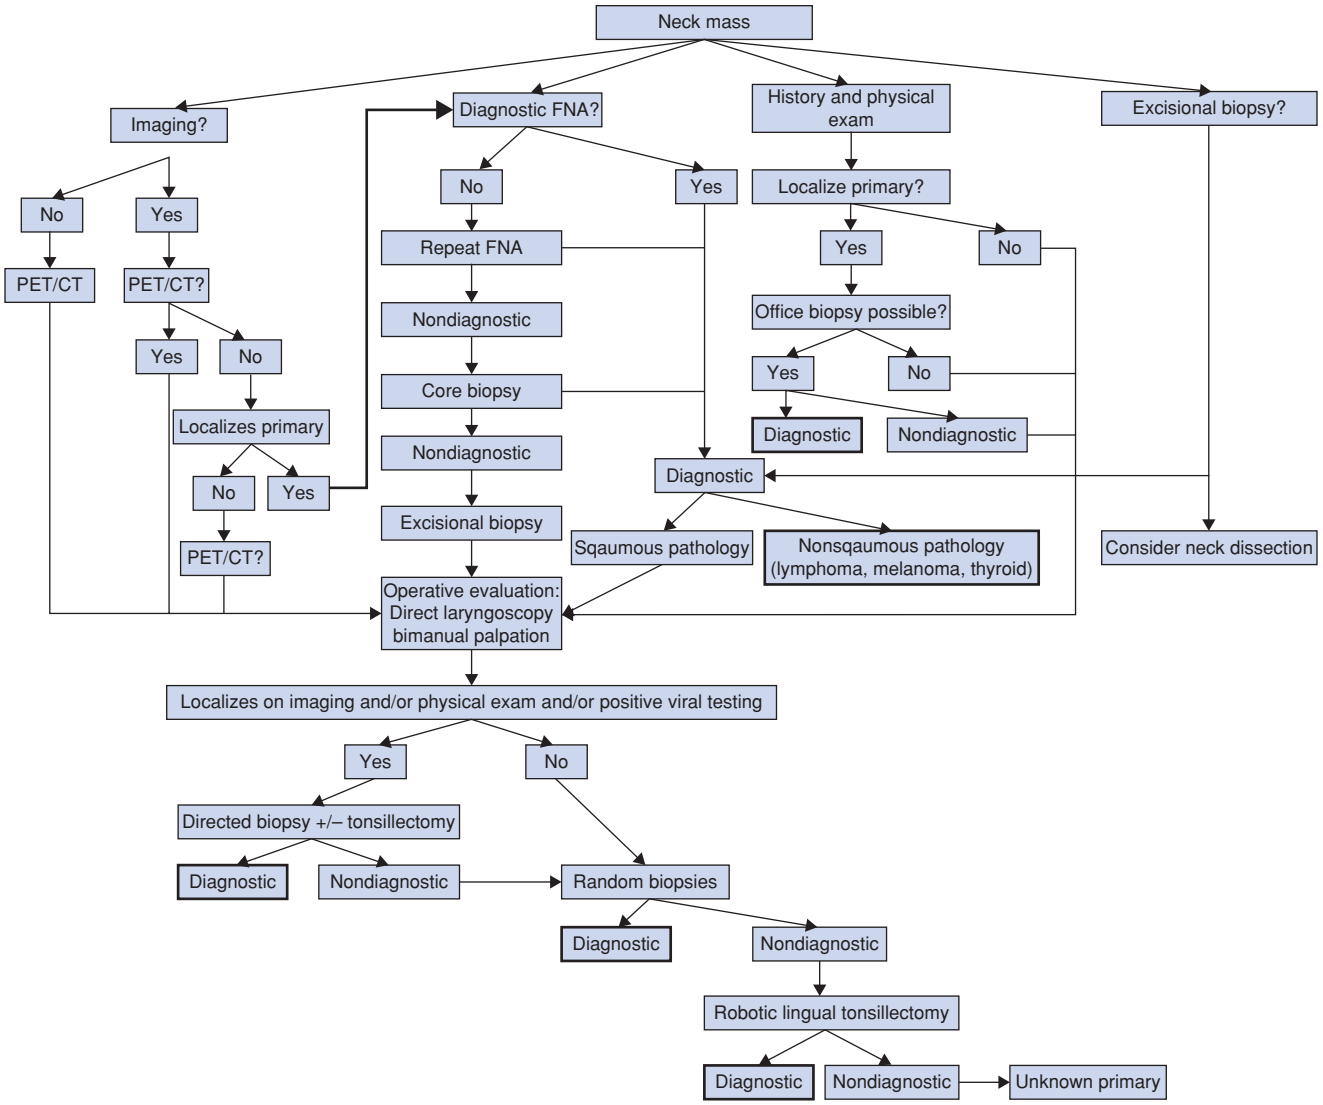

**FIGURE 15-1.** Algorithm for diagnosis and management.

have vastly different prognostic factors, staging, and therapeutic options. Failure to accurately define a primary tumor of origin may potentially result in ineffective or inappropriate therapy as well as unwanted treatment morbidity. A high premium, therefore, is placed on discovery of the site of the unknown primary.

## NATURAL HISTORY

By definition, in unknown primary cancer, the primary tumor is not evident. If left untreated, however, it becomes evident in 13% to 55% of patients after neck surgery alone.[10,19–21] When the primary does emerge, it usually enlarges, becomes macroscopic and symptomatic through locoregional progression. The emerging cancer (usually squamous carcinoma) varies in rapidity of growth, but if left untreated usually assumes aggressive locoregional progression. Locoregional control, therefore, is very important in order to achieve acceptable survival.[22]

Numerous theories attempt to explain the fact that many patients with MCCUP never develop a primary tumor even if the potential primary sites remain untreated. One possible explanation is that the neck mass is the only site of carcinoma and that no primary malignancy ever existed. A third possibility is that spontaneous regression of the primary tumor occurred after the metastatic disease had already become established. A third possibility is that the primary tumor remains viable, but quiescent, and therefore never becomes clinically or radiographically apparent.

The concept that SCC can develop spontaneously in the neck has been a topic of debate in the literature for >100 years. In 1882, Von Volkmann[7] proposed the theory that cervical squamous cell cancer can develop from a branchial cleft cyst. This is based upon the fact that branchial cleft cysts may share similar histopathologic features with metastatic SCC. Cytopathology is not always able to clearly distinguish between benign and malignant cystic squamous lesions of the neck, especially when it comes to separating benign lymphoepithelial cysts with reactive squamous atypia from well-differentiated carcinomas.[23–25] However, the preponderance of evidence argues against this theory as an explanation for cervical lymph node metastasis. One argument against this is that branchial cleft anomalies are

(c) 2014 Wolters Kluwer. All Rights Reserved.

in themselves rare. Because almost all patients with unknown primary SCC present with neck masses of recent onset, a large number of subclinical brachial cleft cysts would have to be present to account for the number of cases of unknown primary SCC. Therefore, on the basis of probability alone, this hypothesis is unlikely. Furthermore, with the advent of P16 and high-risk human papillomavirus (HPV) testing to define cystic, cervical nodal metastases from high-risk HPV primary oropharyngeal tumors, this dilemma has largely been resolved.[23–25]

A second possibility that would account for SCC arising solely in the neck would be if epithelial rests present in the neck, either in soft tissue or cervical lymph nodes, underwent malignant degeneration. However, there is no evidence that epithelial rests exist in the soft tissues or lymph nodes of the neck; so this does not seem to be a viable explanation for the presence of MCCUP. Occasionally, the primary tumor spontaneously regresses, presumably because of the body's natural immune process.[26] Possibly, a small primary site has expended itself during the process of metastasis or because of victory of local immune factors over alien neoplasia. Leukoplakia,[27,28] which is sometimes a precursor to invasive cancer, has been reported to regress in 37% to 44% of cases and even when dysplasia is present it has been reported to regress in 10%[29] of cases. In surgical-only treatment of unknown primary metastasis, most of the time no primary tumor develops.[30] Then, one must assume that in some of the cases where no primary tumor develops, the primary tumor has, in fact, regressed. There is also the possibility of local immunity being responsible for local tumor containment. In squamous cell cancer, different tumors possess different genetic mutations accounting for malignant degeneration. It is possible that some tumors possess mutations that allow metastasis rather than uncontrolled growth. If the metastatic disease then undergoes additional metastasis allowing for uncontrolled growth, or if the native environment of the lymph node enables uncontrolled growth of the tumor, patients could present with an undetectable microscopic primary lesion and a large cervical metastasis. Mutations that allowed degradation and migration through the basement membrane could account for such behavior. Despite the significant increase in research that has been performed on the molecular genetics of SCC, no significant data yet exist to support this theory. Although the development of the primary tumor is a major concern in patients with unknown primary cervical squamous cell cancer, the most important prognostic factor for these patients is nodal stage.

## STAGING

The staging for MCCUP follows the tumor, node, metastasis (TNM) guidelines established for other sites in the head and neck (Table 15.1). After workup, all patients by definition are classified as T0 due to the absence of an obvious primary site and N + due to the presence of nodal metastasis. Nodal staging is assigned as with other sites in the head and neck.

## CLINICAL PRESENTATION

The typical presentation of a patient with MCCUP is a unilateral painless neck mass that has enlarged over recent months. The patients usually present to a primary care physician and usually at the time of diagnosis have received several courses of antibiotics. Persistence of the painless, enlarging mass should then be evaluated by a head and neck surgeon. Studies have demonstrated that the median interval of symptom onset to accurate diagnosis by a head and neck surgeon is 3 months.[31] The median age of presentation for these patients is 55 to 65 years, although patients as young as 15 years have been reported.[32]

**TABLE 15.1 AJCC Staging for Metastatic Cervical Carcinoma with an Unknown Primary**

| | |
|---|---|
| T0 | No evidence of primary tumor |
| NX | Regional lymph nodes cannot be assessed |
| N1 | Metastasis in a single ipsilateral lymph node ≤3 cm in greatest dimension |
| N2a | Metastasis in a single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension |
| N2b | Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension |
| N2c | Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension |
| N3 | Metastasis is in a lymph node >6 cm in greatest dimension |
| M0 | No distant metastasis |
| M1 | Distant metastasis |
| MX | Distant metastasis are indeterminate |

Based on Edge SB, Byrd DR, Compton CC, et al: AJCC Staging Manual, 7th edition, New York, NY: Springer-Verlag, Inc., 2010.

The first step in the workup of a patient with unknown primary SCC is a thorough office examination with a history and physical examination. Each component of the office examination is essential to directing the operative plan to rule out a primary and determine whether the patient is a true unknown primary and thus dictates the treatment plan.

## HISTORY

Many aspects of the history can alter a head and neck's suspicion for a primary site. Historically, most patients diagnosed with head and neck squamous cell carcinoma (HNSCC) were older males with a significant tobacco and alcohol history. However, with the recent epidemic of HPV-related oropharyngeal SCC, there has been an increase in younger patients and a more even distribution among sexes. HPV-related malignancy is often a distinct entity from smoking- and alcohol-related malignancy with a different prognosis. Therefore, it is no longer safe to assume that a young female patient with a neck mass is unlikely to have a malignancy or to assume that she has a significant tobacco or alcohol history and that her prognosis is the same.

The patient's symptoms, if any, may help identify the primary site. Epistaxis, nasal obstruction, or complaints consistent with otitis media point to a nasopharyngeal primary. Complaints of otalgia, dysphagia, or dysarthria may suggest an oropharyngeal or hypopharyngeal primary lesion. Laryngeal lesions often result in voice and respiratory changes. The time course of the tumor growth can often be helpful in formulating the differential.

A careful medical history can also be very helpful. A history of previous skin cancer or immune suppression can be essential in directing the investigation for the primary. The social history can also be useful, with particular attention to tobacco use, alcohol use, sexual history,[33] ethnicity/race, foreign travel, sun exposure, and radiation exposure.

Personal and institutional review of the outside records of any ancillary testing such as imaging and pathology is strongly encouraged to ensure nothing is overlooked. When reviewing the pathology, particular attention should be paid to the histopathology

(c) 2014 Wolters Kluwer. All Rights Reserved.

of the tumor and HPV status. When reviewing radiology, it is important to examine the location of the metastasis and its relationship to surrounding structures. For instance, a poorly differentiated tumor with basaloid features and a large cystic level II lymph node in a young never-smoker female has a high probability of being an HPV-related tumor of the oropharynx.

Regardless of the patient's symptoms (or lack thereof), a history and physical examination by a head and neck surgeon is essential to the workup.

## PHYSICAL EXAM—NECK

### Location of Metastasis

A careful examination of the neck metastasis is essential, paying particular attention to its location and relationship to surrounding structures. The most frequent cervical metastatic site in patients with MCCUP is level II, which is the circumstance in >50% of patients.[2,31,34–36] After level II, level I and level III lymphatics are next most common. Lower neck and supraclavicular metastasis are also common and are more frequently associated with a primary site located below the clavicles.[3,24,37] Unilateral nodal involvement is the most common presentation, but bilateral nodes are seen in 10% of cases.[12,14,38] If multiple bilateral enlarged nodes are encountered, infection, lymphoma, and nasopharyngeal cancer should be placed higher in the differential diagnosis. Presentation with only a single node occurs in 44% to 52% of patients[10,38] and the median nodal size is 5 cm (2–14 cm).[12] An isolated nodal mass in the submental triangle is rarely cancer. Typically, these masses are inflammatory or related to benign salivary gland conditions. Posterior palpable nodes in a young patient are usually benign, many resulting from inflammation. By identifying the nodal stations involved and understanding patterns of lymphatic drainage with regard to primary sites, more focused diagnostic procedures and treatment strategies can be developed (Table 15.2). Therefore a thorough understanding of the anatomy of the neck is essential. Below is a description of the levels of the neck with their corresponding sites of drainage.

Level I includes the submental and the submandibular nodes. Level IA drains the floor of the mouth, the anterior tongue, the anterior inferior alveolar ridge, and the lower lip. Level IB drains the oral cavity, the anterior nasal cavity, and the soft tissue of the midface. Level II encompasses the upper internal jugular nodes. Level II nodes most commonly receive drainage from the oral cavity, the nasopharynx, the oropharynx, the larynx, the hypopharynx, and the parotid gland. Level III, which includes the middle jugular nodes, receive drainage from the oral cavity, the nasopharynx, the oropharynx, the larynx, and the hypopharynx. Level IV, which encompass the lower jugular nodes, typically receives drainage from the larynx, the hypopharynx, the thyroid, and the esophagus. Level V covers the entire posterior triangle and drains the nasopharynx, the oropharynx, and the skin of the posterior scalp. Level VI is the main drainage basin for the thyroid, the subglottic larynx, the hypopharynx, and the esophagus. Level VII overlies the tracheal esophageal grooves and the superior mediastinum from the manubrium to the superior edge of the inominate vein. The retropharyngeal nodes are not assigned a level, they drain the nasopharynx, the hypopharynx, and the larynx. The supraclavicular nodes are also not assigned a level, but are considered separately from levels I to VII. They drain from the thoracic duct on the left or the accessory thoracic duct on the right. When these nodes are present without superior neck adenopathy, the diagnostician should search for a primary site in infraclavicular or subdiaphragmatic locations. The location of the lymph nodes can help guide the search for a primary because 63% of patients with supraclavicular nodal presentation are found to have infraclavicular primaries compared to 5% of patients with jugular nodal presentation,[20] 3% to 8% of patients with unknown primary SCC to have a lung primary.[27,38–40] A study by Jones et al.[18] showed that infraclavicular primary lesions occurred in 30 of 267 patients (11%), whereas head and neck primary lesions were found in 174 of 267 patients (65%). Eighty-three percent of infraclavicular primary lesions discovered were in the lung. Fifteen of the 25 lung cancers were identified during the initial workup whereas 10 were identified during follow-up or at autopsy. These data are summarized in Table 15.2.

**TABLE 15.2 Toolbox for Possible Primary Site**

| Neck Level | First Echelon Drainage |
|---|---|
| I | Anterior oral cavity |
| | Anterior nasal cavity |
| II | Oral cavity |
| | Oropharynx |
| | Nasopharynx |
| | Larynx |
| | Hypopharynx |
| | Parotid |
| III | Oropharynx |
| | Nasopharynx |
| | Larynx |
| | Hypopharynx |
| IV | Larynx |
| | Hypopharynx |
| | Thyroid |
| | Esophagus |
| V | Nasopharynx |
| | Posterior scalp |
| Virus | Possible primary site |
| HPV | Oropharynx |
| EBV | Nasopharynx |

## PHYSICAL EXAM—PRIMARY SITE

Once the neck has been appropriately examined, we then proceed in the physical to the search for the primary tumor. A careful scalp examination is essential because skin cancers can be hidden by hair and may go unrecognized. Enlisting the consultation of a dermatologist may be helpful in this regard if the patient has many skin lesions. A careful oral cavity and pharyngeal examination is performed, looking for subtle mucosal abnormalities and focusing on areas of particular risk relative to the location of the neck mass. Areas such as the nasopharynx and the oropharynx are more likely to be the primary mucosal sites of origin in unknown primary squamous cell cancer of

(c) 2014 Wolters Kluwer. All Rights Reserved.

the neck and as such need special diagnostic attention. Flexible fiberoptic examination is essential to properly examine the nasopharynx and provides an excellent look at the base of tongue and the valleculla, as well as the larynx and the hypopharynx. Examination of the oropharynx, with palpation of the tonsils and the base of the tongue, is also essential. These techniques may reveal tumors not otherwise visible. The base of the tongue is an area in which the more time-honored method of a hand mirror and headlight can also provide more information than flexible fiberoptic examination. Additionally, digital palpation of the tongue is invaluable in certain tumors predisposed to submucosal spread.

## OFFICE BIOPSY AND FINE-NEEDLE BIOPSY

If a primary site is suspected, a biopsy can often be performed in the office, thereby expediting the diagnosis. Regardless of the presence or lack of a primary site, a fine-needle aspiration (FNA) of the neck mass should be performed at the outset. Depending on circumstances, it is preferable to obtain basic imaging of the head and neck before the FNA; however, it can be done before the imaging. If there is uncertainty of the diagnosis, the FNA can usually be accomplished on the initial visit to confirm the diagnosis of malignancy. If available, the use of a cytopathologist at the time of aspiration can be very helpful. A cytopathologist can ensure that an adequate cytologic sample has been obtained. In addition, if lymphoma or a nonsquamous pathology is suspected, additional material can be obtained to initiate the appropriate immunohistochemical or molecular diagnostic studies needed for the diagnosis, and, under these circumstances, the diagnostic pathway that follows is tailored differently than in epithelial cancers.

If the patient comes with a biopsy already performed, several features of the report can be helpful in directing the physical exam and possible operative examination. The degree of differentiation and gross appearance can be helpful in the investigation. For instance, if the histologic examination shows a poorly differentiated (basaloid) microscopically and grossly cystic tumor, it is highly suggestive of a HPV-positive tumor originating from the oropharynx.[41] If viral testing has not been performed at the outside institution, we suggest viral testing of the biopsy for HPV 16, P16, and Epstein-Barr virus (EBV). It has been shown that 27% to 28% of metastatic lymph nodes from an occult primary are HPV +.[41,42] Furthermore, several studies suggest that if HPV is detected in the neck metastasis, it is a reliable indicator that the origin of the tumor is in the oropharynx.[43] Therefore, viral testing can both assist in directing the surgeon's investigation for the primary site and assist in determining a patient's prognosis.

Additionally, even if a biopsy specimen shows histologic features consistent with lymphoepithelial carcinomas originating from the nasopharynx, testing for HPV and EBV is still strongly recommended because a morphologic variant of HPV-HNSCC in the nasopharynx that is microscopically indistinguishable from EBV-related carcinoma exists.[44] However, P16 immunohistochemistry is a reliable marker for separating EBV-related and HPV-related carcinomas of Waldheyer's ring.[45] It has been proposed that P16 may be a surrogate marker for HPV testing, but the authors suggest testing for both P16 and high-risk HPV. The reason is that studies have shown that P16 overexpression is not always linked to high-risk HPV integration and may be found in benign lymphoepithelial cysts. This observation limits the role of p16 staining as a surrogate marker of HPV 16 infection. P16 is therefore a useful adjunct to HPV testing in distinguishing between benign and malignant cystic squamous lesions of the neck.[23]

## IMAGING

Historically, the radiographic workup of MCCUP has consisted of CT of the head and neck and sometimes of the thorax. The goal of this study is to locate the primary site of the tumor. A report from the University of Florida showed that in 50% of patients with normal physical examinations, CT and/or MRI imaging revealed the site of origin of the primary tumor.[17] Areas of obvious or questionable radiographic abnormality can be closely examined and biopsied during subsequent panendoscopy. For this reason, all imaging studies should be obtained before panendoscopy. In addition to guiding biopsies so as to include suspicious areas, obtaining imaging before the panendoscopy is important because inflamed biopsy sites may mimic subtle tumor on imaging, particularly if positron emission tomographic (PET) scans are obtained.[46] Features of the neck metastasis on CT or MRI can also be helpful in the investigation for a primary. For instance, if the neck metastasis is cystic, it indicates strongly that the primary is a HPV-related tonsil cancer.[47]

The role of PET and/or PET/CT in the workup of patients with MCCUP has increased greatly during the last few years. A meta-analysis published in 2004 by Rushtoven et al. examined the efficacy of PET in the detection of primary tumors in patients with MCCUP.[48] In that study, PET scans had a sensitivity and specificity of 88.3% and 74.9%, respectively. In patients with MCCUP in which the CT and panendoscopic findings were negative, PET scans revealed a primary tumor in 29% to 39% of patients.[49,50] Several published studies examined the use of PET scans in the detection of distant metastasis and found that PET scans also discovered a site of distant metastasis in 11.2% of patients. PET scans also proved useful in identifying primary sites outside of the head and neck because 24.3% of primary tumors were found to be infraclavicular. PET scans localized the primary tumor in 24 of 27 patients with infraclavicular primaries.[48] PET scans, however, have a higher false-positive than false-negative rate. They tended to overread tonsillar cancers and in that particular area demonstrated a false-positive rate of 39.3%. The false-positive rate was also higher in the base of the tongue than other areas at 21.4%. PET scans, in general, are highly sensitive, although PET scans are least sensitive at the base of the tongue with the sensitivity being 81.5%, compared to 90.5% in other sites in the head and neck. The lack of sensitivity in the base of the tongue is thought to occur from the high baseline level of fluorodeoxyglucose (FDG) uptake in that area. PET scans showed the highest accuracy in tumors of the larynx and hypopharynx, with a specificity and sensitivity of 100%.[48]

PET/CT is widely available at this time, and many head and neck oncologists use this technology. Because the principles behind CT and PET scans are different, the former providing anatomic information and the latter metabolic information, a combination of the two imaging modalities have the highest yield in discovering the site of unknown primary cancers. Studies have suggested that PET/CT is superior to either PET or CT alone in the workup of head and neck cancer.[51–53] Although a positive PET scan helps guide the surgeon to a primary tumor site, a negative PET scan does not alleviate the need for a careful panendoscopy with random guided biopsies. The limitations of PET/CT are still to be fully defined, but it is well known that it is unclear how helpful this modality is in detecting nonsquamous primaries such as salivary gland and thyroid malignancies.[54] An additional benefit of PET/CT is that the recent national lung screening trial found CT scans to be superior to chest x-ray in reducing mortality from lung cancer[55] in people who are high risk for lung cancer.

Therefore, obtaining this imaging modality allows for examination of the neck metastasis features/location, search for the primary via the anatomical and metabolic modality and the

(c) 2014 Wolters Kluwer. All Rights Reserved.

CT can screen for a lung primary. PET/CT is an essential adjunct to the workup of a patient with the unknown primary. Fundamental to good diagnostic methodology, however, is a well-done direct examination, for which there is no technologic substitute.

## PANENDOSCOPY, BIOPYSY, AND TONSILLECTOMY—OPERATIVE MANAGEMENT

Panendoscopy under general anesthesia is an essential component of the workup of all head and neck squamous cell cancers and is especially important in the workup of MCCUP because it dictates the modality and extent of therapy. No matter how thorough a clinician is in the office, a more detailed and complete examination is possible with the patient asleep. It is difficult to determine the yield of panendoscopy in patients with MCCUP, but used in conjunction with PET/CT, studies have revealed the primary site during panendoscopy in approximately 40% to 60% of patients.[18,52,56,57] Older studies, done before the routine use of flexible fiberoptic laryngoscopy, tend to report a higher yield on panendoscopy. With that said, however, in patients with laryngeal cancer, the issues of intralaryngeal mobility and restriction of mucosal fluidity are essential; for the analysis of either of these, the visualization of the "awake" larynx in the upright patient in the office setting is essential to proper evaluation. General anesthesia and/or intubation greatly hinders this process.

With the patient under general anesthesia, careful palpation of the nasopharynx, and the oropharynx, can be performed, and this may reveal a small mass that was not appreciated in the office. Direct laryngoscopy should be done to evaluate the oral cavity, the oropharynx, the larynx, and the hypopharynx, with particular emphasis placed on an examination of the pyriform sinuses that are difficult to adequately visualize in the office.

Esophagoscopy should also be performed because the esophageal inlet is not otherwise well visualized. The use of bronchoscopy in the workup of patients with head and neck cancer is individualized and has largely been replaced by PET/CT. Lung cancer rarely presents as upper or middle jugular chain adenopathy. It can, however, present as lower jugular chain (supraclavicular or tracheoesophageal groove) adenopathy. In patients with masses in locations suspicious for a lung primary, a bronchoscopy should be performed.

If no primary site of origin is identified after a thorough direct laryngoscopy and esophagoscopy, guided mucosal biopsies should be done. Overall, the most common sites of origin of unknown primary head and neck cancer are the tonsil, the base of tongue, the nasopharynx, and the hypopharynx.[58] The use of guided mucosal biopsies of the more common sites of primary tumor location should be performed. In addition, if any of these areas was negative on clinical examination but suspicious for malignancy on imaging, that area should be biopsied carefully. A study by Lee et al. was performed in 33 patients with MCCUP in which all of these sites were analyzed, and random guided biopsies revealed the primary site in three of these patients.[59] Guided mucosal biopsies of the nasopharynx, the base of tongue, and the hypopharynx are often done using cup forceps. When biopsying the nasopharynx, it is essential to carefully examine the area being biopsied because HPV have been detected in these biopsy specimens and are thought to represent extension from oropharyngeal primaries.[45]

The tonsil, however, is a cryptic structure, and small mucosal abnormalities may be present that are not visible on either clinical examination or radiologic imaging and are not appreciated by palpation. Use of a cup forceps to sample the tonsil may result in a geographic miss of a small tumor. Because of this, the routine use of tonsillectomy is recommended for the workup of unknown primary cancer. A study of 122 patients with MCCUP by Waltonen et al. demonstrated that the overall yield of finding an occult primary carcinoma in the tonsil was 3.2% for deep tonsil biopsies versus 29.6% for tonsillectomies.[56] A study by Randall et al. was performed in 829 patients with head and neck cancer. Of the 34 patients with no identifiable tumor whose charts were available for review, 6 had the diagnosis made by tonsillectomy.[60] Lapeyre et al. performed tonsillectomy in 87 patients with unknown primary cancer, and that endeavor revealed the site of cancer in 23 patients.[61] However, the authors do not mention whether radiologic imaging was obtained, so presumably some of those cancers would have been identified without tonsillectomy if CT or PET scans had been obtained. A study by Mendenhall et al. found that tonsillectomy detected the site of the primary tumor in 10% of patients with a negative physical examination and negative radiologic imaging.[17] Additionally, two separate studies showed that if a neck node is HPV positive, it is necessary to perform palatine tonsillectomy and lingual tonsillectomy[41,62] to look for unknown primaries.

Most authors advocate ipsilateral tonsillectomy for patients with MCCUP, but some advocate bilateral tonsillectomy. A study by Koch et al. showed that of the 16 patients with unknown primary head and neck cancer whose cancer was eventually found in the tonsil, 4 patients had cancer in the contralateral tonsil.[63] A handful of other case reports demonstrating contralateral tonsil cancer in patients with unknown primary squamous cell cancer are also present in the literature.[64] There are potential advantages to bilateral tonsillectomy. In addition to the low but real possibility that cancer may be present in the contralateral tonsil, the asymmetry resulting from ipsilateral tonsillectomy may be a source of confusion in the future if the patient's care is transferred to another physician who is unsure of the details of the patient's history. The most important point to be made regarding the tonsil in the workup of MCCUP is that the standard of care for the histologic analysis of that structure is the tonsillectomy, whether unilateral or bilateral, and possible ligual tonsillectomy. With a careful history and physical examination, appropriate imaging, panendoscopy with random guided biopsies, and tonsillectomy, the site of origin can be discovered in >50% of tumors[43,52,56,57,59] that were initially classified as MCCUP. Our institutional practice is to perform directed biopsies based on the office examination, imaging studies, and pathology. If operative laryngoscopy does not yield a primary site, we proceed with bilateral tonsillectomy, robotic lingual tonsillectomy, and finally random directed biopsies, usually as a single surgical procedure with frozen section analyses if a suspected tumor is noted after tonsillectomy. Once these procedures are performed and all primary sites ruled out, we then proceed with treatment for MCCUP.

## OPEN BIOPSY

In general, open biopsy is probably overused in the workup of neck masses; however, it still can be essential in select patients. If a patient's FNA is indeterminate, and radiologic workup and panendoscopic findings are negative for cancer, an open biopsy may be required for diagnosis. Before performing such a biopsy, however, a core (or cutting) needle method can be performed. This can often yield a diagnosis even when an FNA has failed. In addition, a core needle biopsy usually does not impact future treatment, whereas an open biopsy might. One study reviewing the usefulness of core needle biopsy in 32 patients with advanced head and neck cancer obtained useful histological specimens 100% of the time.[65] Although the high yield may be somewhat optimistic, it does suggest real value to having this technique in the surgeon's armamentarium. Because of the fundamental concern about needle tract seeding, the FNA remains the standard of

(c) 2014 Wolters Kluwer. All Rights Reserved.

the two when possible. If all nonsurgical attempts at obtaining a diagnosis have failed, an open biopsy can be performed. Open techniques should be used with caution because of the risk of tumor spillage and disruption of fascial planes, which normally act as a barrier to tumor spread. All aspects of the surgical incision and subsequent dissection are at risk for disease recurrence and therefore require treatment. This may result in the need for more aggressive surgery or radiation to achieve disease control. If an open biopsy is performed, it is important to plan the surgical incision so that if a diagnosis of malignancy is obtained on frozen section, the procedure can be converted to a formal neck dissection without making multiple incisions or violating the basic principles of neck dissection.[66] However, if there is risk of an indeterminate frozen section, the classic technique should be modified to include the excision of the skin surrounding the biopsy site from which the tissue was removed, so that a subsequent neck dissection may be performed easily if needed. In those cases in which the initial phase of the treatment strategy is nonsurgical, that consideration of incision planning is still important; and when properly designed, it should not compromise oncologic integrity. It should be noted that the issue of open biopsy safety is associated with some controversy as to whether it has a negative effect on disease control. A study by Mcguirt et al. showed a worse outcome in patients with cervical metastasis who underwent cervical node biopsy before referral for definitive treatment of the neck.[67] These patients suffered a significant increase in the risk of recurrence in the neck and distant metastasis. A similar study from the University of Florida, on the other hand, did not show a difference in neck control, distant metastasis rate, or survival between patients who had an open cervical node biopsy before definitive treatment and those who did not.[68] A study from MD Anderson Cancer Center that reviewed 39 patients with MCCUP, who were treated with an excisional biopsy and posttreatment radiation therapy, found no recurrences in the neck. Although an open biopsy is frequently overused in the treatment of unknown primary head and neck cancer, the evidence does not necessarily confirm a negative impact on the patient's outcome.[69] It is essential that the workup, the biopsy, and the therapy be prospectively planned with the overall strategy in mind. Too often, one encounters circumstances in which a rush to biopsy and/or treatment has led to an ill-conceived treatment strategy.

## TREATMENT AND OUTCOMES

The treatment of MCCUP is controversial with regard to both the extent of radiation of the possible primary sites and what combination of surgery and radiotherapy should be used for the neck. The results of the EORTC 24001-22005 "Randomized Phase III Study on the Selection of the Target Volume in Postoperative Radiotherapy for Cervical Lymph Node Metastasis of Squamous Cell Carcinoma from an Unknown Primary"[70] was unfortunately closed due to lack of accrual. The next two sections will tackle the radiation oncologic and surgical aspects of patient care. Surgery is traditionally the performance of a comprehensive neck dissection, owing to the inability to predict the risk of uninvolved ipsilateral nodal drainage sites in MCCUP. Postoperative radiation to the involved neck and the possible mucosal sites is the standard treatment modality, and good outcomes have been achieved with minimal morbidity; patient survival is approximately 60% to 90% at 5 years with approximately 60% to 90% locoregional control at 5 years.[71–73] These data may be confounded by HPV-positive tumors which tend to have better survival.

After primary therapy, the development of the primary tumor is a major concern in patients with unknown primary cervical squamous cell cancer, and the most important prognostic factor for these patients is nodal stage. The prognosis of patients with MCCUP is similar to that of patients with known primary tumors and the same nodal stage.[2,74] Other prognostic factors include HPV status, the number of positive lymph nodes, cytologic grading, the presence of extra capsular extension, patient age, and the patients' overall performance status.[74–77] It should be noted that there is some evidence to support the fact that the emergence of a primary tumor carries a worse prognosis, with a median survival of 15 months and 5-year survival of 20%[34,78,79] of patients in that group. Whether or not this represents a biologic acceleration of the tumor is unknown. Overall, the progression of cervical lymphadenopathy inpatients with MCCUP is similar to that of patients with known primary tumors. If left untreated, nodal disease can extend through the lymph node capsule to involve adjacent structures. Such invasion can encroach on and involve the skin, the sternocleidomastoid muscle, the jugular vein, the posterior belly of the digastrics muscle, the external and the internal carotid artery, the vagus, the spinal accessory, and/or the hypoglossal nerves. Distant metastasis is associated with and proportionate to nodal stage in patients with N1 disease having a distant metastatic rate of 26% and patients with N3 disease having a distant metastatic rate of 52%.[80] The location of nodal disease also seems to correlate with distant metastasis. Patients with disease in the lower neck have a 27% rate of distant metastasis whereas in patients with disease in the upper neck, that rate is only 13%.[81] Distant metastasis and extracapsular spread decrease survival rate significantly.[75] However, tumors that are found to be HPV positive generally have a better outcome,[82] but the entity of HPV + MCCUP patients has not been studied specifically against HPV– MCCUP.

## RECURRENCE

Recurrence in patients with MCCUP is an ominous prognostic factor, as it is with most cancers of the head and neck. Recurrence in these patients can either be in the neck (either ipsilateral or contralateral) or as the development of a primary site. Additionally, patients with MCCUP can also develop second primary lesions that maybe difficult to differentiate from progression of primary tumors because by definition the primary was unknown. The management of recurrence depends both on the site of recurrence (neck vs. primary) and on the previous treatment given to that site. If disease presents in a primary site, it can represent development of the previously unknown primary or a second primary. If the patient is presenting as a recurrence, the previous treatment zones (relative to the location of the recurrence) and surgical treatment is essential to plan any further treatment. When evaluating the natural history of patients with MCCUP, it is important to distinguish the development of infraclavicular primary lesions from the development of distant metastasis. There is currently no literature to support specific treatment of MCCUP neck recurrence. Current standard of care for treatment of the recurrent neck would be to follow guidelines for a recurrent neck with a known primary. Re-irradiation with intensity-modulated radiotherapy (IMRT) and possibly concurrent chemotherapy should be considered in patients with recurrent unknown primary carcinoma although further studies are needed in this area.

## FUTURE DIRECTIONS: MOLECULAR TESTING?

In addition to continued clinical research into the outcomes of patients with MCCUP, there are also many novel methods that may be employed in the future to find the location of primary tumors and possibly assist in dictating treatment even if all mucosal biopsies are histologically negative.

Microsatellite analysis may prove useful in identifying the site of origin. Califano et al. looked at 18 patients with MCCUP. Using

(c) 2014 Wolters Kluwer. All Rights Reserved.

microsatellite analysis, the benign mucosal biopsies taken randomly from the typical sites (the nasopharynx, the oropharynx, and the hypopharynx) were compared with that of the neck mass.[83] Ten of the 18 patients were found to have genetic alterations in certain biopsy specimens corresponding to those found in the cervical metastasis. All patients who subsequently developed a primary tumor had similar genetic mutation in the tumor and in the original random biopsy. These mucosal sites included three cases of tonsil cancer, one of pyriform sinus cancer, three cases of base of the tongue cancer, one case of floor of the mouth cancer, one case of false vocal fold cancer, and two with combined pyriform sinus and tonsil cancer. This suggests that the mucosal sites of origin can be inferred in some patients, even if the original site is histologically negative for cancer. Although this concept is not yet employed clinically, it may play a larger role in the future.

Barker et al. performed an excellent study looking at microRNA signatures of unknown primary lesions in the head and neck. Altered microRNA (miRNA) expression alterations has been associated with head and neck cancer.[84] They used quantitative real-time polymerase chain reaction (PCR) to identify miRNA expression profiles of SCC of the tonsil, the base of tongue, and the postnasal space, as well as their corresponding metastatic lymph nodes, from six patients. Their results revealed that each cancer maintained its expression profile between the primary site and the nodal metastasis. In addition, each anatomical subsite maintained a distinct miRNA profile between individual patients. Finally, between subsites, the miRNA profiles were also distinct. This study provides an indication that miRNA expression analysis may be useful to predict the primary site of origin of metastatic disease, when the primary site remains obscure.[85]

## SUMMARY

The proper management of the unknown primary continues to evolve as our ability to isolate primaries improves. The recent identification of HPV as a risk factor for HNSCC and prognostic marker, the use of PET/CT, robotic lingual tonsillectomy, and other modalities have altered the way we investigate MCCUP. It is unclear whether the incidence of true MCCUP has decreased as a result of these innovations. A thorough and thoughtful history, physical exam, review of imaging, and pathology are required to direct surgically based investigation in the hope of defining a primary tumor site and treating the cancer appropriately. Continued translational studies that allow for better identification of primary sites will allow for de-escalation of therapy and decrease patient morbidity and mortality.

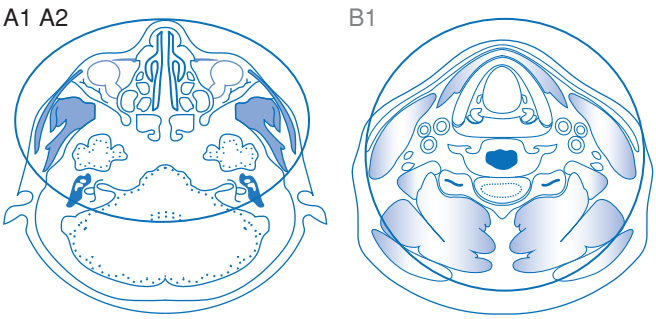
# PART B:
# Radiologic Imaging Concerns

Jeffrey A. Bennett



The optimal diagnostic imaging evaluation for patients presenting with cervical lymph node metastases from an unknown source is still controversial. The purpose of imaging is to help identify potential sites to pay special attention to panendoscopy with directed biopsies. Currently, it is recommended that patients receive a contrast-enhanced CT scan or MRI of the head and neck, and FDG-PET/CT should be considered.[1] Suggested CT and MRI protocols are given in Figures 15-2 and 15-3. The location of the cervical lymph nodes is important as patients with lymphadenopathy primarily in levels II and III will most often have a primary in the tonsillar fossa or the tongue base,[2] whereas patients with low neck lymphadenopathy, primarily in level IV and the supraclavicular fossa, will often have a primary tumor below the clavicles.[3] CT or MRI may identify a submucosal mass that could not be detected on physical exam or endoscopy. Alternatively, a small tumor located deep in the

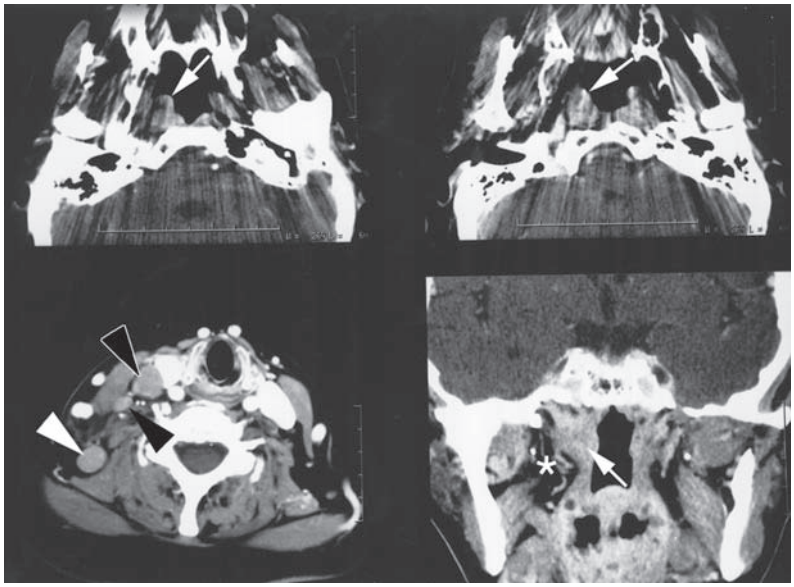

**FIGURE 15-4.** Early nasopharyngeal cancer. Enhanced axial computed tomography and direct coronal view **(bottom right)** show several pathologic right-sided neck nodes (*arrowheads*) in a patient with squamous cell carcinoma of unknown primary. Axial and coronal views show a T1-stage lesion of the right nasopharynx (*arrows*). The parapharyngeal space is normal (*asterisk*).

crypts of lymphatic tissue in the nasopharynx, the palatine tonsils, or the tongue base may produce asymmetry that could guide the endoscopist to a location to biopsy (Fig.15-4). The problem arises though, that normal lymphatic tissue is quite asymmetric, especially in the palatine tonsils and the lingual tonsil, and so a better approach is to use the asymmetry to guide a search for deep invasion into the parapharyngeal space or the tongue musculature, which is a clear sign that cancer is present (Fig. 15-5).

Several investigators have advocated for FDG-PET/CT to be performed in patients with an unknown primary tumor[4–6] and claim that this study is potentially slightly better than CT or MRI (Fig. 15-6), with the limitation of a high false-positive rate, secondary to normal tracer uptake in lymphoid tissue. A meta-analysis of the literature on the diagnostic accuracy of FDG-PET and FDG-PET/CT to detect an unknown head and neck primary was performed by Dong et al. in 2008.[7] This resulted in a pooled sensitivity of 81%, specificity of 82%, and false-positive rate of 28.6% for the tongue base. FDG-PET/CT had a higher sensitivity and specificity than did FDG-PET alone. An additional literature review by Rusthoven et al.[8] identified 16 studies in which altogether the primary site was found by FDG-PET in 74 out of 302 patients (24.5%). The sensitivity was 88.3% and specificity was 74.9%. There were 47 false-positives with rates of 39.3% for the tonsillar fossa, and 21.4% for the base of the tongue. Wong et al.[9] studied 78 patients with cervical lymphadenopathy and an unknown primary. PET/CT revealed a suspicious area in 46 of the patients (59%), and cancer was confirmed in 30 of the patients (38.5%). The sensitivity was reported as 100%, specificity 66.7%, positive predictive value 65.2%, and negative predictive value 100%. These studies contrast with that of Cianchetti et al.[1] where none of 21 patients who underwent FDG-PET or FDG-PET/CT had the primary site detected by this imaging modality.

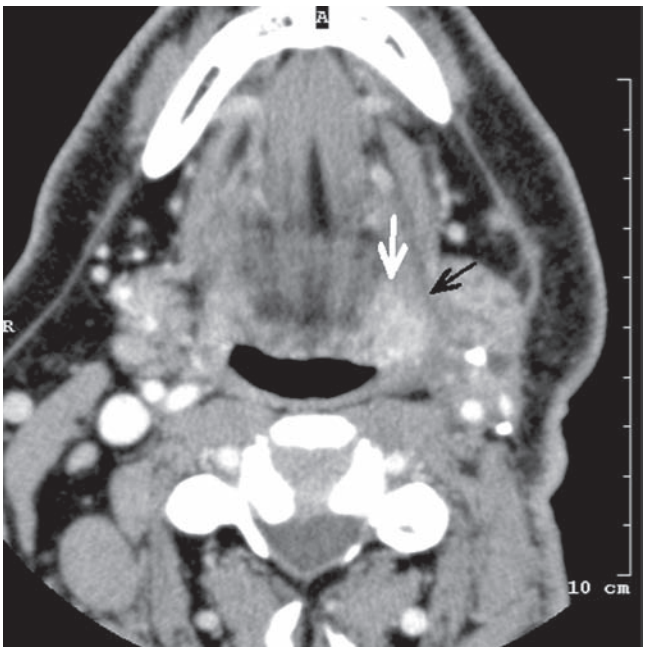

**FIGURE 15-5.** Axial contrast enhanced CT scan of a patient presenting with left level 2 lymphadenopathy and an unknown primary shows asymmetry of the lymphatic tissue at the tongue base. There is a mass in the left tongue base (*white arrow*) that has subtle penetration into the deeper soft tissue planes of the tongue. The parapharyngeal space fat is effaced on the left (*black arrow*) between the tongue base and submandibular gland compared to the right.

(c) 2014 Wolters Kluwer. All Rights Reserved.

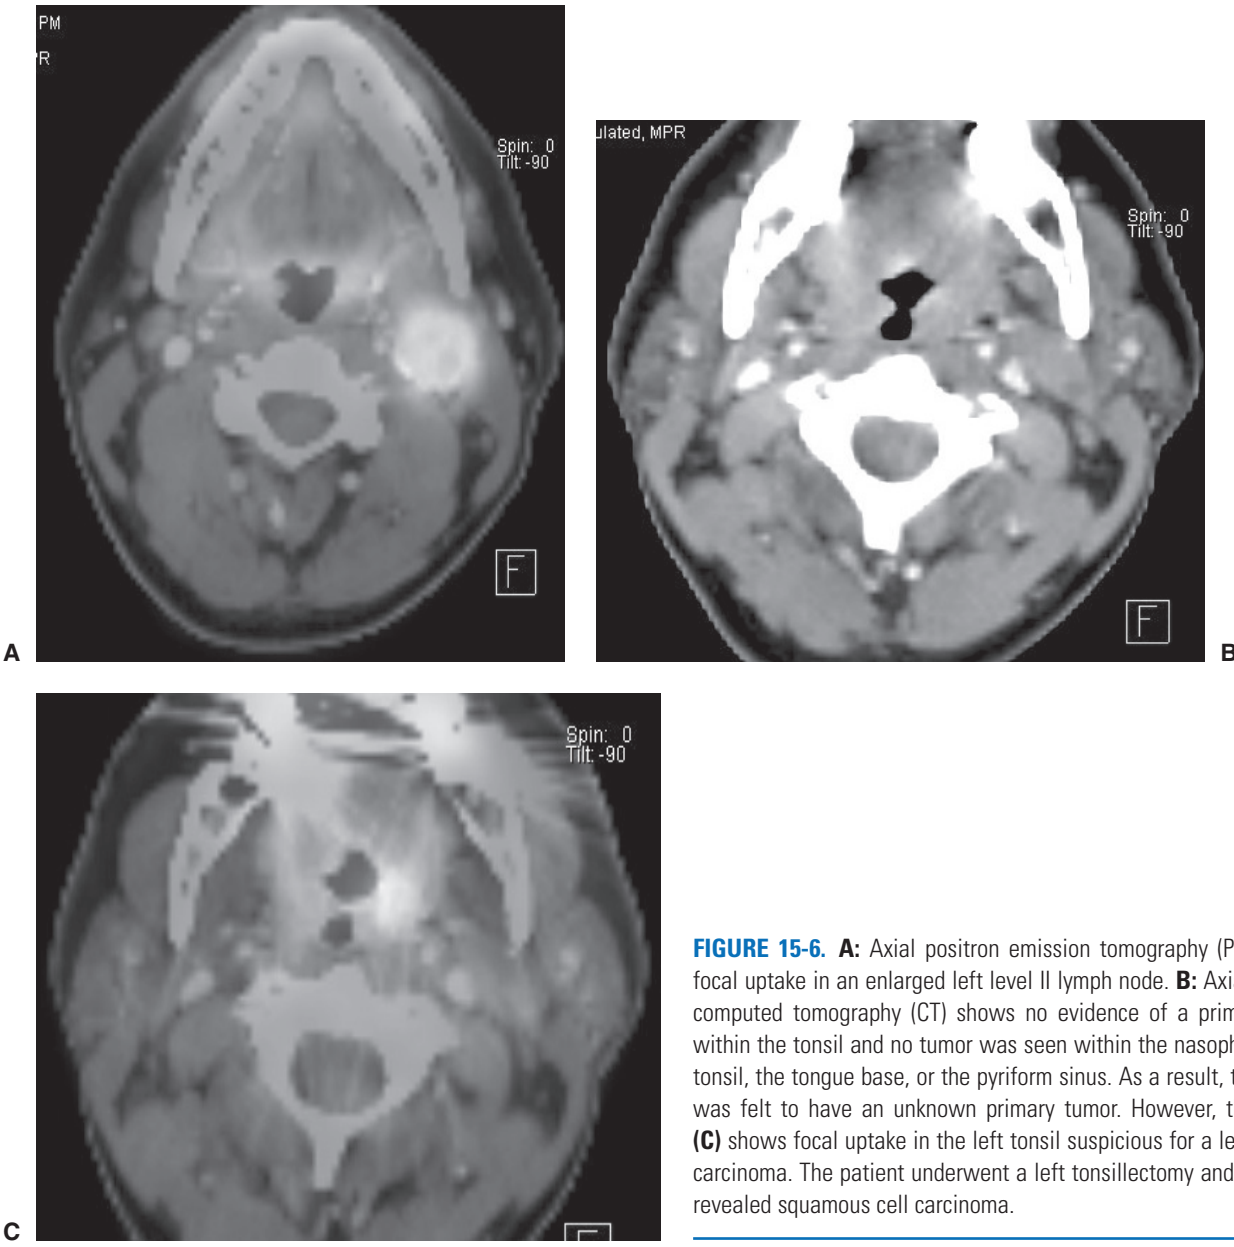

**FIGURE 15-6.** **A:** Axial positron emission tomography (PET) shows focal uptake in an enlarged left level II lymph node. **B:** Axial contrast computed tomography (CT) shows no evidence of a primary tumor within the tonsil and no tumor was seen within the nasopharynx, the tonsil, the tongue base, or the pyriform sinus. As a result, the patient was felt to have an unknown primary tumor. However, the PET/CT **(C)** shows focal uptake in the left tonsil suspicious for a left tonsillar carcinoma. The patient underwent a left tonsillectomy and pathology revealed squamous cell carcinoma.

# PART C:
# Radiation Therapy Technique

William M. Mendenhall

The cervical lymph node area most often involved with cancer from an unknown head and neck primary site is level II. The most likely primary tumor sites are the base of the tongue and the tonsillar fossa. Accordingly, our philosophy has been to treat the unknown primary of the head and neck as if it were a T1 oropharyngeal cancer.[1] The probable primary site and the upper neck are encompassed in equally weighted parallel-opposed fields. The field borders are the thyroid notch, the posterior spinous process of C2, the floor of the sella turcica, and 2 cm anterior to the tonsillar fossa (Fig. 15-7).[2] The anterior and/or posterior borders may need to be enlarged depending on the extent of disease in the upper neck nodes. Although the likelihood of a nasopharyngeal primary is low, outside of areas where it is endemic such as Hong Kong, the risk of involved retropharyngeal nodes is relatively high, which means that part of the nasopharynx must be included in the portals.[3] Modest enlargement of the portals to include the nasopharynx with a tight margin adds little morbidity and reduces the risk of recurrence in this site. The low neck is treated with an anterior portal with a tapered midline larynx block. The lateral fields are treated once daily to 64.8 Gy in 36 fractions, with a reduction of the spinal cord at 45.0 Gy. The dose to the posterior strips may be boosted on the involved side with 8 to 10 MeV electrons after the field is reduced off the cord.

Because the occasional patient presenting with a level III node is more likely to have a hypopharyngeal or supraglottic primary cancer, these sites are included in the portals in this situation (Fig. 15-8).[2]

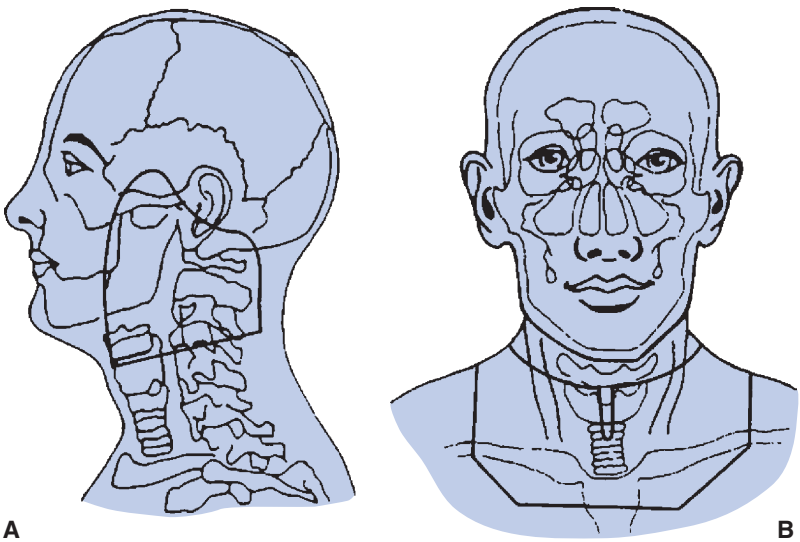

**FIGURE 15-7.** Radiation therapy portals used to treat head and neck mucosal sites and upper cervical lymph nodes **(A)** and lower cervical and supraclavicular lymph nodes **(B)**. The inferior border for lateral portals is placed at the superoanterior border of the thyroid cartilage, shielding the hypopharynx and the larynx.

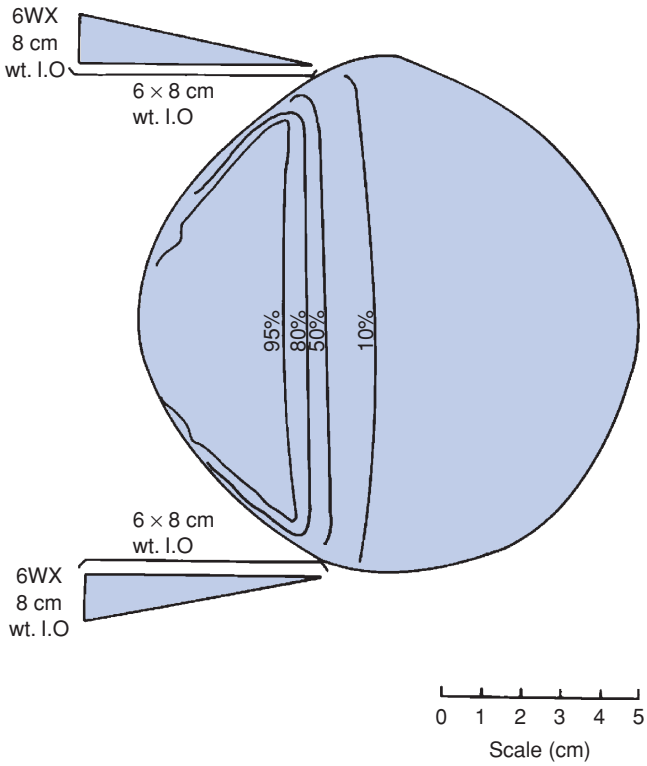

**FIGURE 15-9.** Anterior and posterior 6-MV x-ray portals used to treat the neck.

*Source:* From Million RR, Cassisi NJ, Mancuso AA. The unknown primary. In: Million RR, Cassisi NJ, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach* . 2nd ed. Philadelphia, PA: JB Lippincott Co; 1994:311–320 (Fig. 15-4D, p. 318), with permission.

It may be necessary to irradiate the positive neck nodes to a higher dose than the head and neck mucosa, depending on the extent and fixation of the nodes. In this situation, the grossly involved nodes are irradiated with anterior and posterior, 6 MV x-ray or $^{60}$Co portals, excluding the mucosa (Fig. 15-9).[4] The advantage of this technique compared with use of high-energy *en face* electrons is that some of the skin receives a lower dose, thus reducing the risk of postoperative complications if a neck dissection is to follow radiation therapy[5,6] in addition, and the spinal cord receives no exit dose. The boost may follow the treatment of the head and neck mucosa or may be given once or twice a week as a concomitant boost with a minimum 6-hour interfraction interval.

Intensity-modulated radiotherapy (IMRT) is employed primarily in patients with ipsilateral positive nodes, where it may be possible to adequately irradiate the oropharynx and nasopharynx, as well as the grossly positive nodes to 64.8 Gy at 1.8 Gy per fraction, once daily, and limit the contralateral parotid mean dose to 26.0 Gy or less.[7] The positive nodes are treated to approximately 70.0 Gy either concomitantly due to dose inhomogeneity, or as a separate boost. The low neck is treated with a separate portal, with a midline block to reduce the dose to the larynx. Clinically negative nodal areas that are electively irradiated to doses ranging from 49.5 to 54.0 Gy include ipsilateral levels IB II, III, IV, V, and the retropharyngeal nodes, as well as contralateral levels II, III, and IV.[8] An example of a patient treated with IMRT is depicted in Figure 15-10. Care must be taken to limit the dose to the anterior oral cavity, which will receive more irradiation compared with conventional field arrangements. Although it may be possible to adequately treat patients with low-volume contralateral positive nodes with IMRT, it is often difficult to achieve the goal of limiting the contralateral mean parotid dose to 26.0 Gy or less, in which case conventional fields are employed. Patients usually receive weekly concomitant cisplatin during the course of IMRT. Patients undergo a computed tomographic (CT) scan 1 month after RT to determine whether a neck dissection is indicated.[9]

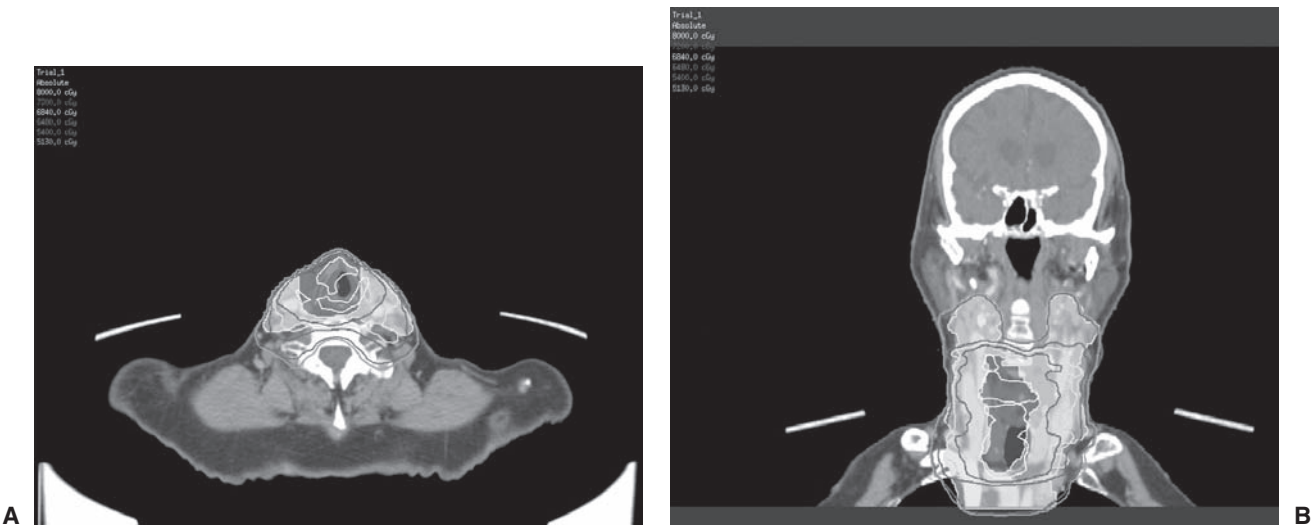

**Figure 15-10. A & B:** Patient with a T0N2B squamous cell carcinoma from an unknown primary site with left neck adenopathy. The patient is treated with IMRT with 6-MV X-rays. The oropharynx and positive nodes receive 64.8 Gy at 1.8 Gy per once-daily fraction. The gross disease is boosted to 70 Gy. The standard-risk clinical target volume (SR-CTV) receives 50 Gy. **A)** Axial contour; **B)** Sapittal contour. A PET-CT is obtained after radiotherapy and a left dissection is performed if the response is incomplete. (See color insert)

(c) 2014 Wolters Kluwer. All Rights Reserved.

Patients who are in poor condition, as well as those treated with palliative intent, are treated to the involved neck alone using the anterior and posterior field arrangement previously described.[10]

CHAPTER 16

# Cancer of the Oral Cavity

## PART A:
## General Principles and Management

Wayne M. Koch, Edward Stafford, Christine Chung, and Harry Quon

### INTRODUCTION: INCIDENCE, ETIOLOGY, AND EPIDEMIOLOGY

Cancer of the oral cavity is actually a collection of distinct and overlapping disorders with differing etiology, clinical manifestation, and treatment. Tumors are most commonly categorized by anatomical location and histologic diagnosis. The quintessential oral cancer arises in an individual who has used tobacco and alcohol. These lesions tend to occur on the lateral or ventral tongue, the floor of mouth (FOM), or the alveolar ridge, most often in men between the ages of 50 and 70 years, and are differentiated squamous cell carcinomas (SCC). However, there is increasing awareness that nonsmokers also can develop oral SCC (OSCC), most often on the lateral tongue but also elsewhere including the buccal mucosa and the alveolar ridge, often in younger and older patients, including disproportionately more women. Patients with lip cancer also have distinct demographic and clinical patterns, whereas minor salivary gland cancers are much less common and occur without known risk profile. These distinct categories support the hypothesis that the underlying process of tumorigenesis is also quite different among the broad cohort of patients with oral cancer.

Oral cancer is potentially a devastating disease. At late stages, it is very difficult to control and can result in a miserable demise. Even when detected early, treatment necessarily brings collateral damage to a region of the body that has great functional importance for communication and deglutition as well as cosmetic and therefore psycho-social impact.

According to the 2012 Cancer Facts and Figures of the American Cancer Society, there will be an estimated 26,740 cases of cancer of the oral cavity including tongue, mouth, and "other" regions in the United States in 2012. One-third of these cases will arise in women. During the same year, there will be 5,520 American deaths due to these cancers. Oral cavity and oropharyngeal cancers together comprise the eighth most common cancer in American men (3% of cancers). The rate of oral cancer declined by 1% per year in American women from 2004 to 2008, and the death rate for oral cavity and oropharynx cancers has declined over 30 years by 1.2% in men and 2.2% in women. This latter statistical observation may be partly due to a proportional increase in human papillomavirus (HPV)-related oropharyngeal cancers included in data collection, a subpopulation with markedly improved response to therapy that is not seen for cancers of the oral cavity. Survival rates for African Americans with oral cancer remains well behind that of White Americans (45% 5-year survival vs. 65%).[1]

Worldwide, the American Cancer Society estimates that oral cavity cancer is the 10th most common cancer among men with 170,900 cases estimated in 2008 (the last year with data available). Most of these cases were expected to be from developing countries (107,700), and most of those cases result in cancer-related death (61,200).[2] In South Central Asia and Melanesia, oral cancer is the second most common cancer among adult males.

Using the Surveillance, Epidemiology, and End Results (SEER) database, from 1998 to 2001, Piccirillo and coauthors have calculated relative survival for patients with oral cancer. Relative survival is defined as the ratio of observed survival divided by the survival that would be expected for a cancer-free individual from the same age, gender, and racial group. These data are derived from >40,000 individuals with head and neck cancer living in 12 geographic areas of the United States including 8,637 cases of tongue cancer (base of tongue and oral tongue combined), 3,286 cases of FOM cancer, and 5,946 cases of "gum and other mouth" cancers. The 5-year relative survival rate was found to be 53.1% for tongue, 59.5% for gum, and 52.7% for FOM tumors. Broken down by gender and race, survival is slightly better for women and markedly poorer for black than for white patients in all three anatomic groups. Outcome varies with stage of cancer declining from 70% to 96% 5-year survival for stage I oral cancer to 26% to 48% for stage IV cancers (Tables 16.1). Survival for oral tongue compared to base of tongue cancer is better for small tumors (75.9% for stage I oral tongue 5-year relative survival

| Stage III | 56.7 | 47.3 | 38.8 | 35.8 | 45.1 |
| Stage IV | 48.1 | 36.7 | 26.5 | 29.7 | 40.0 |

compared to 51.5% for stage I base of tongue lesions) but worse for all later stages (26.5% relative 5-year survival for stage IV oral tongue compared to 41.9% for stage IV base of tongue).[3] Survival of oral cancer patients also varies widely in different parts of the world. According to American Cancer Society Global statistics, 5-year relative survival for oral cancer patients is highest in the United States and Germany (60.7%) and lowest in Poland, Thailand, and India (36%–37%).[2]

Cancer of the lip has a distinctive demographic pattern in the United States. It affects principally white men, who account for 80% of cases in the published SEER database analysis of 12 regions.[3] Lip carcinoma accounts for roughly 12% of all noncutaneous head and neck cancers. White women make up another 17.8% with African Americans accounting for only 1.1% of cases. The vast majority of cases are diagnosed and treated at an early stage (83.2% stage I), accounting for an overall excellent outcome (93.5% relative 5-year survival). This is the lowest disease-related mortality among oral cancers. The incidence is reported to be high in Australia and New Zealand (10.2 per 100,000 men).[4] More than 90% of carcinomas of the lip involve the lower lip, attributed to sun exposure. The upper lip (2%–7%) and commissure (<1%) are less frequently involved. A variety of malignant histologies arise in the lip, most commonly basal cell and squamous cell carcinoma and less common lesions such as minor salivary gland tumors, melanoma, and sarcoma.

Cancer of the hard palate accounts for 10% of the neoplasms of the oral cavity. There is a great variety of malignant neoplasms that arise in the hard palate, including tumors of epithelial, salivary, hematopoietic, and mesenchymal tissues. SCC comprise only about 50% of these tumors. Carcinomas originating from minor salivary glands are the most common non–squamous cell malignancies in this region. Inexplicably, salivary cancers typically arise near the foramen of the descending palatine artery near the second molar tooth and the hard palate–soft palate junction. Less common malignancies presenting in the hard palate include hematologic malignancies such as lymphoma and plasmacytoma, polymorphic reticulosis (or lethal midline granuloma), Kaposi sarcoma, and mucosal melanoma.

## Risk Factors for OSCC

The use of alcohol and tobacco account for approximately 75% of all cases of OSCC worldwide.[5] It is widely agreed that tobacco plays the major role in this risk profile. Poor oral hygiene and nutritional deficits are also invoked, but because these factors often coexist with alcohol and tobacco abuse, their relative contribution is difficult to assess. In a large pooled case-control international study, smoking alone, among alcohol abstainers, was associated with a relative risk of over threefold for the development of OSCC in Europe and South America, with a somewhat lower risk estimated for persons from South Asia and North America.[6] These differences may reflect the level of carcinogens in tobacco products sold in different regions. The risk of cancer increased with exposure measured in pack years from about 1.5-fold for light smokers (<10 pack years) peaking at fourfold for those individuals who have >30 pack years of smoking. Alcohol alone in persons who do not use tobacco imparts a risk for OSCC only when a threshold of >15 units per week is reached, and then the relative risk is modest, around threefold.[7] Nonsmokers who use alcohol at this level are more prone to develop cancers of the hypopharynx and the larynx. It has long been recognized that the combined use of alcohol and tobacco in the same individual conveys a multiplied or synergistic degree of risk for OSCC.[8] The American Cancer Society reports that cigarette smoking among adults in the United States declined 50% from 1965 to 2005 (from 42% of the population to 21%) but an estimated 45 million Americans continue to smoke. The gender gap narrowed in the 1980s, and now there is a 4% difference in smoking prevelance between White men and women and a 9% difference between African American men and women. Smoking among teens has declined in the first half of the current decade, estimated at 23% in 2005.[9] The risk of cancer due to tobacco exposure is thought to decline with time. However, as there are more ex-smokers in recent years, it may be discovered that the appearance of cancers in this segment of the population has been underestimated previously. Elderly patients who have quit smoking decades earlier can develop cancer of the maxillary alveolus or buccal mucosa.[10]

The association of the use of smokeless tobacco with oral cancer is less well substantiated than that of cigarettes and alcohol use. Smokeless tobacco use causes visible changes in the oral mucosa including wrinkling with slight elevation and, in some cases, leukoplakia. However, when these areas are biopsied, histologic findings of dysplasia is unusual and somewhat more commonly seen among snuff users than with chewing tobacco use.[11] The risk of developing cancer appears to be even more remote. The use of snuff and chewing tobacco has been shown to produce alterations in cell proliferation, apoptosis, and activation of inflammatory elements which, in turn, may be linked to cancer development.[12] Typical individuals who develop oral cancer after

(c) 2014 Wolters Kluwer. All Rights Reserved.

smokeless tobacco do so after many decades of use, as late as their eighth decade of life.[13]

Oral submucous fibrosis in the setting of areca nut use appears to be a special case of premalignancy associated with oral cancer development. Clinically, this condition is manifested by palpable sheets of fibrous tissue in buccal and labial regions with loss of elasticity and accompanying trismus. Histologically, submucous fibrosis is diagnosed when dense, avascular collagenous connective tissue is present in affected areas together with chronic inflammation and epithelial atrophy.[14] In India, oral submucous fibrosis occurs in men five times more often than in women and affects predominantly members of lower socioeconomic classes. The use of areca nut is often combined with other potential carcinogens including snuff, alcohol, and cigarette smoking. The incidence of submucous fibrosis progressing to cancer is estimated between 2% and 7%.[15,16] The use of alcohol and tobacco-free betel quid accounts for an increase in cumulative risk of oral cavity cancer of >60% resulting in an earlier age of diagnosis than seen in nonusers.[17] Individuals of South Asian ethnicity are increasingly bringing betel-quid and areca nut use to other regions worldwide.

## OSCC in the Absence of Known Carcinogen Exposure

Americans with OSCC that have not used tobacco or alcohol (nonsmokers/nondrinkers [NS/ND]) are disproportionately women (>70% in some series). This group is also more likely to present with early-stage disease. Lateral tongue, buccal, and maxillary alveolar sites are typical.[10,18] These patients are quite concerned about why they have oral cancer, and no certain answers exist. Often, the individual patient will have a theory; dental irritation, mouthwash use, cinnamon gum use, and dietary, occupational, and environmental factors have all been suggested. Solid epidemiologic studies of this phenomenon are few, hampered by the small numbers of individuals involved. Still, the appearance of lateral tongue cancer in nonsmokers may be on the increase and constitutes a potentially very fruitful field of inquiry. Myers and others reviewed the M.D. Anderson Cancer Center experience over a 22-year period and found that the percentage of patients with tongue cancer who were <40 years of age increased from 4% in 1971 to 18% in 1993.[19] Using the SEER database, an increase of 111% of oral tongue cancer among young white women has been reported between 1975 and 2007 whereas the incidence in all other sites and subpopulations was decreasing.[20] It is intriguing that there is such site specificity in this population, predominantly affecting the lateral oral tongue on one side only. Tumors arising on the lateral tongue in NS/ND are sometimes associated with persistent hyperkeratosis to mild to moderate dysplasia in a field around the original tumor site after treatment. In these cases, return of malignancy can occur even after many years of quiescence. Tenderness to certain foods along with increased thickness and friability of lesions are bellwethers of malignant progression. In other cases, simple excision of early tongue SCC results in a nearly undetectable linear scar with no mucosal indication of persistent atypia. In these cases, disease control may be life-long.

Lichen planus (LP) is a chronic inflammatory disease that preferentially affects the buccal and lateral tongue mucosa and is seen in 1% to 2% of the adult population. It presents as a superficial, lacy leukoplakia that fluctuates in intensity in affected individuals over time. Anecdotal observation indicates that OSCC can arise within the field of LP in isolated cases. In these cases, the shallow erosive region occasionally seen in LP may develop a thickened and friable central area of red ulceration indicative of the neovascularity of malignant transformation (Fig. 16-1). The rate of malignant transformation in LP is judged to be quite low (<2%).[21]

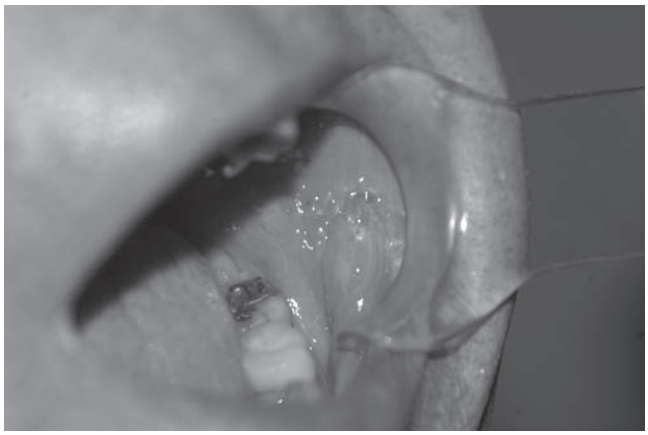

**FIGURE 16-1.** Erosive lichen planus involving the buccal mucosa.

Following the precedent of LP, an autoimmune cause has been widely postulated for the broader phenomenon of SCC in NS/NDs. Chronic inflammation causes a high rate of cell turnover and proliferation in an environment of altered cytokines and reactive oxygen species all of which may contribute to cancer initiation.[22] Alternatively, there may be some undiscovered genetic predisposition to oral tongue cancer. One example is Fanconi anemia, a rare inherited genetic condition that leads to early hematologic malignancy. Survivors of this childhood leukemia have a high risk for oral tongue cancer that also arises at a young age.[23]

OSCC is also seen in other persons who are immunosuppressed after bone marrow or other organ transplant attributed to graft versus host disease (GVHD). These cancers often arise on the alveolus, the buccal, the FOM, or the tongue mucosa.[24–25] GVHD is a severe complication of allogenic bone marrow transplantation manifesting chronic inflammation of the oral mucosa as well as the skin, the GI tract, and the liver. Whole-body irradiation for the initial malignancy may increase the risk of secondary cancer. Most second cancers following bone marrow transplantation are hematologic, although SCC is the most common form of solid tumor seen in these individuals.[24] OSCC in the setting of GVHD is not limited to the lateral tongue but can affect the dorsal tongue mucosa, the alveolar ridge, and other regions that have been affected by GVHD. These individuals are often much younger than typical OSCC patients, with lesions arising 2 to 10 years after GVHD.

Finally, there may be an undiscovered viral cause of lateral tongue cancer in NS/NDs. Although HPV is widely accepted as a causal factor for cancer arising in the lymphoepithelium of the oropharynx, its presence in lesions of the oral cavity is less common and its contribution to cancer development is controversial. When rigorous detection methods such as *in situ* hybridization (ISH) are used for HPV assessment, the rate of HPV positivity in oral cancers is small.[26] In fact, some tumors that originate in the palatine or lingual tonsil may be mislabeled as oral cavity tumors due to spread from the adjacent epicenter which may have been previously altered by diagnostic biopsy/tonsillectomy. More promiscuous detection techniques based on polymerase chain reaction (PCR) technology may overcall HPV positivity. When detected in very small amount, HPV, although present, may not play a biologically important role in tumorigenesis, bringing into question the relevance of its detection.[27] Investigators at University of North Carolina have found that 11/25 lateral tongue cancers from young patients (aged 18–39 years) had overexpression of p16(INK4a) but not HPV-16 by *in situ* hybridization. In this small series, p16 expression was associated with

(c) 2014 Wolters Kluwer. All Rights Reserved.

improved survival (hazard ratio [HR] = 0.23, $p$ = 0.01).[28] In a similar study, none of 32 mobile tongue cancer specimens was found to contain high-risk HPV DNA as assessed by *in situ* hybridization, although six cases had p16(INK4a) overexpression.[29] Risk factors for palate SCC include tobacco and alcohol use, including reverse chutta (cigar) smoking, although denture trauma and poor oral hygiene, as well as a history of syphilis or vitamin deficiency, are sometimes invoked.[30]

***Oral Cancer Screening.*** Over the last decade, there has been increasing attention given to the potential community health benefit of oral cancer screening. Both otolaryngologists and dental health professionals have promoted oral screening as a means to improve outcomes of oral cancer care through identification of lesions at the earliest stages. Screening pertains primarily to the oral cavity because of the accessibility of those mucosal surfaces to simple visual inspection. Evaluation elsewhere in the upper aerodigestive tract is more challenging and requires special expertise and equipment.

The Yul Brynner Society, now the Head and Neck Cancer Alliance (http://www.headandneck.org), sponsors an annual national oral cancer awareness campaign that has continued with oral cancer awareness week held each April since 1998. The public health efficacy of oral cancer screening has yet to be demonstrated. One question is who should undergo oral cancer screening. Oral cancer is relatively uncommon, and while there are well-known risk factors for the development of oral malignancy, individuals at risk are often less conscientious about maintaining good health practices and may not avail themselves of screening opportunities.[31] Finally, because of the rarity of oral cancers, few primary care dentists and physicians have seen enough oral cancer lesions to develop familiarity and expertise in early detection.

A variety of technological tools have been promoted to assist in oral screening. These tools have in common efforts to enhance visual or spectroscopic features of altered surface epithelium in cases of premalignant or malignant change. One such device, the VELscope, uses autofluorescence technology to examine the oral mucosa. A published study comparing the rate of identification of oral lesions using white light alone versus white light and autofluorescence showed a greater sensitivity for identification of premalignancy on biopsy using VELscope (100% vs. 17%) but also showed a lower specificity for VELscope (74% vs. 97%).[32] However, another study failed to show an advantage to autofluorescence over white light visualization with only 81% specificity and 50% sensitivity for autofluorescent detection of lesion compared to 98% specificity and 50% sensitivity for white light.[33] Narrow-band imaging endoscopy is another new technology that has been investigated for use in oral cancer detection. This method can be used to identify "brownish spots" within an oral cancer, a feature that may be useful for de novo cancer detection.[34] Toluidine blue staining has also been proposed as an adjunct to visual inspection for oral cancer detection. In one recent report, the sensitivity and specificity for detection of cancer or dysplasia was 65.5% and 73.3%, respectively, using toluidine blue.[35] Some dental providers now charge patients for the added evaluation using assisted devices such as VELscope. In order to address potential clinical and ethical concerns related to this practice, the American Dental Association (ADA) hosted a working group to review the evidence for device efficacy in the literature. The conclusion of the working group was "that there is insufficient evidence to determine if screening alters disease-specific mortality in asymptomatic people seeking dental care." Furthermore, the group found, "insufficient evidence that commercial devices based on autofluorescence, [or] tissue reflectance enhance visual detection beyond that achieved through a conventional visual and tactile examination."[36] It would appear that there is no substitute for a clinician being aware of the possibility of oral cancer, the degree of risk born by a particular patient, taking the time to look at the oral mucosa with a good light, knowing what makes a lesion suspicious for malignancy, and exercising appropriate vigilance to arrange a biopsy when indicated.

Another technological adjunct to oral cancer screening is the use of cytologic brush "biopsy." Oral brush biopsy with computer-assisted analysis is commercially available (OpCDx) and has been reported to have a positive predictive value of 84% and negative predictive value of 98%.[37] This may be helpful in deciding which lesions to refer for surgical biopsy. However, such surgical biopsy remains the gold standard for rigorous and accurate diagnostic assessment of the degree of cancer-associated alteration present in visible lesions of the oral mucosa. The utility of brush biopsy may vary with the degree of experience of the clinician; highly experienced observers may rightly discern degree of suspicion based on subtle aspects such as lesion friability, thickness, tenderness, or variegated coloration, which would render the additional benefit of brush cytology less necessary. The ADA notes that "there is insufficient evidence to assess the validity of transepithelial cytology of seemingly innocuous mucosal lesions," but the method can "identify dyplastic cells in lesions with a high potential for malignancy."[36] Once again, clinical judgment is a key factor in the detection of oral cancer.

## Anatomy of the Oral Cavity

The oral cavity extends from the skin-mucosal junction of the vermillion border of the lips to the oropharyngeal inlet posteriorly. The oropharyngeal–oral junction is bounded superiorly by the hard–soft palate junction, laterally by the anterior tonsillar pillar, and inferiorly by the circumvallate papillae. The lining of the oral cavity is a nonkeratinized stratified squamous epithelial mucous membrane. The submucosa is rich with minor salivary glands, with a high concentration within the hard and soft palates. The oral cavity may be divided into subsites (Fig. 16-2) including the lips, the buccal mucosa, the FOM, the retromolar trigone (RMT), the oral tongue, the hard palate, and the alveolus (maxillary and mandibular). As has been noted, the natural history characteristics of oral carcinoma vary greatly depending on the subsite in which the primary lesion is located. We will therefore consider each of these subsites separately when discussing both anatomy and the management of oral carcinoma.

*Lips.* The vermilion zone includes the red lip which extends from the fixed gingiva of the labiogingival sulcus up to the vermilion border. The surface landmarks of the lips include the labial commisure laterally, philtrum (Cupid's bow), and labial tubercle just inferior to the philtrum (upper lip).

*Buccal Mucosa.* The buccal mucosa is a smooth surface epithelium extending from the oral commissure anteriorly to the

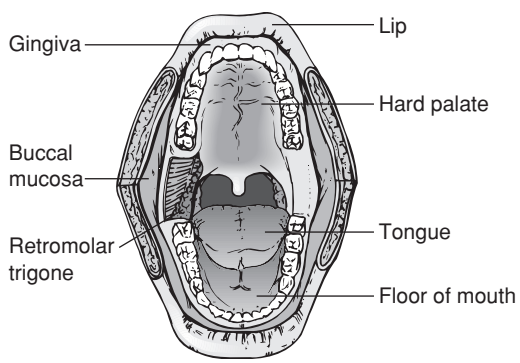

**FIGURE 16-2.** Primary sites in the oral cavity.

(c) 2014 Wolters Kluwer. All Rights Reserved.

retromolar gingiva posteriorly. The mucosa terminates at the gingivobuccal sulcus of both the maxillary and mandibular gingiva. Its sole landmark is the papule of Stenson's duct opposite the second maxillary molar. The buccinator muscle lies just deep to the thin mucosa with the buccal fat pad just beyond. The mucosa may be stippled with submucosal minor salivary glands manifest by cream or white colored small, slightly raised spots of approximately 2 mm diameter, called Fordyce spots.

*FOM.* Tissues of the FOM occupy a semilunar space bounded by the inner aspect of the lower alveolar ridge and the undersurface of the tongue. The transition from FOM to ventral tongue is continuous and indistinct. The posterior extent reaches the base of the anterior tonsillar pillar. The FOM is supported by a muscular sling composed of the mylohyoid, the geniohyoid, and the genioglossus muscles. The sling supports the submucosal sublingual glands, the Wharton ducts, and the minor salivary glands. The lingual and the hypoglossal nerves traverse the submucosal space of the FOM. Surface anatomy includes the lingual frenulum, the Wharton duct papillae, and the sublingual salivary ridge. Prominent veins often are visible below the mucosa as well.

*RMT.* The RMT is bounded posteromedially by the anterior tonsillar pillar, laterally by the buccal mucosa, and superiorly by the maxillary tubercle. It consists of two surfaces, one facing anteriorly just behind the third mandibular molar and the other facing medially just over the ascending ramus of the mandible. Submucosa here is very thin with bone near the surface.

*Oral Tongue.* The oral tongue comprises the anterior two thirds lying anterior to the line of circumvallate papillae. The dorsum of the tongue is covered with a thick epithelium interspersed with fungiform, filiform, and circumvallate papillae. Because of the thickness of this mucosa, it may have a wide variety of color which may change in a single individual over time. The thickness also may account for the paucity of neoplasms that arise on the tongue dorsum. The transition to the thin mucosa of the lateral tongue is relatively abrupt. However, in the posterior corner of the oral tongue, the fungiform papillae form vertical ridges which are more red in color than the lateral mucosa more anteriorly. Tongue mucosa lies directly over tongue musculature without intervening fat or salivary gland tissue. The intrinsic tongue musculature (the superior longitudinal muscle, the inferior longitudinal muscle, the transverse muscle, and the vertical muscle) make up the bulk of the freely mobile portion whereas the extrinsic tongue musculature, including the genioglossus, the hyoglossus, the styloglossus, and the palatoglossus comprise its root. The intrinsic muscles are responsible for the remarkable dexterity of the tongue, important in fine motions of articulation and bolus preparation while the extrinsic muscles elevate, depress, protrude, and retract the tongue. The muscles and their neurovascular bundles are bisected by a median raphe made of a fatty-fibrous material. The undersurface (ventral) of the tongue is lined by thin mucous membrane. The lingual frenulum serves as ventral attachment to the FOM. A deep lingual vein is often visible through the mucosa lateral to the lingual frenulum.

*Hard Palate.* The hard palate is a semilunar area bounded by the upper alveolar ridge anteriorly and laterally and the soft palate junction posteriorly. The submucosa here is tough and thick. A bony torus palatine may provide surface contour to an otherwise regular concavity. The greater palatine foramen is located in the palate bone near the second molar tooth and contains the descending palatine artery on each side that services the palate mucosa.

*Alveolar ridge.* Bony structures supporting the teeth and periodontal tissue arise from the FOM and descend from the hard palate. Here the mucosa is thin and tightly adherent to the periosteum. When teeth have been extracted, the bony elevation is often partially lost, particularly on the lower ridge. Mucosa here envelopes the neck of teeth with a small periodontal sulcus. Dental hygiene affects the quality of this mucosa with common inflammation and retraction of soft tissue from the teeth when hygiene is insufficient, and gingival hypertrophy in the setting of certain diseases and drug therapy.

The blood supply of the oral cavity is derived from branches of the paired external carotid arteries. The arterial supply of the lips is the labial arteries, which are branches of the facial artery. These paired arteries anastomose in the midline. The buccal mucosa likewise is supplied from branches of the facial artery. The lingual artery supplies the tongue, coursing deep in the extrinsic musculature below the digastric tendon and the posterior border of the hyoglossus muscle. The anterior tongue derives all of its blood supply from the lingual artery, with little contribution from the FOM mucosal vessels. The dominant blood supply of the hard palate is via the greater palatine artery and the superior alveolar arteries. Branches of the internal maxillary artery and inferior alveolar artery supply the maxillary and mandibular alveolar ridge. Branches of the facial artery supply the submandibular gland, the sublingual gland, and some of the FOM mucosa.

The oral cavity has a complex system of lymphatic drainage, supplying the first echelon basins of the submental, the submandibular, and the upper jugular systems and has recently been the subject of a review.[38] A more detailed analysis of lymphatic drainage patterns is included in the management section for each subsite.

Innervation of the oral cavity can be classified as sensory, special sense, and motor. The trigeminal nerve is the primary sensory supply of the oral cavity through its maxillary and mandibular branches. The lingual nerve (V3) supplies the sensory distribution to the anterior two thirds of the tongue and adjacent FOM. Taste fibers course with the lingual nerve after originating in the geniculate ganglion and traversing in the chorda tympani, then joining the lingual nerve. Motor control of the tongue is supplied by the hypoglossal nerve. Sensation of the lower lip and gum is provided by the mental nerve, a branch of V3. The hard palate, upper gum, and upper lip are innervated by the palatine and the labial branches of V2. The muscles of mastication are controlled by the second and third divisions of the trigeminal nerve whereas the lip and cheeks are innervated by the facial nerve.

## Natural History of Oral Cancer (Pathology, Pathogenesis, and Patterns of Spread)

***Molecular Underpinnings of Oral Cancer.*** Over the past two decades, a great deal of insight has been gained into the molecular processes that lead to the development and behavior of malignant neoplasms, including cancer of the oral cavity. It is increasingly recognized that tumor-specific genetic and epigenetic alterations affect key physiologic pathways that control functions such as cell proliferation, DNA repair, neoangiogenesis, motility, and metastasis. Genetic alterations include mutation, chromosomal rearrangement, and loss or amplification of segments of DNA while epigenetic alterations, particularly promoter hypermethylation, affect gene function through alteration of transcription. The effect of specific molecular alterations interweave in a complex manner such that a single event or intervention may have widely variable phenotypic result. Point mutation of the *p53* gene occurs in more than one half of all OSCC,[10] eliminating or reducing important cellular activities affecting cell cycle control and programmed cell death (apoptosis) in response to genotoxic stress. However, this genetic alteration alone is insufficient to account for the cancer

(c) 2014 Wolters Kluwer. All Rights Reserved.

phenotype, and the discovery of other genes with a substantial rate of mutation in HNSCC has not occurred. New data are emerging indicating that not all *p53* mutations have the same effect, with those that disrupt the DNA-binding domain three-dimensional configuration being associated with poorer clinical outcome.[39] Another tumor-specific target commonly affected in HNSCC is the *Rb* pathway which regulates the cell cycle. Loss of function of *Rb* and other members of this pathway including *p16* results in deregulation of cell growth and tumorigenesis. Mutations of *p16* are rare in HNSCC, but homozygous deletion occurs in >50% of cases. In another substantial group of cases, *p16* transcription is blocked by hypermethylation of the promoter region.[40]

Promoter hypermethylation is one form of epigenetic control of gene expression. Many regions of tumor-specific promoter hypermethylation have been described in HNSCC, accounting for a lack of expression of other genes with key tumor suppressor functions.[41] One distinct example is the Deleted in Colon Carcinoma (DCC) gene, frequently mutated in colon cancer, but rarely in HNSCC. Promoter hypermethylation of Deleted in Colon Carcinoma has been shown to be a frequent event in HNSCC.[42] Other key genes so altered included *MDM2*, *Interferon-alpha*, and *RAR-β*. MicroRNA, short 22-base sequences that can selectively block gene transcription, promises to provide yet another substantial mechanism for epigenetic tumor-specific alteration.

Studies of the rate and type of genetic alterations in oral premalignant lesions have helped sketch a tumor progression pathway for oral mucosal malignancy. By examining a spectrum of histologic lesions from atypia to dysplasia to carcinoma *in situ* to invasive cancer, and cataloging the molecular events present, a general pattern of accumulated alterations correlated with progressive phenotypic change has been established.[43] Some genetic alterations such as loss of *p16* expression, occur with high frequency in very early lesions such as atypia and dysplasia and do not increase greatly with further histologic progression. Other alterations only appear with substantial frequency in invasive SCC. The spectrum of genetic alterations in oral premalignant lesions may serve a prognostic role, providing evidence as to the risk of progression to invasion. Several studies have shown that loss of heterozygosity (LOH) of key gene regions including 3p, 9p, and 17p portend a significantly increased rate of progression.[44,45]

***Patterns of Spread.*** Malignant lesions of the oral mucosa arise from a region populated by clonally altered cells, a phenomenon known as *field cancerization*.[46] The involved field may be clinically apparent with regions of leukoplakia and erythroplakia, but more often it is unapparent and undetectable without sampling and sophisticated molecular methods. Enhanced visualization may be provided by supravital staining with tolonium chloride, or with measures of reflectance or absorbance of specific wavelengths of light.[47,48] The effect of field cancerization is to spawn neighboring lesions either contemporaneous to an index lesion or some time later (field recurrence). The ventral tongue and FOM are common locations for this phenomenon, presumably due to common exposure to carcinogens.

***Tumor Histology.*** By far, the majority of oral cavity cancers are OSCC. SCC arises from a series of genetic and epigenetic alterations that abrogate the function of key tumor suppressor genes at the crossroads of functional pathways.[43] The typical progression from cytologic atypia and hyperplasia to various degrees of dysplasia to *in situ* carcinoma and then invasive carcinoma may be manifest as erythroplakia, leukoplakia, or be largely unapparent. Leukoplakia, or white patch, may occur in the absence of malignant progression in the setting of local trauma or irritation. Palpable thickness, firmness, and friability (ready blushing or bleeding with manipulation) are telltale features of malignant transformation.

There are distinct patterns of tumor growth that characterize subclasses of OSCC. Verrucous change is one such variant. This

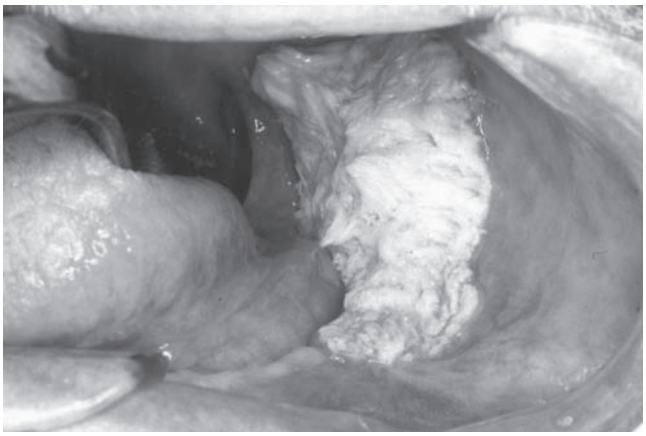

**FIGURE 16-3.** Verrucous carcinoma of the edentulous lower gum.

entity is prone to recur after excision and sometimes spreads across mucosal surfaces to involve large portions of the oral cavity. White, patchy, thickened change of the mucosa characterizes early verrucous leukoplakia. More advanced verrucous change becomes velvety and exophytic (Figs. 16-3 and 16-4). Histologically, these lesions exhibit bland cytologic change with broad pushing borders of the invasive component. This feature, together with the thick nature of advanced lesions, makes the diagnostic distinction between invasive and preinvasive verrucoid lesions difficult, with many biopsies failing to obtain full thickness of tissue that adequately demonstrates the infiltrative interface.[49]

The anatomic features of different regions within the mouth affect the pattern of tumor growth and spread. The dorsum of the tongue and the hard palate with their thick mucosa and submucosa are somewhat impervious to the development of OSCC. These regions are also located above pooled secretions which may reduce their exposure to carcinogens. Once cancer invades the intrinsic musculature of the tongue, there is no substantial barrier to its further spread between muscle fascicles. This fact makes delineation of the necessary deep boundary of resection difficult.

Detection of invasion of tumor into the mandible is important for staging and treatment planning. While cortical bone provides a substantial barrier to tumor, the lack of cortex in an empty tooth socket permits entry of invasive cancer into the marrow

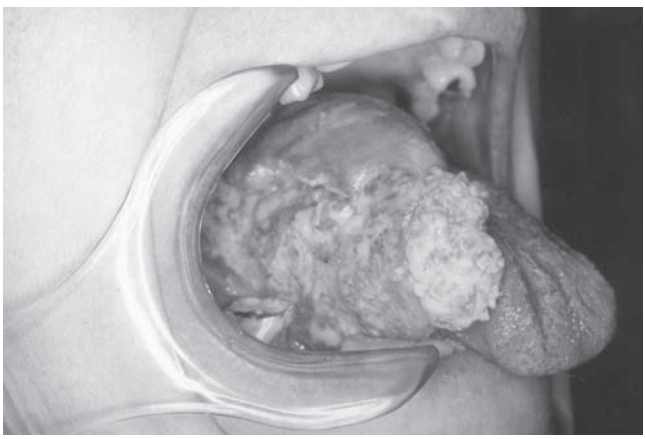

**FIGURE 16-4.** Exophytic, papillary, well-differentiated squamous cell carcinoma of the oral tongue.

(c) 2014 Wolters Kluwer. All Rights Reserved.

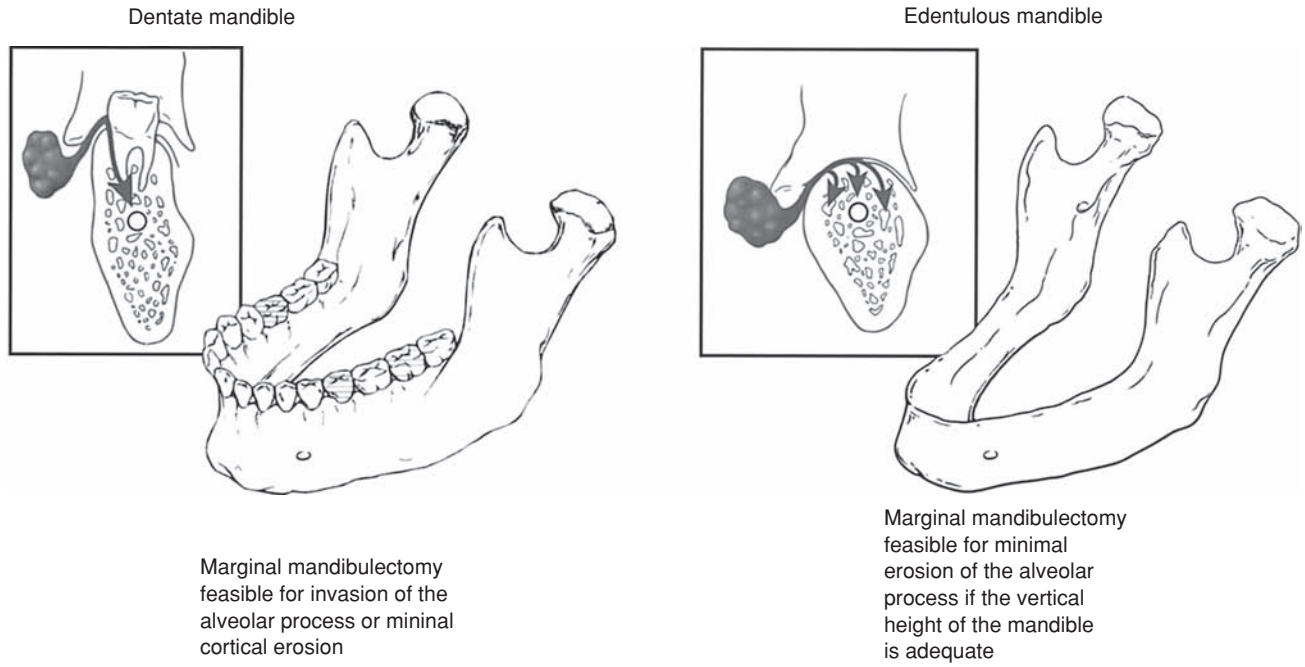

**FIGURE 16-5.** Routes of spread to mandible from oral cancer in dentate and edentulous mandible.

space and mental nerve canal. Once this has occurred, tumor can spread laterally and medially to the extent of the marrow space without obvious external evidence (Fig. 16-5).[50] Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning all can help detect the presence and degree of bone invasion (Fig. 16-6).[51]

**FIGURE 16-6.** CT scan with bone windowing shows erosion of the inner cortex of the left mandible, lingual surface due to an adjacent floor of mouth tumor.

***Nonsquamous Oral Cancers.*** In addition to SCC, the oral cavity may develop minor salivary glandular carcinomas and a variety of sarcomas. Minor salivary gland tumors are malignant in the majority of cases. Specific malignant lesions include mucoepidermoid carcinoma, polymorphous low-grade adenocarcinoma, adenoid cystic, acinic cell, clear cell, and myoepithelial carcinoma, to name several. The most common location for all tumors in that series was the palate, accounting for 57% (89/156) of cases including most of the mucoepidermoid carcinomas, polymorphous low-grade adenocarcinomas, and adenoid cystic carcinomas.[52] Some of these entities have distinctive clinical presentations, such as polymorphous low-grade adenocarcinoma, which along with pleomorphic adenoma tend to arise laterally at the hard palate–soft palate junction. In a report from a single institution spanning 20 years of case accumulation, mucoepidermoid carcinoma was the most common histologic category among minor salivary gland malignancies of the oral cavity, accounting for 22% of 156 collected cases.

A wide variety of sarcomas arise within the oral cavity, although all are rare. Kaposi sarcoma is a distinctive entity typically affecting individuals with untreated human immunodeficiency virus (HIV) disease. It begins as an inflammatory, hyperplastic, angiogenic lesion. The gingiva, the palate, and the tongue are most commonly affected. HAART has reduced the rate of Kaposi sarcoma by up to 50%.[53] Osteosarcoma of the mandible and maxilla is the most common sarcoma of the oral cavity, presenting as a painless mass or accompanied by dental pain and loose teeth.[54] Other sarcomas that may appear in the oral cavity include chondrosarcoma, leiomyosarcoma, alveolar soft part sarcoma, fibrosarcoma, and liposarcoma.[55]

## Lymphatic Metastasis from Oral Cancer

Lymphatic extension from the oral cavity follows well-described patterns (Fig. 16-7). Level I nodes are the primary echelon basin for spread from the anterior FOM and the tongue tip, central lips, and mesial alveoloar surfaces of the maxilla and the mandible. Level II nodes drain the lateral FOM and the tongue. Several

(c) 2014 Wolters Kluwer. All Rights Reserved.

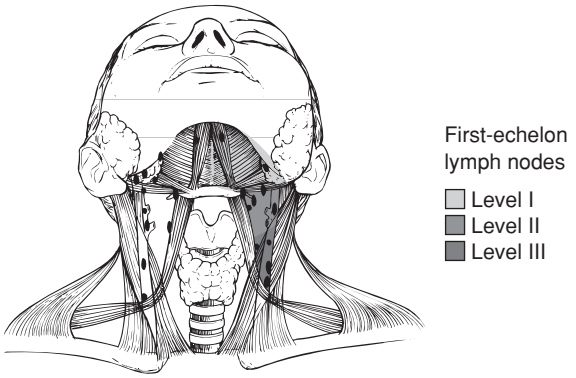

**FIGURE 16-7.** First-echelon lymph nodes at risk for metastasis from carcinoma of the oral cavity are located in the supraomohyoid triangle.

series have documented the relationship between tumor thickness of cancers of the FOM with the likelihood cervical metastasis, with tumor thickness >1.5 mm associated with an increased risk of lymph node metastasis.[56,57] Likewise, for tumors of the FOM or the oral tongue, Spiro and others, in a review of 105 patients staged N0, reported a 12% rate of regional failure with a primary tumor thickness <2 mm as opposed to a failure rate of 47% for tumors thicker than 2 mm. Clearly, those patients with clinically N0 necks with a tumor thickness >1.5 to 2 mm warrant consideration for proactive management of the neck.[58] Whereas tumor thickness has heretofore been determined by microscopic evaluation of a full-thickness tumor biopsy, intraoral ultrasound has been explored as a noninvasive alternative.[59]

Distant dissemination of OSCC is uncommon, particularly at the time of initial presentation. Spread to liver, lung, and bones does occur, more commonly in advanced cases, particularly in the setting of extensive nodal metastasis.
