ABSTRACT

The bonding of fiber reinforced plastic (FRP) plates is an effective and efficient method to improve the bending capacity of concrete beams. In the literature, various design methodologies have been proposed and several of them have been found to compare well with test data or to provide reasonable lower bounds. However, almost all the experimental data are obtained from laboratory-size specimens that are several times smaller than members in real structures. On close examination, different design methodologies exhibit significantly different trends of load capacity vs member size. With no test results on larger specimens, it is not possible to determine which approach is more appropriate for designing real size members. In this investigation, geometrically similar reinforced concrete beams with steel ratio of 0.01, and depth ranging from 0.2 m to 0.8 m were prepared. Some RC beams were tested as control while others were retrofitted with 2 to 8 layers of Carbon fiber reinforced plastic (CFRP) sheets to achieve the same CFRP/concrete area ratio. All the beams were tested to failure to investigate the variation of failure load with member size. The results of the present investigation are expected to provide useful information for (i) the extrapolation of small specimen results to large members of practical size, and (ii) the checking of theoretical models for design.

Reinforced Concrete, Fiber Reinforced Plastics, Structural Retrofitting, Experimental Testing

INTRODUCTION

After years in service, many concrete structures have deteriorated and are in need of repair. In some cases, due to change of usage, members need to be strengthened through retrofitting to provide a load carrying capacity higher than that of the original design. For the flexural strengthening of concrete beams, the bonding of fiber reinforced plastic (FRP) plate to the tensile side has been shown to be an effective means (Saadatmanesh and Ehsani, 1991, Triantafillou and Plevris, 1992, Meier et al, 1993,

Arduini et al, 1997). Besides extensive laboratory studies, the application of FRP to strengthen beams in real structures has also been reported by Meier (1995) and Tan (1997).

For the widespread use of FRP strengthening in practice, a comprehensive design guideline is required. Any design guideline should include a method to accurately predict the failure load of the strengthened member. In the literature, various approaches have been proposed for failure prediction of FRP strengthened members. Some approaches (Teng et al, 2000) are based on the direct fitting of experimental data. Others (El-Mihilmy and Tedesco, 2001 , Raoof and Hassanen, 2000) are based on analytical models, and test data are employed to verify the theoretical prediction. In any case, the full verification of design models relies on the availability of experimental data covering a wide range of design variables. Most available data in the literature, however, are obtained from laboratory-size specimens, that are much smaller than members in real structures. For example, out of the 127 test results on flexural strengthening from 23 studies collected by Bonacci and Maalaj (2001), over 80 of them were obtained from specimens with depth of 300 mm or less. There are only 15 results with beam depth of 400mm or above, and the largest beam was 574mm in depth (with only data from one test). In real structures, beam members are rarely below 400 mm in depth, and very often deeper than 600 mm. Therefore, very few available existing data are representative of real members.

To see the effect of size on member strength, the best way is to calculate the normalized ultimate moment M/bd^2 for sections with similar reinforcement ratio but different size. In Fig.1 below, theoretical prediction of the size effect are carried out with 5 different models (El-Mihilmy and Tedesco, 2001, Oehlers, 1992, Raoof and Hassanen, 2000, Teng et al, 2001, Ziraba et al. 1994). In the analysis, geometrically similar beams 220, 440, 660 and 880 mm in depth are considered. The beam length (L), is 12 times the depth. Loading is applied at one-third points along the span. The steel reinforcement ratio is 1%. The width of the FRP plate (E=235 GPa) is the same as the beam, and the plate thickness is 0.2% the beam depth. The cut-off point of the plate is at a distance L/12 from the support. For each curve, the normalized failure moment (M/bd^2) (Here, d is taken to be the total beam depth, as the FRP is glued to the bottom) is further normalized with its value for the 220 mm depth beam. The predicted trend of failure load vs size can then be easily compared. From Fig.1, it can be seen that the different models show significantly different effects of member size.

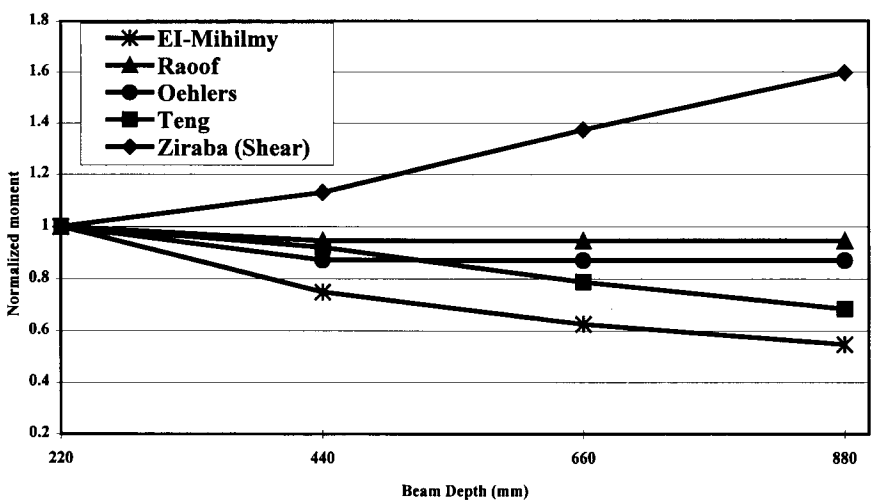

Figure1 Effect of Size on the Normalized Failure Moment of FRP retrofitted Beams

Note that each of these models has been compared with a significant number of experimental data for small specimens, with reasonable agreement achieved. However, even if we empirically 'calibrate' each model (e.g. by multiplying the predicted value with an empirical constant) to give similar results for laboratory size specimens (at 220 mm depth), the predicted failure moment for large members can differ a lot. We suspect that the increasing trend predicted by Ziraba et al.'s model is an artifact of the model, but even if this curve is taken out, the other models still show significant differences. The implication is very clear: experimental results on large members are necessary for the proper validation of design models for flexural failure of strengthened beams.

TESTING PROGRAM

Specimen Design, Preparation and Testing

To study the effect of size on the bending behaviour of FRP strengthened beams, nine reinforced concrete beams were prepared in three different sizes: 75mm (width) x 200mm (depth) x 2m (length), 150 mm x 400 mm x 4 m and 300 mm x 800 mm x 7.5 m. For all the beams, high yield steel reinforcement (σ_y=460 MPa) was employed and the thickness of cover (c) to the tensile reinforcement was 0.075d. The tensile steel reinforcement ratios in the beams (A_s/bh, where h = d-c) were respectively 1.13%, 1.09% and 1.13%. Also, all beams were over-reinforced in shear to ensure that failure would occur under bending. During testing, the loading spans for the three types of beams were respectively 1.8m, 3.6m and 7.2 m. 4 point loading was carried out, with loading applied at one-third points along the loading span. All the specimens were prepared at the same time, with concrete from a ready mix supplier. The design strength of the concrete (f_{cm}) was 30 MPa. Considering standard deviation of concrete, the mean strength should be close to 40 MPa. When the beams were tested, compression strength was also determined with concrete cubes. The average cube strength was found to be 47 MPa.

After the reinforced concrete beams were prepared and cured for over a month, 6 of the beams (2 for each size) were strengthened with bonded carbon fiber reinforced plastic (CFRP) strips. The Young's modulus of the CFRP is 235 GPa while its strength is 4.2 GPa. The CFRP is supplied in the form of a flexible sheet (0.11mm in thickness) with impregnated resin. In the retrofitting process, the bottom surface of the concrete beam was first roughened with a needle gun. A primer was then applied onto the concrete surface. Alternate layers of resin and CFRP were applied under the required thickness was attained. Note that the applied resin contains a hardener and will cause the CFRP sheet to harden and bond strongly to the concrete. For the three beam sizes, 2, 4 and 8 layers of CFRP were applied, and they were cut off at 0.2m, 0.4m and 0.8m from each support respectively. The width of CFRP was the same as the width of the beam. At least 7 days was allowed for the resin to attain maximum strength before testing of the beams were carried out.

All tests were performed with a Dartec loading system of 250 tonne capacity. In all specimens, strain gauges have been installed on both the steel reinforcements and CFRP sheet to monitor the failure process during the test. Besides the applied load, the displacement at mid-span was also measured with a LVDT. For some of the beams, the complete testing was videotaped to capture the damage processes leading to final failure.

Test Results

As mentioned above, a lot of information has been obtained from each individual test. Complete analysis of all the experimental data is still in progress and will be reported in an upcoming publication. In this short paper, we will only focus on the normalized moment for beams of various sizes, the maximum strain measured on the FRP and the percentage increase in load capacity due to strengthening. The experimental values are summarized in Table 1 below.

TABLE 1
EXPERIMENTAL RESULTS FOR BEAMS OF VARIOUS SIZES

Member	Type	Section Dimensions	Load Capacity (kN)	Max. FRP Strain ($\times 10^{-6}$)	M/bd^2 (N/mm^2)	% Increase in Load Capacity
SB1	Control	200 mm (d) x 75 mm (b)	61.02	-	6.102	-
SB2	Strengthened		69.56*	6634*	6.956*	14.0*
SB3	Strengthened		75.74	9737	7.574	24.1
MB1	Control	400 mm (d) x 150 mm (b)	212.02	-	5.301	-
MB2	Strengthened		274.14	7752	6.854	29.3
MB3	Strengthened		272.54	6976	6.813	28.5
LB1	Control	800 mm (d) x 300 mm (b)	822.78	-	5.142	-
LB2	Strengthened		1017.56	6400	6.360	23.7
LB3	Strengthened		1033.00	6673	6.456	25.5

* For specimen SB2, there was a problem with the surface preparation, so the CFRP debonded prematurely, with no concrete sticking to its surface. The result is hence an underestimate for the load capacity of a properly retrofitted beam.

From the above table, the effect of member size on the normalized moment can be observed. When going from the smallest to the largest member, (M/bd^2) decreases by roughly 15%. This size effect is considered quite moderate, considering the fact that the largest specimen is four times the size of the smallest one. In all members, failure was associated with debonding of the FRP from the bottom of the beam. The debonded region was not confined to one side of the beam but extended through the middle span. After testing, the failure surface of the FRP was inspected, and only a thin layer of stuck concrete was found. From our experience, this type of failure was induced by the opening of flexural cracks in the middle of the beam, rather than by stress concentrations near the plate cut-off point. Indeed, in the test on the largest beam, we were able to capture the failure sequence with a video camera. On replaying, it was clear that interfacial failure first started below a flexural crack near one of the loading points, and then propagated towards the end of the bonded plate.

The maximum strain measured on the FRP also suggested the presence of a size effect. Since the magnitude of measured strain also depends on the location of the gauge relative to the flexural cracks, the comparison of maximum strain between various members cannot be considered exact. However, a clear qualitative trend can be observed from the results. With a smaller specimen, it was possible for the FRP to reach a higher strain before failure. This observation is consistent with the size effect on normalized moment of the beam.

A very interesting observation from our result is that the size effect also exists for normal reinforced concrete members that are not strengthened. Indeed, if we consider the percentage increase of load capacity through FRP strengthening, the intermediate member exhibits the highest improvement, while the large and small members show about the same increase. Note that the tensile reinforcement ratio in the intermediate member was a bit smaller than the other two beams. The amount of added FRP reinforcement was hence relatively higher. This may partially explain the higher strengthening ratio. Overall, if one considers the percentage of load increase for members of all three sizes, the size effect is not too significant.

CONCLUSION

In this paper, the effect of member size on the load carrying capacity of FRP strengthened reinforced concrete beams is studied. The result shows that the size effects on the normalized moment of strengthened beams and percentage improvement in load capacity are quite moderate. To our knowledge, this investigation is the first ever study of its kind. It provides useful results for (i) extrapolation of laboratory results to real structural members, and (ii) checking of theoretical models. Based on the test data, any correct theoretical model for FRP debonding failure should not exhibit a large effect of size on the failure load.

ANALYTICAL BEHAVIOUR OF CONCRETE BEAMS REINFORCED WITH STEEL REBARS AND FRP RODS

H. Y. Leung, S. Kitipornchai, R. V. Balendran and A. Y. T. Leung

Department of Building and Construction, City University of Hong Kong,
Tat Chee Avenue, Kowloon, Hong Kong

ABSTRACT

Reinforced concrete (RC) beam embedded with steel reinforcement usually gives a ductile behaviour but low strength whereas use of fibre-reinforced-plastic (FRP) rods provides a higher ultimate strength but limited ductility. It is thus thought that a combined use of steel rebars and FRP rods in concrete beam can offer a ductile and strong performance. To verify this, an analytical model is generated. The model computes the flexural behaviour of concrete members reinforced with conventional steel reinforcing bars and novel FRP rods. The model implementation is based on the use of the true stress-strain relationships for plain concrete, steel rebar and FRP rod. The main variable considered in this study is arrangement/depth of steel rebars and FRP rods. This paper presents some particular findings from the model. Most results are also compared with that of concrete beam reinforced only with steel rebars.

KEYWORDS

Concrete, RC beam, reinforcement, steel rebar, FRP rod, flexural strength

INTRODUCTION

Reinforced concrete (RC) beam embedded with conventional steel reinforcement usually gives a ductile behaviour but low strength whereas use of novel fibre-reinforced-plastic (FRP) rods provides a higher ultimate strength but limited ductility. Instead of exploring new materials as reinforcement so as to enhance the performance of reinforced concrete beam, it is thought that a mix use of steel rebars and FRP rods in concrete beam can offer a ductile and strong performance. Tentatively, concrete beams reinforced with both steel rebars and FRP rods exhibit one of the following flexural failure modes:

1. Concrete crushing occurs before steel yields and FRP breaks.
2. Steel yields followed by concrete crushing while FRP remains intact.
3. Steel yields followed by steel breaks while FRP remains intact.
4. Steel yields followed by FRP snaps.

These failure modes depend largely on the material properties of the ingredients and the configuration of the beam section. It is apparent that the first failure mode occurs only in over-reinforced sections. Since the aim of this study is to investigate the effect of addition of FRP rods into the steel-reinforced section, the latter three failure modes are desired. In this paper, an analytical model is generated to compute the flexural behaviour of concrete section reinforced with conventional steel reinforcing bars and novel FRP rods. Some results, including the strains, neutral axis depth, moments and curvatures, are discussed.

ANALYSIS & ASSUMPTIONS

A simple analytical procedure is developed to calculate the strains and stresses in concrete and reinforcements, moment and curvature in a rectangular concrete cross section reinforced with steel rebars and FRP rods. The procedure, which is derived from force equilibrium and strain compatibility, is applicable to conventional steel reinforced sections, FRP reinforced sections, as well as concrete sections reinforced with a combination of steel rebars and FRP rods. Fig. 1 shows the rectangular concrete beam section used in this study. The basic assumptions made include (1) linear strain distribution across the depth of section, (2) no bond slip of reinforcement, (3) reinforcement stress can be obtained from its stress-strain relationship, (4) tension concrete ignored, (5) shear deformation neglected and (6) failure of section is defined by either concrete crushing or reinforcement snapping.

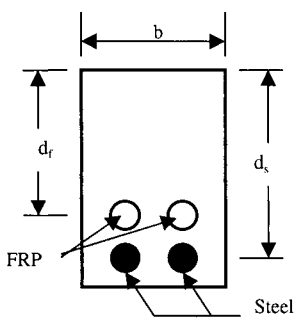

Figure 1: Beam cross section

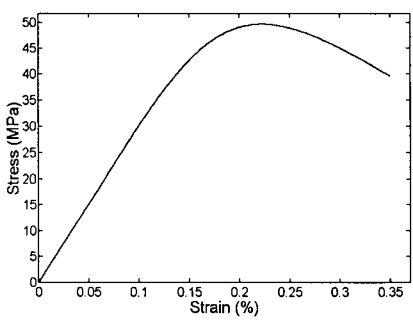

Figure 2: Stress-strain curve for concrete in compression

STRESS-STRAIN RELATIONSHIPS

Concrete in compression

The nonlinear stress-strain model of concrete in compression developed by Almusallam & Alsayed (1995) is used. This model was found to fit well the experimental results for normal strength and high strength concretes. In the model, the relationship between concrete stress (σ_c) and concrete strain (ε_c) is expressed by Eqn. 1.

$$\sigma_c = \frac{(K - K_p)\varepsilon_c}{\left[1 + \left(\frac{(K - K_p)\varepsilon_c}{\sigma_0}\right)^n\right]^{\frac{1}{n}}} + K_p\varepsilon_c \qquad (1)$$

where K = initial slope of the curve; K_p = final slope of the curve; σ_0 = reference stress; and n = curve-shape parameter. The equations of all these model parameters are listed in Appendix. Fig. 2 shows a stress-strain curve of compression concrete where the ultimate concrete strength $\sigma_c^{'} = 50\,\text{MPa}$. As can be seen in Fig. 2, the stress-strain curve terminates at an assumed strain value of 0.0035.

Tensile steel embedded in concrete

The stress-strain curve of steel reinforcing bars embedded in concrete is assumed to be bi-linear and was modelled by Wang & Hsu (2001). The relationship between steel stress (σ_s) and steel strain (ε_s) can be expressed by the following two equations (Eqn. 2 and Eqn. 3):

$$\text{for } \varepsilon_s \le \varepsilon_n \qquad \sigma_s = E_s \varepsilon_s \tag{2}$$

$$\text{for } \varepsilon_s > \varepsilon_n \qquad \sigma_s = \sigma_y \left[(0.91 - 2B) + (0.02 + 0.25B)\frac{\varepsilon_s}{\varepsilon_y} \right] \tag{3}$$

where E_s = elastic modulus of steel; σ_y = yield stress of steel; B = stress parameter; ε_y = strain of steel at yield; and ε_n = strain of steel at average stress when initial yielding occurs. All the model parameters are again given in the Appendix. This model, unlike others, accounts for the fact that the stresses in the steel bars between concrete cracks will be less than the yield stress at the cracks. An averaged value of steel stress across the cracks is thus adopted.

To facilitate generating a curve, some parameters are assumed and they include the breadth of concrete section (b = 200 mm); depth of steel rebars (d_s = 300 mm); area of steel (A_s = 157 mm^2); yield stress (σ_y = 420 MPa); and elastic modulus (E_s = 200 GPa). The resulting curve is shown in Fig. 3.

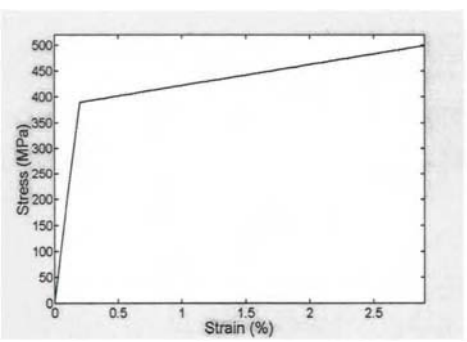

Figure 3: Stress-strain curve for steel

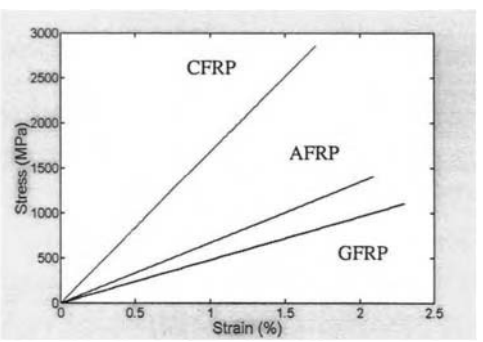

Figure 4: Stress-strain curve for FRP

Tensile FRP rod

The relationship of FRP stress (σ_f) and FRP strain (ε_f) under tension is assumed to be linear and is defined by Eqn. 4 and Eqn. 5.

$$\text{for } \varepsilon_f \le \varepsilon_f^u \qquad \sigma_f = E_f \varepsilon_f \tag{4}$$

$$\text{for } \varepsilon_f > \varepsilon_f^u \qquad \sigma_f = 0 \tag{5}$$

where E_f denotes the elastic modulus of FRP.

The three common FRPs used in construction industry are C(carbon)FRP, A(aramid)FRP and G(glass)FRP, and some of their properties (values obtained from Leung & Burgoyne, 2001) are given in Table 1. Using these values, the stress-strain curves for the three FRPs can then be generated and they are illutrated in Fig. 4.

TABLE 1
PROPERTIES OF FRPS

Materials	CFRP	AFRP	GFRP
Elastic modulus E_f	168 GPa	67 GPa	48 GPa
Ultimate strain ε_f^u	0.017	0.021	0.023

DERIVATIONS

A strain incremental technique is used in the derivation of different parameters. The strain in the extreme fibre of concrete (ε_c^{top}) is increased in a fixed increment, from zero to the ultimate (failure) strain value, to generate the moment-curvature relationship. Fig. 5 shows the distributions of strain and stress across the cross section.

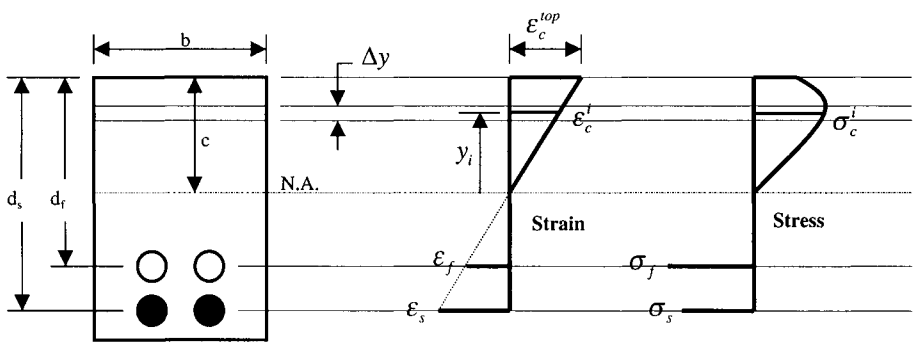

Figure 5: Strain and stress distributions

Once the value of ε_c^{top} is determined, a value of c is assumed. The compression concrete is divided into slices. Strains in the i^{th} compression concrete slice (ε_c^i), FRP rods (ε_f) and steel rebars (ε_s) are then calculated, in terms of ε_c^{top}, by the following three equations (Eqns. 6 to 8):

$$\varepsilon_c^i = \varepsilon_c^{top} \times \left(\frac{y_i}{c} \right) \tag{6}$$

$$\varepsilon_f = \varepsilon_c^{top} \times \left(\frac{d_f - c}{c} \right) \tag{7}$$

$$\varepsilon_s = \varepsilon_c^{top} \times \left(\frac{d_s - c}{c} \right) \tag{8}$$

where y_i is the distance of the i^{th} concrete slice measured from the neutral axis; c is the depth of neutral axis; d_f and d_s are the depth of FRP rods and steel rebars respectively. The stresses in the i^{th} concrete slice (σ_c^i), FRP rods (σ_f) and steel rebars (σ_s) are found from the corresponding stress-strain curves.

The concrete compressive force (F_c) is determined by summation of the product of elemental stress and the corresponding elemental area ($b \times \Delta y$) over the entire compression concrete portion. It is expressed by Eqn. 9.

$$F_c = \sum_i \left(\sigma_c^i \times b \times \Delta y \right) \tag{9}$$

The tensile FRP force (F_f) and steel force (F_s) are found by multiplying the FRP stress by the FRP area (A_f) and the steel stress by the steel area (A_s) respectively (Eqns. 10 and 11).

$$F_f = \sigma_f \times A_f \tag{10}$$

$$F_s = \sigma_s \times A_s \tag{11}$$

Equilibrium of internal forces is imposed by using Eqn. 12:

$$F_c = F_f + F_s \tag{12}$$

If the above equation is not satisfied, the location of the neutral axis (c) is adjusted until force equilibrium is achieved.

The internal resisting moment (M) is then calculated by summing the moments of all internal forces about the neutral axis, and it can be expressed, by Eqn. 13, as follows:

$$M = \sum_i \left(\sigma_c^i \times b \times \Delta y \right) y_i + F_f \times \left(d_f - c \right) + F_s \times \left(d_s - c \right) \tag{13}$$

As indicated by Eqn. 14, the curvature (κ) is also found by dividing the extreme concrete fibre strain by the neutral axis depth.

$$\kappa = \frac{\varepsilon_c^{top}}{c} \tag{14}$$

A small increment on ε_c^{top} is applied and the procedure repeats. The analysis terminates when ε_c^{top} goes beyond 0.0035.

RESULTS & DISCUSSION

To generate analytical results from the above procedure, some material and geometric parameters are assumed. To do this, the model parameters used in generating the curves in Fig. 2 and Fig. 3 are adopted, GFRP is chosen as the internal reinforcement and its properties are obtained in Table 1. It should be noted that a breaking strain of 10% is imposed for tensile steel rebars embedded in concrete. Assumed that $A_f = A_s$, the single variable left is the depth of GFRP rods (d_f) and its value is altered so as to investigate its effect on the flexural behaviour of the beam section (as shown in Fig. 1). Some analytical results are generated and are shown in Figs 6 to 10.

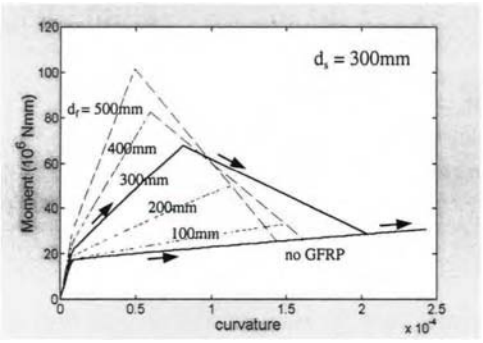

Figure 6: Moment against curvature

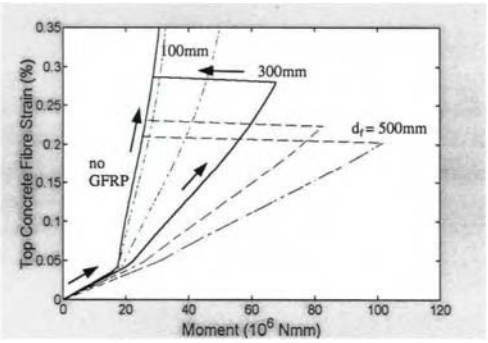

Figure 7: Concrete strain against moment

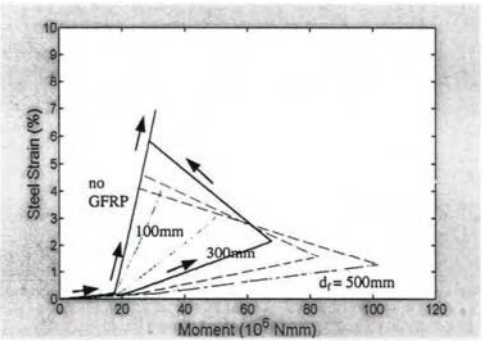

Figure 8: Steel strain against moment

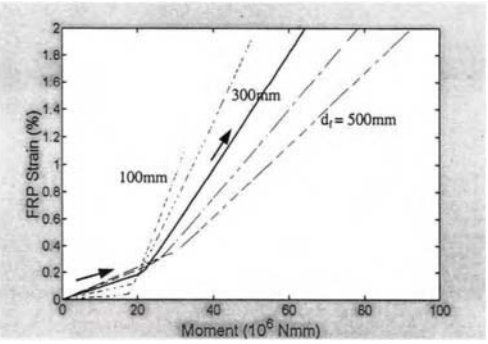

Figure 9: GFRP strain against moment

Fig. 6 shows the variation of moment against curvature for different values of d_f, the curve for no GFRP is also plotted. Since under-reinforced section is adopted, all different sections show occurrence of steel yielding. From the figure, it is clear that the beam section, with no GFRP, becomes a conventional steel-reinforced section and its moment-curvature relationship is bi-linear. Notice that when GFRP rods are added, the initial stiffness and the yield moment seem to increase slightly. When larger value of d_f is adopted, the resisting moment increases in a faster way and higher peak value is resulted. When the two curves with $d_f = 100mm$ and $d_f = 200mm$ are considered, they show an increase up to a peak and then stop. The two curves generally show a similar shape of the steel-reinforced section, except the increase in moment capacity and reduction in ductility. From Figs 7 to 9, it can be seen that the strains of steel bars and GFRP rods for

$d_f = 100mm$ and $d_f = 200mm$ are smaller than their corresponding ultimate strain values, while the concrete strain increases rapidly to 0.0035. This demonstrates that concrete crushing occurs before steel or FRP snaps. For the remaining three curves, a reverse situation is found; reinforcement breaks before concrete crushing occurs. As can be seen in Figs 8,9 and 10, the variation of steel strain remains in its plastic range while GFRP rods have reached its breaking point at failure. This explains the abrupt drop in moment-curvature relationship for $d_f = 300mm$, $d_f = 400mm$ and $d_f = 500mm$, as indicated in Fig. 6. It should also be noted that when larger value of d_f is used, the decrease in moment is more rapid. After GFRP rods have broken, the beam section contains only steel rebars and the moment-curvature curve for steel-reinforced section is followed.

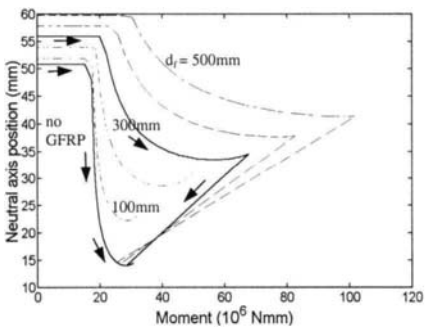

Figure 10: Neutral axis depth against moment

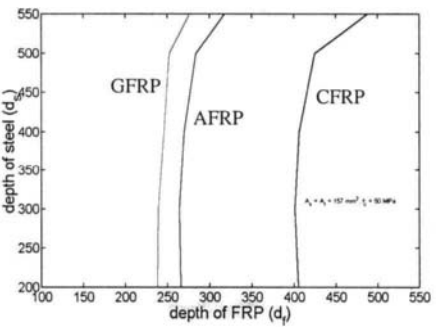

Figure 11: d_s versus d_f

It is interesting to study the neutral axis depth for section containing both kinds of reinforcements. As can be seen in Fig. 10, when no GFRP is used, the neutral axis remains fairly constant. Upon loading, it shifts upward when yielding of steel occurs. The neutral axis slightly goes downward when the section is about reaching its failure, this is explained by the fact that a reduction in concrete stress after its peak value and an increase in stresses in tensile reinforcement give rise to an increase in neutral axis depth. A similar situation is found when the depth of GFRP rods is not large ($d_f = 100mm$ and $d_f = 200mm$). When d_f is further increased, an abrupt upward shift in neutral axis is expected since the failure is governed by snapping of GFRP. Once the GFRP loses its action, the neutral axis depth must be reduced to balance the force between compression concrete and remaining steel rebars.

A similar analysis can be carried out for AFRP and CFRP using values in Table 1. Instead of plotting the strains, neutral axis depths, moments and curvatures, an interaction diagram for different failure modes is produced in Fig. 11. Three different curves are plotted for the three FRPs. Each curve represents the condition that concrete crushing and breaking of FRP rods break simultaneously. The area to the left of the curve indicates that concrete crushing occurs prior to snapping of FRP while the area to the right suggests FRP breaks followed by concrete crushing.

The current investigation provides some results on concrete flexural members reinforced with a mix of tension reinforcements, but there are limitations from a practical point of view. Firstly, it is rare to have steel rebar snapped at ultimate state as the breaking strain of steel is very much in excess of that for FRP. Besides, d_f greater than 300 mm is not common in daily practice. However, these two conditions are considered for the completeness of study.

CONCLUSIONS

From the analytical results, it is possible to conclude that:

1. Failure of steel-reinforced section with adddition of FRP rods is usually governed by concrete crushing or FRP snapping. The steel breaking failure mode is rare.
2. When steel rebars and FRP rods are employed, concrete crushing is usually accompanied by small value of FRP depth whereas breaking of FRP is normally the case for large value of FRP depth.
3. When FRP snaps, the beam section returns to the conventional steel-reinforced section.
4. Interaction diagram, which shows different failure modes, is produced.

ABSTRACT:

The bonding properties between GFRP rebar and concrete are tested and analyzed to ensure feasible application of GFRP rebar in concrete structures. It is found that the bonding strength between GFRP bar and concrete is comparable with that between steel rebar and concrete. Also when there is special surface treatment, the bonding can be significantly improved. Then concrete beams with GFRP rebar embedded as reinforcement are tested and analyzed. It is found that the bonding is acceptable, and the bending capacity is larger using GFRP rebar, except that serviceability is difficult to satisfy.

KEYWORDS

GFRP, bond property, concrete structure, beam, bending

INTRODUCTION

Composites have been introduced into civil engineering structures mainly in the last decade. The application of composites in structural concrete mainly has three forms, FRP bars (tendons), sheets and composite tubes. Compared with conventional steel reinforcement, composite or fiber reinforced plastic (FRP) offers some excellent advantages. They are non-corrosion, non-magnetic, lightweight , and they have excellent handling property, high specific strength, availability in long lengths avoiding the need for lapping, and good fatigue and creep characteristics.

Nanni (1993) analyzed behavior and a design method for concrete beams with different concrete strengths, different kinds of FRP and different reinforcement ratios. Nanni et al (1996) systematically introduced components, and studied the behavior and applications of anchorage systems for FRP tendons. Dolan and Burke (1996) studied the behavior of concrete flexural members prestressed with pretensioned FRP tendons.

GFRP rebar has the advantages of high strength/weight ratio, corrosion resistance, and is also economical comparing with CFRP. Furthermore, when used as a prestressing tendon, its low Young's Modulus brings the unique benefit of lower prestress loss. Its disadvantages include non-ductility, instability at high

temperature, etc. However, by carefully selecting the application situation and methodology, GFRP materials can be very useful in civil engineering structures.

In this study, the push-out method is adopted for studying the bonding property between GFRP rebar and concrete, and the results are found to be satisfactory. Then, the four-point bending test is carried out to study the effect of GFRP rebar as conventional reinforcement. It is found that bonding between GFRP rebar and concrete is acceptable but the serviceability problem prevents the full utilization of GFRP's high ultimate tensile strength.

BOND PROPERTY STUDY

The bond between the composite rod and concrete was studied using the push-out test method, developed by Li et al (1998). The material used is GFRP rod with a glass fiber volume ratio of 67% and Young's Modulus of 51 GPa, and one the diameter is 8 mm. As shown in Table 1, six different formulas are used, with 2 kinds of GFRP rod: one has a smooth surface and the other is sand blasted on the surface. On addition, specimens of formula 1 with smooth surface steel bar were tested as control specimens.

TABLE 1
FORMULAS USED FOR SPECIMEN PREPARATION

		Water	cement	sand	PVA	CEP	Metakaolin	Silicon fume	Slag
1	Plain mortar matrix (cement+sand, w/c=35%, c/s=1:1	0.35	1	1					
2	PVA powder modified matrix (1%) (cement+sand+PVA, w/c=35%, c/s=1:1	0.35	1	1	0.01				
3	Cellulose Ether Powder modified (0.2% of methocel added)	0.35	1	1		0.002			
4	cement+sand+silica fume (replace 5% of cement with s.f.)	0.35	0.95	1				0.05	
5	cement+sand+metakaolin (replace 5% of cement with metakaolin)	0.35	1	1			0.05		
6	cement+sand+slag (replace 50% of cement with slag)	0.35	0.5	1					0.5

A typical load push-out curve as a function of displacement is shown in Figure 1. The load curve shows a linear-elastic stage, a nonlinear ascending stage, then a sudden drop followed by a stable constant force stage. This indicates that the push-out process includes interfacial crack propagation phenomenon.

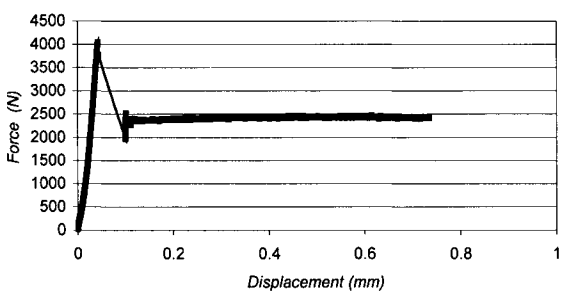

Figure 1: A typical push-out load curve as a function of displacement

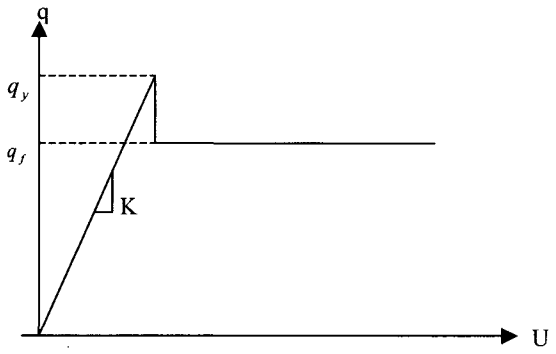

Figure 2: Constitutive model for interfacial shear force

Figure 2 shows the simplified constitutive model for the interfacial bonding stress between GFRP rod and cement mortar.

Calculation of the interfacial bonding stress was carried out using equations 1 to 5

$$\begin{cases} U^* = U(L) = \dfrac{P^* - q_f a}{E_s A \omega}\coth[\omega(L-a)] + \dfrac{P^* - 0.5 q_f a}{E_s A} a & (1) \\ q_f = \dfrac{\omega P^*_{\max}}{a\omega + \sinh[\omega(L-a)]\cosh[\omega(L-a)]} & (2) \\ q_y = q_f \cosh^2[\omega(L-a)] & (3) \\ \tau_y = \dfrac{q_y}{2\pi R} & (4) \\ \tau_f = \dfrac{q_f}{2\pi R} & (5) \end{cases}$$

where,
U: rebar displacement;
P: push force at x = L;
q: shear force per unit length acting on the rebar;
q_f: frictional shear force per unit length;
q_y: interfacial yield parameter;
a: debonding length;
L: rebar embedment length;
A: rebar cross-sectional area;
R: rebar radius;

$$\omega = \sqrt{\frac{k}{E_s A}}$$

Since the only unknown is the debonding length, a, its solution will result in the length of the debonded zone at the peak load, $P^*_{\max}$. After obtaining the value of the debonding length, a, the frictional shear bond

strength q_f and the value of q_y were determined. Then bonding strength measures τ_y and τ_f were calculated, as shown in Table 2 and Table 3.

TABLE 2
RESULTS FOR THE SMOOTH GFRP ROD AND SMOOTH STEEL ROD

Mix Formula	*W*	τ_y *(MPa)*	τ_f *(MPa)*
Formula 1	14.44	6.63	6.1
Formula 2	26.85	5.32	4.07
Formula 3	26.72	7.00	5.29
Formula 4	33.91	8.47	5.48
Formula 5	27.60	8.06	6.04
Formula 6	29.55	8.30	5.98
Formula 1 with Steel rod	7.98	7.33	6.85

TABLE 3
RESULTS FOR THE SAND BLASTED GFRP ROD

Mix Formula	*w*	τ_y*(MPa)*	τ_f*(MPa)*
Formula 1	49.89	17.50	13.64
Formula 2	44.78	10.63	7.14
Formula 3	20.75	10.02	8.84
Formula 4	30.35	19.69	16.26
Formula 5	27.51	16.25	14.07
Formula 6	42.38	18.41	15.34

As shown in Table 2, the silica fume modified matrix had the maximum bond strength, which was comparable to that of the control specimen, with a smooth-surface steel rod in plain cement mortar.

It can be seen in Table 3 that GFRP rod with the sand blasting surface treatment has improved bonding with cement mortar, increasing from 67% to 196%. It can be concluded that GFRP rod with proper surface treatment can significantly improve the bonding property and hence can be utilized as normal reinforcement in concrete structures.

GFRP as normal reinforcement

Beam specimens with dimensions of 100 x 150 x 2000 mm were prepared for the 4-point bending test with an effective cross section depth d = 120 mm. Two Φ8mm sand-blasted GFRP rebars were embedded in the concrete beam as reinforcement, with a reinforcement area A_{frp} of 100.5 mm^2.

The four-point bending test arrangement at Material Testing System (MTS) is shown in Figure 3. Strain gauges are attached to the surface of the concrete beam, and two Linear Variable Differential Transducers (LVDTs) are used to measure the deflection at the bottom of the beams in the pure bending region.

Figure 4 shows the schematic layout of the test specimen, with S = 600 mm, and L = 1800 mm.

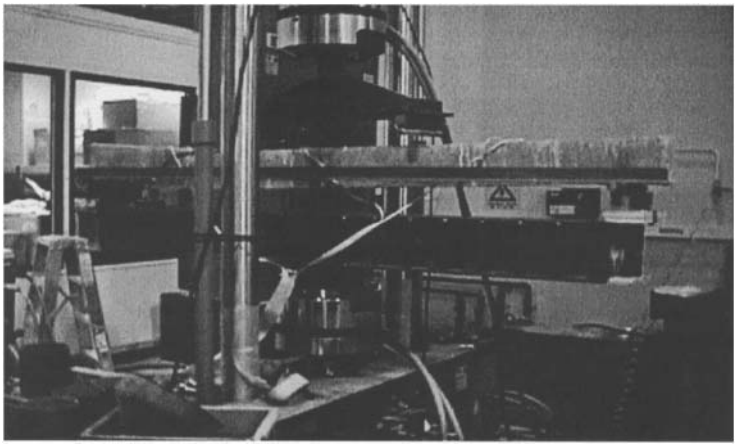

Figure 3: Set up of 4-point bending test

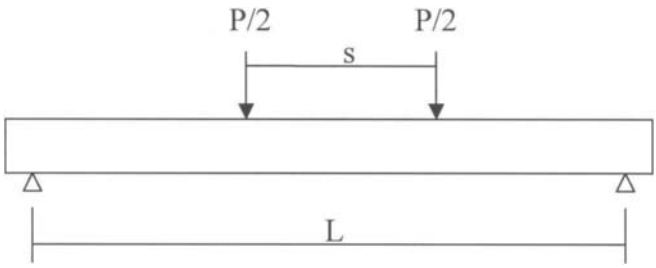

Figure 4: Schematic layout of test specimen

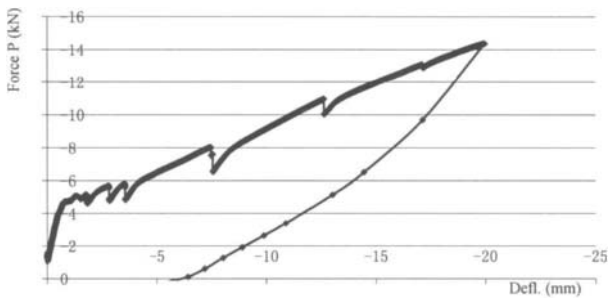

Figure 5: Force vs deflection curve for beam specimen 1

The force vs deflection relationship of beam specimen 1 is shown in Figure 5. It is loaded in deflection control mode until its deflection reaches 20 mm, and then unloaded. The maximum deflection to load span ratio is 1/82, which is far beyond the serviceability requirement. It is observed that several main cracks occurred in the pure bending region, with their depths extending to over ¾ of the beam depth. This

implies that the bonding between GFRP rebar and concrete is acceptable, otherwise the beam would have failed. The turning point where the slope changes rapidly indicates the occurrence of a crack at the bottom surface of the beam where tensile stress exceeds the ultimate tensile strength of the concrete. This turning point has a value of force P as about 5 kN.

The several sudden drops in the force vs deflection curve may be caused by some partial failure in the bonding between GFRP rebar and concrete. Since the sand blasted on the GFRP rebar surface is not quite uniform, at some weak position the sand can separate from the rebar causing partial debonding, which is also observed in the push-out test.

The strain vs Time curve in Figure 6 shows the same characteristic as that of the force vs deflection curve.

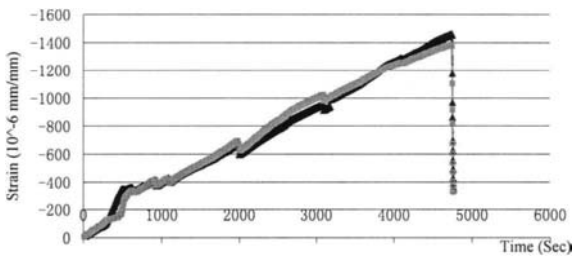

Figure 6: Strain on bottom of beam vs time for beam specimen 1

Another two specimens were tested using deflection control mode until failure occurred. Figure 7 shows the force vs deflection curve for beam specimen 2, which is quite similar to that of beam specimen 1. The turning point is at a force of about 5 kN, as is the case for beam specimen 1. The maximum deflection to load span ratio is 1/61, which is even larger than beam specimen 1. The failure mode is in shear, where the concrete cover burst out due to partial debonding between GFRP rebar and concrete, as can be seen in Figure 8.

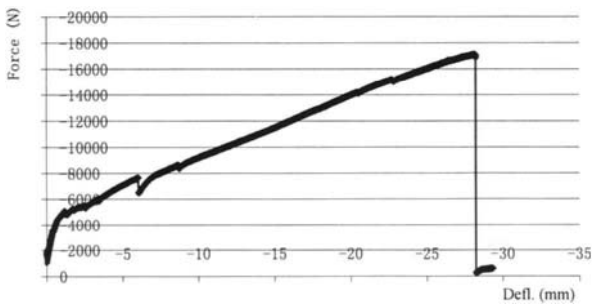

Figure 7: Force vs deflection curve of beam specimen 2

Beam specimen 3 has a behavior similar to that of beam specimens 1 and 2. The maximum deflection to load span ratio is 1/49, which is the largest among the three. Shear failure occurs and the ultimate load P_u is 19.9 kN.

All three specimens show a similar crack propagation manner. The first crack appears in the pure bending region, and then in this region several cracks subsequently occur. The bending cracks continue to extend upward, as long as the beam is still capable of carrying loading. The occurrence and propagation of shear crack leads to shear failure, and part of the concrete below the shear crack at the bottom side of the beam debonds from the GFRP bar and bursts out.

Bending Capacity Calculation

If we assume bonding between GFRP and concrete is satisfactory, and fcu is 40 MPa, and f_{frp} is 1100 MPa, hence Mu is calculated as 11kN•m, and the corresponding Pu is 36.7 kN

Shear Capacity Calculation

Similarly, we can get the shear capacity Vu = 10.7 kN, corresponding Pu = 21.4 kN

With the assumptions, shear capacity is shown to be less than bending capacity, so is aspect controls and the failure mode is a shear failure, and this agrees with the test result. The prediction of shear failure load Pu = 21 kN is close to the test results, and the difference in values may be caused by non-uniformity of specimens, inaccurate assumptions, inaccuracy in calculation method, etc.

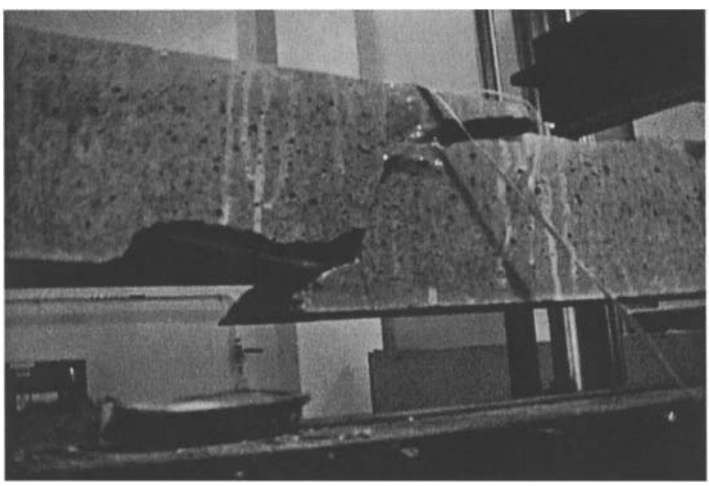

Figure 8: Shear failure of beam specimen 2 (shear crack)

CONCLUSION

The bonding between GFRP rebar and concrete is comparable to that between steel bar and concrete. And the bond property can be significantly improved using proper surface treatment of the GFRP rebar. This, in a sense, ensures the possible application of GFRP rebar as reinforcement for concrete structures.

Due to the low elastic modulus of GFRP rebar, concrete beams with GFRP as reinforcement usually have lower flexural rigidity, so the serviceability requirement usually controls the design. Some possible ways to overcome this limitation on the usefulness of GFRP, are to carefully control the application situation to avoid the serviceability problem. Combination of GFRP reinforcement and steel reinforcement, adopting prestressing system to solve the serviceability problem are two possibilities.

A GENERIC STRUCTURAL ENGINEERING APPROACH TO RETROFITTING RC BEAMS IN BUILDINGS BY ADHESIVE BONDING LONGITUDINAL PLATES

Deric J. Oehlers and Rudi Seracino
Department of Civil and Environmental Engineering, The University of Adelaide
Adelaide, South Australia, SA5005, Australia

ABSTRACT

Retrofitting reinforced concrete structures by adhesive bonding steel or FRP plates to their surfaces is an efficient and inexpensive form of rehabilitation that is rapidly gaining in importance. The main problem with adhesive bonding plates to reinforced concrete is the very weak tensile strength of the concrete that allows premature debonding of the plate that can occur even before the serviceability loads are reached. There has been published much research on premature debonding, particularly for tension face plates, from which have been developed: design rules of thumb; analyses based on stress concentrations; and those based on fracture mechanics. Much of this research may appear to be confusing for structural engineers as they are often not based on a structural engineer's understanding of the familiar behaviour of reinforced concrete. In this paper, a new, simple and generic structural engineering approach is described for designing plated structures that are based on the fundamental principles and mechanisms of behaviour familiar to structural engineers who design reinforced concrete structures. It will be shown that this new approach can be applied to longitudinal plates: of any material type such as FRP or steel; of any size; of any cross-section such as flat plates, angle sections and U-sections; and that are adhesively bonded to any position such as the tension face, compression face and sides of the RC beams or slabs.

KEYWORDS

Retrofitting, rehabilitation, plating, reinforced concrete, beams, slabs, FRP plating, steel plating.

INTRODUCTION

Many non-structural engineering researchers appear to make the problem of retrofitting reinforced concrete buildings by adhesive bonding longitudinal plates sound extremely complex and outside the scope of understanding of structural engineers. This is wrong. It is shown in this paper that the fundamental understanding that structural engineers have of the behaviour of reinforced concrete structures is essential to the understanding of the plated RC structure, and allows a simple generic design approach to be developed and used. In this paper, the retrofitting of an internal continuous beam in an RC

building is used as an illustration. At first, the variety of materials that can be used is discussed, this is followed by the structural engineering reasons for choosing the positions of the longitudinal plates, which is then followed by a description of the structural engineering debonding mechanisms and where they occur. The paper is concluded with an application of a design approach.

MATERIAL AND SECTIONAL DUCTILITY

The material behaviour of the plate affects the structural behaviour of the plated section. Structural engineers are familiar with the behaviour of steel as shown in Fig.1 which in its elastic range is relatively stiff (E_s) after which there is a large ductile plateau before the onset of strain hardening at very high strains. Hence, if a steel plate is designed to yield prior to debonding then the plated section will behave in a ductile fashion and moment redistribution can occur. In contrast, fibre reinforced polymer (FRP) is a linear elastic material that is relatively flexible, then fractures without any material ductility. Hence in an FRP plated beam, the force in the FRP plate keeps increasing until crushing of the concrete or debonding, so that the curvature at failure is relatively low allowing little if any moment redistribution.

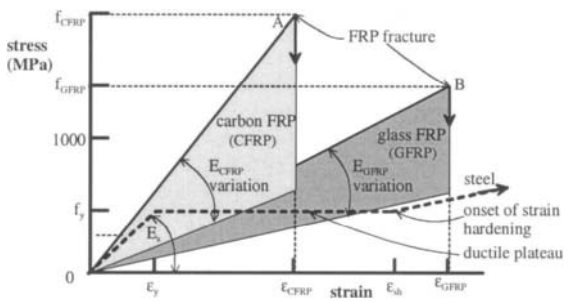

Figure 1: Plate material properties

LONGITUDINAL PLATE POSITIONS

Probably the most common form of longitudinal plating is to adhesively bond plates to the tension faces of continuous beams as shown in Fig.2, so that the internal lever arm of the axial plate force is maximised. However as structural engineers well know, the addition of tension reinforcement reduces the sectional ductility which imposes a limit to the amount of strengthening that can occur. Furthermore, tension face plates are prone to debonding due to the interaction of the plate stress fields with those of the tension reinforcing bars, such that debonding occurs at the level of the tension reinforcement.

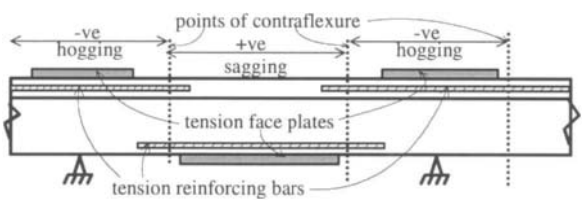

Figure 2: Tension face plates

An alternative approach is to adhesively bond plates to the sides as in Fig.3. These plates are less prone to debonding as they are less likely to interact with the tension reinforcing bar stress fields, so that the plane

of debonding occurs in the concrete adjacent to the adhesive layer and not at the level of the tension reinforcing bars. Furthermore, side plates have less of an effect on the sectional ductility particularly when there are deep side plates as in A in Fig.3, in which case the sectional ductility may increase. It may also be worth noting that sides plates can also increase the shear capacity.

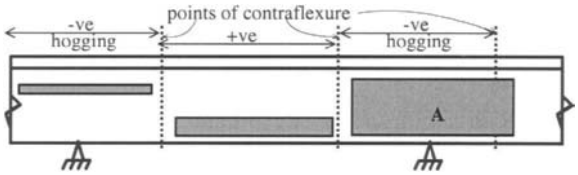

Figure 3: Side plates

PREMATURE DEBONDING MECHANISMS

An example of a retrofitted beam is shown in Fig.4. This beam reached its moment capacity at large rotations even though some debonding cracks were visible. The aim of the structural engineer is to ensure that premature debonding of the plate does not occur to such an extent as to weaken the structure or reduce its ductility. The following three major debonding mechanisms have been identified.

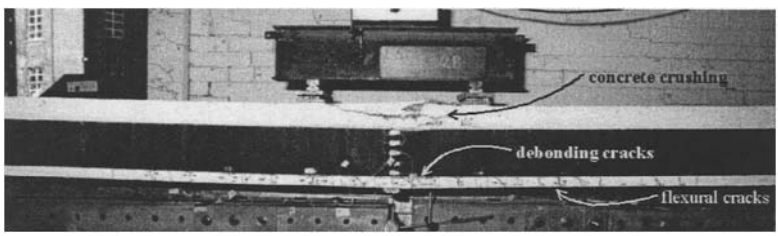

Figure 4: Retrofitted beam

Plate End (PE) Debonding

An example of plate end (PE) debonding is shown in Fig.5. The stress concentrations due to the termination of the plate induce cracks that start at the plate end and propagate inwards, gradually at first and then rapidly until complete debonding occurs at which the strains in the plate reduce to zero so that the beam now acts as unplated.

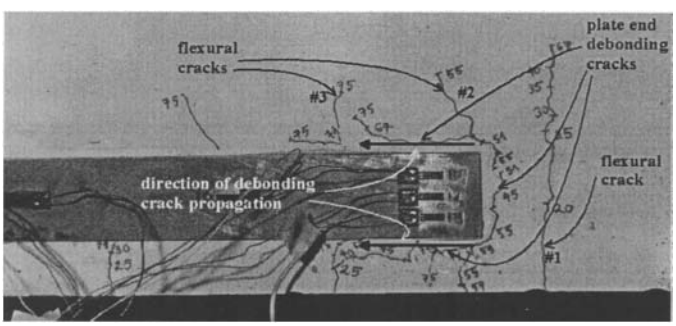

Figure 5: Plate end debonding of a steel side plate

The mechanism of PE debonding is illustrated in Fig.6 for a tension face plate, where it can be seen in Fig.6(a) that the curvature of the plated beam induces a moment M_c and axial force P_a in the plate. These stress resultants M_c and P_a, caused by the curvature of the beam induce the plate/concrete interface forces in Fig.6(a) and stresses in Fig.6(b) and (c) that result in debonding. Hence a simple solution to preventing PE debonding is to terminate the plate at a point of contraflexure where the curvature is zero. Sometimes it may not be possible to terminate the plate at a point of contraflexure due to envelopes induced by variations in load. In which case, the plates can be terminated in regions of low moment, where the section apart from tensile cracking can be assumed to be elastic; design rules are available for tension face plates (Oehlers and Moran 1990), side plates (Oehlers 2000), angle sections (Nguyen et al 1998) and compression face plates (Mohamed Ali et al 2002) to ensure that premature debonding does not occur. It can be seen that PE debonding controls the extent of plating, that is the length of plate required.

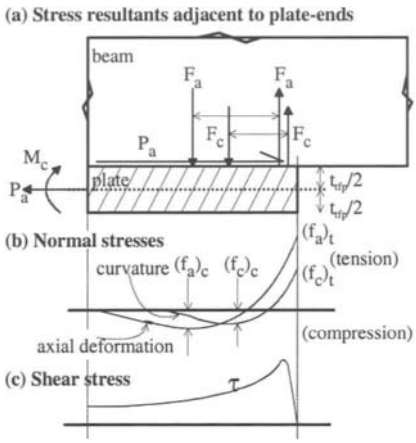

Figure 6: Plate end debonding mechanism

Intermediate Crack (IC) Debonding

Intermediate crack (IC) debonding of a tension face plate is shown in Fig.7. The interface IC debonding cracks propagate from the intercept of the intermediate cracks, induced by combinations of applied flexural or shear forces, with the longitudinal plate. The IC debonding cracks propagate towards the plate ends gradually joining up until a large length of plate between the plate ends has separated from the beam. Hence, to all intents and purposes the plate has debonded even though the plate ends may still be attached, as the plate contribution is now negligible.

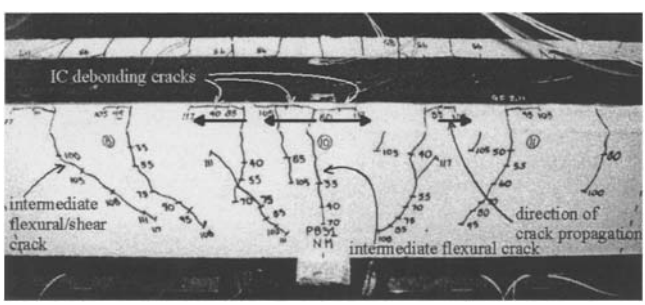

Figure 7: IC debonding of tension face plate

The mechanism of IC debonding is illustrated in Fig.8. To accommodate the formation of the flexural intermediate crack adjacent to the plate requires infinite strains in the plate which of course cannot occur, so that the strains are relieved by the formation of the interface IC debonding cracks. Much research has been done on IC debonding (Teng et al 2002). For example it has been shown the stress at which debonding occurs is proportional to $\sqrt{(E_p\sqrt{f_c})/t_p}$ where E_p and t_p are the plate stiffness and thickness respectively; so that thin stiff plates are less likely to debond and IC debonding will usually start in regions of maximum flexure. Therefore, the thickness of a steel plate can be adjusted so that yield will occur before IC debonding, so that the cross section fails in a ductile mode that allows moment redistribution. In contrast, FRP plates will debond whilst still elastic, often at a stress of about 30% of the ultimate FRP strength, so that failure tends to be brittle and little moment redistribution can occur. It can be seen that IC debonding controls the flexural strength and ductility.

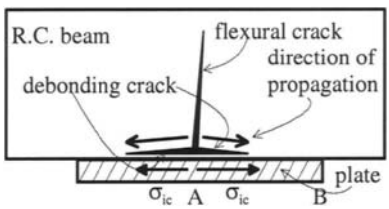

Figure 8: Mechanism of intermediate crack debonding

Critical Diagonal Crack (CDC) Debonding

Critical diagonal crack (CDC) debonding is due to the vertical shear displacement across a critical diagonal crack as shown in Fig.9(a) for a beam without stirrups and in Fig.9(b) for a beam with stirrups. The debonding crack propagates catastrophically from the intercept of the diagonal crack with the plate to the plate end. Tests have clearly shown that the longitudinal plates debond before the stirrups can be stretched so that debonding occurs at the strength of the concrete beam without stirrups. However these tests have also shown that the longitudinal plates inhibit the formation of the critical diagonal crack. Hence a lower bound to the shear load at which debonding occurs V_{cdc} is the shear strength of the beam without stirrups V_{uc} (Zhang 1997) and the contribution from the stirrups V_{us} is negligible or zero.

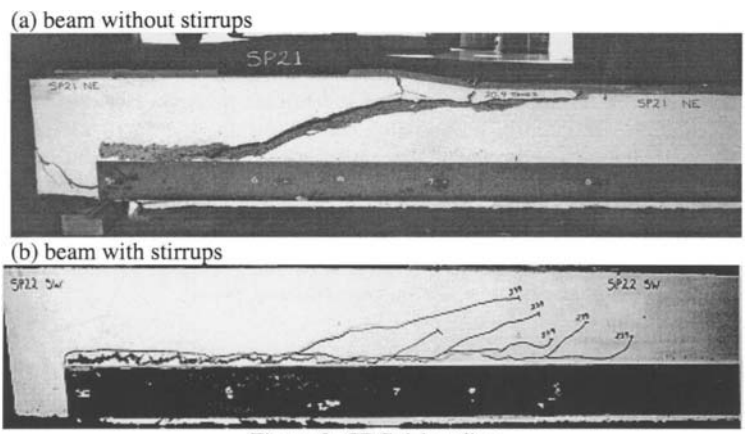

Figure 9: CDC debonding

If a shear capacity greater than V_{uc} is required for the longitudinally plated region, then methods of analysis are available for determining the vertical shear load to cause a longitudinal plate to debond V_{cdc}, which depends on whether the plate is attached to the tension, side or compression face (Jansze 1997; Mohamed Ali et al 2001, 2000, 2002). The method of analysis is illustrated in Fig.10 for a side plated beam. For each possible position of a diagonal crack, it is necessary to determine the shear load to cause the diagonal crack to develop V_{cr} and the shear resistance against sliding across this diagonal crack V_u. The intercept as in Fig.10 defines both the position of the critical diagonal crack and the vertical shear to cause debonding V_{cdc}. It is worth noting in Fig.10, that for each position of the diagonal crack, the resistance to sliding depends on the IC debonding resistance across the diagonal crack P_{ic} in the top half of the figure. It can be seen that CDC debonding relies on the IC debonding strength but IC debonding is not the same as CDC debonding as IC debonding depends on axial deformations in the plate whilst CDC debonding depend on shear deformations in the RC beam.

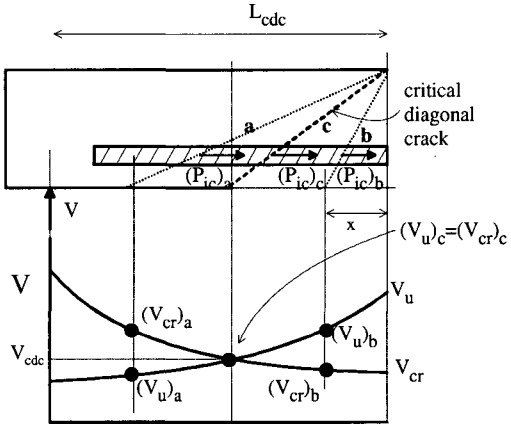

Figure 10: Analysis of CDC debonding resistance

OCCURRENCE OF DEBONDING MECHANISMS

The distribution of the major debonding mechanisms are illustrated in Fig.11(a) for tension face plates. It can be seen that IC debonding initiates in the regions of maximum moment, where the strains in the plate are at their largest, and propagate towards the plate ends. IC debonding controls the flexural capacity and flexural ductility and hence the ability of the beam to redistribute moment. CDC debonding depends on the vertical shear capacity, ignoring the contribution due to stirrups, and hence is often more likely to occur in the negative or hogging regions where the vertical shear is at its highest and where often stirrups are required. Hence in slabs where stirrups are rarely used, CDC debonding is unlikely to affect design as most slabs are designed for V_{uc} only. In contrast in the negative regions of continuous beams where the vertical shear is at its highest and where stirrups are required then it may not be possible to adhesively bond plates. PE debonding always occurs at the plate ends and propagate inwards and can be simply prevented by terminating the plate near to a point of contraflexure.

Sometimes the plates are placed or terminated in the compression face as in Fig.11(b). In which case in the compression face zones, IC debonding cannot occur but CDC and PE debonding can occur as shown. The same debonding mechanisms also apply to side plates beams as in Fig.11(c). Hence it can be seen that these are generic debonding mechanisms.

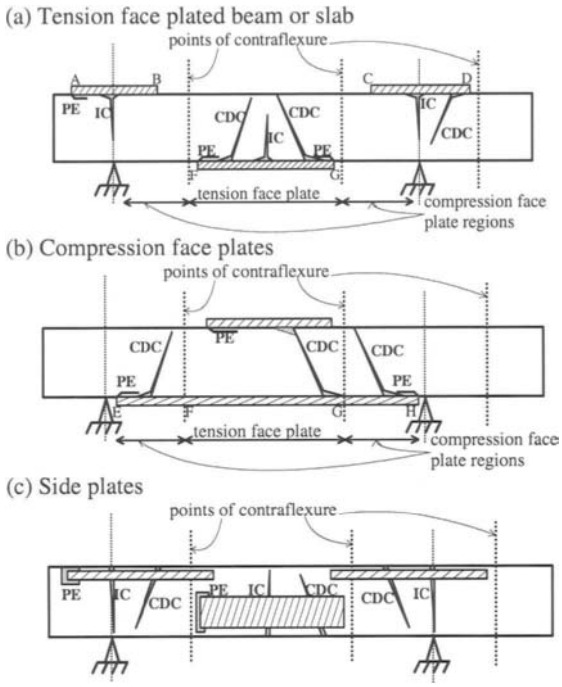

Figure 11: Distribution of debonding mechanisms

APPLICATION OF DESIGN APPROACH

The continuous member in Fig.12 is used to illustrated the generic plating approach.

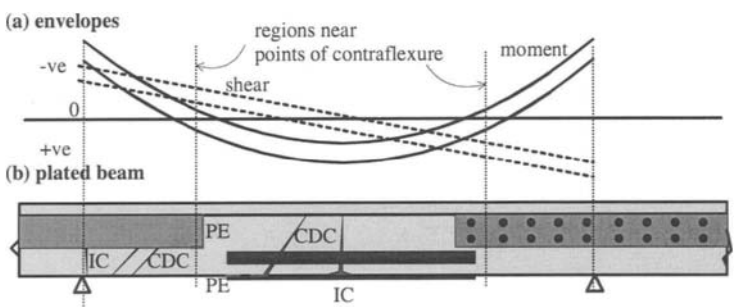

Figure 12: Generic plating approach

Let us first assume that the continuous member in Fig.12 is a slab and hence does not have stirrups, so that the vertical shear capacity is V_{uc} which is the shear resistance of the critical diagonal crack of the unplated section. The addition of plates will inhibit the formation of the critical diagonal crack which will increase the vertical shear capacity to V_{cdc}, the shear load to cause CDC debonding. V_{cdc} is now both the shear load to cause debonding as well as the shear capacity of the plated slab. Hence CDC debonding is unlikely to occur anywhere along the slab, just as long as the new design shear load due to retrofitting

does not exceed V_{cdc} which is the likely scenario. PE debonding can be prevented by terminating the plates in regions of low moment so this should also not be a problem. Hence this leaves IC debonding which can occur at the positions of maximum moment in both the -ve and +ve regions. FRP plates are usually the preferred option due to their ease of application and handling and durability. These can be used in both the –ve and +ve regions if little or no moment redistribution is required. If, however, the -ve regions are required to redistribute moment to the positive region then steel plates may be the preferred option in the –ve regions as the steel plates can be designed to yield before IC debonding. Hence there is a possibility that the final design will use both steel and FRP plates.

Let us now assume that the continuous member in Fig.12 is a beam and hence does have stirrups so that the vertical shear capacity is now $V_{uc} + V_{us}$ which is the shear resistance of the unplated section. As with the slab, plate end debonding can be prevented by terminating the plate at the point of contraflexure. In the +ve region the vertical shears here are relatively small, compared with those in the –ve region, so that V_{us} may be relatively small. Just as long as $V_{cdc} < V_{uc} + V_{us}$ of the +ve region, then CDC debonding may not occur particularly as tests have shown that plating can increase V_{cdc} to twice V_{uc}. However, in the –ve region it may not be possible to prevent CDC debonding due to the high value of V_{us} in which case it may be necessary to bolt the plates as shown. As with the slabs, IC debonding and its effect on ductility may control where FRP and steel plates are used.

EFFICIENCY OF STRENGTHENED R. C. COLUMNS

Prof. Dr. M. Akram Tahir

University of Engineering and Technology, Lahore-Pakistan.

ABSTRACT

An experimental study was conducted, in which a large number of full-scale models of columns were cast and later strengthened by preparing different types of surface conditions between the existing and added concrete. The core was encased in the jacket cast from fresh concrete by placing properly tied additional reinforcement in the jacket. Five types of surface condition were studied during the strengthening program. The other parameters of the study were the strengths of concrete and steel both in the core and jacket. It was interesting to note that surface conditions of existing concrete had little effect on the strength of strengthened columns in case load was applied concentrically. However, in case of eccentrically loaded columns, the surface conditions resulting in poor bond showed drastic decrease in strength as compared to those providing better bond between old and new concrete. Another interesting fact was noted that for the efficient strengthening of the columns the strength of the two materials in the jacket should be at least equal to or greater than those of the respective core materials.

KEYWORDS:

Strengthening, eccentrically loaded columns, full-scale models, concrete jacket, surface conditions.

INTRODUCTION

During renovation of buildings often it becomes necessary to strengthen the existing columns in order to increase their load carrying capacity. The strengthening becomes inevitable due to increase in the service loads or loss of member strength. The strengthening is provided by adding an additional section, termed as jacket, around the existing column section, named as core. Additional longitudinal bars that are properly tied are provided in the jacket. The bond between the surfaces of core and jacket-concretes has sharp influence on the integrity of the strengthened column. The core is subjected to the stresses prior the strengthening is done where as the jacket has to take the share of load by transition. The strength of the materials in core and jacket is usually different. These factors make the problem of strengthening a bit more complex. In this study a number of columns were cast and strengthened. Two concretes with nominal strengths of 21 MPa and 28 MPa were used during casting and strengthening operations with two grades of steel i.e., 280 MPa and 420 MPa. The details of the test program are presented in the following section.

EXPERIMENTAL PROGRAM

A number of full-scale models were cast, strengthened, and tested to destruction. The main variables of the study were the strength of concrete and steel in the core and jacket, the eccentricity of loading, and surface condition of the core concrete. The test program was completed in three series. First of all a pilot study was conducted on 75-mm square sections strengthened to 150-mm square sections. The concrete was made using coarse river sand as fine aggregate; 12-mm maximum size crushed lime stone aggregate, and ordinary Portland cement. The concrete mixtures were designed for two grades with nominal strengths of 21 MPa and 28 MPa. Two grades of deformed mild steel with nominal yield strength of 280 MPa and 420 MPa were used as reinforcement. The columns were cast using molds in vertical direction. The columns were cured for twenty-eight days and then left for weathering for quite a some time. The test program was completed in three different series. The details are presented.

The Pilot Program

The concrete mixtures were designed for nominal strengths of 21 and 28 MPa at 28 day. Five surface conditions of the old concrete, as listed in the following, were prepared before strengthening during the pilot test program:

S1. The same old dried surface without cleaning was used for strengthening.
S2. The cover was removed of the old steel reinforcement before strengthening.
S3. The old surface was cleaned thoroughly before strengthening the section.
S4. The surface was painted and aged before strengthening.
S5. The surface was prepared wet by using cement water.

The columns were cast, cured, and then left for aging in weather. These columns were later strengthened with the five surface conditions of old concrete. The strengthened columns were cured and then tested to destruction by applying both concentric and eccentric loads. The characteristics of the columns cast and tested during the pilot study are reported in Table 1.

Table 1
THE COLUMNS CAST IN PILOT STUDY

S,No	Old Section (Core)				New Section (Jacket)			
	b, h mm	f'_c MPa	f_y MPa	A_s	b, h mm	f'_c MPa	f_y MPa	A_s
1	75	21	280	4#4	150	21	280	6#4
2	75	21	280	4#4	150	21	420	6#4
3	75	21	280	4#4	150	28	420	6#4
4	75	21	420	4#4	150	28	280	6#4
5	75	28	280	4#4	150	21	420	6#4
6	75	28	420	4#4	150	21	280	6#4

Note: The length of the columns was 2 m. Twenty-two columns were cast in this part of the program. The main reinforcement in core and jacket sections were tied properly using #3 bar-square ties spaced at 75 mm and 150 mm respectively.

Results of The Pilot Test Program

Table 2
EXPERIMENTAL STRENGTHS OF THE COLUMNS LISTED IN TABLE 1.

Sr. No	P, kN (e=0 mm)					P, kN (e= 50mm)				
	S1	S2	S3	S4	S5	S1	S2	S3	S4	S5
1	774	776	774	774	764	321	331	311	264	324
2				843					321	
3				950					367	
4	936			929		386	415		321	
5				914					364	
6				860					307	

The strengthened columns were cured and later tested to destruction in a 100-Ton Buckton universal testing machine. The machine may accommodate 4m long columns. It can be observed from the tabulated results that surface conditions of old concrete have little influence whatsoever on the load carrying capacity of the strengthened columns where the load was applied concentrically. The strength results of the columns listed at serial no. 1 confirm this fact when loaded concentrically. However, in case of eccentric loading, severe segregation occurred at the interface of the old and new concretes for the surface condition S4, where the old surface was painted and put for aging before strengthening. The most effective surface condition for strengthening was S2, where the old concrete cover was removed prior the strengthening was performed.

FULL SCALE MODELS

The tests on full-scale models were carried out in two series. In the first of the series, twenty-two 100x100 mm columns were cast and later strengthened to 200 x 200 mm. The height of the columns

TABLE 3
DETAILS OF THE COLUMNS CAST AND TESTED DURING 2ND SERIES.

S. No	Old Section		New Section		P, kN, e= 50mm		P, kN, e= 100mm

11	21	280	21	280	587	507		
12	21	280	21	420	653	570		
13	21	420	21	420	667	590		
14	21	420	21	280	604	534		
15	21	280	28	280	713		397	280
16	21	280	28	420	780		456	336
17	28	280	21	280	626		355	265
18	28	280	21	420	674		415	305
19	28	420	21	420	680			
20	28	420	21	280	607			

was fixed at 2500 mm. The materials used in this series were same as those employed in the pilot study. The combinations of two concrete mixtures with nominal strengths of 21 and 28 MPa were used in core and jacket. The details of the columns and experimental strengths are reported in Table 3

The comparison of axial strengths of the columns tested in series 2 is depicted in Fig.1. It is interesting to note that strength reduces appreciably with the reduction in strengths of jacket steel and concrete. The concrete strength is less effective than steel strength in enhancing the load carrying capacity of the strengthened columns

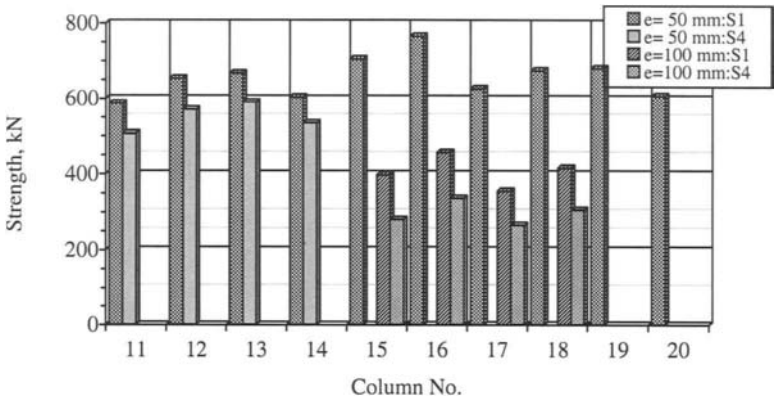

Figure 1. Ultimate strength of the columns tested in series 2.

Another set of ten columns was cast and strengthened in the third series. The length of these members was 3000 mm and core size was 150 mm square and jacket size was 300 mm square. The reinforcement in core was 4#6 bars and that in jacket was 6#4 bars. The concrete of the same two nominal strengths, 21 and 28 MPa was used in core as well as in jacket. The same reinforcement of the two nominal grades, 280 MPa and 420 MPa, was used. The details of the columns are given in Table 4 and the test results are reported in Figure 2.

TABLE 4

THE DETAILS OF THE COLUMNS CAST AND TESTED DURING SERIES 3.

Sr. No	Old Section 150x150 mm			Strengthened Section 300x300 mm		
	f'_c MPa	f_y, MPa	Reinforcement	f'_c MPa	f_y, MPa	Reinforcement
21	21	280	4#6	21	280	6#4
22	21	280		21	420	
23	21	420		21	420	
24	21	420		21	280	
25	21	280	4#6	28	280	6#4
26	21	280		28	420	
27	28	280	4#6	21	280	6#4
28	28	280		21	420	
29	28	420		21	420	
30	28	420		21	280	

The length of the columns was 3000 mm and they were strengthened with surface condition S5. These columns were properly tied to avoid bulging of longitudinal steel. The tabulated concrete and steel strengths are nominal. The loading eccentricity was kept constant at 150 mm.

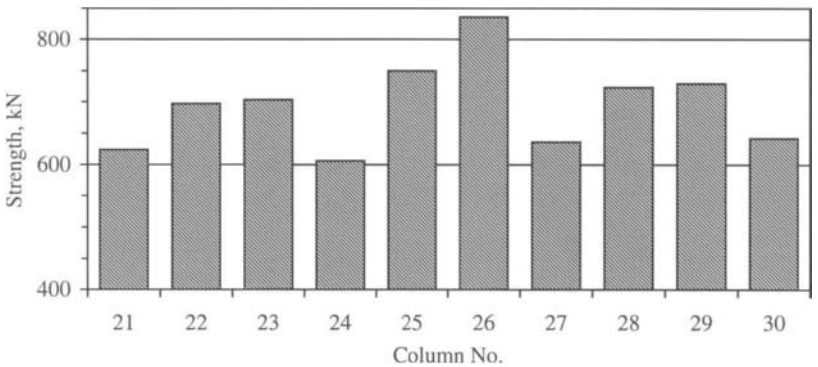

Figure 2. The axial strengths of the series 3 columns loaded with eccentricity=150 mm

DISCUSSION OF THE RESULTS

A very interesting picture emerges as the axial strengths of various columns are compared. The results of the two series are compared with respect to the change in strengths of steel and concrete both in core and jacket. The comparisons for series 2 tests are presented in Figure 3. It can be noted from Figure 3a and 3b that change in strength of steel or concrete in core does not affect the strength of strengthened column appreciably. For example, compare the strengths of the two columns, in each of the pairs (11,14), (12,13), (17, 20) and (18,19). The jackets of the two columns in each pair are cast from the same set of materials. The core of the two is also cast from the same concrete. The steel reinforcement, however, in the core of the two columns in each pair is different. It can be seen that increasing yield strength of core steel from 280 MPa to 420 MPa does not enhance the strength of the columns appreciably. The change is merely in the range of 1 to 3%. A similar picture is emerged from the comparison of the two columns in each of the pairs; (11,17), (12,18), (13,19) and (14,20). The two columns in each pair are cast from identical materials except that the concrete in the cores of the two is of different strength. It can be confirmed from Figure 3b, that increasing strength of core concrete from 21 MPa to 28 MPa does not affect the strength of column significantly. The change in strength is in the range of 1 to 6%, with an average of 3%. Similar trends can be observed from Figure 4, which confirm that core strength is not that important for eccentrically loaded strengthened columns.

However, an increase in either concrete- or steel-strength of jacket appreciably enhances the strength of strengthened column. These comparisons are based on the steel strength in jacket and are depicted in Figure 3c and those on concrete strength of jacket are shown in Figure 3d. It can be observed from Figure 3c, that strengths of the columns increase in the range of 7-12% when strength of reinforcement is changed from 280 MPa to 420 MPa. Similarly the increase in strength of jacket concrete from 21 MPa to 28 MPa enhances the strength of column by 20%. Similar observations can be made from Figure 4c and d. It may be noted that increase in the strength of jacket concrete is more effective than that of steel in increasing the load carrying capacity of the strengthened columns.

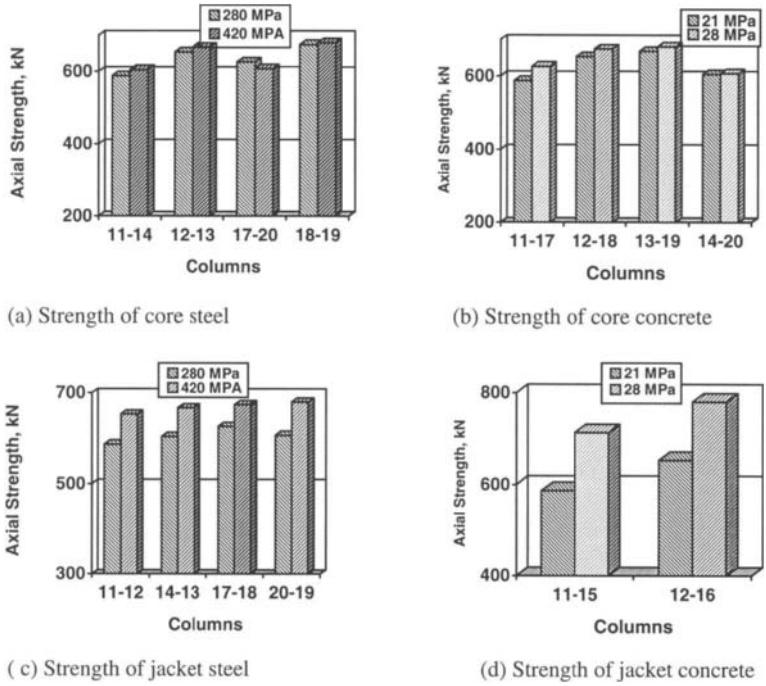

Figure 3. Comparison of strengths based on concrete and steel strengths in core and jacket. (Results from series 2.)

Another important observation made from the comparison of series 2 test results is that surface condition S4 causes a sever reduction in the strength of strengthened columns when loaded eccentrically. This reduction is more pronounced when eccentricity is increased from 50 mm to 100 mm. Compare the drop in strength of the columns with surface conditions S1 and S4, at serial numbers 11 to 14 and 15 to 18 as shown in Figure 1. The surface condition of old concrete, i.e.,, interface between core and jacket is an important parameter of strengthening. If a perfect bond is not established between the old and new concretes, a sever segregation is observed at testing time when load is applied eccentrically. This effect becomes more and more pronounced with increase in loading

CONCLUSIONS

Two important conclusions can be drawn from the results observed in this study. Firstly the ultimate strength of concrete and yield strength of steel in jacket should be kept at-least equal to the strengths of the two materials used in core for an efficient strengthening of existing columns. It means that use of stronger materials in jacket makes the strengthening more efficient. Secondly, there should be a perfect bond between old and new concretes at the interface of core and jacket to avoid segregation of concrete during load application. The surface of old concrete should be prepared thoroughly before the strengthening operations are carried out. It may be noted, however, that there is quite a sharp difference between the test conditions and the actual situation in buildings where the columns would have be strengthened. In these tests, the core and jacket were simultaneously stressed whereas in real

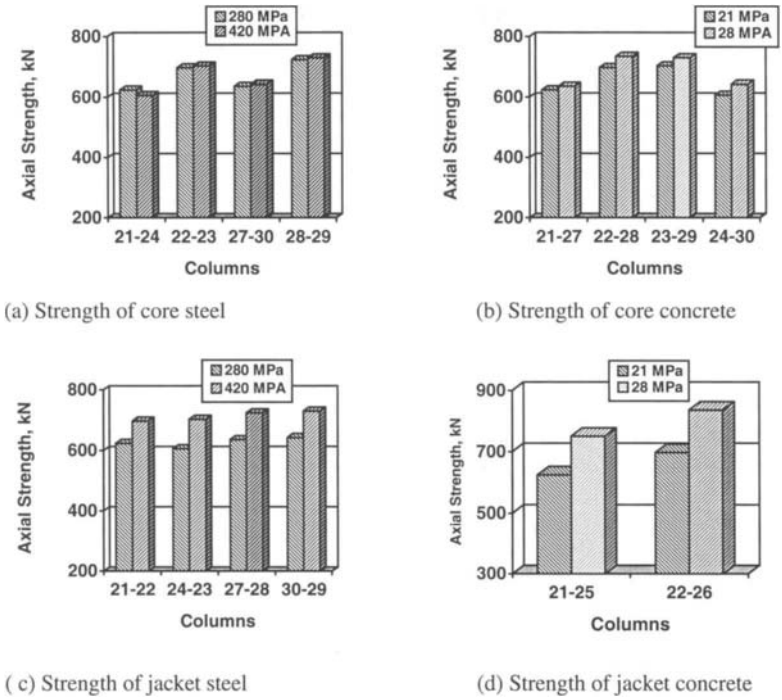

Figure 4. Comparison of strengths based on concrete and steel strengths in core and jacket (Results from series 3.)

buildings the core would be stressed prior the strengthening process would have been carried. Therefore it would be necessary to provide some stress transfer mechanism between old and new concrete sections. It may be provided in the form of the shear bolts, by surface roughening or by providing epoxy coating on the surface of existing section.

REHABILITATION OF REINFORCED CONCRETE COLUMNS BY EXTERNAL PLATE BONDING

B. Uy[1]

[1]School of Civil and Environmental Engineering, The University of New South Wales, Sydney, NSW 2052, AUSTRALIA

ABSTRACT

Rehabilitating reinforced concrete elements using external steel plates has been applied to both beams and slabs in bridge and building construction over the last two decades. The effect of applying external steel plates increases the strength of beams and slabs. This technique can also be applied to reinforced concrete columns to increase their strength with a minimal increase in the cross-sectional dimensions of the member. This paper presents an experimental programme used to ascertain the behaviour of both short and slender columns. These columns had steel plates bonded to them by the use of both bolting or gluing and bolting. A simplified theoretical model based on composite construction techniques is then presented and calibrated with the experiments to determine the strength increase and recommendations for further research are then made. Furthermore, recent research on the compressive behaviour of carbon fibre reinforced plastic (CFRP) plates and their effects on rehabilitating reinforced concrete elements is also discussed.

KEYWORDS

buckling, columns, composite structures, concrete structures, rehabilitation

INTRODUCTION

Rehabilitation or retrofitting of reinforced concrete structures often provides a more logical and economical alternative than demolition or replacement. This has been made evident with the many applications where steel plating has been used to increase both the stiffness and strength of existing reinforced concrete slabs and beams. To further increase the range of applicability of steel plate bonding, research into the retrofitting of reinforced concrete columns needs to be carried out as illustrated in Figure 1. The advantages of this include increasing both the strength and stability of a column without a significant increase in cross-sectional dimensions. Reinforced concrete columns may need to be strengthened for a number of reasons, which may be due to increasing the gravity load on a structure, or upgrading a structure for lateral loading such as wind or earthquake.

This paper presents an experimental and analytical study to consider the effects of steel plate bonding on the strength and stability of reinforced concrete columns. The experiments involved testing both short and slender columns. A series of theoretical models is then presented and calibrated with the experiments for determining the axial and flexural strengths. The paper concludes with suggestions for further research into the rehabilitation and retrofitting of concrete structures in particular in relation to the use of carbon fibre reinforced plastic plating.

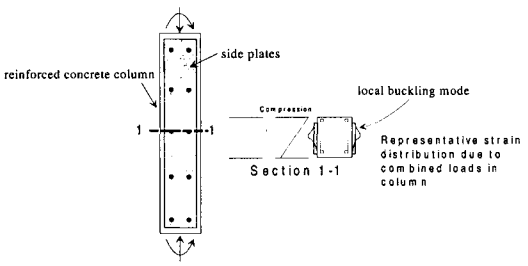

Figure 1: Application of CFRP plates to reinforced concrete columns

EXPERIMENTS

This paper will present the results of two series of experiments. Two series of experiments were conducted on short reinforced concrete columns to assess the increase in both axial stiffness and strength obtained by plate bonding. The concrete in these two series was exactly the same. A model to assess the axial stiffness and strength is then presented and calibrated with the experimental results. The following section outlines the two series of tests conducted. All of the plain reinforced concrete specimens were designed according to the Australian Standard for Concrete Structures, AS3600-1994, (Standards Australia, 1994).

Test Series 1

This set of tests consisted of constructing six identical reinforced concrete columns of 150 x 150 mm in cross-section, which were all of 450 mm in length. Each of these columns contained minimal longitudinal reinforcement consisting of four deformed Y12 bars and was detailed with sufficient lateral ties. Two plain specimens were tested and denoted as Plain 1 and Plain 2. Two specimens were tested with plates bolted to their sides and were denoted as Bolted 1 and Bolted 2. A final set of columns was tested with plates glued and bolted to their sides and these specimens were denoted Glued & Bolted 1 and Glued & Bolted 2. For this series of tests, plate coupons were tested in tension to establish their yield strength and elastic modulus, which are summarised in Table 1. Furthermore, a series of concrete cylinders were tested in compression to establish their mean compressive strength as summarised in Table 2.

Test Series 2

This set of tests also considered six identical reinforced concrete columns of 150 x 3000 mm of 815 mm in length. Again each of these columns was reinforced with minimal longitudinal reinforcement and detailed with sufficient lateral ties. This diagram also shows the location and extent of stiffeners used to initiate failure of the columns away from the ends of the specimen. The difference in these tests was that they were bonded with steel plates on only two opposite sides. Again two plain

specimens were tested and denoted as Plain 1 and Plain 2, two specimens were tested with plates bolted to their sides and denoted as Bolted 1 and Bolted 2 and two specimens with plates glued and bolted to their sides were denoted Glued & Bolted 1 and Glued & Bolted 2. Also concrete cylinders were tested in compression and steel plate coupons were tested in tension to assess their stress-strain characteristics, which are again summarised in Tables 1 and 2 respectively.

REINFORCING TESTS

	Nominal Diameter (mm)	Nominal Area (mm^2)	Yield Stress (N/mm^2)	Ultimate Stress (N/mm^2)
Mean	12	113	478	594

Short Column Tests

The short column tests, which included both Test Series 1 and 2, were conducted under pure compression in a Denison 5,000 kN capacity servo-controlled testing machine. The column ends were set in large steel plates and cast in high strength mortar to ensure uniform loading conditions and thus uniform compression loading. The short column tests were designed so that the ends were fully fixed, which virtually eliminated any second order effects from developing.

RESULTS

The following section outlines the results of each of the test series as well as summarising the results of the material property tests.

Test Series 1

The results of these tests are summarised in Table 4. The comparisons of axial strength show one that by the application of bolting a 16% increase in axial strength is achieved whereas gluing and bolting achieves a 32 % increase in axial strength. There is very little difference in axial stiffness created by steel plate bonding, although it seems to lie between 0 and 20 %. Failure modes of these columns are

illustrated in Figure 2 which highlights local buckling of the steel plates and local crushing of the concrete.

TABLE 4
SERIES 1 COMPARISONS

Type	N_u Strength (kN)	N_u Average (kN)	Relative Value
Plain 1	1031		
Plain 2	1125	1078	1.00
Bolted 1	1251		
Bolted 2	1255	1253	1.16
Glued and Bolted 1	1359		
Glued and Bolted 2	1476	1418	1.32

Figure 2: Failure mode of short steel plated reinforced concrete column

Test Series 2

Results from the second series of tests were slightly different from those of Test Series 1 and the comparisons of axial strength are summarised in Table 5. Firstly, two plain samples were tested and these gave a base strength for the reinforced concrete member. Now the glued and bolted specimens achieved a lower strength than the specimens, which were bolted only, with an 11% and 20% increase respectively.

TABLE 5
SERIES 2 COMPARISONS

Bolted 2	2476	2425	1.20
Glued and Bolted 1	2252		
Glued and Bolted 2	2229	2240	1.11

THEORETICAL MODEL

In order to be able to predict the strength of externally plated reinforced concrete columns, a theoretical model is proposed. The axial strength of the steel plated reinforced concrete columns is determined by employing the principle of superposition, which yields the following equation

$$N_u = N_{uc} + N_{ur} + N_{us} \tag{1}$$

where the concrete contribution to the axial strength is

$$N_{uc} = \alpha f_c A_c \tag{2}$$

where α is the factor associated with compression of the columns. The factor based on back analysis of the reinforced concrete columns was determined to be approximately 0.70 for Series 1 and Series 2. The reasons for this supposedly lower concrete strength can be explained by the fact that the cross-sections had a significantly large cover are compared with core area and thus this concrete suffered from premature spalling. The reinforcing steel contribution is given by

$$N_{ur} = f_{yr} A_r \tag{3}$$

The contribution of the steel plate was calculated as

$$N_{us} = f_{ys} A_s \tag{4}$$

when local buckling did not occur, or a reduced strength was used which was dependent on the local buckling strength, so that

$$N_{ol} = f_{ol} A_s \tag{5}$$

where the critical stress is given by

$$f_{ol} = \frac{\pi^2 E_s I_s}{A_s L_{bb}^2} \tag{6}$$

This buckling load may be higher if the adhesive restricts the steel plate from buckling out of plane. However in Series 2 the glue may have promoted buckling at a much earlier stage due to creating some initial imperfections. The steel plate undergoes a restrained buckling mode, which essentially reduces the effective length. An adequate buckling model assumes the plates are clamped at the bolt locations, however the unloaded edges are assumed to be free, which is essentially a column buckling approach with fixed ends.

COMPARISONS

The model developed for axial strength is compared with the experimental results of test Series 1 and 2. For both Series the concrete strength used a factor of 0.70 for the concrete cylinder strength as discussed previously. Tables 6 and 7 show the comparisons between the experiment and theory for the axial strengths. One can see that the model is very accurate in predicting the axial strength. The ratio of experimental to predicted strength is shown to be greater than 1.0 in all cases, thus showing

that the model is conservative. The mean value for this ratio was 1.06 and 1.09 for Series 1 and 2 respectively, with a standard deviation of 0.08 in both cases. In both Series 1 and Series 2 plate buckling governed the strength of the steel plating, and this was substantiated by the experiments where plate buckling was noted to be one of the failure modes.

In addition to comparing the test results with the theoretical model proposed, it was also compared with the suggested ultimate strength and design strengths from the Australian Standards for Concrete Structures, AS3600. Tables 6 and 7 shows the ratio of the experimental strength to predicted ultimate strength, as well as the ratio of experimental to assumed design strength.

The AS3600 model was used with nominal strengths, so that the nominal concrete compressive strength was 40 MPa and the nominal reinforcing steel strength was 400 MPa as ordered. The nominal yield strength for the steel plate was taken as 250MPa. This comparison therefore resulted in some interesting observations. If one was to use the AS3600 strength model with nominal strengths, a mean value of 1.02 and 1.06 was established with a standard deviation of 0.11 and 0.08 respectively for Test Series 1 and 2.

If one compares the experimental strengths with the design strengths as suggested by AS3600, a standard deviation of 1.70 and 1.78 with a corresponding standard deviation of 0.32 for both test series. This shows that for design, the AS3600 model will certainly provide a factor of safety of approximately 2.5, by the time load factors are introduced.

CARBON FIBRE PLATING IMPLICATIONS

Recent studies on the compressive behaviour of carbon fibre plates restrained by a rigid medium have shown that these plates are more susceptible to local instability than steel plates, due to the high level of anisotropy which is existent in unidirectional plates, (Uy and Aw, 2001 and Uy and Yang, 2001). Further experiments have also shown that due to the very low transverse stiffness and strength, small out of plane deformations of the plate in compression can lead to transverse splitting which is a highly undesirable failure mode. Further experiments of these plates when used in conjunction with reinforced concrete columns should be conducted to assess the suitability of this material for rehabilitation purposes.

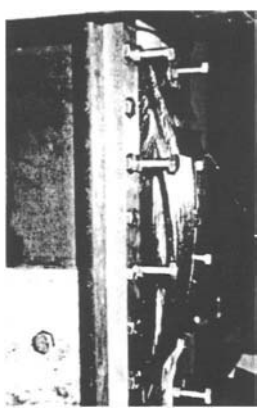

Figure 3: Failure mode of carbon fibre reinforced plastic plating under compression

CONCLUSIONS

This paper has presented a benchmark set of tests for reinforced concrete columns bonded with steel plates under axial flexural loading. The paper has illustrated that bonding steel plates to reinforced concrete columns can increase both the stiffness and strength of the member. Both bolting and gluing and bolting were investigated. Bolting steel plates was shown to produce a higher strength and stiffness than the control specimens. Gluing and bolting also produced an increase in strength and stiffness and in the case of the slender columns, this was totally effective in eliminating local buckling and slip and thus allowing full composite action to be achieved. A theoretical model has also been presented to determine the axial stiffness and strength. This model was calibrated with sufficient accuracy with the test results and in all cases the model is shown to be conservative. However further research is required before this approach could be adopted in design as only a limited amount of specimens were tested. Furthermore, given the growing use of fibre reinforced plastic plates in retrofitting concrete structures, further tests should be conducted using these forms of plates.

ABSTRACT

A newly developed 2-*D* mesoscopic thermoelastic damage (MTED) model is used to study the thermal stress field and associated fracture in a cement-based composite with multiple circular inclusions at high temperatures. It is found that the thermal stress field and the associated cracking are dominated by the interaction of inclusions, and the heterogeneity. The macrocracks occur firstly between the two inclusions which have the shortest distance apart if coefficient of thermal expansion (CTE) of the inclusion is greater than that of matrix. The resistance of inclusion with higher strength against crack is also found. The MTED model yields a good agreement between the proposed numerical simulations and the available experimental results.

INTRODUCTION

When a cement-based composite material is subjected to elevated temperatures, the difference in thermal deformations of the cementitious matrix and the aggregate inclusions induces thermal stresses and possibly cracking in the material. Previous investigations [Venecanin, 1990; Khoury,1992] have shown that the greater the mismatch in the mechanical and thermal properties between the matrix and the inclusion, the more significant the reduction of strength, elasticity modulus, and durability of concrete would be. The deteriorations of these properties were mainly due to the thermal induced cracking. Venecanin (1990) experimentally studied the effects of thermal incompatibility of concrete components (TICC) by measuring their CTE, and the CTE heterogeneity of aggregate inclusions. The results showed that TICC was one of the reasons for thermal cracking. Kristensen and Hansen (1994) lent a support to the Venecanin's view in their investigation of the thermal cracking of cement paste and concrete using ultrasonic pulse velocity techniques. Their experimental results indicated that cement paste and concrete could be damaged by internal cracking due to differential stresses at differential temperature between core and surface of specimen. Later, based on the fracture mechanics and micromechanics approaches, an analytical

model (Sumarac et al., 1998) was proposed to study the reduction of elastic modulus with temperatures due to the mismatch in the CTE between mortar and aggregate, assuming a uniform distribution of cracks. Recently, both analytical modeling and numerical simulation (Hsueh, et al., 2001) were used to analyze residual thermal stresses and CTE in two-phase composites. It was found that the predicted CTE of a two-phase material was dependent on the Young's modulus ratio and the difference between the CTE of the two phase-materials. If the intergranular phase had a greater CTE than that of the grain, the intergranular phase and the grain would be stressed in tension and hydrostatic compression, respectively. Although the studies on the thermal stress and the thermal crack have been conducted numerically or experimentally, the studies of the thermal cracking processes – the initiation, propagation and linkage of crack in concrete at elevated temperatures is still limited.

As observed in experiments (Tijissens et al., 2001; Mier et al., 1997), concrete is a highly heterogeneous material that can be quantified in three levels: macroscale, mesoscale and microscale. The heterogeneity is an indispensable reason to cause the concentration stress and local failure (Brandt, 1996; Hsu, 1963). At room temperature, the effects of heterogeneity on the fracture processes in concrete have been reported in literatures. However, the previous studies do not consider the effects of heterogeneity among the phase materials of concrete on the stress development and cracking process under high temperatures. The complex structure of concrete is unable to be described by an analytical model. The process of thermal cracking of heated concrete has not been visually demonstrated till now.

This paper presents a series of numerical studies to quantify/qualify the effects of the interaction and CTE of multi inclusions on the thermal stresses and associated cracking in a cement-based composite. Consequently, a more realistic thermal stress field and the thermal cracking in meso-structure can be observed visually and dynamically by the newly developed mesoscopic thermoelastic damage (MTED) model (Fu et al., 2002).

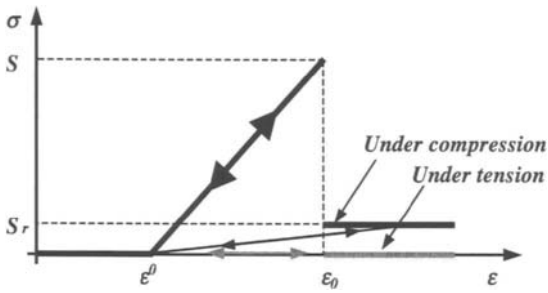
NUMERICAL METHOD

Brief Outline Of Mesoscopic Thermoelastic Damage (MTED) Model

The cement-based composite is made of two phase materials (matrix and inclusion), each of which at mesoscale is heterogeneous. The interface bonding between the matrix and the inclusion is assumed to be perfect. A statistical Weibull Distribution is used to describe the heterogeneity of the phase material using a homogeneity index. The mechanical properties (such as strength, elastic modulus and Poisson ratio) are randomly allocated to each representative volume element (RVE) to account for the inherent variability in the phase material, using the Monte-Carlo method.

In this study, we implicitly assume that the macroscopic mechanical behavior of the composite is a result of the growth of microcracks, and is captured in the damage evolution law for RVE. A smeared crack concept is adopted to construct the constitutive law of RVE. The crack is not considered as a discrete displacement jump, but rather a variation in the mechanical properties according to a continuum law, such as damage mechanics. A separation function of damage is deduced to describe the softening process of the material. A full description of the MTED model is available in the paper (Fu et al., 2002). The schematic of the thermoelastic behavior law of the material is shown in Fig.1. It is assumed that the stress-strain relationship of a RVE is linearly elastic till its peak-strength is reached, and thereafter follows an abrupt drop to its residual strength. Under compression, RVE remains a residual strength after peak-strength; whereas, under tension, the residual strength of RVE is equal to zero. Parameters S and S_r are used to denote the uniaxial compressive/tensile strength and residual strength; ε^0, ε_0 are the initial thermal strain and the strain corresponding to the peak strength of RVE, respectively. This model is able to capture the complete

thermal cracking processes including the initiation, propagation and linkage of cracks. In the present study, the CTE and mechanical properties of the matrix and inclusions are considered to be independent of temperature variations.



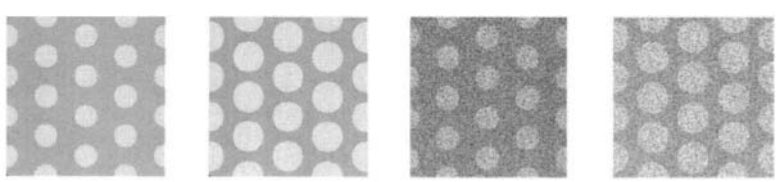


Fig.1 Constitutive relation of RVE

Numerical Specimens

Four numerical square specimens with different thermal and geometrical properties (see Table.1) are presented here to simulate the thermal induced cracking process in the composite with multi-inclusions. Specimen no.1 and no.2 with multi circular inclusions of same CTE (see Fig.2) are set to investigate the influence of the interaction between inclusions on the thermal stress field, and the only variable is the inclusion diameter. The proportion of the inclusions in Specimens no.1 and no.2 are 28.3% and 50.2%, respectively. For the former, the diameter of inclusion is 15mm. For the latter, the diameter of inclusion is 20mm. Specimens no.3 and no.4 (see Fig.2) are similar to those of Specimens no.1 and no.2 respectively, except the former ones have a higher degree of heterogeneity (h=3 in matrix and inclusions). All specimens are subjected to uniform temperature field changes (steady state) ranging from 20°C till 620°C, at an increment of 10°C.

NUMERICAL RESULTS AND DISCUSSION

Thermal Stress Field

Effects of interaction of inclusions

In case of Specimen no.1 with multi inclusions of 15mm diameter, a diamond-shaped region surrounded by the inclusions (see Fig.3a) is chosen to explain the influence of the arrangement of inclusions. In this region, the distance between the inclusions ***A*** and ***B*** is larger than that between the inclusions ***C*** and ***D***. Consequently, in the sub-region Ψ_1 the stress in the *X*-direction is smaller than 0, $\sigma_x<0$, and in the *Y*-direction is larger than 0, $\sigma_y>0$; whereas in the sub-region Ψ_2 the stress in the *X*-direction is larger than 0, $\sigma_x>0$, and in the *Y*-direction is smaller than 0, $\sigma_y<0$ (as shown in Fig.3c). In the locally enlarged pictures of the principal stress contours of the sub-regions Ψ_1 and Ψ_2

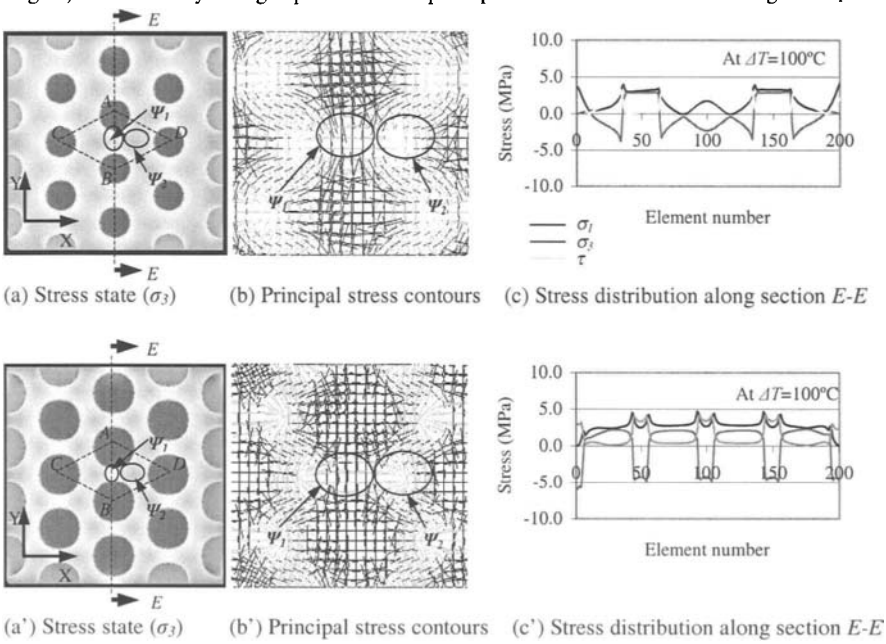

Fig.3 Thermal stress field in Specimens no.1 and no.2

(see Fig.3b), a dark line is a trajectory of a maximum principal stress and a light is the trajectory of the minimum principal stress. It is evident that the values of all principal stresses approach zero in the sub-region Ψ_2, but the principal stresses in the sub-region Ψ_1 have the highest value in the whole matrix (see Fig.3c). There are six sub-regions of low stress like Ψ_2 around each inclusion in the composite. Hence, the elements in Ψ_1 have higher probability of failure than those in Ψ_2. Similar stress states in Ψ_1 and Ψ_2 are observed in Specimen no.2 with larger multi inclusions of 20mm diameter (see Fig.3a', 3b'). The calculated results have a good agreement with those reported in the literature (Hsueh et al., 2001; Hsu, 1963). The results from Specimen no.2 further prove that the stress induced by the cross-effect of the inclusions is one of the reasons to cause the stress concentration. From Fig.3c and Fig.3c', it is found that the principal stresses between the inclusions ***A*** and ***B*** are increased by 20%. Such also occurs between the inclusions ***A*** and ***C***, or ***C*** and ***B***, or ***B*** and ***D***, or ***D*** and ***A***.

Consequently, the stress concentration occurred in the matrix due to the cross-effect of multi inclusions makes the elements in the matrix more prone to fail.

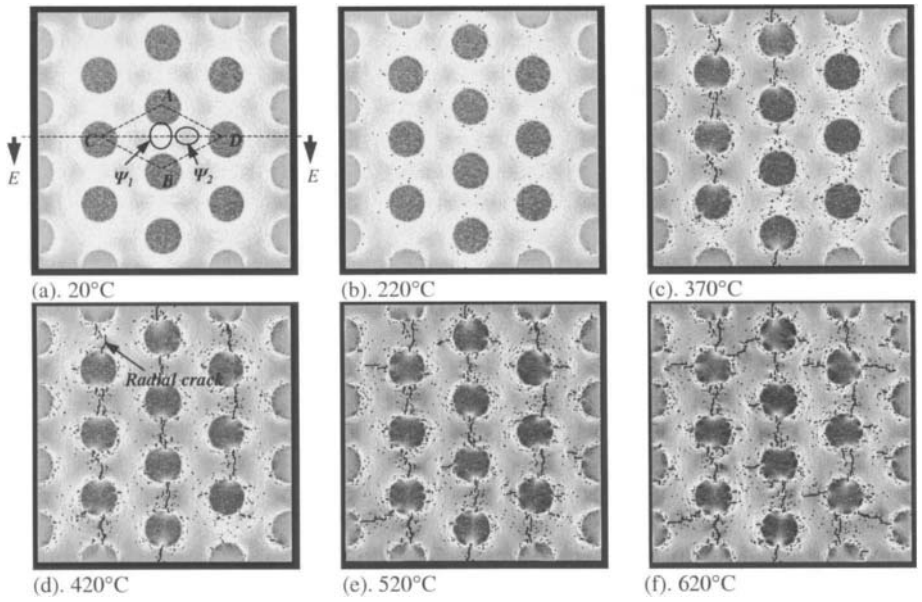

Fig.4 Thermal cracking process of Specimen no.3

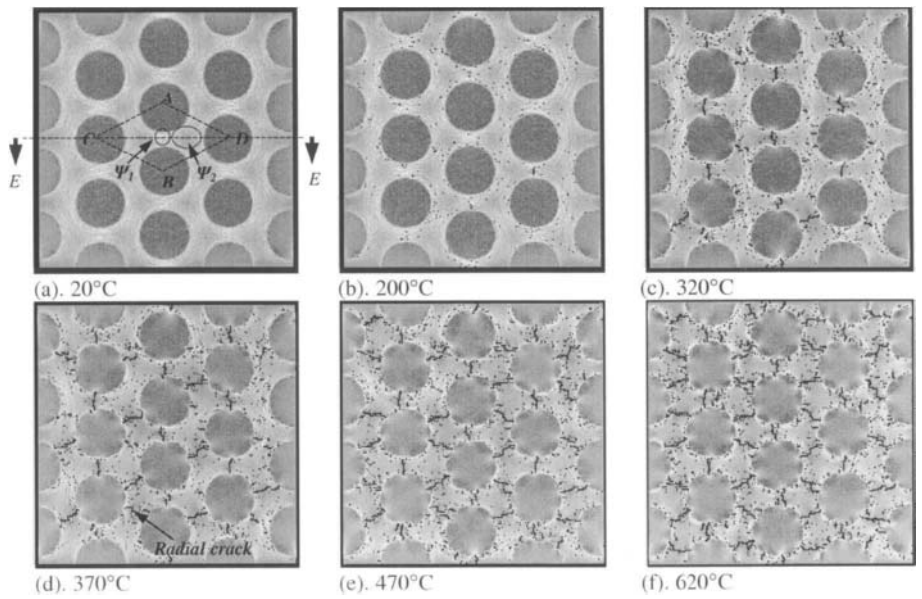

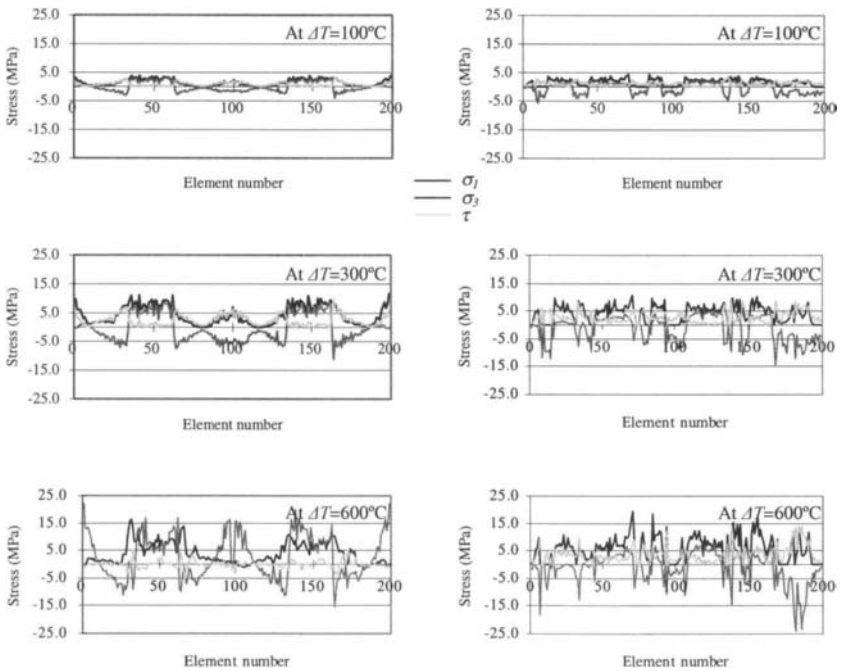

Fig.5 Thermal cracking process of Specimen no.4

Effects of heterogeneity

Fig.4a shows the thermal stress field of Specimen no.3 that has heterogeneous matrix and inclusions. Gray scale indicates minimum principal stress values. Comparing the stress distribution along the mid-section *E-E* of Specimen no.3 (Fig.6a) with that of Specimen no.1 with homogeneous phase materials (Fig.3c), it is very clear that heterogeneity causes local fluctuation of stresses in matrix and inclusion even before crack initiates (see Fig.6a), even though their macroscopic thermal stress fields are same from the view point of statistics. With increasing the temperatures, the number of the broken elements is also increased. Due to this reason, the degree of the stress fluctuation becomes severe (see Fig.6a). With the increase of number of the damaged elements, the original stress distribution is changed. For example, at temperature increment of 620°C (see Fig.4f), the high stresses have been transferred to the tips of the irregular cracks, whose distributions are closely associated with the change in the heterogeneous mesostructure. This transfer of thermal stress field with the variation of mesostructure cannot be easily observed in experiments.

(a) Specimen no.3 (b) Specimen no.4

Fig.6 Thermal stress distribution along mid-section *E-E* of Specimens no.3 and 4

Thermal Fracture

Effects of interaction of multi inclusions

The cross-effect on stresses between the two neighborhood inclusions makes the elements in sub-region Ψ_1 more prone to fail. The commence of crack development is largely dependent on the distance between any given two inclusions. For example, for Specimen no.3, when the elements around the inclusions firstly reach their strength, cracks begin to develop at the interface of the matrix and the inclusion, and then propagate towards to the middle of the two neighborhood

inclusions (see Fig.4). For Specimen no.4 with larger inclusions, cracks are firstly formed in the middle of the two neighborhood inclusions which have the shortest distance apart, rather than at the interface of the matrix and the inclusion, and then propagate towards the two neighborhood inclusions (see Fig.5b). As the diameter of inclusions increases, the distance between ***A*** and ***C***, or ***C*** and ***B***, or ***B*** and ***D***, or ***D*** and ***A*** in Specimen no.4 reduces (see Fig.5). As a result, inclined cracks making an angle of about 30° to the horizontal line are developed (see Fig.5e-f) instead of the horizontal cracks occurred in Specimen no.3 with smaller circular inclusions (as shown in Fig.4e-f).

Effects of heterogeneity

In case of Specimen no.3, a diffused damage initially appears randomly in the whole region of the matrix at temperature of 220°C (see Fig.4b). It means that the failure of an element is dependent both on the thermal induced local stress and on the strength of the element. The strength distribution of the elements is mainly dependent on the heterogeneity at meso-scale. Under the same stress field, the elements with a higher ratio of the stress to the strength have higher probability to fail than those with a lower ratio. Consequently, the shape of the crack path is irregular, rough and bifurcate.

Another interesting phenomenon can be observed from Fig.4 and Fig.5. The crack development is resisted by an inclusion with high elastic modulus and strength. When the tip of a radial crack touches an inclusion with higher elastic modulus and strength, the inclusion obstructs the radial crack propagation. For example, in case of Specimen no.3, after the radial cracks coalesce between two-neighborhood inclusions linking up in the *Y*-direction, they do not propagate when the tips of the cracks approach such an inclusion (see Fig.4c-f). Instead, the radial cracks in the *X*-direction begin to initiate and propagate, since the stresses have been redistributed and transferred into the tips of these horizontal cracks. Thus the inclusion can play an important role to (i) resist further propagation of crack, (ii) consume more energy required by failure, and (iii) dictate the redistribution of the stresses. These results are consistent with the viewpoints in the literature (Kristensen et al., 1994) that thermal cracking probably travel in all directions in mortar due to the presence of aggregate in concrete.

The numerical results also reveal that discontinuous cracks grow simultaneously at the poles of the different inclusions. Increasing number of such cracks eventually result in the irregular radial cracks, length of which is greater than the direct distance between the two corresponding inclusions because of the irregular path of crack. It lastly impairs the cohesive properties of the bond phase material (matrix). From the observation of the thermal fracture processes, it appears that heterogeneity can be used to interpret the randomization of crack origin and crack shape. It can also be used to explain the reason of local thermal fracture.

CONCLUSIONS

In this paper, a newly developed mesoscopic thermoelastic damage model (MTED) has been implemented to numerically simulate the thermal stress field and the crack formation, extension and coalescence in a cement-based multi-inclusions composite at elevated temperatures. From the results presented in this study, some main conclusions are summarized as follows.

1. The thermal stress field being studied is focused on the effects of thermal mismatch and the arrangement of inclusions. When the CTE of inclusion is larger than that of the matrix, the inclusion and the matrix are subjected to statistically hydrostatic compression and a combination of compression and tension, respectively. A high stress region is induced at the interface between the matrix and the inclusion by the thermal mismatch, and in the area between any two-neighborhood inclusions with the shortest distance apart.

2. The initiation and path of cracks depend on the heterogeneity at meso-scale. When the CTE of inclusion is larger than that of matrix, the interaction of inclusions is another factor affecting the thermal cracking. The cracks form, propagate and coalesce firstly along direction between the two inclusions which have the shortest distance apart. When the inclusion diameter increases, the cross-effect of stress concentration around the two neighborhood inclusions increases the probability of failure of the elements locating between these two inclusions. However, when the strength of the inclusion is higher than that of matrix, the inclusion can prevent the further propagation of the cracks to a certain extent.

In this paper the temperature-dependent properties (strength, elastic modulus and CTE) of each component material of the composite at high temperatures, which can substantially affect the thermal cracking, have not been quantified. Further work on this direction will be conducted. Nevertheless, the numerical study by using the proposed MTED model offers an understanding of the thermal stress redistribution and cracking process of a cement-based composite, from which various mechanisms of thermal induced stresses and associated cracking have been identified.

APPLICATIONS OF COPPER GANGUE WITH HIGH CONTENT OF Fe_2SiO_4 AS CEMENT ADMIXTURE AND FOR CEMENT PRODUCTION

Lin Zongshou Wan Huiwen Zhao Qian Huang Yun

School of Materials and Engineering, Wuhan University of Technology , Wuhan,Hubei,P.R.China,430070

Abstract:

Copper gangue (CG) is an inactive industrial waste generated from a copper refinery. Making good use of this waste will be beneficial to the sustainable development of society. In this study, the copper gangue was firstly used as a cement admixture. The results showed that with the replacement of 5~25% CG, 3-day and 28-day strengths decreased by 5~32%. However the long-term strength of the specimens with 10% CG, especially after the samples cured for 3 months, approached that of plain mortar. Its mechanism was studied by electron probe microanalyzer (EPM), and the results indicated that a small quantity of $Fe(OH)_3 \cdot nH_2O$ slowly formed from Fe_2O_3 in the presence of $Ca(OH)_2$, and accordingly the hardened cement paste became more dense. Secondly, the CG as iron material for cement production was also researched. Optical microscope analyses showed that CG containing Cu, Zn, Ti, Mn, Ag etc microelements, can decrease clinker burning temperature and liquid viscosity, and enhance migration of the CaO and SiO_2. A blended admixture with low content of CaF_2-$CaSO_4 \cdot 2H_2O$ could take a partial mineralization effect and further benefits the clinker burning.

Key words:

Industrial waste, Copper gangue, Cement admixture, Microelement

1. Introdution

Copper residue is an industrial waste that is discharged by a copper refinery. In order to extract some useful metals, a cooling technology for removing residue is introduced by slowly cooling (48h) rather than quickly cooling so that some metals ions grow. Such copper residue contains 4~5% copper, 1.01g/t gold, 24g/t silver and 42% magnetite. After one more flotation for copper and magnetic by extraction of iron, the discharged residue is called copper gangue (CG). But CG grains mostly are in the range 0.037~0.10mm and contain a large amount of water. CG still contains approximately 48% fayalite (mostly Fe_2SiO_4) and 28% fine crystal magnetite (mostly Fe_2O_3 and less FeO), while copper content is only 0.3~0.4%.

It is well known that raw material containing high iron oxide can be used as an alterative material for cement production. Because iron oxide can form liquid phase in clinker burning, the addition of

CG can enhance migration of the CaO and SiO_2, and benefit the clinker sintering forming calcium aluminoferrite [1]. J.O.Odigure's researches [2-5] showed that abrasive slurry containing high metallic particles (Fe^{3+}, Fe^{2+}, Fe) content, could significantly improve the clinker mineral chemical composition, morphology and phase ratio. The kinetics of chemical reactions in hardening cement mortar produced from the raw mix containing metallic particles, differ from those of ordinary Portland cement using raw materials of natural origin.

This research is aimed at investigating the influence of CG used as a cement admixture on cement mortar strength and the influence of CG used as a raw material on cement clinker mineral morphology. It will be helpful to the recycling and reuse of this industrial waste.

2. Experiment

2.1 Chemical composition and microanalysis of CG

The chemical composition and mineral analysis of CG are presented respectively in Tables 1 and 2. The X-ray diffraction pattern of is shown in Fig.1, which indicates that the mineral components of CG are mainly composed of Fe_2SiO_4, Fe_2O_3, FeO and a small quantity of amorphous SiO_2.

2.2 CG used as cement admixture

The CG was dried and manually dispersed. Portland cement (surface area 300m^2/kg) was provided by Jinyue cement plant, the chemical composition of the clinker is shown in Table 3. CG substitution percentages by weight relative to cement were 0%, 5%, 10%, 15%, 20% and 25%, respectively. All samples were mixed for 6h in an automatic blender and then normal consistency and setting time were measured according to GB 1346-92 (Chinese standard). Specimens for testing mechanical strength, after demoulding, were cured in water 28 days at 20±2℃and then cured to prescribed ages in the ambient conditions. Compressive strengths were measured according to GB 175-92. CG substitution ratios and physical properties of cement are presented in Table 4.

Table 4 CG substitution ratios (mass %) and physical properties of cement

In order to study the influence of the Fe_2SiO_4 and Fe_2O_3 into CG on mechanical strength of cement and avoiding interfere with the iron phase contained in Portland cement, the following experiments were carried out. (1) Incorporating 25% CG in white Portland cement to make paste sample A. (2) At the same condition, 25% CG in Portland cement to make paste sample B (curing 3 months, curing system as before). (3) Their microstructure and composition were studied using EPM (Figs. 2 and 3).

2.3 CG used as raw material for cement production

The raw materials used for the experiments were limestone, clay, coal, gypsum, fluorite and CG. For the making of coal ash, coal was put in an earthen box and burnt in an electric furnace using silicon-heating elements. The burning temperature was 1200℃, with a duration of 6h at the maximum temperature. Coal ash content was 25.8%. The compositions of the raw materials are presented in Table 5. The compositions of the raw mixes were determined (shown in Table 6). The dried raw materials mixed in the required proportion were ground to a fineness of 6 to 8 mass % residue on an 80-μm size mesh using a laboratory ball-mill. They were then watered and manually pressed into a Φ10×30mm column. Those columns were dried and burnt in an electric furnace using silicon-heating elements. The burning temperature was gradually raised to 1450℃, the rate of rise of temperature was controlled to 200~250℃/h, with a duration of 45 min at the maximum temperature. The clinkers were cooled in the air. The clinker samples were analyzed with an optical microscope and the microstructural images are shown in Figs. 4 and 5. The result determined of the free CaO is shown in Table 6. The produced clinker and 4% gypsum were ground approaching a surface area of $310m^2/kg$. The mechanical strengths of the clinkers, determined by the above method, are presented in Table 6.

Table 5 Chemical composition of raw materials

Material	Oxides contents, mass %							
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	CaF_2	LOI*
Limestone	5.64	1.65	0.76	48.50	1.77			40.38
Clay	63.48	13.76	5.93	2.25	1.62			9.60

3. Results and discussion

3.1 Petrographic features of the CG

The mineral analyses of Table 2 show that CG comprises mainly fayalite, magnetite and amorphous silicate minerals. From Fig. 1, it is clear that the diffraction peaks of Fe_2SiO_4, Fe_2O_3, FeO and SiO_2. EPM (Fig. 2) show that Fe_2O_3 particle is partially wrapped in Fe_2SiO_4. The grains of CG are distributed mostly in the range 0.037~0.10mm with tough surface and dense structure. Its density is 5.20g/cm^3.

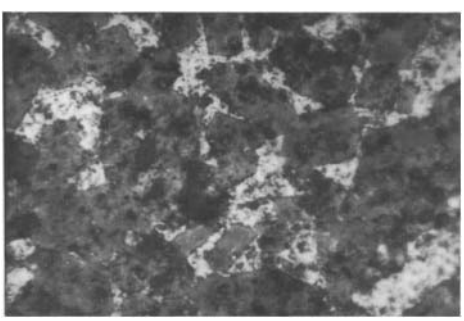

Fig. 4 Optical photograph of sample 7

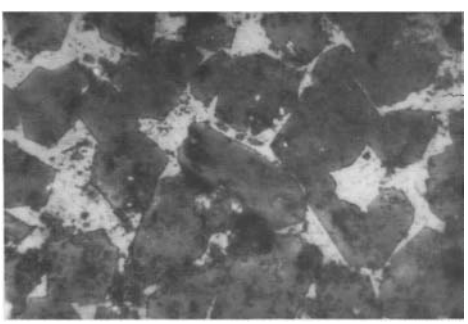

Fig. 5 Optical photograph of sample 8

3.2 The influence of CG used as admixture on strength of the cement

Table 4 shows that if the setting time of the cement is prolonged normal consistency of the cement decreased gradually with the increase of CG substitution. The effect of CG on the mechanical

properties was remarkable. An investigation was made over a period of one year. It is found that the CG substitution led to a decrease of strength, and the higher the replacement, the lower the compressive strength. To increase understanding of the influence of the CG substitution on strength, the strengths at various ages are expressed in term of the strength ratio, which is presented in bracket of Table 4. It can be seen that the strength ratios of 3-day and 28-day were approximately equal at the same substitution ratio, and both reduce from 0.95(or 0.96) with 5% CG to 0.68 with 25% CG. However the strength ratios at 3 months and 1 year increased, even exceeding the control group and reached 1.02 within the substitution ratio was 10% CG. This implies that the CG has a positive effect on the long-term strength.

It is easy to understand that cement strength decreased with the increase of CG due to its inactivity. The long-term strength increase was related probably to Fe_2O_3 and FeO, which is contained in CG. The interactions between the oxides and the cement matrix could be that $Fe(OH)_3 \cdot nH_2O$ gradually form through the reaction of Fe_2O_3 in the presence of $Ca(OH)_2$. Even in the atmosphere, FeO can also slowly form $Fe(OH)_3 \cdot nH_2O$ in a solution of $Ca(OH)_2$ [6]. The volume of $Fe(OH)_3 \cdot nH_2O$ is much bigger than that of Fe_2O_3 and FeO, and thereby hardened cement paste becomes more compact. Fig. 3 shows that there is still a small quantity of unhydrated C_2S after curing for 3 months and the strength hence further increased after 3 months. Fig. 2 shows that a part of Fe_2O_3 was wrapped in Fe_2SiO_4. By composition analyses of bare Fe_2O_3 particles using EPM, the results showed that the chemical composition around the Fe_2O_3 particles differed obviously from those of Fe_2O_3 particles in the centre. This implies that a small quantity of $Fe(OH)_3 \cdot nH_2O$ probably formed on the surface of the Fe_2O_3 particles. When the samples were kept in the atmosphere for 1 year, a little $Fe(OH)_3 \cdot nH_2O$ was continuously formed increasing local stress and $Fe(OH)_3 \cdot nH_2O$ lost nH_2O increasing pore ratio. These factors resulted in only a slight decrease of the one-year compressive strengths with high content of Fe_2SiO_4 and Fe_2O_3. This phenomenon will be continuously observed.

3.3 The influence of CG on mineral composition and microstructure of clinker

Table 6 shows that 2.52% free CaO existing in sample 7 was higher than in samples 8 and 9. It indicated that CG helped clinker burning, because CG contains Cu, Zn, Ti, Mn, Ag etc microelements, which can decrease burning temperature of clinker and liquid viscosity [7]. In sample 9, free CaO was of its lowest content, indicating that CaF_2-$CaSO_4 \cdot 2H_2O$ partially shared mineralization effect, greatly accelerating sintering reaction [8]. The results showed that CG used as raw material for cement production is not disadvantageous to cement strengths. An Optical photograph of sample 7 (Fig.4) shows the predominance of hexagonal alite crystals 30~40 μ m in length, and minerals partially eroded and containing about 50% alite. Sample 8 (Fig.5), which was burnt in the same condition, has larger uniform size alite crystals predominantly 50~60 μ m in length, profile of alite clarity and containing over 55% alite. This could be attributed to early formation of a large quantity of liquid phase and consequently enhanced migration of the CaO and SiO_2.

4. Conclusion

When the CG was used as a cement admixture, the early strengths of the cement decreased with the increase of CG, however the long-term strengths of the cement, especially after 3 months, clearly increased. Analyses of EPM show that there was probably $Fe(OH)_3 \cdot nH_2O$ slowly forming through the reaction between Fe_2O_3 and water in the hardened cement paste.

CG substitution percentage by weight of cement should be controlled below 20%, as the compressive strengths at 1 year incorporating more than 20% CG decreased lightly.

CG used as a raw material, due to the Cu, Zn, Ti, Mn, Ag etc microelements contained can decrease clinker burning temperature and liquid viscosity, with advantage to clinker burning. A little CaF_2-$CaSO_4 \cdot 2H_2O$ added to raw meal, is of further benefit to clinker burning.

PROPERTIES OF LIGHTWEIGHT AGGREGATE FOR LIGHTWEIGHT CONCRETE PRODUCTION

Tommy Y. Lo, H.Z. Cui

Department of Building & Construction
City University of Hong Kong

ABSTRACT

The increasing demands for the speed of construction and the greater use of prefabrication units in the building industry have urged the need for exploring new innovative construction materials. The adoption of lightweight aggregate concrete in prefabrication of structural panels for building works can minimize the foundation load, reducing the size of structural members, speeds up the construction program and has better control on material quality. All lightweight aggregates are porous in nature that water absorption is much greater than normal weight aggregate. The great absorption rate of aggregate will lowers the water content at the aggregate/cement paste interface and affects critically the mix design, workability of fresh lightweight concrete. Since characteristic of lightweight aggregate varies with the production plants, operation and the raw material used in the production process, the surface characteristic, size and pore structure of the lightweight aggregate differs from one type to the others. Surface topography and pore distribution of the aggregate surface dominate the water absorption characteristic of the aggregate, affect critically the properties of the resulting lightweight aggregate concrete and the bonding with the cement matrix. This paper presented a detail study on the physical properties of a locally available lightweight aggregate made from expanded clay. Density and strength of the lightweight aggregate of different density ranges and their relationship with water absorption characteristic and internal microscopic were examined.

KEYWORDS

Lightweight aggregate, porosity; strength, water absorption, microstructure

1. INTRODRUCTION

The adoption of lightweight aggregate concrete in prefabrication of structural panels for building works can minimize the foundation load, reducing the size of structural members, speeds up the construction program, achieving better quality control and provides a green building construction environment. In other part of the world, high-rise buildings have been built with structural lightweight aggregate concrete [LWAC]. The 42 storeys Prudential Life Building in Chicago and the famous "Nordhordland" bridge are good examples of the applications of structural LWAC (1). A cost model of an eight-storey height office building compared the construction cost of using LWC and NWC reinforced concrete finding that a LWC building could save 1½ week in the construction period. Although the cost of LWAC is 5% higher than traditional normal weight concrete, the overall cost saved 4% (2).

However, the lightweight concrete currently adopted in Hong Kong is limited to non-structural applications (3,4). The available type of ready mixed lightweight concrete is limited to foam concrete or polystyrene bean concrete. Although research finding indicated that structural lightweight concrete with density below 1600kg/m^3 can be made with a locally available expanded clay lightweight aggregate (5), the development on the use of structural LWAC is hindered by the lack of research data on concrete properties, in particular the long-term durability characteristics. Moreover, overseas experience may not apply to Hong Kong because properties of the LWAC vary with the type and characteristic of the lightweight aggregate use.

2. MATERICALS

The LWA used in this experimental work is a lightweight expanded clay aggregate [LECA] produced by bloating clay under high temperature firing of over 1200°C in the rotary kiln [Figure 1 & 2]. Because of the porous nature of the aggregate core, it is extremely light in weight and the insulation property is good. The aggregate is stable, inert to acid corrosion, not attacked by fungi, non-absorbent and frost resistant.

Figure 1: General view of coarse LECA (10mm size)

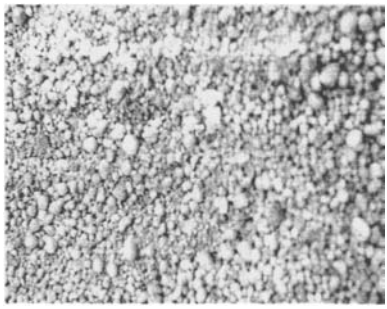

Figure 2: General view of fine LECA

3. RESEARCH SIGNIFICANCE

This paper presented the results on the physical properties, internal microstructure and water absorption of a locally available LECA aggregate. The finding is crucial in understanding the characteristic of LECA aggregate for the development of prefabricating structural lightweight members.

4. RESULTS AND DISCUSSIONS

Bulk density and strength

Most of the lightweight aggregates [LWA] are cellular in structure; the bulk densities are considerably less than those of normal weight aggregate [NWA]. As seen in table 1, 5mm, 14mm and 25mm sizes LECA aggregate were compared. The measured bulk density ranging between 450-850kg/m^3 was only ¼ to ½ the density of NWA. The oven-dry density also fall within the standard ranges of 400~1200kg/m^3 for fine lightweight aggregates and 250~1000kg/m^3 for coarse aggregate (6).

Strength and density of lightweight aggregate varies with the type of aggregate, source of raw materials and production method. Aggregates can be strong and hard or weak and fragile depending on the shape and size of aggregate. Microscopically speaking, it is related to the volume and distribution of the micro pores and whether the pores are inter-connected within the aggregate. Shell thickness is also one of the controlling factors. Simple tube compressive strength was used to examine the average strength of lightweight aggregate. Detail of the tube strength equipment was given in figure 3 (7). Results of the tube strengths of the LECA aggregate are presented in figure 4 and co-related with the bulk densities. Aggregate with a density of 450kg/m^3, 650kg/m^3 and 850kg/m^3 achieved tube strength of 35kN, 50kN and 65kN respectively. In general, aggregate with low bulk densities achieves low tube strengths.

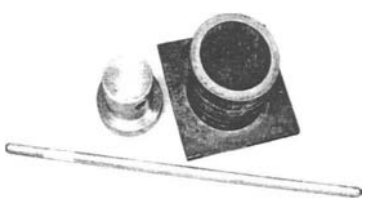

Figure 3 : Equipment for Tube strength determination

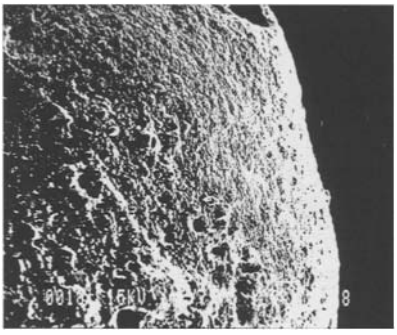

Figure 4 : Surface topography of a typical lightweight aggregate

Microstructure and water absorption of aggregate

Figure 4 shows the surface topography of a typical LECA aggregate. It is seen the aggregate is round with a rough surface texture. The porous surface of the aggregate is good in forming a mechanical bond with the surrounding mortar enhancing the aggregate/cement pastes interface, and reduces the formation of micro-cracks inside the concrete matrix (8).

Water absorption of the porous lightweight aggregates is generally higher than the normal weight aggregate. Finding from past research (9) suggested that seventy percent of the 23-h water absorption took place within the first 30s of absorption. Water absorption rate also differ significantly between cut and whole aggregates. The 1-h water absorption rate of the cut sample was 58% higher than that of whole aggregate. The great variation in water absorption rate was attributed to the presence of an outer shell that controls the ingress of water and the number of voids and fissures that appeared in the

aggregate core, pore size and its distribution within the aggregate core affects critically the density, water absorption and strength of the resulting concrete (7).

The cross-sections of the aggregate microstructure were shown in Figs 5,6 and 7. The microstructure of the 3 grades of aggregate with densities 450kg/m^3, 600kg/m^3 and 850kg/m^3 were compared. For aggregate with density 850kg/m^3, it is seen that micro pores were evenly distributed throughout the aggregate particles and were not inter-connected with each other. Comparing to the aggregate of density 450kg/m^3, the internal microstructure composed with large inter-connected voids and fissures. In general, the number of inter-connected pores increases with the decrease in bulk density of aggregate.

Water absorptions of the 3 grades of aggregate were compared and results were shown in Figure 8. It indicated that the initial absorption of 6mm aggregate was greater than that of 25mm. The absorption rate of 14mm aggregate was the lowest. Around 50-65% of the 24 hours absorption took place at the first few minutes. The absorption increases with time but the absorption ranking was the same. The finding confirmed with past research result by Swamy (9). Moreover, the absorption rate was irrelevant to the size of aggregate.

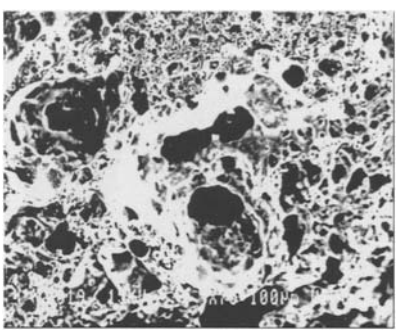

Figure 5: Lightweight Aggregate (Density 450 kg/m^3)

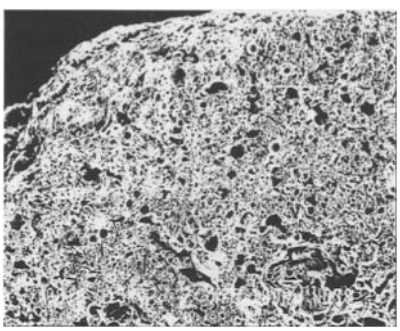

Figure 6: Lightweight Aggregate (Density 600kg/m^3)

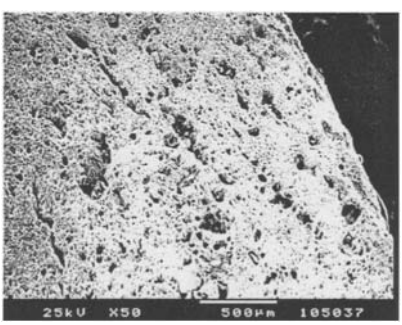

Figure 7: Lightweight Aggregate (density 850 kg/m^3)

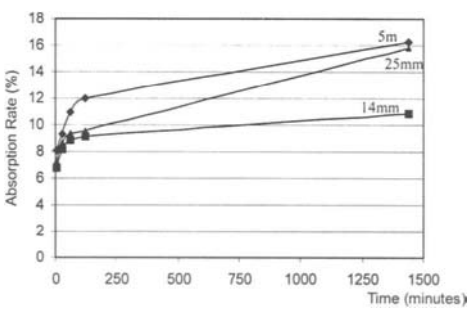

Figure 8: Water absorptions of the lightweight aggregates

Table 1 summarized the pore distribution of the 3 aggregate samples with different density. It is seen that the majority of the pore are sized between 1µm to 100µm for all three density graded aggregate. When the total volume of micro pore increases, the aggregate density decrease. This also explains why water absorption of cut (or fragmented) aggregate was greater than that of whole aggregate. When the

lightweight aggregate broken, the number of open pores increases leading to a larger water absorption rate of the absorption. Therefore, a thick and dense aggregate shell is necessary in ensuring the blockage of water path passing into the aggregate core.

TABLE 1
PORE SIZE AND THE VOLUME DISTRIBUTION WITHIN CORE OF LIGHTWEIGHT AGGREGATE

Aggregate Density (kg/m^3)	Aggregate size	Pore Distribution				
		<0.01 μm	0.01-1μm	1-10 μm	10-100 μm	>100 μm
400	25 mm	0.3	87.4	728.6	171.8	7.9
600	5 mm	0.4	36.8	652.3	156.5	3.9
800	14 mm	0.2	53.5	459.6	102.1	4.5

* Above data is the average of ten samples

It is also interesting to note that the density of aggregate does not necessarily directly related to the size. For example, the density of the 5mm aggregate was greater than that of the 25mm aggregate but was lower than the density of a 14mm aggregate. This phenomenon can be explained by the presence of substantial amount of large pore (>100μm) within the 25mm sized aggregate.

5. CONCLUSION

Based on the findings, the following conclusions can be drawn:

1) Pores size of the locally available LECA aggregates mainly ranged between 1 μm to 100 μm.
2) When the total volume of micro pore decreases, the aggregate density increase.
3) The initial water absorption is 50-65% of the 24 hours absorption
4) Tube strength of aggregates is related to the pores volume and bulk density. The aggregate strength decreases with the increase of total pore volume within the aggregate core.
5) The number of inter-connected pores increases with the decrease in bulk density of aggregate.

PRELIMINARY RESULTS ON THE USE OF GFRP AS AN EXTERNAL REINFORCEMENT FOR AUTOCLAVED AERATED CONCRETE

Ali M. Memari* and Ayca Eminaga*

*Department of Architectural Engineering, The Pennsylvania State University
104 Engineering A, University Park, Pennsylvania, USA

ABSTRACT

The bond strength between Glass Fiber Reinforced Polymer (GFRP) sheets and Autoclaved Aerated Concrete (AAC) surface is investigated. Specimens made of two small AAC blocks attached together with two strips of GFRP are pulled apart by using a hydrolic jack. Bond length is a variable in the study. The results show that the bond strength between AAC and GFRP is comparable to that between Carbon FRP and normal concrete surface.

KEYWORDS

Fiber reinforced polymer, autoclaved aerated concrete, bond strength, external reinforcement.

INTRODUCTION

Although Autoclaved Aerated Concrete (AAC) products have been used in Europe and several other countries in Asia and the Middle East for a few decades, this lightweight concrete has been introduced in the U.S. market primarily since 1995. According to Woodard *et al.* (1999), "This new building material combined the advantage of wood and cement products – it could be cut, drilled, and nailed like wood while maintaining high strength, excellent durability, thermal insulation, sound insulation, and fire resistance. Subsequently, it gained rapid acceptance in Europe and throughout the world." There is good optimism for the growth of AAC in the U.S. market. Chusid (1999) predicts that if the announced plans for a few more factories realize, "there will be three million cubic yards of annual capacity in North America within the next two to three years, equivalent to over 150 million square of wall, floor and roofs and enough for an estimated 10,000 to 15,000 buildings per year." Currently, the primary use of AAC in the U.S. is in the form of masonry blocks, wall and floor panels, and lintels. Panels and lintels are reinforced to carry superimposed loads. Three of the key references on AAC are Wittmann (1983), Wittmann (1992), and Aroni *et al.* (1993). The book by Wittmann (1983) includes a bibliography chapter on AAC that lists 492 documents on AAC. Even though many publications exist on AAC, only a fraction of the studies have addressed structural aspects.

Unlike Normal Weight Concrete (NWC), one of the deficiencies associated with the use of steel bars to reinforce AAC elements is the weakness of the bond between the steel surface and the surrounding AAC. According to Aroni *et al.* (1993), because of the low alkali reserve and high porosity of AAC, reinforcement should be covered with anti-corrosion material (such as protective bituminous coating). According to Hanecka (1992), because of corrosion protection coating, the bond properties and their effects on the response of AAC members under load are not sufficiently understood. Aroni *et al.* (1993) clearly mentions the deficiency: "The bond strength between the reinforcement and AAC is much lower than that in normal concrete." Because of such a problem, the anchorage of reinforcement cannot be provided by bond, and therefore, cross bars welded to longitudinal reinforcement must be used. In such cases, the anchorage is provided by the bearing of the cross bars against the AAC. The pullout strength of longitudinal bars is limited by the smaller of the spot weld capacity of cross bar-longitudinal reinforcement connections and bearing capacity of the cross bar-AAC interface (Boutros and Saverimutto 1997). Therefore, practically the bond strength between steel and AAC is ignored. However, according to Aroni *et al.* (1993), if any bond strength is to be allowed in design, the capacity has to be verified by a pullout test based on RILEM Recommendation AAC 8.1.

In an effort to find an alternative reinforcement system or an approach for supplemental reinforcement (in addition to what is usually provided in precast AAC members), this paper explores the possibility of using Fiber Reinforced Polymers (FRP) as an externally applied reinforcement. Before the experimental program is described, a brief background on the use of FRP on NWC and the basis for the experimental study reported here is mentioned.

BACKGROUND ON THE USE OF FRP ON NWC AND THE BASIS FOR THE EXPERIMENTAL STUDY

Over the past decade, FRP composites have evolved as reliable alternative reinforcing products for repair and rehabilitation of aging concrete and masonry structures. Currently, three types of fibers, namely, carbon, aramid, and glass are widely manufactured, which when the fibers are embedded in a polymeric resin (matrix), the composites are referred to, respectively, as CFRP, AFRP, and GFRP. From the three types of composites, CFRP provides the largest strength and is commonly used to strengthen existing reinforced concrete members. Given that AAC is a weaker material then NWC, the use of high strength CFRP is not justified (Vadovic 2000) and therefore, GFRP was determined to be suitable for use with AAC in this study.

The effectiveness of using externally bonded FRP composites to strengthen concrete beams has been well established. The primary objective of this study is to investigate the suitability of externally bonded GFRP composites to be used for AAC lintels and floor and wall panels. However, before experiments on beams and wall panels are carried out, the characteristics of the bond between the externally applied GFRP sheets and AAC surface should be determined. Several investigators have performed such studies for bond characteristics between CFRP and NWC. Maeda *et al.* (1997) used two small concrete blocks (100 mm x 100 mm in cross section) that were attached together with 50 mm wide strips of CFRP on two sides of the blocks, but with a gap between the blocks. The tension force to the CFRP was applied by pulling two steel rebars that were inside the concrete prisms. In that study, bond length and concrete strength was varied and the resulting data provided information on the variation of bond strength with bond length and concrete strength in addition to strain distribution. Brosens and Van Gemert (1997) have also performed tension tests on two concrete prisms (150 mm x 150 mm x 300 mm) attached with CFRP laminates on two opposite sides. Tensile force is applied on steel plates glued on the other sides (opposite to CFRP sheets) of the prisms. During the displacement controlled tests, information on the applied load, relative movement of the prisms and the strains of the

CFRP were taken. In that study, too, the bond length and concrete strength were varied. Representative results from these studies will be compared with the results of AAC tests reported in this paper.

EXPERIMENTAL PROGRAM

The diagram of the test setup for this study is shown in Figure 1. The test specimen consists of two AAC prisms (100 mm x 100 mm x 275 mm) connected together by two GFRP strips, which are attached to two opposite faces of the AAC prisms. In order to apply tension to the GFRP strips, a loading jack is placed between the two AAC blocks such that it can push them apart. The loading jack, which is operated by a hydraulic pump, has a 88 kN capacity.The test specimen is loaded in a load controlled manner. The load on the specimen is obtained from reading the pressure recorded. Displacements of the prisms are recorded using potentiometer and also an oscilloscope connected to the potentiometer. Figure 2 shows a photograph of the test setup. In the first part of the study reported here, only bond length was varied. The GFRP strips used had a width of 50 mm, but the bond length was varied from 50 mm to 200 mm at 50 mm increments.

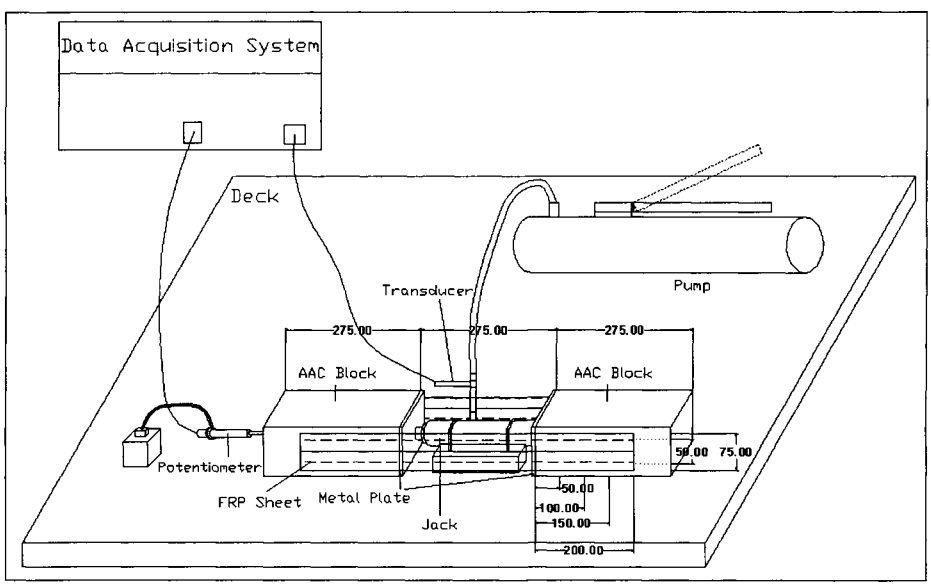

Figure 1: Illustration of test set up (dimensions are in mm).

The AAC used, which was produced by a HEBEL plant in the state of Georgia in US and now owned by Babb International, Inc., Matrix PAAC Division, had a nominal compressive strength of 5 MPa and a unit weight of 720 kg/m^3. The GFRP used is manufactured by Master Builders, inc. and is designated MBrace EG 900 E-glass fibers, which according to Tysl (2000), is more economical compared to carbon or aramid FRP for use with AAC. The matrix (resin) used consists of MBrace Primer, MBrace Putty, and MBrace Saturant.The EG 900 material used is unidirectional, weighs 900 grams/m^2, and has a strength of 525 N/mm of width. Table 1 shows the matrix of specimen configurations used in this

part of the study. For each bond length, three tests were performed. Further tests are ongoing (but not reported here) to investigate the effects of GFRP width and the AAC compression strength.

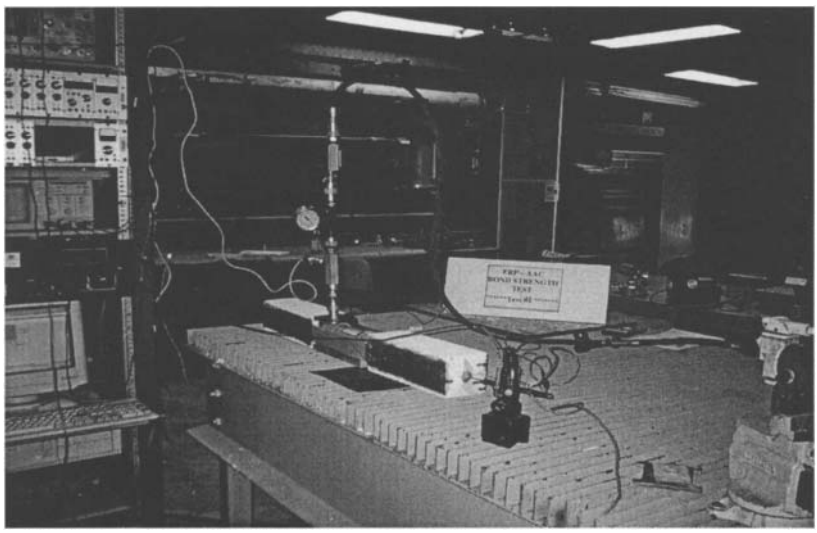

Figure 2: A photograph of the test set up of specimen d1.

*; Data could not be received. So assumptions are made regarding to other similar specimens to plot result graphs.

TEST RESULTS AND DISCUSSION

The results of the tests are listed in Table 1 and also plotted in Figures 3 to 5. Moreover, photographs of typical failure modes are shown in Figures 6 to 9 (one for each bond length). As can be seen in Figure 3, an increase in bond length does not necessarily lead to an increase in bond strength. This result has also been reached in the Maeda *et al.* (1997) study. Looking at the photographs of failed specimens helps the understanding of the behavior. Figure 6 shows the mode of failure of specimen a3 with a bond length of 50 mm. As can be seen, the failure is not a bond failure; rather, it is a shear failure in the AAC prism. Figure 7 shows the typical failure mode for specimens b1 to b3 with a bond length of 100 mm. The failure mode here seems to be a combination of bond failure and shear failure. The same type of failure can be seen in Figure 8 for specimens c1 to c3. However, Figure 9 shows a pure bond failure for the longest (200 mm) bond length used.

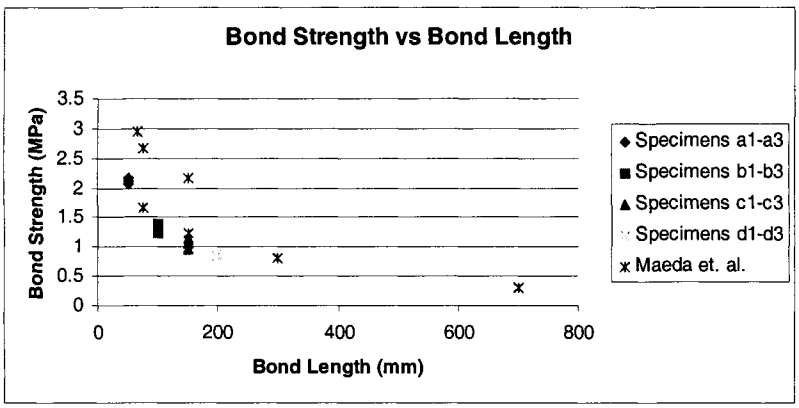

Figure 3: Graph of bond strength versus bond length.

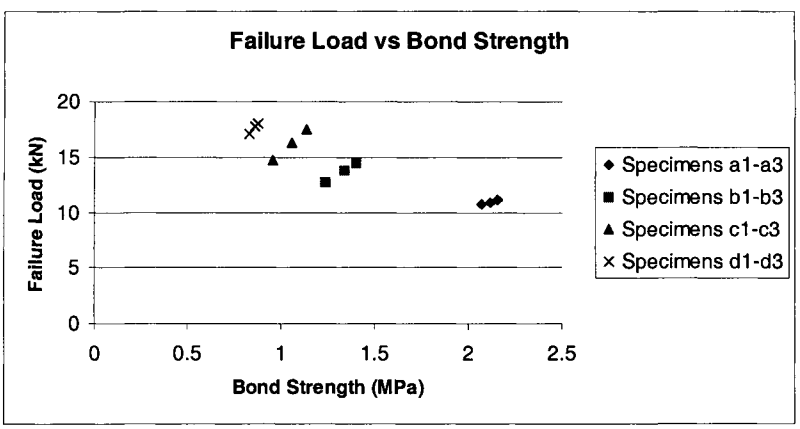

Figure 4: Graph of failure load versus bond strength.

The plotted results in Figure 3 show that bond strength between GFRP and AAC surface for longer contact surface approaches 0.83 MPa (for bond length of 200 mm) from a high value of 2.16 MPa for the short bond length of 50 mm. It should be noted that the bond strength values are only nominal values obtained by diving the failure load by the bond area (on two faces) regardless of the mode of failure. For practical situations, where the FRP sheet is applied rather continuously at the bottom of a beam, the bond strength to be expected is then the value close to that for the longest bond length, i.e., approximately 0.83 MPa. According to the study by Maeda *et al.* (1997) as shown in Table 2, bond strength between CFRP and NWC varies from 0.31 to 2.94 MPa with bond strength decreasing with increasing bond length. A significant observation here is that this range of bond strength is very close to that obtained in this study. Of course, tests on the use of GFRP on NWC will be conducted as a follow-up in this study to confirm this conclusion. Yet another observation is that while the ratio of an average bond strength for long bond lengths (0.75 MPa) from Maeda *et al.* (1997) study to the NWC compressive strength (say 43.3 MPa) is 0.017, the ratio from this study is 0.83/5.0 or 0.166, or 10 times larger. This is another reason for the suitability of the use of GFRP as an external reinforcement of AAC flexural members.

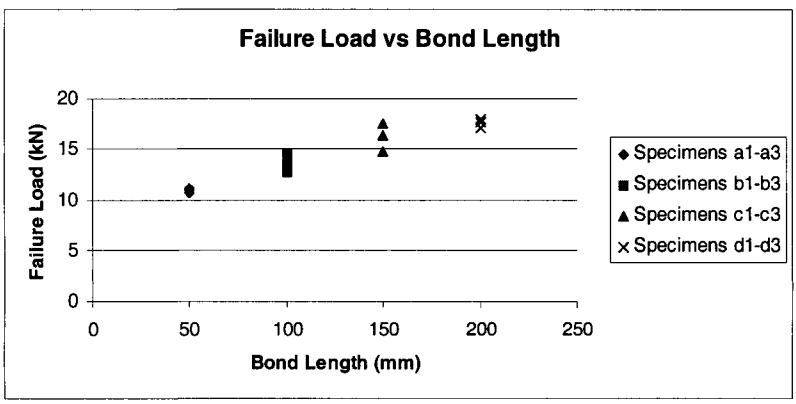

Figure 5: Graph of failure load versus bond length.

TABLE 2.
Experimental Results of *Maeda et. al. (1997)*

Bond Length(mm)	Ultimate Load (kN)	Average Bond Strength (MPa)
75	11.6	1.67
150	18.4	1.23
300	23.9	0.8
75	20	2.67
150	14.6	0.97
65	19.1	2.94
150	32.5	2.17
700	20	0.31

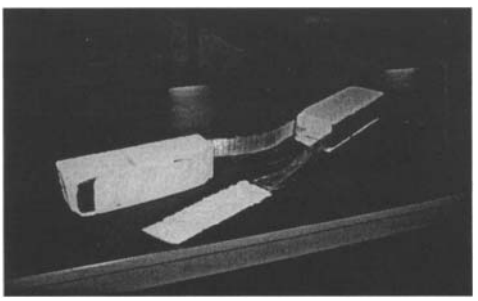

Figure 9: Failure of specimen d2.

CONCLUSION

The study has shown that the bond strength between AAC and GFRP is comparable to that between NWC and CFRP. This shows the stability of GFRP sheet to be used as an external reinforcement on NWC. Further tests are needed, however to establish the characteristics of bond and strength enhancement when GFRP sheets are applied to beams and panels for use under flexural conditions.

ACKNOWLEDGEMENT

The materials for this study were donated by Babb International, Inc. and Master Builders, Inc. and Cyprus Fulbright Commision has provided a fellowship for the second author for an M.S. Degree in Architectural Engineering at Penn State University. All contributions are gratefully acknowledged.

HIGH PERFORMANCE FIBRE REINFORCED CONCRETE

S. Mindess[1] and A.J. Boyd[2]

ABSTRACT

Since its introduction in the late 1960s, fibre reinforced concrete (FRC) has become an increasingly common building material. It is estimated that, in North America, over 15% of the concrete produced now contains fibres of some kind. At present, almost all of the FRC is used in relatively "low level" applications: slabs-on-grade, control of plastic shrinkage, fibre shotcrete for repairs and tunnel linings, and so on. However, there are still very few truly *structural* applications of FRC; it is rarely used in conjunction with conventional steel reinforcement to improve the mechanical behaviour of concrete in civil engineering structures. As well, fibres are still most commonly used with relatively low strength concretes. In the present work, the use of fibres with both high strength concrete (HSC) and steel reinforcement is described. It is shown that with conventionally reinforced HSC, the fibres improve the post-peak behaviour of the system. Under impact loading, fibres greatly improve the toughness of the composite, particularly when the concrete is subjected to uniaxial or biaxial confinement; fibres may also change the mode of failure, from brittle shear fracture to more ductile flexural failure in both beams and plates.

KEYWORDS

Fibre reinforced concrete, plates, beams, impact loading, uniaxial confinement, biaxial confinement, steel reinforcement.

INTRODUCTION

Plain concrete is a brittle material, strong in compression, but with very low tensile stress and strain capacities. In traditional concrete construction, continuous steel reinforcing bars are used to carry the tensile and shear forces in concrete structures, and to provide some degree of ductility (or energy absorption capacity). However, since about 1970, *fibre reinforced concrete* (FRC) has become an increasingly common building material. The short, discrete, randomly distributed fibres bridge across the microcracks that develop as the concrete is subjected to stress (due to loading, drying shrinkage, thermal changes, and so on), and may impart considerable *"pseudo-ductility"* to the concrete. Thus, the FRC may continue to carry significant stresses at deflections far beyond those required to crack the plain matrix; that is, it acquires *post-peak load carrying capacity.*

Currently in North America, it is estimated that about 15% of the concrete that is placed contains fibres of some type. The majority of the FRC is used in what might be termed "low-level" (i.e., non-structural) applications: for control of plastic shrinkage cracking, in slabs-on-grade, for fibre shotcrete tunnel linings, and for repair of damaged concrete. There are still very few truly structural applications of FRC, in which it is used in conjunction with conventional reinforcing bars to help carry the design loads and deformations. Moreover, fibres are still most commonly used with relatively low strength (ordinary) concretes.

In the present work, the use of fibres with both high strength concrete (HSC) and steel reinforcement is described, with particular reference to recent experimental work carried out at the University of British Columbia. It is shown that, with conventionally reinforced HSC, fibres greatly improve the post-peak behaviour of the system. Under impact loading, fibres greatly improve the toughness of the composite materials, particularly when the specimens are subjected to lateral confinement; in these cases, the fibres may also lead to a change in the mode of failure.

COMPRESSION

Plain concrete fails in a relatively brittle manner. For HSC ($f'_c > 70$ MPa), it exhibits nearly elastic behaviour up to a stress of about 0.7 f'_c; at higher stress levels its behaviour becomes increasingly nonlinear as the microcracks which have developed begin to coalesce, leading eventually to failure. The addition of fibres to a high strength matrix has little effect on f'_c, though it tends to increase somewhat the stress level at which the σ-ε curve becomes noticeably nonlinear. However, by bridging across the cracks, the fibres lead to multiple cracking and hence the ability of the FRC to exhibit much greater strains at failure. For fibre volumes less than about 1.5%, the fibres simply lead to the formation of more (and finer) cracks, and consequently to a greater toughness. For higher fibre volumes, however, a ductile mode of failure occurs, characterized by the development of a few inclined shear cracks. The effects of high volumes of various fibres in a HSC matrix ($f'_c = 70$ MPa) are shown in Fig. 1.

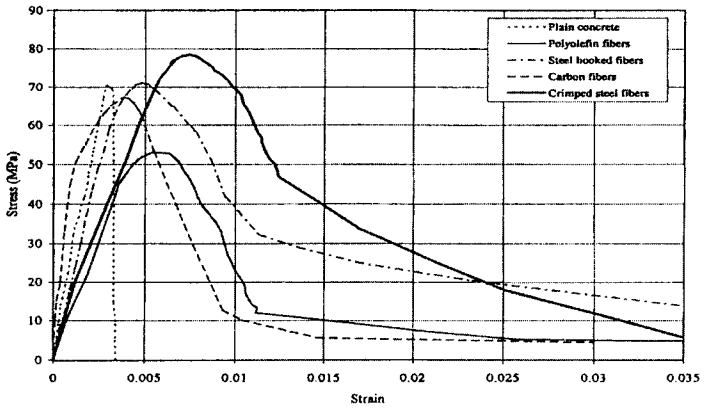

Figure 1(a): Stress-strain curves for HSC at 2.0% by volume of fibres (adapted from Campione and Mindess (1999)).

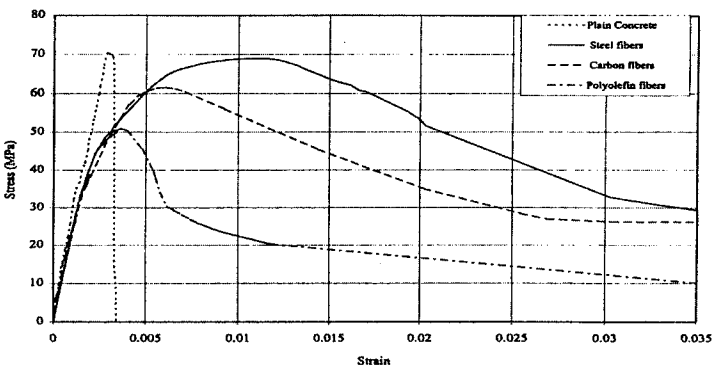

Figure 1(b): Stress-strain curves for HSC at 3.0 percent by volume of fibers (adapted from Campione, Mindess and Zingone, (1997)).

The slight reduction in strength at the highest fibre volumes is due to the difficulty of compacting the concrete fully at such fibre volumes. For similar volumes of carbon fibres, greater reductions in strength were observed, again due to difficulties in compaction, though the increases in toughness were about the same as those found with the steel fibres (Campione *et al.*, 1999b).

The real advantage of using high volume FRC, however, comes when the fibres are combined with conventional steel reinforcement. (Campione et al., 1997; Campione and Mindess, 1999; Campione et al, 1999b; Campione and Mindess, 2000; Campione, et al. 1999). When FRC cylinders containing more than 2% by volume of fibres were reinforced with spiral steel reinforcement, a number of effects were noted:

- Both the ultimate strength and the corresponding strain were increased;
- Beyond the peak load, the failure of the specimen was characterized by successive yielding of the steel spirals at different sections. This occurred because the fibres were able to carry the load transferred to the matrix when a spiral ruptured, as may be seen in Fig.2.

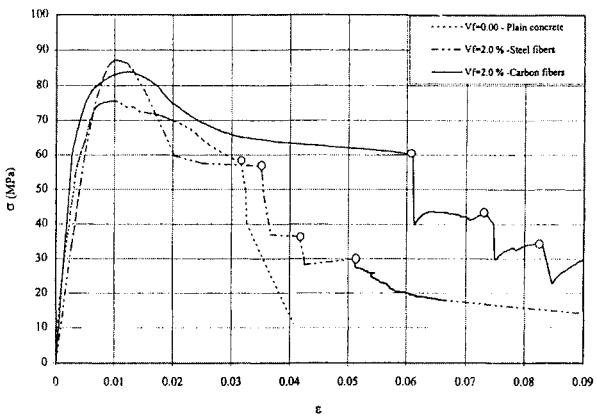

Figure 2: Stress-strain curves for confined HSC at different fiber volumes spiral reinforcement ρ=0.02592 -o failure of steel spirals. (adapted from Campione and Mindess, 1999).

- Thus, the combination of FRC and steel spirals may lead to a considerable increase in the specimen ductility (or ability to absorb energy).
- The maximum strain corresponding to the failure of the steel spirals increased.
- The concrete cover over the spiral steel exhibited less spalling; primarily, spalling was confined to the regions of rupture of the spiral steel.

Fibres combined with spiral steel reinforcement were also found to be very effective under *cyclic* compressive loading. In these tests, specimens similar to those described above were tested under cyclic loading, between 90% of the ultimate stress and 10% of the ultimate stress, to obtain the complete envelope of the cyclic $\sigma-\varepsilon$ behaviour, as shown in Fig.3.

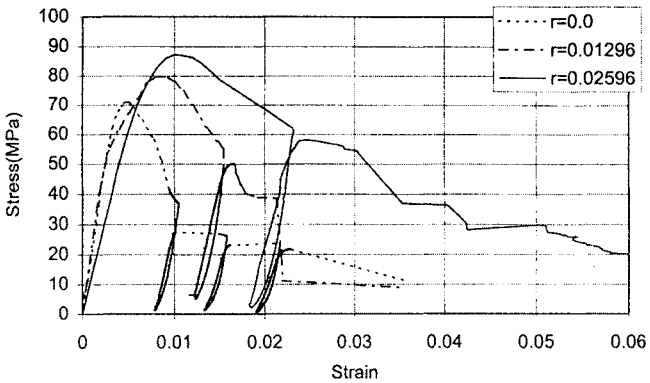

Figure 3: Cyclic stress-strain curves for confined HSC with 2.0% by volume of hooked steel fibers and different steel spiral volumes (Campione et al., 1999a)

The envelope of the cyclic loading curves corresponds closely to that of the monotonic σ–ε curve (measured on a companion specimen). In addition,

- The failure strain under cyclic loading between two fixed stress levels depends only on the maximum stress level in the matrix;
- The toughness of the material under cyclic loading is higher than that under monotonic loading.

FLEXURE

As in the case of compression, the addition of high fibre volumes also increases the residual (post-cracking) strength and energy absorption capacity (toughness) of high strength concrete beams. Under cyclic loading (Campione *et al.*, 2000) showed that FRC with a fibre volume of 3% could withstand very high strains without significant losses in strength. At even higher fibre volumes (≈3.8%), Balaguru and Franklin (1999) showed that steel FRC could withstand approximately 75% of the ultimate load at large deflections, even under reverse cyclic loading. This has obvious implications for concrete structures in severe seismic areas.

High fibre volumes are particularly effective in increasing the shear capacity of high strength, conventionally reinforced beams (Campione and Mindess, 1999; Campione *et al.*, 2000a; Campione *et al.*, 2000b). Although there was no particular increase in the load carrying capacity of the FRC beams compared to those made with a plain concrete matrix, the brittle compressive failure of plain concrete over-reinforced beams was transformed to a "ductile" compressive failure. However, the current provisions for calculating ductility factors appear not to be suitable for FRC reinforced beams.

IMPACT

Both plain concrete and FRC are highly strain rate sensitive materials, with their apparent strengths increasing with increasing strain rates. However, we are still unable to predict their behaviour under impact or dynamic loading on the basis of static tests. Also, because of the inherent difficulties in carrying out properly instrumented impact tests, the available experimental data are often *artifacts* of the particular testing system and specimen geometry employed. Nonetheless, there are enough data reported to permit the following general observations to be drawn:

- The addition of fibres to concrete increases the measured impact strength. The increase obtained in a particular test depends upon the fibre volume, fibre geometry , and matrix strength.
- As with plain concrete, the fracture energy (toughness) of FRC is increased under impact loading (Banthia *et al.*, 1994).
- The strain rate sensitivity of FRC increases both with increasing fibre content and fibre aspect ratio. This is generally attributed to the strain rate sensitivity of the fibre-matrix bond strength (Naaman and Gopalaratnam, 1983).
- Adding fibres to the concrete matrix will significantly improve the bond between the concrete and conventional steel reinforcing bars (Yan and Mindess, 1991; Yan and Mindess, 1994). The composite becomes more ductile, absorbs more energy, and exhibits a higher ultimate bond stress.

The effects of fibres can be particularly dramatic when the FRC is subjected to multiaxial loading. As shown in detail by Sukontasukkul (2001) and Sukontasukkul *et al.* (2001).

- When compression specimens are confined laterally, the mode of failure changes from the usual shear cone appearance to a columnar or vertical splitting type. Both the strength and strain at peak load are increased.
- For beams and plates, an increased lateral confining stress gradually changes the mode of failure from flexure to shear. Both the strength and toughness increase with increasing confinement.
- Higher confining stresses and higher fibre contents permit more impact energy to dissipate through the specimens, and at the same time permit the specimens to absorb more energy.

CONCLUSIONS

The combination of high strength concrete, high fibre volumes and conventional reinforcement can lead to dramatic improvements in the mechanical behaviour of concrete members, for both static and dynamic loading conditions. Despite the higher *material* costs of such systems, both the structural properties and durability of concrete structures can be greatly improved. As yet, the available building codes do not make it easy to exploit these improved properties, since most codes are based entirely on *strength* considerations, and do not take into account the *toughness* of the material. It can only be hoped that the codes will soon reflect the advances made in enhancing the properties of cement-based composite materials, so that this new generation of construction materials can be exploited to their full extent.

DIFFERENTIAL SCANNING CALORIMETRY STUDY OF THE HYDRATION PRODUCTS IN PORTLAND CEMENT PASTES WITH METAKAOLIN REPLACEMENT

W. Sha

School of Civil Engineering, The Queen's University of Belfast, Belfast
BT7 1NN, UK

ABSTRACT

The hydration products in Portland cement pastes mixed with metakaolin (MK) replacement have been examined using differential scanning calorimetry (DSC). The amounts of calcium hydroxide remaining in the pastes after long ages were evaluated in particular by measuring the enthalpy of its decomposition. Reasonable agreements are demonstrated between the results from the present work and previous studies by other investigators.

KEYWORDS

Hydration products, thermal analysis, fly ash, metakaolin, Portland cement, calorimetry.

INTRODUCTION

Recent years have seen a significant amount of research on the use and properties of cement and concrete mixed with cement replacement materials. These include pulverised fuel ash (pfa, or fly ash), condensed silica fume (csf, or microsilica), ground granulated blast furnace slag (ggbs) and metakaolin (MK). The large quantity of literature published in this area has been accompanied by an increased use of these replacement materials in construction [Sindu (2000)], mostly because of environmental and economical benefits. Increased use of cement replacement materials has also been driven by the requirement for enhanced durability.

In 1999, the author and his colleagues used differential scanning calorimetry (DSC) to study the hydration products in Portland cement (PC) paste [Sha et al. (1999)]. This was extended to PC with metakaolin [Sha & Pereira (2001a)], pulverised fuel ash [Sha & Pereira (2001b)] and slag [Sha & Pereira (2001c)] replacements. The present work is a continuation of the research by Sha & Pereira (2001a), but concentrates on hydration after longer times. Specifically, the longer times are for ages

beyond 230 and 190 days for the PC with 20% and 30% metakaolin, respectively. Results are also compared with previous data for samples at shorter ages.

The work in Sha et al. (1999) involves using DSC in an investigation of the thermal behaviour of hydration products in Portland cement as a function of age. The two-step loss of water from calcium silicate hydrate, dehydroxylation of calcium hydroxide, and decarbonation of calcium carbonate contribute respectively to the three major endothermic peaks in the DSC curves. Peaks due to the formation of ettringite and iron-substituted ettringite, C_4AH_{13} and Fe_2O_3 solid solution were also found.

The work in Sha & Pereira (2001a) has demonstrated that DSC analysis can be used to trace the hydration process of cement with metakaolin replacement. The pozzolanic reaction of metakaolin and its effect on cement hydration can be monitored. The technique, combined with theoretical analysis based on reaction stoichiometry, can contribute to the understanding of these processes.

In Sha & Pereira (2001b), hydration products in normal Portland cement mixed with 30% fly ash were analysed. The phases detected include calcium silicate hydrate, iron-substituted ettringite, C_4AH_{13}, calcium hydroxide, calcium carbonate and amorphous phases in fly ash. In addition, ggbs powder was investigated, revealing peaks due to the crystallisation of the amorphous phases. Due to their relatively preliminary nature and the limit of article space, the results of the powders and pastes were not closely correlated, and some of the experimental results remained unexplained with regard to their hydration/pozzolanic processes, or the resulting engineering implications. At the then stage of the research development in the area, there was a lack of proper understanding of the implications of the DSC testing results on engineering properties particularly at early ages. The result presented could not possibly give a full meaningful interpretation of the role of fly ash or slag in concrete, although there was a catalogue of data that may prove crucial in the course of further research. Chemical analyses of quenched samples either side of peak temperatures was expected to help in understanding the mechanisms involved. Unfortunately, there was some wrong assignments of the DSC peaks in Sha & Pereira (2001a,b).

The work reported in Sha & Pereira (2001c) involves an investigation of the thermal behaviour of hydration products in ggbs. The two-step loss of water from calcium silicate hydrates and dehydroxylation of calcium hydroxide ($Ca(OH)_2$) contribute, respectively, to the two major peaks in the DSC curves. Peaks due to the formation of ettringite and Fe_2O_3 solid solution were also found. The crystallisation peaks from amorphous phases in the ggbs are also significant in the DSC thermograms.

The DSC used in these studies has high temperature sensitivity, but the accuracy of the enthalpy measurement is limited to approximately 20% relative error. Compared to other analytical methods, DSC measurement of phases is fast, but the identification of phases relies on previous knowledge of their decomposition or transformation temperatures and enthalpies.

There has been other work, by de Silva & Glasser (1990, 1992, 1993), Frías & Cabrera (2001), Frías et al. (2001), Kinuthia et al. (2001), Murat (1983), Pera & Ambroise (1998), Péra et al. (1998, 2001), and Serry et al. (1984).

MATERIALS

The work reported in this paper was carried out on the same pastes as used in Sha & Pereira (2001a), using the same procedure and apparatus. Therefore, the experimental details will not be repeated here, for which Sha et al. (1999) and Sha & Pereira (2001a,b,c) can be consulted. The chemical

composition, phase analysis, fineness and some other physical properties of metakaolin and cement are given in Table 1. The water/solid ratio is 0.45.

TABLE 1
CHEMICAL COMPOSITION AND SOME PHYSICAL PROPERTIES OF CEMENT AND METAKAOLIN

Compound	Cement	Metakaolin
SiO_2	21.8	54.8
Al_2O_3	4.2	41.2
Fe_2O_3	2.5	0.57
CaO	65.1	0.02
MgO	-	0.31
Na_2O	0.13	0.04
K_2O	0.72	2.27
TiO_2	-	0.01
SO_3	2.4	2.4
Loss on ignition	-	0.8
Specific gravity	3.15	2.52

RESULTS AND DISCUSSION

20% Metakaolin

Samples were analysed at two ages, 230 and 420 days, after storing continuously under water at 20°C from one day after mixing (Figure 1). A number of peaks are shown in the curve.

It has been established by a range of different authors, that the reaction of MK with CH, either as added CH or from hydrating PC, produces C-S-H gel and C_4AH_{13} and, often at a rather later stage, C_2ASH_8. At long curing periods (beyond 28 days) hydrogarnet (C_3AH_6) may develop particularly at elevated temperatures. At high MK:CH, or MK:PC, C_2ASH_8 is favoured relative to C_4AH_{13}. If carbonation occurs or carbonate is available, which is often the case, carboaluminates, $C_3A.0.5C\underline{C}.0.5CH.H_{11.5}$ and/or $C_3A.C\underline{C}.H_{11}$, form together with C_4AH_{13}. In addition, if sulphate is available in the system, this is normally the case, ettringite forms rapidly, within the first few hours. Gehlenite hydrate, C_2ASH_8, is often not crystalline in its initial stages of formation. It normally shows a weight loss band on thermogravimetry analysis (TGA) and an exotherm on differential thermal analysis (DTA) at 160–200°C, C_4AH_{13} and related carboaluminate phases at 220–280°C and hydrogarnet at 350–400°C. Ettringite usually loses its water at 80–130°C and C-S-H gel, although it loses its water over a wide temperature range, loses the greatest proportion of its water between 120 and 160°C. The DSC measures the energy change of these dehydration or dehydroxylation reactions rather than the weight loss (TGA) or differential temperature (DTA). The transformations, however, occur in the same temperature regions, in the same way that those for $Ca(OH)_2$ and $CaCO_3$ do.

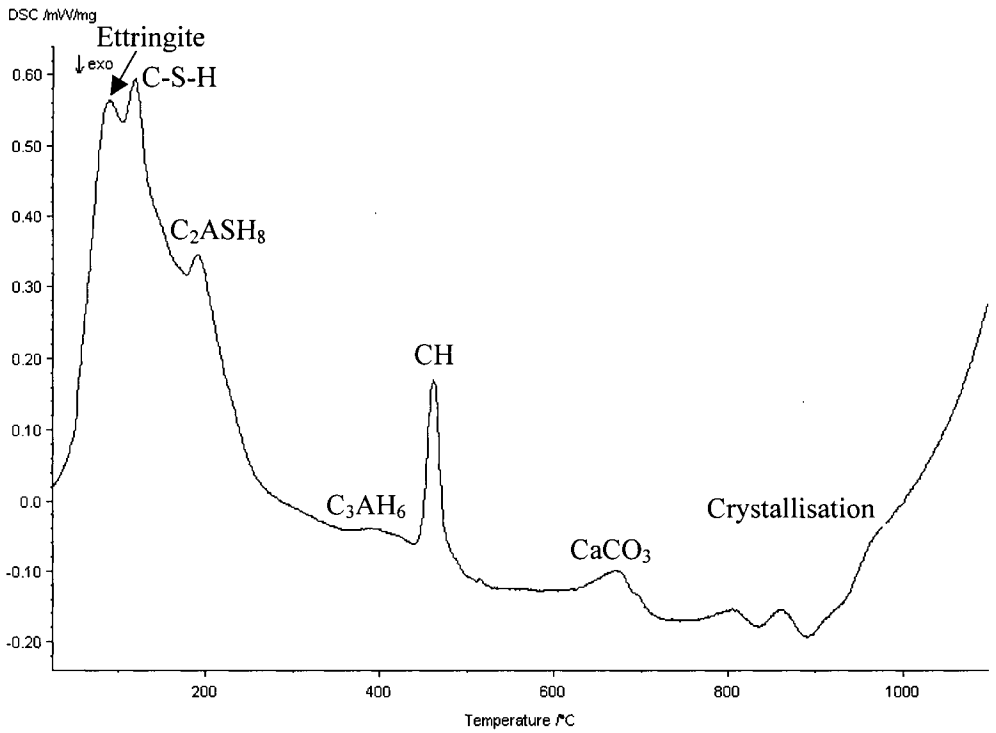

Figure 1: Differential scanning calorimetry curve of Portland cement paste with 20% metakaolin at 230 days

It was found that there was no significant change between the two ages studied, indicating that no significant reaction had occurred, including in particular the pozzolanic reaction. Calculation showed that with 15% or higher metakaolin replacement, there should be no calcium hydroxide left in the system after hydration and pozzolanic reactions are complete [Sha & Pereira (2001a)]. The large amount of calcium hydroxide ($Ca(OH)_2$, or CH) remaining in the samples was not surprising, however. Reaction products are formed in such a way that they inhibit further reaction. For example in concrete with only PC as binder, after many years of PC hydration there is still unhydrated PC remaining. Wild & Khatib (1997) conclude that replacement levels of PC by MK considerably in excess of 15% would be required to fully consume all the CH in MK-PC pastes and mortars. This is based on their hypothesis that an inhibiting layer of reaction product is formed on the MK particles. This is also discussed in Kinuthia et al. (2001). Considering that there is no calcium hydroxide after similar age in cement with 30% metakaolin replacement (see next section), it appears that the theory used in the calculations is essentially valid but the coefficients need to be adjusted. The amount of calcium hydroxide, 24 J/g, is equivalent to 2.4% of the paste, or 4.2% of the original amount of cement. This is lower than the values reported by Frías & Cabrera (2000), but the overall trend for the change of CH amount with age is in agreement with Sha & Pereira (2001a). The same qualitative comparison can be made with work by Wild & Khatib (1997), although the DSC work did not reveal the drop of CH content at around 14 days [Sha & Pereira (2001a)]. The lower CH level found in this work compared to the literature [Wild & Khatib (1997), Frías & Cabrera (2000)] should be related with the different materials and mixes used. It is difficult however to separate the influence of different metakaolin and cement compositions, different physical properties of the materials, and different water/solid ratio.

Calculating enthalpy values for combined adjacent peaks was applied to the peaks previously identified as from crystallisation of the amorphous materials [Sha & Pereira (2001a)]. The double crystallisation peak starts to appear in samples at 52 days, but the total enthalpy remains the same until 420 days, averaged at 43±5 J/g.

30% Metakaolin

For PC paste with 30% metakaolin replacement, samples at two ages were analysed, 190 and 380 days (Figure 2). As for 20% metakaolin, data for earlier ages were given in Sha & Pereira (2001a). The paste with 30% metakaolin exhibited significant acceleration of the speed and degrees of the pozzolanic reaction. Figure 3 shows DSC thermograms for pastes at the ages of 2, 24, 38 and 73 days, respectively. The separation of the crystallisation peak is complete after 38 days (Figure 3), half of the age for this in the paste with 20% metakaolin. In addition, the peak corresponding to the decarbonation of $CaCO_3$ starts to grow large at an earlier age. There is an overlap of peaks at this region, with possible additional contribution from solid-solid transformations [Bhatty (1991)]. Therefore, the obvious dual peak phenomenon in this temperature range may be attributed to this transformation. It is also interesting to note the significant peaks corresponding to gehlenite hydrate and C-S-H, at 24 days (Figure 3). These continue to increase with longer age, overlapping to cause the large peak in the curve for 73 days (Figure 3). As gehlenite hydrate and C-S-H are both pozzolanic reaction products from MK, this difference from the behaviour of 20% metakaolin paste is as expected. Figure 4 shows the variation of peak temperature as a function of age.

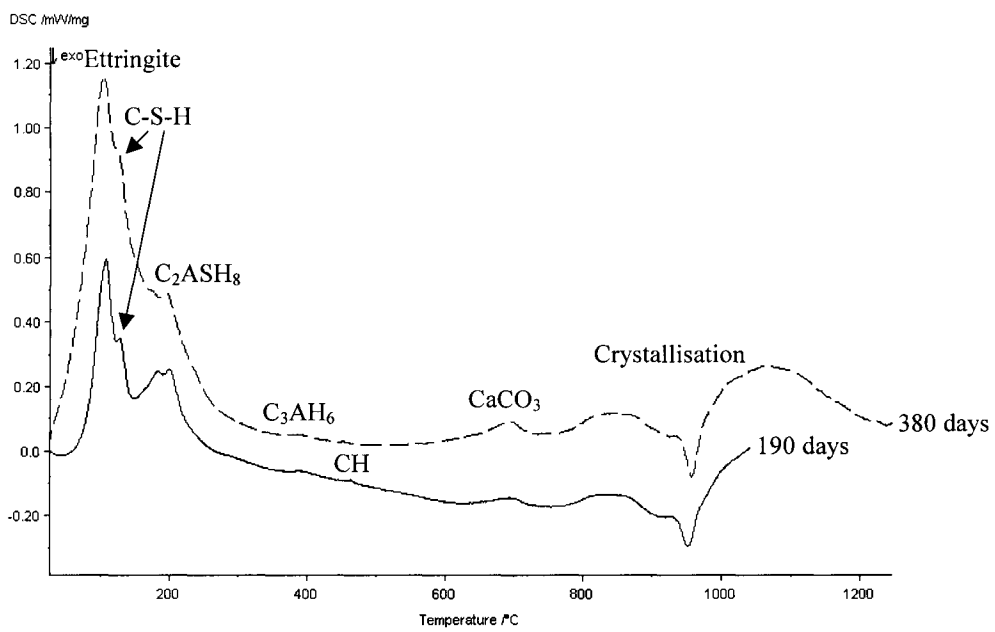

Figure 2: Differential scanning calorimetry curves of Portland cement paste with 30% metakaolin at 190 days (solid line) and 380 days (dashed line)

There is no significant change apart from the complete disappearance of the calcium hydroxide peak after 380 days, from the absence of CH peak in Figure 2. There is a peak for the sample after 190 days, but it is very small and almost invisible in the printed DSC curve.

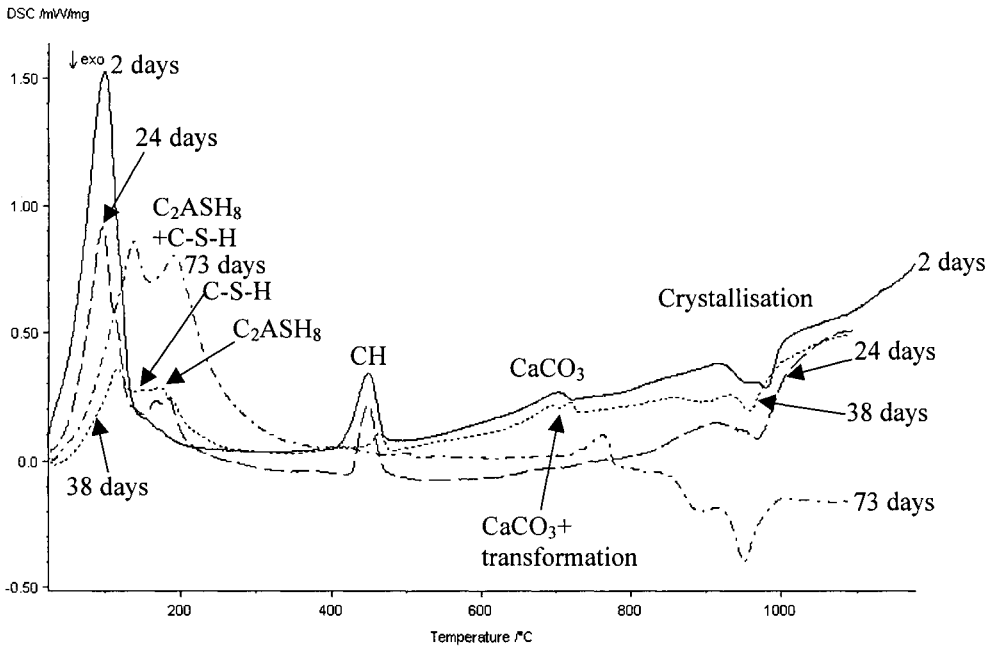

Figure 3: DSC thermograms from hardened paste containing 30% metakaolin replacement at 2 (solid line), 24 (long dashed line), 38 (short dashed line) and 73 days (dash dot line)

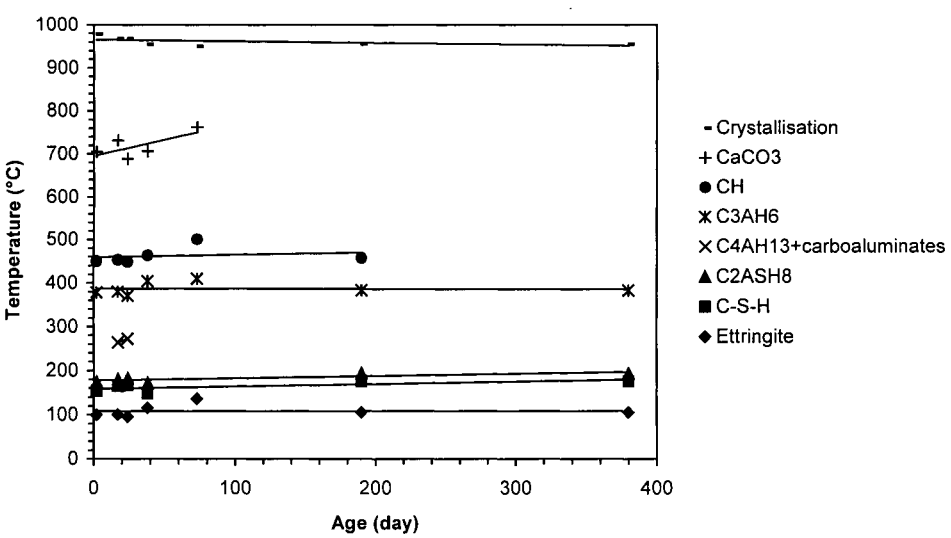

Figure 4: DSC peak temperatures from the mix with 30% metakaolin replacement

The increase of metakaolin level from 20% to 30% replacements pushes up the crystallisation temperatures. The average total enthalpy from the crystallisation peaks for ages of 73, 190 and 380 days is 106±8 Joule per gram of sample.

CONCLUSIONS

Differential scanning calorimetry analysis showed that in cement paste with 20% metakaolin replacement, the amount of calcium hydroxide after 230 and 420 days hydration remains the same, 2.4% of the paste. With 30% metakaolin replacement, there is only a minute quantity of calcium hydroxide after 190 days, and this completely disappears after 380 days.

ACKNOWLEDGEMENT

The author thanks Professor P.A.M. Basheer for discussion and the provision of concrete laboratory facilities.

ULTIMATE MOMENT EQUATION OF CIRCULAR HSC MEMBERS

Y. Sun and K. Sakino

Department of Architecture, Graduate School of Human Environment Studies,
Kyushu University, Hakozaki 6-10-1, Fukuoka, 812-8581, JAPAN

ABSTRACT

It has been widely accepted that confinement of concrete by transverse reinforcement is effective in upgrading deformation capacity of high strength concrete (HSC). In order for structural engineers to conduct reasonable design of confined HSC members, they are of fundament importance 1) to make clear correlation between the amount of transverse steels and the mechanical properties (e.g. ultimate moment capacity, etc) of the confined member, and 2) to develop a sound design method that can take into account effects of primary structural factors, particularly of confinement by transverse steels.

Purpose of this paper is to propose a simple design equation for computing ultimate flexural strength of circular confined HSC or NSC (normal-strength concrete) members. The emphasis is placed on HSC members. The proposed design equation has a very simple mathematical expression so that structural engineer can conduct the complicated calculation of the ultimate moment of confined concrete members by hand. Another significant feature of the proposed design equation is that it can take into account effects of circular transverse steels on the ultimate moment of confined circular members. Experimental results of confined concrete columns available are used to verify validity of the proposed equation. The predicted ultimate moments agreed very well with the measured ones, which implies that the proposed design equation could provide a powerful tool for structural engineer to appropriately and directly calculate the ultimate moment of a circular HSC member.

KEYWORDS

Circular concrete member, high-strength concrete, confined concrete, confinement effect, circular steel tube, ultimate moment, confinement design

INTRODUCTION

Due to its high load-carrying capacity and durability, HSC has recently gained increasing use in high-rise building structures and highway constructions. To promote use of HSC in structures located on seismic regions, prevention of brittle failure mode of the HSC becomes an important issue.

Confinement of concrete by transverse reinforcement is effective in enhancing ductility of the HSC.

Traditionally, the transverse spirals or hoops have been widely used to confine concrete members, and their beneficent effects on the mechanical behavior of concrete members have been studied by many researches as reviewed in the ACI state of art report [ACI, 1997]. Nevertheless, there has not yet been a reliable and comprehensive design method enabling structural engineers to simply compute the ultimate capacities of confined HSC columns. Particularly true is this for the circularly confined HSC columns due to lack of information on the ultimate flexural behavior of circular columns.

The authors have conducted an integrated experimental and analytical studies of mechanical behavior of circularly confined HSC columns, aiming at setting up a rational design method for the ultimate capacities of the circular columns. In the authors' previous experimental works [Sun and Sakino, 1999, 2000], the test columns were confined by circular steel tubes with various thickness in lieu of common circular hoops, to quantitatively study confinement effect of circular transverse reinforcement on the mechanical properties of the "pure" confined concrete. Based on their experimental data, the authors have developed an unified stress-strain model for the circularly confined concrete [Sun and Sakino, 2001]. This confinement model has been proved applicable to the concrete confined by conventional circular hoops, the concrete confined by circular steel tubes, and the concrete in circular CFT column. Furthermore, as the first step toward simplification of ultimate capacity design for the circular HSC columns, Sun and Sakino [2001] have also proposed a equivalent rectangular stress block for the compressed concrete in a circular column section and a design procedure to predict ultimate capacities of circularly confined HSC columns. However, as can be seen later, that method involves the use of complicated expressions and still needs help of a computer.

To overcome these shortcomings in the previous design method, this paper propose a much simpler design equation for computing the ultimate flexural strength of circularly confined HSC members. The mathematical expression of the proposed design equation, which defines the correlation between the axial load and the ultimate moment for a given circular column, is developed by utilizing the rectangular equivalent stress block proposed by the authors [Sun and Sakino, 2001]. Study of this paper will focus on circular columns confined by steel tube. Development of the design equation for calculation of ultimate moment of the columns confined by common circular hoops is in progress, and will be reported in near future.

OUTLINE OF EQUIVALENT RECTANGULAR STRESS BLOCK

Interaction diagram between the axial load N and the ultimate moment (referred to as N-M interaction diagram hereafter) is usually adopted to compute the flexural strength of concrete columns. Generally, for a given column, the N-M interaction diagram can be obtained by conducting flexural analysis, i.e., by computing the moment-curvature response of the column section under various levels of axial load. If a sound stress-strain model for the confined concrete is assumed, the flexural analysis can give fairly accurate prediction of the flexural strength, in which confinement effect of transverse steels can be taken into account. This general approach, however, is very tedious and needs help of a computer program, since it involves an iterative procedure to find the depth of the neutral axis for the internal forces to balance the external applied load.

On the other hand, if the stress state of the compressed concrete at the peak moment can be simplified, it is possible to simplify the calculation procedure of the N-M interaction diagram. By conducting parametric study of flexural response for circularly confined columns, the authors have proposed an equivalent rectangular stress block to replace the actual stress state for the compressed concrete in a circular column section as the first step toward simplification of flexural strength calculation [Sun and Sakino, 2001]. Figure 1 shows outline of the proposed stress block for the circularly confined concrete. As shown in Figure 1, the equivalent stress block has width of αD_c and depth of βX with uniform stress f_{cc}, where D_c is the diameter of core concrete, X is the depth of the neutral axis, and f_{cc} ($=K f_P$) is the strength of confined concrete. Utilizing the stress block, the axial compressive force N_B and the first moment M_B sustained by the concrete at ultimate state can be calculated as follows:

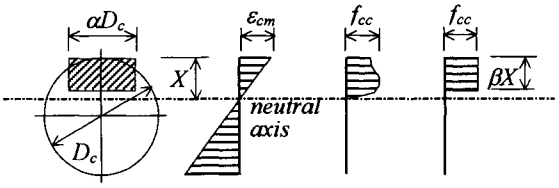

Figure 1: Equivalent rectangular stress block for the compressed concrete in a circular column

$$N_B = \alpha\beta K f_p D_c X, \qquad M_B = \alpha\beta K f_p D_c X\left(\frac{D_c}{2} - \frac{\beta}{2}X\right) \tag{1}$$

where α and β are the stress block parameters, K is the strength enhancement ratio of confined concrete, f_p is the unconfined concrete strength, D_c is the diameter of concrete core, and X is the depth of the neutral axis. Based on the theoretical results concerning with the flexural behavior of circularly confined concrete columns, the authors have developed mathmatical expressions to compute the stress block parameters α and β in forms of

$$\alpha\beta = A(K, X_n) - B(K, X_n)\frac{f_p}{42}, \quad \frac{\beta}{2} = C(K, X_n) - D(K, X_n)\frac{f_p}{42} \tag{2}$$

where

$$A(K, X_n) = \frac{0.723 + 0.061K}{0.112 + X_n}X_n, \quad B(K, X_n) = \frac{0.048K^{-2}}{0.072K^{-1.5} + X_n}X_n \tag{3}$$

$$C(K, X_n) = (0.476 + 0.051K)\left(1 - 0.132X_n{}^2\right), \quad D(K, X_n) = 0.017\left[1 - (0.024 + 0.187K)X_n{}^2\right] \tag{4}$$

in which X_n is the normalized depth of the neutral axis. The strength enhancement ratio K of concrete confined by circular steel tube can be obtained by applying famous Richart formula as follow

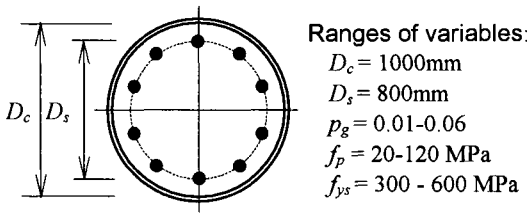
$$K = \frac{f_{cc}}{f_p} = 1 + 4.1\frac{2}{D/t - 2}\frac{f_{yt}}{f_p} \tag{5}$$

where f_{cc} is the confined concrete strength, f_{yt}, t, and D are the yield strength, thickness, and outside diameter of the steel tube, respectively.

FEATURES OF THE ULTIMATE *N-M* INTERACTIVE DIAGRAM

To investigate features of the ultimate *n-m* interactive curve for circularly confined concrete columns and get fundamental information for development of design equation, parametric flexural study was conducted. Figure 2 shows details of the sample section as well as varying ranges of the main variables. As obvious in Figure 2, parametric study covered a wide range of concrete strength and steel amount, which implies the wide applicability of the to be proposed design equation in terms of the concrete strength and the amount of longitudinal bars.

To compute the ultimate *n-m* interactive curve using the equivalent stress block, they are assumed that



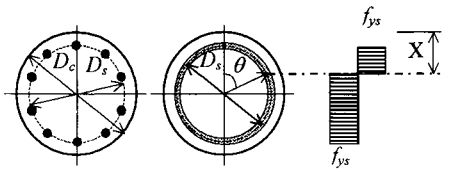


Figure 2: Details of the sample column section

(a) longitudinal bars (b) equivalent steel tube (c) stress distribution

Figure 3: Concept of the equivalent axial steel tube of the longitudinal bars

1) the tensile strength of concrete can be neglected, 2)the concrete sustained axial force as well as moment can be replaced by those of the stress block shown in Figure 1, 3) the longitudinal bar is a rigid-plastic material, and 4) the longitudinal bars can be replaced with an equivalent axial steel tube having identical reinforcement area (see Figure 3).

Based on these assumption, the calculation procedure for ultimate *N-M* interaction diagram doesn't involve iterative calculation, and can be summarized as follows.

1) Calculate the strength enhancement ratio K of confined concrete by substituting D/t ratio and yield strength f_{yt} of the steel tube and the unconfined concrete strength f_p, into Eq. 5.
2) Give an initial value (e.g. 0.02π) to θ, the radial angle of the section and calculate the normalized depth of the neutral axis X_n by Eq. 6.

$$X_n = X/D_c = 0.5(1 - D_s \cos\theta / D_c) \tag{6}$$

where D_c is the diameter of confined core concrete, and D_s is the distance between the centroids of the longitudinal bars. (see Figure 3)

3) Calculate the stress block parameters $\alpha\beta$ and $\beta/2$ from Eq. 2 through Eq. 4 and compute the axial force N_B and moment M_B sustained by the concrete by using. 1
4) Based on the last two assumptions above mentioned, the axial force N_s and moment M_s sustained by longitudinal bars can be calculated as

$$N_s = \frac{f_{ys} p_g D_c^2 (2\theta - \pi)}{4}, \quad M_s = \frac{f_{ys} p_g D_c^2 D_s \sin\theta}{4} \tag{7}$$

where f_{ys} and p_g are the yield strength and the steel ratio of the longitudinal bars, respectively.

5) The normalized axial force n as well as the normalized moment m corresponding to the given radial angle θ are then given by

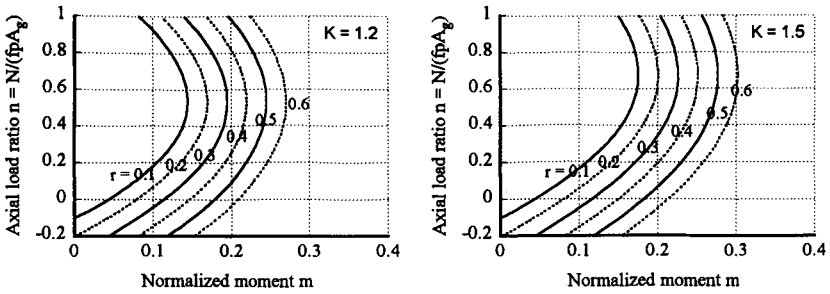

Figure 4: Examples of the calculated *n-m* interactive diagrams of the sample columns

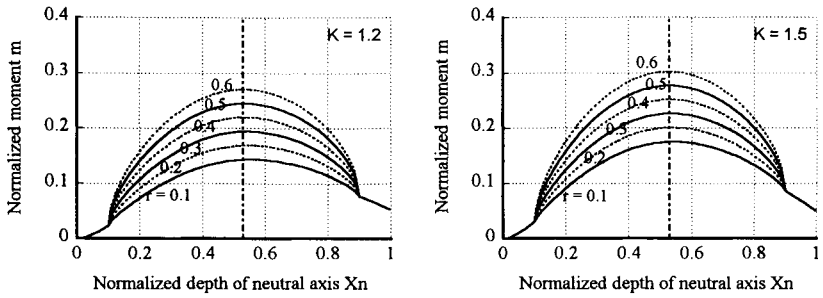

Figure 5: Relationships between the normalized neutral axis depth *Xn* and the moment m

$$n = \frac{N_B + N_s}{A_g f_p} = \frac{4}{\pi}\alpha\beta \bullet K \bullet X_n + \frac{1}{\pi}\frac{f_{ys}\rho_g}{f_p}(2\theta - \pi) \tag{8}$$

$$m = \frac{M_B + M_s}{A_g D_c f_p} = \frac{4}{\pi}\alpha\beta \bullet K \bullet X_n\left(\frac{1}{2} - \frac{\beta}{2}X_n\right) + \frac{1}{\pi}\frac{f_{ys}\rho_g}{f_p}\frac{D_s}{D_c}\sin\theta \tag{9}$$

6) The normalized ultimate *n-m* interaction diagram can be completely determined by incrementing θ till θ = π, and repeating the calculation step 2) through step 5) above.

Figure 4 plots several ultimate *n-m* interactive curves of the sample column section obtained utilizing the calculation procedure described above, while Figure 5 shows relationships between the normalized ultimate moment *m* and the neutral axis depth. In Figures 4 and 5, the confinement effect of circular steel tube is represented by the strength enhancement ratio K of confined concrete as defined by Eq. 5, and the factor *r* expresses the normalized steel ratio of the longitudinal bars and is given by $r = f_{ys}\rho_g / f_p$.

From Figures 4 and 5, one can observe the following features for the ultimate *n-m* interactive curves of circularly confined concrete columns:

1) For a circular column confined by the steel tube with a specific K value, the *n-m* interactive curves expand outwards as increment of the amount of longitudinal bars. On the other hand, the normalized moment *m*, as a function of the axial load ratio *n*, tends to reach its maximum at a axial load level that is nearly independent of the amount of longitudinal bars.
2) The axial load ratio n_o at the peak point of each *n-m* interactive curve increases with the K value, while the peak moment m_o at each *n-m* interactive curve increases as increment of both the K value

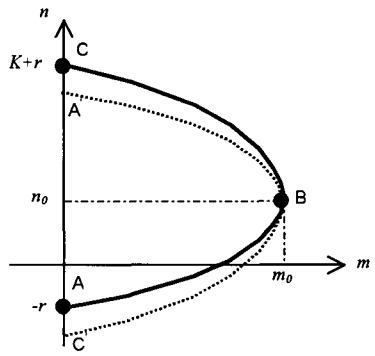

Figure 6: Idealization of the ultimate *n-m* interactive diagram

and the amount of longitudinal bars.

3) Regardless of the confinement degree (i.e. the K value) and the amount of longitudinal bars, each ultimate *n-m* curve reaches its peak moment as the normalized neutral axis depth X_n is between 0.52 through 0.55 with a mean value of 0.53.

PROPOSAL OF A DESIGN EQUATION

The calculation method using the equivalent stress block does really simplify the computation of flexural strength for the circularly confined members as compared with the method using the general flexural analysis. However, this method is still complicated as can be seen from Eq. 2 through Eq. 4. To provide a simpler and more powerful tool enabling structural engineers to more quickly and reasonably conduct the confinement design, a design equation is developed in this section.

Based on the results of parametric study described in the previous section, the ultimate *n-m* interactive curve can be idealized as the curve ABC shown in Figure 6. Obviously, to represent the features observed in the ultimate *n-m* interactive diagrams, the design equation, which defines the relationship between the normalized moment m and the axial load ratio n, should satisfy the following conditions:

$$\begin{aligned} m|_{n=-r} &= 0, & m|_{n=K+r} &= 0 \\ m|_{n=n_0} &= m_0, & \left.\frac{\partial m}{\partial n}\right|_{n=n_0} &= 0 \end{aligned} \tag{10}$$

where m_0 and n_0 are the peak moment of each *n-m* curve and the corresponding axial load ratio, respectively.

The four conditions given by Eq. 10 can determine a single cubic curve, but a cubic curve containes four constants, which might results in new complexity. By carefully analyzing the ABC curve shown in Figure 6, one can find that dividing the *n-m* curve into two parts, the ascending portion AB and the descending part BC, will result in a much simpler expression for the *n-m* curve. In fact, the AB curve can be taken as the ascending half of a parabola ABA', while the BC curve as the descending half of a parabola C'BC.

Considering that the both parabolas, ABA' and C'BC, have the line defined by $n=n_0$ as their common symmetric axis, the mathematical expression for the ultimate *n-m* curve can be simply written as follow:

$$m = \begin{cases} m_0\left[1-\left(\dfrac{n-n_0}{n_0+r}\right)^2\right], & n \le n_0 \\ m_0\left[1-\left(\dfrac{n-n_0}{n_0+K+r}\right)^2\right], & n > n_0 \end{cases} \tag{11}$$

The two parabolas defined by Eq. 11 are continuous at the peak point. Apparently, the proposed design equation is a two-parameter model. Only if the peak moment m_0 and the corresponding axial load ratio n_0 are given, one can completely determine the ultimate *n-m* curve.

As described in the previous section, each *n-m* curve reaches its peak as the normalized depth of neutral axis is between 0.52 and 0.55 with a mean value of 0.53 regardless of the values of both K and r. Hence, substituting X_n=0.53 into Eq. 3 and Eq. 4, and then Eq. 8 and Eq. 9, one can obtain close approximations for m_0 and n_0. Noting that as X_n=0.53,

$$\theta \approx \frac{\pi}{2} \;\Rightarrow\; \sin\theta \approx 1.0$$

exists, and by conducting regression analysis on the approximations of m_0 and n_0, the following expressions were derived to compute m_0 and n_0:

$$\begin{aligned} n_0 &= \frac{1}{\pi}\left(0.1K^2 + 1.3K - 2.2K^{-1}f_p \times 10^{-3}\right) \\ m_0 &= \frac{1}{\pi}\left[0.31K + (0.61K - 0.85)f_p \times 10^{-3} + r\frac{D_s}{D_c}\right] \end{aligned} \tag{12}$$

It can be seen from Eq. 11 and Eq. 12 that the proposed design equation enables structural engineers to calculate the ultimate flexural strength by hand.

VERIFICATION OF THE DESIGN EQUATION

The experimental results of bending tests by Sun and Sakino [2000] are used to validate the proposed design equation. The previous tests comprised of eleven columns made of HSC. These columns were confined in circular steel tubes having inner diameter of 250mm and five kinds of wall thickness varying between 1.2mm and 4.5mm. The concrete strengths were 55.4MPa and 89.2MPa. In each column, the longitudinal steel was ten D13 deformed bars (12.7mm diameter) placed uniformly along the perimeter with 25mm of cover to the steel centroids to give a steel ratio of 2.54%.

The circular steel tubes were fabricated by welding folded steel plate having the targeted thickness at laboratory. The steel tubes were used only to confine concrete rather than to directly sustain the axial stress due to external loads.

Table 1 lists the experimental outlines of these test column along with the measured ultimate moments as well as the calculated results. For comparison, the theoretical predictions based on the stress block are also given in Table 1. It can be seen that the theoretical moments obtained by the proposed design equation agree very well with the experimental results, having the same accuracy as the calculated results by the equivalent stress block.

CONCLUSIONS

A simple design equation has been proposed in this paper to calculate the ultimate flexural strength of concrete columns retrofitted by circular steel tubes. The Proposed design equation has a very simple expression and can take into account confinement effect of steel tubes on the flexural strength. Because of its simplicity and comprehensiveness, the proposed design equation can provide a powerful tool enabling structural engineers to conduct rational retrofitting design for the existing concrete columns.

PERFORMANCE TEST OF A MODEL FOR PREDICTING STRENGTH DEVELOPMENT OF FLY ASH-CONCRETE

Tahir M. A.[1] and Nimityongskul P.[2]

[1]Professor, Department of Civil Engineering, University of Engineering and Technology, Lahore, Pakistan
[2]Program Coordinator, Structures and Construction Program, School of Civil Engineering, Asian Institute of Technology, Bangkok, Thailand.

ABSTRACT

The main features of a model that takes into account the chemical composition and physical properties of the binder materials for predicting strength development of fly ash-concrete are discussed. The model is based on the Feret's Law enriched by the concept of maximum paste thickness. The performance of the model is tested using the strength data from an experimental program in addition to the data adopted from several researchers. The model predictions agree very well with the experimental data. In an extensive theoretical study the sensitivity of the model to the changes in chemical composition of cement and fly ash is also evaluated. It is found that the model performance is just in line with the accepted principles of the hydration and pozzolanic chemistry.

KEYWORDS:

Strength, chemical composition, fineness, fly ash, hydration, maximum paste thickness, pozzolana.

INTRODUCTION

Tahir and Nimityongskul (1998) presented a model for predicting strength development of fly ash-concrete. The model bases its predictions on the chemical composition and fineness of both the Portland cement and fly ash incorporated in the concrete. Further, it considers the effect of aggregate content and grading on the strength development of concrete. The model was calibrated and validated using data from a huge experimental program conducted at AIT (Tahir, 1998) in addition to the data adopted from several researchers around the globe. The nature of the data involved in calibration and validation made the model site independent and it could be used for design of fly ash concrete mixtures quite confidently. In this study the performance of the model is tested in view of the established facts from the chemistry of hydration and pozzolanic reactions. The chemical compositions of the cement and fly ash are varied within the practical limits and influence is evaluated on the strength development of concrete. The selected material compositions are adopted from published data.

THE MODEL

The model is described briefly; the detailed derivation of the model has been presented elsewhere (Tahir, 1998). The model predicts the strength on the basis of the four Bogue Compounds in Portland cement and four major oxides in the fly ash, namely CaO, SiO_2, Fe_2O_3, Al_2O_3, and the alkali contents of the binder, in terms of the equivalent Na_2O. In the following a brief outline of the model is presented, the detailed derivation of the model are presented elsewhere. The strength development of a fly ash concrete is based on the modified Feret's Law (De Larrard and Tondat, 1993) as given below:

$$f_c'(t) = A\ \Lambda^B \left[\frac{V_h(t)}{V_c + V_f + V_w + V_v}\right]^2 \tag{1}$$

where

$$V_h(t) = V_h(28) + \Delta V_h(t) \tag{2}$$

In which $V_h(28)$ denotes the solid volume of hydrated pasted at the age of 28-day and $\Delta V_h(t)$ denotes the change in the former with time. The solid volume at any age t, $V_h(t)$), is expressed in terms of Hyd_i and Poz_i, the hydraulic and pozzolanic parameters, r_W and r_F, the physical parameters and NaEq, the sodium equivalent of the mixture, as

$$\begin{aligned} V_h(t) = {} & \alpha \log\frac{t}{28} + \sum_{i=1}^{6}(\beta_i + \beta_i' \log\frac{t}{28})\,Hyd_i + \sum_{i=1}^{4}(\gamma_i + \gamma_i' \log\frac{t}{28})\,Poz_i \\ & + (a + a' \log\frac{t}{28})\,r_W + \sum_{i=1}^{2} b_i + b_i' \log\frac{t}{28})\,[r_F]^{\frac{1}{i}} + (c + c' \log\frac{t}{28})\,NaEq \end{aligned} \tag{3}$$

$$V_h(t) = \sum_{i=1}^{6}\beta_i\,Hyd_i + \sum_{i=1}^{4}\gamma_i\,Poz_i + a\,r_W + \sum_{i=1}^{2} b_i\,[r_F]^{\frac{1}{i}} + c\,NaEq \tag{4}$$

$$\Delta V_h(t) = (\alpha + V_h(28)) \log\frac{t}{28} \tag{5}$$

The 6-hydration parameters have been defined as follows:

$$Hyd_1 = \Omega_C \frac{C_2S}{C_2S + C_3S} x \frac{C_3A}{G_C} \quad ; \quad Hyd_2 = \Omega_C \frac{C_2S}{C_2S + C_3S} x \frac{C_4AF}{G_C}$$

$$Hyd_3 = \Omega_C \frac{0.994\,C_2S}{G_C} \quad ; \quad Hyd_4 = \Omega_C \frac{C_3S}{C_2S + C_3S} x \frac{C_3A}{G_C}$$

$$Hyd_5 = \Omega_C \frac{C_3S}{C_2S + C_3S} x \frac{C_4AF}{G_C} \quad \text{and} \quad Hyd_6 = \Omega_C \frac{0.75\,C_3S}{G_C} \tag{6}$$

in which C_3A, C_2S, C_3S and C_4AF denote the weights of the four Bogue Compounds respectively from the cement per unit volume of the concrete mixture, G_C denotes the density of cement and Ω_C denotes the fineness index of the Portland cement which can be obtained from the Blaine surface areas of the Portland cement used and a reference cement, F_c and F_{co}. F_{co} is taken equal to300 m^2/kg.

$$\Omega_C = \sqrt{\frac{F_C}{F_{CO}}} \tag{7}$$

The four pozzolanic parameters are defined in the following; when $SiO_2 < S_d$:

$$Poz_1 = \Omega_F \frac{2.85\,SiO_2}{G_F} x \frac{1.321\,CaO}{CH_p}$$

$$Poz_2 = \Omega_F \frac{2.85\,SiO_2}{G_{CF}} x \frac{0.215\,C_2S + 0.487\,C_3S - 0.305\,C_4AF}{CH_p}$$

$$Poz_3 = \Omega_F \frac{Al_2O_3}{G_{CF}} \quad \text{and} \quad Poz_4 = \Omega_F \frac{Fe_2O_3}{G_{CF}} \tag{8}$$

in which G_F and Ω_F respectively denote the density and fineness index of fly ash. The latter is defined in terms of the fineness of fly ash used, F_F, and that of a reference fly ash, F_{Fo}, as follows:

$$\Omega_F = \left[\frac{F_F}{F_{FO}}\right]^{1/3} \tag{9}$$

where F_{F0} is taken equal to 300 m^2/kg. The symbols CaO, SiO_2, Al_2O_3 and Fe_2O_3 denote the weights per unit volume of concrete of the calcium oxide, silica, alumina and ferric oxide respectively from the fly ash. The symbols CH_P and S_d appearing in the above expressions respectively denote the net calcium hydrate available for taking part in the pozzolanic reaction and the silica demand of the mixture. The two are calculated as follows:

$$CH_p = 1.321\ CaO + 0.215\ C_2S + 0.487\ C_3S - 0.305\ C_4AF \tag{10}$$

$$S_d = 0.541\ CH_p \tag{11}$$

The four parameters Poz_1 to Poz_4 are defined in the following; when $SiO_2 \geq S_d$:

$$Poz_1 = 1.541\ \Omega_F\ S_{co}\ \frac{1.321\,CaO}{G_F}$$

$$Poz_2 = 1.541\,\Omega_F\ S_{co}\ \frac{0.215\,C_2S + 0.487\,C_3S - 0.305\,C_4AF}{G_{CF}}$$

$$Poz_3 = \Omega_F\ S_{co}\ \frac{Al_2O_3}{G_{CF}} \quad \text{and} \quad Poz_4 = \Omega_F\ S_{co}\ \frac{Fe_2O_3}{G_{CF}} \tag{12}$$

in which, S_{co} denoted the silica coefficient and is defined as follows:

$$S_{co} = \left[\frac{SiO_2}{S_d}\right]^{0.2} \tag{13}$$

The symbol G_{CF} appearing in the above equations denotes the density of that material, which takes part in the hydration reaction from the fly ash and Portland cement, to produce pozzolanic $C_3S_2H_3$:

$$G_{CF} = 0.649\ G_C + 0.351\ G_F \tag{14}$$

The only chemical parameter is equivalent sodium content of the mixture NaEq, expressed as:

$$NaEq = NaEq(OPC) + NaEq(FA) \tag{15}$$

Where NaEq(OPC) and NaEq(FA) denote the weights of the alkali oxides from Portland cement and ash. The two alkali oxides (Na_2O and K_2O) are expressed as equivalent of Na_2O. The two physical parameters water-binder ratio, r_W and fly ash-cement ratio, r_F are defined as:

$$r_W = \frac{W}{C+F} \tag{16}$$

$$r_F = \frac{F}{C} \tag{17}$$

Where W, C and F denote the weights of water, cement and fly ash respectively per unit volume of concrete. The values of the 29 constants in Eqn. 2 are given in the following table. These values were determined by calibrating the model from a versatile data.

Constant	β_1	β_2	β_3	β_4	β_5	β_6	γ_1	γ_2	γ_3	γ_4
Value	-26.2	22.9	2.49	6.66	-5.76	1.06	.169	.025	.594	.279

PERFORMANCE TEST

The model was calibrated and validated using data from a large number of researchers from several countries around the globe. The details of the data have been published by Tahir (1998). The scatter of the predicted and test data is plotted in Figure 1. It can be seen that model predictions agree very closely to the experimental observations. In addition to this a performance test was run on the model using Portland cements and fly ashes of various chemical compositions. The solid volume resulting from the hydration and pozzolanic reactions was computed from the strength data of the mixtures. It was estimated by the model. The trends were tested and compared with the standard norms of the chemistry of hydration and pozzolanic reactions.

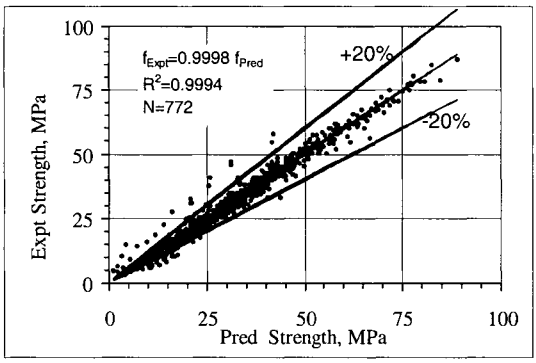

Figure 1. Scatter of model predictions and experimental data

Once the calibration and validation of the model was performed, the performance of the model was tested using Portland cements and fly ashes of different chemical compositions and fineness. In the first part of the performance test a Portland cement of constant composition was used with fly ashes of different compositions. The properties of a partial list of the binders are given in Tables 1 and 2.

(c) SiO_2, Al_2O_3 and CaO constant

(d) SiO_2, CaO, and Fe_2O_3 constant

Figure 2. Change in pozzolanic solid volume due to variation in oxide composition of fly ash.

However, the rate of change of the solid volume with age is much slower compared to that caused by the same variation in the silica content. It can be observed from the figure that the higher the calcium content of the ash, the earlier the pozzolanic reaction starts contributing to the solid volume. The change in the solid volume is nonlinear with the change in calcium content of ash. For all replacement

ratios, an increase in Fe_2O_3 content of ash causes an increase in the solid volume. The influence of Al_2O_3 on the pozzolanic reaction is shown in Fig 2d. The solid volume increases appreciably with an increase in alumina content of the ash. It can be noted that for the same increase in the two oxide contents, Al_2O_3 produced the solid volume about five times more than that produced by Fe_2O_3. This phenomenon is just in line with the observed facts from the hydraulic and pozzolanic behavior of the low and high calcium fly ashes

In the second part of the performance test the Bogue's compounds are varied as shown in Table 3. The properties of ash used with these cements are listed in Table 4. The results of this study are shown in Fig. 3.

C4AF=5%	30	50	8	5	0.17	0.5	Variation
C4AF=7%	30	50	8	7	0.17	0.5	of
C4AF=9%	30	50	8	9	0.17	0.5	C_4AF

TABLE 4

PROPERTIES OF THE FLY ASH CONSIDERED IN THE PERFORMANCE ANALYSIS

$\%SiO_2$	$\%Al_2O_3$	$\%F_2O_3$	%CaO	$\%Na_2O$	$\%K_2O$	Surface Area
29.2	19.2	13.2	23.4	2.00	1.90	300 m^2/kg

It can be observed from Figure 3 that an increase in C_4AF causes increase in solid volume and strength at all ages. On the other hand an increase in C_3A reduces the solid volume of hydration, which means that an increase in C_3A causes reduction in the strength of hydrated paste at all ages. This observation is in line with the established facts of the hydration chemistry. The increase in C_3S or C_2S causes increase in solid volume of hydration at all ages. However, the change caused by C_2S variation is more pronounced at later ages as compared to that caused by C_3S. This observation is again in line with the established facts of hydration chemistry.

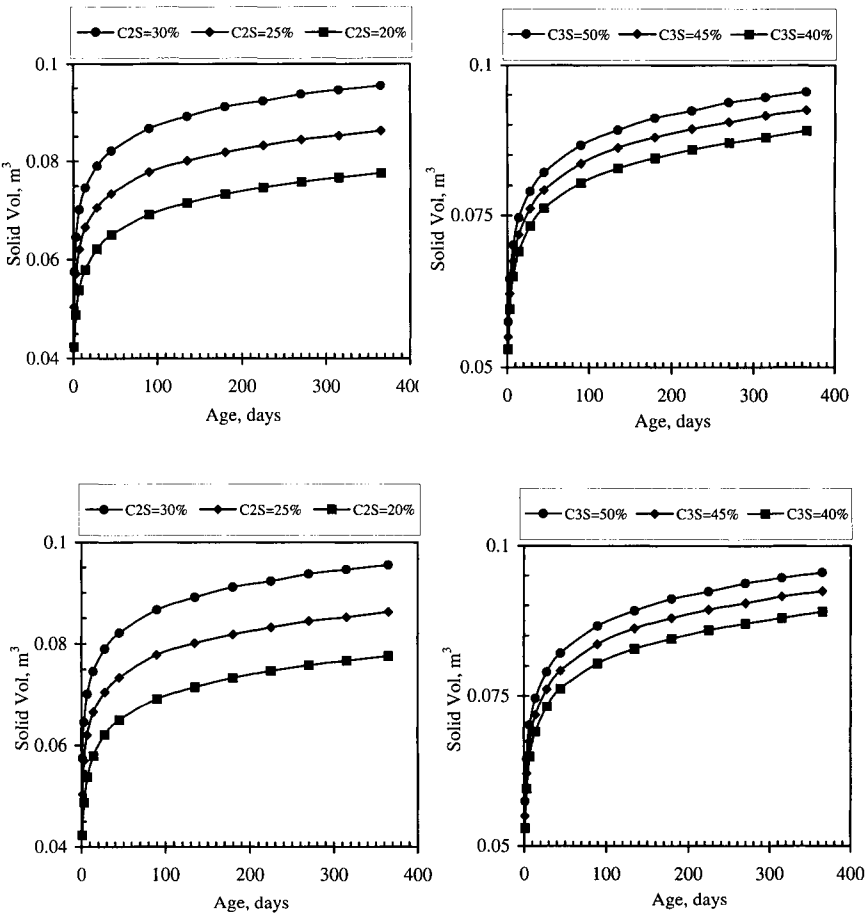

Figure 3. Change in solid volume due to variation in compound composition of cement.

CONCLUSIONS

The quality of calibration and validation of the presented model is found quite satisfactory and the predicted strengths agree closely to the experimental strengths. It has been observed from the performance tests on the model that an increase in SiO_2, CaO and Fe_2O_3 results in increase of strength at all ages and the relationship is quite similar for the three oxides. However, the change in Al_2O_3 content affects the strength in quite a different way. It is further seen that an increase in C_3A content of cement results in decrease of strength at al ages, which is a confirmation of the basic fact of the chemistry of hydration and pozzolanic reactions. The model predictions further confirm that an increase in C_4AF causes increase in the solid volume of hydration and hence in strength of hardened

paste. All the tests and observations confirm the site independence of the model and hence it can be used confidently in designing mixtures incorporating fly ash of variable characteristics.

ABSTRACT

Raw materials such as Ninguo ordinary Portland cement (produced by Anhui province), crushed lime stone, Fengcheng fly ash, mixture additive, etc were used in optimizing the design of mix proportions for slip-form paving cement concrete pavement in Jiangxi provincial national highway 323. Experimental results indicated that these raw materials could fully meet the engineering requirements and the slip-form paving cement concrete had good workability and mechanical properties. And, it was economically reasonable and feasible. This was proved with the achievement of more than 90 kilometers of highway and 20,000m^3 cement concrete. The proposed methods for controlling and adjusting mix proportions are helpful for practical highway construction projects.

KEYWORDS: Slip-form paving, Optimizing design, Mixture proportion, Workability

1. INTRODUCTION

Slip-form paving cement concrete is a special pavement material. Its mix proportions are central to one of the pivotal constructional techniques in ensuring high-performance slip-form paving cement concrete pavements in a high-grade highway. The technical requirements for mix proportions of cement concrete pavement for National Highway 323 are as follows: Firstly, it has suitable workability. The slump of fresh cement concrete is less than 5 cm, and it should match the speed of paving and meet the capacity of mechanical vibration. Secondly, it should have excellent mechanical properties. Bending strength after 28 days is 5.2MPa, and the structural bending strength should not be less than 4.5MPa. Thirdly, it should have good durability. The service life of the slip-form paving cement concrete pavement is required to be 10 years longer than that of an ordinary concrete pavement. Lastly, it should be economically reasonable and feasible. In this study, many attempts have been tried to fulfill the above requirements for highway construction, and a satisfactory result was achieved on a practical project.

2.RAW MATERIAL

The ordinary Portland cement(32.5 degree) was produced by the Ningguo cement works, Anhui province. A middle coarse river sand was employed as fine aggregate while a 531.5mm crushed limestone as coarse aggregate. Fengcheng Class II dry fly ash was used as mineral admixture. The chemical additives were used Type FDN-R water-reducer and Type JS-2 water reducer and retarder, which were produced Hubei and Hunan, respectively.

3. MIXTURE PROPORTION DESIGN

3.1MIXTURE PROPORTIONS

To achieve the mixture proportions for slip-form paving cement concrete it was first necessary to determine its water/cement ratio and sand ratio. There is an empirical formula to calculate water/cement ratio, which designs mixture proportions mainly in terms of bending strength. But the mixture proportion should be adjusted by the accumulated experience. In fact, water to cement ratio has a greater influence on compressive strength on than bending strength to a certain extent. Except for cement type and aggregate factor, cement content is the most significant factor affecting the bending strength of cement concrete. Sand rate of slip-form paving cement concrete is higher than that in ordinary cement concrete, so as to ensure the adhesion and compactness of cement concrete. There is an optimum sand ratio for a specific aggregate and water to cement ratio, with which the best properties of cement concrete can be achieved. According to our experience, when total volume of cement mortar, including cement, water, sand and air void, was 0.55~0.59m^3 in each cubic meter at concrete, the comprehensive properties were much better. Of course, the experimental result was decisive. Based on the engineering demands, the primary mix proportions requirements are shown in table 1.

TABLE 1
TECHNICAL REQIREMENT OF MODIFIED SLIPFORM PAVEING CEMENT CONCRETE NATIONAL HIGHWAY 323

Strength requirement	Setting time	Slump	Workability
Bending strength after 18 days is more than 5.2 MPa	Initial setting time is 6-7 hours and final setting time is 8-10 hours at 20.	The slump of fresh cement concrete was less than 6cm. Constructional slump is more than 2cm.	Excellent adhesion and workability, no weeping

The design of mixture proportions is based on experience based parameter and formulae. In order to agree with the requirements for bending strength and relevant technical properties, experiments were carried out to test and adjust mixture proportions in the lab. The results are showed in table 2.

18	90	45	35	3.00	4.34	5.20	Excellent adhesion, little bleeding

Firstly, workability: the orthogonal test analysis showed that primary factors influencing the slump was the additive and cement content next, and then water to cement ratio.
Secondly, bending strength: the most important factor influencing strength was cement content, water to cement ratio next, and then cement type. Cement content had the greatest influence among them. During the construction of slip-form paving cement concrete, water cement ratio, water content and cement content were strictly controlled. It is important to use a water-reducing agent and air-entraining agent properly. Based on the research results, the constructional mixture proportions were as follows.

TABLE 4
RECOMMENDED MIXTURE PROPORTION

Cement	Fly ash	Water	Sand	Broken stone	Mixture additive.
300	60	151	704	1225	JS-2 4.32

3.3 ADJUST AND CONTROL MIXTURE PROPORTION

Mixture proportion test and adjusting, including workability of fresh mixing cement concrete, air void content, density and strength was done to make these relevant standards meet the requirement.

3.3.1 ADJUST MIXTURE PROPORTION

Firstly, according to the recommended mixture proportion, the feasibility test was conducted, and raw materials, adhesion of the fresh concrete, bleeding and surface status of the concrete were taken into account. The result in table 5 showed that the fresh concrete had good workability.

TABLE 5
TESTING RESULT OF FRESH-MIXING CEMENT CONCRETE

Item	Slump (mm)	Density (kg/m^3)	Air void content (%)	Workability
Initial	60	2390	5.0	Excellent adhesion, little bleeding
1/2h	35	2410	4.3	Excellent adhesion, little bleeding
1h	25	2420	3.9	Excellent adhesion, no bleeding

Secondly, the air void content was determined. The air void content of freshly mixed cement concrete was measured based on Test JTJ 053-94. It agreed with the requirement for freeze-resisting properties as to the air content and met the pavement engineering need. Thirdly, the mixture proportion of freshly mixed cement concrete was adjusted. The mixture proportion test assumed the density method in this study. The density of fresh-mixing cement concrete was 2390 kg/m^3 after vibrating, which was less than designing density. Because of the bleeding, a conversion coefficient was used as follows.

$$\beta=R_1/R_2 2390/2444=0.978 \quad (1)$$

$$ScSd\times\beta \quad (2)$$

Mixture proportions after adjusting are as shown table 6.

TABLE 6
MIXTURE PROPORTION AFTER ADJUSTING

Cement	Fly ash	Water	Sand	Broken stone	Mixture additive
293	59	148	688	1198	JS-2 4.3

Lastly, the bending strength was determined. The beam samples were made based on the relevant standards. In this test, the water content was kept constant, but the water to cement ratio was increased or decreased 0.05, respectively. Two groups of samples were tested for determining bending strength. The results are shown in table 7. Test result agreed to the requirement.

TABLE 7
TEST RESULT OF BENDING STRENGTH

Type	Bending strength after 7 days (MPa)	Bending strength after 28 days (MPa)
W/C = 0.42	5.28	6.40
W/C = 0.47	5.15	6.20
W/C = 0.37	5.50	6.50

3.3.2CONTROL CONSTRUCTIONAL MIXTURE PROPORTION

It is necessary to adjust and control mixture proportion according to ambient temperature, transport distance, raw materials, especially water content of the aggregates, proportion of sand and crushed stone after mixing. The purpose is to ensure mixture proportion parameters fulfill the design

requirements for concrete workability, bending strength and durability.

Firstly, raw materials on site must be tested when they are received. Slip-form paving is mechanized construction as a large scale. During construction, cement, sand, crushed stone and mixture additives are tested regularly. Only qualified material can enter the site. It was necessary to adjust mixture to meet constructional requirements when the quality of qualified material fluctuated. The regular test result of Hailuo P42.5 Portland cement showed that its quality fluctuated only slightly and the properties remained stable. Properties of fly ash were up to standard except for color changes. Water-reducer content varied a little with single mixture additive. The calculation system broke down easily with higher injection of mixture additive. Screening tests indicated that modulus of fine sand and the grading of 5-16mm of crushed stone varied greatly, but other relevant standards qualified.

Secondly, the precision of the mixing system was calibrated regularly. The precision of slip-form paving cement concrete is required to the higher than that of ordinary cement concrete and be calibrated before construction. Measuring error requirements were as follows: cement±1%, fly ash±2%, crushed stone ±2%, water±1% mixture additive±2%. If the measuring error was out of the requirement, the measuring system had to be re-calibrated during construction. If the automatic measuring system broke down, the pavement construction had to be stopped until the breakdown was fixed. When a trial batch was used on the 323-highway construction site, bleeding was found in the pavement. The reason was that the error of the binding material system beyond the requirement limits. The measuring system for chemical additives easily broke down or went out of control for low contents and complex composition. So it was important to test and calibrate that measuring system.

Thirdly, the quantity of the sand, crushed limestone and water were adjusted according to the moisture contents of sand and crushed stone, fineness modulus of sand and gradation of aggregate. Moisture contents of the raw materials varied with weather conditions, locations and exposure time etc., hence, the moisture contents of these materials had to be kept monitored. Sand ratio and fineness modulus differs for different batches. Sand ratio was adjusted when fineness modulus varied obviously. Increasing sand ratio was based on pavement requirement. Sand ratio for slip-form paving cement concrete, fineness modulus, water content of raw material and stone proportions were tested every day before mixing in 323 Engineering. The tests were performed by professional quality inspectors. On the construction site on Highway 323, the mix proportions were adjusted according to slump changes. With these measures, the quality of the pavement was further improved.

Lastly, the mixture proportions were adjusted according to paving conditions on site. The quality of the slip-form paving depends on weather conditions, pavement conditions, concrete delivering distance. So it is necessary to adjust mixing parameters according to paving condition to ensure high-quality of pavement. The 323 Engineering experienced all sorts of strict tests, including high-temperature, long-distance transportation and bad constructional conditions. When the transporting distance was about 18km and the temperature in summer was 47, the slump of cement concrete reduced quickly. In order to improve the slump and to meet the slump requirement of more than 20mm on site, a water-reducing agent was accordingly added. Dense mortar layer on the pavement surface was 2 to 4mm thick. In order to ensure the quality of cement concrete, a finer aggregate was chosen, and the reducing-water agent content was increased and the water content reduced accordingly. Transporting assembly line had to be organized well, avoiding traffic jam and breakdown.

Freshly mixed cement concrete conformed to the requirement for slip-form paving by testing and controlling the constructional mixture proportion. Acceptance quality of the pavement engineering approached a good level and achieved complete success.

4. CONCLUSIONS

4.1 The concrete prepared with Niangua ordinary Portland cement, crushed limestone, Fengcheng class II fly ash and water-reducers was able to meet the requirements for slip-form paving construction in Jiangxi Provincial National Highway 323.

4.2 The cement concrete prepared based on the mixture proportions in table 6 exhibited suitable workability, excellent mechanical properties and economy.

4.3 The mixture proportion designed for the slip-form paving concrete in Highway 323 engineering had been firstly used in slip-form paving construction of Jiangxi Province. These satisfactory results were achieved is proved by the completion of the qualified construction projects including more than 90 kilometers of highway and 20 thousands cubic meters cement concrete.

ADVANCES IN THE STUDY OF FATIGUE BEHAVIOR OF HIGH PERFORMANCE CONCRETE IN CHINA

XIAO Jian-Zhuang and CHEN De-Yin

Department of Building Engineering, Tongji University, Shanghai 200092 P.R. China

ABSTRACT

With the wide application of high performance concrete in civil engineering, in such as high-speed railroads, maglev transrapid, offshore platforms and super high-rise buildings, the fatigue behavior of high performance concrete has had more and more attention by civil engineers. Based on the investigations reported in relevant home references, using the comparative analysis method, the fatigue behavior of high performance concrete is reviewed and the factors affecting fatigue behavior are studied, including fatigue damage mechanism analysis, fatigue failure characteristic and fatigue concept design. Finally some suggestions on the fatigue-resistance of high performance concrete are given.

KEY WORDS

High performance concrete, fatigue test, fatigue behavior, fatigue design, number of cycles, cumulative damage

HIGH PERFORMANCE CONCRETE

Concrete, since the 19th century, has developed rapidly from plain concrete to reinforced concrete, pre-stressed concrete, and special concrete into which additives are added. Although the new members in the family of concrete----high strength concrete and high performance concrete [1], came into use only a few years ago, as they meet the demands of suitable strength and excellent durability in structures, they will be used widely in civil engineering in the future.

FATIGUE PROBLEMS ON STRUCTURES OF HIGH PERFORMANCE CONCRETE

Under repeated load, many structures in civil engineering have collapsed suddenly, in which the stress is less than the design value. This is called fatigue failure [2]. Since World War II, many such accidents have occurred. Before the 1970's, the fatigue problems of concrete structures were not paid so much attention as steel structures. This is because fatigue failure occurred infrequently when the permissible stress method was adopted in structural design. But with the development and wider application of

concrete structures, fatigue damage can not be ignored in some structures under repeated load, especially for some important structures in a condition of high stress, such as high-speed railroads, maglev transrapid, offshore platforms and super high-rise buildings. Therefore, several scholars in China have carried out many tests and conducted research on the fatigue behavior of concrete. It should be pointed out that although high performance concrete or high strength concrete is not mentioned in much literature, as the relevant performance of the concrete used in the tests approaches or reaches the basic behavior of high performance concrete such as high strength, good fluidity, or excellent durability, they can be effectively considered as high performance concrete.

FATIGUE TESTS ON HIGH PERFORMANCE CONCRETE

Different methods are used in classifying fatigue tests. For example, fatigue tests can be classified as low-cycle fatigue tests and high-cycle fatigue tests according to number of cycles. Because the stress level in low-cycle fatigue tests is high, the tests are called fatigue tests under high stress, while high-cycle fatigue tests are called fatigue tests under low stress. Fatigue tests may also be classified as constant-amplitude loading tests and variable-amplitude loading tests [3] which can be sub-classified as one stage constant-amplitude, multi-stage constant-amplitude, incremental stages loading and so on. For this aspect of loading status, the fatigue tests are classified as under compression, tension, flexure, flexure and shear. The main fatigue tests in China in recent years are listed and described in Table 1. Based on those advances in the study of the problems of fatigue performance of high performance concrete nowadays is put forward in this paper.

FACTORS AFFECTING FATIGUE BEHAVIOR OF HIGH PERFORMANCE CONCRETE

Effect of Admixtures

The common mechanism of fatigue failure of concrete is described as follows. There are subtle defects such as subtle cracks, holes, low-strength interfaces or impurities. When the defects are subjected to loading, a stress concentration is produced. Under repeated load, damage emerges and accumulates so much so that structures fail. Fatigue failure is a process of cumulative damage. But adding some special admixtures such as silicon ash, and fly ash and others can reduce initial defects in concrete. The admixtures can prevent cracks from emerging and developing, and the fatigue behavior of the concrete is raised. Another kinds of admixture are fibers, including steel fiber, carbon fiber and polypropylene fiber. These fibers can be included singly or mingled. The fatigue behavior of high strength concrete is improved markedly by mixing proper contents of steel fiber [4]. The reason is obtained easily. Under repeated load, the initial defects in concrete develop into tiny cracks and stress concentrations appear at the tip of tiny cracks. However the cracks are stopped by the intersections with steel fibers. At the same time stress concentration is released by steel fibers. So fatigue behavior is improved. But when the number of cycles increases further, the ability of steel fibers holding cracks is limited so that cracks expand across steel fibers and finally the concrete fails from cumulative damage exceeding the limit value. It is suggested in the test [5] that the compressive strength of steel

fiber concrete under static loading is closed to that of normal strength concrete, but there are obvious differences in fatigue behavior, such as fatigue life. The fatigue life of steel fiber concrete is 7.9-13.7 times that of concrete without steel fibers. It is also proved by the test that steel fiber is effective in aspects of fatigue behavior in reinforced pre-stressed concrete beams [6].

When part of the cement is replaced with silicon ash in high strength concrete [4], variation happens in structures due to the characteristics of the interfacial zone between aggregate and matrix. The effect of silicon ash and fly ash eliminates tropism and enrichment of the crystal of $Ca(OH)_2$. The boundary between interface and matrix blurs and this means the weakness of the interface is alleviated or disappears. So the interfacial bond between aggregate and cement is strengthened and interface failure will be avoided when loading is applied. Thus, the fact that silicon ash has an overall effect on fatigue

behavior can be explained by the reduction in amount and size of the initial cracks.

The following conclusions can be obtained from the comprehensive analysis of test results described in Table 1. There have different effects improving fatigue behavior depending on the different admixtures used. Steel fiber is effective for confining the prolongation of cracks especially, while silicon ash is good at reducing the source of cracks. Carbon fiber has good rigidity with poor toughness and polypropylene fiber is the other way round. Under the same conditions, carbon fiber improves the fatigue behavior of concrete more effectively than polypropylene fiber. But if fiber and silicon ash are intermixed, fatigue behavior is improved greatly because they make full use of their respective advantages and make up for each other's shortcomings. In the test [4], it is suggested that when the number of cycles is the same, high strength concrete in which the same ratio of silicon and steel fiber are mixed can increase 2 times in strength, and when the level of stress is the same, the number of cycles is increased over 10 times. If carbon fiber and polypropylene fiber are mixed together, a superimposed effect exists and fatigue behavior is improved greatly because the polypropylene fiber increases the tenacity of concrete and carbon fiber improves the ability to resist load. When the volume content of carbon fiber and polypropylene fiber reach 0.015 and 0.009 respectively, fatigue life [7] can be increased by up to 10 times that of pure concrete.

Effect of Loading

The effect of loading is referred to as the effect of stress level and sequence of loading. Generally, when its stress level is high, fatigue life is short; and when stress level is low, fatigue life is long. However, there are different opinions about the exact relationship between them. For example, one researcher thinks that single logarithm relationship exists [8], and others think that double logarithm relationship exists [9].

The varieties of fatigue behavior affected by stress level mostly lie in the way of cracks develop and the speed of cumulative damage. When the stress level is low, at the beginning of stage, cracks are few and short. With the cycles increasing, these cracks develop steadily or increase slowly. With a number of cycles increasing further yet, new cracks emerge so much so that structures fail due to new cracks and old cracks intersect and run through. When its stress level is high, at the early stage there are more cracks. With number of cycles increasing further, old cracks develop continuously and new cracks also emerge rapidly. Eventually the cracks intersect and become so wide that the structures fail. As for high strength concrete, it is suggested by the test [10] that under high stress, the fatigue life of high strength concrete is greater than that of normal strength concrete under the same conditions, while under a low stress level, normal strength concrete has a longer life.

The effect of the sequence of variable-amplitude loading on fatigue behavior is different. The loading history in which the early stress level is lower (or higher) and the late stress level is higher (or lower) is often referred to. Different load sequences are mainly attributed to transformation of cumulative damage. According to this idea, controlling the number of early stress level cycles is very important. When the cycles are less than a critical number, the subtle cracks in concrete tend to close back; otherwise the subtle cracks tend to develop. It is inferred from the tests [11, 12] that when the number of cycles at low (or high) stress levels at the early stage is less than the critical number, the surplus fatigue life improves much more than the corresponding life when it only remains in high (or low) stress level.

Relationships Between Admixtures Effects and Loading

The effect of admixtures on fatigue behavior is related to the sequence of loading. This conclusion is obtained from the relationships between the varieties and content of admixtures and the sequences of loading. Fatigue behavior is obviously increased when the proper content is controlled according to various stress levels. Also a critical number for the early stress level exists depending on the various

loading regimes. The critical number is related to the behavior of concrete. It is concluded from the test [7] that when fibers are intermixed, corresponding to a certain stress level, the flexure fatigue behavior is improved as the content increases. In the study [6] on the shear fatigue behavior of concrete with fiber, it is clear that steel fibers are effective in controlling the development of cracks while the function of steel fibers is also related to the cyclic characteristics. In the tests under variable-amplitude loading [11, 12], the low-high loading sequence, fatigue life improves as long as under low stress, the number of cycles do not exceed a critical number. The critical number is different for various concrete. The detailed relationship will need to be studied further. From the above descriptions, it can be deduced that fatigue behavior is affected by the inner characteristics of the concrete and the exterior factors of loading.

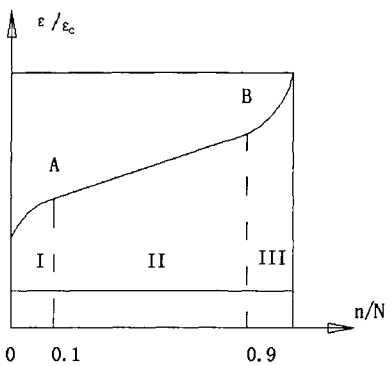

Figure 1: The ideal curve of the three-phrased fatigue deformation development

FATIGUE DEFORMATION OF HIGH PERFORMANCE CONCRETE

Fatigue Deformation Characteristics

First, under repeated load, fatigue failure takes a long time, but at the moment of failure, it is brittle. Moreover the internal force is complex and it is more appropriate to relate fatigue failure with deformation. As for high performance concrete and high strength concrete, when failure happens, the brittleness is obvious and ductility is weak. Second, during the course of cumulative damage, damage is usually measured by deformation and elastic modulus. Finally many tests suggest that the characteristics of fatigue deformation of concrete under repeated load are similar [13]. With stress level and number of cycles increasing, the longitudinal fatigue deformation increases. A three-phased law described by the ideal curve line in Figure 1 has been proposed. In the figure, the phase of deformation develops rapidly before point A and longitudinal strain increases slowly after that. The second phase is the relatively steady phase. This phase also fits the normal working phase of concrete structures under repeated load. The longitudinal strain varies as a linear function as the number of cycles increases. This phase ends of point B. After B, the failure phase is entered. The longitudinal strain increases sharply, develops rapidly and failure occurs.

Criterion of Fatigue Failure

Deformation of concrete under repeated load demonstrates general characteristics and its durability behavior of a concrete structure declines as a result of cumulative damage. Although the final failure has not emerged, the durability has reduced so much that structures are not in a safe condition any longer. Based on this, the deformation due to cumulative damage is looked as the criterion to judge

fatigue failure. This indicates [14] that when the residual strain of high strength concrete reaches 35% longitudinal total strain while the number of cycles is up to 85% of the total number of cycles, high strength concrete has lost the ability to resist repeated load. Under repeated load [6], the failure characteristics for oblique section in beams is that when oblique cracks have appeared under static loading, the strain in the shear-compression zone at the tip of the individual oblique cracks mostly comes up to the ultimate compressive strain.

FATIGUE DESIGN OF HIGH PERFORMANCE CONCRETE

Fatigue design of concrete can be divided into conventional fatigue design and fatigue design based on probability.

Conventional Fatigue Design

The size of the section of members is designed according to static loading and the fatigue check is carried out at the critical points in the section. Based on the requirement for structure design, it is necessary for the structural resistance to be greater than the internal force. The internal force is a function of repeated load, while the resistance of the structure is a function based on the fatigue strength. So in the study of conventional fatigue design, the first thing is to determine fatigue strength. Fatigue strength can be acquired by fatigue tests on the concrete under the basic constant-amplitude repeated load.

The relationship between stress and number of cycles at failure (S-N) needs to be obtained and the fatigue limit diagram needs to be considered to obtain the relationship between the effect of constant-amplitude and variable-amplitude. A series of studies on fatigue behavior of concrete under conditions of tension, compression, flexure, shear, and torsion have been carried out, it is rarely reported that relationships among them are found. The fatigue limit diagram is such a chart [3] that describes the relationship between cyclic loading regimes. From the chart, variable-amplitude loading can be transformed to constant-amplitude loading in order to acquire fatigue strength. However in this field, the studies so far are insufficient and are affected by the randomness of the date. So further study needs to be carried out to obtain the correct fatigue limit curve.

Fatigue Design Based on Probability

Nowadays, although reliability is considered in fatigue design, the design still actually depends on combination of experience and probability. Two problems that need to be solved are for given reliability how to calculate the critical number and for given critical number how the reliability can be checked. Most of the research abroad and at home is mainly focused on the distribution of random variables and the relationship of S-N under certain distributions.

CONCLUSIONS

1) Both similarities and differences are found in the fatigue performance of normal concrete and high performance concrete.
2) The factors affecting fatigue behavior of high performance concrete, including the different varieties and contents of admixtures, are related to certain stress level and the sequence of loading.
3) In the study of fatigue behavior of normal strength concrete, fatigue strength is mostly focused upon. While for high performance concrete, the deformation characteristics can be seen as important and should be investigated under repeated load.
4) Study of the fatigue behavior of high performance concrete should be combined with the research

on its durability.

5) Admixtures, including silicon ash, fly ash, steel fiber, carbon fiber and polypropylene fiber, can enhance the fatigue behavior of high performance concrete. However further study is needed.

HIGH PERFORMANCE POLYMER CONCRETE

R Y Xiao and C S Chin

Department of Civil Engineering, University of Wales Swansea, UK SA2 8PP

ABSTRACT

This paper presents experimental investigation and analysis of high performance polymer concrete (HPP) in which volume fraction of fibres was varied. Test results indicate that both compressive, tensile strength of concrete could be increased with the inclusion of fibre. Moreover, the use of fibres to improve the shear resistance has also been shown to be very effective for beams. HPP fibres have significantly increased the ultimate shear strength of reinforced concrete beam.

KEYWORDS: high performance polymer (HPP); superplasticizer; compressive strength; flexural strength; cylinder splitting strength; shear strength; design formulae.

INTRODUCTION

Cementitious materials in the form of concrete are attractive for use as construction materials since they can be readily molded and complex shapes may be fabricated. Concrete lends itself to a variety of innovative designs as a result of its many desirable properties. Concrete is brittle and weak in tension; these characteristics have limited its use. The development of fibre reinforced concrete has provided a technical basis for improving these deficiencies [(1)].

The main reason for the growing interest in the contribution of fibres in cement-based materials is the desire to increase the tensile properties of the basic matrix. However recent developments made polypropylene fibres the most widely used fibre in concrete, with the UK usage for 1995 estimated at 1000 tonnes. Polypropylene fibre provides a simple effective and economical means, even in small quantities, have dramatic effect on suppression of early cracking and thereby eliminate the main causes of weakness [(2)].

Goldfein [(3)] firstly suggested polypropylene fibres as an admixture to concrete in 1965 for the construction of blast-resistant buildings for the U.S. Corps of Engineers. His work comprised the incorporation of fibres in mortar and neat cement. This research gave the incentive for the early trials on polypropylene film fibre in concrete by Shell International Chemical Co. Ltd. who gave the material the name Caricate [(4)]. For centuries, man has attempted to reinforce concretes with various types of fibres. There are biblical references to the use of straw fibers in the molding of bricks. Later, the Roman Empire used hair fibres in structural mortars. Today, fibres are used in concrete to minimize cracking. Cracking happens in concrete when external stress exceeds strain capacity. By increasing concrete's strain capacity, stresses from intrinsic and external forces can be better managed. Fibre reinforcement redistributes stress in concrete and therefore cracking can be minimized [(5)].

The concept of using traditional steel and polypropylene fibres as reinforcement is not new, it is well known that both flexural and ductility of concrete could be increased with the inclusion of fibre. Moreover, the use of fibres to improve the shear resistance has also been shown to be very effective for beams. Handling steel fibres for concrete mixing may cause construction hazardous while traditional polypropylene fibres tend to form bundles in the concrete mixing if the volume ratio is high which will affect the strength contribution.

These are the reasons why that the new generation of HPP has been designed and produced. This type of fibre has the similar to that of steel fibres and could also be bent and has dents on its surface. Clearly, this will increase its workability in the concrete also improve its bond strength with the mortar of concrete. HPP fibre is extruded from 100% virgin polypropylene and mechanically deformed in a proprietary shape to maximize anchorage for reinforcement in cementitious composites. S-152 High Performance Polymer fibre is manufactured as a coarse filament with an engineered contoured profile. HPP fibre, because of the low modulus, provides good toughness response for large crack openings. Typical relevant properties of HPP fibres are shown in Table 1 [5].

Water Absorption	0

RESEARCH SIGNIFICANCE

The research reported in this paper shows the effect of HPP fibres in improving the compressive strength, tensile strength and shear capacity of concrete. The test results obtained prove that HPP fibre could improve material properties and clearly increase the shear strength of the reinforced concrete beams Combination of minimum links and fibre reinforcement forms an effective system of shear reinforcement in a structural member. Experimental results suggest a simple means of predicting the flexure, cylinder splitting strength, and ultimate shear strength of fibre reinforced concrete beam. The paper presents useful data on material properties of fibre reinforced concrete, particularly for test data separating fibre contents.

TEST PROGRAM

Ordinary Portland cement, HPP fibres, crushed gravel with maximum size of 6mm coarse aggregate, beach sand and tap water were mixed to make the concrete. The specimens were cast from two different mixes. Mix A had cement: water: sand: coarse aggregate (6mm) ratio of 1: 0.52: 1.83: 3.25 and Mix B had a cement: water: sand: coarse (6mm) aggregate ratio of 1:0.51: 1.61: 2.57. A variety of mixers have been used in practice, some requiring an adjustment to the existing equipment, some none at all. Previous research has shown that he tumble form of mixer is a good way of mixing the fibres. The absence of blades in the tumble mixer helped to ensure good fibre distribution in the mixture. The aggregates, sand, and cement were added with water and mixed for three minutes. The polypropylene fibres were then evenly sprinkled over the surface, and mixing resumed for three minutes. Finally, superplaticizers were poured to the mix without pre-mixed with other admixtures.

6 non-reinforced beams (100 x 100 x 500mm), 48 cubes (6 x 6 x 6in), 10 cylinders (6 x 12in) and 12 reinforced beams (120 x 150 x 1000mm) were cast from each batch of mix. All specimens

were cast perpendicular to the testing direction were then removed from the molds and stored in air at room temperature after 24 hours until testing at 30 days of age.

PRESENTATION OF TEST RESULTS

TABLE 2
RESULTS OF CUBE, CYLINDER AND BEAM TESTS

Beams	Fibres content	Web steel	Concrete strength			First shear crack strength	Ultimate shear strength
			Compressive strength	Cylinder splitting tensile strength	Modulus of rupture		
	%		N/mm^2	N/mm^2	N/mm^2	N/mm^2	N/mm^2

Compressive Strength

Nine cubes had no fibres and twenty-seven cubes had HPP fibres of varying amount (0.8%, 1.0%, 1.2%) were cast to make more effective comparison between plain concrete and fibrous concrete reinforced by HPP fibres. Three cubes were tested for each batch of mixes to obtained the average value. The compressive strength increase with the percentage of fibres but there is a drop in compressive strength as percentage of fibres is over 1%; however the figure shows that the compressive strength is still higher than that of plain concrete. This can be concluded that HPP fibres have increased the compressive strength of concrete. The results from the cube crushing tests are shown in Table 2.

Flexural Strength

The flexural strength for fibrous concrete that contained 0.8 per cent of HPP fibres is slightly lower than that plain concrete. This applied to flexural test for both Mix Type A and B. However the flexural strength is increased when 1.0 and 1.2 per cent of HPP fibres were added. The flexural strength increased to a maximum value of 30% for beam that contained 1.2 per cent of HPP fibres. The failure pattern of the samples highlighted the benefit of inclusion of fibres. The plain sample failed with a sudden brittle where as the fibrous samples failed in more ductile manner.

Cylinder Splitting Strength

The cylinder splitting strength is increased by 20% when 0.8 per cent of HPP fibres were added to the mix. But the splitting strength is decrease when more than 0.8 per cent of HPP fibres were added. The splitting strength for cylinder that contained 1.0 and 1.2 per cent of HPP fibres became close to the plain cylinder. This may be explained that 0.8 per cent of HPP fibres had increased the splitting strength to the maximum value of 20%. The failure pattern of the samples that were similar to the samples used in flexural beam tests again highlighted the properties of fibrous concrete. The test results can be seen in Table 2.

RELATIONSHIP BETWEEN COMPRESSIVE AND TENSILE STRENGTH

The compressive strength of concrete is its property commonly considered in structural design but for some purposes the tensile strength is of interest [6]. It is possible to form an empirical relationship between the compressive strength and the tensile strength of the concrete. The relationship however is not directly proportional because as the compressive strength increases the tensile strength increases at different rate. A number of ratios have been suggested but they are all subjected to variation by a number of factors. As the tensile strength is so small it is much more sensitive to variation in constituents and production. The amount of fine and coarse aggregate and the overall grading of the aggregate can also affect the ratio.

Eight cylinders and four beams of different fibre contents have been tested. The test results obtained from the flexure and cylinder splitting tension test suggest two empirical relationship between compressive and indirect tensile strength of the fibrous concrete as follows:

$$f_t = 0.21 * (f_{cu})^{2/3} * \left(\frac{1}{V_f}\right)^{0.45} \quad (1) \qquad f_f = 0.398 * (f_{cu})^{2/3} * V_f^{0.85} \quad (2)$$

where f_f = Flexure strength of fibrous concrete, N/mm^2
f_t = Cylinder splitting strength of fibrous concrete, N/mm^2
f_{cu} = Characteristic strength of fibrous concrete, N/mm^2
V_f = Percentage of fibres added into the mix, %

Figure 1: Relation between tensile strength and compressive strength and percentage of fibres

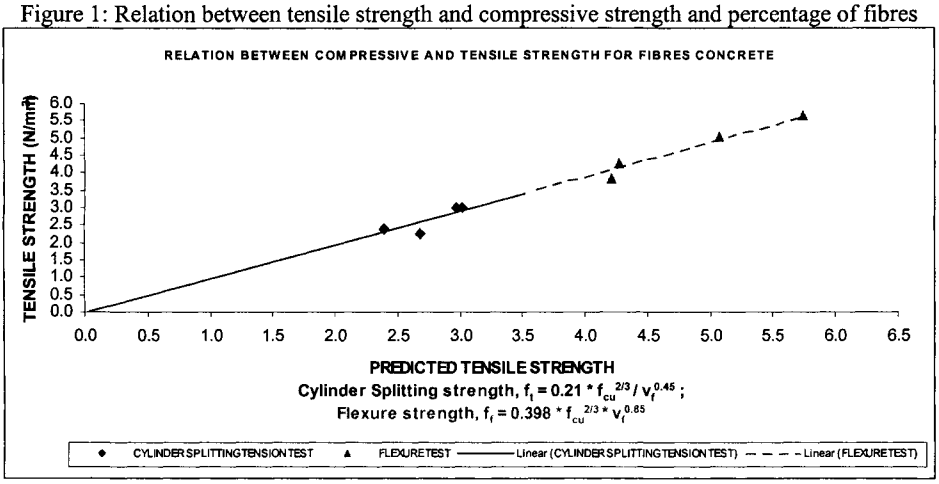

Figure 1 shows good straight-line correlation between the tensile strength obtained from both flexure and cylinder splitting tension test and the suggested equation stated above. The comparison between test results and predicted strength using equation (1) and (2) are shown in Table 3.

PREDICTION OF ULTIMATE SHEAR STRENGTH

As Ref. [9], the development of a general simple formula to predict the shear strength of fibres reinforced concrete beams is critical to the successful application of fibres as shear reinforcement in practice. However, from the test results reported here, it appears that the splitting tensile and the flexural strength are the important material parameters that reflect the ultimate shear strength.

From the previous report [9], parameters that influence the ultimate shear strength other than flexure and splitting strength are the shear span-effective depth ratio and the reinforcement ratio. It is not possible to include the effect of beam size in this formula because all tests were on a single beam size. However, computational studies seem to indicate similar shear strength predicted when beams of different size scale were entered. But, ultimate shear strength reduces with the beam size particularly the beam depth; that is, larger beams are proportionately weaker than smaller beam [8]. If so, an additional factor indicating dependence on effective depth of the beam must be included. Thus, the shear strength of a fibre reinforced concrete beam are expressed as:

$$f_v = (0.368) * (f_f * f_t)^{5/6} * \left(\frac{1000 * A_s}{b_v * a_v * d^{0.6}} \right)^{1/3} \qquad (3)$$

where f_v = Predicted ultimate shear strength of fibre reinforced concrete beam;
f_f = Flexure strength of fibrous concrete, N/mm^2;
f_t = Cylinder splitting tensile strength, N/mm^2;
A_s = Area of tension steel provided, mm^2;
b_v = Width of the beam, mm;

a_v = Shear span, mm;

As proposed by Sharma [10], the ultimate shear strength of a fibres reinforced concrete beam with web reinforcement can be expressed as

$$v_{nf} = f_v + f_s \tag{4}$$

where v_{nf} = Nominal shear strength of fibres reinforced concrete section in combined bending and shear, N/mm^2;

f_v = Ultimate shear strength of the fibrous concrete, N/mm^2;

f_s = Shear strength due to web reinforcement, N/mm^2.

Shear strength due to web reinforcement f_s can be evaluated by using equation (5) as proposed in BS 8110 [11],

$$f_s = \left(\frac{0.95 * f_{yv}}{b_v}\right) * \left(\frac{A_{sv}}{S_v}\right) \tag{5}$$

where f_{yv} = Characteristic strength of links

b_v = Breadth of the section, mm;

A_{sv} = Total cross-section of links at the neutral axis, at a section, mm^2;

S_v = Spacing of links along the member, mm.

Figure 2 shows good straight-line correlation between the ultimate shear strength and the predicted ultimate shear strength through the origin. To show that equation (3) give a reasonable estimate of the ultimate shear strength of fibres reinforced concrete beams, results from this investigation are compared in Table 4. All the beams with fibres reinforcement are used in the correlation. The ratio of experimental to predicted shear strength is calculated. There is a definite trend, as shown in Table 4, that fibres reinforcement in beams increase the ultimate shear strength of beams

Figure 2: Relationship between ultimate shear strength and material and geometrical properties. (Unit for horizontal axis are in $N^{5/3} / mm^{2/3}$)

CONCLUSIONS

From the experimental observations reported in this paper, the following conclusions can be drawn:

1) Polypropylene fibres (S-152) are effectively in increasing the compressive, tensile, and shear capacity of concrete.
2) Flexural strength increased with fibre percentage, as there was a 30 per cent increase in tensile strength for the 1.2 per cent fibres beam while the splitting tension test has a 20 per cent increase in tensile strength with the 0.8 per cent HPP fibres cylinder but decrease in tensile strength was observed with the 1.0 and 1.2 per cent fibres cylinder. The increase in splitting strength with fibre percentage however was less well defined. Anyway, the failure pattern of the all the samples highlighted the benefit of the inclusion of HPP fibres. The plain sample failed with a sudden brittle failure where as the fibrous samples failed in more ductile manner. This shows that HPP fibres can reduce crack widths and prevent brittle failure of concrete. The results from both tests were used to generate empirical formulae, relating the compressive and tensile strengths of the fibrous concrete.
3) However, HPP fibres have significantly increased the ultimate shear strength of reinforced concrete beam. As reported by Sharma [11], for a practical solution, tests have shown that a combination of minimum links and HPP fibre forms an effective system of shear reinforcement in a structural member. With these combinations, HPP fibres have changed the failure mode of the specimen beams from shear to flexure failure. Fibres reinforced concrete beams have more ductility and significant amount of energy absorption than normally reinforced concrete beams. The presences of polypropylene fibres (S-152) in concrete restrict propagation of cracks and allow more uniform cracking. Reasonable estimation shear strength of HPP fibres reinforced concrete beams can be made by using the semi empirical equation derived.

ABSTRACT

A new type of solidified material mainly composed of phosphogypsum, fly ash and lime was prepared in this study. Its mix proportions were optimized. The test results suggested that the ratio of phosphogypsum and fly ash at 1 : 1 and the content of the lime solidified material 6~8% was the optimum mix proportion. This kind of solidified material could be used as road base course material when its compacting ratio is 93~96%. It could also be used as sub-base material when its compacting ratio is around 93%. Crushed stone stabilized with it could be used as road base material. The microstructure of this kind of materials was observed with SEM and the mechanism of strength formation is discussed.

KEYWORDS: Phosphogypsum, Fly ash, Solidified material, Road base

1. INTRODUCTION

Recycling of solid waste is significant to sustainable development. Phosphogypsum and fly ash are the vital solid waste sources in China. Large amounts of them are left without treatment. The lime-fly ash road base material has been widely used in China. But its early age strength was very low [1,2], and this limited its extensive usage. The development of a new type of solidified material is described in this study. The solidified material is mainly composed of phosphogypsum, fly ash and lime. Its strength at early age was much higher than that of the ordinary lime-fly ash road base materials. It can be used as road base material and sub-base material. It can also be used as road base filling material. When stabilized with crushed rock it can be used as road base material.

2 MATERIALS AND TEST METHODS

2.1 MATERIALS

Phosphogypsum was obtained from Xianfan Liming Chemistry Ltd and the fly-ash from Xiangfan lignite power station. The stabilizer was made of lime and 10% of additive. The crushed rock was obtained from Xianshan stone plant, Xangfan, Hubei province.

TABLE 1:CHEMICAL AND MINERALOGICAL COMPOSITIONS OF THE RAW MATERIALS (w%)

materials	chemical composition

Notes: PG-phosphogypsum; FA-fly ash; ST-stabilizer

2.2 TEST METHODS

Tamping test of phosphogypsum-fly ash-lime solidified material was carried out conforming to the specifications of test method T0804-94, which was published by the Ministry of Communication of China. The unconfined compressive strength was carried out conforming to test method T0804-94. The phosphogypsum-fly ash-lime solidified material was shaped within a $\Phi 5.0\times5.0cm^3$ mould while the phosphogypsum-fly ash-lime solidified material stabilized crushed rock was shaped within a $\Phi 10\times10cm^3$ mould.

3 RESULT AND DISCUSSION

The effect of the composition of phosphogypsum-fly ash-lime solidified material on the dry density and strength of the solidified material was studied. And the suitable mixture proportions of phosphogypsum-fly ash-Lime solidified material were optimized by means of the 7 days strength. By providing silica and calcium oxide respectively, fly ash and lime also play an important role in the solidified material. In this paper it described how the crushed rock stabilized with phosphogypsum-fly ash-lime solidified material was prepared as road base material.

3.1 THE PROPORTION OF THE PHOSPHOGYPSUM-FLY ASH-LIME SOLIDIFIED MATERIAL

In this test the effect of mix proportions and the influence of stabilizer on the strength of phosphogypsum-fly ash-lime solidified material was studied. The content of stabilizer varied from 4:96 to 10:90. The testing cylinder was made with compactness ratio of 96%. The phosphogypsum-fly ash-lime solidified material was stabilized with ashed lime stabilizer, slaked lime on quick lime. The strength and maximum dry density of phosphogypsum-fly ash-lime solidified material with different proportions are listed in table 2.

TABLE 2: MIX PROPORTION TEST OF PG-FA-QL SOLIDIFIED MATERIAL

No	ST : PG : FA	γ_{dm}(g/cm^3)	W_{pt}(%)	R_{7d}(MPa)
1-1	8 : 20 : 72	1.401	18.34	2.56
1-2	8 : 30 : 62	1.446	17.62	2.76
1-3	8 : 40 : 52	1.464	16.35	3.13
1-4	8 : 50 : 42	1.487	16.21	3.24
1-5	8 : 60 : 32	1.491	16.21	3.19
1-6	8 : 70 : 22	1.498	15.76	3.10
1-7	8 : 80 : 12	1.493	14.91	3.04
1-8	4 : 50 : 46	1.487	16.21	2.01
1-9	6 : 50 : 44	1.487	16.21	2.76
1-10	10 : 50 : 40	1.487	16.21	2.65
*1-11	8 : 0 : 92	1.312	19.30	0.90

Notes: ST-stabilizer; *: ST is slaked lime; +: ST is quicklime; γ_{dm}-Maximum dry density Notes; W_{pt}-Optimum water content; R_{7d} is compressive strength

Table 2 show that the maximum dry density of the phosphogypsum-fly ash-lime solidified material increased with the increase of the phosphogypsum content since the phosphogypsum has a density higher than that of the fly ash. When the ratio of fly ash and phosphogypsum was about 1:1, the phosphogypsum-fly ash-lime solidified material had the highest strength. When the stabilizer content of phosphogypsum-fly ash-lime solidified material was about 6% the solidified material obtained the highest strength. From the results we can preliminarily concluded that the suitable proportion is the ratio of fly ash and phosphogypsum of about 1:1 and the stabilizer content about 8~9%.

3.2 COMPACTNESS RATIO OF THE PHOSPHOGYPSUM-FLY ASH-LIME SOLIDIFIED MATERIAL

The phosphogypsum-fly ash-lime solidified material is a material with high porosity. The porosity was dependent on the forming pressure and compacting work while the products (specimens) were made. Porosity can govern the properties of the materials, especially affecting material strength. High porosity will result in low material strength, whereas decreasing porosity can enhance material strength. The cylindrical specimens of this study were compacted to the compactness ratio of 93% and 96%. The strengths at 7 and 28 days are listed in table 3.

TABLE 3: PG-FA-QL SOLIDIED MATERIAL'S COMPRESSIVE STRENGTH AT DIFFERDNT COMPACTION RATIO

No	ST : PG : FA	93% compaction ratio	96% compaction ratio
		R_{7d}/R_{28d}(Mpa)	R_{7d}/R_{28d}(MPa)
2-1	8 : 30 : 62	1.57/2.21	2.76/3.75
2-2	8 : 40 : 52	1.89/2.34	3.13/4.97
2-3	8 : 50 : 42	2.04/2.85	3.24/4.86
2-4	8 : 60 : 32	1.97/2.67	3.19/4.51

Table 3 shows that the strength of the phosphogypsum-fly ash-lime solidified material with the compactness ratio of 96% had a much higher strength than that with the compactness ratio of 93%. This strength is satisfactory when the material is used as road base material or sub-base material. If the compactness ratio of the phosphogypsum-fly ash-lime solidified material is below 93%, it can only be used as road base filling material.

3.3 PHOSPHOGYPSUM-FLY ASH-LIME SOLIDIFIED MATERIAL STABILIZED CRUSHED ROCK

The base course material of high grade road must have a great deal of aggregate as framework. we use the phosphogypsum-fly ash-lime solidified material to stabilize crushed rock. The compactness ratio was 98%. The test result of the strength is listed in table 4.

TABLE 4: COMPRESSIVE STRENGTH OF CRUSHED ROCK STABILIZED BY ST-PG-FA MATERIAL AND LIME FLY ASH

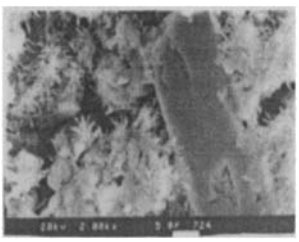
No	Mix proportion ST : FA : PG : CS	γ_{md}/(g/cm^3)	W_{pt}/ (%)	R_{7d}/ (MPa)	Cv/ (%)
3-1*	5 : 30 : 65	1.880	9.90	0.823	5.81
3-2+	5 : 30 : 65	1.885	9.90	0.995	3.88
3-3	5 : 30 : 65	1.885	9.90	1.100	7.82
3-4	5 : 10 : 20 : 65	1.887	9.50	1.200	5.38
3-5	5 : 15 : 15 : 65	1.890	9.40	1.480	8.84
3-6	5 : 20 : 10 : 65	1.891	9.30	1.680	6.85

Notes: ST-stabilizer; *: ST is slaked lime; +: ST is quicklime;
γ_{dm}-Maximum dry density Notes; W_{pt}-Optimum water content

The strength of the phosphogypsum-fly ash-lime solidified material stabilized crushed rock was about 40~100% higher than that of the lime-fly ash stabilized crushed rock. The strength of this material is about the range of the standard of "Lime-Fly ash Solidified Materials" of Ministry of Communication of China. Hence, it can be used as road base material for various grades of highway.

3.4 THE MECHANISM OF STENGTH FORMATION

When the lime was added into fly ash, the pozzolana reaction took place. The reaction can be qualitatively described as fellow [3].



$$xCa(OH)_2+SiO_2+nH_2O \rightarrow xCaO\cdot SiO_2\cdot (n+x)H_2O$$

$$yCa(OH)_2+Al_2O_3+nH_2O \rightarrow yCaO\cdot Al_2O_3\cdot (n+y)H_2O$$

When there is plenty of phosphogypsum ($Ca_2SO_4.2H_2O$), the product $yCaO\cdot Al_2O_3\cdot (n+y)H_2O$ was substituted by AFt. The phosphogypsum hastened the pozzolana reaction also. So the strength of the phosphogypsum-fly ash-lime solidified material is much higher than that of the lime-fly ash road base material[4].

$$3Ca(OH)_2+Al_2O_3+3CaSO_4\cdot 2H_2O+26H_2O\rightarrow 3CaO\cdot Al_2O_3\cdot 3CaSO_4\cdot 32H_2O$$

The SEM images of the phosphogypsum-fly ash-lime solidified material show the microstructure of material and the crystal of phosphogypsum.

a. MICROSTRUCTURE OF MATERIAL

b. FLAKY CRYSTAL OF PHOSPHOGYPSUM

Fig 1: SEM PICTUREOF 28d PG-FA-QL BINDER

The phosphogypsum-fly ash-lime solidified material is a material with a large number of pores. The morphology of the phosphogypsum is flake-like crystal[1] while AFt is needle-like crystal[5], according to the SEM images. The fractional force between phosphogypsum grains is larger than that between fly ash grains. This also contributed to the strength formation also.

4 SUMMARY AND CONCLUSIONS

A suitable proportion for the phosphogypsum-fly ash-lime solidified material was a ratio of fly ash to phosphogypsum at 1:1 and a stabilizer content was about 8~9%.

The strength of the phosphogypsum-Fly Ash-Lime Solidified Material with a compactness ratio of 96% had a much higher strength than that with a compactness ratio of 93%. A 96% one can be used as road base material or sub-base material. Materials with a compactness ratio of 93% and below can only be used as road base filling material.

The strength of the phosphogypsum-fly ash-lime solidified material stabilized crushed rock was about 40~100% higher than that of lime-fly ash stabilized crushed rock. This strength reached the required range of lime-fly ash solidified materials of the standard of the Ministry Communication of China. Hence, it can be used as road base material for various grades of highway.

When there is sufficient plenty phosphogypsum($Ca_2SO_4.2H_2O$), the product of $yCaO\cdot Al_2O_3\cdot (n+y)H_2O$ was substituted by AFt. The phosphogypsum hastens the pozzolanic reaction also. So the strength of the phosphogypsum-fly ash-lime solidified material was much higher than the lime fly-ash road base material. The fractional force between phosphogypsum grains is also larger than that between the fly ash grains. This also contributed to the strength formation.

ON THE LOCAL OPTIMAL CONTROL COUNTERFORCES IN ACTIVE CONTROLLED STRUCTURES

N.D. Anh[1], L.D.Viet[2]

[1] Institute of Mechanics, 264 Doi can, Hanoi, Vietnam

ABSTRACT

The paper presents a so called local feedback-feedforward control law to find local optimal magnitude and location of control counterforces to reduce undesired vibrations in active controlled structures. Using information on state response and a part of external excitations, the counterforces are applied to structures in such a way to minimize the local performance index. Numerical simulations are carried out for a two-degree-of-freedom structural system. The comparison between performance indexes shows the effectiveness of local feedback-feedforward control to the classical linear quadratic regulator control.

KEYWORD: *Structural Control, Local Optimal Feedback-Feedforward Control, Local Optimal Location of Counterforces.*

1. INTRODUCTION

In recent years much progress and new concepts have been achieved in the development of structural control in reducing the response during excessive vibrations due to environmental disturbances, see, for example, [5-8, 11,12]. Since the objective is to reduce the structural response due to external disturbances, one may expect that the control problem would be more simplified if both structural response variables and external disturbances could be measured during structural motion. But, in many practical situations, one is unable to measure the external excitation while the structural response can often be measured. Many new and interesting control strategies and concepts have been proposed to overcome this difficulty, see, for example, [1-4, 9-10, 13]. The control of structure motions can be done by various means. Among them active control [14] is one of promise aspects which uses the control counterforces produced by actuators to balance or reduce the energy of the environmental loading. There are some basic problems in the active control such as control law, magnitude and location of the control counterforces. The latter problem is investigated in the paper. Some components of the external excitation are assumed to be known. The problem identifying external excitations will be investigated latter by using identification algorithm [1]. Using information on state response and a part of external excitations, the counterforces are applied to structures in such a way to minimize the so called local performance

index. Numerical simulations are carried out for a two-degree-of-freedom structural system and show the effectiveness of local feedback-feedforward control to the classical linear quadratic regulator control.

2. GLOBAL OPTIMAL FEEDBACK-FEEDFORWARD CONTROL

Suppose that the controlled structure is modeled by a multi-degree-of-freedom system, whose state equation is described in the form

$$\begin{cases} \dot{z}(t) = Az(t) + Bu(t) + Hf(t), \\ z(0) = z_0, \end{cases} \tag{1}$$

where $z(t) = [x(t) \quad \dot{x}(t)]^T$ is the 2n-dimensional state vector, the superscript ^{T} indicates vector or matrix transpose, A is the 2n × 2n system matrix, u(t) is the m-dimensional control force vector, f(t) is an r-vector representing external excitation, B and H are 2n × m and 2n × r location matrices specifying the locations of controllers and external excitations in the state-space, respectively. The control force u(t) is to be chosen in such a way that a global performance index J, defined as

$$J = \int_0^{t_f} [z^T(t)Qz(t) + u^T(t)Ru(t)]dt, \tag{2}$$

is minimized. In the above, the time interval $[0,t_f]$ is defined to be longer than that of the external excitation, Q and R are weighting matrices, Q is a 2n×2n positive semi-definite matrix and R is a mxm positive definite matrix. Their magnitude depends on the relative importance attached to the state variables and to the control forces in the minimization procedure. The global feedback-feedforward control law is taken as [11]

$$u(t) = G_z z(t) - R^{-1}B^T p(t) \tag{3}$$

where G_z is determined as

$$G_z = -R^{-1}B^T P \tag{4}$$

P is a solution of the Riccati equation

$$PA - PBR^{-1}B^T P + A^T P + Q = 0 \tag{5}$$

and p(t) is determined from the differential equation

$$\begin{cases} \dot{p}(t) - (PBR^{-1}B^T - A^T)p(t) + PHf(t) = 0, \\ p(t_f) = 0 \end{cases} \tag{6}$$

It is seen from (3), (6) that the control law requires the full knowledge of state response and the excitation force. Thus, the control is called as global FB-FW control.

3. LOCAL OPTIMAL FEEDBACK-FEEDFORWARD CONTROL

The full knowledge of state response and excitation force required in global FB-FW control may be unrealized in practical application to large structures. For that purpose consider so called local FB-FW control problems in each of which a local optimal control force is to be determined for one excitation force component, $f_i(t)$. Denote

$$u(t) = \sum_{j=0}^{r} u^j(t), \tag{7}$$

$$z(t) = \sum_{j=0}^{r} z^j(t), \tag{8}$$

where z^0 and z^i, i=1,2,..,r, are 2n-dimensional vectors, which satisfy the differential equations, respectively,

$$\begin{cases} \dot{z}^0(t) = Az^0(t) + Bu^0(t), \\ z^0(0) = z_0, \end{cases} \tag{9}$$

$$\begin{cases} \dot{z}^i(t) = Az^i(t) + Bu^i(t) + H_i f_i(t), \\ z^i(0) = 0 \end{cases} \tag{10}$$

where H_i is the ith column vector of matrix H. The local optimal control forces $u^j(t)$, j =0,1,..r, are chosen to minimize the local performance indexes

$$J_j = \int_0^{t_f} [z^{jT}(t)Qz^j(t) + u^{jT}(t)Ru^j(t)]dt. \tag{11}$$

Thus, the local optimal control forces are determined as

$$u^0(t) = G_z z^0(t) \tag{12}$$

$$u^i(t) = G_z z^i(t) + G_i f_i(t) \qquad (i=1,2..r) \tag{13}$$

where G_z is found from (4), G_i are column vectors which will be determined latter. Substituting (13) into (10) yields

$$z^i(t) = \int_0^t exp[(A + BG_z)(t-s)](BG_i + H_i) f_i(s)ds. \tag{14}$$

Denote

$$T_i(t) = \int_0^t exp[(A + BG_z)(t-s)]Bf_i(s)ds, \tag{15}$$

$$V_i(t) = \int_0^t exp[(A + BG_z)(t-s)]H_i f_i(s)ds. \tag{16}$$

Thus, one gets

$$z^i(t) = T_i(t)\, G_i + V_i(t). \tag{17}$$

Substituting (17) into (13) yields

$$u^i(t) = [G_z\, T_i(t) + If_i(t)]G_i + G_z V_i(t) \tag{18}$$

where I denote the m × m identity matrix. Substituting (17) and (18) into (11) gives

$$\begin{aligned} J_i = & \int_0^{t_f} (G_i^T T_i^T + V_i^T) Q (T_i G_i + V_i)\, dt + \\ & \int_0^{t_f} [G_i^T (G_z T_i + If_i)^T + (G_z V_i)^T] R [(G_z T_i + If_i) G_i + G_z V_i]\, dt \end{aligned} \tag{19}$$

The necessary condition for minimum of J_i is

$$\frac{\partial J_i}{\partial G_i} = 0 \tag{20}$$

or,

$$2\int_0^{t_f} \{(G_i^T T_i^T + V_i^T) Q T_i + [G_i^T (G_z T_i + If_i)^T + (G_z V_i)^T] R (G_z T_i + If_i)\} dt = 0 \tag{21}$$

Denote:

$$S_i = \int_0^{t_f} [T_i^T Q T_i + (G_z T_i + If_i)^T R (G_z T_i + If_i)]\, dt \tag{22}$$

$$W_i = \int_0^{t_f} [V_i^T Q T_i + (G_z V_i)^T R (G_z T_i + If_i)]\, dt \tag{23}$$

Using (21)-(23), one has

$$G_i = -((S_i)^{-1})^T W_i^T \tag{24}$$

Thus, the local optimal feedback-feedforward control law is determined as (4), (7), (12), (13), (15), (16), (22)-(24) with the corresponding performance index

$$J_L = \int_0^{t_f} [(\sum_{j=0}^{r} z^{j^T}(t)) Q (\sum_{j=0}^{r} z^j(t)) + \sum_{j=0}^{r} (u^{j^T}(t)) R (\sum_{j=0}^{r} u^j(t))]\, dt. \tag{25}$$

The effectiveness of the local optimal feedback-feedforward control proposed above will be illustrated in the next section.

4. NUMERICAL SIMULATION

Consider a model in Fig.1 taken from Soong [11]

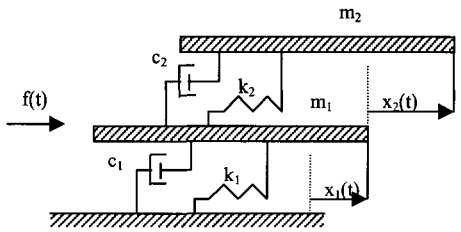

Fig.1. Two-degree-of-freedom structural system

The state equation of uncontrolled two-story structural system has the form

$$\dot{z}(t) = Az(t) + Hf(t)$$

where

$$z(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ x_4(t) \end{bmatrix}, A = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -0.5 & 0.25 & -0.02 & 0.01 \\ 0.25 & -0.25 & 0.01 & -0.01 \end{bmatrix}, H = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}$$

$x_1(t)$ is the relative displacement of the first floor with respect to foundation and $x_2(t)$ is the relative displacement of the second floor with respect to first floor. A wind-type excitation is expressed by

$$f(t) = \begin{bmatrix} 10 \\ 3 \end{bmatrix} \sin \omega t + \begin{bmatrix} 1 \\ 5 \end{bmatrix} \sin 2\omega t + \begin{bmatrix} 1 \\ 7 \end{bmatrix} \sin 3\omega t + \begin{bmatrix} 1 \\ 4 \end{bmatrix} \sin 4\omega t$$

where ω = 0.309. This value of ω is close to the first frequency of the structure. The first component of the external excitation is assumed to be known. The time duration of action of the external excitation is T=[0,50]. The control to be applied to the structure is assumed to be of the form Bu(t), where u(t) is a scalar. Two cases are considered:
Case A: B^T=[0,0,1,0], control applied at first floor only
Case B: B^T=[0,0,0,1], control applied at second floor only
The weighting matrices are chosen as:

$$Q = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, R = 100$$

Three methods are used to control:
- LQR control
- Local Feedback-feedforward control (LFB-FF)
- Global Feedback-feedforward control (GFB-FF)

In case A and B, counterforces are scalars. Because only the first component of the external excitation is known, so the values of matrix G_z and column vector G_1 are:

$$Case\,A: \quad G_z = [-0.0316 \quad -0.0057 \quad -0.2404 \quad -0.2143], G_1 = [-0.6578]$$

$$Case\,B: \quad G_z = [0.0044 \quad -0.0449 \quad -0.0920 \quad -0.2929], G_1 = [-0.5519]$$

The histories of relative displacements are shown from Fig.2 to Fig.4. The maxima of relative displacements and counterforces, the performance indexes J are compared in Table 1.

TABLE 1
MAXIMUM RESPONSE AND MAXIMUM COUNTERFORCE

		Counterforce	1st floor displacement	2nd floor displacement	Performance index ($\times 10^5$)
Uncontrolled			332.07	515.58	34
Case A	LQR	16.19	96.64	134.53	8.132
	LFB-FF	15.74	66.97	85.97	6.39
	GFB-FF	15.8	40.12	58.86	5.156
Case B	LQR	13.25	83.17	91.69	4.436
	LFB-FF	13.03	58.98	51.48	3.132
	GFB-FF	9.42	46.51	39.52	2.375

From Table 1, in comparison between performance indexes, one can see that local FB-FF control proposed is more efficient than LQR control. We also note that, because equation (6) is solved backwards from the terminal time t_f then control force of global FB-FF control is not equal zero at initial time. So, although global FB-FF control has the least performance index but it is infeasible in many structural control situations. Besides, in comparison between case A and case B, the counterforce in case A is larger than in case B but the displacements in case A are larger than case B. So, it is more efficient to place the controller on the second floor than on the first. It is noted that when f(t)=0, the solution of local feedback-feedforward control will return the solution of LQR control. So, LFB-FF control is more general than LQR control.

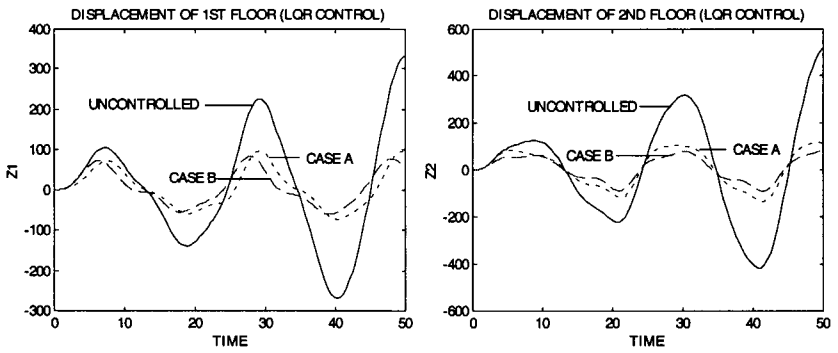

Fig.2. Displacements (LQR control)

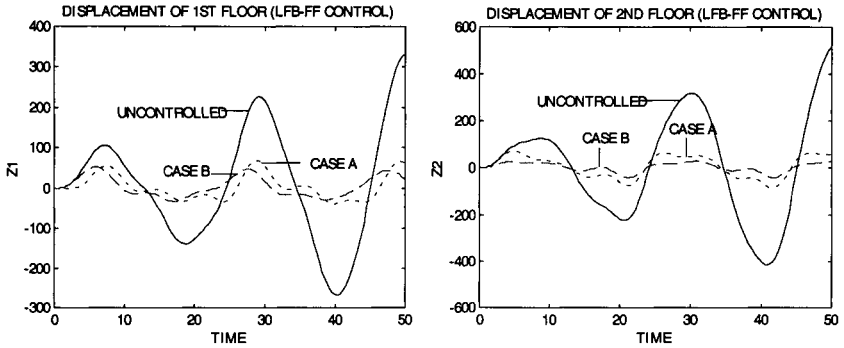

Fig.3. Displacements (local feedback-feedforward control)

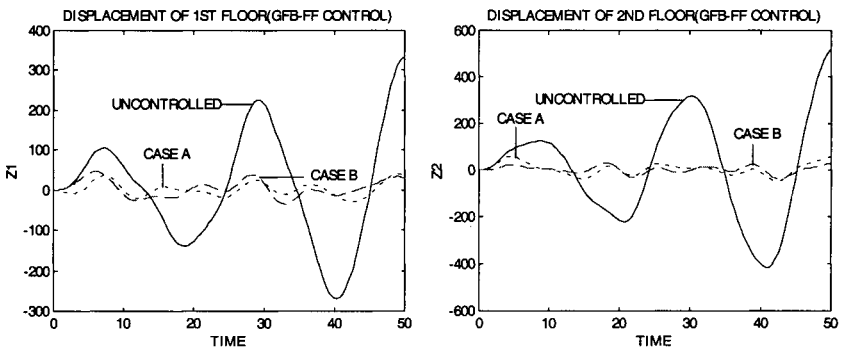

Fig.4. Displacements (global feedback-feedforward control)

5. CONCLUSION

In recent years, active control is one of the promising aspects which uses the control counterforces produced by actuators to balance or reduce the energy of the environmental loading. There are some basic problems in the active control such as control law, magnitude and location of the control counterforces. This paper use local feedback-feedforward control to find local optimal magnitude and location of counterforces. The comparison between local FB-FF control and LQR control shows the good effect of local FB-FF control. The results look promising and encourage further extending. The combination of the LFB-FF control proposed with the identification algorithm (Anh [1]) will be applied in the future to the case where the external forces are unknown.

ABSTRACT

Structural performance of the vibration control elements made by steel bar and advanced fiber reinforced cementitious composites was experimentally observed. These vibration control elements will be applied for reducing damage as well as response of RC structures under the performance based design system. Since stiffness of RC structures is relatively higher than that of steel structures, stiffer vibration control elements compared to the conventional one mainly applied for steel structures are required for reducing the seismic response of RC structures drastically. The advantage of the vibration control elements is selective structural performance, strength, stiffness, and ductility, by changing configuration, bar arrangements and type of materials used. The experimental results indicate that elemental ductility is much increased with decreasing damage when the advanced cementitious composites are applied to the vibration control elements. It means cementitious damper for structural control is available which has merit in performance and cost.

KEYWORDS

Advanced cementitious composites, Damage free, Damage reduction, RC building structures, Restoring force characteristics, Vibration control elements

INTRODUCTION

In researching methods to enhance safety, reparability and durability of concrete structures the authors have developed some types of advanced cementitious composites that have a high ductility and at the same time are able to reduce damage through formation and dispersion of micro cracks. Advanced cementitious composites with 1 to 2 % of short fibers by volume mixed with a mortar matrix show a strain hardening property as well as a multiple micro-cracking property. The stress in these composites does not decreases until the strain increases to about 1 to 2 % after the first crack appears under a

tensile stress following which multiple cracks appear. Some fibers have material properties similar to concrete confined by lateral reinforcing bars in which their compressive stress gently decreases after attaining the maximum compressive strength. Therefore, the failure mechanism, ductility, hysteresis, and damage of reinforced concrete (RC) members can be appropriately controlled. Moreover, stiffness and strength can be easily controlled by the configuration of members. It may therefore be possible to assemble vibration control elements using advanced cementitious composites such that they are more effective than conventional vibration control devices in controlling seismic response of buildings. As part of an effort to get a better understanding of the properties of advanced cementitious composite, a structural test with cyclic lateral force loading on cement members with different bar arrangements and cementitious materials to examine their hysteresis property.

BACKGROUND OF THE RESEARCH

In order to deal with recent global environmental issues, such as energy saving and waste minimization, it is imperative to increase the longevity of short-lived buildings subject to the conventional model of repetitive demolish and build. A fundamental improvement in structural durability is indispensable for increasing longevity of buildings. Additionally, technological advancements are required which make it possible to control and, even, prevent damage and deterioration caused by external loadings such as a large-scale earthquake during the service life of buildings. Only then will it be possible to secure the continuous use of buildings with simple repair works or preferably without any repair works after a large-scale earthquake.

This demand for control and prevention of damage against a large-scale earthquake has emerged after the Hyogoken-Nanbu Earthquake (Kobe Earthquake) in 1995, when many buildings that had protected human lives had to be demolished and reconstructed due to the large cost of extensive repair works. This underscores the importance of the concept of life cycle cost by which it is not enough just to consider general structural performances such as safety and serviceability, but also reparability of structures as well.

At present, seismic retrofit is being applied to the existing structures worldwide. However, the seismic design is based on the principle of protection of human lives but not necessarily the prevention of damage. Therefore, it is possible that in the near future buildings are severely damaged in a large-scale earthquake and the huge repair cost could turn into a serious social problem. Furthermore, a large number of buildings constructed during the period (1960s-1970s) of high economic growth are now reaching a phase of reconstruction. Therefore, it is imperative to expeditiously develop new technology for extending the lives of these buildings while at the same time reducing reconstruction costs and minimizing waste.

To sum up, there is a growing demand for structures with long service lives and are relatively free from collapse and damage.

VIBRATION CONTROL ELEMENTS FOR DAMAGE REDUCTION

Fig. 1 shows an independent wall member used as a vibration control element by its energy absorption, for reducing response displacement of an entire structure thereby reducing damage of each component in the structure. Since wall members built of advanced cementitious composites have high stiffness, high strength and ductility, they can efficiently absorb energy through small deformations. Then they are suitable damper for RC structures with high stiffness. The stiffness and strength of a wall element built of advanced cementitious composites can be easily changed by varying the configuration, bar

arrangement, and type of materials used in composites. Moreover, these elements are built of cement materials that can be molded freely. Thus, it is possible to design energy absorption elements whose properties and configurations are optimized to any given structure. By using these elements in nonstructural wall that are normally disregarded in structural design, the performance of a building can be enhanced with minimal or no change to the original design. Another advantage is that these elements are more cost effective than conventional energy absorption devices.

In these elements reinforcing bars are mainly expected to absorb energy as in conventional energy absorption elements used in concrete structures. The introduction of advanced cementitious composites will assist in securing a better integration of reinforcing bars in the matrix so that vibration control members will exhibit an enhanced, more effective energy absorption performance and at the same time be capable of undergoing large deformations. More specifically, advanced cementitious composites prevent brittle failures, such as shear failure, bond-splitting failure, and anchorage failure, even after the reinforcing bars have yielded. On many occasions vibration control elements undergo rotational deformations within a frame and thus experience large compressive forces. The use of advanced cementitious composites is expected to prevent brittle compressive failure as well.

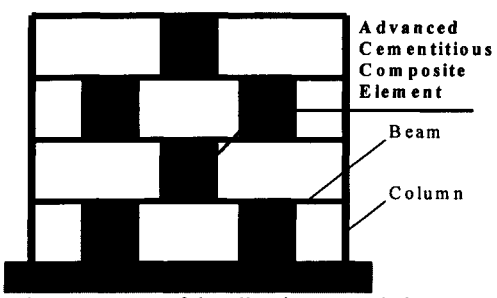

Figure 1 Image of the vibration control element

OUTLINE OF TESTS

Test Specimens

The specimens used in the tests are representative of independent wall members. The dimensions and bar arrangements of the test specimens are shown in Figure 2 and Table 1, respectively. Variables in the tests are bar arrangement and type of cementitious material used. The three types of bar arrangements used are: Type 1- Main reinforcing bars arranged in parallel, with shear reinforcement; Type 2 - Main reinforcing bars arranged in an X-shape, without shear reinforcement; and Type 3 - Main reinforcing bars arranged in an X-shape, with shear reinforcement by auxiliary reinforcing bars (4-D6) arranged in parallel. Screw-ribbed re-bars were used for main reinforcement and were tied directly to a loading steel plate by rock nuts. Three types of cement materials were used: mortar, PE-HPFRCC, and PS-HPFRCC. The mortar had a water-cement ratio of 45 %, and a sand-cement ratio of 40 %. Mortar with an identical mix proportion was mixed with 1 % polyethylene fibers by volumetric ratio in the case of PE-HPFRCC while 1% polyethylene fibers and 1% steel cords by volumetric ratio were mixed for PS-HPFRCC. Test specimens were named according to the type of material, MO for mortar, PE for PE-HPFRCC and PS for PS-HPFRCC and the type of bar arrangements, 1, 2, or 3, following the material designation with a hyphen in between. For example, MO-1 is a test specimen made of mortar and having a Type 1 bar arrangement.
Material properties and the stress-strain relation of HPFRCC are shown in Table 2 and Figure 3,

respectively. Tensile tests and cyclic tension-compression tests on HPFRCC were conducted following the method described in Sato, Fukuyama & Suwada (2001). The loading on the compressive side in the cyclic tension-compression tests was limited to 1/3 of the maximum compressive strength.

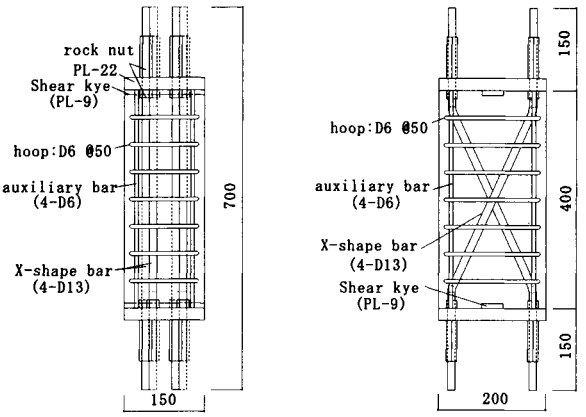

Figure 2 Configuration and bar arrangement of specimens (in case of bar arrange type-3)

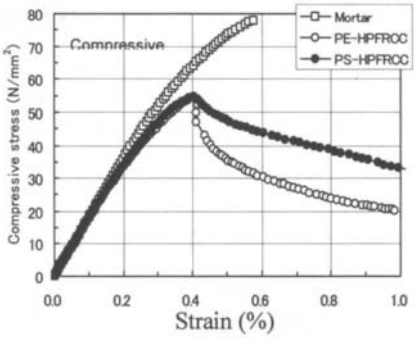
Table 1
TEST SPECIMENS

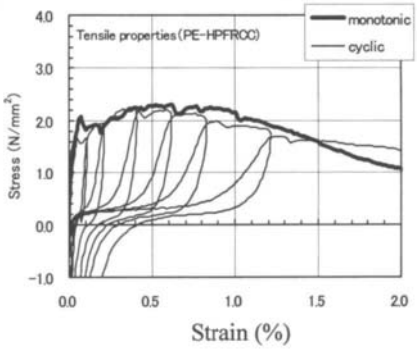
Name of specimen	Cross section	Type of bar arrangement	Main bar	Hoop	Cementitious material
MO-1	150×200 (mm)	1	4-D13(parallel)	2-D6@50	mortar
PE-1					PE-HPFRCC
PS-1					PS-HPFRCC
MO-2		2	4-D13(X-shaped)	None	mortar
PE-2					PE-HPFRCC
PS-2					PS-HPFRCC
MO-3		3	4-D13(X-shaped)	2-D6@50	mortar
PE-3					PE-HPFRCC

Table 2
MATERIAL PROPERTIES

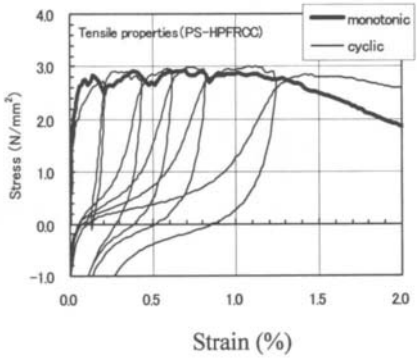
Cementitious material	Compressive strength N/mm^2	Young's modulus N/mm^2	Steel bar	Yield stress N/mm^2	Yield strain μ
mortar	78.0	1.83×10^4	D13	342	1892
PE-HPFRCC	55.1	1.77×10^4	D6	425	2474
PS-HPFRCC	54.5	1.82×10^4			



Test Methods



The load was applied under anti-symmetrical moment condition using the loading equipment in Building Research Institute. Cyclic load was applied under a displacement control. An initial axial force was not introduced but an axial jack was used to restrain any axial elongation resulting from rotation at the end of the specimen.



TEST RESULTS

Hysteresis Properties

Figure 4 shows the relation between average shear stress, lateral force divided by cross section (150 x 200 mm), and angle of rotation of the member, lateral deflection divided by specimen height (400mm), hereinafter referred to as the τ - R relation, for each test specimen.

The Type 1 specimens showed hysteresis properties that were remarkably much better for the specimens with advanced cementitious composites. MO-1, with only a regular mortar, showed a decrease in strength as a base collapsed when the main reinforcing bars yielded at R = 0.03 radian. On the other hand, PE-1 and PS-1 showed steady hysteresis properties without any decrease in strength until R was equal to 0.067 radian and 0.093 radian, respectively. On the whole, there was little difference between PE-1 and PS-1; however, compared to PE-1, the strength of PS-1 tended to increase with deformation even after flexural yielding. PS-1 showed a smaller number of shear cracks with narrower width and a smaller amount of shear deformation (a larger amount of rotational deformation) than PE-1. Judging from the state of ultimate failure and changes in crack width, it is considered that the strength of PS-1 increased due to the larger additional axial tension acting on PS-1. The better performance of HPFRCC demonstrated the effect of shear reinforcement and effect of restraint on the compressive side.

In the case of Type 2 specimens, without shear reinforcement, when each test specimen attained its maximum strength, a diagonal shear crack widened abruptly along an X-shaped main reinforcing bar, as if it split a compressed strut formed on the member, following which the strength decreased rapidly. There was an obvious difference in ductility according to the type of material with HPFRCC showing by far the superior behavior and PS-2, in particular, showing steady hysteresis properties until R was $\pm$0.04 radian.

As for Type 3 specimens, the strength of PE-3 increased with deformation more remarkably than for MO-3. This may be the result of the difference in axial compression force, similar to the difference seen between PE-1 and PS-1 in Type 1 specimens. All Type 3 specimens showed a reversed S-shaped hysteresis curve and not a spindle-shaped curve that shows superior energy absorption ability. A possible explanation for this lower performance is considered to be the opening of cracks (caused by slip of main reinforcing bars) along a critical section. Another reason is that in the tests, an axial jack

was used to restrain deformations cased by rotation in the axial direction and this lead to an excessive increase in the shear force on one of the compressive struts of the members. In fact, one of the specimens using mortar lost strength at a relatively small deformation, as the base collapsed and cracks occurred along one of the struts. The results of the tests show that HPERCC was most effective for both tensile and compressive resistance mechanisms.

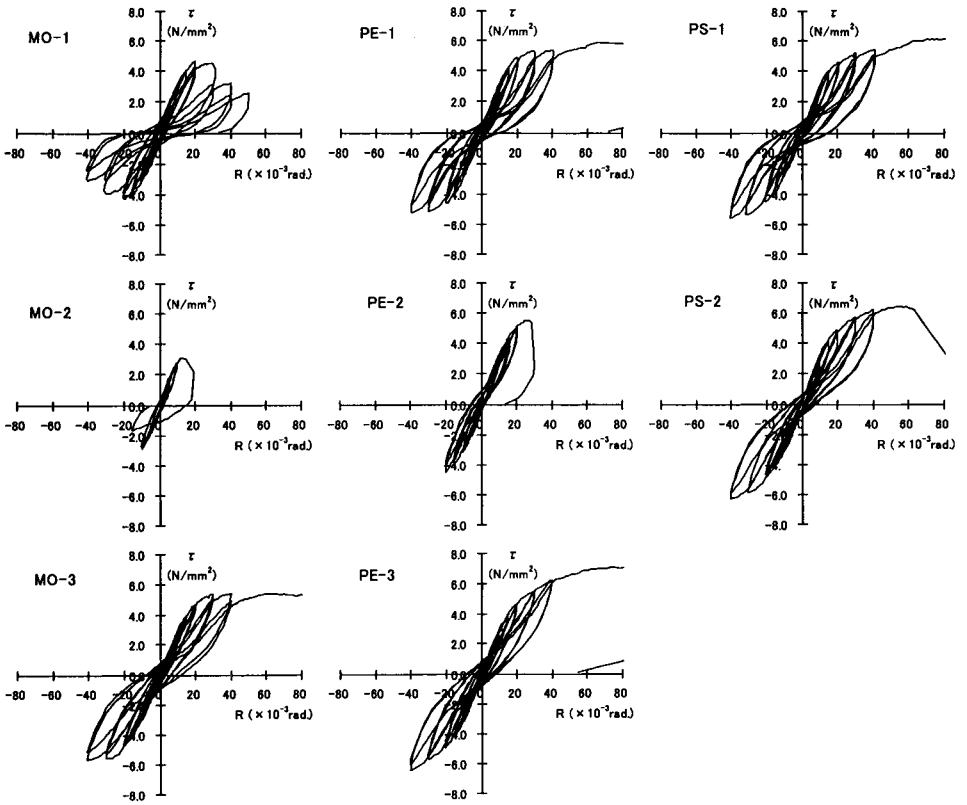


Figure 4 Relationships between average shear stress(τ) and deflection angle(R)

Damage Properties

Figure 5 shows the state of ultimate failure. Figure 6 shows the relation between maximum shear crack width and deflection angle of members (hereinafter referred to as the Wcr-R relation) at the peak of each cycle. These photos and figures clearly indicate that occurrence of cracks is greatly influenced by bar arrangement and material type. All Type 1 specimens with main reinforcing bars arranged in parallel and with shear reinforcement showed 45-degree diagonal cracks all over the members resulting in a truss-like stress transfer for resisting the input shear force. On the other hand, Type 2 specimens showed a crack only along an X-shaped main reinforcing bar, which ultimately developed into a crack that seemed to split members diagonally. The occurrence of cracks in Type 3 specimens was intermediate between Type 1 and Type 2, implying that damage properties can be controlled through shear reinforcement using auxiliary bars with X-shaped main reinforcing bars. Test specimens using HPERCC seemed to have been significantly damaged at a first glance as was apparent by the

appearance of cracks traced with a marker. In reality, as the changes in cracking width showed, micro cracks dispersed (to form multiple cracking), which made visual inspection difficult.

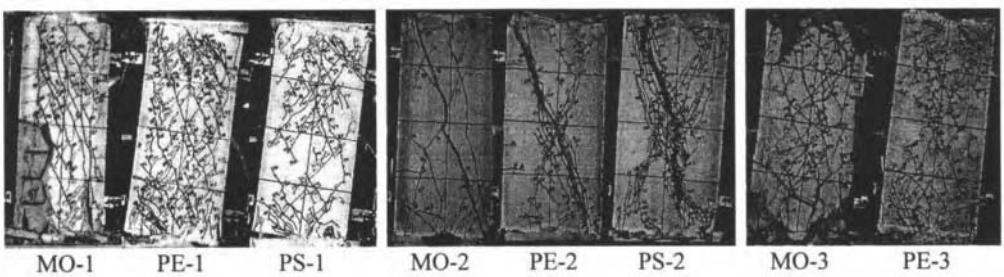

Figure 5 Final failure patterns

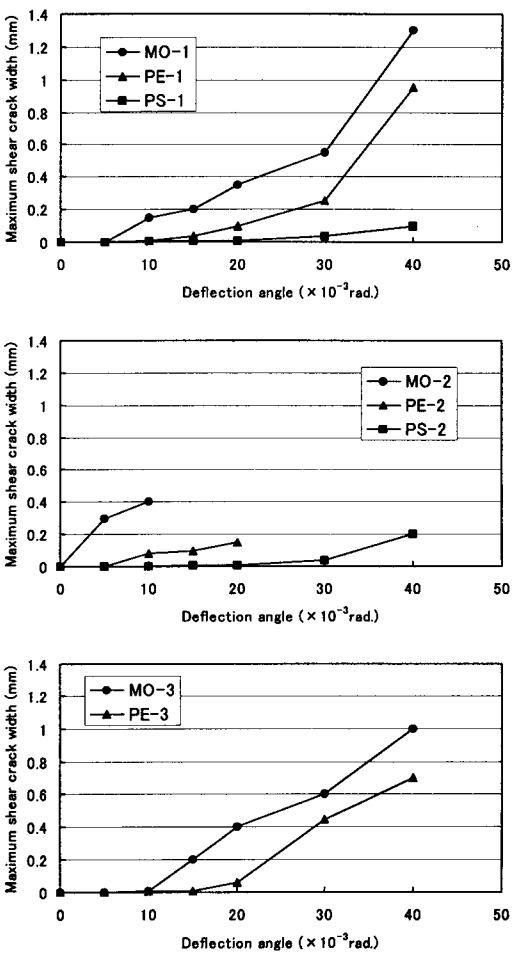

Figure 6 Maximum shear crack width—deflection angle relationships

Fluctuating Axial Compression by Deformation Restraint

In the tests the axial elongation caused by rotation was restrained using a jack in the axial direction. Consequently, an additional, fluctuating axial compression acted on test specimens. Figure 7 shows the relation between axial force ratio (axial stress / compressive strength on cementitious materials) and the deflection angle of members, hereinafter referred to as the η -R relation, at the peak of each cycle. The additional axial compression caused by restraining the axial deformation lead to an increase of 0.36 in the axial ratio.

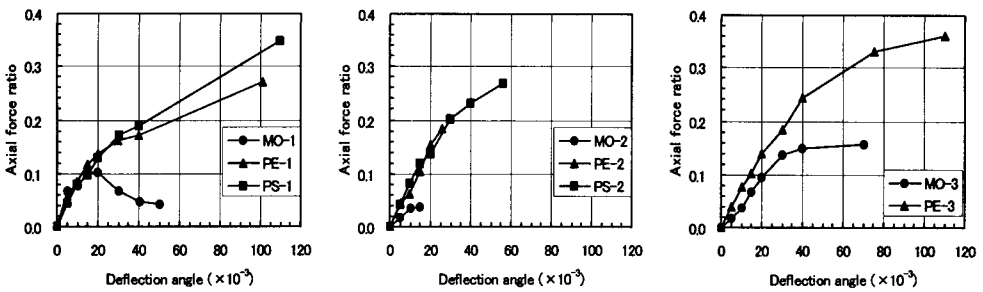

Figure 7 Axial force ratio - deflection angle relationships

CONCLUSION

Cyclic loading tests were carried out on independent wall members with different bar arrangements and cementitious materials in order to determine if the application of HPFRCC to concrete members is effective in controlling their failure mechanism, ductility, hysteresis properties, and damage. The findings obtained from the tests are:

(1) Using HPFRCC, steady hysteresis properties can be obtained up to relatively large deformations if the deformation caused by rotation is restrained. It will act as a cementitious damper for structural control.

(2) Using HPFRCC, the opening in cracks can be prevented and damage can be reduced.

SEISMIC DAMAGE EVALUATION OF A 38-STOREY BUILDING MODEL USING MEASURED FRF DATA REDUCED VIA PRINCIPAL COMPONENT ANALYSIS

J. M. Ko, X. T. Zhou, Y. Q. Ni

Department of Civil and Structural Engineering,
The Hong Kong Polytechnic University, Kowloon, Hong Kong

ABSTRACT

This paper presents an experimental study on seismic damage evaluation of a 38-storey tall building model using measured frequency response function (FRF) data and neural network technique. The 1:20 scale structural model was tested on a shaking table by exerting successively enhanced ground earthquake excitations to generate trifling, moderate, severe and complete (nearly collapsed) damage, respectively. A total of 27 accelerometers were instrumented on the structure for the measurement of FRFs in healthy state and after incurring each of the damage scenarios. A multi-layer neural network with FRF data as input variables is configured and trained for damage occurrence and extent detection in the structure. In order to circumvent the difficulty of huge dimension of input vector when using full-size FRF data with neural network, principal component analysis (PCA) is introduced to compress the size of FRFs, and the projection of measured FRFs onto the most significant principal components is finally used instead of raw FRF data as neural network input for damage identification. The results show that this approach can indicate the structural damage condition with high fidelity.

KEYWORDS

High-rise building, seismic damage evaluation, frequency response function, principal component analysis, neural network.

INTRODUCTION

Structural damage detection using measured frequency response functions (FRFs) has been widely studied (Roitman et al. 1992; Lew 1995; Wang et al. 1997; James et al. 1998; Thyagarajan et al. 1998; Sampaio et al. 1999; Lee and Shin 2002). Since natural frequencies and mode shapes are indirectly-measured test data, they could be contaminated by measurement errors as well as modal extraction errors, and provide less information than FRF data. In this sense, it is more reasonable and reliable to use directly-measured FRF data for structural damage detection, especially for structures with closely spaced modes. On the other hand, artificial neural networks (ANNs) have been a promising

computation tool for damage identification due to their strong capabilities such as pattern recognition and classification, data interpretation, function approximation, etc. The use of measured FRF data with ANNs for structural damage detection was reported in the literature. For example, Wu et al. (1992) addressed the damage detection of a three-storey frame by using selected frequency points of response spectrum as input to a neural network. Chaudhry and Ganino (1994) used frequency response data over a specified frequency range to train a neural network for delamination identification in a beam structure. Manning (1994) trained a neural network using active member transfer function information to classify damage and predict damage extent. Rhim and Lee (1995) studied damage detection using a neural network with input data being transfer functions of auto-regressive model. Luo and Hanagud (1997) used FRF data obtained from PVDF sensors to train a neural network for delamination detection. However, a bottleneck remaining for the use of FRF data with ANNs is the huge size of FRF data. The direct use of full-size FRF data will lead to the neural network with a large number of input nodes, which may also result in the problem of training convergency and computational efficiency. If only using partial FRF data, improper selection of data points from frequency windows may lead to a loss of important information. It is known that using the FRF data in the vicinity of resonant frequencies is not necessary to provide the most reliable damage detection. In order to circumvent the above difficulty, Zang and Imregun (2001) recently proposed a novel approach to compress FRF data for damage detection application. Based on principal component analysis (PCA), they obtained size-reduced projection of measured FRFs on significant principal components and used such compressed FRFs as ANN input variables for structural damage detection.

This paper reports an experimental study on seismic damage evaluation of tall building structures based on a combined use of measured FRF data and ANN technique. A 1:20 scale 38-storey tall building model was tested on a shaking table by incurring successively enhanced ground earthquake excitations to generate trifling, moderate, severe and complete (nearly collapsed) damage, respectively. After experiencing each damage scenario, the structure was subjected to a low-intensity white-noise random excitation and a total of 27 accelerometers were deployed along the structure height to collect acceleration responses in both east-west and south-north directions. According to the distribution of the sensors, the structure is divided into nine regions along the vertical direction. For each region, at least one FRF is measured for the intact structure and for each of the damage scenarios, and a four-layer feed-forward neural network is trained to predict the damage occurrence and extent in this region. The compressed FRF data, obtained by the projection of the raw FRF on 13 principal components, are used as input variables to train the neural network. In order to quantitatively assess damage extent for each scenario, the output of the neural network is designated to be a value between 0 and 1, indicating the damage level.

FRF REDUCTION USING PCA

Principal Component Analysis

Principal component analysis (PCA) can be viewed as a classical method of multivariate statistical analysis for achieving a dimensionality reduction (Jolliffe 1986; Dunteman 1989). Usually, a small set of uncorrelated variables is much easier to understand and use in further analysis for damage detection than a larger set of correlated variables (Worden and Manson 1999). Using an orthogonal projection, the original set of variables in an N-dimensional space is transformed into a new set of uncorrelated variables, the so-called principal components (PCs), in a P-dimensional space such that $P<N$. Namely, it seeks to project the high-dimensional data into a new low-dimensional set of Cartesian coordinates $(z_1, z_2, \cdots, z_P)$. The new coordinates have the following property: z_1 is the linear combination of the original x_i with maximal variance, z_2 is the linear combination which explains most of the remaining variance and so on. If the N-coordinates are actually a linear combination of P ($<N$) variables, the first

P principal components will completely characterize the data and the remaining (N–P) will be zero. The calculation can be described as follows: Given original data set $\{x\}_i = \{x_{1i}, x_{2i}, \cdots, x_{Mi}\}$, i=1, 2, ···, N, form the covariance matrix $[C]$

$$[C] = \sum_{i=1}^{N} \{x\}_i \{x\}_i^T \tag{1}$$

and perform singular value decomposition for $[C]$

$$[C] = [A][\Lambda][A]^T \tag{2}$$

where $[\Lambda]$ is diagonal. The transformation to principal components is then

$$\{z\}_i = [A]^T (\{x\}_i - \{\bar{x}\}) \tag{3}$$

where $\{\bar{x}\}$ is the vector of means of the x-data. From the point of view of dimension reduction, the PCA works by discarding those linear combinations of the data which contribute least to the overall variance or range of the data set.

FRF Reconstruction

In order to determine how many principal components are enough for reserving the most information of original FRF data, FRF reconstruction using only a few principal components will be conducted firstly. The projection of the original FRF matrix $[H(\omega)]_{M\times N}$, which has M rows of FRFs and each with N frequency points, onto the N principal components is given by

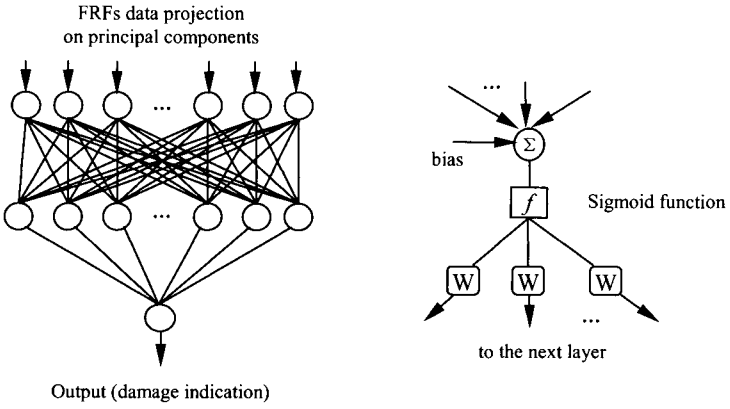
$$[P]_{M\times N} = [H(\omega)]_{M\times N}[A]_{N\times N} \tag{4}$$

The projection matrix $[P]$ and the principal components matrix $[A]$ can be portioned into two sub-matrices with P important principal components and (N–P) remaining principal components as

$$\begin{aligned} [P]_{M\times N} &= [[P_1]_{M\times P} \vdots [P_2]_{M\times(N-P)}], \\ [A]_{N\times N} &= [[A_1]_{N\times P} \vdots [A_2]_{N\times(N-P)}]. \end{aligned} \tag{5}$$

The FRF matrix now can be reconstructed for P principal components only

$$[H_R] = [P][A]^T = [[P_1]_{M\times P} \vdots [P_2]_{M\times(N-P)}][[A_1]_{N\times P} \vdots [A_2]_{N\times(N-P)}]^T \approx [P_1]_{M\times P}[A_1]^T_{P\times N} \tag{6}$$



Representation of Damage Feature

After dividing the principal components matrix $[A]$ into two sub-matrices, the projection of the original FRF matrix $[H(\omega)]_{M\times N}$ onto the first P principal components is regarded as damage feature and taken as input to neural network

$$[P]_{M\times P} = [H(\omega)]_{M\times N}[A_1]_{N\times P} \tag{7}$$

NEURAL NETWORK BASED DAMAGE IDENTIFICATION

Figure 1 illustrates the multi-layer feed-forward neural network employed in this study. One neural network is configured and trained for each of the nine structural regions to indicate the damage state in the corresponding region. The compressed FRF relevant to the region, represented by the projection of raw FRF onto a number of principal components, is taken as input to the neural network.

Figure 1: Neural network configuration for damage identification

EXPERIMENTAL DESCRIPTION

The tested model is a 1:20 scale 38-storey tall building structure. Its overall dimensions are 2.370 m long, 2.160 m wide and 6.515 m high. For the convenience of damage location, the structure is divided into nine regions along the vertical direction as shown in Figure 2, each consisting of 4~5 stories. The scaled model simulates the prototype tall building structure well. It is constructed with bottom floors (No. 1 ~ No. 3), transfer plate, typical floors (No. 4 ~ No. 38) and top machine floors (No. 39 ~ No. 42). Most elements in the prototype structure are simulated in the model without simplification except for the top equipment stories. In the model structure, sizes of the concrete beams, columns, slabs and walls are strictly fabricated according to the similitude law. The section and number of reinforcement are designed to meet the requirement of reinforcement ratio used in the prototype structure.

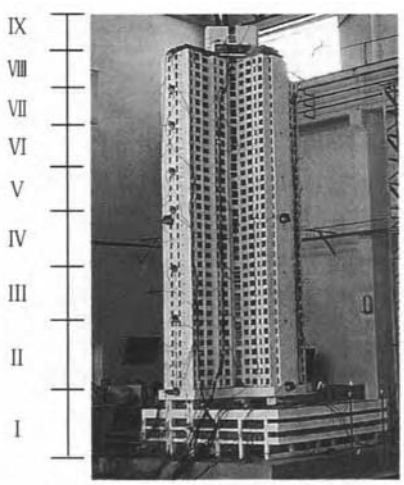

Figure 2: Tested model of a 38-storey tall building

The structure was tested on a 5m×5m, 6-DOF shaking table by exerting successively enhanced earthquake waves. Accordingly, it incurred seismic destroy extending from trifling, moderate, serious damage till to catastrophic one. A total of 27 accelerometers are instrumented uniformly along the height, to track acceleration responses at east-west and south-north directions. After the earthquake excitation at each level, a 20-minute white-noise random excitation was applied to measure the FRFs under each level of damage. Due to the limitation of power supply, the 20-minute white-noise random excitation is divided into 6 segments, each with about 3 minutes, exerting on the base of the tested model. The sampling frequency of all accelerometers is taken as 100 Hz in the testing. The loading level of random excitations is considerably low. So the structure can be regarded to hold the original damage state during the random excitations.

ANALYSIS AND RESULTS

Compression of FRFs

In order to determine the appropriate number of principal components (PCs) which can retain the most information of original FRFs and meanwhile reduce the dimensionality considerably, reconstruction of FRFs using different numbers of principal components based on Eq. (6) is firstly conducted. Figures 3, 4 and 5 show the reconstruction results of FRFs at the floor C34 for the intact structure and moderate damage case, using 5, 13 and 30 principal components respectively. It is seen that the reconstructed FRF using only 5 PCs deviates considerably from the original one, whereas for the cases of using 13 and 30 PCs, this deviation is negligible. The reconstructed and original FRFs are almost identical for the latter two cases. As a trade-off between retaining the most original information and reducing the dimensionality farthest, the reconstructed FRFs using 13 PCs are regarded as damage indicators in the present study.

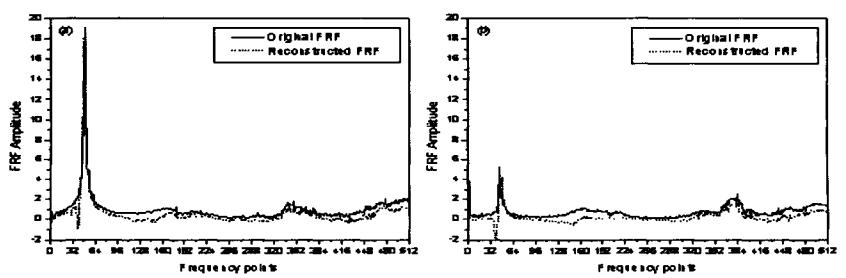

Figure 3: Reconstruction of FRFs using 5 PCs: (a) intact structure; (b) moderate damage case

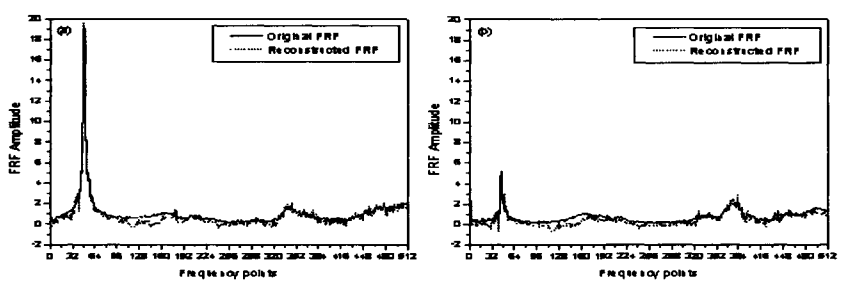

Figure 4: Reconstruction of FRFs using 13 PCs: (a) intact structure; (b) moderate damage case

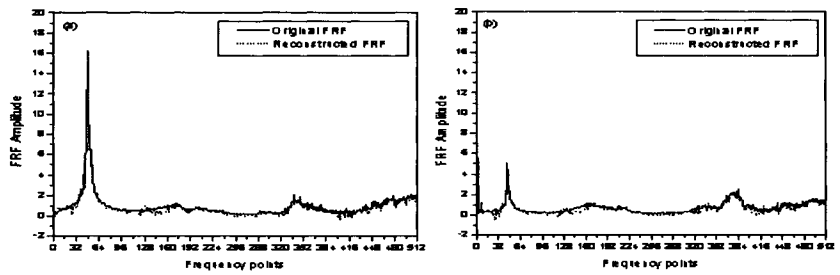

Figure 5: Reconstruction of FRFs using 30 PCs: (a) intact structure; (b) moderate damage case

Damage Identification Results

In the damage identification using neural network for each structural region, the compressed FRF, which is obtained by the projection of the measured FRF from the relevant region onto 13 principal components, is taken as input to the neural network. A four-layer neural network configuration is employed and trained with back-propagation (BP) algorithm. The two hidden layers take 15 and 18 neurons respectively, and the output layer has only one node that indicates damage severity of the specified region. To quantitatively evaluate the five damage scenarios, the target output of the neural network at training phase is designated as a definite value, while the actual output at testing phase is classified into a tolerant range, as indicated in Table 1.

A total of 500 training samples and 500 testing samples are selected from the measured FRFs which are more or less polluted by noise. No overlap exists between the training and testing samples. If and only if the output value of one testing sample lies in the tolerant range of the corresponding damage scenario, we account the testing sample as being correctly identified. Table 2 summarizes the identification results of all damage scenarios for 100 testing samples, obtained from the FRF measured at the floor C34 (7th structural region). In this table, the identification accuracy (percentage) is defined as the ratio of the number of correctly identified samples to the number of total testing samples (100). Figure 6 illustrates the output results of the neural network for all damage scenarios by using FRF data measured at the floor C34, where N, T, M, S and C denote the testing samples of no damage, trifling damage, moderate damage, serious damage and completely damaged scenarios, respectively. It is seen that for the overwhelming majority of testing samples, the predicted output results lie in the respective tolerant ranges. This concludes that the constructed neural network can predict the relative damage severity with high fidelity. The neural network identification results using compressed FRFs measured from other structural regions are also obtained but not presented in this paper due to the limit space. A similar consequence is achieved from those results.

TABLE 1
NEURAL NETWORK TARGET OUTPUT AND TOLERANT OUTPUT

Damage scenarios	Target output	Tolerant output
No damage (N)	0.1	< 0.2
Trifling damage (T)	0.3	$0.2 \sim 0.4$
Moderate damage (M)	0.5	$0.4 \sim 0.6$
Serious damage (S)	0.7	$0.6 \sim 0.8$
Completely damaged (C)	0.9	> 0.8

TABLE 2
IDENTIFICATION ACCURACY FOR ALL DAMAGE SCENARIOS

Damage Scenarios	Number of testing samples	Number of correctly identified samples	Identification accuracy (%)
No damage (N)	100	97	97
Trifling damage (T)	100	87	87
Moderate damage (M)	100	91	91
Serious damage (S)	100	87	87
Completely damaged (C)	100	92	92

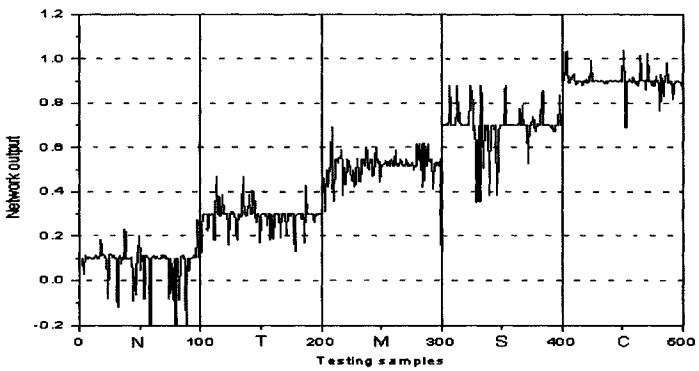

Figure 6: Output values of neural network

CONCLUSIONS

A combined use of frequency response function (FRF) data and neural network technique for seismic damage detection of tall building structures has been studied in this paper. The applicability of the proposed method has been experimentally verified by using a 38-storey tall building model. The model structure was tested on a shaking table to suffer from trifling, moderate, severe and complete (nearly collapsed) damage, respectively. The FRFs of the structure after each damage scenario was measured and the compressed FRFs through principal component analysis (PCA) were used as input variables to neural networks for structural damage identification. The identification results show that: (i) The PCA technique is powerful tool for reducing the dimensionality of measured FRFs. The reconstructed FRFs using a few principal components coincide well with the raw FRFs; (ii) Introducing the PCA technique for dimension reduction greatly facilitates the configuration and training of neural networks with FRF data as input variables; (iii) The proposed method can indicate the structural damage occurrence and relative severity region-by-region with high fidelity.

TOWARDS NEXT GENERATION SEISMIC ISOLATION TECHNOLOGY

George C. Lee and Zach Liang

Multidisciplinary Center for Earthquake Engineering Research
State University of New York at Buffalo, Buffalo, NY 14261, USA

ABSTRACT

Seismic isolation modeled as a single degree-of-freedom (S-DOF) system has been successfully applied to vibration reduction of equipment and structures in the fields of mechanical and aerospace engineering for many decades. More recently, the civil engineering profession has gradually introduced the technology for seismic protection of infrastructure systems (buildings, bridges, nonstructural components, lifeline systems, etc.) against strong earthquake ground motions. It has evolved as a specialty area in earthquake engineering, known as (structural) base isolation (as versus shock and vibration isolation). The application of base isolation technology in civil engineering therefore has stemmed from S-DOF models traditionally used in the mechanical/defense/aerospace industry. However, a large number of civil engineering structures are complex multiple degree-of-freedom (M-DOF) systems. Recent developments in structural dynamics, computing and experimental capacities have shown that there are shortcomings of using over-simplified S-DOF based seismic isolation design practice for civil engineering structures. This paper advances the concept of developing the next generation seismic isolation technology for civil engineering structures based on M-DOF models by first pointing out a number of key issues current technology does not address, followed by the suggestion of a hybrid semi-active/passive base isolator system to indicate future goal of developing intelligent seismic isolation bearings.

KEYWORDS

base isolation principles, M-DOF systems, semi-active/passive, intelligent bearings

1. INTRODUCTION

Base isolation is generally regarded as a relatively matured technology in earthquake engineering. Many buildings and bridges have been installed with seismic isolation bearings in many regions of the world. The isolation technique has also been shown to be reliable, inexpensive, and effective in many other applications. Most of the successful applications are to those structures and equipment that can be modeled by a single degree-of-freedom model. In many civil engineering structures, the responses due to earthquake ground motions cannot be adequately modeled by a S-DOF system. This paper addresses

some key issues in current state-of-practice in seismic isolation design based on more appropriate M-DOF models. An "intelligent seismic isolation bearing" is proposed to deal with issues identified in order to better control the performance of base isolated structures. This proposed system is considered to be the first attempt towards the development of intelligent seismic isolation bearing system for civil engineering applications.

2. SOME KEY DESIGN ISSUES OF BASE ISOLATION

In the following, a few important design issues for base isolation are briefly outlines. Many of them should be considered by using M-DOF models.

Ground Motions

Using proper input excitations is an important issue in earthquake engineering design. This is true not only for seismic isolation purposes. However, the matter of considering the ground motion direction has not been given adequate attention in the past (Lee and Liang, 1998). Using a given ground motion record with different incident, the maximum and minimum peak responses of a given structure can be considerably different. This may be explained by using two horizontal earthquake ground motion components. Since any seismic ground motions can be projected onto a pair of Cartesian coordinate axes, denoted by x_g" and y_g", the peak values of the projected time histories will be different for different sets of projections. It follows that the resulting peak values of the structural responses will also be different. Choosing different Cartesian coordinate is equivalent to choosing different incident angle of the earthquake motion direction. By using an earthquake-record in the standard "normal/parallel" directions will not likely yield the worst case of response calculation. In addition, it is not well understood that the seismic incident will affect the design of response magnification devices such as the base isolators caused by "directional or cross effect." Penzien and Watabe (1975) defined principal axes of ground motions as a pair of mutually $\perp$ axes about which the cross correlation function of x_g" and y_g" equals to zero. This defines a special incident angle of a given ground motion for which engineers have a method to calculate structural responses. It is not a criterion of choosing the incident for maximum structural responses because the seismic responses of a structure depend on both the ground excitation and the dynamic properties of the structure itself. This fundamental issue is often misunderstood or ignored by many engineers by assuming that using the ground motions defined by Penzien will automatically yield maximum structural response for the purpose of design. This is a misinterpretation of the original concept of Penzien. Lopez et al. (2000) had suggested a formula to modify the existing CQC3 method to calculate the maximum peak response based on design spectrum in the period domain, which has great advantage of accuracy and simplicity. However, it cannot be used for performance based design, where time domain responses are necessary.

Design Response Spectra

In seismic isolation design based on response spectrum, the general guiding principle is to achieve lower acceleration of the superstructure by providing adequate longer period of a structure, for a given damping ratio (Kelly, 1993). If, for a certain reason, the period cannot be shifted to a longer value, more damping may be used to lower the acceleration. This guiding principle is very approximate and should not be used for all cases. For example, reduction of superstructure acceleration can only be achieved when the dominant frequency of the ground motion is 41% greater than the fundamental frequency. Furthermore, the reduction of superstructure acceleration should not be the sole criterion of base isolation. In many cases, reduction of base shear and/or bearing displacement is more important. For different performance

objectives, different design parameters and different approaches are needed. They often require the consideration of M-DOF models.

Near Field Effect and Bearing Displacement

The design of isolation bearings is importantly related to the velocity pulses because of the large displacement and the structural responses (observed in recent large earthquakes). They are the results from both the nature of excitations and the dynamic behavior of the isolation system. To actually reduce the bearing displacement, we may use non-linear bearing to modify the phase different of the motion of the superstructure and the base as far from 180^0 as possible. Or, we may introduce structural control technologies to modify the responses of the structure. To consider these methods properly, again, M-DOF models should be used.

Role of Large Damping

Large damping can be introduced in isolation systems to reduce the resonant amplitude of structural response. However, the isolation should not be designed to have a resonance to begin with. In the design-response-spectrum approach, large damping is introduced to reduce the acceleration (actually, only the pseudo acceleration can be reduced). Large damping is also thought to be helpful to reduce the bearing displacement by many. However, bearing displacement is difficult to be reduced if linear restoring and damping force are used (see Kelly 1999 and Hall 1999).

Cross Effect

One of the challenging areas in structural dynamics of base-isolated structures is the "cross effect" or "directional coupling." The authors have been pursuing a study to quantify the dynamic responses of structures in the perpendicular direction of loading (Lee and Liang, 1998). There are several factors contributing to this special response of dynamically loaded structures. The authors believe that the cross effect can be very large in base isolated structures if the isolation system is not properly designed. In general, when a system does not have the same pair of principal axes in the horizontal directions, along the vertical axis and/or at different loactions of sub-structures, horizontal input in one direction will cause response in its perpendicular horizontal direction. Structures with initial imperfections in geometry and/or unsymmetrical distribution of mass and damping properties can further magnify the cross effect. In most cases, we typically cannot treat base isolated structures as S-DOF systems or as decoupleable M-DOF systems. For example, certain isolation bearings only have one pair of cross-sectional principal axes in one of the three mutually $\perp$ directions. The combined structure-bearing system will certainly have response couplings under dynamic loading. The challenge is not about their existence but their magnitude. We need to quantify them in order to properly design the seismic isolation as well as other response modification systems for structures.

3. REAL-TIME STRUCTURAL PARAMETER MODIFICATION FOR BASE ISOLATION SYSTEMS

In the previous section, we briefly discussed four of the important issues that should be considered in developing a new generation of seismic isolation technology. Some issues require fundamental research in structural dynamics both theoretically and experimentally. In order to proceed with the improvement of present day seismic isolation technology, the authors advocate the use of a hybrid control scheme to improve the performance and to provide fail-safe capacity in base isolation applications. In the remainder of the paper, this new concept will be described. It represents the beginning of a new generation of seismic isolation design, primarily based on M-DOF system models (Lee and Liang, 2002).

As pointed out earlier, one of the shortcomings in current base isolation design is the possibility of underestimating the bearing displacement and the inefficiency of the "linear bearing." We suggest the application of real-time structural parameter modification (RSPM) technology together with passive base isolators. RSPM is a special kind of semi-active control technology, containing sensory, decision-making and execution components, assembled as a single device (function switch) to provide "switching" functions to extend the capacity of a passive device. RSPM uses less power to control solenoid valves to modulate the stiffness and viscosity of the function switch, which in turn varies the dynamic behavior of the passive isolators, changing the stiffness and damping from linear to nonlinear variables. Kobori et al. (1993) introduced the concept of semi-active control to earthquake engineering applications. Liang et al. (1999) introduced the function switch device in vibration and shock isolation. Ruan (1997) discussed the possibility of using the RSPM technology for building base isolations. In the following, we first discuss the advantages and limitations of using passive nonlinear base isolation, followed by describing the approach of using the RSPM technology to obtain optimal nonlinear responses of the bearings.

Nonlinear Base Isolation

Using linear isolation bearing, the motion of the structure is 180^0 out of phase with the ground motion. This will result in large bearing displacement. If this phase difference can be modified to either greater or smaller than 180°, the bearing displacement will be reduced.

Large linear damping can shift the phase angle, but the amount is insignificant. Therefore, introducing large nonlinear damping to the passive base isolation is a reasonable approach. In addition, if an isolated building can be modeled as a linear SDOF system, damping force has a 90^0 phase difference from the restoring force. In linear MDOF system, the change of phase difference will not be significant. By using nonlinear isolators, the phase difference can be greatly changed. This suggests that we can modulate the restoring forces in developing the nonlinear base isolators.

Figure 1 shows the normalized bearing displacements, as a comparison between linear and nonlinear isolation bearings. Here, normalized plots are used for the purpose of comparison. It is clearly seen the phase difference. One of the reasons that the displacement of nonlinear bearing can be considerably smaller, from this figure, that the phase difference is modulated. In this example, the linear damping force is calculated by using a constant 30% damping ratio. The nonlinear curve is obtained from a constant slope roller bearing (linear restoring force) together with viscous damping force and constant restoring nonlinear force, as well as friction nonlinear damping forces (Lee and Liang, 2002). The response spectrum of this new type of slope roller bearing does not have notable peak responses because a constant slope with angle 2^0 to 3^0 is used to achieve a constant restoring force. For this configuration, the acceleration of the superstructure is almost a constant.

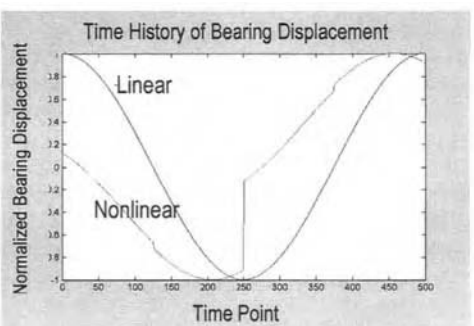

Figure 1: Linear and Nonlinear Bearing Displacements

Figure 2 shows the energy dissipation loops, where the nonlinear loop can dissipate about twice the energy than the linear loop. Figure 3(a) shows typical experimental result of the bearing displacement under the Kobe earthquake excitation, where the peak-to-peak value is about 4 inches. Figure 3(b) shows a separate experimental result of the nonlinear slope-roller bearings, where the peak-to-peak value is less than 1.5 inch. The reduction of bearing displacement of the nonlinear system is rather significant, although the latter is still large.

There are several other issues regarding the design parameters for nonlinear seismic isolation. They will not be described in this concept paper due to length limit.

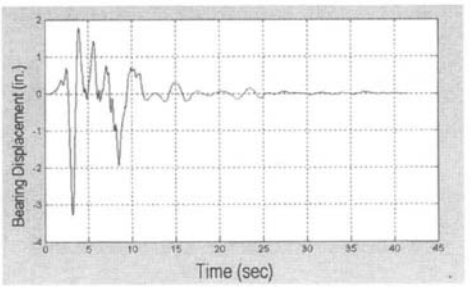

Figure 3(a): Displacement of linear bearing

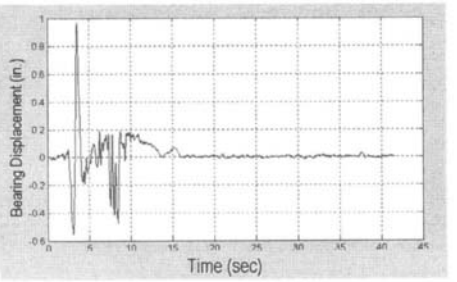

Figure 3(b): Displacement of nonlinear bearing

An Intelligent Base Isolation System

As an example of developing intelligent base isolators, a semi-active control element is added to a passive seismic isolation system, which is considerably more economical than using an active control system in order to achieve the same objective.

The RSPM technology mentioned earlier can vary the stiffness and damping coefficients of a passive bearing. With a given external excitation, the variable stiffness and damping device can generate appropriate restoring and damping forces. Figure 4 shows displacement that using RSPM to simulate the nonlinear bearing. It is seen that this semi-active control system can closely simulate the desired nonlinear displacement. In this simulation, the RSPM performs a switching function that adds or disconnects a pair of stiffness to the main bearing stiffness. By suddenly drop (disconnect) the added stiffness, the result shown in Figure 4 can be achieved.

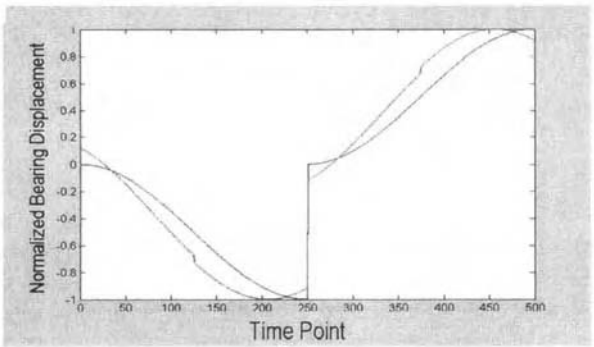

Figure 4: Passive and RSPM nonlinear bearing displacements

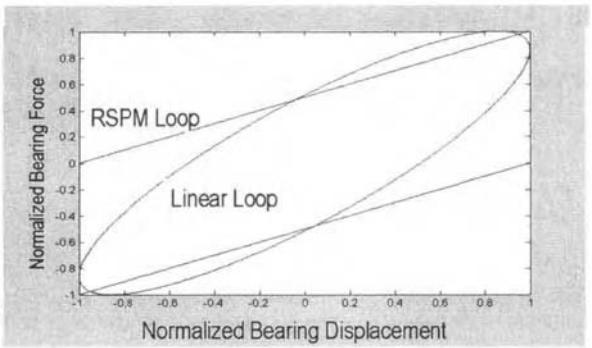

Figure 5: Linear and RSPM bearing constitution loop

Figure 5 is the comparison of energy dissipation between the RSPM technology and linear bearing. It is seen that the RSPM-controlled isolation can absorb significantly more energy than does the linear bearing. In fact, the former technology can achieve the maximum energy dissipation by using two functional switches in the push-pull pair (see Liang et al., 1999).

Figures 4 and 5 are normalized plots which cannot indicate the effectiveness of how to use RSPM to adaptively vary the bearing parameters. This is a rather complex issue that will not be explained in this paper (see Liang et al., 1999).

Figure 6(a) shows a simulated example of the responses of the RSPM-controlled base isolations. The excitation is Mexico earthquake, whose long period can make bearing displacement quite large. As a comparison, we also plot the bearing displacement by using a 50% linear damping. It is seen that a significant reduction can be achieved. In figure 6(b), we also plot the comparison of the resulted base shears. It is seen that the base shear of RSPM-controlled isolation system is significantly reduced, too.

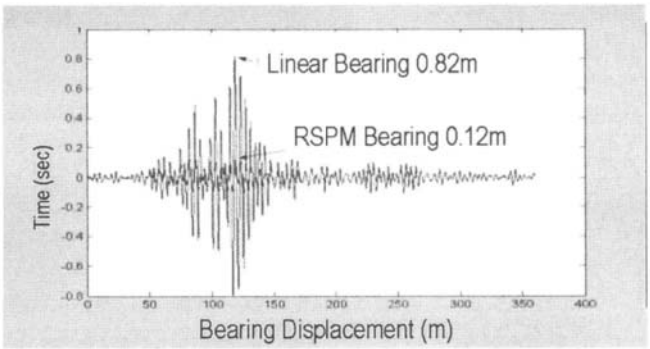

Figure 6(a): Comparison of bearing displacement

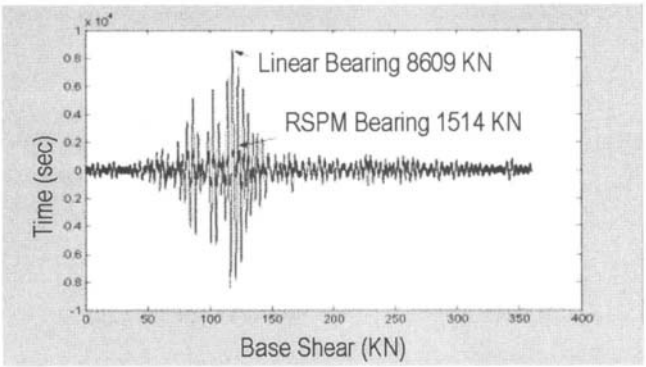

Figure 6(b) Comparison of base shear

SUMMARY

Advances in theoretical analyses and experimental observations in structural dynamics, coupled with the maturity and experiences in the earthquake engineering profession, have suggested the opportunity to begin the development of next generation seismic isolation technology for civil engineering applications at the Multidisciplinary Center for Earthquake Engineering Research (MCEER). This paper is an attempt

to summarize some of the key issues that should be addressed through M-DOF theoretical modeling and experimental studies. Although the concept of an intelligent seismic isolation system is proposed, the objective of the paper is to describe the vast area of research opportunities towards the development of next generation of seismic isolation technologies for earthquake engineering applications.

ACKNOWLEDGEMENT

This study is supported jointly by the National Science Foundation (Grant No. ECC-9701471) and the Federal Highway Administration (Contract No. ETFH61-98-C-00094). The work of RSPM-controlled base isolation is partially contributed by Dr. S. Ruan.

ABSTRACT

Recent studies show that semi-active vibration control systems using Magnetorheological (MR) dampers have most of the good characteristics of passive and active control systems. Their applications in mitigating dynamic effects produced by seismic and wind loads on civil engineering structures are quite promising. In this paper a new form of semi-active damping device using MR Fluid for vibration control of structures is proposed. A model of the proposed MR damping device was developed. This paper presents the results of the studies as well as proposals on further research on the MR damping device including experimental tests and control strategies so that the potential of its applications in seismic and wind-induced vibration control of structures can be further explored.

KEYWORDS

Magnetorheological fluid, MR fluid, damping device, semi-active vibration control, control strategy.

INTRODUCTION

A significant amount of research on vibration control and civil engineering application has been conducted in the past decade. Four basic categories of control systems were identified and definitions

were given in Housner *et al* (1997), namely, passive, active, hybrid, and semi-active control systems. Passive control systems, such as base isolation, metallic yield dampers, viscoelastic dampers, viscous wall, friction dampers, tuned mass dampers, tuned liquid dampers, employ supplemental devices, which respond to the motion of the structure to dissipate vibration energy in the structural system. They do not require external power source. The energy in a passive control system cannot be increased by the passive control devices. Active control systems, such as active tendon system, active bracing system, active tuned mass damper, active mass drivers, operate by using external energy supplied by actuators to generate forces on the structure in a prescribed manner, in accordance with the response of the system measured with physical sensors. The generated forces can result in adding or dissipating energy. They normally require a significant amount of power for the operation. Hybrid control systems combine two or more passive and active control systems to reduce the responses of a structure. There are two main systems: the hybrid mass damper systems and the active base isolation system. Semi-active control systems may be considered as a class of active control systems that require relatively small amount of external energy sources, or as controllable passive devices, yet they have most of the good characteristics of passive and active control systems. The following damping devices belong to the semi-active control systems: variable-orifice fluid dampers, controllable friction dampers, and controllable fluid dampers which include the magnetorheological (MR) fluid dampers and the electrorheological (ER) fluid dampers. Semi-active control devices do not add mechanical energy to the structure. Semi-active systems, especially the MR dampers, perform significantly better than passive devices and may achieve, or may even outdo, the performance of fully active systems. Semi-active control systems also do not induce adverse effects on the stability of the structure. The potential of applications of semi-active vibration control systems in civil engineering is quite promising

THE NEW PROPOSED SEMI-ACTIVE DAMPING DEVICE USING MR FLUID

Magnetorheological (MR) fluid dampers were investigated in recent years and promising results of mitigating dynamic effects on buildings have been achieved. Most of the MR dampers studied belong to the valve mode in the control of fluid flow. A new shear mode damping device using MR fluid is proposed and developed herein. The proposed damping device consists of two 10 mm thick steel plates placed parallel to each other with a gap of 15 mm in between. This gap is filled with MR fluid. Another steel plate, which can slide freely between the two parallel plates, is immersed in the fluid to a depth of about 30 mm. The width of the sliding plate in contact with the MR fluid is 50 mm. Details of the damping device are shown in Figure 1. A coil is placed at the lower part of the device in between the two parallel plates to produce an electromagnetic circuit. When an electric current passes through the coil, a magnetic field is generated, which in turn, generates a resisting force against the movement of the sliding plate. The force generated is due to the change of yield stress of the MR fluid. Only a current of less than two amperes is required. Damping forces that vary with the magnitude of the induced magnetic field passing through the MR fluid are generated. Thus vibration control can be achieved when the applied current is regulated by a suitable feedback control algorithm.

MR fluids contain suspensions of micro-sized particles that can be easily magnetized. When a magnetic field passes through the fluid, the suspended particles align with the direction of the field like chains, which obstruct the movement of the fluid within the area. Thus the yield stress of the fluid is altered and can be controlled by the magnetic field applied to it. This is a major favourable characteristic of the MR fluid. The free-flowing, viscous fluid can be changed to a semi-solid to solid stage in milliseconds when varying magnetic field passes through it. MR fluids also have other favourable properties of high strength, fast response time, low viscosity, maintain stable condition over a wide range of temperature and are insensitive to impurities. Furthermore, they only need minimal power to operate. Silicon steel is used and considered satisfying the requirements of high magnetic permeability and saturation. MR Fluid MRF-132LD produced by Lord Corp. is used. It has the following properties: the dynamic shear yield stress is less than 45 kPa; the range of operating temperature is from -40^0 to 150^0C; the plastic viscosity is from 0.25 to 0.9 Pa-sec; there is no effect on most chemical impurities; the required response time is just a few milliseconds; the required current is only 1 to 2 Ampere when a 12 V DC power supply is used. All these properties are favourable to damping devices for vibration control.

SHEAR FORCES IN THE PROPOSED MR DAMPING DEVICE

For a flowing MR fluid with an applied magnetic flux, the Bingham's equations may be used (Mark 1998), the fluid stress is given by $\tau = \tau_y(H) + \eta \dot{\gamma}$

where $\dot{\gamma}$ = fluid shear rate, $\tau_y(H)$ = yield stress induced by the magnetic field, η = plastic viscosity at no applied magnetic field.

The actual behavior of MR fluid departs slightly from the Bingham model. MR fluid shows non-Newtonian behavior even with no applied magnetic field. Nevertheless, the Bingham model still provides a useful basis for the design of MR damping devices. The shear force developed in the shear mode device is $F = F_\eta + F_\tau = \frac{\eta V_R A}{g} + \tau_y(H)A$

where V_R = relative velocity of the plates, A = shear area $\approx 2 L_p w$, L_p and w = length and width of the contact area respectively, g = gap width of the flow channel between the plates.

ELECTROMAGNETIC CIRCUIT DESIGN AND FINITE ELEMENT ANALYSIS

The design of electromagnetic circuit requires the optimization of magnetic field energy in the fluid gap and minimization of the magnetic flux loss in other areas of the circuit. There should be adequate steel areas so as to keep the magnetic field intensity low. Design procedure (Lord 1999) involves the determination of the magnetic flux density B_f in the MR fluid to give the required yield stress τ_o. B_f can

be obtained from the τ_0-B_f curve of the MR fluid, and in turn the magnetic field intensity H_f in the fluid can then be determined from the B-H curve of the fluid.
For continuity of magnetic flux, $\phi_i = \phi j = \phi_k = ...$and $\phi = B_f A_f = B_s A_s$, where A_f and A_s are effective areas of the fluid and the steel respectively; and B_s is the magnetic flux density in the steel. Thus B_s can be calculated from $B_s = \phi / A_s = B_f A_f / A_s$. From the B-H curve of the steel, the magnetic field intensity H_s in the steel can be determined.

In a magnetic circuit, NI = $\oint Hdl$, where NI is the number of amp-turns required in the coil.

Thus NI = $\sum HiLi = H_f g + H_s L_s$, where g = total gap width filled with the fluid, and L_s = Length of the segment of the circuit through the steel, by assuming uniformly distributed magnetic flux across the effective areas and no losses incurred.

The electromagnetic circuit design and the configuration of the MR damping device have been verified using the finite element computer program, COSMOS/M. Results of the two-dimensional finite element analysis indicate that there are losses and non-uniform distribution of fluxes at junctions and boundaries, especially at the parallel steel plates. Results of the finite element computer analysis showing the non-uniform distribution of the magnetic flux and the MR fluid are shown in Figure 2. From the equations in the previous paragraph and assuming uniform flow of magnetic flux across the areas with no loss of flux, the calculated magnetic flux densities are 0.56 Tesla at the MR fluid and sliding steel, 1.65 Tesla at the parallel plates, and 0.62 Tesla at the coil. The results from the finite element analysis are 0.43, 1.3 and 0.68 Tesla at the corresponding locations respectively. The losses of flux vary at different locations.

MECHANICAL MODEL OF THE PROPOSED MR DAMPING DEVICE

It is required to have a mechanical model to predict the measured responses and the behaviour of the damping device. The Bouc-Wen model (Wen 1976) has been used extensively to simulate nonlinear hysteretic system. The mechanical model developed by Yi and Dyke *et al.* (2001), based on the Bouc-Wen model, for shear mode MR damper is considered suitable and is adopted herein for the damping device. The model is shown in Figure 3. In this model, the force in the system consists of two parts, the non-hysteretic component and the hysteretic component, as follows:

$$p = c_o \dot{x} + \alpha z$$

where z = a hysteretic variable and depends on the time history of the response; x = displacement of the device; c_o = damping coefficient, α = a parameter and is a function of the input current.
The following differential equation containing x and z must be satisfied:

$$\dot{z} = -\lambda_1 |\dot{x}| z |z|^{n-1} - \lambda_2 \dot{x} |z|^n + \lambda_3 \dot{x}$$

The parameters of c_o, α, λ_1, λ_2, λ_3, and n control the scale and general shape of the hysteresis loop and

the smoothness of the force-displacement curve. The parameters can be adjusted so as to match the measured response of the system from experiments.

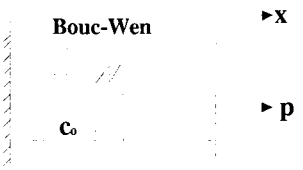

Figure 3 - Mechanical Model of the MR Damping Device

The response time of the MR damping device is an important factor affecting the performance of the device. Yang *et al.* (2002) indicated that the use of a current driver instead of a voltage-driven power supply could reduce the response time of a MR damper significantly and proved to be effective in practice. It can be shown that the governing equation for the current i in the coil, and the desired current i_d, using current driver is $L\frac{d^2i}{dt^2} + R\frac{di}{dt} + \mu i = \mu i_d$

The time required to reach the desired current i_d is $t_1 = \frac{2L}{R\beta}(\pi - \tan^{-1}\beta)$

where L = coil inductance, R = coil resistance, μ = proportional gain, $\beta = \sqrt{[(2\gamma L)/R^2 - 1]}$.
Due to the existence of residual magnetic field in the steel plates, Yang *et al.* (2002) indicated that the response time required to reduce the force in the MR damper to its minimum value was much longer than that required to increase the force in the upward direction. This phenomenon is not desirable. In order to reduce the response time when the force decreases, the current in the coil was recommended to be back-driven. Therefore, a negative current was introduced to demagnetized the steel before the current was set back to zero. It was shown that the back-driven current approach could significantly reduce the response time to an acceptable level. The back-driven current approach and a current driver are adopted in this project. Using this method, regular steel with higher carbon content may be used for the damping device instead of low carbon steel.

CONTROL STRATEGY

Dyke *et* al. (1996, 1997) has proposed a clipped-optimal control strategy based on acceleration feedback for MR dampers. Dyke and Spencer (1996) have extended the control algorithm to control MR dampers installed at different floors of a multi-storey structure. Similar research has been conducted by Yoshida and Dyke *et al.* (2001), and also Yi and Dyke (2001). It has been proved that the proposed control strategy was effective. The principles of this control algorithm are adopted herein for the nonlinear semi-active damping devices. A summary of the control strategy is given below. For a multi-storey structure with n number of damping devices, the equations of motion are as follows:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = -\mathbf{M}\mathbf{R}\ddot{x}_g + \mathbf{H}\mathbf{p}$$

$$\dot{\mathbf{z}} = \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{p} + \mathbf{C}\ddot{x}_g \qquad \mathbf{y} = \mathbf{D}\mathbf{z} + \mathbf{E}\mathbf{p} + \mathbf{F}\mathbf{v}$$

Where $\ddot{x}_g$ = one dimensional ground acceleration; $\mathbf{p}$ = vector of measured forces in the n damping devices = $[p_1, p_2, \ldots p_i, \ldots p_n]$, and each force is calculated from the mechanical model based on the Bouc-Wen model as discussed above; $\mathbf{R}$ = a unit vector; $\mathbf{H}$ = a matrix depends on the locations of the dampers; $\mathbf{z}$ = state vector; $\mathbf{y}$ = vector of measured responses, such as measured acceleration at certain locations, measured displacements of the damping devices and the measured control forces; $\mathbf{v}$ = measurement noise vector; $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, $\mathbf{D}$, $\mathbf{E}$ and $\mathbf{F}$ are matrices in terms of $\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}$, $\mathbf{R}$, and $\mathbf{H}$.

In order to produce a desired control force p_{di} in each MR damping device, n force feedback loops are required. The vector of the desired control forces is $\mathbf{p_d} = [p_{d1}, p_{d2}, \ldots p_{di}, \ldots p_{dn}]^T$

To determine the value of $\mathbf{p_d}$ from values of $\mathbf{p}$ and $\mathbf{y}$, a linear optimal controller $\mathbf{K_c}(s)$ is required, through the Laplace transform L{ }, as follows:

$$\mathbf{p_d} = L^{-1}\left\{-\mathbf{K_c}(s)L\left\{\begin{matrix}\mathbf{y}\\ \mathbf{p}\end{matrix}\right\}\right\}$$

The Linear Quadratic Gaussian, H_2/LQG strategies can be used to obtain $\mathbf{K_c}(s)$. Acceleration feedback control strategies, instead of full state feedback strategies or velocity feedback strategies, are adopted.

The relative structural displacements and velocities at the MR damping devices determine the response of the MR damping devices. The force generated by each MR damping device depends on the command current applied to the current driver of the damping device. By comparing the measured force to the desired force, the command signal for the command current is determined so as to generate the corresponding desired optimal control force p_{di} in each MR damping device.

Based on the modified clipped-optimal control algorithm developed by Yoshida and Dyke *et al.* (2001) and the use of a current driver, when the measured force, p_i, is smaller in magnitude than the desired force, p_{di}, $|p_{di}| > |p_i|$ the command current to drive the MR damping device is set to $i_i = I_{ci}$, and the magnitude of the control force increases, otherwise, when the measured force is larger than the desired force, $|p_{di}| < |p_i|$, the command current is back-driven and then set to zero.

When the measured force and the command force have opposite signs, the command current is also back-driven and then set to zero.

$$i_i = I_{ci} H(\{p_{di} - p_i\} p_i) \qquad I_{ci} = \begin{cases} a_i p_{di} & for\ p_{di} \le p_{\max} \\ I_{\max} & for\ p_{di} > p_{\max} \end{cases}$$

Where H( ) is the Heaviside step function, p_{max} is the maximum force produced by the control device and a_i is a factor showing the relationship between the command current I_{ci} and the desired force p_{di}.

Various building structural models, consist of steel members as columns and beams; and steel plates as slabs, for experimental verification of vibration control have been designed, with MR damping devices to be installed. Optimum locations of damping devices in the model will then be established so as to mitigate the dynamic effects of seismic and wind vibration. Vibration tests on building models with MR damping devices installed will be performed on a shake table to simulate earthquake excitation. Wind tunnel tests will also be performed to simulate wind excitation.

CONCLUSION

A new form of semi-active shear mode MR damping device is introduced. Results of studies on the configurations of the device and the magnetic field distributions in the device under a controlled electric current are presented. Further research including experimental tests and control strategies necessary for further development of the device has also been proposed and discussed. Preliminary results have shown that the proposed damping device will provide a positive and practical alternative for mitigating dynamic effects in buildings due to wind and earthquake loads.

ABSTRACT

This paper presents an experimental study of using a hybrid platform to mitigate vibration of a batch of high tech equipment installed in a building subject to nearby traffic-induced ground motion. A three-story building model and a hybrid platform model are designed and manufactured. The hybrid platform is mounted on the building floor through passive mounts and controlled actively by an electromagnetic actuator with velocity feedback control strategy. A series of shaking table tests are then performed on the building model without the platform, with the passive platform of different parameters, and with the hybrid platform. The experimental results demonstrate that hybrid platform is very effective in reducing the velocity response of a batch of high tech equipment in the building subject to nearby traffic-induced ground motion if dynamic properties of the platform and control feedback gain are selected appropriately.

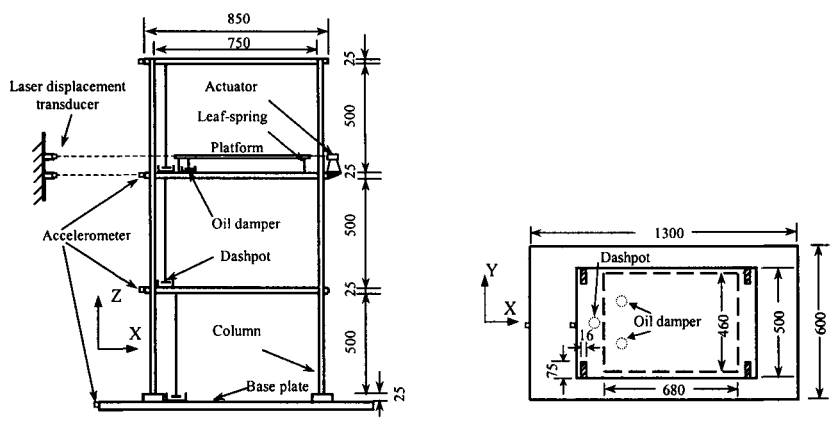
KEYWORDS

Experimental study, high tech equipment, nearby traffic-induced ground motion, hybrid platform.

INTRODUCTION

With rapid advancement in high tech equipment such as that used for the production of semiconductors and optical microscopes, vibration criteria for high tech facilities (buildings), in which high tech equipment is installed, become more and more stringent (Gordon, 1991). One of the major sources of vibrations of concern in relation to high tech facilities is nearby road and rail traffic-induced ground motion. Thus, to ensure the high quality of ultra-precision products, it is imperative to find effective and efficient ways to reduce velocity response of a batch of high tech equipment in a modern high tech facility against nearby traffic-induced ground motion.

Using passive mounts (spring-damper systems) to isolate individual high tech equipment from building floor vibration is a very common practice in high tech equipment industry. To reduce vibration to a sufficient level, the frequency of the passive mount is expected to be as low as possible but the passive mount of low frequency will result in excessive drift. The passive mount of very low frequency may



also lead to static instability of high tech equipment. To overcome these problems, a hybrid control by coupling active actuators with passive mounts to prevent individual high tech equipment from building floor vibration has been recently investigated (Nakamura et al, 1999; Yoshioka et al, 2001). However, most of the previous studies take the building floor vibration as a direct excitation to high tech equipment. Dynamic interaction between the building and the high tech equipment either passively isolated or hybrid-controlled is not considered.

This paper thus carries out an experimental study to examine the effectiveness of a hybrid platform for mitigating the vibration of a batch of high tech equipment installed in a building subject to nearby traffic-induced ground motion. A three-story building model and a hybrid platform model are designed and manufactured. The hybrid platform is mounted on the building floor through passive mounts and controlled actively by an electromagnetic actuator of velocity feedback control. A series of shaking table tests are then performed on the building model without the platform, with the passive platform of different parameters, and with the hybrid platform.

EXPERIMENTAL ARRANGEMENT

Building Model and Platform Model

The building model used in the experiment was designed and built as a three-storey shear building. The steel frame of the building model consisted of three rigid plates and four flexible columns (see Fig.1). The overall dimension of the building model was measured at 1575mm x 850mm x 500mm. The four columns of the building model were eventually welded to a thick steel plate that was in turn bolted into a shaking table. The building model motion was restricted in the x-direction only, leading to a planar frame in the x-z plane for the investigation. To properly simulate the inherent energy dissipation capacity of the real building, the small dashpots were installed between every two floors.

(a) Elevation (Unit: mm) (b) Plane (Unit: mm)

Figure 1: Configuration of model building and platform

To reduce velocity response of a batch of high tech equipment installed in a building subject to ground motion, high tech equipment is now to be installed on the hybrid platform rather than on the building floor. Therefore, the control performance of the platform is assessed by comparing its absolute velocity with that of the corresponding building floor without the platform under the same traffic-induced ground motion. The platform was mounted on the second floor of the building model through two leaf

springs. The platform was clamped on the leaf spring using three steel clamps: one fixed in the middle of the leaf spring and two designed movable in opposite direction to change the horizontal stiffness of the platform. Two shear type oil dampers were designed and installed between the platform and the second floor of the building model. Different damper damping coefficients could be achieved. An electromagnetic exciter JZK-5 was selected as an actuator to control the platform. The maximum force which could be generated by the actuator was 50 N. The force exerted on the platform by the actuator was measured using a load cell installed between the actuating rod of the actuator and the platform.

Ground Motion and Instrumentation

The experiments were carried out on the shaking table of the Hong Kong Polytechnic University. The traffic-induced ground motion was simulated using a uniformly modulated nonstationary random process (Yang and Agrawal, 2000). As the shaking table used was a seismic simulator and the building model was light, the maximum simulated ground acceleration was taken as 0.06g to ensure the normal operation of the seismic simulator, where g is the acceleration due to gravity in m/s^2. Such high ground acceleration may not be subjected by high tech facilities in real situation. However, since the linear building and platform and the linear control algorithm are concerned in this experiment, the normalized velocity responses of both the building and platform obtained from the experiment still provide a good indication of the performance of hybrid platform. Fig.2 shows the ground acceleration time-history generated by the shaking table to reproduce the nearby traffic-induced ground motion and recorded by the accelerometer installed on the surface of shaking table in the horizontal direction. The duration of the simulated ground motion was 15 seconds. The dominant frequency of the simulated ground motion ranged from 6 Hz to 35 Hz. The sampling frequency of the ground acceleration time histories was 100 Hz.

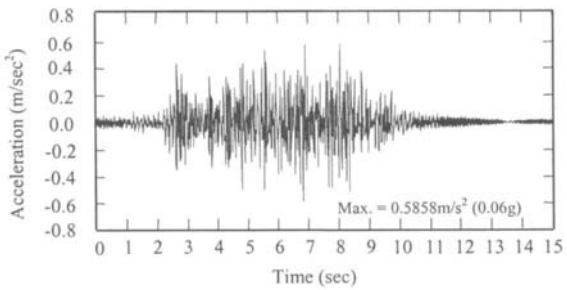


Figure 2. Compressed ground acceleration time history used in experiment

Each building floor was equipped with one B&K 4370 accelerometer in the x-direction (see Fig.1). Two Keyence LK-503 laser displacement transducers were used to measure the absolute horizontal displacement responses of both the platform and the second floor of the building (See Fig.1). The difference between the two displacement responses gave the platform drift. The signal from each B&K 4370 accelerometer was transferred to the B&K 2635 signal conditioner by which the acceleration signal could be amplified and/or converted into velocity signal using the built-in electronic circuit. The signal from the signal conditioner was then passed to a dSPACE DS1005 real-time simulator system. The displacement signal from the laser displacement transducer was also transferred to the dSPACE DS1005 real-time simulator system and sampled at 100 Hz. A power amplifier YE587 was used to provide the power to the electromagnetic exciter. The power amplifier was controlled by the dSPACE real-time simulator system. The hybrid control of the platform in this experiment was realized by using the dSPACE real-time simulator system together with the MATLAB/Simulink program on the host computer via Real Time Interface (RTI).

DYNAMIC PROPERTIES AND HYBRID CONTROL

Dynamic Properties

The natural frequencies, mode shapes, and modal damping ratios of the building model without platform were identified experimentally. The first three natural frequencies of the building model were 8.64 Hz, 25.29Hz, and 38.91 Hz. The platform can be seen as a single degree of freedom system in the x-direction. The mass of the platform together with the six clamps and two worms were weighed as 20.5 kg. For a given position of the two movable clamps and a given gap of the oil damper and with the actuator being switched off, the natural frequency and damping ratio of the platform were identified. The given position of the two movable clamps was designated in terms of the distance between the two movable clamps. The distance was selected in this investigation as 100mm (refer to D1), 250mm(refer to D2), and 300 mm (refer to D3). The gap of the oil damper was selected as 1mm (refer to C3), 2mm (refer to C2), and 3mm (refer to C1), respectively. If the gap of the oil damper exceeded 6mm, the piston of the damper did not touch any oil, leading to a no damper case (refer to C0). The natural frequencies and damping ratios of the platform were identified from the transfer functions using the bandwidth method for a series of the clamp position and the damper gap and listed in Table 1.

TABLE 1
IDENTIFIED NATURAL FREQUENCIES AND DAMPING RATIOS OF THE PLATFORM

Clamp distance D(mm)	Disk gap d(mm)	Natural frequency (Hz)	Damping ratio(%)
100	1	6.15	12.70
	2	6.15	10.53
	3	6.05	8.07
	No damper	5.66	6.04
250	1	8.20	7.15
	2	8.20	6.75
	3	8.01	6.17
	No damper	7.91	4.94
300	1	11.8	4.97
	2	11.8	4.55
	3	11.7	3.76
	No damper	11.7	3.76

Hybrid Control

For the active control, there was always a trade-off between the response reduction and the control power required. In the present work, the maximum driving force that could be generated by the electromagnetic actuator was 50N. From a practical point of view, it is difficult, if not impossible, to measure the response of all the building floors and the platform. The sub-optimal control strategy was adopted in the experiment. The sub-optimal control strategy used only the absolute velocity of the platform as a feedback variable. By trial and error, a nominal feedback control gain between the selected feedback velocity response of the platform and the control force of the actuator was determined as 640 N.s/m. Then, the feedback control gain used in the experiment changed from 20% to 100% of the nominal feedback control gain at an interval of 20%.

EXPERIMENTAL RESULTS AND ANALYSIS

Building without Platform and with Passive Platform

The building model without the platform was first tested under the nearby traffic-induced ground motion as shown in Fig.2. Fig. 3a displays the velocity response time history of the second floor of the building without the platform. The measured maximum and rms velocity responses of the second floor are 90.04mm/s and 26.13mm/s, respectively. For the case of the building without the platform, high tech equipment is supposed to be installed on the second floor of the building. Thus, the measured velocity response of the second floor of the building without platform provides a basis for the evaluation of the effectiveness of the platform by comparing it with the velocity response of the platform.

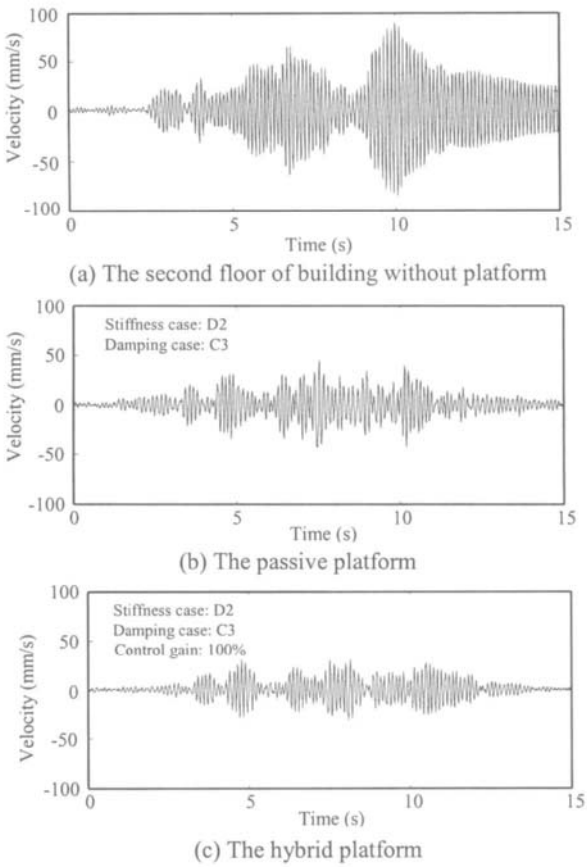

Figure 3. Comparison of absolute velocity response time histories

The building model with the passive platform presented and with the actuator switched was then tested under the traffic-induced ground motion selected. The stiffness of the passive platform varied from case D1 to case D3 in an ascending order, and the damping ratio of the passive platform altered from case C0 to case C3 also in an ascending order. There were a total of 12 test cases. The measured absolute velocity response of the passive platform was then divided by the absolute velocity response of the second floor of the building without platform to obtain the normalized velocity response (velocity response ratio) of the passive platform.

Depicted in Fig.4 are the normalized maximum velocity responses of the passive platform against the frequency and damping of the platform. The normalized maximum velocity response less than one indicates that the response of the passive platform is less than that of the second floor of the building without platform, that is, the velocity response of high tech equipment is reduced. It can be seen that except for stiffness case D3, all the normalized maximum velocity responses of the passive platform are less than one. The maximum velocity response of high tech equipment can be reduced to as low as 36% of the corresponding second floor velocity response of the building without platform. It is also seen that the platform of smaller stiffness has lower velocity response and larger velocity response reduction. Fig. 4 also shows a trend that larger damping ratio of the passive platform produces larger velocity response reduction for high tech equipment.

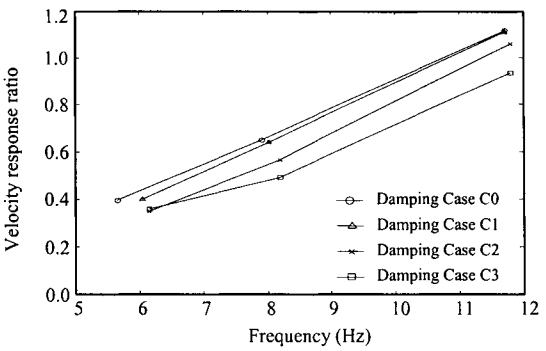

Figure 4. Normalized maximum velocity response of platform

Fig. 3b displays the velocity response time history of the passive platform with case D2 for its stiffness and case C3 for its damping ratio under the same traffic-induced ground acceleration as shown in Fig.2. It clearly demonstrates that the velocity response of the passive platform is much smaller than that of the second floor of the building without the platform as shown in Fig.3a. The maximum and rms velocity responses of the passive platform are 44.38 mm/s 11.64 mm/s only, leading to 51% and 55% reduction, respectively. This signifies that if high tech equipment is installed on the passive platform, its velocity response to traffic-induced ground motion via the building floor will be much smaller than that if it is directly installed on the building floor.

Building with Hybrid Platform

The building model with the hybrid platform was finally tested under the traffic-induced ground motion selected. For a given platform stiffness and damping ratio, the velocity feedback control gain of the hybrid platform varied from 20% to 100 % of the nominal control gain of 640 N.s/m at an interval of 20%. There were a total of 60 test cases. The measured absolute velocity response of the hybrid platform was then divided by the absolute velocity response of the second floor of the building without the platform to obtain the normalized velocity response (velocity response ratio) of the hybrid platform.

Plotted in Fig. 3c is the time history of velocity response of the hybrid platform with stiffness case D2, damping case C3, and 100% control gain. The maximum and rms velocity responses of the hybrid platform are 31.22 mm/s and 9.30 mm/s, respectively. The maximum and rms velocity responses of the hybrid platform are only 35% and 36% of the corresponding response of the second floor of the building without the platform. It is also smaller than the absolute velocity response of the passive platform by 30 % for the maximum response and by 20% for the rms response.

Fig.5 shows variations of the normalized maximum velocity response of the hybrid platform with control gain for three stiffness cases from D1 to D3 and one damping case C3. It is seen from Fig.5 that as the stiffness of the platform decreases from case D3 to case D1, the velocity response of the passive platform reduces from 94% to 36% of the second floor velocity response of the building without the platform. The velocity response of the hybrid platform at 100% control gain reduces from 65% to 24 % of the second floor velocity response of the building without the platform, and from 69% to 67% of the velocity response of the passive platform. These results demonstrate the effectiveness of the passive platform and the superior performance of the hybrid platform over the passive platform.

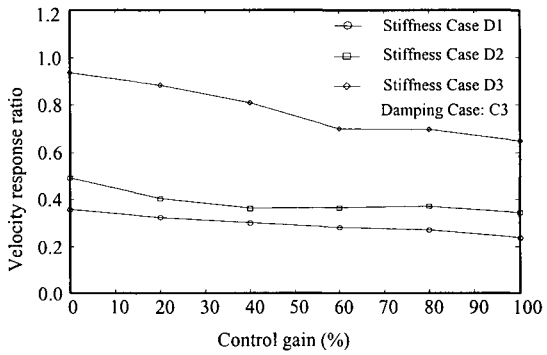

Figure 5. Normalized maximum velocity response of hybrid platform vs. control gain & stiffness

While the use of hybrid platform can significantly reduce the velocity response of high tech equipment, it can also reduce the drift of the platform compared with the passive platform. Fig. 6 shows variations of the normalized rms drift (drift ratio) of the platform with control gain for three stiffness cases from D1 to D3 and one damping case C3. The rms drift of the hybrid platform plotted in Fig.6 is normalized by the rms drift of the corresponding passive platform. It is seen that with the increase of control gain, the drift of the hybrid platform decreases. The drift of the hybrid platform can be reduced to 61%, 54%, and 49% of the drift of the corresponding passive platform for stiffness case D1, D2 and D3, respectively. The significant reduction of the platform drift benefits the practical use of the hybrid platform. The high performance of the hybrid platform is attributed to the control force or control power provided by the actuator. Fig.7 shows variations of the maximum control force with control gain for the building under the selected ground motion of peak acceleration of 0.06g and for the platform of three stiffness cases from D1 to D3 and one damping case C3. It is seen that with the increase of control gain, the velocity response and drift of the hybrid platform are reduced as shown in Figs. 5 and 6, but the required control force increases as shown in Fig.7. It is also seen that the platform of higher stiffness needs larger control force. However, it was found that the control power required was not significantly larger in the case of higher control gain or larger control force.

CONCLUSIONS

An experimental study has been carried out to examine the effectiveness of a hybrid platform for mitigating the vibration of a batch of high tech equipment installed in a building subject to nearby traffic-induced ground motion. A series of shaking table tests have been performed on a three-story building model without the platform, with the passive platform of different parameters, and with the hybrid platform of velocity feedback control. The experimental results demonstrated that the passive platform is effective in reducing the velocity response of high tech equipment in the building subject to nearby traffic-induced ground motion if the stiffness of the platform is small. The hybrid platform is

more effective than the passive platform in reducing both the velocity response of a batch of high tech equipment and the drift of the platform, in particular when the stiffness of passive platform is high.

ABSTRACT

A comprehensive experimental investigation on dynamic characteristic and seismic response of adjacent buildings linked by fluid dampers is carried out using a 4m x 4m seismic simulator. Two building models are built as one five-story steel frame 5m high and the other six-story steel frame 6m high. The fluid dampers connecting the two building models are of linear force-velocity property. The control performance of fluid dampers is assessed through the comparison of dynamic characteristic and seismic response of the adjacent buildings linked by fluid dampers with those linked by rigid rods or without any connections. The effects of the number, location, and linking pattern of fluid dampers on control performance are then investigated. The experimental results show that the installation of fluid dampers can significantly reduce the seismic responses of both buildings. The number, location, and linking pattern of fluid dampers should be considered properly to achieve good control performance.

KEYWORDS

Seismic response control, adjacent buildings, fluid damper, rigid rod, seismic simulator.

INTRODUCTION

Buildings in a modern city are often built closely to each other because of limited land available and centralized services preferable. Most of these buildings are separated without any structural connections. Some of adjacent buildings are linked by sky bridges at several locations to provide a horizontal transportation system for access to the two buildings. Some of adjacent buildings are rigidly connected by stiff plates or beams at a few locations to enhance the lateral stiffness of the buildings. The concept of linking adjacent buildings using passive dampers, semi-active dampers, or active dampers has been thus proposed to improve their seismic resistant performance.

Westermo (1989) analytically investigated the seismic behavior of adjacent buildings connected by hinged rigid links. Kobori et al.(1988) developed bell-shaped hollow connectors to link adjacent buildings in a complex. Zhang and Xu (2000) presented a framework for estimating modal damping ratios and stochastic seismic responses of adjacent buildings connected by fluid dampers. Apart from

passive control, Seto and Matsumoto (1996) suggested using active actuators to connect a group of buildings and investigated how to prevent spillover problem. Xu and Zhang (2002) presented a closed form solution for seismic response of adjacent buildings with LQG controllers. Christenson et al (1999) investigated the semi-active control of adjacent buildings using modern smart dampers with a clipped-optimal control strategy.

The experimental investigations of adjacent buildings linked by passive control devices are very limited. Xu et al. (1999) experimentally investigated dynamic characteristic and response of adjacent buildings connected by fluid dampers. The experimental was, however, conducted by applying a harmonic excitation in one direction only. As a continuing investigation, this paper thus performs a series of experiments of adjacent buildings linked by fluid dampers on a 4m x 4m seismic simulator. The experimental arrangement, including the design of two large-scale building models and the instrumentation, is introduced. The performance of fluid dampers is then assessed through the comparison of seismic responses of the adjacent buildings linked by fluid dampers with those linked by rigid rods or without any connections. Effects of the number, location, and linking pattern of fluid dampers on control performance are also investigated.

EXPERIMENTAL ARRANGEMENT

Two building models of 1:4 length scale were designed and built. Building 1 was constructed as a symmetric single-bay six-story steel frame while Building 2 was made as a symmetric single-bay five-story steel frame (see Fig. 1). The overall dimensions of Building 1 were 1.95m×1.95m in plane and 6.0m in elevation while Building 2 had a dimension 2.0m×1.08m in plane and 5.0m in elevation. The story height for each building was 1.0m. The two building models were set on the shaking table side by side with a distance of 637mm for the installation of fluid dampers. Fluid dampers used in the experiment were 1.5x 4 d-series linear fluid dampers with a 102 mm stroke and a maximum damping force of 8900 N, designed and manufactured by Taylor Devices Inc., USA. The d-series fluid dampers were extensively calibrated and tested by Constantinou and Symans (1993). The damping coefficient of the used fluid damper at zero frequency was about 15.41 N.s/mm.

The experiments were carried out on a six-degree-freedom seismic simulator of the State Key Laboratory for Disaster Reduction in Civil Engineering at Tongji University in Shanghai, China. The shaking table was manufactured by the MTS corporation, USA, with the size 4.0m×4.0m in plane and the maximum specimen weight 250KN. The simulated seismic motion can be generated in two horizontal directions and one vertical direction simultaneously with the maximum accelerations of 1.2g, 0.8g, and 0.7g, respectively. A total of 23 accelerometers were arranged in the two buildings to measure their absolute acceleration responses in the x-, y-, and z-directions and their absolute angular acceleration responses about the z-axis. The locations of the accelerometers are indicated in Fig. 1. The dynamic displacement responses of both buildings were obtained from the measured acceleration response time histories through double integration with a proper filter. Subsequently, the relative dynamic displacement of each floor to the shaking table was acquired by subtracting the shaking table displacement from the absolute floor displacement. A total of 6 fluid dampers were available and each fluid damper was installed together with a load cell to measure damper damping force. The signals from all the sensors were directly sent to the data acquisition/processing system of the MTS seismic simulator. The sampling period was 0.01 second for all the tests.

TEST CASES

The whole experiment in this study was divided into 4 phases with 22 cases. Phase 1 is mainly to assess the performance of fluid dampers through the comparison of seismic responses of the adjacent

buildings linked by fluid dampers with those linked by rigid rods or without any connections. Each fluid damper or rigid rod was connected to a building through a hinge. In this phase, the two buildings without any connections were first tested under the El Centro 1940 N-S ground motion of 0.2g peak acceleration in the x-direction only (Case 1) and then under the El Centro ground motions of 0.1g, 0.08g, and 0.06g peak accelerations in the x-, y- and z-directions correspondingly (Case 4). The two buildings were then connected by two rigid rods at the 5th floor at an oblique (45^{o}) angle and tested under the El Centro ground motion in the x-direction only (Case 2) and then under the three directional El Centro ground motions (Case 5). Finally, the two rigid rods were replaced by two fluid dampers at the same position to connect the two buildings, which were also tested under the El Centro ground motion in the x-direction only (Case 3) and then under the three directional El Centro ground motions (Case 6).

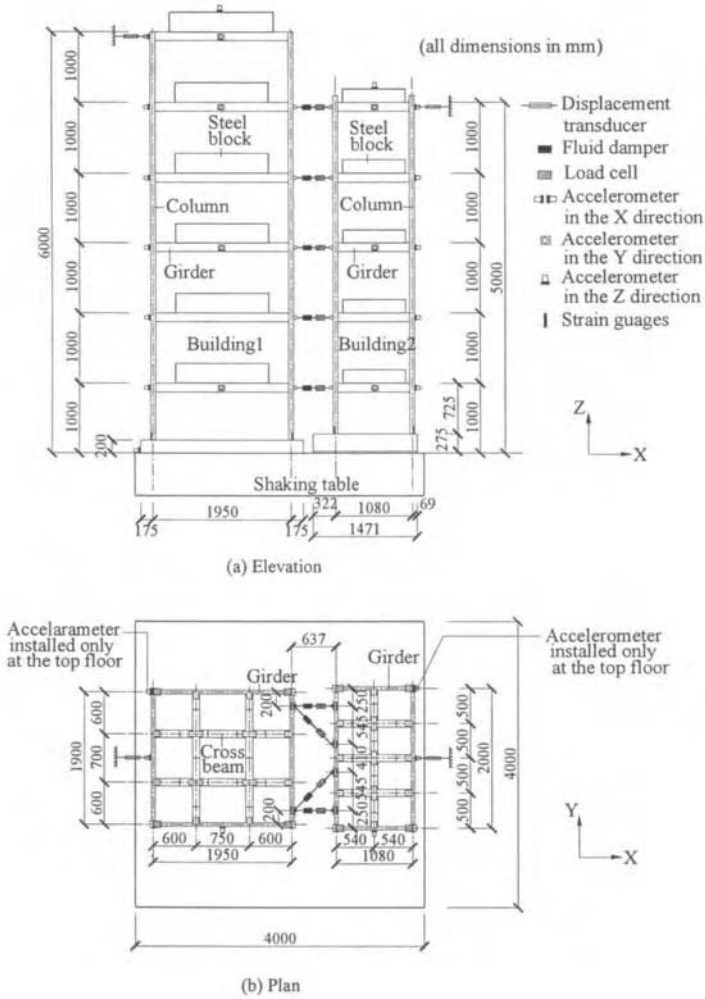

Figure 1: Configuration and instrumentation of adjacent buildings with fluid dampers

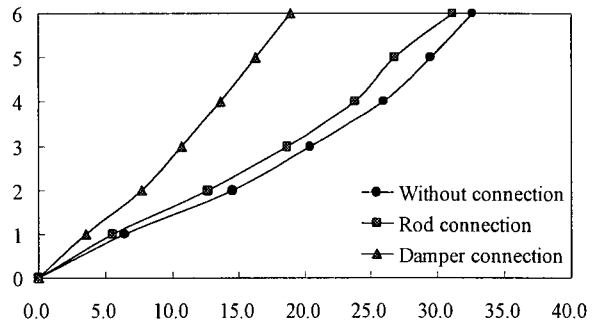
Phase 2 is mainly to investigate effects of the number, location, and linking pattern of fluid dampers on control performance. There were a total of 8 cases in Phase 2. In Case 7 to Case 11, the two buildings were connected by two parallel fluid dampers per floor at the 1st floor only (Case 7), at the 3rd floor

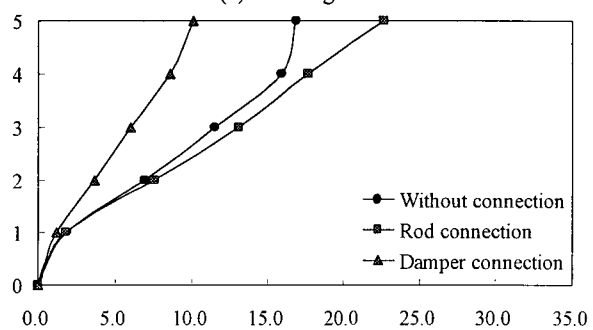
only (Case 8), at the 5th floor only (Case 9), at the 2nd and 4th floors (Case 10), and at the 1st and 3rd and 5th floors (Case 11) under the El Centro ground motion of 0.2g peak acceleration in the x-direction only. In Case 12 to Case 14, the two buildings were connected by two oblique dampers per floor at the 5th floor only (Case 12), at the 2nd and 4th floors (Case 13), and at the 1st and 3rd and 5th floors (Case 14) under the El Centro ground motions of 0.2g and 0.16g peak accelerations in the x- and y-directions, respectively. Because of space limitation, only part of the work involved in phase 1 and phase 2 is presented in this paper.

PERFORMANCE OF FLUID DAMPER



Dynamic Characteristics

To identify the natural frequencies and modal damping ratios of the two buildings with and without connections, a 0.07g white noise ground motion was inputted into the shaking table to excite the two buildings. The recorded acceleration responses were then processed to obtain the transfer functions, from which the natural frequencies and modal damping ratios were estimated. In the x-direction, the first three natural frequencies of Building 1 without any connections were 1.86 Hz, 5.86 Hz, and 9.77 Hz while the first three natural frequencies of Building 2 without any connections were 3.42 Hz, 10.35 Hz and 16.02 Hz, respectively. For the two buildings pin-connected by the two rigid rods at the 5th floor and at a 45° angle, the first three natural frequencies of Building 1 were the same as those of Building 2 with the values of 2.34 Hz, 5.76 Hz, and 9.86Hz, respectively. This result implies that the two buildings are strongly coupled in the x-direction. For the two buildings connected by two fluid dampers at the same position as the two rigid rods, the first three natural frequencies dominated by Building 1 were 2.05 Hz, 5.86 Hz, and 9.77 Hz while those dominated by Building 2 were 3.71 Hz, 10.55 Hz, and 16.02 Hz, respectively. Evidently, the installation of the fluid dampers only slightly changed the first natural frequency of each building while remaining the higher frequencies almost unchanged. The retention of the natural frequencies of the unlinked buildings is especially desirable for the adjacent buildings that have already been built and need to be strengthened. The more important result is that with the installation of fluid dampers, the first modal damping ratio dominated by Building 1 was increased from 1.78% to 7.14% and that dominated by Building 2 was enhanced from 1.67% to 10.80%. For the rigid rod connection, the modal damping ratios changed only slightly compared with the buildings without any connections.



Seismic Response to One Directional Excitation

The seismic responses of the two buildings with and without connections presented in this section were obtained under the El Centro ground motion of 0.2g peak acceleration in the x-direction only. The seismic responses obtained from the recorded time-histories included the maximum and root-mean-square (RMS) relative displacement response, the maximum and RMS absolute acceleration response, and the maximum and RMS story drift. Because of space limitation, only a small part of results can be presented in this section. Figs. 2a and 2b depict variations of the maximum relative displacement responses of the two buildings to the shaking table with building height. It is seen that with the rigid rod connection, the maximum relative displacement responses of Building 1 are only slightly reduced while those of Building 2 are actually increased significantly at the top floor by 33.8 % compared with the building without connection. With the fluid dampers installed, the maximum relative displacement responses of both buildings are considerably reduced with the maximum reduction by 42.1 % at the top of Building 1 and by 40.6 % at the top of Building 2. These results are consistent with the changes in the measured modal damping ratios and natural frequencies. As for the maximum story drifts of the two buildings, with the rigid rod connection the maximum story drifts of Building 2 were actually increased by up to 62.0 % except for the 1st floor. The maximum story drifts of Building 1 were increased at the 3rd and 6th floors but reduced at the 1st, 2nd, and 4th floors. For the two buildings connected by the two fluid dampers, the maximum story drifts of both buildings were significantly reduced with the

maximum reduction by 44.4 % for Building 1 and by 55.4 % for Building 2 at the 2nd floor. The above results clearly demonstrate the effectiveness of fluid dampers in reducing the seismic responses of both buildings.

(a) Building 1

(b) Building 2

Figure 2: Variations of maximum relative displacement responses with building height

Seismic Response to Three Directional Excitations

The two buildings with and without connections were also tested under 3-D El Centro excitations with 0.1g, 0.08g and 0.06g peak accelerations in the x-, y- and z-directions, respectively. It was found that the seismic responses of both buildings in the z-direction were very small and seemed not to affect the seismic responses of both buildings in the x- and y-directions. In the x-direction, it was found that the measured seismic responses of the two buildings with and without connections were almost proportional to those under the x-directional El Centro excitation described in the last section. The fluid dampers were quite effective in reducing the seismic responses of both buildings whereas the rod connections enlarged the maximum relative displacement response of Building 2 and slightly reduced the maximum relative displacement response of Building 1.

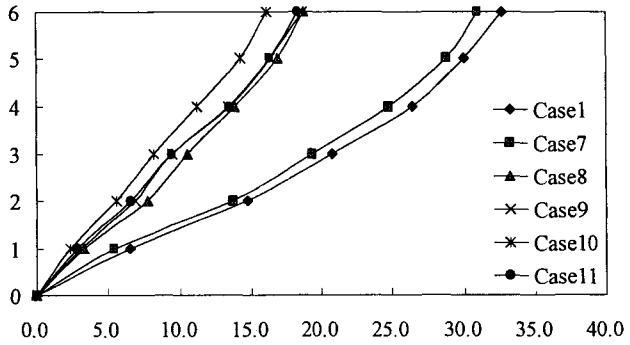
In the y-direction, it was found that the installation of fluid dampers remarkably reduced the seismic responses of Building 2 but only slightly abated that of Building 1. The rod connections could not reduce the seismic response of Building 1 and only slightly reduced that of Building 2. For the two building models investigated, the connection of the two buildings by either rigid rods or fluid dampers under the y-directional excitation introduced some small torsional vibration to both buildings. Compared with the rod connection, the fluid dampers induced much less torsional response to the buildings. Though the use of fluid dampers to connect the two symmetric buildings may introduce

some small torsional vibration when the ground motion in the y-direction, it may be able to reduce excessive torsional vibration for two buildings of irregular shape but it needs further investigation.

EFFECTS OF DAMPER NUMBER AND LOCATION

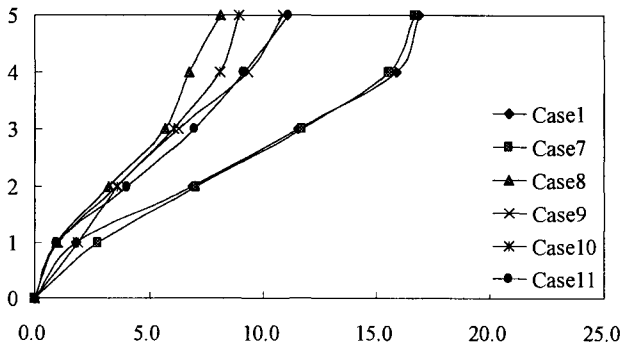
Parallel Arrangement of Dampers

To investigate effects of the number and location of fluid dampers on control performance, the two buildings were connected by two parallel fluid dampers per floor at the 1st floor only (Case 7), at the 3rd floor only (Case 8), at the 5th floor only (Case 9), at the 2nd and 4th floors (Case 10), and at the 1st and 3rd and 5th floors (Case 11). The 0.07g white noise ground motion was first used to identify the natural frequencies and modal damping ratios for each case. The El Centro ground motion of 0.2g peak acceleration was then inputted into the shaking table in the x-direction to record seismic responses of the two buildings.



In Case 7 where the two fluid dampers were installed at the 1st floor, the first three natural frequencies dominated by either building remained almost the same as those of the building without any connection. The first three modal damping ratios dominated by Building 1 were moderately increased but those dominated by Building 2 changed slightly compared with the building without connection. When the two dampers was moved to the 3rd floor (Case 8), the 2nd natural frequency of Building 1 could not be clearly identified from the transfer function while the first three natural frequencies dominated by Building 2 were changed slightly. The identified first modal damping ratios dominated by Building 1 and Building 2 were 9.14% and 15.5%, respectively. The higher modal damping ratios were not easy to be identified because the measured transfer function became flat around the higher natural frequencies. In Case 9 where the two dampers were installed at the 5th floor, the first three natural frequencies dominated by either building changed slightly compared with those without connection. However, the first modal damping ratio dominated by either building was significantly increased to more than 8%. The results from Case 7 to Case 9 clearly demonstrate the effects of damper location on the dynamic characteristics of the two buildings. When the number of dampers were increased to 4 (Case 10) and 6 (Case 11), the two buildings were strongly coupled and the first natural frequency of both buildings became the same of 2.25 Hz for Case 10 and 2.34 Hz for Case 11. The first modal damping ratios of the buildings were increased to above 6.78% in Case 10 and 6.90 % in Case 11. No higher natural frequencies and modal damping ratios could be identified.

Figures 3a and 3b depict the maximum relative displacement responses of Building 1 and Building 2, respectively, against building height for each case under the El Centro ground motion of 0.2g peak acceleration in the x-direction. For Building 1, the most effective arrangement of fluid dampers is either Case 10 using four fluid dampers or Case 8/Case 9 using two dampers only. The maximum relative displacement response of the top floor is reduced by 50.6 % in Case 10 and by 42.4 % in Case 8. For Building 2, the most effective arrangement is Case 8 where only the two dampers were arranged at the 3rd floor. The maximum relative displacement response of the top floor is reduced by 52 %. It is interesting to see that the use of more dampers (Case 11) may not achieve larger vibration reduction for Building 2. This may be because the damping coefficient of dampers used in the tests is not optimal for Case 11.



Oblique Arrangement of Dampers

This section examines the two buildings connected by two oblique dampers per floor at the 5th floor only (Case 12), at the 2nd and 4th floors (Case 13), and at the 1st and 3rd and 5th floors (Case 14). In such arrangements, not only the effects of damper number and location but also the effects of damper damping coefficient on control performance could be examined. This is because when a fluid damper

was arranged at an angle of 45^0 to the building motion, its original damping coefficient would be reduced by 50% in the direction of building motion.

(a) Building 1

(b) Building 2

Figure 3: Effects of number and location of fluid dampers

The first three natural frequencies and modal damping ratios dominated by either building in the x-direction or the y-direction in Case 12 were the same as those in Case 3. For the two buildings connected at the 2^{nd} and 4^{th} floors (Case 13), the first natural frequency dominated by Building 1 in the x-direction had a slight change to 2.05 Hz and the higher natural frequencies had almost no change compared with the building without connection. The first modal damping ratio dominated by Building 1 had an increase to 6.75 %. For Building 2, only the first natural frequency could be clearly identified as 3.71 Hz and the corresponding modal damping ratio was 7.68%. In the y-direction, the natural frequencies and modal damping ratios identified from Case 13 were close to those from Case 12. When the two buildings were linked at the 1^{st}, 3^{rd}, and 5^{th} floors (Case 14), the first natural frequency of both buildings became the same of 2.05 Hz but the higher natural frequencies could not be accurately identified. The first modal damping ratio was 10.8% for Building 1 and 11.9% for Building 2. Compared with Case 11 in which the two buildings were connected at the 1^{st}, 3^{rd}, and 5^{th} floors but with parallel arrangement of dampers, one may find that the first modal damping ratio of either building with oblique arrangement of dampers was considerably increased. This confirms that the damper damping coefficient used in Case 11 was not optimal.

Corresponding to the changes in natural frequencies and modal damping ratios, the most effective arrangement of fluid dampers for Building 1 and Building 2 was Case 14 in the x-direction. The maximum relative displacement response of the top floor of Building 1 was reduced by 49.6% for

Building 1 and 49.1% for Building 2. The reduction of RMS relative displacement response was even larger. In the y-direction the three cases gave almost the same control performance. The maximum relative displacement response of the top floor was reduced by 8.9 % for Building 1 and 51.6% for Building 2.

CONCLUSIONS

A comprehensive experimental investigation on dynamic characteristic and seismic response of adjacent buildings linked by fluid dampers has been carried out on a 4m x 4m seismic simulator using a five-story steel frame 5 m high, a six-story steel frame 6 m high, and a few Taylor fluid dampers. The experimental results showed that the installation of fluid dampers of proper parameters could significantly increase the modal damping ratios and reduce the seismic responses of both buildings while remaining the natural frequencies of both buildings almost unchanged. The seismic performance of adjacent buildings linked by fluid dampers was more superior than that of the adjacent buildings linked by rigid rods. The number, location, and linking pattern of fluid dampers should be properly selected in order to achieve good control performance. For the two buildings investigated, two fluid dampers installed at the 3rd floor gave the best performance. The use of more dampers did not necessarily achieve larger vibration reduction. The oblique damper arrangement could reduce the seismic responses of both buildings in two directions but it could introduce some torsional effects.

SEISMIC RESPONSE CONTROL OF MULTI-STORY BUILDINGS USING SEMIACTIVE FRICTION DAMPERS

C.L. Ng and Y.L. Xu

Department of Civil and Structural Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong

ABSTRACT

This paper presents an investigation on the seismic response control of multi-story buildings using semi-active friction dampers (SAFD) in conjunction with the ordinary braces. Piezoelectric materials are used to control the clamping force of a friction damper so as to regulate the slip force of the damper through simple feedback of stick or slip status of the damper. The performance of SAFD in suppressing structural vibration is assessed by considering first a single-story building under white noise excitation and then a multi-story building under El-centro seismic ground motion. The responses of the buildings with SAFD are compared with those of the buildings without control and with passive friction dampers (PFD). The simulation results demonstrate the effectiveness of semi-active friction dampers and the robustness and adaptability of the buildings with SAFD to different excitation intensities and damper parameters.

KEYWORDS

Multi-story building, seismic response, semi-active friction damper, control algorithm, parametric study, comparison.

INTRODUCTION

Passive friction damper (PFD) is one of the widely accepted energy dissipating devices for vibration control of civil engineering structures. Not only the performance of passive friction dampers in abating seismic response of structures has been verified by numerous experimental and analytical studies, but also they have been implemented into many real buildings and structures of a variety of configurations in the past twenty years. Pall and Marsh (1982) developed the friction devices for X-bracing in frame structures, which were further put in practical application by Pall and Pall (1993) in the aseismic design and construction of some new buildings and retrofitting of existing buildings. An efficient numerical modeling for Pall friction device was described by Filiatrault and Cherry (1989) who proposed a simplified design procedure for the friction damped braced frames in 1990 leading to a greater acceptance of the design.

As the friction dampers are operated in passive nature, a specific slip force should be decided so as to optimize the reduction of structural vibration for particular ground excitation. However, the slip force preset based on one ground excitation may not be optimal parameter for another excitation. In this connection, semi-active friction dampers (SAFD) of which the slip force can be adjusted in real time may be able to overcome the problem and further enhance the efficacy of friction devices. Akbay and Aktan (1991) and Kannan et al (1995) proposed an actively regulated friction slip braces where the pre-specified clamping load was regulated by a fixed increment in response to the stick and slip status of the damper. A similar device was considered by Dowdell and Cherry (1994) by employing two semi-active control algorithms, the off-on control scheme and the continuously variable amplitude friction damper scheme.

Most of previous studies on semi-active friction dampers employed hydraulic actuators to regulate the clamping forces of dampers. This paper suggests using piezoelectric materials as an actuator to regulate the slip force of the damper through a simple feedback of damper motion status. The control algorithm adopted in the study was suggested by Akbay and Aktan which attempts to reverse the sticking and sliding status of the damper at the friction interface by reducing or increasing the slip force by one pre-specified increment at fixed time intervals to initiate early energy dissipation. This control algorithm is preferred due to the advantage that only local feedback information is sufficient to achieve the feedback control of structure, which is also motivated from both economical and practical points of view. The performance of SAFD in suppressing structural vibration is assessed by considering first a single-story building under white noise excitation and then a multi-story building under El-centro seismic ground motion in this paper. The responses of the buildings with SAFD are then compared with those of the buildings without control and with passive friction dampers.

FORMULATION AND ANALYTICAL PROCEDURE

Equation of Motion of Friction Damped Buildings

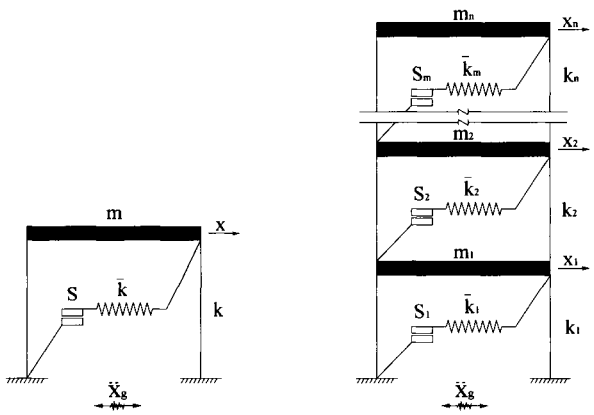
Consider an n-story building in which m friction dampers of each connected in series with an elastic axial member are installed in selected story units as shown in Fig. 1. The system is idealized as an n-degree-of-freedom linear system and is subjected to one-dimensional ground acceleration $\ddot{x}_g$. The equation of motion of the system is given by

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = -\mathbf{M}\mathbf{l}\ddot{x}_g + \mathbf{B}\mathbf{u} \tag{1}$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the $n \times n$ mass, damping and stiffness matrices of an n-story unbraced frame, respectively; $\mathbf{x} = [x_1, x_2, \ldots, x_n]^T$ is the n-dimensional lateral displacement vector relative to ground; $\dot{\mathbf{x}}$ and $\ddot{\mathbf{x}}$ are the velocity vector and acceleration vector, respectively; $\mathbf{l}$ is the $n \times 1$ unit vector denoting the influence of the horizontal ground acceleration $\ddot{x}_g$ to the masses; $\mathbf{B}$ is the $n \times m$ matrix describing the locations of semi-active friction dampers; and $\mathbf{u} = [u_1, u_2, \ldots, u_m]^T$ is the m-dimensional control force vector depending on the sticking and slipping status of the damper as follows:
(i) If the i^{th} damper is sticking, $|u_i| \leq S_i$

$$u_i = \bar{k}_i (d_i - e_i) = \bar{k}_i z_i \tag{2}$$

$$\bar{\mathbf{K}} = \mathrm{diag}[\bar{k}_1, \bar{k}_2, \ldots, \bar{k}_m] \tag{3}$$



in which $\bar{k}_i$ is the i^{th} element of the lateral diagonal brace stiffness matrix $\overline{\mathbf{K}}$; d_i and e_i are the inter-story drift and lateral slip deformation of friction damper on the i^{th} story, respectively; z_i denotes the elastic lateral deformation of the brace; and S_i is the lateral slip force of the i^{th} friction damper.
(ii) If the damper is slipping, $|u_i|>S_i$

$$u_i = S_i \, \mathrm{sgn}(z_i) \tag{4}$$

$$\mathrm{sgn}(z_i) = \begin{cases} 1 & \text{if } z_i > 0 \\ -1 & \text{if } z_i < 0 \end{cases} \tag{5}$$

where the lateral brace force is tensile if $\mathrm{sgn}(z_i)$ is positive and vice versa. When the aforementioned damped brace system is operated passively, the lateral damper slip force S_i is fixed. However, in respect to semi-active control, if the damper slips in the previous decision interval, the slip force is raised to achieve more energy dissipation. On the other hand, if slippage does not take place in the previous decision interval, the slip force is lowered to come into slipping stage and invoke the energy dissipation. Therefore, the slip force S_i is regulated by a constant slip load increment ΔS_i with time and is given by,

$$S_i(t_i) = \begin{cases} S_i(t_{i-1}) - \Delta S_i & \text{(sticking)} \\ S_i(t_{i-1}) + \Delta S_i & \text{(slipping)} \end{cases} \tag{6}$$

(a) Single-story model (b) Multi-story model

Figure 1: Schematic diagrams of friction damper-building systems

Numerical Simulation

Equation of motion of friction damped system expressed by Eq. 1 can also be written in incremental form as

$$\mathbf{M}\Delta\ddot{\mathbf{x}} + \mathbf{C}\Delta\dot{\mathbf{x}} + \mathbf{K}\Delta\mathbf{x} = -\mathbf{M}\mathbf{I}\Delta\ddot{x}_g + \mathbf{B}\Delta\mathbf{u} \tag{7}$$

Based on the Wilson-θ method, the incremental pseudo-static equilibrium equation is given by

$$\hat{\mathbf{K}}\hat{\Delta}\mathbf{x} = \hat{\Delta}\mathbf{P} \tag{8}$$

where

$$\hat{\mathbf{K}} = \mathbf{K} + \frac{6}{\tau^2}\mathbf{M} + \frac{3}{\tau}\mathbf{C} \tag{9}$$

$$\hat{\Delta}\mathbf{P} = \theta\Delta\mathbf{P} + \theta\mathbf{B}\Delta\mathbf{u} + \mathbf{M}(\frac{6}{\tau}\dot{\mathbf{x}} + 3\ddot{\mathbf{x}}) + \mathbf{C}(3\dot{\mathbf{x}} + \frac{\tau}{2}\ddot{\mathbf{x}}) \tag{10}$$

$$\Delta\mathbf{P} = -\mathbf{M}\mathbf{I}\Delta\ddot{x}_g \tag{11}$$

$$\tau = \theta\Delta t \tag{12}$$

As explained in Eqs. 2 and 4 that the control force vector $\mathbf{u}$ is a function of displacement vector $\mathbf{x}$. However, it can be observed from Eqs. 8 and 10 that the pseudo-displacement increment vector $\hat{\Delta}\mathbf{x}$ is a function of control force increment vector $\Delta\mathbf{u}$. Therefore, successive iterations should be employed in solving Eq. 8.

Definition of Key Parameters

To find beneficial parameters of dampers for achieving the maximum reduction of seismic response of the passively controlled building through parametric studies, the stiffness ratio λ and the slip force ratio β are defined as,

$$\lambda = \frac{\bar{k}_i}{k_i}; \qquad \beta = \frac{S_i}{N_i} \tag{13}$$

in which $\bar{k}_i$ and k_i are corresponding to the lateral brace stiffness and the lateral frame stiffness of the i^{th} story unit; S_i is the slip force of the i^{th} friction damper; and N_i is the maximum lateral force in the brace on the i^{th} story under the applied ground excitation where no slippage of the dampers are expected. For studying the performance of semi-active friction damped system with the selected control algorithm, two more parameters, that is, the decision time interval t_d and the slip load increment ΔS_i should be defined, in which the slip load increment is related to the slip force increment ratio as

$$\alpha = \frac{\Delta S_i}{S_i} = \text{Slip force increment ratio} \tag{14}$$

Clearly, the slip force ratio equal to zero represents the case of the building without any brace and control while the slip force ratio equal to one stands for the braced building without control.

COMPUTATION RESULTS

To demonstrate the application of the control method and to examine the performance of semi-active friction dampers, computation results are obtained and presented. Two building models are considered: a single-story building and an eight-story building.

Single-story Building

The single-story building is assumed to have a mass of 345.6×10^3 kg, a lateral frame stiffness of 6.8×10^5 kN/m, and a 2% structural damping ratio. The building is subjected to white noise ground

acceleration over a 5 sec duration as shown in Fig.2, of which the time step is 0.001 sec and the root mean square (RMS) acceleration is 0.632 m/s^2. The RMS drift response of the building is computed with stiffness ratio λ ranging from 0.5 to 5 and illustrated in Figs.3 to 6. It is seen from Fig.3 that the seismic response of the building can be significantly reduced with PFD, compared with the building without PFD ($\beta = 0$) and the building with brace only ($\beta = 1$). There is an optimal slip load for PFD associated with a minimum RMS drift for a given stiffness ratio.

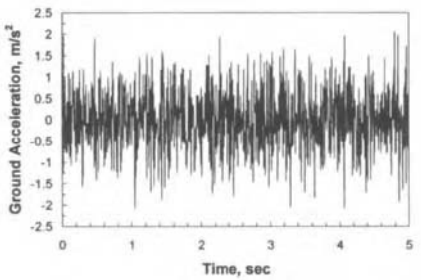


Figure 2: White noise ground excitation

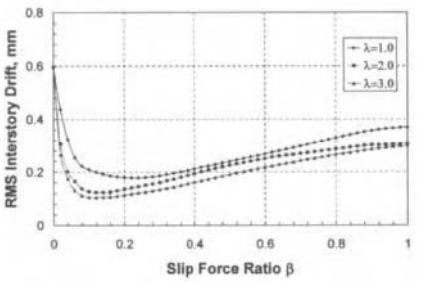

Figure 3: Variation of RMS drift for PFD

Fig. 4 shows a comparison of the RMS drift of the building between PFD and SAFD with λ=1.0, α=0.01, and t_d=0.001. It is demonstrated that the PFD system is sensitive to the preset slip force while the performance of the semi-active friction damper is almost independent of the preset slip force. Practically, the actual slip force in a damper may deviate from the preset slip force due to uncertainties in installation and environmental changes. Thus, the SAFD system demonstrates its robustness: the steady control performance can be guaranteed even though the slip force is changed. However, the maximum drift reduction using the SAFD system is slightly less than that using the PFD system around the optimal slip force.

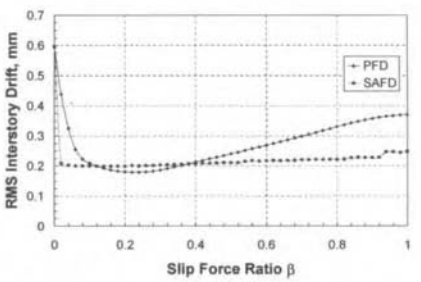

Figure 4: Comparison of PFD and SAFD

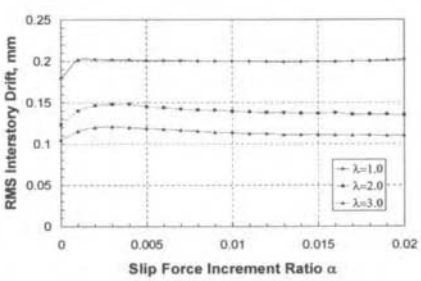

Figure 5: Variation of RMS drift for SAFD

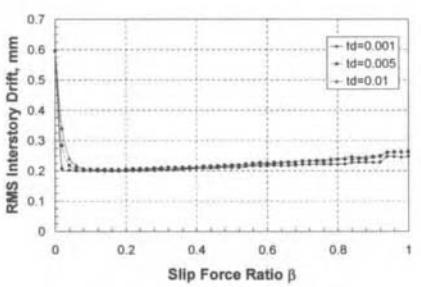

Figure 6: Effect of decision time interval

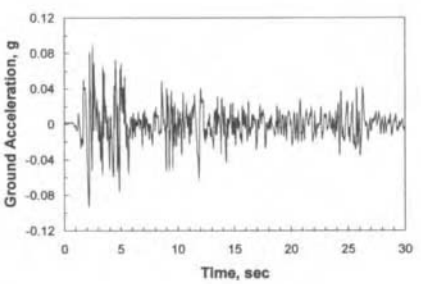

Figure 7: 30% of El Centro earthquake

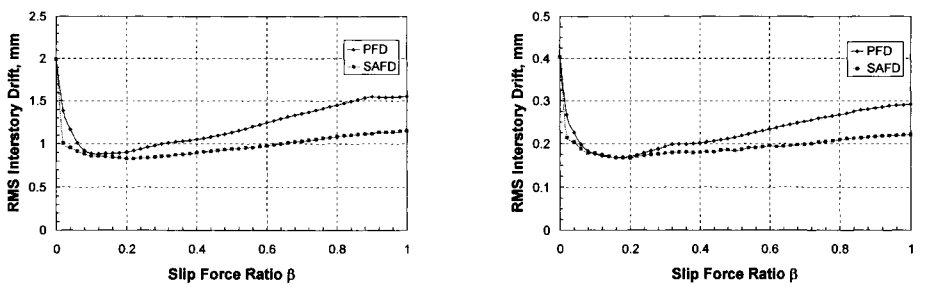

The sensitivity of SAFD to the slip force increment ratio and the decision time interval is illustrated in Figs. 5 and 6 respectively. It can be observed that the performance of semi-active friction damper is quite steady when the slip load increment ratio α is above 0.002. The RMS drift reduction achieved by the semi-active friction damper is slightly less than that by the passive friction damper with the optimal slip force but such difference becomes smaller when the stiffness ratio is higher. Fig. 6 demonstrates that the performance of the SAFD remains almost unchanged when different decision time interval t_d is implemented.

Eight-story Building

A shear-type eight-story building model with the following properties is considered. The mass and stiffness are identical for every story unit with $m_i=345.6\times10^3$ kg and $k_i=6.8\times10^5$ kN/m. The modal damping ratio of 2% is assumed for the first and second vibration mode of the unbraced building where the corresponding first two natural frequencies are 1.30 Hz and 3.86 Hz. The El Centro earthquake ground acceleration scaled to 30% of its original intensity (see Fig. 7) is used as the base excitation. It is supposed that one friction damper is mounted on every story. The stiffness of brace connected to the friction damper is considered to be identical for every story unit. The stiffness ratio chosen in the computation is $\lambda=1$, and the first and second natural frequencies of the braced building are then shifted to 1.84 Hz and 5.46 Hz, respectively. The present slip force distribution for the friction dampers along the height of the building is selected according to the maximum drift distribution of the braced building under the selected earthquake excitation.

$$S = S_1[1 \quad 0.95 \quad 0.89 \quad 0.80 \quad 0.68 \quad 0.54 \quad 0.38 \quad 0.20]^T \tag{15}$$

where S_1 is the slip force for the friction damper at the first story, which is now taken as S_i in Eq. 13 together with N_1 replacing N_i for the multi-story building. This distribution is also applied to the building with semi-active friction dampers initially and then is changed with the slip force increment ratio $\alpha=0.001$.

(a) 1st floor (b) 8th floor

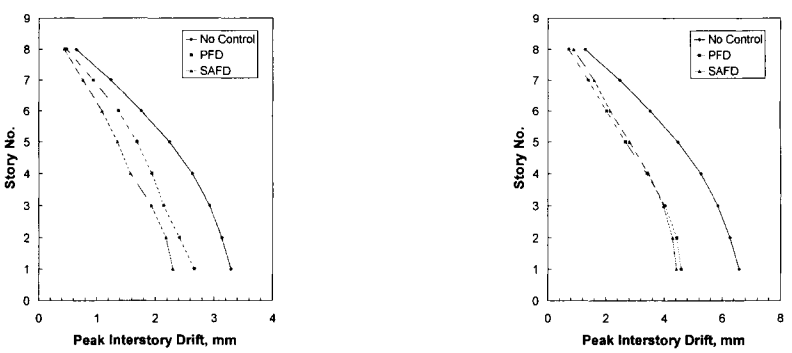

Figure 8: Comparison of RMS drift between PFD and SAFD

Displayed in Figs. 8a and 8b are the RMS drift of the building with passive and semi-active friction dampers against slip force ratio for the first floor and the eighth floor, respectively. It is seen that for the eight story building, the SAFD can not only achieve larger response reduction but also keeps its robustness: less sensitive to the preset slip force. This characteristic of slip force insensitivity enhances the actual application of semi-active friction dampers.

To investigate the sensitivity of both PFD and SAFD to the change of ground excitation, the drift responses of the building under 15% El Centro earthquake are computed using the optimal slip force found in the case of 30% El Centro earthquake. Table 1 lists the peak drifts x_p and RMS drifts x_{rms} of three systems: (i) braced building without control; (ii) braced building with passive friction dampers; and (iii) braced building with semi-active friction dampers. These results are also presented in Figs. 9a and 9b. The results manifest that both the PFD system and the SAFD system are effective in reducing seismic responses of the building. However, when the intensity of ground motion is changed, the control performance of the PFD decreases. The reduction of peak responses achieved by SAFD is larger than that by PFD under 15% El Centro earthquake. The reason for such phenomenon is that the slip forces of SAFD are continuously regulated to low enough slip forces to initiate the energy dissipation which cannot be performed in PFD system which are particularly designed for higher seismic intensity. Although the peak response alleviation achieved by SAFD system under 30% El Centro earthquake is not absolutely improved in comparison with that by PDF system of optimal slip force, the SAFD system can perform further reduction near the end of the earthquake duration (see Fig. 10). As a result, the RMS drifts x_{rms} of the building with SAFD are smaller than that with PFD.

CONCLUSIONS

The application of semi-active friction dampers to reduce seismic response of multi-story buildings has been investigated in this paper. The computation results demonstrate that the semi-active friction dampers have no obvious advantage in reducing the peak drifts comparing with the passive friction dampers designed with optimal slip forces. However, the semi-active friction dampers demonstrate a dominant adaptability in abating the seismic response of buildings under ground motion of different intensities. Moreover, the insensitivity characteristics of semi-active friction dampers to preset slip force, slip force increment, and decision time interval enable them to displace passive friction dampers in real applications.

ABSTRACT

Geographical Information System (GIS) is a computer system for capturing, storing, managing, and analyzing spatial data. GIS has been applied in many areas to deal with the geographic distribution of spatial features, such as natural resources management, urban planning, calamity monitoring and others. Currently, most of the GIS applications are based on two-dimensional (2D) vectors or images and are weak in handling three-dimensional (3D) spatial information. Although structural health monitoring information for bridges can be partially managed by 2D GIS, it would be much more efficient with a 3D GIS. This paper presents a design of structural health monitoring and management system for bridges based on 3D GIS. A discussion on the implementation of the design and analysis of the technique are also presented.

KEYWORDS

Three-dimensional data model, Geographical Information System (GIS), bridge, structural healthy monitoring system

INTRODUCTION

Structural health monitoring works provide valuable information in the evaluation of structure integrity, durability and reliability. Taking the monitoring data and bridge location information of Ting Kua Bridge in Hong Kong as our research objects, we have established a prototype of GIS-based structural health monitoring and management system. This system integrates large commercial database, GIS and network techniques. The system can run on Local Area Network or Internet. GIS software is used to manage regional map on which locations of bridges are indicated, and location information about sensors. It also provides users an interactive interface between user and the system. Large database system, such as SQL Sever, is used to manage huge dataset captured from the sensors (Shi, 2002). However, 2D GIS are limited in showing the bridge 3D graph, sensors location at bridge, and health of bridge structures. In recent years, 3D GIS have been developed and applied in many domains,

such as urban planning, ocean, mine and so on. It is obvious that 3D GIS can manage bridge health monitoring information more efficiently than 2D GIS. In this paper, we analyses the necessity design a Bridge Structural Health Monitoring And Management System (BSHMAMS) based on 3D GIS. Secondly, we compare the similarities and the differences between a CAD-based bridge model and a 3D GIS data model. Thirdly, we proposed a conceptual framework of the BSHMAMS. Fourthly, The integration technique of GIS, VR and the Internet is put forward to implement the system development, and the system functions were discussed. Lastly, some conclusions are given.

DEMOND ON A 3D GIS MODEL

Currently, most commercial GIS packages are 2D. Thus 3D spatial objects are simplified and represented two dimensionally by points, lines, and polygons in vector or raster data structures. Although these 2D data are in digital forms and can be handled efficiently, however many 3D applications are either impossible or unable to demonstrate the potential GIS.

In the BSHMAMS, some kinds of information, such as, bridge location map, bridge drawing, sensor position in the bridge, structure monitoring data coming from sensors and the analysed result, attribute (health) about the bridge bodies, should be managed efficiently. See table 1, these data have different features, such as graphic, non-graphic, static, dynamic, very large data. GIS is adopted to manage graphic information such as the map (bridge location), bridge (body) drawing, and locations of sensors, visualize the bridge structures health in special method such as colour, texture. In 2D GIS, some information could not be represented, because all the spatial information is projected into horizontal level or profile. For example, it is impossible if users want to see the bridge bodies, bridge structures, and sensors in different direction, or to view the scene of the bridge location. 3D GIS have the ability to manage 3D spatial information and can overcome the above problems; so it is necessary to establish bridge structural health monitoring system based on 3D GIS model.

COMPARISON BETWEEN CAD AND 3D GIS MODELS

Features Analysis of CAD

Computer Aided Design (CAD) is a computer technology system, which used widely to design drawing of machine, construction, engineering and production. The products that can be designed are from airplane to CMOS chip. Geometrical modeling and 3-D geometric representations, which can represent surfaces and solids of 3-D objects, were developed and applied for decades in Computer Aided Design (CAD) and computer graphics systems. However, in CAD packages, the geometric description of objects is of the first priority; while non-spatial information, especially, GIS topologic and attribute information, is not considered. This identifies the most significant difference between CAD systems and GIS.

The designed objects in CAD are regularly shaped, and can be described by 3-D geometric representations with predefined primitives, such as boxes, cylinders, spheres and others. In CAD, the design works is very detail for bridge engineering. A suspension bridge, for example, although the main structures are fewer such as anchor, tower pier, main cable, cable band, suspender, deck, beam and girder and so on, but the detailed structures are very complex and thousands of drawings are needed to describe the detailed structures. Except for the design view scene, the design works include from the three-dimensional scene to the dimension of an accessory. The main structures of a suspension bridge are seen in figure1.

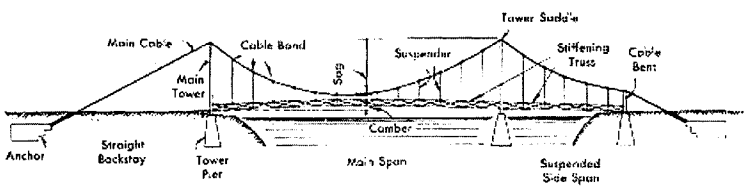

Figure 1: Suspension bridge main structures

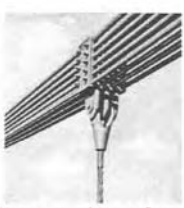
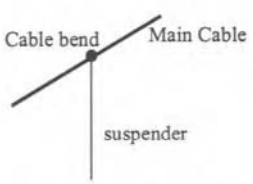
3D GIS Model

3D geometric representations provide geometric descriptions of objects for storing, geometric processing, displaying, and management of 3-D spatial data by computers in GIS. In real worlds, there are some regular manual constructions, such as buildings, bridges, dams and so on; but in some applications, such as digital mapping, geosciences, and ocean engineering, the objects are so called free forms. In GISs, the regular and irregular objects should be represented. For this purpose, some 3D geometric representations have already been proposed. According to the geometric characterizations of data structures, 3-D geometric representations are classified into two groups, namely surface based and volume based representation.



Surface based 3D geometric representations depict geometric characteristics of objects by using micro surface cell or surface primitives. There are four popular and important surface based representations, namely grids, shape models, facet models, and boundary representations. Grids, shape models and facet models are suited for describing objects surfaces with irregular shapes, and Boundary representation (B-reps) could represent not only

regularly shaped objects such as building, bridge and machine part, but also freeformed surfaces like car body surfaces, and terrain models. Volume based geometric representations describe the interior of objects by using solid information, instead of surface information. With these representations, solid information of objects can be presented, analyzed and visualized. There are four kinds of representations, such as binary arrays, needle models, octrees, and Constructive Solid Geometry models (CSG). The former three representations are capable of representing objects with irregular shapes and CSG representations are suited very well for describing regularly shaped objected.



Obviously, it is impossible to design a data model that is suitable for all kinds of 3D applications. We should design a special 3D spatial data model based on the characteristics of objects in the applications.

Transferring CAD Model into 3D GIS

CAD is suited for describing regular objects and emphasizing the details and geometric dimension of objects. 3D GIS models are more complex than CAD model. It could not only describe the regular and irregular objects, but also insist the geometric relationship among objects and the attributes. If a CAD model is transferred into GIS model, generalization should be made when using 3D GIS model to describe the objects and the attribute should be transferred at the same time. See figure 2, for example, (a) is close-up view of main cable, cable bend and suspender, and (b) is the general GIS model about (a), and this model comprise of three objects i.e. main cable, suspender and a node. It is obvious that simplified works have been made to implement the model transformation. In 3D GIS model, cylinders with different diameter can be used to describe the main cable and the suspender, and spheres can be used to describe the cable bend. The B-reps and the CSG are suited for representing the bridge bodies, and the grid and TIN could be used to describe terrain model of the bridge location.

CONCEPTUAL FRAMEWORK DESIGN

The system objective of the BSHMAMS is to establish a data management, analysis and visualization system based on 3D GIS model. The system could be run in Internet, and has the functions of 3D visualization and interaction to the graphic and attribute information, database management ability to the captured data from the sensors, and the analysis ability to the structural health monitoring data. In the Server-side, 3D models of bridge and the location map should be established; captured data database should be created, and the structural health analysis module should be provided. In Client-side, users can view the 3D scene of bridge and

terrain in different azimuth, interact on the model and further retrieve the attribute or monitoring data of selected objects in the model.

Large Relationship Database Management System (RDBMS), such as SQL Sever or Oracle, is an effective tool of data management. The RDBMS based on Client/Server architecture provides more efficient means to manage and share very large data. So we can use them to manage huge dataset captured from the sensors. For example, in the Sever-Side, by using the data input and database maintain module, the captured data that come from data capturing system of the bridge monitoring system, can be imported into the central database termly, and the period data are backup. The create database scheme, which one days' capture data creating a daily database, is very conveniently to create database, database backup and restore, and retrieve data from database. 3D GIS are the powerful tools to integrate and to manage different sources of spatial data and attribute data. We can use it to manage the scene of bridge location map, the 3D model of bridge body, and the sensors in the bridge model. Conceptual design of the system is illustrated in figure 3.

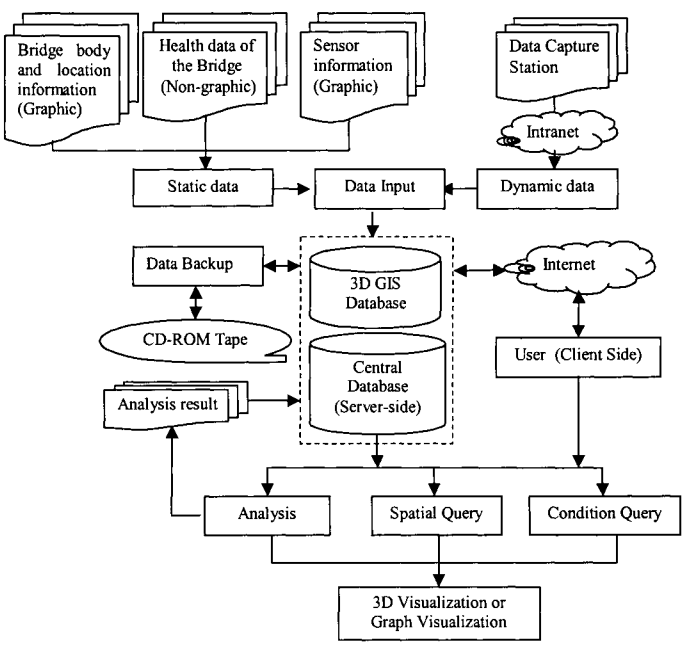

Figure 3: System conceptual design

The capture data acquired from typical sensors are firstly transmitted from the data capture station to user's computer via Internet or Intranet techniques. Under the control of user with control program, the transmitted data are pre-processed, including data classification, data filtering, etc. The pre-processed data are reorganized according to sensor ID and channel ID into a dynamic database that can be updated dynamically. The data in the dynamic database can be updated automatically with a regular interval. Users can also manually update it in both time interval and data amount. Following this process, the existing data in the database will be backup and replaced regularly by new data.

Analysis module can access the dynamic database and make special analysis, such as frequency analysis of captured data, structural health monitoring, damage detection, fatigue analysis and so on. Some analysis results, especially statistics results, can be stored in an analysis results database (ARD) for long-term use. The static information, such as original structural information and sensor system information, are stored in a static database (SD). The entire dynamic database, static database and analysis database are compose of the central database in Server-side.

Visualization program include 3D visualization of spatial information and the graph visualization of the time and frequency domain information of structural response and environmental loading data from the databases.

SYSTEM IMPLEMENTATION MECHANISM

For implementing this system, we can adopt the integration technique of GIS, VR and the Internet. This integration mechanism can be implemented through the use of Virtual Reality Modelling Language (VRML), an ISO standard for describing interactive 3D objects and worlds to be experienced on the World Wide Web. Through VRML, in conjunction with Java and HTML, GIS, VR and the Internet can be combined in different ways to support Web-based modelling, visualization and analysis. In such integration, GIS provides rather rich spatial data, VR helps to visualize the large volume of data in a rather realistic format, and the Internet facilitates information dissemination. There are two basic applications to deploying GIS or any other complex, data driven applications on the Internet: server-side and client-side applications.

The sever-side application, having main software and databases on the server side that are linked with the Web server through a Common Gateway Interface (CGI) script, significantly simplify development, deployment and maintenance of the Internet GIS software. The results transmitted to a Web client are in standard HTML formats that can be viewed in any browser. The disadvantages of server-side are associated with limited user interface and poor performance. Client-side solutions typically are implemented by augmenting the Web browser in the form of plug-in, ActiveX or Java. The primary advantages of client-side solutions are the abilities to enhance the user interface and improve performance. In summation, both methods should be considered complementary rather than competitive in practice. Hence the integration of client- and server-side solutions, typically in the form of Java and CGI, is a better approach. It can provide not only a user-friendly interface by use of Java but also a powerful data processing server by using CGI-linked exiting GIS functions. In general, complex spatial data processing task are performed on the server side, while tasks of user interaction and the system controlling are carried out on the client-side.

For satisfying the above integration plan, we can adopt the three-tier Client/Server pattern. This pattern consists of three components: the Client, the Server and the middleware. See figure 4. The client side provides Web pages embedded with Java applets. The user then submits the request in the form of Unique Resource Locator (URL) to the server via a CGI program. After receiving the URL request from Java-based client, the application server extracts all the necessary parameters, processes them, and delivers the results in HTML-compatible format to the client for displaying. The result could be 3D VRML model or a 2D map. The interaction with VRML worlds can now be realized by interface Java or JavaScript with VRML 2.0. Two methods are used for the interaction, namely using Script node in

VRML and the External Authoring Interface (EAI). We can use the EAI method for a flexible interaction with the VRML scene generated by the 3D visualization module. For the graph visualization of the capture data, frequency data and the attributes of the interest objects, we can use JDBC technique to access the central database. After retrieving the wanted data (data package), use Java applets to visualize the data in client.

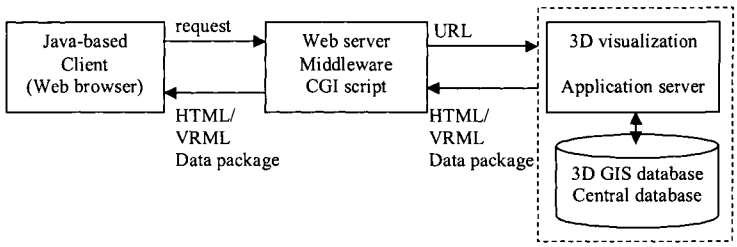

Figure 4: Three-tier Client/Server architecture

SYSTEM FUNCTIONS

Considering the system architecture, functional requirements of the BSHMAMS base on 3D GIS Model, there are several mainly functions: data input, data management, database backup and restore, data analysis, data query and visualization. Their implementation mechanisms are discussed in the section of the conceptual framework design.

Data input module are used to continuously import the source data into the centralized database via Intranet, and input the graphic and attribute information of the BSHMAMS into the system by using GIS software directly or transferred from CAD model.

In data management module, the capture data and the analysis result are managed by RDBMS, and the graph and attribute information are managed by GIS software. All the information are spatially maintained and integrated in unique information systems in sever side.

Database backup and restore module can backup the dynamic database into the secondary storage devices, such as CD-ROM, and restore it when user want to retrieve the data.

Spatial query include: query attribute by 3D VRML interface, and query graph by attributes.

Data analysis includes frequency domain analysis of captured data, statistical calculation, etc. It can be implemented by advanced language program in server side.

Visualization includes 3D Visualization of the bridge scene; different types of graphic display of captured data, visualization of frequency domain analysis and so on.

CONCLUSIONS

This paper presented a design of the prototype of the BSHMAMS based on 3D GIS model. Based on our design work, we can get following conclusions.

- It is necessary and feasible to establish the BSHMAMS based on 3D GIS model based on a view of technical solutions and method.
- 3D GIS model is more efficient to manage 3D spatial information, and can enrich the visualization of bridge scene and interaction between users and the system.
- The integration of the techniques, such as GIS, VR and the Internet is a better solution scheme about these systems running in Internet.
- In the course of CAD model transferring into 3D GIS model, generalization should be made and attribute should be transferred at the same time.
- SQL Server database can be used to manage the very large quantity data. The create database scheme that One days' capture data creating a daily database has some advantages.

System design is the first steps for developing the overall System, and further work is to implement this system. The integration of the technologies will be applied, such as GIS, VR and the Internet, the transformation from CAD model into GIS 3D model, and the interaction between user and system in VRML scene. The implementation of this system will finally improve the efficiency of bridge structural health monitoring and management system.

SEISMIC DESIGN METHOD OF STRUCTURES WITH ACTIVE VARIABLE STIFFNESS SYSTEMS

Bo Wu Fen-tao Liu De-min Wei

(Department of Civil Engineering, South China University of Technology, Guangzhou 510640, P. R. of China)

ABSTRACT

It has been demonstrated that active variable stiffness (AVS) systems may be effective for response control of building structures subjected to earthquake excitations. The dynamics of structures with AVS systems are highly nonlinear because the stiffness of each story unit, in which the AVS system is installed, varies as a function of time. Hence, the classical seismic design method for linear structures, such as the mode-superposition response-spectrum method, is not feasible to structures with AVS systems. In this paper, a seismic design method based on the approximate mode superposition (AMS) approach suggested by the authors (Wu et al., 2001) is proposed for building structures equipped with AVS systems. First, the AMS approach for structures with AVS systems is briefly introduced. Then, the accuracy of this approach for estimating the maximum interstorey shear forces of structures is investigated through extensive numerical simulations, and some revision is given to the approach, in order to improve the simulation precision. Simulation results indicate that the revised AMS approach is effective in estimating the maximum interstorey shear forces in structures with AVS systems. Subsequently, the distribution of the maximum interstorey shear forces between structural members and AVS systems are discussed. Finally, a seismic design method based on the AMS approach is primarily presented for building structures equipped with AVS systems.

seismic design, semi-active control, active variable stiffness system, mode superposition

INTRODUCTION

It has been demonstrated that so-called active variable stiffness (AVS) systems, introduced originally by Kobori at the end of the 1980s, may be effective for response control of structures subjected to earthquake excitations. Owing to the advantage of not requiring the input of extensive power and energy, the AVS systems have received considerable attention in recent years. Extensive efforts have been devoted to the theoretical and practical development of AVS systems. Different control strategies for the AVS systems have been investigated by, for example, Kobori et al. (1990), Kobori and Kamagata (1992), Kamagata and Kobori (1994), Yang et al. (1994, 1996), Yamada and Kobori (1995) and Nasu et al. (2001). Such systems have also been tested experimentally and installed on a full-scale test building in Japan (Kobori

et al., 1990, 1991a and 1991b).

The AVS systems consist of stand-by bracings attached to selected storey units of building structures, and the locking and unlocking devices. During the earthquake ground motion, some of the bracings may be locked at a particular time instant, to increase the stiffnesses of the corresponding story units. The locking and unlocking of different bracings at each time instant are regulated by a control algorithm in order to reduce the structural responses to an earthquake. One of the control algorithms proposed by Kobori and Kamagata is based on engineering insight as follows. Since the locking of bracings increases the stiffness restoring force, the bracings should be locked if the interstorey drift, $x(t)$, and its velocity, $\dot{x}(t)$, are both positive or both negative, i.e., $x(t)\dot{x}(t) > 0$. On the other hand, if $x(t)$ and $\dot{x}(t)$ are in the opposite direction (different sign), i.e., $x(t)\dot{x}(t) < 0$, then bracings should be unlocked. Such a control algorithm is quite effective, so it is adopted in the study described in this paper.

The dynamics of structures with AVS systems are highly nonlinear. Hence, a classical seismic design method for linear systems is not applicable to active variable stiffness structures. At present, the seismic design of structures equipped with AVS systems is always conducted using a time-history analysis method, which is inconvenient to engineers. The purpose of this paper is to present a simple design method for building structures with AVS systems, which is based on the approximate mode superposition (AMS) approach that was suggested by the authors and has been proven to be effective in estimating the maximum displacements relative to the ground and the maximum interstorey drifts in structures equipped with AVS systems (Wu et al., 2001). In this paper, the AMS approach is briefly introduced first. Then, the accuracy of this approach for estimating the maximum interstorey shear forces in structures is investigated through extensive numerical simulations, and some revision is given to the approach, in order to improve the simulation precision. Simulation results indicate that the revised AMS approach is effective in estimating the maximum interstorey shear forces in structures with AVS systems. Subsequently, the distribution of the maximum interstorey shear forces between structural members and AVS systems is discussed. Finally, a seismic design method based on the AMS approach is primarily presented for building structures equipped with AVS systems.

APPROXIMATE MODE SUPERPOSITION (AMS) APPROACH

The equation of motion for an n-story building structure equipped with AVS systems in selected storey units and subject to a horizontal ground acceleration $\ddot{x}_g(t)$ can be written as:

$$M\ddot{X} + C\dot{X} + KX + HU(t) = -MI\ddot{x}_g(t) \tag{1}$$

in which M、C and K are $(n \times n)$ mass, damping and stiffness matrices of the uncontrolled structure, respectively, X is an n vector with the jth element x_j being the displacement of the jth floor relative to the ground, I is a column vector of "ones"; H is a constant matrix depending on the locations of the AVS systems, and $U(t)$ is a control vector with the jth element $u_j(t)$ being:

$$u_j(t) = g_j(t)\Delta k_j(x_j - x_{j-1}) \quad j > 1; \qquad u_j(t) = g_j(t)\Delta k_j x_j \quad j = 1 \tag{2}$$

where Δk_j is the additional stiffness of stand-by bracings of the AVS system installed in the jth story unit. If there is no AVS system installed in the jth story unit, then $\Delta k_j = 0$ and $u_j(t) = 0$.

The control strategy for the structure with AVS systems is one of the control algorithms proposed by Kobori and Kamagata as follows:

if $j > 1$ and $(x_j - x_{j-1})(\dot{x}_j - \dot{x}_{j-1}) \geq 0$: $g_j(t) = 1$; if $j = 1$ and $x_j\dot{x}_j \geq 0$: $g_j(t) = 1$

if $j > 1$ and $(x_j - x_{j-1})(\dot{x}_j - \dot{x}_{j-1}) < 0$: $g_j(t) = 0$ if $j = 1$ and $x_j\dot{x}_j < 0$: $g_j(t) = 0$

The mode shape matrix Φ_s, mode circular frequency vector ω_s, and mode damping ratio vector ξ_s of the uncontrolled structure are, respectively, expressed as:

$$\Phi_s = [\phi_{s1},\ldots,\phi_{si},\ldots,\phi_{sn}],\quad \omega_s = [\omega_{s1},\ldots,\omega_{si},\ldots,\omega_{sn}]^T,\quad \xi_s = [\xi_{s1},\ldots,\xi_{si},\ldots,\xi_{sn}]^T \tag{3}$$

in which ϕ_{si}、ω_{si} and ξ_{si} are, respectively, the natural mode vector, circular frequency and damping ratio of the i th mode for the uncontrolled structure.

Consider the condition that all the stand-by bracings in the structure are locked. Here, the mass and damping matrices of the controlled structure are equal to M and C in Eq.(1), respectively, but the stiffness matrix of the controlled structure should be a sum of K in Eq.(1) and an additional stiffness matrix $\Delta K_{\max}$, which is of the same form as K except that k_j is replaced by the additional stiffness Δk_j. Now the mode shape matrix and the mode circular frequency vector are, respectively, given as:

$$\Phi_c = [\phi_{c1},\ldots,\phi_{ci},\ldots,\phi_{cn}],\qquad \omega_c = [\omega_{c1},\ldots,\omega_{ci},\ldots,\omega_{cn}]^T \tag{4}$$

Suppose the displacement response of the structure with AVS systems can be approximated by a linear combination of several natural modes: $X \approx \sum_{r=1}^{l} q_r(t)\phi_{sr}$ $(l \le n)$. Introducing the expression of X into Eq.(1) and then premultiplying each term in this equation by ϕ_{si}^T gives:

$$\phi_{si}^T M\sum_{r=1}^{l}\phi_{sr}\ddot{q}_r(t) + \phi_{si}^T C\sum_{r=1}^{l}\phi_{sr}\dot{q}_r(t) + \phi_{si}^T(K+\Delta K)\sum_{r=1}^{l}\phi_{sr}q_r(t) = -\phi_{si}^T MI\ddot{x}_g(t) \tag{5}$$

in which ΔK is the additional stiffness matrix due to the stand-by bracings of AVS systems equipped in the structure. If all the stand-by bracings in the structure are locked, ΔK is equal to $\Delta K_{\max}$; on the other hand, if all the stand-by bracings are unlocked, ΔK is a null matrix. If some stand-by bracings are locked and the others are unlocked, ΔK is range from a null matrix to $\Delta K_{\max}$.

Utilizing the orthogonality property of the natural mode vectors of the uncontrolled structure, Eq.(5) can be written as:

$$\ddot{q}_i(t) + 2\xi_{si}\omega_{si}\dot{q}_i(t) + \frac{\phi_{si}^T(K+\Delta K)\sum_{r=1}^{l}\phi_{sr}q_r(t)}{\phi_{si}^T M\phi_{si}} = -\gamma_i\ddot{x}_g(t) \tag{6}$$

in which $\gamma_i = \phi_{si}^T MI / \phi_{si}^T M\phi_{si}$ is the modal participation factor of the i th mode.

Suppose the controlled structure vibrates only in the i th mode. Now only two states exist for all the stand-by bracings in the structure: locked simultaneously or unlocked simultaneously (He and Feng, 2000). When all the stand-by bracings are unlocked $(q_i(t)\dot{q}_i(t) < 0)$, ΔK is equal to a null matrix and Eq.(6) may be further written in a simplified form:

$$\ddot{q}_i(t) + 2\xi_{si}\omega_{si}\dot{q}_i(t) + \omega_{si}^2 q_i(t) = -\gamma_i\ddot{x}_g(t) \tag{7}$$

On the other hand, when all the stand-by bracings are locked $(q_i(t)\dot{q}_i(t) > 0)$, ΔK is equal to $\Delta K_{\max}$. In such a case, replacing the elements of Φ_s, in the third term on the left-hand of Eq.(6), approximately by the corresponding elements of Φ_c gives:

$$\ddot{q}_i(t) + 2\xi_{si}\omega_{si}\dot{q}_i(t) + \omega_{ci}^2 q_i(t) = -\gamma_i\ddot{x}_g(t) \tag{8}$$

Eqs.(7) and (8) may be regarded as two special cases of a SDOF active variable stiffness structure that is:

$$\ddot{q}_i(t) + 2\xi_{si}\omega_{si}\dot{q}_i(t) + \omega_{si}^2 q_i(t) + \frac{\omega_{ci}^2 - \omega_{si}^2}{2}(1 + sign(q\dot{q}))q_i(t) = -\gamma_i\ddot{x}_g(t) \tag{9}$$

in which $sign(\bullet)$ denotes symbol function.

Referring to the equivalent relationship between the SDOF structure with AVS system and the so-called special linear structure, which is determined according to the principle that the peak point on the steady-state displacement amplitude-excitation frequency curve of the latter structure is in good agreement with that of the former structure (Wu et al., 2001), Eq.(9) may be approximately expressed as:

$$\ddot{q}_i(t) + 2\xi^* \omega_m \dot{q}_i(t) + \omega_m^2 q_i(t) = -\gamma_i \ddot{x}_g(t) \tag{10}$$

in which $\omega_m^2 = \omega_{si}^2(1+\eta_e)$, $\xi^* = \xi_e + \xi_{si}$, and η_e and ξ_e are related to $\alpha = (\omega_{ci}{}^2 - \omega_{si}{}^2)/\omega_{si}{}^2$ and ω_{si}. In this way, the ith modal coordinate $q_i(t)$ can be determined by solving Eq.(10), and then the displacement response of the n-story structure equipped with AVS systems can be approximately determined by $X \approx \sum_{r=1}^{l} q_r(t)\phi_{sr}$.

REVISION OF THE AMS APPROACH

Based on the AMS approach, the maximum interstorey shear force $V_{j\max}$ of the jth story unit of the structure equipped with AVS systems can be written as:

$$V_{j\max} = \max\left|F_j + F_{j+1} + \cdots + F_n\right| \tag{11}$$

in which $F_j = m_j[\sum_{r=1}^{l} \ddot{q}_r(t)\varphi_{srj} + \ddot{x}_g(t)]$ is the seismic action at the jth-floor level, m_j is the mass of the jth floor, and φ_{srj} is the jth element of the rth mode vector ϕ_{sr}.

Extensive numerical simulations, using the time-history analysis method and the AMS approach, are carried out for structures equipped with AVS systems and subjected to different artificial earthquake excitations listed in Table 1. Simulation results indicate that the maximum interstorey shear force of each storey unit may be effectively estimated by the AMS approach with some revision --- multiplying the maximum interstorey shear force of each storey unit determined by Eq.(11) with modification parameter β. Here β is given as:

$$\beta = \begin{cases} 0.0285n + 1.4764 & \textit{Top floor} \\ 0.0239n + 1.2461 & \textit{Other floors} \end{cases} \qquad (5 \le n \le 12) \tag{12}$$

Consider a 5-story building with the following properties. The mass and stiffness of each storey unit are identical with $m_j = 100$ t and $k_j = 4.87 \times 10^4$ kN/m, respectively, for $j = 1,2,.....,5$. A Rayleigh damping matrix is adopted, and the damping ratio in the first and the second modes is specified by ξ_{s1}=ξ_{s2}=0.05. Suppose one AVS system is installed in every storey unit, where the additional stiffness of stand-by bracings is $\Delta k_j = k_j = 4.87 \times 10^4$ kN/m. The 30 artificial earthquakes listed in Table 1 are used as the input excitations. Using the revised AMS approach with coefficient β, the maximum interstorey shear forces of each storey unit under 30 artificial earthquakes are obtained. For comparison, corresponding results using the time-history analysis method are also obtained. Assume Q is the ratio of the maximum interstorey shear force of each storey unit using the time-history analysis method to that using the revised AMS approach. Simulation results of Q corresponding to different storey units and different artificial earthquakes are shown in Figure 1.

Next, a 12-storey building with the following properties is considered. The mass and stiffness of each storey unit are identical with $m_j = 400$ t and $k_j = 4.4 \times 10^5$ kN/m, respectively, for $j = 1,2,.....,12$. A Rayleigh damping matrix is adopted, and the damping ratio in the first and the second modes is specified

TABLE 1
PARAMETERS OF ARTIFICIAL EARTHQUAKES

Site	Dominating period of site (s)	Number of earthquakes	Average peak Ground acceleration (gal)	Standard deviation of peak ground acceleration (gal)
Class II	0.3	10	253.94	25.46
Class II	0.3	10	127.78	9.46
Class III	0.4	10	67.9	5.18

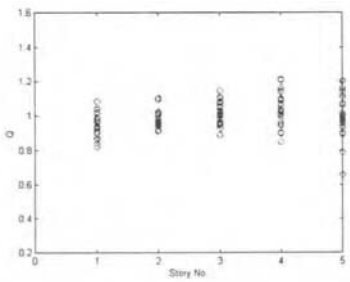

Figure 1 Five-story structure

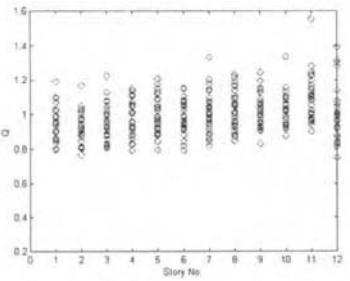

Figure 2 Twelve-story structure

by $\xi_{s1}=\xi_{s2}=0.05$. Suppose one AVS system is installed in every storey unit, where the additional stiffness of stand-by bracings is $\Delta k_j = k_j = 4.4\times10^5$ kN/m. The 30 artificial earthquakes listed in Table 1 are used as the input excitations. Using the revised AMS approach with coefficient β, the maximum interstory shear forces of each storey unit under 30 artificial earthquakes are obtained. For comparison, corresponding results using the time-history analysis method are also obtained. Simulation results of Q corresponding to different storey units and different artificial earthquakes are shown in Figure 2.

It is observed from Figures 1 and 2 that the value of Q fluctuates around 1.0. Among the total 150 data in Figure 1, 117 data (78.0%) are within the range of [1.0/1.1, 1.0/0.9], and 139 data (92.7%) are within the range of [1.0/1.15, 1.0/0.85]. Further, among the total 360 data in Figure 2, 229 data (63.6%) are within the range of [1.0/1.1, 1.0/0.9], and 297 data (82.5%) are within the range of [1.0/1.15, 1.0/0.85]. Hence, the maximum interstorey shear force of each storey unit may be approximately estimated using the revised AMS approach with an error mostly less than 10%.

In order to improve the simulation precision of the AMS approach for maximum interstorey shear forces of structures with AVS systems, another equivalent relationship between the SDOF structure with AVS system and the so-called special linear structure may be established, according to a new principle that the peak point on the steady-state acceleration amplitude-excitation frequency curve of the latter structure is in good agreement with that of the former structure. Again, Eq.(9) may be approximately expressed as Eq.(10), and $\omega_m^2 = \omega_{si}^2(1+\eta_e)$, $\xi^* = \xi_e + \xi_{si}$, but now η_e and ξ_e should be given as:

$$\eta_e = (0.0315\alpha - 0.0233)\omega_{si} + 0.3788\alpha + 0.1113 \tag{13}$$

$$\xi_e = (0.0002\alpha^2 - 0.0015\alpha + 0.0007)\omega_{si} - 0.0056\alpha^2 + 0.0403\alpha + 0.0282 \tag{14}$$

in which $\alpha = (\omega_{ci}^{\ 2} - \omega_{si}^{\ 2})/\omega_{si}^{\ 2}$.

Extensive numerical simulations, using the time-history analysis method and the AMS approach based on the new equivalent relationship, are carried out for structures equipped with AVS systems and subjected to different artificial earthquake excitations listed in Table 1. Simulation results indicate that the maximum interstorey shear force of each storey unit may be further effectively estimated by multiplying

the corresponding result of each storey unit determined by Eq.(11) with modification parameter β, but now β should be rewritten as:

$$\beta = \begin{cases} 0.0270n + 1.2911 & \textit{Top floor} \\ 0.0250n + 1.1025 & \textit{Other floors} \end{cases} \qquad (5 \le n \le 12) \qquad (15)$$

Consider the above two example structures again. Simulation results of Q, which is the ratio of the maximum interstorey shear force of each storey unit using the time-history analysis method to that using the revised AMS approach, corresponding to different storey units and different artificial earthquakes are, respectively, shown in Figure 3 and Figure 4 for the 5-storey and 12-storey buildings.

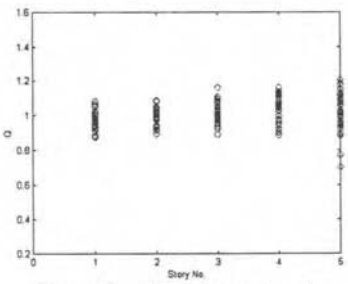

Figure 3 Five-storey structure

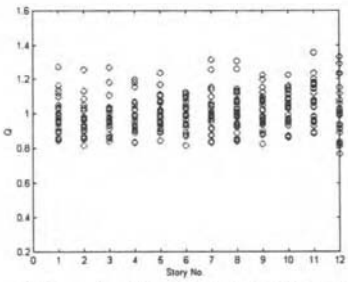

Figure 4 Twelve-storey structure

Among the total 150 data in Figure 3, 126 data (84.0%) are within the range of [1.0/1.1, 1.0/0.9], and 147 data (98.0%) are within the range of [1.0/1.15, 1.0/0.85]. Further, among the total 360 data in Figure 4, 244 data (67.8%) are within the range of [1.0/1.1, 1.0/0.9], and 308 data (85.6%) are within the range of [1.0/1.15, 1.0/0.85]. Comparing Figure 1 and Figure 2, it can be seen that the simulation precision of the revised AMS approach, based on the new equivalent relationship, is better than that based on the old equivalent relationship.

DISTRIBUTION OF MAXIMUM INTERSTORY SHEAR FORCE

At any time instant, the interstorey shear force of the j th storey unit of the structure equipped with AVS systems is balanced by the interstorey damping force, the stiffness restoring force $k_j(x_j - x_{j-1})$ related to the structural members, and the additional stiffness restoring force related to the AVS system installed in the j th floor, which are equal to $\Delta k_j(x_j - x_{j-1})$ and 0 for locked and unlocked stand-by bracings, respectively.

Figure 5 shows the time-history curves of the interstorey shear force, the stiffness restoring force and the additional stiffness restoring force for the base floor of the aforementioned five-storey example structure subjected to a certain artificial earthquake. It is observed from this figure that: (1) At any time instant, the sum of the stiffness restoring force and the additional stiffness restoring force is approximately equal to the interstorey shear force, so the effect of interstorey damping force on balancing the interstorey shear force is quite limited. In this way, the interstorey shear force may be approximately distributed between the structural members and the AVS system according to their lateral stiffnesses. Here, the stiffness of the structural members is constant at any time instant, but the stiffness of the AVS system varies with the locking and unlocking of stand-by bracings. (2) The maximum stiffness restoring force and the maximum additional stiffness restoring force occur at almost the same time as the maximum interstorey shear force, so the former two forces may be approximately determined by distributing the latter force according to the lateral stiffnesses of the structural members and the AVS system.

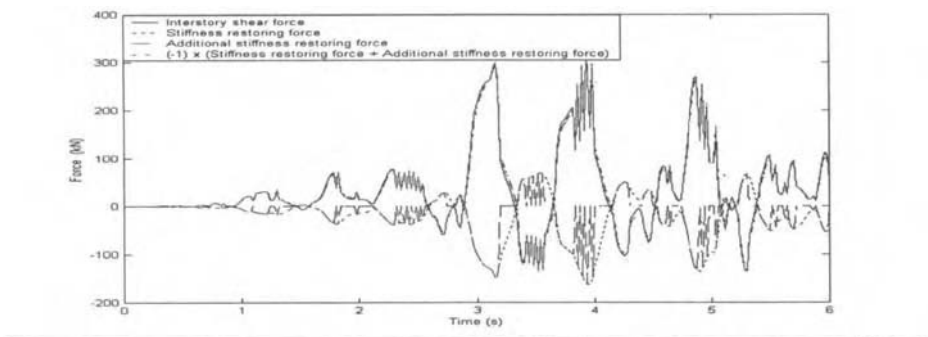

Figure 5 Time-history curves

SEISMIC DESIGN METHOD OF STRUCTURES WITH AVS SYSTEMS

Based on the revised AMS approach and referring to the seismic design procedure for uncontrolled structures, the seismic design method of structures with AVS systems may be summarized as:

(1) Using the AMS approach, the nonlinear equation of motion of the structure with AVS systems is transformed into a set of uncoupled linear equations as shown in Eq.(10).

(2) Using the acceleration response spectrum with large damping ratio in the Seismic Design Code of China (GB50011-2001), $V_{ij\max}(j=1,2,\cdots,n)$, the maximum interstorey shear force of the j th storey unit for the i th mode, is determined.

(3) According to the *square-root-of-sum-of-squares* (SRSS) rule for modal combination, the maximum interstorey shear force of the j th story unit is primarily determined as $V_{j\max}^{*}=\sqrt{\sum_{i=1}^{I}V_{ij\max}^{2}}$.

(4) Using the modification parameter of β shown in Eq.(15), the maximum interstorey shear force of the j th storey unit is further determined as $V_{j\max}=\beta V_{j\max}^{*}$.

(5) According to the lateral stiffnesses of the structural members in the j th floor and the AVS system installed in the same floor, $V_{j\max}$ is distributed between the structural members and the AVS system.

(6) Combining the stiffness restoring force and the additional stiffness restoring force with other load effects, the detail design of the structural members and the AVS systems may be carried out.

CONCLUDING REMARKS

The following conclusions may be drawn from the study reported here.

1. The maximum interstorey shear force of each storey unit in structures with AVS systems may be estimated using the revised AMS approach with parameter of β shown in Eq.(12), based on the equivalent relationship between the SDOF structure with AVS system and the so-called special linear structure presented by Wu et al., 2001.

2. The simulation precision of the maximum interstorey shear force of each storey unit of structures with AVS systems may be improved using the revised AMS approach with parameter of β shown in Eq.(15), based on the new equivalent relationship between the SDOF structure with AVS system and the so-called special linear structure presented in this paper.

3. The maximum interstorey shear force of the j th storey unit of the structure with AVS systems may be approximately distributed between the structural members in the j th floor and the AVS system installed in the same floor, according to their lateral stiffnesses. The maximum stiffness restoring force and the maximum additional stiffness restoring force of the j th floor occur at almost the same time as the maximum interstorey shear force of the same floor.

4. The seismic design method for structures with AVS systems presented in this paper is similar to that for uncontrolled structures, so it is convenient to engineers for practical structural design applications.

Damage Detection of A Health Monitoring Benchmark Building Using Hilbert-Huang Spectral Analysis*

Jann N. Yang, Silian Lin and Shuwen Pan

Department of Civil & Environmental Engineering, University of California, Irvine, CA. 92697, USA.

ABSTRACT

Based on the Hilbert-Huang spectral analysis, a system identification and damage detection approach is proposed and applied to the ASCE structural health monitoring benchmark structure. The cases analysed involve the damage detection and assessment in the weak direction of the test structure using a 4-DOF linear shear-building model. In this approach, the structural parameters, including stiffness and damping before and after damage are identified first and then the location and severity of the damage are assessed by a comparison. The effect of measurement noises has been taken into account. Simulation results demonstrate that the accuracy of the proposed method in identifying the structural damages is very plausible, and it represents a new and viable system identification and damage detection approach for linear structures.

Structural Health Monitoring, System Identification, Damage Detection, Data Analysis Techniques, Hilbert Transform, Frequency-Time Decomposition.

INTRODUCTION

For structural health monitoring, appropriate data analysis techniques are needed to interpret the measured data and to identify the state of the structure and its damage after a severe event, such as earthquake. Various data analysis techniques have been available in the literature for the health monitoring of linear structures [e.g., Chang (1997, 1999, 2001)]. In order to facilitate a comparison of available techniques on the common basis, the ASCE Task Group on Structural Health Monitoring has established a benchmark problem recently. The benchmark structure is a 4-story building model and the corresponding analytical models have been developed [Johnson, et al (2001)]. The disturbances are assumed to be unknown random uncorrelated forces (white noise processes) applied to each floor of the building. Damage is introduced into the structure by removing braces in the analytical model. Only acceleration measurements are available and each

* This research is supported by the National Science Foundation through Grant No. CMS-98-07855.

acceleration measurements are also polluted by uncorrelated noise. Details of the benchmark problem are given in [Johnson, et al (2001)], and various different approaches have been presented [e.g., Beck et al (2001), Yang et al (2001), Dyke et al (2000)].

In this paper, a new approach based on the Hilbert-Huang spectral analysis [Huang et al (1998)] is proposed and applied to the damage identification and assessment of the benchmark structure. In this approach, the cross-correlation functions of the measured floor acceleration responses are first decomposed into different modal components using the Empirical Mode Decomposition (EMD) method and band-pass filters [Yang et al (2001)]. Then, the Hilbert transform is applied to each modal component to obtain the time-dependent (instantaneous) phase angles, frequencies and amplitudes. All the natural frequencies and damping ratios can be identified using only a single measurement. When the acceleration responses at all floors are measured, the mode shapes and the stiffness and damping matrices can be identified using the proposed approach. Based on a comparison of the stiffness of each story unit prior to and after damage, the damage locations and severities can be identified. Simulation results are presented for the damage patterns in the weakest direction of the benchmark structure using a 4-DOF linear shear building available in [Johnson, et al (2001)].

CROSS CORRELATION FUNCTION AND MODAL CONTRIBUTION

The equation of motion of an n DOF structure can be expressed as

$$\mathbf{M}\ddot{\mathbf{X}}(t) + \mathbf{C}\dot{\mathbf{X}}(t) + \mathbf{K}\mathbf{X}(t) = \mathbf{F}(t) \tag{1}$$

in which $\mathbf{X}(t) = [x_1, x_2, \ldots, x_n]^T$ = n-displacement vector, $\mathbf{F}(t)$ = n-excitation vector, and $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ are $(n \times n)$ mass, damping and stiffness matrices, respectively. With the assumption of the existence of normal modes, the displacement and acceleration responses can be decomposed into n real modes,

$$\mathbf{X}(t) = \sum_{j=1}^{n} \mathbf{\Phi}_j q_j(t) \quad ; \quad \ddot{\mathbf{X}}(t) = \sum_{j=1}^{n} \mathbf{\Phi}_j \ddot{q}_j(t) \tag{2}$$

in which $\mathbf{\Phi}_j$ is the jth modal vector, and $q_j(t)$ is the jth modal coordinate. Substituting Eq.(2) into Eq.(1) and using the orthogonal properties of mode shapes, one can decouple Eq.(1) into n modes

$$\ddot{q}_j + 2\zeta_j\omega_j\dot{q}_j + \omega_j^2 q_j = \mathbf{\Phi}_j^T\mathbf{F}(t)/m_j^* \tag{3}$$

in which ω_j = jth modal frequency, ζ_j = jth modal damping ratio, and m_j^* = jth modal mass. When the excitation $\mathbf{F}(t)$ is a stationary white noise vector, the cross-correlation function of the floor responses, denoted by $R_{rs}(\tau)$, can be obtained as

$$R_{rs}(\tau) = E[\ddot{x}_r(t)\ddot{x}_s(t+\tau)] = \sum_{j=1}^{n} \phi_{rj}\,\alpha_{sj}\, e^{-\zeta_j\omega_j\tau} \sin(\omega_{dj}\tau + \theta_{sj}) \tag{4}$$

in which ϕ_{rj} is the rth element of the jth modal vector $\mathbf{\Phi}_j$, $\omega_{dj} = \omega_j(1-\zeta_j^2)^{1/2}$ is the jth damped modal frequency, θ_{sj} is the phase lag, and α_{sj} a positive constant. For simplicity of analysis, the time difference τ will be denoted by t and Eq. (4) will be expressed as follows,

$$R_{rs}(t) = \sum_{j=1}^{n} R_{rs,j}(t) = \sum_{j=1}^{n} |\phi_{rj}|\,\alpha_{sj}\, e^{-\zeta_j\omega_j t} \cos(\omega_{dj}t + \theta_{sj} + \frac{3\pi}{2} + \varphi_{rj}) \tag{5}$$

in which

$$R_{rs,j}(t) = B_{rs,j}\, e^{-\zeta_j\omega_j t} \cos(\omega_{dj}t + \theta_{sj} + \frac{3\pi}{2} + \varphi_{rj}) \tag{6}$$

and

$$B_{rs,j} = |\phi_{rj}|\alpha_{sj}; \qquad \varphi_{rj} = \begin{cases} \pm 2m\pi, & \text{if } \phi_{rj} \geq 0 \\ \pm(2m+1)\pi, & \text{if } \phi_{rj} < 0 \end{cases} \tag{7}$$

In Eqs.(5)-(7), $R_{rs,j}(t)$ is the contribution from the jth mode, referred to as the jth modal contribution. The cross-correlation function $R_{rs}(t)$ will be decomposed into modal contributions $R_{rs,j}(t)$ (j = 1, 2, ..., n) using the Empirical Mode Decomposition (EMD) method and band-pass filters. Then, the Hilbert transform will be applied to each modal contribution $R_{rs,j}(t)$ in Eq.(6) to determine the modal frequency ω_j, the modal damping ratio ζ_j, and the mode shape vector $\boldsymbol{\Phi}_j$ (with ϕ_{rj} as the rth element). Assuming that the mass matrix M in Eq. (1) is known, the generalized masses m_j^* can be obtained as

$$\boldsymbol{\Phi}^T\mathbf{M}\boldsymbol{\Phi} = \text{diag}\,(m_1^*, m_2^*, ..., m_n^*) \tag{8}$$

in which $\boldsymbol{\Phi}$ is the modal matrix consisting of the modal vector $\boldsymbol{\Phi}_j$ as the jth column. After determining m_j^*(j =1, 2, ..., n), the modal stiffness k_j^* and the modal damping c_j^* can be obtained as

$$k_j^* = m_j\,\omega_j^2; \text{ and } c_j^* = 2m_j\zeta_j\omega_j \tag{9}$$

Since $\boldsymbol{\Phi}^T\mathbf{K}\boldsymbol{\Phi} = \text{diag}\,(k_1^*, k_2^*, ..., k_n^*)$ and $\boldsymbol{\Phi}^T\mathbf{C}\boldsymbol{\Phi} = \text{diag}\,(c_1^*, c_2^*, ..., c_n^*)$, the stiffness matrix **K** and the damping matrix **C** in Eq. (1) can be identified as

$$\mathbf{K} = \boldsymbol{\Phi}^{-T}\text{diag}\,(k_1^*, k_2^*, ..., k_n^*)\,\boldsymbol{\Phi}^{-1}; \quad \mathbf{C} = \boldsymbol{\Phi}^{-T}\text{diag}\,(c_1^*, c_2^*, ..., c_n^*)\,\boldsymbol{\Phi}^{-1} \tag{10}$$

For a shear-beam building model, the stiffness of each story unit can be obtained from **K**.

HILBERT-HUANG TRANSFORM

Suppose x(t) is a general measured signal such as the cross-correlation functions $R_{rs}(t)$ in Eq. (5). The Hilbert transform (HT) of x(t), denoted by $\tilde{x}(t)$, is given by

$$\tilde{x}(t) = HT[x(t)] = \int_{-\infty}^{+\infty} \frac{x(\tau)}{\pi(t-\tau)}\,d\tau \tag{11}$$

where $\tilde{x}(t)$ can be computed numerically using the efficient Fast Fourier transform [Huang et al (1998, 1999)]. The analytical signal Y(t) of x(t) is expressed as

$$Y(t) = x(t) + \underline{i}\,\tilde{x}(t) = A(t)\,e^{\underline{i}\,\theta(t)} \tag{12}$$

in which A(t) is the instantaneous amplitude, $\theta(t)$ is the instantaneous phase angle, and $\underline{i} = (-1)^{1/2}$. The instantaneous frequency $\omega(t)$ of the signal is obtained as

$$\omega(t) = d\theta(t)/\,dt \tag{13}$$

From Eqs.(11)-(13), there is only a single frequency ω at any time t, if the general signal x(t) is processed through the Hilbert transform. On the contrary, for a general signal x(t) at any time t, there is a distribution of frequencies at that time rather than just a single frequency. Consequently, to obtain a meaningful decomposition of a signal in the frequency-time domain, it was proposed by Huang et al (1998) to first decompose the signal x(t) into m Intrinsic Mode Functions (IMFs) using the EMD method. Then, the Hilbert transform is applied to each IMF to form a meaningful frequency-time decomposition of a general signal, referred to as the Hilbert-Huang spectral analysis. Such an approach will be used herein to detect the damage in the benchmark building.

The method of Empirical Mode Decomposition (EMD) will be used to decompose the cross-correlation function $R_{rs}(t)$ into "Intrinsic Mode Functions" (IMFs) that admit well-behaved Hilbert transform. The procedure of EMD is to construct upper and lower envelopes of the signal by spline fitting, and the average (mean) of both envelopes are computed. Then, the signal is subtracted from the mean, referred to as the

sifting process. By repeating the sifting process until the resulting signal becomes a monocomponent, i.e., one up-crossing (or down-crossing) of zero will result in one local peak (or trough). Such a monocomponent signal admits a well-behaved Hilbert transform and it is referred to as an IMF. The original signal is then subtracted from the IMF, and the repeated sifting process is applied to the remaining signal to obtain another IMF. The process is repeated to obtain m IMFs, i.e.,

$$R_{rs}(t) = \sum_{j=1}^{m} c_{pj}(t) + r_p(t) \tag{14}$$

in which $c_{pj}(t)$ for $j = 1,...,$ m are IMFs of $R_{rs}(t)$, and $r_p(t)$ is the residue, which is the mean trend (or a constant) of the signal. Such a process is referred to as the Empirical Mode Decomposition (EMD) method. The IMFs obtained from the sifting process described above may contain more than one frequency, which is not the modal contribution $R_{rs,j}(t)$. During the sifting process in EMD, one can also impose an intermittency frequency, denoted by ω_{int}, so that the resulting IMF will not contain any frequency components smaller than ω_{int}. By successive applications of the EMD method with intermittency frequency in respective range of modal frequencies, it is possible to extract the modal contribution $R_{rs,j}(t)$ as described e.g., in Yang et al (2000a,b, 2001), i.e.,

$$R_{rs}(t) \approx \sum_{j=1}^{n} R_{rs,j}(t) + \sum_{j=1}^{m-n} c_{pj}(t) + r_p(t) \tag{15}$$

Another alternative approach is to use the band-pass filter and EMD method to extract the modal contribution $R_{rs,j}(t)$ in Eq.(15) as follows: From the Fourier spectrum of $R_{rs}(t)$, the approximate frequency range for each natural frequency, i.e., $\omega_{jL} < \omega_j < \omega_{jH}$ ($j = 1, 2, ..., n$) can be determined. $R_{rs}(t)$ is processed through the band-pass filter with a frequency band $\omega_{jL} < \omega_j < \omega_{jH}$. The resulting time history is then processed through EMD, and the first IMF is quite close to the jth modal contribution $R_{rs,j}(t)$. Repeating the same procedures for $j = 1, 2, ..., n$, one obtains $R_{rs,j}(t)$ in Eq.(15).

Taking the Hilbert transform of $R_{rs,j}(t)$, denoted by $\tilde{R}_{rs,j}(t)$, and forming the analytical function, one obtains for $\zeta_j << 1$ and $\zeta_j << \omega_j$,

$$Y_{rs,j}(t) = R_{rs,j}(t) + i\,\tilde{R}_{rs,j}(t) = A_{rs,j}(t)\exp[i\,\theta_{rs,j}(t)] \tag{16}$$

$$A_{rs,j}(t) = B_{rs,j}\, e^{-\zeta_j \omega_j t} \tag{17}$$

$$\theta_{rs,j}(t) = \omega_{dj} t + \theta_{sj} + \frac{3\pi}{2} + \varphi_{rs,j} \tag{18}$$

where Eqs.(5)-(7) have been used. From Eqs.(17)-(18), one obtains

$$\ln A_{rs,j}(t) = \ln B_{rs,j} - \zeta_j \omega_j t \tag{19}$$

$$\omega_{rs,j}(t) = \frac{d}{dt}\theta_{rs,j}(t) = \omega_{dj} \tag{20}$$

IDENTIFICATION OF STRUCTURAL PARAMETERS

For the identification of natural frequencies ω_j and damping ratios ζ_j for $j = 1, 2, ..., n$, only one cross-correlation (or auto-correlation) function is sufficient. The procedures are described in the following. For small ζ_j, it follows from Eq.(18) that the damped natural frequency ω_{dj} can be obtained from the slope of the phase angle $\theta_{rs,j}(t)$ vs. time t plot, whereas $-\zeta_j\omega_j$ can be estimated from the slope of the decaying amplitude $\ln A_{rs,j}(t)$ vs. time t plot, Eq.(19). For the general case in which ζ_j is not small, both $\theta_{rs,j}(t)$ and $\ln A_{rs,j}(t)$ are not linear functions of time t. In this case, it was proposed in Yang et al (2000a,b, 2001)

to use linear least-square fit procedures to estimate the natural frequencies and damping ratios as follows: (i) The plot of the phase angle $\theta_{rs,j}(t)$ vs. time t is fitted by a straight line using the linear least-square fit procedure. This straight line is referred to as the least-square straight line for the phase angle. Then, the slope of the straight line is ω_{dj}, (ii) The plot of the decaying amplitude $\ln A_{rs,j}(t)$ vs. time t is fitted by a straight line using the linear least-square fit procedure. This straight line is referred to as the least-square straight line for the decaying amplitude. Then, $-\zeta_j\omega_j$ is estimated from the slope of the straight line, (iii) With ω_{dj} and $-\zeta_j\omega_j$ estimated from (i) and (ii), ω_j and ζ_j can be computed using $\omega_{dj} = \omega_j(1-\zeta_j^2)^{1/2}$. As will be demonstrated later in the benchmark example, ω_{dj} can be estimated from step (i) above without any problem. However, when ζ_j is large, the oscillation of $\ln A_{rs,j}(t)$ around the linear least-square line may be significant, so that the slope $-\zeta_j\omega_j$ may be sensitive to the range of time interval used for the linear least-square fit. In this case, we propose to process $\ln A_{rs,j}(t)$ through the EMD to obtain the residue, denoted by $r_{Apj}(t)$. Since the residue represents the mean trend of $\ln A_{pj}(t)$, it is fitted by a straight line using the linear least-square fit procedure. Then, the slope $-\zeta_j\omega_j$ can be estimated from the linear least-square line.

To identify the mode shapes, damping matrix and stiffness matrix, the response time histories at all DOF should be measured. It follows from Eqs.(7) and (19) that the ratio of the absolute value of the modal elements ϕ_{rj} and ϕ_{mj} (r, m = 1, 2, ..., n) can be identified as

$$\left|\phi_{rj}\right| / \left|\phi_{mj}\right| = \exp[A'_{rs,j}(t_0) - A'_{ms,j}(t_0)] \tag{21}$$

in which $A'_{rs,j}(t_0)$ and $A'_{ms,j}(t_0)$ are, respectively, the magnitudes at the time $t = t_0$ of the least-square straight lines for the decaying amplitudes $\ln A_{rs,j}(t)$ and $\ln A_{ms,j}(t)$ obtained previously. Further, the differences between the phase angle $\varphi_{rs,j}$ of the modal element ϕ_{rj} and that of ϕ_{mj} follow from Eq.(18) as

$$\Delta\varphi_{r\,m,j} = \varphi_{rs,j} - \varphi_{ms,j} = \theta'_{rs,j}(t_0) - \theta'_{ms,j}(t_0) \tag{22}$$

in which $\theta'_{rs,j}(t_0)$ and $\theta'_{ms,j}(t_0)$ are, respectively, the magnitudes of the least-square straight lines for the phase angles $\theta_{rs,j}(t)$ and $\theta_{ms,j}(t)$ at the time $t = t_0$ obtained previously. The value of $\Delta\varphi_{r\,m,j}$ above is either $\pm 2m\pi$ or $\pm(2m+1)\pi$, see Eq.(7). With the aid of Eq.(7), the sign of ϕ_{rj} relative to ϕ_{mj} can be determined. Thus, both the absolute values and signs of all elements relative to an arbitrary element in the jth modal vector $\mathbf{\Phi}_j$ have been determined. Repeating the same procedures for all modal contributions j = 1, 2, ..., n, the modal matrix $\mathbf{\Phi}$ can be identified. Finally, the stiffness and damping matrices **K** and **C** can be obtained from Eq.(10).

BENCHMARK RESULTS

The approach described previously is applied to the noisy acceleration data provided by the benchmark problem. To obtain a reasonable estimate of cross spectral density functions, a total of 400 seconds of stationary response data with a sampling rate of 1000Hz is used, after removing the beginning transient parts (first 3 seconds). This allows for 47 averages in computing the cross spectral density functions. The reference floor response is selected to be the acceleration of the fourth floor, i.e., s = 4 in Eq.(4), so that all the modes can be observed in the data. A representative cross spectral density function and the corresponding cross correlation function of the 4th and 1st floors of the undamaged structure are shown in Fig.1.

The EMD method and band-pass filters with bandwidths $\omega_{jL} \le \omega_j \le \omega_{jH}$ (j = 1, 2, 3, 4) are applied to the cross correlation functions of the undamaged structure in Fig.1(b) to obtain the modal components $R_{14,j}(t)$

with ω_{1L} = 7Hz, ω_{1H} = 12Hz, ω_{2L} = 24Hz, ω_{2H} = 27Hz, ω_{3L} = 36Hz, ω_{3H} = 40Hz, ω_{4L} = 46Hz and ω_{4H} = 50Hz. The decomposed modal responses of the cross correlation function in Fig.1 (b) are shown in Fig.2. Due to the phase shift of band-pass filters, the beginning segments in Fig.2 do not represent the free decay characteristics. Hence, a small segment at the beginning will be removed. Then, the Hilbert transform is applied to each modal response to obtain the instantaneous phase angle $\theta_{rs,j}(t)$ and amplitude $A_{rs,j}(t)$. The plots of $\ln A_{rs,j}(t)$ and $\theta_{rs,j}(t)$ versus time t for the first modal response in Fig.2(a) are presented in Fig.3 as dotted curves. These dotted curves are fitted by solid straight lines using the linear least-square procedure. Following the identification procedures presented previously, the first natural frequency ω_1 and damping ratio ζ_1 can be determined from the slopes of two solid lines in Fig.3. Choosing a time instance t_0 in the middle of the range of the solid straight line in Fig.3, i.e., t_0 = 2.5 seconds, one obtains $A'_{rs,j}(t_0)$ and $\theta'_{rs,j}(t_0)$ from Fig.3. Repeating the same procedures for each modal response, the mode shape vector $\mathbf{\Phi}_j$ and modal matrix $\mathbf{\Phi}$ can be identified.

The identified natural frequencies and damping ratios for the undamaged and damaged structures (damage patterns 1 and 2 of Case 1) are presented in Table 1 as denoted by "Id.". Also shown in Table 1 are the theoretical values, as denoted by "Th.", for comparison. The theoretical damping ratio for each mode is 1%. For the damage pattern 1, all braces in the first story unit are removed, whereas for the damage pattern 2, all braces in both the first and third story units are removed. As observed from Table 1, the estimated natural frequencies and damping ratios are quite accurate. Assuming that the mass matrix is known, the stiffness matrix **K** and damping matrix **C** have been estimated. The stiffness in each story unit is computed based on the shear-beam model. The identified results for the stiffness in each story unit, denoted by k_1, k_2, k_3 and k_4, respectively, are presented in Table 2. Also shown in Table 2 are the theoretical values for comparison. From the identified stiffness in each story unit presented in Table 2, the damage locations and damage severities have been detected and identified quite accurately.

CONCLUSIONS

Based on the Hilbert-Huang spectral analysis, a method of system identification and damage detection is proposed and applied to the ASCE benchmark building model. All the natural frequencies and damping ratios of the structure can be identified with only one measurement of the acceleration response that may be polluted by noises. When the acceleration responses at all DOF are measured, the modal matrix, stiffness matrix and damping matrix can be identified assuming that the mass matrix is known. Damages in the structure can be identified by a comparison of the stiffness in each story of the building prior to and after the damage event. Simulation results demonstrate that the proposed method is quite accurate in identifying the structural damages, including the damage locations and severities. The method is shown to be quite effective for the system identification and damage detection of structural health monitoring.

PARAMETER OPTIMIZATION OF MULTI-TMDS FOR WIND-EXCITED VIBRATION SUPPRESSION OF TALL BUILDINGS

G. Zheng, Y. Q. Ni, H. Li, Y. F. Duan

Department of Civil and Structural Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong

ABSTRACT

Owing to shortage in the supply of land in Hong Kong, buildings in the urban areas of Hong Kong are often built to be tall and slender. Mitigation of wind-induced vibration by using supplemental damping devices has been required in design of some slender tall buildings to satisfy stringent criteria resulting from Hong Kong's typhoon wind climate. Tuned mass/liquid dampers (TMDs/TLDs) provide a cost-effective means for this purpose. This paper describes a study on optimizing the parameters of multiple tuned mass dampers (multi-TMDs) for wind-excited vibration suppression of high-rise buildings. Based on three-dimensional finite element model for design analysis of tall buildings, a reduced-order lumped mass MDOF model with the same modal properties as original model is developed for multi-TMDs design. By dividing the building-damper system as two sub-structures, transfer functions of the building with multi-TMDs attached at arbitrary stories are explicitly derived, and random vibration response of the building-damper system is accurately expressed by adopting appropriate wind force spectrum and accounting for spatial correlation of the excitation. With these analytically derived formulations, the genetic algorithm is then applied to search optimal parameters of the multi-TMDs that achieve maximum response suppression for the building. The damper parameters concerned include the stiffness, mass and damping. A case study of an actual 50-story tall building using multi-TMDs for wind-excited response mitigation is given as an example.

KEYWORDS

Multiple tuned mass dampers (multi-TMDs), tall building, wind excitation, vibration suppression, parameter optimization, genetic algorithm.

INTRODUCTION

Tuned mass dampers (TMDs) have been widely used in high-rise buildings worldwide for wind- and earthquake-induced vibration mitigation (McNamara 1977; Kwok 1984; Ueda et al. 1992; Kwok and Samali 1995; Kitagawa and Midorikawa 1998; Breukelman and Haskett 2001). The TMD consists of a mass, a spring and a viscous damper attached to a vibrating main system. By tuning natural frequency of the TMD close to natural frequency of the main system, the vibration energy is dissipated through the damping of the TMD. One of the disadvantages of a single TMD system is its high sensitivity to

fluctuation in natural frequency of the structure and/or that in damping ratio of the TMD. The effectiveness of a TMD is decreased significantly by mis-tuning frequency or off-optimum damping. As a result, the use of multiple tuned mass dampers (multi-TMDs) has been proposed for improving the control effectiveness and robustness (Yamaguchi and Harnpornchai 1993; Abe and Fujino 1994; Igusa and Xu 1994; Kareem and Kline 1995; Jangid and Datta 1997; Rana and Soong 1998). In the majority of existing studies on multi-TMDs, the primary system was assumed to vibrate in a single mode and idealized as a mode-generalized SDOF model. However, tall buildings usually exhibit multi-mode dynamic response under the action of wind or seismic loading. Multi-TMDs have been shown effective in controlling multiple structural modes (Rana and Soong 1998).

In this paper a method for parameter optimization of multi-TMDs for controlling multi-mode structural response of tall buildings under random wind excitation is presented by using the genetic algorithm, and its application to a 50-storey building in Hong Kong is described. Based on the accurate analysis model for structural design, a reduced-order lumped mass MDOF model is formulated for multi-TMDs design. Making use of sub-structuring, transfer functions of the building-damper system are explicitly derived, and the root-mean-square response expression is further obtained by considering appropriate wind force spectrum and accounting for spatial correlation of the excitation. The genetic algorithm is then implemented to search optimal parameters of the multi-TMDs that achieve maximum structural response reduction. In the case study, the wind excitation spectrum used is determined according to the Hong Kong Code of Practice on Wind Effects and the wind profile suggested by the Hong Kong Building Department.

FORMULATION

Wind Force Spectrum

The mean wind speed profile can be approximated either by a logarithmic law or a power law, i.e.,

$$V(z)=\frac{1}{k}V^{*}\ln\frac{z}{z_0} \quad \text{or} \quad V(z)=V_g\left(\frac{z}{\delta}\right)^{\alpha} \tag{1a, b}$$

A power exponent of 0.19, i.e., $\alpha = 0.19$ is suggested for the mean wind profile at general terrain in the Hong Kong Building Department Notes for Wind Tunnel Tests. The wind pressure is related to the wind speed by

$$P=\frac{1}{2}\rho V^2 \tag{2}$$

According to the Code of Practice on Wind Effects (1983) for Hong Kong, the wind pressure at 250 m or above is 4.3 kN/m^2 at general terrain. The wind speed at the height of 250 m or above is obtained as

$$V(250) = 81.96 \text{ m/s} \tag{3}$$

The mean wind profile is determined by

$$V(z) = V(250)\times(z/250)^{0.19} \tag{4}$$

and the mean wind velocity at 10 m height is

$$V_{10} = 44.46 \text{ m/s} \tag{5}$$

The wind velocity spectrum is taken as Davenport spectrum with the expression (Davenport 1961)

$$W(f) = 4k\bar{v}^2(10)\frac{x^2}{f(1+x^2)^{4/3}} \tag{6}$$

$$x = L_v^{*}\cdot f/\bar{v}(10) \tag{7}$$

where k is the coefficient about the ground surface coarse, being 0.02 for open sea area; $\bar{v}(10)=V_{10}$ is

the mean wind speed at 10 m height above the ground; L_v^* is the integral length scale, generally taken as 1200; f is frequency in Hz.

The coherence function between two points at different heights is taken as the expression

$$coh(f) = \exp(-\frac{C_z \cdot f \cdot \Delta z}{V_{10}}) \tag{8}$$

where the constant C_z is taken as 10; Δz is the vertical distance between the two concerned points; V_{10} is the mean wind speed at 10 m height and is taken as 44.46 m/s in the present study. Then the co-spectrum of the wind velocity on a tall building at height i and height j is

$$W_{ij} = coh(f) \cdot \sqrt{W_{ii} W_{jj}} = \exp(-\frac{10 f \cdot \Delta z_{ij}}{44.46}) \cdot \sqrt{W_{ii} W_{jj}} \tag{9}$$

The co-spectrum of wind load is obtained by

$$S_{Wij} = \rho^2 C_{D,i} C_{D,j} A_i A_j \overline{v}_i \overline{v}_j W_{ij} \tag{10}$$

in which the coefficient ρ is taken as 1.28 kg/m^3; C_D = 1.2; and the factor A representing the equivalent projection area along wind direction at heights i and j is taken as 1 in the present study. So,

$$S_{Wij} = 1.28^2 1.2^2 A^2 \overline{v}_i \overline{v}_j W_{ij} = 2.3593\, \overline{v}(z_i)\, \overline{v}(z_j) \exp(-\frac{10 f \cdot \Delta z_{ij}}{44.46}) W(f) \tag{11}$$

Response of Building without Multi-TMDs

For a tall building with arbitrary stories, the governing equation of motion can be expressed as

$$\boldsymbol{M}\ddot{\boldsymbol{x}}(t) + \boldsymbol{C}\dot{\boldsymbol{x}}(t) + \boldsymbol{K}\boldsymbol{x}(t) = \boldsymbol{F}(t) \tag{12}$$

where $\boldsymbol{M}$, $\boldsymbol{C}$, $\boldsymbol{K}$ are the mass, damping and stiffness matrices of the building, respectively, which are usually obtained from the finite element model for structural design analysis. Based on modal analysis of the finite element model, the structural response $\boldsymbol{x}(t)$ can be expressed in modal coordinates as

$$\boldsymbol{x} = R_1\{\boldsymbol{\varphi}_1\} + R_2\{\boldsymbol{\varphi}_2\} + \cdots + R_N\{\boldsymbol{\varphi}_N\} = [\boldsymbol{\Phi}]_{N\times N}\{\boldsymbol{R}\}_{N\times 1} \tag{13}$$

where $[\boldsymbol{\Phi}]$ are mode shape matrix obtained from modal analysis; $\{\boldsymbol{R}\}$ is modal coordinate vector. By substituting Eq. (13) into Eq. (12) and then left-multiplying Eq. (12) with $[\boldsymbol{\Phi}]^T$, we get

$$[\overline{\boldsymbol{M}}]\{\ddot{\boldsymbol{R}}\} + [\overline{\boldsymbol{C}}]\{\dot{\boldsymbol{R}}\} + [\overline{\boldsymbol{K}}]\{\boldsymbol{R}\} = [\boldsymbol{\Phi}]^T\{\boldsymbol{F}\} = \{\overline{\boldsymbol{F}}\} \tag{14}$$

where

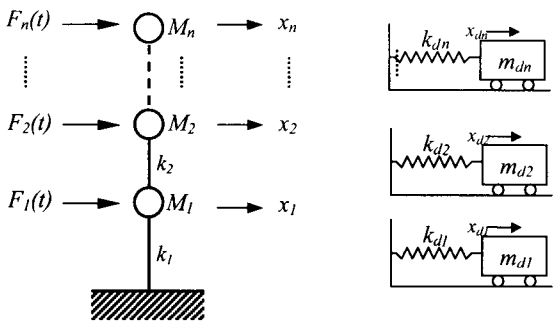
$$[\overline{\boldsymbol{M}}] = [\boldsymbol{\Phi}]^T[\boldsymbol{M}][\boldsymbol{\Phi}], \quad [\overline{\boldsymbol{C}}] = [\boldsymbol{\Phi}]^T[\boldsymbol{C}][\boldsymbol{\Phi}], \quad [\overline{\boldsymbol{K}}] = [\boldsymbol{\Phi}]^T[\boldsymbol{K}][\boldsymbol{\Phi}] \tag{15a, b, c}$$

are all diagonal matrices under the assumption of proportional viscous damping.

The transfer function in modal coordinates is obtained as

$$\begin{aligned} \boldsymbol{H}_s(\omega) &= \left[-\omega^2 \overline{\boldsymbol{M}} + i\omega \overline{\boldsymbol{C}} + \overline{\boldsymbol{K}}\right]^{-1} \\ &= \left[\boldsymbol{Diag}(\omega_1^2 - \omega^2, \cdots, \omega_N^2 - \omega^2) + i\, \boldsymbol{Diag}(2\zeta_1\omega_1\omega, \cdots, 2\zeta_N\omega_N\omega)\right]^{-1} \end{aligned} \tag{16}$$

Therefore the response co-spectrum in modal coordinates is



$$\boldsymbol{S}_r^M = \boldsymbol{H}_S^*(\omega)\boldsymbol{S}^{MF}\boldsymbol{H}_S^T(\omega) \tag{17}$$

where $\boldsymbol{S}^{MF}$ is the wind load co-spectrum in modal coordinates, defined as

$$\boldsymbol{S}^{MF} = \boldsymbol{\Phi}^T \boldsymbol{S}_W \boldsymbol{\Phi} \tag{18}$$

The response co-spectrum in physical coordinates is obtained by

$$\boldsymbol{S}_X = \boldsymbol{\Phi}\boldsymbol{S}_r^M\boldsymbol{\Phi}^T \tag{19}$$

(a) Substructure of building (b) Substructure of multi-TMDs

Figure 1: Model of building-damper system

Response of Building with Multi-TMDs

When the building is attached with multi-TMDs, the whole system can be considered with two sub-structures as shown in Fig. 1: one is the original building with additional forces due to building-TMD interaction and the other is the multi-TMDs subjected to forces due to building-TMD interaction.

The governing equation of motion of the building substructure is as follows

$$[\overline{\boldsymbol{M}}]\{\ddot{\boldsymbol{R}}\}+[\overline{\boldsymbol{C}}]\{\dot{\boldsymbol{R}}\}+[\overline{\boldsymbol{K}}]\{\boldsymbol{R}\}=[\boldsymbol{\Phi}]^T\{\overline{\boldsymbol{F}}'(t)\} \tag{20}$$

where

$$\{\overline{\boldsymbol{F}}'(t)\}=\{\boldsymbol{F}(t)\}+\{\boldsymbol{F}_D(t)\} \tag{21}$$

in which $\{\boldsymbol{F}_D(t)\}$ is the vector of interactive forces applied to the building by the tuned mass dampers. It has the expression

$$\{\boldsymbol{F}_D(t)\}=\{k_{d1}x_{d1}+c_{d1}\dot{x}_{d1},\ k_{d2}x_{d2}+c_{d2}\dot{x}_{d2},\ \cdots\ k_{dn}x_{dn}+c_{dn}\dot{x}_{dn}\}^T \tag{22}$$

where k_{dj} and c_{dj} (j=1, 2, ···, n) are the stiffness and viscous damping coefficient of the jth TMD. Substituting Eqs. (21) and (22) into Eq. (20) and applying Laplace transformation yield

$$[\boldsymbol{H}(\omega)]^{-1}\{\widetilde{\boldsymbol{R}}(\omega)\}=[\boldsymbol{\Phi}]^T[\widetilde{\boldsymbol{F}}(\omega)]+[\boldsymbol{\Phi}]^T[\boldsymbol{d}]\{\widetilde{\boldsymbol{x}}_d(\omega)\} \tag{23}$$

where

$$[\boldsymbol{d}]=\boldsymbol{Diag}[k_{d1}+ic_{d1}\omega\quad k_{d2}+ic_{d2}\omega\quad\cdots\quad k_{dn}+ic_{dn}\omega] \tag{24}$$

$$[\boldsymbol{H}(\omega)]^{-1}=\boldsymbol{Diag}[\omega_1^2-\omega^2+2i\zeta_1\omega_1\omega\quad\omega_2^2-\omega^2+2i\zeta_2\omega_2\omega\quad\cdots\quad\omega_N^2-\omega^2+2i\zeta_N\omega_N\omega] \tag{25}$$

in which ω_j's (j=1, 2, ···, N) are the natural frequencies of the building without TMDs.

The governing equation of motion of the TMD substructure is as follows

$$[\boldsymbol{M}_d](\{\ddot{\boldsymbol{x}}\}+\{\ddot{\boldsymbol{x}}_d\})+[\boldsymbol{C}_d]\{\dot{\boldsymbol{x}}_d\}+[\boldsymbol{K}_d]\{\boldsymbol{x}_d\}=0 \tag{26}$$

Applying Laplace transformation to Eq. (26) yields

$$([\boldsymbol{K}_d]-\omega^2[\boldsymbol{M}_d]+i\omega[\boldsymbol{C}_d])\{\widetilde{\boldsymbol{x}}_d(\omega)\}=\omega^2[\boldsymbol{M}_d]\{\widetilde{\boldsymbol{x}}(\omega)\} \tag{27}$$

from which it follows that

$$[\widetilde{\boldsymbol{x}}_d(\omega)]=[\boldsymbol{H}_d]\{\widetilde{\boldsymbol{x}}(\omega)\}=[\boldsymbol{H}_d][\boldsymbol{\Phi}]\{\widetilde{\boldsymbol{R}}(\omega)\} \tag{28}$$

where

$$[\boldsymbol{H}_d]=\boldsymbol{Diag}[h_{d1}\quad h_{d2}\quad\cdots\quad h_{dn}] \tag{29}$$

$$h_{dj} = \frac{\omega^2}{\omega_{dj}^2 - \omega^2 + 2i\zeta_{dj}\omega_{dj}\omega} \qquad (j=1, 2, \cdots, n) \tag{30}$$

in which $\omega_{dj} = \sqrt{k_{dj}/m_{dj}}$ and $\zeta_{dj} = c_{dj}/(2m_{dj}\omega_{dj})$ are the frequency and damping ratio of the jth TMD.

Substituting Eq. (28) into Eq. (23) obtains

$$\{\tilde{\boldsymbol{R}}(\omega)\} = \tilde{\boldsymbol{H}}_d(\omega)[\boldsymbol{\Phi}]^T\{\tilde{\boldsymbol{F}}(\omega)\} \tag{31}$$

where

$$\tilde{\boldsymbol{H}}_d(\omega) = \left[[\boldsymbol{H}(\omega)]^{-1} - [\boldsymbol{\Phi}]^T[\boldsymbol{d}][\boldsymbol{H}_d][\boldsymbol{\Phi}]\right]^{-1} \tag{32}$$

The spectrum expression of Eq. (31) is

$$[\tilde{\boldsymbol{S}}_R(\omega)] = [\tilde{\boldsymbol{H}}_d(\omega)][\boldsymbol{\Phi}]^T[\boldsymbol{S}_F(\omega)][\boldsymbol{\Phi}][\tilde{\boldsymbol{H}}_d^*(\omega)] \tag{33}$$

and thus the response spectrum of the TMD-controlled structure at degree j is obtained as

$$\tilde{S}_{Xjj}(\omega) = \{[\boldsymbol{\Phi}]_{j,1:end}\}^T[\tilde{\boldsymbol{S}}_R(\omega)]\{\boldsymbol{\Phi}_{j,1:end}\} \tag{34}$$

PARAMETER OPTIMIZATION

The RMS responses at degree j of the building without and with multi-TMDs can be obtained by

$$\sigma_j^2 = \int_0^{+\infty} \{[\boldsymbol{\Phi}]_{j,1:end}\}^T[\boldsymbol{S}_R(\omega)]\{[\boldsymbol{\Phi}]_{j,1:end}\}d\omega \tag{35}$$

$$\tilde{\sigma}_j^2 = \int_0^{+\infty} \{[\boldsymbol{\Phi}]_{j,1:end}\}^T[\tilde{\boldsymbol{S}}_R(\omega)]\{[\boldsymbol{\Phi}]_{j,1:end}\}d\omega \tag{36}$$

The ratio between the RMS responses at degree j is defined as

$$\gamma_j = \frac{\int_0^{+\infty} \{[\boldsymbol{\Phi}]_{j,1:end}\}^T[\tilde{\boldsymbol{S}}_R(\omega)]\{[\boldsymbol{\Phi}]_{j,1:end}\}d\omega}{\int_0^{+\infty} \{[\boldsymbol{\Phi}]_{j,1:end}\}^T[\boldsymbol{S}_R(\omega)]\{[\boldsymbol{\Phi}]_{j,1:end}\}d\omega} \tag{37}$$

The TMD system can be optimized to minimize γ_j, which indicates a local optimal TMD system and is referred to as reduction index. A global optimal TMD system is defined by the one that minimizes a weighted sum of γ_j. In the present study, the genetic algorithm (GA) is adopted to search the optimal parameters, including the frequency, damping ratio of each TMD when constrain of gross mass of the multi-TMDs is given, to achieve the maximum response reduction. Description of the philosophy of GA for parameter identification is escaped herein due to the limited space. Some implementation points of this technique for the present problem will be addressed in the following case study.

CASE STUDY

A 162m-high 50-storey building is now under construction in Hong Kong. The initial design of this building was found to not satisfy the wind-resistant requirement prescribed in the Hong Kong design code, and therefore use of multi-TMDs as supplemental damping devices in this building was studied. The total mass of the building is 27,774 ton. Modal properties obtained from a three-dimensional finite element model in the along-wind direction are given in Table 1. Damping ratios for all modes are assumed to be 4.0%. The first two modes, which contribute over 80% in the along-wind response are taken into account in the analysis. The TMDs are only allowed to be installed at the top floor and the 25th floor (facility installation storey). As a result, two TMDs, one at the top-floor and the other at the 25th floor, are considered in the present study.

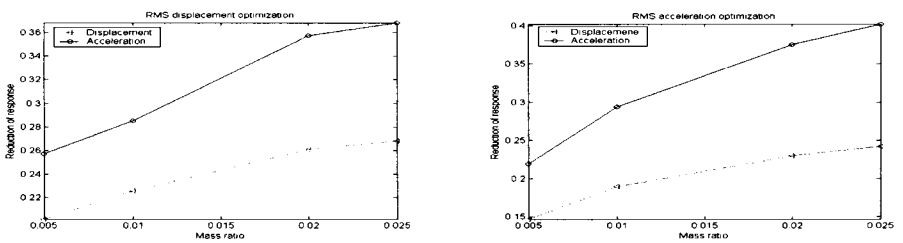


TABLE 1
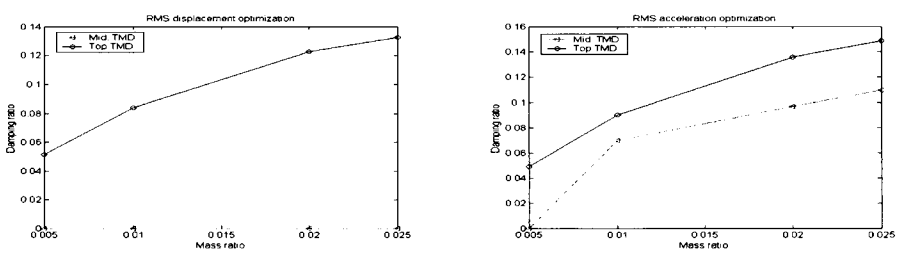
MODAL PROPERTIES OF 50-STOREY BUILDING

Mode order	1	2	3	4	5
f (Hz)	0.216	0.940	2.278	3.941	5.932
ω (rad/s)	1.355	5.904	14.314	24.762	37.269
Mass factor (%)	66.82	13.08	5.51	3.11	1.92

Two strategies for parameter optimization are conducted with the objectives to maximize reduction of the root-mean-square displacement and acceleration at the top floor, respectively. In the optimization search by GA, the range of the frequencies of TMDs is set as 0.7 times the first modal frequency to 1.3 times the second modal frequency of the building, i.e., 0.151 to 1.222 Hz. The damping ratio of each TMD is set between 0 and 0.2. It is found that the convergence speed of GA for displacement and acceleration reduction optimization is fairly rapid. Usually 60 generations can provide acceptable result with a group size of 10, while 120 generations are used in the present study.



In actual application, the gross mass of multi-TMDs should be limited and is generally taken within five percent of the total mass of the building. In this present study, the upper limit of the ratio of the TMD's mass to the building mass is set as 0.005, 0.01, 0.02 and 0.025, respectively. For each case, the optimization to maximize reduction of RMS displacement and acceleration responses at the top floor is carried out. Fig. 2 shows the maximum reduction of RMS responses versus mass ratio. It is evident that the control effectiveness of multi-TMDs, i.e., the reduction in structural response, increases with the TMD masses for both displacement and acceleration responses.

Under various mass ratios, the optimal damping ratios and frequency ratios are obtained as shown in Figs. 3 and 4, respectively. It is observed that the value of reduction index for acceleration is always greater than that for displacement. This means that TMDs perform better for suppressing acceleration than displacement. It is seen from Fig. 3(a) that when displacement optimization is concerned, the

(1)	1.00	1.00	0.2016	0.2256	0.2610	0.2778	0.2601	0.2938	0.3748	0.4021
(2)	1.01	1.01	0.2019	0.2264	0.2612	0.2785	0.2607	0.2948	0.3760	0.4033
(3)	1.02	1.02	0.2022	0.2271	0.2614	0.2791	0.2614	0.2959	0.3772	0.4045
(4)	1.05	1.05	0.2029	0.2290	0.2618	0.2808	0.2633	0.2991	0.3807	0.4081
(5)	1.05	1.02	0.2018	0.2272	0.2609	0.2791	0.2609	0.2962	0.3776	0.4049
(6)	1.05	1.01	0.2014	0.2266	0.2606	0.2786	0.2601	0.2953	0.3765	0.4039

optimal damping ratio of the TMD at the top floor increases with the mass ratio. However, the optimal damping ratio of the TMD at the middle (25th) floor takes zero for all mass ratios. In the case of acceleration optimization, the optimal damping ratios of both TMDs increase with the mass ratio. The optimal damping ratio of the TMD at the top floor is always greater than that of the TMD at the middle (25th) floor. It is seen from Fig. 4(a) that when displacement optimization is concerned, the optimal frequencies of both TMDs decrease with the mass ratio and are around the first mode natural frequency of the building. However, in the case of acceleration optimization, except for mass ratio equal to 0.005, the optimal frequency of the TMD at the middle (25th) floor is around the second mode natural frequency of the building, indicating that higher modes play significant role in acceleration optimization. By comparing Figs. 3 and 4, it is observed that the optimal damping ratio is much more sensitive to the TMD mass than to the TMD frequency.

Table 2 shows the response reduction at the top floor due to a slight increase in the TMD masses while keeping the damping ratios and frequency ratios as their optimal values invariably. Here M'_{d1}/M_{d1} and M'_{d2}/M_{d2} are the masse increment ratios of the TMDs at the middle and top floors, respectively. It is seen that increasing the TMD masses in a same proportion will consistently improve the performance of the multi-TMDs. However, when the masses of the two TMDs are increased in different ratios, the performance of the multi-TMDs might be enhanced or degraded.

CONCLUSIONS

A general method for analyzing wind-induced random response of tall buildings installed with multi-TMDs is formulated in consideration of high order modes of the building and spatial correlation of wind force. The parameter optimization of multi-TMDs for wind-excited vibration control of tall buildings is conducted by means of the genetic algorithm (GA). The case study of a 50-storey building

in Hong Kong draws the following conclusions: (i) The maximum reduction ratio of RMS response increases with the increase of the TMD masses; (ii) The reduction ratio of acceleration is always larger than that of displacement; (iii) The optimal frequency ratio is not sensitive to the TMD masses; (iv) The displacement and acceleration optimizations provide different results in both reduction indices and optimal TMD parameters; and (v) The optimal frequencies of the multi-TMDs may be around the first mode natural frequency of the building or around the higher mode natural frequency.

ABSTRACT

Steel can be used as a substitute for timber and, in addition, can provide many significant advantages; however, the cost differential fluctuates. Steel has traditionally been slightly more expensive on a material basis, but savings offset this in greater structural efficiency, rapid assembly and reduction in rework costs experienced with poor quality timber. Increased global timber demand and diminishing resources are causing erratic timber price increases that are threatening the traditional raw material competitiveness. Steel has a fairly static international base cost. There is also a minimal waste of base material during manufacture, with steel having 1-2% wastage and Timber 5-11% wastage. In this research two steel joist systems are proposed, designed and engineered for flooring and based on manufacturing, design and serviceability criteria are assessed. Practical conclusions are made.

KEYWORDS

joist, flooring, top-hat, c-shape, design criteria

INTRODUCTION

In recent years a number of alternatives to wood as the primary framing material in residential construction have emerged. One of the most promising of these alternatives is the use of light gauge steel framing members as a replacement for dimensional lumber. Today, as the demand for wood products holds strong and the number of old-growth forest diminishes, it is paramount that we continue to search for alternative materials for wood and improve replacements that have been identified.

A wake up call for the residential construction industry came about in late 1992 as the composite price for framing lumber shot up almost 100% in a period of only five months. The composite fell back to earth by July of 1993 only to shoot back to record levels by the end of that year [4]. The warning signs were loud and clear. The rapid use of old-grown forests to produce long, large dimensioned lumber and plywood had reached the breaking point. All that was left, of a once endless supply of lumber, were a

few remaining old-grown forests located on government land and subject to federal logging restrictions [2].

The U.S. Department of Housing and Urban Development aided by the National Association of Home builders spearheaded an effort to identify emerging technologies that had the potential to replace wood. Housing and Urban Development identified a number of alternative materials including [1] foam core, panels, light-gauge steel framing, welded-wire sandwich panels, concrete forming systems and concrete block.

Steel's strength, weight, uniform manufacture, recyclability, termite resistance, and non-combustibility marked it as one of the most promising alternatives to wood in residential steel framing [3]. Now is the time to focus on improving alternatives to wood instead of waiting for the boom of skyrocketing prices to wake us up again. In order to improve the competitiveness of alternative materials we must look outside the box and explore new process and technology. The use of light gauge steel framing in residential construction present the opportunity to apply modern technological concepts and process improvement to the field of construction. Because of steel's high strength and design flexibility, innovative systems are possible which are not possible using other materials. It can span greater distances offering larger open spaces and increased design flexibility without requiring intermediate columns or load bearing walls. The structural integrity and overall quality of light gauge framing is well recognized amongst designers and builders in the residential construction industry as a superior building material. Light gauge is specified in an increasingly larger percentage of new housing starts especially where seismic and high wind loadings are a consideration. Because a steel framed home can be resistant to natural forces, some homeowners may save as much as 30% insurance premiums.

The higher quality and dimensional stability is responsible for eliminating virtually all nail pops and squeaky floors. The environmental benefits of light gauge steel framing are also significant. Among these are the fact that steel is inert and will not contribute to poor indoor air quality, it can be manufactured using 100% scrap steel, is 100% recyclable without material property degradation and does not contribute fuel to fire like wood [5]. The environmental arena is one of the fastest changing segments of society today. Experts in many fields are looking for new building strategies and technologies that will help sustain affordable growth into the next century. Steel is one for those building materials. By selecting recyclable materials for the structures built today, we can "precycle". Our descents will be able to re-use the steel we use today.

Based on engineering principles and certain manufacturing, design and serviceability criteria of two system steel joists, C -shape and Top-hat are proposed, designed and tested to determine their performance and liability for flooring industries. Special recommendations are given for best use.

MANUFACTURING CRITERIA

One of the most quantifiable and perhaps the most influential factors in the decision making process when choosing between two different steel materials is the initial cost of each one. The components of the total cost can be classified into four categories [6]: Material costs, fabrication cost, erection labour cost and other costs which include outside services other than erection, shop drawings and the additional costs associated with risk, the need for contingency, and the schedule requirements of the project.

It is seldom feasible to use more than one or two combinations of bolts diameters and grades on a project. The use of different diameters for different grades simplifies the quality assurance task of ensuring that each strength grade was used in the proper location [7, 9]. It allows more shop efficiency in the drilling or punching operations. Material that will involve many joints, bends, components, will

require more time to fix the numerous bolts during installation. Top hat purlins will take less time to install.

Stacking and handling are considered two crucial factors in any manufacturing process. Top hat is easy to stack on top of each other, which is also an advantage over other shapes.

DESIGN CRITERIA

Cold-formed steel (CFS) floor joists are normally treated as simply supported or continuous span bending members subjected to uniform and/or concentrated loads. Floor joists are also designed considering the compression flanges (top flanges) to be continually braced by the sub-flooring, thus providing lateral restraint. For the design of floor joists, any one of several criteria may control the design depending on the configuration of the section, thickness of material and member length. Six design checks are usually performed when designing CFS floor joists [8]. These are deflection, bending moment, shear, web, crippling, combined bending and web crippling and combined shear and bending.

Deflection limits imposed on the design of floor joist to minimize the impact on the finish material can significantly impact allowable joist spans. Deflection limits have to be carefully considered and justified. The amount of deflection that a joist member experiences under a certain uniform load is determined by the joist moment of inertia, Ix. The moment of inertia can be obtained from manufacture's catalogues or calculated in accordance with the American Iron and Steel Institute (AISI) Specification.

The grade of steel and the effective section modulus of the joist, Se, determine the allowable bending moment. The type of steel should be obtained from the manufacturer. The section modulus can be either calculated or obtained from the manufacturer. The calculation of the section modulus may be complex sometimes, as the effective widths for the compression components of the web, flanges, and lips have to be determined. Consequently, the effective section involves removal of portions of the compression flange, web and lip if each is sufficiently slender.

Web shear normally does not control the design of CFS floor joists for simple spans unless the members have a large web height to steel thickness ratio (h/t). However, the AISI specification requires web shear to be checked for all floor joists. The nominal shear strength, (Vn), of a web consisting of two or more sheets is calculated as the sum of the nominal shear strength of each sheet (web). Each sheet is considered as a separate element carrying its share of the shear force.

CFS joists have thin webs that are susceptible to localized web buckling at concentrated loads or bearing locations. AISI Specification section C3.4 provides design equations for single-web and I-sections with stiffened or partially stiffened flanges and un-stiffened flanges [8, 10]. These equations are limited to joists with web height to thickness (h/t) ratio of less than or equal to 200. Joists with (h/t) ratios greater than 200 shall be provided with adequate means of transmitting concentrated loads and/or reactions directly into web, the thickness of the steel, and the length of the bearing are the most critical components in the AISI web crippling equations. Other factors such as steel material, and bend radius play a lesser role.

The critical location for web crippling is at the member's ends for single joist spans and at the member's ends and intermediate supports for multiple spans. Most manufacturers tabulate the web crippling strength of simply supported joist spans in their technical catalogs. The design equations of the AISI Specification section C3.4 can be used if this information is not readily available [8,10].

AISI specification section C3.5 requires a combined bending and web crippling check for un-reinforced joist webs. Three equations are provided in AISI Specification Section C3.5: Single un-reinforced webs,

multiple unreinforced webs (such as I-beams), and Two nested Z-shapes (support point). Interaction equation for shapes having single unreinforced webs is normally used to design floor joist [8].

The combination of a bending stress and a shear in a web produces a further reduction in the capacity of the web. The degree of the reduction depends upon whether the web is stiffened or not. The presence of negative moment (reversed bending) at the interior supports of multiple span joists require certain measures to be taken to ensure the joists are not overstressed. AISI Specification section C3.3 requires combined shear and bending check for multiple span joists. The interaction equation for unstiffened webs is a circular formula based upon an approximation to theoretical interaction of local buckling resulting from shear and bending. The interaction equation for stiffened webs is linear and not as severe because of the greater post- buckling mode. The un-reinforced web equation is normally used when designing floor joists [8, 10].

The floor is designed to carry the specified loads within the acceptable deflection and vibration. The floor is designed for the combinations of live and dead loads. The floor may not be designed for wind and snow loads. The acting load must not be more than the strength of the materials and must not deflect joist more than required nor cause unnecessary vibration. Loads are primary considerations in any building design because they define the nature and magnitude of hazards or external forces that a building must resist to provide reasonable performance (i.e. safety and serviceability) throughout the structures useful life. The anticipated loads are influenced by a building's intended use (occupancy and function), configuration (size and shape), and location (climate and site conditions). Ultimately, the type and magnitude of design loads affect critical decisions such as material selection, construction details, and architectural configuration. Thus, to optimize the value (i.e. performance versus economy) of the finished product, it is essential to apply design loads realistically. High strength materials will be able to carry loads effectively.

SERVICEABILITY

Careful considerations must be addressed to serviceability issues, which arise with any floor system, of any type. The design of any floor is governed by serviceability limit states, which include deformation or deflections affecting the appearance or effective use of the floor and vibrations causing discomfort to people or damage to finishes or fixtures.

The dynamic (bounce) of flooring systems is a limiting state in design. The response can result in shaking or rattling.

ASSESSMENT

Two systems of joists, figure 1, are designed in this research, top-hat purlins and C-shaped member. Their specifications are summarized in Table 1.

The method used to calculate the strength of the joust is based on the uniform distributed load equivalent W, using the standard equation that governs floor design [11].

$$W = 1.2G + 1.6Q \tag{1}$$

Then the maximum bending moment M^* is determined by using the following formula for simply supported boundary conditions.

$$M^* = \frac{wl^2}{8} \tag{2}$$

The dead and live loads applicability limits for first floor are 0.48KN/m^2 and 1.92KN/m^2 respectively [12].

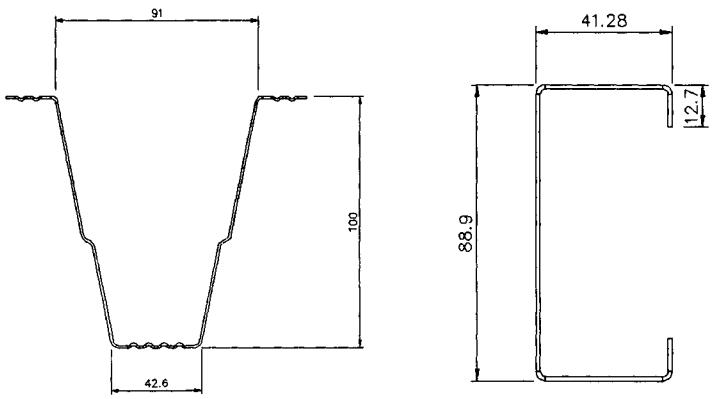

Figure 1: Joist Geometric Shapes: (a) – Tophat (b) – C-shaped

TABLE 1
JOIST SPECIFICATIONS

Specifications	Top-hat purlin	C-shape
Thickness (mm)	0.95	0.95
Web (mm)	100	88.9
Yield strength (Mpa)	345	228
Finish	Galvanized	Galvanized
Designation/Grade	HST250	ASTM A525
E (GN/m^2)	200	200
Spacing (mm)	1700	1200
Span (m)	2	2
Y_{max} (m)	56.6	44.45
I_x (mm^4)	386861.2	294347.9
Flange (mm)	42.6	41.28
Lip/Toe (mm	35	12.7

The limiting moment is determined using the formula

$$\phi_b M_n = \phi_b S_e f_y \tag{3}$$

with

$$S_e = \frac{I_x}{y_{max}} \tag{4}$$

The serviceability, however, is determined by calculating the maximum dead load deflection δ_G,

$$\delta_G = \frac{5w_G L^4}{384EI} \tag{5}$$

and the live load deflection as

$$\delta_Q = \frac{5w_Q L^4}{384EI} \tag{6}$$

Then calculating Δ_T

$$\Delta_T = \delta_G + 0.7\delta_Q \tag{7}$$

The vibration is checked by determining the deflection Δ using the formula for simply supported beam with a concentrated load as follows:

$$\Delta = \frac{wL^3}{48EI} \tag{8}$$

The results are summarised in Table 2 for the two joists.

TABLE 2
DESIGN PARAMETERS

	Design Parameter	Top-hat	C-shaped
Strength	$\phi_b M_n$ (kNm)	2.12	1.36
Deflection	Dead Load Deflection (mm)	8.41×10^{-5}	1.11×10^{-4}
	Live Load Deflection (mm)	3.23×10^{-4}	4.25×10^{-4}
	Δ_T (mm)	8.33×10^{-3}	8.33×10^{-3}
Vibration	Δ (mm)	0.0148	0.018
	Δ_{limit} (mm)	1	1

DISCUSSION AND CONCLUSION

Comparing the calculated variables with the design variables indicates that the strength, serviceability and vibration for the two joists are within the limits; however, some remarks are due as summarised in Table 3.

TABLE 3
COMPARISON BETWEEN TOP-HAT PURLINS AND C-SHAPED

FACTORS	Hat Purlins	C-shaped
Cost	Cheaper	
Time	Quicker to Install	Installation will take longer
Stacking/Handling	Better	Intricate
Appearance	Better	Good
Strength	56% Better	
Deflection	24% Better	
Vibration	18% Better	

The data presented and the conclusion drawn in this paper, represent only the beginning of a long-term industrial research for obtaining an efficient and economical steel joist. A larger database of tested different shapes of steel joist materials for flooring is needed to improve the accuracy of the proposed design criteria. It will be reasonable to investigate more shapes of joist manufactured by other companies.

APPENDIX -Symbols and Definitions

Symbols	Definitions
Se	Elastic section modulus of effective section
E	Young's Modulus of elasticity
I_x	Moment of inertial
F_y	Yield stress
W_G	Dead load
W_Q	Live load
M*	Maximum Bending moment
W	Load
L	Span
M_n	Nominal flexural strength
ϕ_b	Resistance factor for buckling strength
δ_G	Dead load deflection
δ_Q	Live load deflection
Δ	Deflection
Δ_T	Total deflection

ANALYSIS PLANE STEEL FRAME WITH SEMI-RIGID CONNECTIONS AND RIGID-ZONES WITH CONSIDERATION OF THE SECOND ORDER EFFECT

Vu Quoc Anh

Faculty of Civil Engineering – Hanoi Architectural University
Km 10 Nguyen Trai, Thanh Xuan, Hanoi, Viet Nam

ABSTRACT

The most recent European and American Codes allow the actual response of joints to be incorporated in frame design [3]. AISC -LRFD specification (1994) designed two types of construction according to the level of connection rigidity. There are Type FR (Fully Restrained) and Type PR (Partially Restrained) constructions. Type FR frames can be designed based on the specification in which the second order effects are considered to estimate column end moments and frame drift. However, even though semi-rigid frames (Type PR) must be designed considering flexible connections as well as second order effects, the specification has not described the design procedure for this type of structure in detail. The main objective of this technical note is to present a practical and accurate method for analysis of plane steel frames with semi-rigid connections and considering the second order effects.

KEYWORDS

Semi-rigid connections, Second order effect, Rigid zones (Rigid offsets), Stiffness matrix, Geometric stiffness matrix, Geometric nonlinearity

1. INTRODUCTION

For most building structures, especially tall steel buildings, the P-Delta effect most concern occurs in the columns due to gravity load, including dead load and live load. The column axial forces are compressive, making the structure more flexible against lateral loads. The P-Delta analysis accounts for the effect of a large axial load upon the transverse bending behavior of frame elements. Axial compressions reduce the flexural stiffness of frame elements, and axial tension stiffens them.

Comparing with reinforced concrete structure, member rigidity of steel structure is less, and displacement of steel structure is larger than that of reinforced structure, so the secondary moment due to axial force has to be considered, i.e., the problem of second order effects. In steel framed structures the lateral deflections along each element span (i.e., P-δ effects), the relative drift between the element

ends (i.e., P-Δ effects), and the effects of flexural moments on the axial stiffness cause nonlinear behavior with additional moments and displacements. There nonlinear geometrical effects alter not only the stiffness matrix of each element and that of structure as the whole, but the stability of each element and that of entire structure. For instance, the P-δ effects may lead to individual member buckling or local collapse, while P-Δ effects may lead to overall structural instability or story buckling.

One aspect that we have so far neglected is extremely important for practical applications. In most frames, the joints are not perfectly rigid but flexible, that is, the ends of the beam column can rotate with regard to the joint. This means that one must introduce an effective rotational spring at each end of the beam-column to take the deformability of the connection into account [5]. One must then distinguish between the rotations of the ends of the beam-column and of the joint, and add to the system of equations of the springs deformation relations involving these rotations.

2. TO ESTABLISH THE GEOMETRIC STIFFNESS MATRIX $[k_\sigma^*]$ AND STIFFNESS MATRIX $[k^*]$ FOR BEAM ELEMENT WITH SEMI-RIGID CONNECTIONS AND RIGID ZONES

To incorporate the connection rigidity into the member stiffness, it is a common practice to model the semi-rigid connection as massless and zero length rotational spring. Although semi-rigid connections exhibit nonlinear response characteristics throughout their whole loading history, it is generally accepted that under service loading conditions the semi-rigid connections can be assumed to behave linearly [4].

Structural model of beam with semi-rigid connections, Fig. 1, beam with semi-rigid connections and rigid-zones, Fig. 2. Where:$\{X\}$ vector of nodal point displacements of beam with semi-rigid connections;$\{F\}$vector of nodal point forces of beam with semi-rigid connections; e_1, e_2 length of rigid-zones (rigid offset) of connections; $\{X^*\}$ vector of nodal point displacements of beam with semi-rigid connections and rigid-zones ;$\{F^*\}$ vector of nodal point forces of beam with semi-rigid connections and rigid-zones ; k_1; k_2 rotation spring stiffness of connections;

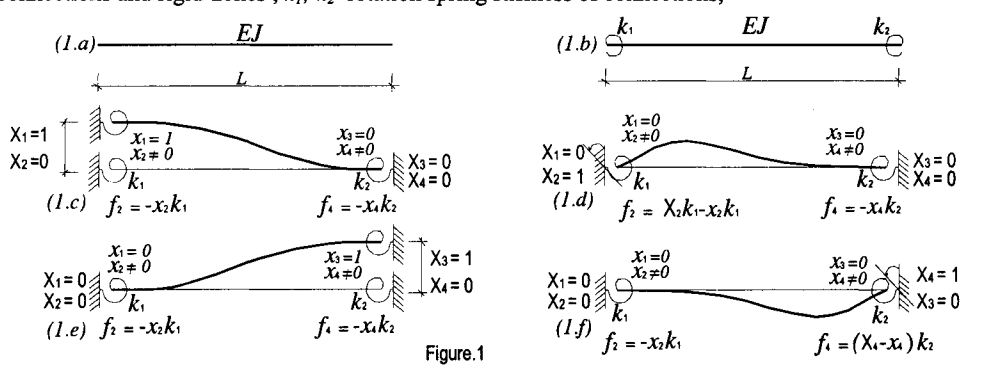

Figure.1

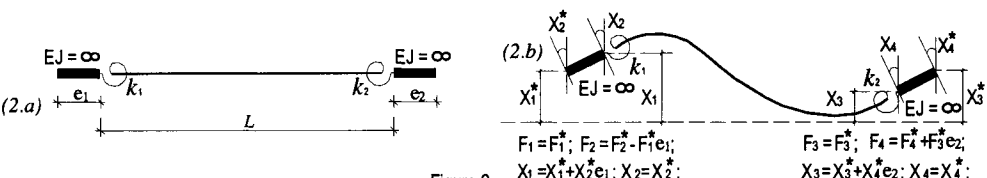

Figure.2

For a single element with semi-rigid connections and rigid-zones, the work balance with consideration of P-delta effect becomes

$$\int_{e}\{\delta\varepsilon\}^{T}[E]\{\varepsilon\}dV+\{\delta u_{k}\}^{T}[k_{k}]\{u_{k}\}+\int_{e}\{\delta u^{\cdot}\}^{T}[S]\{u^{\cdot}\}dV=\int_{e}\{\delta u\}^{T}\{q\}dV \tag{3.1}$$

Where $\{\delta u\}$ and $\{\delta\varepsilon\}$ are respectively small arbitrary displacements and their corresponding strains, [E] is the material property matrix, $[k_k]$ is the stiffness matrix of the springs, $\{\delta u_k\}^T$ are the small displacement of the springs, $\{q\}$ are body forces, and volume integration is carried out over the element volume V_e.

Using usual notation, we have for displacement field $\{u\}$ (which is a function of both space and time)

$$\{u\}=[N]\{x\};\qquad \{x\}=[T]\{X\};\qquad \{X\}=[e]\{X^{*}\};$$

$$\{u\}=[N][T][e]\{X^{*}\};\quad \{u^{\cdot}\}=[G]\{x\}=[G][T][e]\{X^{*}\};\quad \{u_{k}\}=\begin{bmatrix}x_{1}^{k} & x_{2}^{k} & x_{3}^{k} & x_{4}^{k}\end{bmatrix}^{T}; \tag{3.2}$$

$$\{\varepsilon\}=[B]\{x\}$$

$$\{\delta u_{k}\}^{T}[k_{k}]\{u_{k}\}=\delta x_{2}^{k}.k_{1}.x_{2}^{k}+\delta x_{4}^{k}.k_{2}.x_{4}^{k}=\begin{bmatrix}\delta x_{1}^{k} & \delta x_{2}^{k} & \delta x_{3}^{k} & \delta x_{4}^{k}\end{bmatrix}\cdot\begin{bmatrix}0 & 0 & 0 & 0\\ 0 & k_{1} & 0 & 0\\ 0 & 0 & 0 & 0\\ 0 & 0 & 0 & k_{2}\end{bmatrix}\begin{bmatrix}x_{1}^{k}\\ x_{2}^{k}\\ x_{3}^{k}\\ x_{4}^{k}\end{bmatrix}$$

$$\{u_{k}\}=\{X\}-\{x\}=\{X\}-[T]\{X\}=([I]-[T])\{X\}=([I]-[T])[e]\{X^{*}\} \tag{3.3}$$

$$\begin{aligned}&[k]\cdot\{x\}_{1}=[k_{k}]\cdot[\{X\}_{1}-\{x\}_{1}];\quad [k]\cdot\{x\}_{2}=[k_{k}]\cdot[\{X\}_{2}-\{x\}_{2}]\\ &[k]\cdot\{x\}_{3}=[k_{k}]\cdot[\{X\}_{3}-\{x\}_{3}];\quad [k]\cdot\{x\}_{4}=[k_{k}]\cdot[\{X\}_{4}-\{x\}_{4}]\end{aligned} \tag{3.4}$$

In general we have :

$$[k]\cdot\sum_{i=1}^{4}\{x\}_{i}=[k_{k}]\cdot\sum_{i=1}^{4}[\{X\}_{i}-\{x\}_{i}] \tag{3.5}$$

Where:

$$\{x\}_{i}=[T]\cdot\{X\}_{i}\Rightarrow\sum_{i=1}^{4}\{x\}_{i}=[T]\cdot\sum_{i=1}^{4}\{X\}_{i}=[T]\cdot[1\quad 1\quad 1\quad 1]^{T} \tag{3.6}$$

$$[k]\cdot[T]\cdot[1\quad 1\quad 1\quad 1]^{T}=[k_{k}]\cdot[1\quad 1\quad 1\quad 1]^{T}-[k_{k}]\cdot[T]\cdot[1\quad 1\quad 1\quad 1]^{T} \tag{3.7}$$

$$[k]\cdot[T]=[k_{k}]\cdot([I]-[T])\Rightarrow[k_{k}]=[k]\cdot[T]\cdot([I]-[T])^{-1} \tag{3.8}$$

In Eqs. (3.2), shape functions [N] are functions of space [2], [T] and [e] are transformation matrices (see [1]). Thus Eqs. (3.2) represent a local separation of variables. Combination of Eqs. (3.1) and (3.2) yields

$$\begin{aligned}&\{\delta X^{*}\}^{T}[\int_{e}[e]^{T}[T]^{T}[B]^{T}[E][B][T][e]\{X^{*}\}dV+[e]^{T}([I]-[T])^{T}[k_{k}]([I]-[T])[e]\{X^{*}\}+\\ &\int_{Ve}[e]^{T}[T]^{T}[G]^{T}[S][G][T][e]\{X^{*}\}dV]=\{\delta X^{*}\}^{T}[\int_{e}[e]^{T}[T]^{T}[N]^{T}\{q\}dV]\end{aligned} \tag{3.9}$$

Since $\{\delta X^*\}$ is arbitrary, Eq (3.3) can be written as:

$$[k^*]\{X^*\}+[k_\sigma^*]\{X^*\}=([k^*]+[k_\sigma^*])\{X^*\}=\{F^*\} \tag{3.10}$$

Where $[k^*],[k_\sigma^*]$ are the stiffness matrix, geometric stiffness matrix of the element with semi-rigid connections and rigid-zones; $\{F^*\}$ are external load vectors; $\{X^*\}$ is the displacement vector of the element with semi-rigid connections and rigid-zones;

The stiffness matrix, geometric stiffness matrix and external load vectors of the beam element with semi-rigid connections and rigid-zones are defined as:

$$\begin{aligned}
[k^*] &= \int_{Ve}[e]^T[T]^T[B]^T[E][B][T][e]dV+[e]^T([I]-[T])^T[k_k]([I]-[T])[e] \\
&=[e]^T[T]^T[\int_{Ve}[B]^T[E][B]dV][T][e]+[e]^T([I]-[T])^T[k_k]([I]-[T])[e]= \\
&[e]^T([T]^T[k][T]+([I]-[T])^T[k_k]([I]-[T]))[e]= \\
&=[e]^T([T]^T[k][T]+([I]-[T])^T[k][T][I]-[T])^{-1}([I]-[T]))[e]=[e]^T[k][T][e]
\end{aligned} \tag{3.11}$$

$$\begin{aligned}
[k_\sigma^*] &= \int_{Ve}[e]^T[T]^T[G]^T[S][G][T][e]dV=[e]^T[T]^T[\int_{Ve}[G]^T[S][G]dV][T][e] \\
&=[e]^T[T]^T[k_\sigma][T][e]
\end{aligned} \tag{3.12}$$

$$\{F^*\}=[e]^T[T]^T\{f\};\ \text{Where [2]}\ \{f\}=\int_{Ve}[N]^T\{q\}dV \tag{3.13}$$

3. COMPUTATIONAL ALGORITHM FOR A PROBLEM HAVING GEOMETRIC NONLINEARITY

The structure is divided into finite elements in the usual way. We can begin with zero initial displacements, $\{X^*\}_0=\{0\}$, or with a better estimate for $\{X^*\}_0$ if one is available. The load $\{F^*\}$ is applied and the corresponding $\{X^*\}$ is sought by iteration as follows. Computational details are explained subsequently [2].

1. Form the tangent-stiffness matrix $[K^*_t]$ of the structure in the current configuration $\{X^*\}_t$ (which is $\{X^*\}_0$ initially, $\{X^*\}_1$ after the first computational cycle, etc.).
2. Use displacements $\{X^*\}_t$ to form resisting loads $\{F^*_R\}_t$, which are loads applied to structure nodes by the deformed elements. (In the first computational cycle, these loads are zero if $\{X^*\}_0=\{0\}$.)
3. Solve for displacement increments $\{\Delta X^*\}_{t+1}$ and update the configuration to $\{X^*\}_{t+1}$

$$\{X^*\}_{t+1}=\{X^*\}_{t+1}+\{\Delta X^*\}_{t+1}\ \text{ where }\ \{\Delta X\}_{t+1}=[K^*_t]^{-1}(\{F^*\}+\{F^*_R\}_t)$$

Net loads $\{F^*\}+\{F^*_R\}_t$ are an imbalance between externally applied and internally generated nodal loads. The load imbalance drives the structure toward a configuration that reduces the imbalance. In an equilibrium configuration, the imbalance is zero.

4. Check for convergence; for example, see if $\|\Delta X^*_{i+1}\|<e\|X^*_{i+1}\|$, where e is a small number chosen by the analyst. If not converged, return to step 1.

5. NUMERICAL EXAMPLE TO VERIFY

A two-story, three bay frame is analyzed with rigid and semi-rigid connections, and with and without geometric nonlinearity. Fig 3 shows the frames configuration (I_{beam} = 8356 cm^4, I_{column} = 5696cm^4, E = 210+E6), dimensions, loading and numbering of members and joints. And instead of the spring stiffness the joint stiffness ration α= k/i_x is used; k spring stiffness (kNm/rad).The results of the analysis are presented in table 1 and 2. This example is taken in order to demonstrate the validity of the program written by Pascal language following the $[k_\sigma^*]$ and $[k^*]$ created in part 2. It also shows the effects of connection flexibility and geometric nonlinearity on displacements and moments.

Connection flexibility effects both force distribution and deformation in beams and columns of the frame, and must be accounted for in a structural analysis. This can be done by conducting a second-order analysis of the frame, one that addresses both geometric nonlinearity and connection flexibility. The softening of the connections results in the large increase in the building drift.

6. SUMMARY AND CONCLUSIONS

The linear elastic analysis assumes that the deformations are relatively small, and the equilibrium equations can be formulated with respect to initial geometry. When increasing applied loads cause

significant changes in the structure's geometry, the equilibrium and compatibility equations are nonlinear and the resulting stiffness matrix contains terms that are functions of axial forces and deformations. The stiffness matrix to represent this behavior must include the effect of geometric nonlinearity. In addition, for members with flexible connections at the ends, the stiffness matrix must be modified to account for the effect of connection flexibility.

The first-and second-order stiffness matrices of beam column of double symmetrical cross section with semi-rigid connections and rigid zones are derived in classical manner. The derived matrices can be used in the stability, first- and second-order elastic analysis of steel frames with semi-rigid connections and rigid zones.

Connection flexibility and geometric nonlinearity influence the distribution of forces in the structure. Both effects contribute to a significant increase in the drift of the frame. The semi-rigid connections cause a shift in moments from the beam ends to the span; and as a result, the overall maximum moments decrease in beams. The connections may be used to balance positive and negative moments in beams to effect economic designs.

ABSTRACT

In Australia, post-tensioned concrete floor systems are now the preferred type of construction for many large buildings, for reasons of economy and superior performance. The authors review relevant current Australian code requirements, design methods and construction practices and illustrate some typical design details for post-tensioned floors. After considering anticipated building trends in Australia, the authors conclude that the use of post-tensioned concrete floor systems will continue to increase.

KEYWORDS

Post-tensioned concrete, Performance based design, Partially prestressed, Load balancing, Bonded tendons, Internal stressing pockets.

INTRODUCTION

In Australia, since the mid nineteen eighties, post-tensioned concrete floor systems have become the preferred type of construction for many large buildings, including high-rise residential and office buildings, hotels, car parks, shopping centres and warehouses. This increase in popularity of post-tensioned floors has come about because, compared with more traditional reinforced concrete and structural steel floor systems, they offer advantages of:

Economy: The higher initial costs of the post-tensioning steel are more than off-set by cost savings arising from reduced floor thicknesses (which save materials and space and reduce column and footing loads), faster construction cycles, and lower on-going maintenance costs.

Performance: Post-tensioned floors are reliable and safe and provide excellent control of concrete cracks and deflections. They also have superior performance under heavy wheel and racking loads, such as occur in warehouses. At the time of transfer of full prestress loads to a floor, it is subjected to the highest loads it is likely to encounter and has virtually been 'proof loaded".

Design Flexibility: Post-tensioned floors permit buildings to be designed with large column free and wall free open spaces. Building services are not restricted in location by large beams intruding into ceiling spaces. There is considerable design flexibility in positioning openings and ducts.

Ease of Analysis: Another important factor which has increased the popularity of post-tensioned concrete is the ready availability of commercial software design computer programs (e.g RAPT: Reinforced and Post-Tensioned Concrete Design, introduced in Australia in 1987). Before such programs came onto the market, design methods were tedious, and largely the province of specialist prestressing firms.

AUSTRALIAN CODES FOR POST-TENSIONED CONCRETE

In Australia, all concrete structures, whether unreinforced, reinforced or prestressed, are covered by a single standard, AS 3600: Concrete Structures (2001), which contains design and detailing rules and performance criteria. The current third edition of AS3600 was issued in May 2001, to incorporate some amendments and rule changes, pending a major review of the code, now underway.

The code is supplemented by a commentary, AS3600.1 (1994), which explains the intent of the major elements of the code. AS 3600 also references about thirty other related Australian codes covering areas such as requirements for materials, material testing, admixtures, formwork, and loads on structures.

AS 3600 replaced earlier separate codes for prestressed and reinforced concrete and moved substantially from "prescriptive" to "performance" based design, in which designers have increased freedom to select design parameters. Whilst experienced designers can use this freedom to produce more efficient and economical design solutions, there is some potential for designers without experience in prestressed concrete to make serious mistakes, particularly if they do not understand some of the limitations of the computer design packages now widely available.

Australian code requirements for post-tensioned concrete floors are discussed where relevant in following sections of the paper.

AUSTRALIAN DESIGN METHODS FOR POST-TENSIONED FLOORS

Post-tensioned floors are invariably designed with bonded (grouted) tendons, since AS 3600 prohibits the use of unbonded tendons except for slab-on-ground construction.

AS 3600 permits a range of structural analysis methods for slabs. These include the use of moment coefficients, design strips, idealised frames, linear elastic analysis, and plastic analysis using lower bound and yield line methods. For post-tensioned concrete slabs, designers normally use computer programs, with increasing use of finite element analysis in place of methods based on design strips and idealised frames.

Partially prestressed design of slabs (in which some concrete tension is permitted) is normal, using load balancing techniques to control deflections and the levels of prestress for economical design solutions. Post-tensioned tendons are used to provide for overall load capacity. Reinforcing is added in combination with tendons to provide ultimate strength capacity and crack control. This approach

is found to provide more economical floors than fully prestressed designs, (where concrete tension under working loads is eliminated).

Shear stresses in post-tensioned slabs are analysed by using truss analogy models, as in many other countries. AS 3600 has more liberal shear reinforcing requirements that some overseas codes. Shear reinforcing is rarely needed for band-beam structures, except to resist shear due to specific severe loads. In practice, some shear reinforcing is normally placed adjacent to columns, whether needed or not.

Slab movements under prestressing forces are accommodated by careful detailing around stiff elements, such as lift and stair cores, to prevent cracking. Movement joints are usually provided at 30 to 35 metre centres.

DEFLECTION CRITERIA

Deflections usually govern the design of post-tensioned concrete floor slabs. Deflection criteria need to be chosen carefully and with due regard to the use of the structure, since they have considerable effect on the economy of the design.

Load balancing techniques are used for design, to keep deflections within specified limits under dead loads and some part of the live load. The portion of full live load depends on the type of structure and its occupancy.

AS 3600 limits calculated long-term and incremental deflections for beams and slabs under the design loads for serviceability to span/250 generally, and to span/500 for members supporting masonry partitions, where provision is made to minimise the effects of movement, or to span/1000 otherwise. There is a trend to adopt these stricter limits for other situations, particularly residential apartments, where occupants of expensive apartments expect very high performance standards and are alarmed by noticeable deflections in tiled floors, by vibrations and by any cracking of brittle wall and ceiling materials.

AS 3600 requires the effects of vibrations on concrete structures and elements to be considered. Except where there are known sources of vibrations, control is normally achieved by limiting ratios of span/overall depth for post-tensioned slabs to less than 40, and for beams to less than 30. Specific vibration problems may require dynamic analysis of the structure, normally accomplished by using proprietary computer programs.

AUSTRALIAN CONSTRUCTION PRACTICES FOR POST-TENSIONED CONCRETE FLOORS

In Australia, many high rise buildings are erected without external scaffolding. In these situations, Occupational Health and Safety Regulations require post-tensioning to be carried out from inside the buildings. To accommodate this, slabs and beams are designed to incorporate internal prestressing pockets, as shown in Figures 1 and 2.

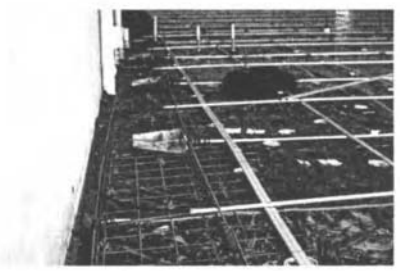

Figure 1: Prestressing Pockets in place

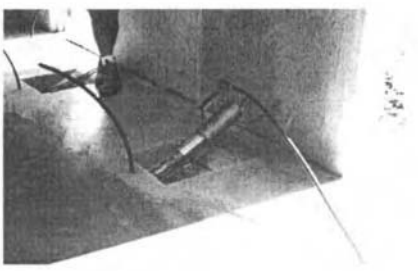

Figure 2: Internal Stressing Pocket

Typical construction cycles for high rise post-tensioned floors, from pouring to stripping of formwork, are five to six days. Typically, floor designs are based on 32 MPa compressive strength concrete. Twenty four hours after a post-tensioned floor is cast, it is usual to apply 25% of the prestressing forces to mitigate against shrinkage cracking. The remaining prestress is applied when the concrete achieves a compressive strength of 22.5 MPa, generally four to five days after pouring. Full prestress can be applied in as little as two to three days with special mix designs and the use of additives. For tall multi-storey buildings, this can reduce construction times by several months, with substantial costs savings when compared with reinforced concrete systems.

Formwork can be stripped immediately after full prestress is applied. Back propping may be required to support the weight of wet concrete from the next floor to be poured. Installation of services can commence as soon as formwork is removed.

For slabs "onion" type anchorages are preferred to swaged end anchors and end plates, for reasons of cost and ease of placement. However, onion anchorages have more potential to fail by pulling through the concrete, so need to be properly detailed and installed to separate individual strands and to ensure concrete can be easily placed and properly vibrated in the region of the anchors. Anti-burst reinforcement is provided at the live and dead end anchorages by helical ligatures around the anchors or by other reinforcing systems. Swaged end plates are preferred for beams, because of the concentration of strands in a small area. Typical end anchorage details are shown in Figures 3, 4 and 5.

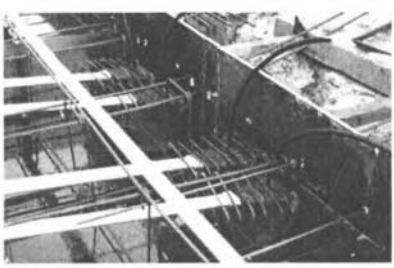

Figure 3: End Anchors with helical anti-burst reinforcement

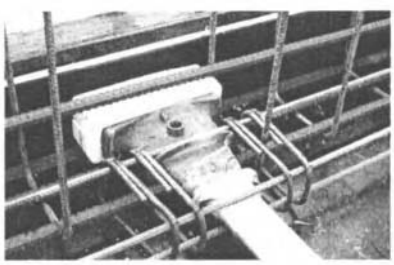

Figure 4: End anchor with anti-burst reinforcing

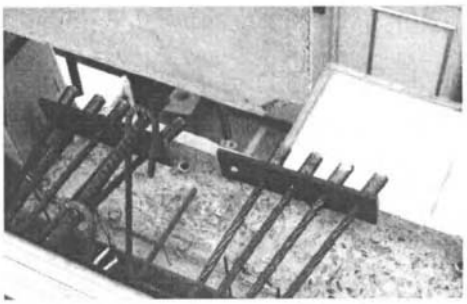

Figure 5: Swaged end anchors with end plates

Some typical details of suspended slabs follow. For a 200 mm thick slab, the main prestressing tendons are spaced at 1500 mm centres. Low levels of transverse prestress, from 0.7 MPa to 2.5 MPa, are applied by transverse cables spaced at 2.5 to 3 metres, to control concrete cracking. Prestressing tendons consist of stress-relieved bundled wire strands, with typical overall diameters of 12.7 mm and 15.2 mm, and ultimate tensile strengths (UTS) of 1840 MPa and 1750 MPa respectively. The tendons are stressed up to a maximum of 85% of their UTS. Tendons are stressed using hand-held hydraulic jacks and each strand is stressed individually.

Mutli-strand ducts are typically 19mm deep by 200 mm wide for four strand applications and 250 mm wide for five strands. Prefabricated cast-steel live anchors are available in sizes to match the ducts. Multi-strand circular ducts are not commonly used in Australia, except where very high prestressing forces are required in large transfer beams support podiums etc.

LONG SPAN POST-TENSIONED FLOORS

Post-tensioned concrete floor systems become increasingly more economical than other floor systems for spans from 8 metres to 12 metres, although they can be used for spans down to about 5 metres for small areas which do not justify any change in the reinforcement systems. For spans of 8 metres and above, the savings in floor thickness can be used to reduce building heights or provide extra space, even extra floors, within the building envelope. For typical post-tensioned suspended floors of spans from 8 to 12 metres, slab thicknesses for residential buildings range from 180 mm to 250 mm.

ONE AND TWO-WAY BANDED FLOOR SYSTEMS

One-way banded floor systems are widely used in Australia for commercial and retail buildings and offices. The building layout may dictate the choice of one or two-way action, but two-way post tensioned floor systems are much less common because of construction difficulties arising from clashes between crossing tendons running in different directions. Post-tensioning permits good control of deflections for band beams (strong bands of tendons), which are typically 2.4 metres wide to suit the available lengths of plywood sheets used for formwork.

Reinforced concrete slabs are used between post-tensioned band beams, for infill spans up to about 6 metres, because required reinforcement levels are low and the high costs of prestressing cannot be justified for such short spans. "Bondek" steel formwork, which remains in place and forms part of the slab reinforcement, can also be used when formwork costs are prohibitive.

In Melbourne, particularly for residential apartments, it is usual to construct single thickness floors, with the "strong bands" of tendons accommodated within the overall slab depth. Formwork is simple and service pipes, ducts, etc, can be installed without being restricted by the structure.

Designers usually avoid steps to balconies, because of difficulties in profiling and placement of tendons. An upstand concrete hob at the junction of the main slab and the balcony is provided for ease of weather proofing

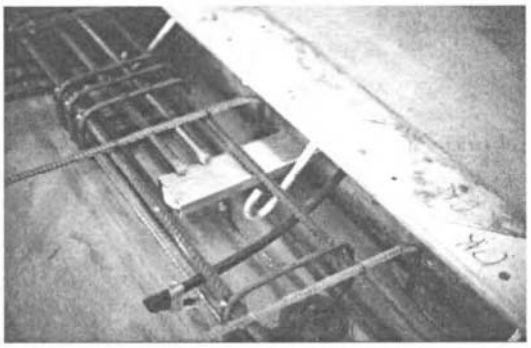
POST-TENSIONED CAR PARK STRUCTURES

Nearly all recent Melbourne multi-storey car parks have used post-tensioned concrete floors for reasons of economy, since they permit large column-free spans which suit typical car parking layouts. There is a move from enclosed to open deck car parks because the fire restrictions are less onerous for the latter.

Typically, car bays are 2.4 to 2.6 metres wide. Band beams are at 8.5 metre centres and span 10 metres or more, with cantilever overhangs of up to 2.5 metres. Slab thicknesses are 160 to 180 mm and beams are 250 to 400 mm (10m span). Design live loads are 3 kPa.

SLAB-ON-GROUND CONSTRUCTION

Post-tensioned slabs-on-ground have proven to be very effective for heavily loaded industrial floors of large dimensions and with large pour areas. Cracks can be controlled and construction joints can be eliminated or reduced, avoiding the effects of impact wheel loads at joints and reducing long-term maintenance. Reinforced slabs typically have joints at 5 to 6 metre spacings in both directions, whereas post-tensioned slabs are poured in bays of 35 metres square, or even larger, without joints.



Tendons are not required to be bonded. Large slabs are usually analysed using commercial computer programs as plates on elastic foundations (eg. on a semi-infinite elastic half space). Since it is notoriously difficult to quantify the elastic properties of subgrades, sensitivity analysis is carried out by increasing and reducing soil parameters by a factor of 10.

Slab-on-ground thicknesses are typically 125 mm up to 250 mm. A recent Melbourne example is a wharf container terminal, with wheel loads from a 35 tonne forklift carrying a 20 tonne container and with containers stacked four high over large areas.

For large areas which require multiple pours, both movement and construction joints must be carefully detailed. Slabs rest on double membranes or single membranes on sand, to reduce subgrade drag and to permit shortening under prestressing with minimum prestressing losses. A typical movement joint is shown in Figure 6.

Most floors are poured inside already erected precast wall panels and, for aesthetic reasons, it is usual to have a 1.2 metre wide pour-strip at each end of the slab to accommodate stressing anchors,

rather than using stressing pockets and to avoid having to cut off exposed grout tubes. The pour-strips are eventually filled with reinforced concrete.

CONCLUSION

In Australia's largest cities there is ongoing movement of residents back to the city centres. Housing needs are being satisfied by construction of high quality and expensive residential buildings on prime sites. Occupants want large column-free and wall-free spaces, and expect their apartments to be crack free. Commercial properties and warehouses are becoming larger and owners are looking for economic solutions and low ongoing maintenance costs.

Post-tensioned concrete floor systems are safe, reliable and provide economic and performance advantages for many of these buildings. Consequently it is anticipated that the use of such floors will continue to increase in Australia in response to market forces.

HIGH-TECH OR MOCK-TECH : STRUCTURAL RATIONALITY OF THE HIGH-TECH MOVEMENT IN BUILDING

James G A Croll

Chadwick Professor of Civil Engineering,
University College London, London WC1E 6BT

ABSTRACT

With their abundance of glass, exposed, celebrated, and often muscular structural steelwork and building services, many of the motifs of, so-called, high-tech buildings are being adopted by an increasing circle of architects and engineers. The new aesthetic that is being created is often characterised as providing rational structural solutions. This paper examines the validity of this claimed rationality. It develops a simple approach to the assessment of structural performance by considering comparative estimates of primary structural material volumes of alternative structural solutions. Not only does this methodology allow assessment of the rationality of high-tech building, but it also provides a general approach of immense potential benefit in the conceptual design of structures. Its reliance upon straightforward, physically based structural models, and the consideration that it is amenable to simple hand calculation, make this approach a powerful supplement to the increasing dependence upon computer analysis to inform even conceptual design.

KEYWORDS

Architecture, buidings, engineering, function, form, high tech, rationality, structures.

BACKGROUND

Traditional building construction evolved through a process of trial and error to produce building structures that often present a natural harmony of material, structural form, function and aesthetics. The accumulated craft skills that became amortised in, say, the traditional timber-framed temple of China or the masonry Gothic Cathedrals of Europe, provide convincing support to this argument. In their struggle to come to terms with the disharmony resulting from the development and use of the new strong materials at the beginning of the 19th century, both Pugin[1] and Viollet le Duc[2] in their different ways attempted to evolve an aesthetic appropriate to these new materials. Both were witnessing a disjuncture

not only between structure and form but also in the organisation and institutionalisation of the professions that evolved from the previously united craft traditions.

Increasingly, what one was to actually see in a building was not that required to allow it to stand up. Over a period of time structure was to become more and more implicit, often hidden behind façades that expressed the building's aesthetic qualities. Structure became the preserve of a group who formed themselves into the engineering professions, while form and the aesthetic qualities became the domain of the architectural profession. So it has remained for the past 200 years. Indeed, by the late 20th century the increasing use of glass façades meant that even the cladding of many buildings became implicit, with the ultimate absurdity that both structure and form became invisible. In a lecture which alluded to this aesthetic absurdity, Roger Scruton discussed a new glass building development (over what had been the fine Georgian Tolmer Square) just north of Euston Road. In some revealing images he opined that the only redeeming aesthetic qualities of this building were the somewhat distorted reflections from it of the remnants of a Georgian terrace on the south side of Euston Road.

Seen against this background, the high-tech movement can be viewed as an attempt to 'put Humpty Dumpty back together again'. Within the architecture of Rogers, Foster, Hopkins, Grimshaw, and many others, structure was again to become explicit. No longer hidden from view but celebrated in sometimes muscular forms, structure could once again be read as part of the aesthetic of the building. Making use of steel tubes for compression, rods and cables for tension, cable nets, pylons, cable-stays, metallic castings, counterbalanced spans, ... buildings started to look more like the products of bridge engineering. At one level this is surely a healthy return to the traditional harmonies. Structure and form can be interpreted as being once again reunited, helping to create a new aesthetic of buildings. However, if this harmony is to be complete, in the sense laid down by Ruskin[3] or Viollet le Duc[2], the structural systems being adopted would need to represent a rational and "best use" of the materials being adopted.

Amongst the claims made for high-tech buildings (see for example Davies[4]) is the assertion that their structures are rationally based. With the design often involving collaborations between some of the most respected architects and engineers of our age, it might be anticipated that these claims are firmly based. But are they? This paper examines a limited selection of archetypical high-tech buildings from the perspective of whether they do represent a logical and materially efficient integration of structure and form. It extends a methodology used recently by Croll[5] to examine the relative efficiencies of cable-stayed and catenary-type suspension bridges. This methodology will show that serious questions need to be addressed as to whether the high-tech movement really does represent a rational re-harmonisation of material, structure and form within a new aesthetic of building.

METHODOLOGY

To allow assessment of the structural effectiveness, an extension of the method recently used to compare the relative merits of cable-stayed and catenary-type suspension bridges[5] will be adopted. In this earlier study, the primary load paths all involved pure membrane action, either in the form of compression forces, $C_j(x)$, or tension forces, $T_j(x)$, where x is the axial position along member j. Based upon characteristic material strengths, σ_C and σ_T, for respectively compression and tension, the volume of the primary membrane structural elements may be represented as

$$V_C = \sum_j \left[\int \frac{C_j(x)}{\sigma_C} dx \right]$$

$$V_T = \sum_j \left[\int \frac{T_j(x)}{\sigma_T} dx \right] \tag{1}$$

Both (C_j, T_j) are taken to be positive. For the case of the suspension bridge, the primary structural behaviour could be represented by integrations of the type indicated by eqn (1), since bending behaviour is generally of local, secondary importance. However, in most structures a combination of bending and membrane behaviour must be considered.

Where bending is present, it will be assumed that the structural elements take the form of components in which the dominant bending resistance is in flanges. This would be the case where, say, universal beam or column sections, or hollow rectangular sections, are used in steel construction. In these cases, the volume of steel required to resist the bending moments $M(x)$ would be given by

$$V_B = 2 \int \frac{|M(x)|}{\sigma_B d} dx \tag{2}$$

where σ_B is a characteristic bending stress, and d, the effective depth between the flanges. To this must be added the material volume of the web required to resist the shear force, $Q(x)$.

$$V_Q = \int \frac{|Q(x)|}{\tau_Q} dx \tag{3}$$

where τ_Q is the characteristic shear strength of the web. Very similar relationships would apply for the quantities of steel reinforcement in a reinforced concrete beams. The main differences for concrete beams are that the bending steel volume would be half that given in eqn (2), and d would represent the effective depth between the centroids of the tension reinforcement and the concrete compression block. In the following, just buildings constructed from steel structural components will be considered.

To keep the analyses to simple and explicit forms, use will be made of statically admissible distributions of force. From the static theorem of plasticity, this will result in safe estimates of ultimate state behaviour, with the consequence that material volumes will be slight overestimates of those that would be predicted from more precise analyses which also take into account the requirements of strain compatibility. By careful choice of statically admissible force flows through the systems being analysed, primary material volumes should be reliably predicted and certainly should provide a basis for comparing alternative structural systems.

Before looking at the following examples, it is worth noting the close relationship between the assessment of membrane material volumes of eqn (1), and the concepts of 'pertinacity' introduced by Maxwell.[6] In a remarkable contribution, Maxwell showed that the sum of the algebraic pertinacities of the tension and compression members of a membrane frame is dependent only upon the nature of the position and magnitude of the loading that is applied to the frame. Two pertinacities can be defined:

$$\begin{aligned} \text{PER}_C &= -\sum_j \int C_j \, dx = -\sum_j C_j \cdot l_j \\ \text{PER}_T &= +\sum_j \int T_j \, dx = +\sum_j T_j \cdot l_j \end{aligned} \tag{4}$$

where the second equality applies when (C_j, T_j) are constant over the length l_j of the member j. For any two frames, A and B, having load position and magnitude fixed, the algebraic sum of the pertinacities

$$\text{PER} = \text{PER}_T + \text{PER}_C \tag{5}$$

will be found to be the same. This remarkable lemma was used by French[7] to show an error in my contribution in reference (5). For the situation where the characteristic strengths in tension and compression can be taken as equal, the material volumes for the membrane action, as given by eqn (1), can be seen to be proportional to the sum of the absolute values of the pertinacities, so that

$$V = V_T + V_C \propto |PER_T| + |PER_C| \tag{6}$$

I am grateful to Profession French for drawing my attention to this lemma and for the other insights it opens up in the field of optimisation. Its results and implications deserve to be rather better known.

CASE STUDIES OF CABLE-STAYED BUILDINGS

Single Asymmetric Stays

As an example of an archetypical high-tech building, consider a cable-stayed industrial building of the form shown in Figure 1. This structural solution has, for example, been used in the Grimshaw, 1987, Brentford superstore. It embodies many of the motifs of high-tech architecture: pylons supporting cable-stays to the roof that are in turn counterbalanced by tension back-stays. The echoes of bridge engineering are self-evident.

For the statically admissible distribution of local bending in the roof, it is assumed that the moments at quarter-span are equal to the continuity moment at mid-span; this has the effect of keeping bending steel volumes to a minimum by virtue of ensuring a relatively uniform level of $|M|$, as shown in Figure 1(b). A minimum volume of bending steel will result when $\int |M| dx$ is a minimum. This will be closely approximated when the positive and negative levels of moment are roughly equal.

Associated with the above distribution of bending in the roof girder, the membrane force flow is shown in Figure 1(b). For illustration purposes, angles $(\vartheta_1, \vartheta_2)$ and roof height-to-span h_r/l, and girder depth-to-span ratio, d/l, will be used to characterise the cable-stayed roof geometry. Based upon equations (1) – (3), the total primary steel volumes will, where l_j represents the length of member j, be given as

$$V_T = \sum_{j=1}^{3} \frac{T_j l_j}{\sigma_T} = \frac{ql^2}{\sigma_T}\left[\frac{7}{12}\left(\frac{1}{\sin 2\vartheta_1} + \frac{1}{\sin 2\vartheta_2} + \frac{\tan\vartheta_2}{\tan\vartheta_1}\cdot\frac{h_r}{l}\right)\right]$$

$$V_C = \sum_{j=4}^{7} \frac{C_j l_j}{\sigma_C} = \frac{ql^2}{\sigma_C}\left[\frac{7}{12}\left(\frac{1}{\sin 2\theta_1} + \frac{1}{\sin 2\theta_2} + \frac{\tan\theta_2}{\tan\theta_1}\cdot\frac{h_r}{l}\right) + \frac{h_r}{l}\right]$$

$$V_B = \int \frac{|M|}{\sigma_b d} dx = \frac{23}{18\times 48}\cdot\frac{ql^3}{\sigma_b d}$$

$$V_Q = \int \frac{|Q|}{\tau_Q} dx \approx \frac{ql^2}{8\tau_q} \tag{7}$$

which for the case of w/l = 0.125, $h_r / l = 0.2$, $\sigma_T/\sigma_B = 1.1$, $\sigma_T/\sigma_C = 1.2$, $\sigma_T/\sigma_Q = 1.6$ and $\vartheta_1 = 25^o$ (that corresponds with the minimum total primary steel), the steel volume is given by

$$V_{\text{single stay}} = \alpha[4.640 + 0.0293\, l/d] \tag{8}$$

This may be contrasted with the primary steel required for a more conventional portal frame, shown in Figure 2. To eliminate any uncertainty in total cost that would arise from the provision of foundations having horizontal shear capacity, it has been assumed that a steel tension tie proves the horizontal thrust at the base of the columns. For the purposes of producing a reasonably optimised bending moment distribution in the portal frame, the statically admissible moment distribution has again been taken to

have equal positive and negative moments; the moment and shear force take the form shown in Figure 2(b). For this frame, the various components of primary steel volume are

$$V_T = \frac{T_j l_j}{\sigma_T} = \alpha \left[\frac{1}{16} \cdot \frac{l}{h_r} \right]$$

$$V_C = \sum_{j=2}^{3} \frac{C_j l_j}{\sigma_C} = \alpha \left[\frac{1}{16} \cdot \frac{l}{h_r} + \frac{h_r}{l} \right] \left(\frac{\sigma_T}{\sigma_C} \right)$$

$$V_M = \int \frac{|M|}{\sigma_b d} dx = \alpha \left[0.0771 \frac{l}{d} + 0.125 \frac{l}{d} \cdot \frac{h_r}{l} \right] \left(\frac{\sigma_T}{\sigma_b} \right)$$

$$V_Q = \int \frac{|Q|}{\tau_Q} dx = \alpha \left[0.375 \right] \left(\frac{\sigma_T}{\tau_Q} \right) \tag{9}$$

which, for the same geometric and material properties as were used for the example of Figure 1, gives a total primary steel volume of

$$V_{\text{portal}} = \alpha \left[1.528 + 0.1123 \frac{l}{d} \right] \tag{10}$$

As a function of the span-to-depth ratio, Figure 3 shows that over almost the entire range of practical *l/d* ratios the standard portal frame requires considerably less total primary structural steel than does the cable-stay roof system. At *l/d* = 20, the cable-stayed roof system can be seen to involve 25% more primary steel for the super-structure than the equivalent portal frame. When the foundations are taken into account, the situation becomes considerably worse for the cable-stayed roof.

Whereas the portal frame requires foundations capable of generating just *ql* of vertical compression, the cable-stayed solution requires a compression foundation totalling *3.334ql*; that is, the compression foundation needs to be 233% larger than that for the conventional portal frame. If this foundation disadvantage of the cable-stayed roof system were not enough, it is important to remember that it is also required to develop a tension foundation having capacity of *2.334ql*, some 133% more than the compression capacity required of the foundations for the equivalent portal frame. Allowing for the increased cost of providing tension as compared with compression foundations, it is clear that the foundation costs of the cable-stayed solution will be considerably greater than that for the more conventional portal frame. If for example it is assumed that tension foundation is, force for force, say three times the cost of compression foundation, then the total foundation cost for the cable-stayed frame of Figure 1(a) would be around ten times higher than the equivalent portal frame.

Double Symmetric Stays

An even more common solution for the cable-stayed building is shown in Figure 4. Such a topology has been used by, among others, Rogers, 1979, in a laboratory building in Cambridge and Grimshaw, 1984, in the Oxford ice rink (both cited in Reference (4)). In this case the primary steel volumes are given by

$$V_T = \sum_{j=1}^{3} \frac{T_j l_j}{\sigma_T} = \frac{ql^2}{\sigma_T} \left[0.467 \left(\frac{1}{\sin 2\vartheta_1} + \frac{1}{\sin \vartheta_2} + 1.577 \frac{\tan \vartheta_2}{\tan \vartheta_1} \cdot \frac{h_r}{l} \right) \right]$$

$$V_C = \sum_{i=4}^{7} \frac{C_i l_i}{\sigma_C} = \frac{ql^2}{\sigma_C} \left[0.467 \left(\frac{1}{\sin 2\theta_1} + \frac{1}{\sin 2\theta_2} + 1.577 \frac{\tan \theta_2}{\tan \theta_1} \cdot \frac{h_r}{l} \right) + \frac{h_r}{l} \right]$$

$$V_B = \int \frac{|M|}{\sigma_b d} dx = 0.01032 \cdot \frac{ql^3}{\sigma_b d}$$

$$V_Q = \int \frac{|Q|}{\tau_Q} dx \approx 0.196 . \frac{ql^2}{\tau_q} \tag{11}$$

Support cables have been positioned to provide the optimum distribution of bending moment in the roof girder. This is shown in Figure 4(b) to involve a statically admissible moment distribution having equality of sagging and hogging moments. In this case the total primary steel for the same geometric and material properties as the above examples, with the exception that $\theta_l = 30^o$ is chosen to produce the least steel volume, will be

$$V_{double\ stay} = \alpha \left(3.663 + 0.0114 \frac{l}{d} \right) \tag{12}$$

Although providing a somewhat better super-structural material volume than the single asymmetric cable-stay of eqn (8), it is clear from Figure 3 that this solution is also considerably less efficient than the conventional portal frame, for the same overall scantlings, over a wide range of girder depth to span ratios, *d/l*. With the foundations being required to carry *3.972ql* of compression and *2.972ql* of tension the disadvantages from the additional costs for foundations are however, even more extreme than those for the single asymmetric cable-stay.

To overcome this excessive additional foundation disadvantage in the use of cable-stayed roof systems, a solution along the lines of Figure 5 has sometimes been adopted. This form has been used in for example Ahrends' 1984 supermarket in Canterbury (cited in Davies[4]) and Croydon railway station. However, this solution to the foundation problems can only be adopted for the case of the double symmetric cable-stays. Avoiding the need for tension piling by connecting the lower back-stay to the foot of the pylon has the effect of increasing forces T_3, C_5, and increasing the lengths over which they act. It also requires the development of horizontal foundation forces at the bottoms of the pylons, which, to keep comparisons on the same basis, are assumed to be developed with a self-equilibrating tie connecting the pylons at foundation level. For interest, a symmetric cable-stayed system as shown in Figure 5 would, for the same material and geometric parameters as above, and again with $\theta_l = 30^o$, require a total primary super-structural material volume given by

$$V_{double\ stay} = \alpha \left(5.229 + 0.0114 \frac{l}{d} \right) \tag{13}$$

This can be seen in Figure 3 to compare even less favourably with the equivalent portal frame. However, this solution does have the distinct advantage over the single asymmetric cable-stay of Figure 1 or the double symmetric cable-stay of Figure 4, of requiring a foundation delivering just *ql* of compression, identical with that of the portal frame. A symmetrically placed pair of cable-stays, as shown in Figure5, also has the advantage of offering bracing resistance to horizontal load, whereas those of Figure 1 and 4 would require additional bracing.

Single Symmetric Stays

Another class of cable-stayed sheds is worthy of consideration. When in the form shown in Figure 6, the double-span cable-stay system will require a primary material volume

$$V_{\text{cable-stay}} = \alpha \left(3.340 + 0.0487 \frac{l}{d} \right) \tag{14}$$

while in this case an equivalent double-span portal frame of Figure 7 requires

$$V_{\text{portal}} = \alpha\left(2.855 + 0.1971\frac{l}{d}\right) \tag{15}$$

Given that both of these cases will require foundations having $2ql$ worth of compression capacity and recalling that neither requires either tension or horizontal shear capacity in the foundations, it is clear from the comparison shown in Figure 8 that at practical levels of l/d, the balanced cable-stay has considerable material advantage over the equivalently dimensioned portal frame. It most certainly has considerable structural rationale as compared with the situations where the back stays are not themselves being used to support primary structure, such as the examples of Figures 1, 4 and 5 discussed above. This might be anticipated, given that situations like that shown in Figure 6 are close to the structures often used for major bridge crossings. In contrast with many later adaptations, some of the first high-tech uses of cable-stayed buildings (see for example Rogers 1982 factory in Newport, Wales, or his 1984 laboratory in Princeton, USA, both cited in Reference (4)) were of this single symmetric form. In a slightly modified form involving two cable-stays per span, Grimshaw, 1988, also adopted this form for the leisure centre at Stockbridge.

CABLE-STAYED BRIDGES

These latter single symmetric cable-stayed buildings are very similar to the geometries adopted for cable-stayed bridges. In an earlier article, together with its subsequent discussion, the the cable stayed bridge of form similar to that shown in Figure 9 has over wide parametric ranges been shown (see Reference (5)) to have considerable material advantage as compared with the usual parabolic cable suspension bridge. However, in both the parabolic and cable-stay suspension bridges treated in Reference (5), it was necessary to provide end anchorages that were capable of developing horizontal thrusts of $ql^2/2h_t$. This allowed valid comparisons in situations where the parabolic cable suspension bridge is necessarily required to develop such an end anchorage force. However, if all of the horizontal thrust from the inclined cables of the cable-stayed system, shown in Figure 9, is carried by self-equilibrating compression forces in the deck, then the primary steel volumes (where material below roof level is neglected, since this is common for all systems of this class) can be shown to be

$$V_{\text{stay}} = \frac{2\alpha}{\sin 2\theta}(1+\beta) \tag{16}$$

where $\beta = \sigma_T / \sigma_C$. Equation (16) displays a minimum when $\vartheta = 45°$. It is interesting to compare this with the Michell minimum weight structure, shown in Figure 10. Strictly, this Michell structure would apply only when $\beta = 1$, but with a little licence it can be shown that the optimum Michell truss has a material volume

$$V_{\text{Michell}} = \frac{\pi\alpha}{2}(1+\beta) \tag{17}$$

Compared with the optimum structure, the least weight cable-stay system of Figure 9 can be seen to have 27.3% more material. Allowing for the $2ql$ compression load to be taken over the roof height $0.2l$, assumed for the examples of Figures 1 – 7, and using $\beta = 1.2$, the volumes of materials required for the various two-span systems are

$$V_{\text{stay (minimum)}} = 4.88\alpha$$
$$V_{\text{Michell}} = 3.94\alpha \tag{18}$$

Including these in Figure 8, it can be seen that both the above pure membrane optima can, over certain (admittedly impractical geometries) ranges of l/d, involve greater primary material volumes than the more conventional portal frame and the single cable-stay solution. An explanation for this is that even

for relatively inefficient bending action, if the load path is short it may be more economic to resist the load through bending than to provide a greatly extended membrane load path.

DISCUSSION AND CONCLUSIONS

The question of what constitutes an optimum structural solution, when both bending and membrane primary load resistance are present, is clearly not straightforward. Even for the simple classes of single-span and double-span cable-stayed roofs, the results can be surprising. What is not surprising is the extreme inefficiency of using pylons that do not derive their stability from a functional and symmetrically supported roof. This was the case for the examples treated in Figures 1 and 4. For these cases it is not just the considerable additional super-structural primary structural material that is needed, but crucially, the considerably increased costs of foundations.

There are many structures that adopt similar principles to those considered in Figure 1 and 4. The Hong Kong and Shanghai Bank in Hong Kong, the Centre Pompidou building in Paris, and, closer to my own home, the Camden Town Sainsbury's building in London, all involve very similar structural actions. Space does not permit a full analysis of the structural rationale of these systems. Nevertheless, it is clear, even from the above, that many systems being adopted within the high-tech building movement use structural forms that involve very inefficient use of primary structural material. At the very least this raises interesting questions as to whether the claims often made for the structural solutions for high-tech buildings are entirely rational or whether in many cases they are solutions that merely mock those adopted for rational reasons in other engineering applications.

THE GAMMON SKANSKA CONSTRUCTION SYSTEM

Ted Lawton, Peter Moore, Ken Cox and John Clark

Gammon Skanska Construction Ltd.
Devon House, Quarry Bay, Hong Kong

ABSTRACT

This paper presents the revolutionary and unique "Gammon Skanska Construction System", which is the product of an in house research and development programme into modular construction extending for more than three years. The vision of the programme is to take the construction industry forward to levels of efficiency found in the oil, ship and automobile industries. Heavy investment has been made into the Research and Development programme for the System, including the full scale building of a modular three-storey mock up in Dongguan (see Appendix 1), two modular show flats for the Integer Exhibition at the Tamar site in Hong Kong and the preparation of a promotional video. After two years of patent searching, it would appear that this is the first time that a precast modular design may be readily and economically used for high-rise construction, without compromising structural integrity or weatherproofing.

KEYWORDS

Tang Committee Report, Gammon Skanska Construction System, Precast, Modular, High-rise, Economy, Sustainability, Maintainability, Environmental & Safety.

INTRODUCTION

The Construction Industry Review Committee report on the Hong Kong construction industry, released in January 2001, supports the need for change. The Committee called on the industry to improve its performance, finding that it produced a finished product that was seldom defect-free and in a manner that was labour-intensive, at times dangerous and polluting.

The reality for contractors is that they must now produce high quality products at ever-lower prices, whilst minimising the community impact. Using substantially its own in-house design, engineering and production resources to develop the Gammon Skanska Construction System, Gammon Skanska has learnt, that one way to improve productivity levels and quality is by moving the construction process away from site and into factory controlled conditions.

The system is based on building high quality modular units that are fully fitted out in the factory and then transported to the site for erection. This approach reduces on site work and allows buildings to be delivered more quickly, safely, with much less waste and thus a reduced impact on the local environs where construction work is being undertaken.

The concept behind the Gammon Skanska Construction System is summarised on the general layout of a typical cruciform block, contained within Appendice 2.

CONSTRUCTION METHOD

Container sized, precast concrete modules are firstly manufactured and then fully fitted out in factory-controlled conditions, including M & E, joinery, tiling, bathrooms, kitchens, decoration, fixtures and fittings, before being delivered to site. Modules are then erected and concrete is poured between them, to create vertical in-situ walls, which lock the modules together and also to become the main load bearing structure of the building. The entire core area, including stair wells, lift shafts and lobby areas can be modularized to match the wings, to enable a uniform construction method across each floor.

Unprecedented rates of site construction can thus be achieved, such as a two to three day floor cycle, instead of a six-day floor cycle, which is primarily due to the fact that no floor slab construction and very little wall formwork are required. Additional time is subsequently saved due to the 70% reduction in building finishing works at site. A comparison programme between a traditionally constructed and a modular system construction project are shown in the Appendix 3.

DESIGN PHILOSOPHY

Modular Construction has generally met with limited success and construction has generally been limited to less than twenty storeys, because of the problems associated with jointing, structural integrity and the cumulative weight of stacked modules. Existing solutions to these problems appear to render systems not workable or commercially viable. This system is based on existing, routine Hong Kong construction methods, using only conventional reinforced concrete to form the modules and structure of the building, to produce a homogeneous building, without the use of specialist grouting techniques, welded or bolted

connections. This approach is intended to simplify development and approvals from the relevant Authorities, and to ensure that there will be no future unproven, long-term inspection and maintenance liabilities.

Using professional experience from a wide range of disciplines, a variety of concepts and methods have been used, to integrate and develop the system into a seamless method of Modular Construction. These include: -

Architecture	-	Complimentary floor plans, features and finishes.
Building	-	Precast facade production, enabling the provision of factory produced features and finishes.
Civil Engineering	-	Match-casting of segmental bridge decks, enabling the quick, precision handling and jointing of sets of adjoining modules.
Steelwork Fabrication	-	Accurate dimensional control of casting beds, enabling the casting of sets of modules with repeating precision, for subsequent ready assembly on site.
Structural	-	Innovative integration of specialist designs for high-rise buildings, segmental bridges and precast concrete systems.
Building Services	-	Complimentary cable routing, risers and specially designed connections.

DESIGN DETAILS

Detailed commercial designs have been completed, including tower blocks of over 40 storeys, under the guidance of an RSE, according to all relevant design standards and BD requirements for Hong Kong.

Building Structure

Module walls combine with the in-situ wall pours to generate significant composite structural strength and stiffness, which enhances structural integrity. With the aid of reinforcing bar starters from the module floor slabs, these pours further lock the ends of these slabs together and generate monolithic sections of floor slab. Shear keys on the sides of the slab sections, enhance the generation of global structural floor plate shear action, in a similar, but in much less onerous manner to that of precast segmental bridge construction. Similarly they are suitably preloaded in compression, to ensure load distribution across slab joints without differential movement or cracking of finishes. A building of similar nature and strength to that of a conventional high-rise building is thereby created, consisting of floor plates, shear walls and core where required.

Modules

Each module is designed to span between and individually shed vertical load into the in-situ concrete walls, so that modules do not support their cumulative weight from above. This enables efficient high-rise construction and also ensures that the possibility of resistance to progressive collapse is at least as good, if not higher, than that of conventionally constructed building.

Jointing Method

A precision interlocking jointing system has been developed to readily join sets of modules together, to generate totally open plan rooms of the required size with minimal in-situ work. It is this in-situ work which has historically rendered other modular systems impractical, with regard to maintaining structural integrity, alignment and waterproofing.

ECONOMY AND SUSTAINABILITY

Modular Construction as a direct comparison with traditional construction, is often more expensive, mainly due to the capital costs of the factory and high transportation costs. However, an overall cost study in the SAR/PRC areas, indicates that the shorter construction period of a typical 40 storey residential tower of between 4 and 6 months, can result in savings amounting to millions of dollars (HK) due to the interest saved on capital investment.

Due to the higher level of factory installed products and more focused quality control methods at the factory floor, it is considered that the assembly of the precision engineered units by a skilled workforce will greatly enhance the overall sustainability of tomorrows housing stock providing a much higher durable product.

The modular units have clear uninterrupted space as all beams, wall thickenings and columns are externally designed, providing sustainable accommodation whereby rooms may be partitioned in ways and with products that can be undertaken at any time, to suit Client/End Users requirements. The resulting ability to change from say 2 to 3 bedroom layouts, without moving home or re-building, is a current goal of Hong Kong environmentalists.

MAINTAINABILITY

Potential cracking between modular joints is eliminated by a suitable amount of preload, shear keys, and epoxy glue, as with segmental bridges and also by the in-situ concrete pours. Between modules there is a double floor slab, providing a vented, drained void, which provides a barrier to any water leaks from the flat above to the flat below. Horizontal and vertical joints of the modules are designed for minimum maintenance and traditional sealants, requiring no more maintenance than facade systems.

ENVIRONMENTAL FRIENDLINESS

Modular construction vastly improves the environmental friendliness of construction in Hong Kong. The system enables faster site construction, thereby reducing the impact on neighbouring areas, during the construction process. This is achieved by a number of factors, including a reduced workforce and limited site activities, such as 70% less site placed concrete, whilst the revolutionary slab construction (in that, no supporting falsework and formwork is required), eliminates the consumption of materials, such as timber, steel and aluminum on site, and since the modules are fully fitted out off-site at the factory, there are consequently significantly less waste materials to dispose of. In addition vehicles entering and leaving site are reduced by at least 40% with consequently less noise and reduced impact to the surrounding roads.

For future owners of the completed units, the air void between double floor slab, reduces vertical noise transmission between flats by half, and contributes towards savings in thermal transmission losses, providing benefits in reduced energy requirements.

The environmental benefits of the system are of sufficient merit to warrant being featured in the international Integer Exhibition at the Tamar site in Hong Kong. This includes two modular show flats with alternative internal layouts, a conference room and a rest room facility. Two primary features are clearly demonstrated, the provision of sustainable accommodation, whereby a set of modules may be readily used or repartitioned at any time to provide alternative functions and the units are demountable for use elsewhere, eliminating the demolition process.

SAFETY

The modular solution is a safer method of construction. Due to the dead weight of the modules they are inherently more stable during erection, relatively simple to assemble and the modules act as a working deck for the connection process of the units, with a perimeter access scaffold being provided around the perimeter of the building. Workers follow up with minor riser pipe work and finishing works on the levels immediately below, working safely within the confines of the modular tower. These processes are repetitive and therefore with a trained workforce, the number of operatives working on site is significantly reduced compared to traditional construction works.

APPLICABILITY AND RELEVANCE TO HONG KONG

The Tang Committee Report has called for the Hong Kong Construction Industry to take a leap forward and improve its practices. The Gammon Skanska Construction System does indeed take this substantial step from the current practice of prefabricated facades, floor panels, stairs and prefabricated bathroom pods, to a total modular system and currently the Government led trend, towards providing incentives for developers by the introduction of floor area concessions for precast innovation, mean that the time is right to develop the initial pilot project in Hong Kong and move the next generation of housing design forward.

WHO WINS AND WHAT ARE THE BENEFITS

To summarise, there are many benefits associated with the modular construction and a few of the winners are: -

Developers

- Quicker completion means earlier occupancy ... which means earlier sales and rentals and lower financing costs resulting in tens of millions of dollars in savings for a typical residential development.
- High quality finish – at no more cost than traditional construction – that commands a premium price and reduces maintenance costs.

Residents

- High quality factory produced finishes.
- Air-void between flats reduces sound transmission by half.
- All internal walls are non-structural so they can be moved at anytime.

Workers

- Construction process is inherently safer because it comprises far fewer, more repetitive site-based actions.
- Working environment is generally more pleasant and conducive to safe, productive activity, less noise, dust, pollution and waste.

The Environment

- 75 per cent less construction noise.
- 40 per cent less vehicle movements on-site.
- 60 per cent less dust and noise pollution.

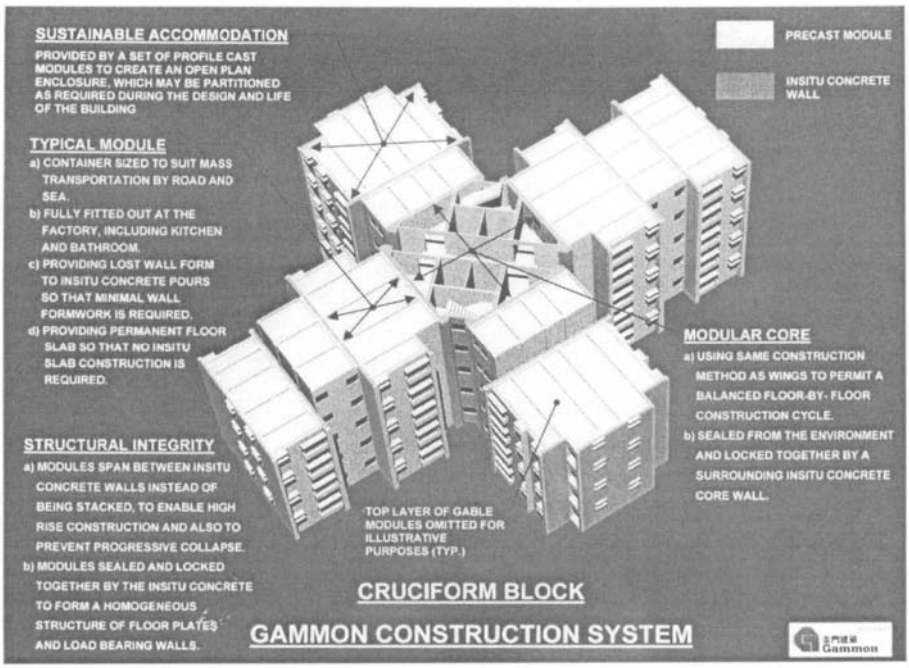
CONCLUSION

The Hong Kong Construction Industry is currently reviewing its practices, in order to adopt the changes affecting our industry. It is believed that the Gammon Skanska Construction System addresses many of the change issues, by taking the production process away from site into a factory controlled climate whereby, quality can be achieved by using a skilled trained workforce and improvements in the time to procure a new project can be achieved by implementing system construction.

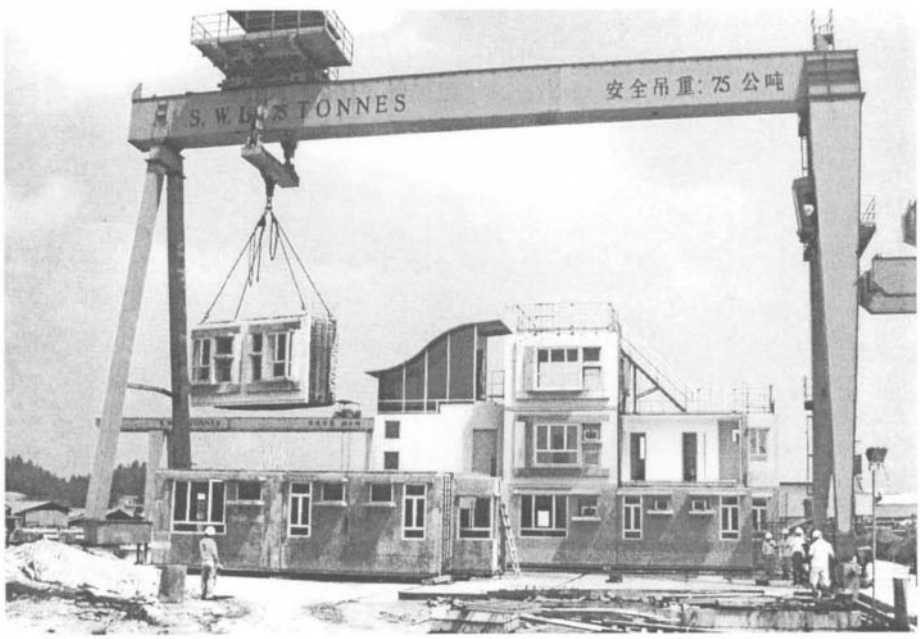
With continued ongoing development, the second generation Gammon Skanska Construction System design is currently examining reduced maintenance on future towers with such item as:

- Self finish external wall treatments with materials such as monolithic wall tiles, or self-cleaning coloured concrete.
- Maintaining risers, plumbing and drainage within the building envelope.
- Reduced thermal transmission through facades.
- The use of lightweight, self-compacting high strength concrete, utilising recycled aggregates.

These enhancements will be incorporated into designs on current potential pilot projects.



The Gammon Skanska system is equally appropriate for other types of buildings including, hotels, educational facilities, prisons, or, linear type developments and can be designed for demountable and re-usable functions.



The system is available for licence both here in South East Asia and elsewhere in the world.

ABSTRACT

This paper addresses the need to build high quality, sustainable housing in a rapidly expanding urban environment like Hong Kong. In order to build faster, yet maintain quality and reduce costs, it is suggested that a step-change in construction technology will be required. The potential for Off-Site Fabrication, in the form of a factory-produced concrete modular system, is described and examples are cited of demonstration buildings in the U.K which suggest that such a system is viable.

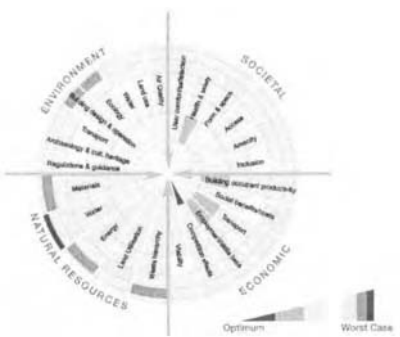
1. SETTING THE SCENE



1.1 Background

Hong Kong is a vibrant, expanding city. With 3.3 million people living inside 125 sq.kms, the area around Hong Kong Island and Kowloon is one of the most densely populated urban centres in the world. The continued economic development of Mainland China, and particularly the Special Economic Zone around Shenzen, means that the regional population is likely to increase significantly over the next 20 years as trade and commercial development gathers pace. All the signs, despite the recent economic slowdown, are that the medium-term trend is growth-oriented and the authorities in the region must plan for an increasing population. The need for high quality, cost-effective, environmentally responsible, residential construction has never been greater. How can this need best be fulfilled?

Within the above context, conventional methods of design and construction have limited attraction. From a quality point-of-view, the need to build more quickly and within tighter budgets pressures contractors to reduce construction quality. From an environmental point-of-view, traditional design approaches have shortcomings and are and in need of improvement. The Hong Kong authorities have clear ambitions in both of these directions and are actively encouraging the development of new ideas and innovative techniques in planning, design and construction. The challenge is to develop communities living in high quality, environmentally friendly, buildings which are swift to construct at economical prices. In every sense of the word, this elusive combination may be described as '**Sustainable Housing**' and this paper puts forward some thoughts on the road to realisation of this ideal.

1.2 The Methodology

The delivery of sustainable housing requires a multidisciplinary and balanced approach to the development of new designs. There are many variables which must be considered simultaneously under the four primary headings of Social, Environmental, Natural Resources, and Economic. Good design requires the harmonisation of all of these. Some form of systematic and disciplined appraisal is therefore necessary if the appropriate balance is to be achieved. Several tools have been developed over recent years for this purpose and, within Arup, the SPeAR system has found widespread favour. Use of a tool such as this can be invaluable if adopted at the outset of a project and used regularly to assess the developing characteristics of a scheme as it goes through the various stages of project development. Fig 1 illustrates this essentially graphic approach, which has been endorsed in the UK recently as an independent tool for assessing residential development schemes (Ref 1).

SPeAR is a sustainability assessment tool which allows the multiple variables being assessed to be presented in a simple visual form. Colour coding utilises green (near the centre of the circle) and red (near the circumference) to represent good and poor performance respectively. A progressive change of colour at intermediate radii deals with cases between the extremes. The circle is divided into four headline zones (Environment; Societal; Natural Resources; Economic). Within each zone, a range of relevant issues are represented as segments and coloured according to assessed performance.

Fig 1: The SPeAR Sustainability Assessment Tool

1.3 Construction Technology

There have been impressive advances in construction technology in Hong Kong over recent years. The construction cycle-time for high-rise dwellings has been systematically reduced to 6 days per storey (and, even to 4 days) by increasingly sophisticated organisation and management on site, plus the widespread adoption of Off-Site Fabrication (OSF) techniques. Principal amongst these is the use of pre-cast concrete for facades. However, there are limits to what can be achieved and there is a danger that the single-minded pursuit of speed can lead to compromises in finished quality and site-safety. In any case, the cycle-times referred to above relate only to the single storey completion time for *structure;* the figures make no allowances for services, finishings and fittings – all of which take a

great deal longer to complete than structural work. And not only do these tasks take longer. It is here that the majority of 'value' is brought to the building. Clearly, if a step-change is to be brought to the *overall* construction/completion cycle, something more all-embracing than pre-cast concrete structure alone must be considered. It is this thinking that leads to the conclusion that factory-built modular housing might be attractive.

Off-site fabrication of volumetric, interior- finished, dwelling units has the following potential advantages

- It allows maximum value to be installed in the factory, thereby allowing capital costs and transport costs to be amortised more easily over any given number of dwellings.
- It allows factory standards of manufacture, finish and reliability to be achieved.
- It removes the maximum possible fraction of labour from site, thereby reducing the likelihood of poor workmanship, accidents, and errors.
- It significantly speeds up the construction/completion cycle, thereby increasing the return on capital employed for developers and reducing the duration and intensity of annoyance to site neighbours.
- It provides secure, safe, factory-based, jobs for the workforce in preference to the relatively dangerous, insecure, site-based jobs, normally associated with the construction industry.

For all of the above reasons, OSF and, particularly, volumetric modular construction, has received a great deal of attention in recent years. In the U.K., the trend began with clients from the hotel and fast-food industries wanting buildings of higher quality and reliability, delivered and commissioned within shorter timescales. Clients in these sectors recorded impressive gains for their businesses (some fast-food retailers claiming a factor of 10 improvement in the installation and commissioning timescale for a typical roadside restaurant). The obvious success of these initiatives prompted interest amongst a wider circle of clients, and residential buildings are a large segment of the construction industry with a potential for big gains.

The next two sections of this paper examine the recent development of a particular sustainable modular housing system in the UK and its potential extension for application to high rise system for Hong Kong and East Asia.

2. MODULAR CONSTRUCTION – CASE STUDIES FROM THE UK

This section outlines two prototype residential buildings which utilise factory-built concrete modular products developed by Meteor Systems (a consortium of Arup, Peabody Enterprises and Taylor-Woodrow). The concept is founded on the following basic precepts:

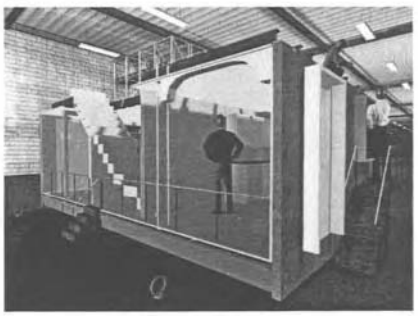
- The product must be the right price (i.e. it must meet or beat conventional build costs).
- The product must satisfy customer needs
- The product must satisfy the demands of the regulatory and financial bodies (i.e it must satisfy regulated performance criteria and it must be mortgageable/insurable).
- The product must be sustainable when measured against the headline parameters identified in Section 1.2.

To deliver a product which meets all of these needs simultaneously requires a 'first-principles' approach to design and production. The materials used, and the production processes, must be developed as an integral part of the product design exercise. Working through this cycle, the defining characteristics of the production facility are found to be:

(i) A flexible manufacturing regime (must produce a wide variety of different products, sometimes in quite small batches and in random sequences).

(ii) Elasticity of output (must be able to cope with peaks and troughs in demand without undue fluctuations in selling price).

(iii) Low capital investment (volumes of production are not sufficient to accommodate mass consumer product levels of capital intensity).



This trio of requirements is unlike the pattern found in 'standard' solutions from other industries. It is not possible, therefore, to transplant an accepted process from elsewhere. The factory design and process layout has been a particular challenge, and the key elements of the system which has been devised are summarised in Fig 2:

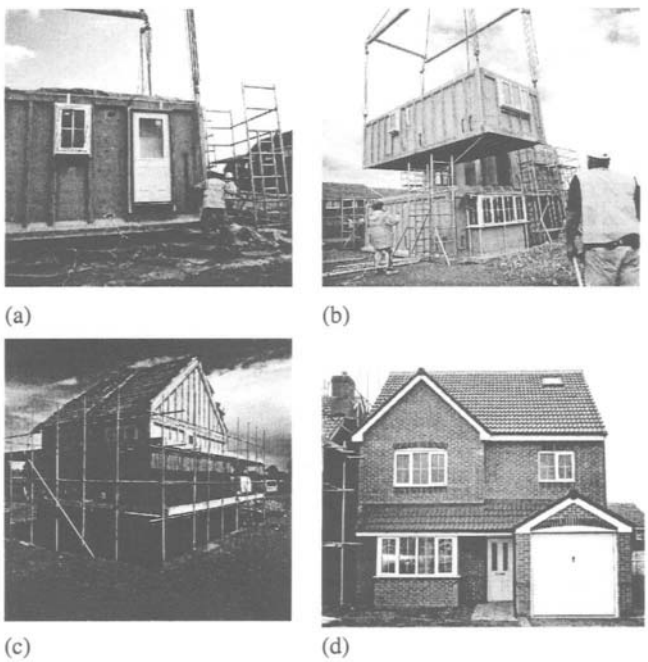
(a)

(b)

(c)

*Initially, flat-panels are produced on high quality (but very simple) shuttering **(a)**. Panels can be of arbitrary length and breadth. The panels are then assembled into boxes (modules) using purpose... designed equipment **(b)**. The boxes then pass down a moving fit-out line where internal equipment is installed and finishings applied.*

Fig 2 : Key Elements of Meteor Systems Production Concept



Based on the principles outlined above, a prototype production facility has been set up and the production of two buildings has been embarked upon. These buildings deliberately represent two extremes of the UK housing market in order to demonstrate the flexibility and design potential of the Meteor System. The first (built in Northampton for one of the UK's leading private housebuilders and completed in the Summer of 2001) is based on an entirely conventional design, un-modified in its layout and appearance from a conventionally-built counterpart. The second is an unconventional, architect-designed terrace of apartments and townhouses, in which an environmentally responsible approach to design has been emphasised. This building has recently won an RIBA design award and

is about to move into construction on site. It will be built at Acton in North London for Peabody Trust. Both Projects are associated with low-rise developments.

2.1 Detached House – Northampton (for Bellway Homes)

This project utilised Meteor Systems' concrete modules to provide a volumetric solution to a traditional requirement. The concrete modules provide a robust, high-quality infrastructure which is overclad with traditional bricks and roof-tiles. The modular solution is flexible enough to accommodate all the 'idiosyncrasies' of a typical design (i.e. the builder's standard layouts were not modified to accommodate factory-imposed inflexibilities). However, the truss-free roof allowed significant improvements to the available space over the basic layout, turning a standard three-bedroom, two-story house into a four-bedroom, three-storey house with additional en-suite facilities.

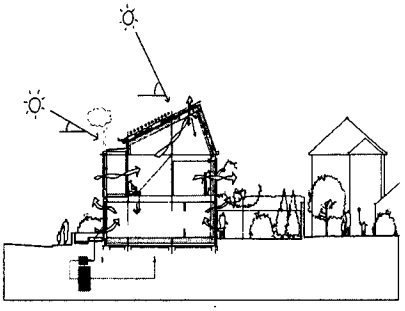
The concrete solution provides high thermal mass and good sound insulation. This house has excellent energy-in-use characteristics with a SAP rating in excess of 106. SAP (Standard Assessment Procedure) is part of the UK building regulations for checking energy usage by checking efficiency of the heating system, the insulation and the building leakage. A SAP rating of 106 is very good. It also has measured sound attenuation characteristics which are well in excess of those measured in traditionally built versions of the same design nearby on the same site.

*The modules for this house were installed within 10 working hours, providing a fully finished, weather tight interior ready for completion of interior joints and overcladding **(a)**; **(b)**. The exterior cladding (bricks and roof tiles) were then applied in a conventional fashion **(c)**. It is estimated that this approach, once established, could reduce typical build times from around 16 weeks to three weeks **(d)**.*

Fig 3 : Construction Sequence for Conventional Detached House

2.2 Terrace of Apartments/Town Houses (for Peabody Trust)

This small development builds on the technical achievements of the Northampton project and seeks to demonstrate the potential of the Meteor System to accommodate a variety of design demands (e.g. unconventional facades; double-height interior spaces; low energy in use; irregular layouts; etc). Comprising some 30 modules, it is intended to be delivered and completed on site within 6 working



weeks – a very substantial reduction from the 40 week programme estimated for the conventional construction of the same building.

(a)

(b)

(c)

This RIBA award-winning design for a small terrace of town-houses and apartments ***(a)*** *will have unconventional facades and dramatic forms of interior layout* ***(b)****. There will also be a heavy emphasis on low energy-in-use and other environmentally responsible design issues* ***(c)****. The application of the Meteor System to this project demonstrates the flexibility of the concept.*

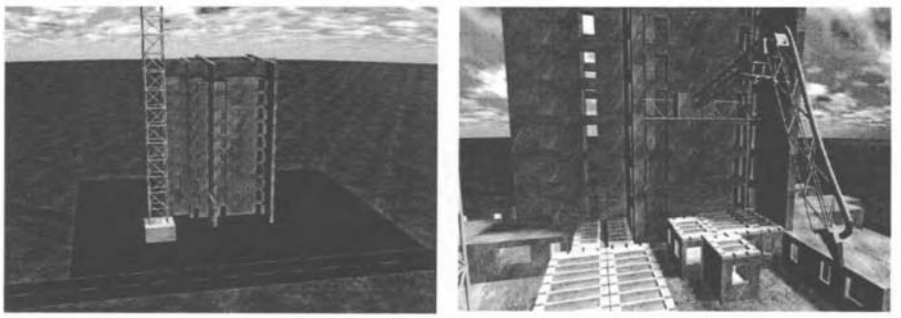


Fig 4 : Environmentally Responsible Design – Town Houses/Apartments to be built in Acton, North London

3. EXTENTION TO HIGH RISE APPLICATIONS FOR EAST ASIA

The basic system for producing high quality, low-cost modular products has already been developed in the U.K. A factory for producing fully-finished modules has been designed, and funding for a pilot factory is being raised.

With some modifications to the engineering design of the modules themselves, the system could be adapted and extended to cope with high-rise situations. Feasibility studies have been conducted which have examined structures up to 40 storeys, and concept designs have been produced. It should be possible to produce a great majority of the design-types most widely seen in Hong Kong (both public and private types) at prices which would compete with conventional delivery. It has been calculated that the completion time of the superstructure of a 35 storey block could be reduced to the order of 12-15 weeks, with on-site labour running at around 25% of conventional levels. The benefits in terms of reduced potential for accidents, errors and poor workmanship are obvious, as is the improvement in return on capital employed for the developer/contractor.

Fig 5 illustrates the concept. The system employs a hybrid approach to construction, using in-situ techniques for the core (slip-forming) and factory-built products for the residential elements. There is also a degree of site automation (for example, the grouting robot used to provide a 'bed' for incoming modules – illustration 5(b)).

(a) (b)

Hybrid construction techniques are proposed for high-rise variants of the concrete modular concept. The core of the building will be slipformed ***(a)*** *with modules shipped to site and placed around the core using heavy lift cranes. The 'grouting arm'* ***(b)*** *is illustrative of the type of site automation which is envisaged.*

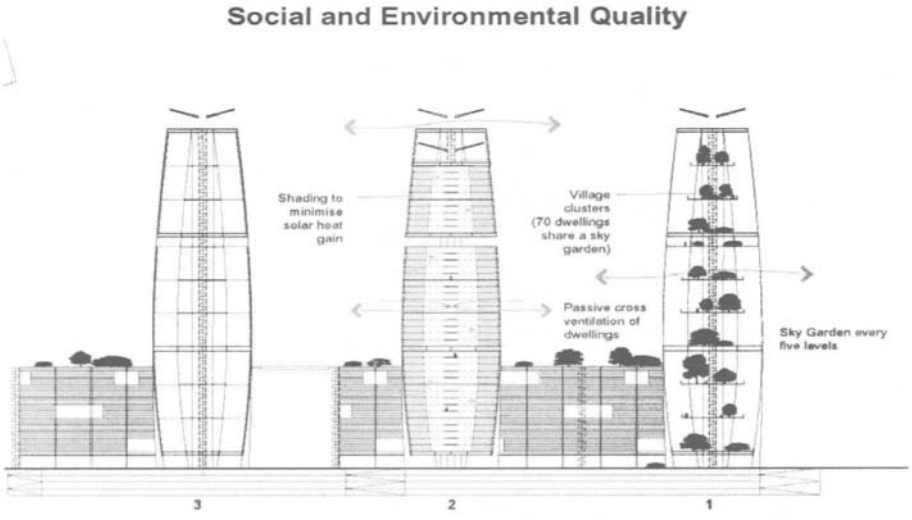
Fig 5 : High Rise Solution Concept for Hong Kong

Further extensions of the concept have been developed for deployment in other climates (e.g. Singapore). Sustainable neighbourhoods were a key theme in the scheme illustrated in Fig 6. Layouts incorporating sky-gardens; passive cooling; renewable energy sources; and neighbourhood 'clusters'; were developed for high-rise communities. Again, this concept could be built to higher standards, and very much faster, than the conventional counterpart.

4. CONCLUSIONS

Off-Site Fabrication (OSF) has an important contribution to make in the continued development of the construction industry. There is a great interest, worldwide, in the pursuit of factory-built quality and environmentally responsible design. The realisation of these goals simultaneous with the achievement of an economic price and social benefit, represents the holistic ideal of sustainable housing design.

Substantial development work in the UK suggests that these ideals can be delivered in a low/medium rise context. Extension to the high-rise context has also been shown to be feasible, and concept designs have been developed and costed. An important barrier, however, to the further progress of these ideas is the capital investment required to complete the detailed designs and set-up a pilot production facility. This demand for investment is faced daily by the major manufacturers of consumer products (cars; white goods; electronic components; etc), but it is an alien concept to the construction industry. In relative terms, the capital at risk is small (a pilot factory, capable of producing some 10,000 modules per year, might cost 120M HK$. A car production facility might cost 50-100 times this amount!). Nevertheless, the risk is real and, without a step of faith, the first move will not be made.



The benefits, if successful, are clear. What is less clear is whether the appetite of the industry is sufficient to make it take the risk and start the ball rolling.

(a)

(b)

(c)

The development of Sustainable Communities is addressed by this high-rise concept for Singapore ***(a)***, ***(b)***. *Dwellings are arranged in Village Clusters around Sky Gardens. Passive cross-ventilation, solar shading and roof-mounted P.V. arrays and water collectors all feature as part of the design concept* ***(c)***.

RECENT RESEARCH ON STEEL-CONCRETE COMPOSITE SHELL ROOFS

J.G. Teng[1], H.T. Wong[1], Z.C. Wang[2], S.L. Dong[3]

[2] Research Centre of Spatial Structures, Shanghai Jiaotong University, Shanghai, China
[3] Department of Civil Engineering, Zhejiang University, Hangzhou, China

ABSTRACT

Steel-concrete composite shell roofs (Comshell roofs) are formed by pouring concrete on a thin stiffened steel base shell which serves as both the permanent formwork and the tensile steel reinforcement. The thin steel base shell, constructed by bolting together open-topped modular units consisting of a base plate with surrounding edge plates, is a steel shell with thin stiffeners in both directions. The new system retains all the benefits of thin concrete shells, but eliminates the need for temporary formwork and minimises the required falsework. Intensive research is currently being conducted by the authors on the behaviour and design of these composite shell roofs. This paper provides a description of this new structural system and a summary of current research on the various possible failure modes of this system.

KEYWORDS

Shells, Roofs, Concrete Shells, Bolted Steel Shells, Composite Construction, Modular Construction, Wet Concrete Loading, Buckling, Design

INTRODUCTION

Many thin concrete shells have been built around the world as large span roofs, but their use has gradually declined over the past few decades. This decline has been due mainly to the high cost of construction and removal of temporary formwork and associated falsework for concrete casting in the construction of a thin concrete shell. This labour intensive and costly process of construction, coupled with the increasing ease in analysing complex skeletal spatial structures offered by advances in computer technology, has made concrete shells much less competitive than they were a few decades ago.

Over the years, there have been several attempts aimed at eliminating the need for temporary formwork in constructing thin concrete shell roofs, but these have met with only limited success. An excellent review of these attempts and other developments of thin concrete shell roofs has been given by Medwadowski (1999) who concluded that forming "remains the great, unsolved problem of construction of concrete thin shell roofs. Any and all ideas should be explored, without prejudice." The latest development in the forming of thin concrete shell roofs is the Conshell roof system proposed by Teng (2001) which is believed to be a very promising solution to this difficult problem. In this paper, this new structural system

is first briefly introduced, followed by a summary of the intensive current research being conducted at The Hong Kong Polytechnic University in collaboration with Shanghai Jiaotong University and Zhejiang University.

THE COMSHELL SYSTEM

The Comshell roof is a steel-concrete composite shell roof formed by pouring concrete on a thin stiffened steel base shell which serves as both the permanent formwork and the tensile steel reinforcement. A brief description of the system is given here, but further details are available elsewhere (Teng, 2001).

The steel base shell is constructed by bolting together modular steel units in the form of an open-topped box consisting of a flat or slightly curved base plate surrounded by edge plates (Figure 1). By adopting different shapes for the base, different shell forms can be achieved but this paper is limited to cylindrical shell roofs only (Figure 2) as they are the easiest to construct by this modular approach.

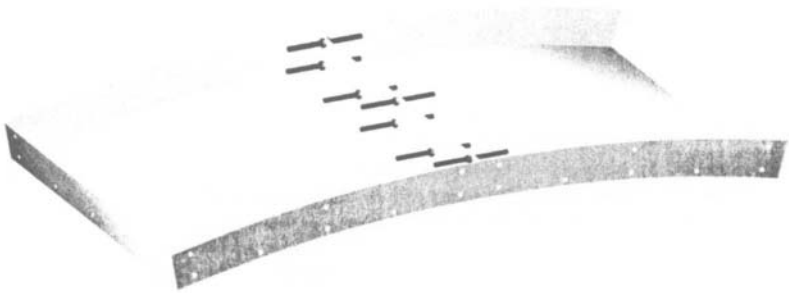

Figure 1: Modular units and bolted connection

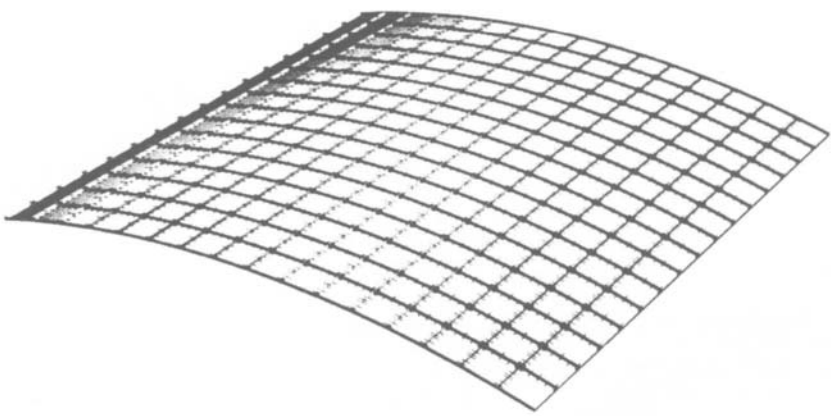

Figure 2: Steel base shell formed from modular units

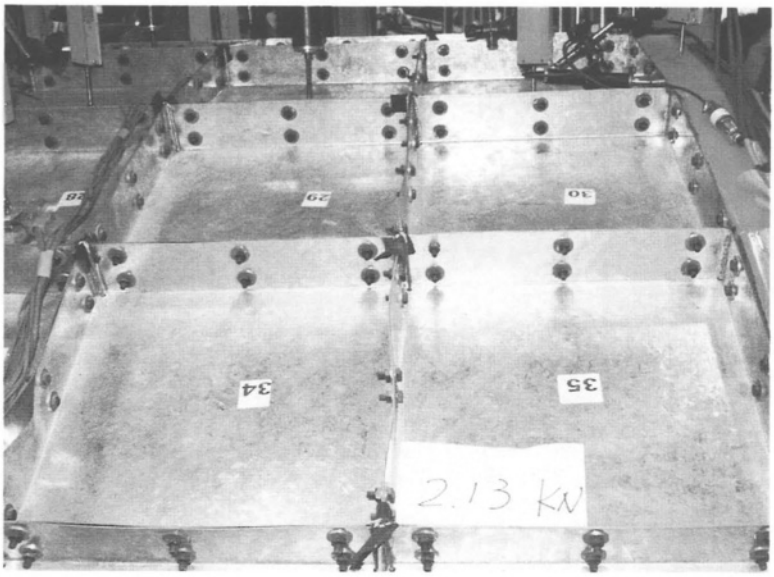
The modular units for cylindrical shell roofs are made with two of the edge plates slightly inclined, so that when they are assembled using bolts, a curved profile of desired curvature results (Figures 1 and 2). Holes are drilled on the edge plates for bolt connections to adjacent units, and the bolted-together edge plates form stiffeners in both directions (Figure 2). The circular profile of the shell can be either approximated by flat bases, or exactly followed by slightly curved bases with all edge plates being perpendicular to the base. In fact, the base may be convex or concave, and slightly corrugated if required, for enhanced resistance to local buckling.

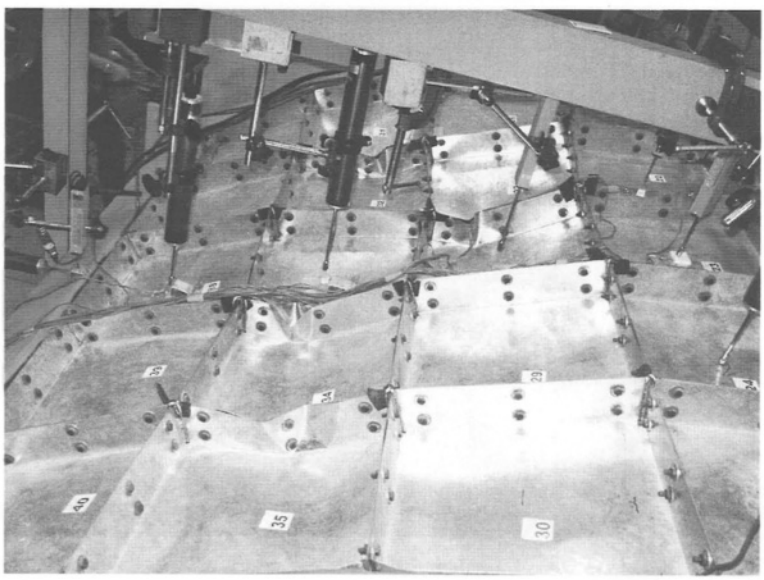
ADVANTAGES OF THE COMSHELL SYSTEM

The Comshell system has many advantages over existing roof systems, which has been fully discussed by Teng (2001) and is thus not repeated here. This modular approach of construction also has many advantages over a more conventional approach of composite construction in which the roof is constructed using large cold-formed thin curved sheets with corrugations running in one direction and with shear studs welded on before concrete casting. These include: (a) mass factory production of the units of a few standard sizes and curvatures is possible, and shells of desired spans and curvatures can be built easily; (b) transportation to and handling on site is easy, and units can be bolted together to form big panels (e.g. half-span arch panels) for lifting; (c) the steel shell so built has many thin stiffeners formed from edge plates, as a result its buckling resistance is greatly enhanced so shoring during construction will be substantially reduced; (d) the stiffeners can prevent wet concrete from flowing down the shell surface; (e) the stiffeners together with bolts act as shear connectors between the steel shell and the concrete, so additional welded shear connectors are unlikely to be required; and (f) the stiffeners can be used as spacers to ensure accurate positioning of reinforcing bars to resistant hogging moments.



With the appropriate use of small corrugations when necessary, steel sheets of 1-2 mm in thickness are expected to be sufficient for the base plate of the modular unit to carry wet concrete loading without excessive deformations, stresses or local buckling. Due to this small thickness, the units can be press formed easily with precise geometric control. The units can be assembled into arch panels on ground before lifting, ensuring a tight control of the geometric shape of the assembled shell and limiting shoring requirement.

FAILURE MODES AND CURRENT RESEARCH



For the Comshell system to be widely used in practice, many issues have to be studied to establish a sound understanding of the behaviour and strength of these shells, and to develop suitable design methods. At the present, a number of failure modes have been identified, and each needs a great amount of research. These failure modes are associated with either the construction stage or the service stage and are currently being investigated at The Hong Kong Polytechnic University in collaboration with Shanghai Jiaotong University and Zhejiang University. These failure modes and associated current research are outlined below.

Construction Stage

During the construction stage, the wet concrete acts as loading on the bolted steel base shell which can fail by either local buckling or overall buckling. Local buckling is in one of two modes: buckling of the bolted stiffeners formed from edge plates and bucking of the base of the modular unit. Figure 3a shows the local buckling mode of stiffeners in a model steel base shell during laboratory experiment (plan size: 2 m x 2m). The particular geometry of this model shell dictated that local buckling occurred before overall buckling, nevertheless the model shell finally collapsed in an overall buckling mode after large post-local buckling deformations of the stiffeners (Figure 3b).

(a) Local buckling

(b) Overall buckling

Figure 3: Buckling modes of a steel base shell

The local buckling mode has a stable postbuckling path, so it does not signify the exhaustion of the load carrying capacity of the shell. Nevertheless, it can lead to excessive deformation which can impair the visual quality, serviceability and strength of the shell. The overall buckling mode leads to the collapse of the shell and is thus a more dangerous mode. Interaction between the two modes is likely to be significant, as local buckling can reduce the resistance of the shell to overall buckling. The sheeting thickness of the steel base shell and hence the economy of the entire system is controlled by these buckling modes. A number of possibilities exist to enhance these buckling loads without increasing the sheeting thickness, including the use of small corrugations for the base plates, the provision of stiffeners to the edge plates, and the casting of concrete in two stages (Teng 2001, 2002).

A program of tests on model steel base shells is currently underway where both the overall buckling mode and the local buckling mode are considered. A scaling problem exists in conducting buckling tests on small-scale models (e.g. using models of 2 m x 2m in base size to simulate real shells with a base size of 20 m x 20 m). Given that the main uncertainty in the behaviour of these bolted steel shells lies in the behaviour of the bolted joints, the purpose of these tests, which are both costly and time-consuming, is mainly to provide test data for the verification of a finite element model which can capture the behaviour of these joints. Once a reliable finite element model is established and verified, numerical analyses can be conducted for a wide range of shell geometries far beyond the confines of small-scale laboratory tests.

Service Stage

Once the shell has been constructed, the main loading on the structure is its self weight, snow loading, wind loading, and seismic loading if the shell is located in a seismically active area. The wind loading is uplifting, provided the shell is not a deep one, so in general, it is beneficial. Self weight, together with snow loading if the structure is located in a cold region, is probably the most important loading condition for a large span Comshell roof. Seismic loading is another important consideration.

The base plate is subject to complex distributions of membrane and bending stresses at the end of concrete casting. After the curing of concrete, the base plate is subject to additional stresses as a result of any additional loading such as snow loading and the removal of any shoring and the long term creep deformations of concrete. The base plate is biaxially stressed and is subject to one of the various combinations of compressive and tensile membrane stresses in addition to bending stresses. It should be noted that if the final stress state of the base plate is compressive in at least one direction, then unilateral buckling of the base plate is a likely failure model. Creep deformations of the concrete under self weight loading will not have the devastating consequence of changing the overall shape of the shell, as the steel base shell controls its overall shape, however they are still important as they will lead to redistribution of stresses between the steel shell and the concrete shell above it. A study of the unilateral buckling of the base plate will be carried out in the near future.

Overall buckling of Comshell roofs under gravity loading is probably the most important controlling failure mode for large spans. The strength in this failure mode is likely to be controlled by the bolted joints which are the weak links in bending resistance in the composite shell. Given the complexity of the buckling problem, the first step must be the development of a nonlinear finite element model and the experimental verification of such a model. The key to the success of such a finite element model lies in its ability to model the behaviour of the joints under combined axial force and bending. To this end, a series of tests have been carried out on slabs and arches with a bolted steel base featuring various types of connections. Figure 4 shows a steel base arch with long connection bolts. Figure 5 shows load defection curves of two composite arches, one (Arch A) constructed using the bolted steel base arch shown in Figure 4 and another constructed with a base arch in which very short connection bolts were employed. Although there is a small difference in the concrete properties of the two arches, the main difference between them lies in the connection bolts: one featured connections with long bolts which were anchored in the cast in-situ concrete and one with short bolts which thus did not have anchorage in the concrete. The strengths and load-deflection curves of the two arches are very different although the failure mode is similar (Figure 6). These tests illustrate the importance of connection details in determining the overall response of such composite arches.

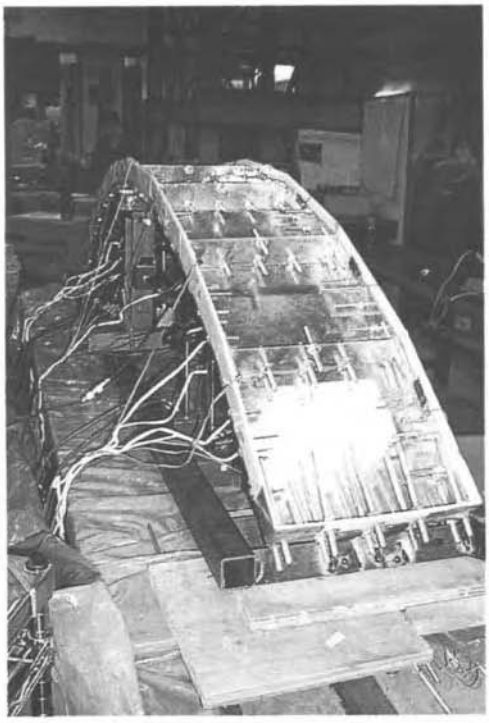


Figure 4: Steel base arch with long connection bolts

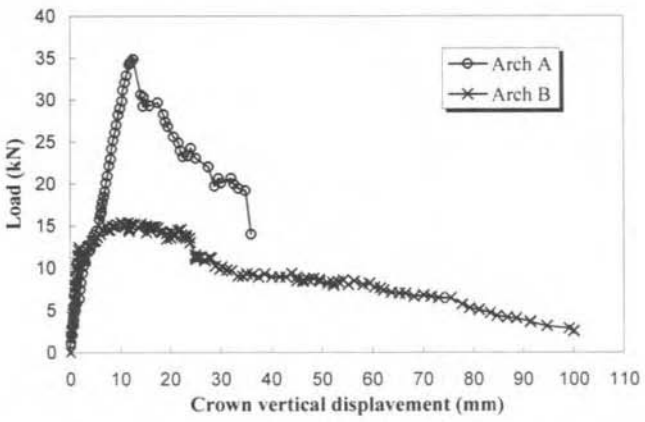

Figure 5: Load-deflection curves of two composite arches

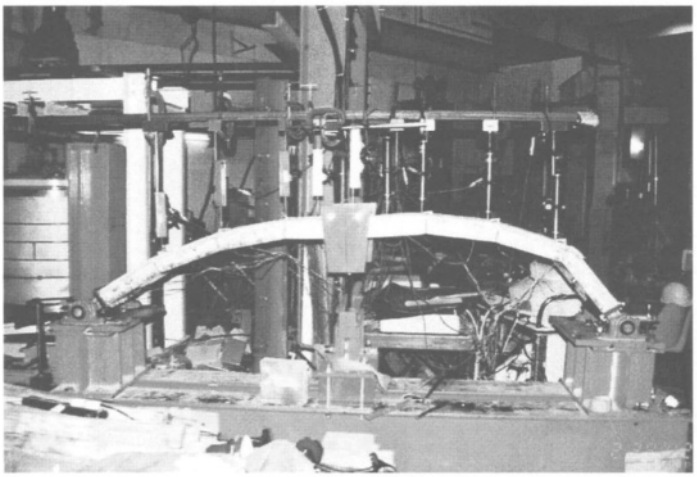

Figure 6: Failure mode of a composite arch

In addition to these arch tests, a series of tests on bolted composite joints has also been completed to study the behaviour and strength of these joints subject to eccentric loading. A method for the modelling of these joints is being developed, which will be compared with the test results. This method, after verification using the joint test data, will be applied to the prediction of the behaviour of the test arches. In the near future, a large-scale model Comshell roof will be built and tested at the Research Centre of Spatial Structures of Shanghai Jiaotong University, which will provide not only insight into the behaviour of the Comshell system, but also test data for the verification of a finite element model incorporating the simple joint modelling method currently under development. Once the finite element model is shown to predict the arch and model shell test results satisfactorily, it will be used to study the buckling behaviour of Comshells with full-scale dimensions.

CONCLUSIONS

This paper has presented an innovative structural system, namely steel-concrete composite shell roofs (Comshell roofs), for enclosing large spaces. These composite shells are formed by pouring concrete on a thin stiffened steel base shell which serves as both the permanent formwork and the tensile steel reinforcement. The thin steel shell, constructed by bolting together modular units consisting of a base plate with surrounding edge plates, is a steel shell with thin stiffeners in both directions. The structural design of this new system is controlled by a number of failure modes that may arise during either the construction or the service stage. These failure modes have been discussed in this paper. A summary of intensive current research has also been given. It is expected that by the end of this research program, the basic behavioural characteristics of the system will have been defined, and suitable numerical methods for analysing these shells established. Sufficient knowledge will also have been developed by then to enable the system to be applied in practice, although a great deal of further research will be required to establish a clear understanding of all major behavioural aspects, refine the construction process, and formulate simple design methods.

ACKNOWLEDGEMENTS

This work has been supported by the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No: PolyU 5059/99E) with additional support provided through a research studentship for Mr. H.T. Wong. The authors are grateful for this support.

EFFECT OF THE SHEAR WALL CUTOFF ON STOREY DRIFTS OF FRAME-SHEAR WALL STRUCTURES

Quanfeng Wang
Department of Civil Engineering, Huaqiao University, 362011 Quanzhou, Fujian, China.

ABSTRACT

In references (Wang et al 1999) and (Wang et al 2001), the seismic responses of frame-shear wall structures with shear wall cutoff have been studied and it is concluded that not all frame-shear wall structures need to extend their shear walls to the height of the entire structure. Continuing from references (Wang et al 1999) and (Wang et al 2001), in this paper the structures are to be analyzed using a member system-storey model under simulated earthquake excitations. The magnitude of interstorey drift is a key index to the amount of structural and nonstructural damage expected in a given storey. Therefore, the study is aimed at determining numerically the effect of shear wall cutoff on storey drifts in frame-shear wall. Contrasting the results to the result from the shaking table, it has an agreement with each other. Finally, a conclusion is given that terminating the wall at the midheight does not affect earthquake response detrimentally, if the shear wall is taller, the effect on the storey drifts is not significant.

INTRODUCTION

Reinforced concrete structural walls are frequently used to provide lateral stiffness for frame-shear wall buildings. Often the walls are interrupted to accommodate a large space for building function. Structural engineers have developed confidence in the design of buildings in which the distributions of weight and stiffness in the vertical direction are more or less uniform. The confidence is reasonably well founded, having been derived from numerous structures and research observations. To the best of our knowledge, there is no work described in the literature aimed at developing a simple method for the earthquake response of a frame-shear wall structure in which the shear wall does not continue up to the roof. Consequently, traditional analytical methods for frame-shear wall system need to be modified or new approaches need to be developed for the accurate assessment of the response of these structures subjected to static and dynamic loadings. In references [1] and [2], the seismic

responses of frame-shear wall structures with shear wall cutoff have been studied and it is concluded that not all frame-shear wall structures need to extend their shear walls to the height of entire structure. Continuing from references [1] and [2], this paper describes the structures analyzed using a member system-storey model under simulated earthquake excitations. Both structural and nonstructural damage sustained during earthquake ground motion are produced primarily by lateral displacement. Thus, adequate damage control can be achieved if lateral deformations are controlled by providing enough lateral stiffness. Drift resistance is a major factor in assessing whether a proposed structure is suitable for a tall building. The taller the building, the greater the need to mobilize all the structural interaction that can contribute to drift resistance. The magnitude of interstorey drift is a key index to the amount of structural and nonstructural damage expected in a given storey. Therefore, the study is aimed at determining numerically the effect of shear wall cutoff on storey drifts in frame-shear walls. The numerical analyses of the structures use the finite element technique with a base motion having peak base accelerations of 0.41g. Contrasting the results to these from a shaking table, these are in agreement with each other. The conclusion given is that terminating the wall at midheight does not affect the earthquake response detrimentally, and if the shear wall is taller than that, the effect on the storey drifts is not significant.

ANALYTICAL METHOD

Motion Equation

Consider a multi-degree-of freedom system excited by a generalized force, $Q^*(t)$, if the viscous damping theory and the Lagrange equation are used, the differential equation of motion is given by

$$[M]\{Y''\}+[C]\{Y'\}+[K]\{Y\}=[M]\{a_g(t)\} \tag{1}$$

in which *[M], [C]* and *[K]* is the mass; damping and stiffness matrices of the system, respectively; *{Y}, {Y'} and {Y''}* is the lateral displacement, velocity and acceleration vectors of the mass, respectively, and $\{a_g(t)\}$ is the ground acceleration vector.

The equation of motion of the (j)th mode in normal coordinates, η, may be written as (Argyris 1991)

$$\eta_j''+2\,\nu_j\omega_j\,\eta_j'+\omega_j^2\,\eta_j=Q_j^*(t) \tag{2}$$

in which ν_j, ω_j are the modal damping ratio and angular frequency of (j)th mode respectively, and

$$Q_j^*(t)=\int_0^H q(t,x)Y_j(x)\,dx \,/\, M_j^* \;;$$

$$M_j^*=\int_0^H m(x)Y_j^2(x)\,dx \;;$$

$q(t, x)$ is the random loading; $Yj\ (x)$ is the function of mode at the (j) th mode; $m(x)$ is the distributed density of the structural mass.

Solution of the Motion Equation

Numerical implementation would be necessary for complicated earthquake-like excitations. In modeling buildings for earthquake response analysis, the "shear beam model" has been used extensively. This simple method, however, is not always practical or accurate since it neglects important effects such as: (1) The flexure of structural system; (2) the interaction between adjacent stories, and various failure modes are not exhibited by the model. Alternatively, member-by-member analysis of frames is frequently used to model structures that exhibit elasto-plastic state of each member at any time due to earthquake excitations. However, there is an excessive number of degrees of freedom in the model. This paper uses an alternative procedure: member system-storey model (Clough 1972 and Muto 1979) that combines the advantages from "shear beam model" and member-by-member analysis of frames to estimate the earthquake responses of frame-shear wall structures with shear wall cutoff. The complete structure stiffness matrix is obtained from the individual frame and frame-shear wall stiffness matrices. The results to be presented later were obtained by numerically integrating Eq.2 using the Wilson - θ method. The time step was chosen to be 0.02 sec. and small enough to provide accurate results.

SEISMIC RESPONSES OF FRAME-SHEAR WALL STRUCTURES WITH SHEAR WALL CUTOFF

Here, the example is assumed to be similar to the test specimens in Moehle (1984), and makes it possible to compare, at least qualitatively, the finding from this study with the observations made in the experimental research. Four small-scale reinforced concrete test structures were constructed. These are identified by the designations FW9, FW4, FW1, and FW0. Each structure is assumed to consist of two identical parallel nine-storey, three-span frames and a central shear wall built parallel to the frames (Moehle 1984). Wall height varies for different structures as explained later on. The material properties are assumed to be the same as the measured values for the test specimen with the nine-storey structure. The concrete has a modulus of elasticity of 19,000 MPa. It is assumed the mass lumped at each level is 470 kg. Structure FW0 comprises the frame only. The structure FW9 includes two nine-storey, three-bay frames and a nine-storey prismatic wall. The other structures FW1 and FW4 are nominally identical to structure FW9 except that the wall extends only to the first and fourth floor levels respectively. Because of the continuity provided by the full height wall, structure FW9 can be considered to represent a building having a reasonably uniform distribution of stiffness over the entire height. In contrast, structures FW1 and FW4 have the wall cutoff at the first and fourth floor levels, respectively.

The Maximum Displacements

The structures are subjected to the first 10 seconds of the NS single horizontal component of the EI Centro recorded during the 1940 Imperial Valley Earthquake. The amount of viscous damping is fixed at 2% of critical value, which is thought to be representative of a concrete structure. The numerical analyses of the structures follow the finite element technique with a base motion having peak base accelerations of 0.39g, 0.34g, 0.41g and 0.32 g for FW0, FW1, FW4 and FW9, respectively. Computed displacement curves of the four structures are plotted

in Fig. 1. Structure FW0 behaves obviously with a typical shear deformation character. In contrast, structures FW1, FW4 and FW9 behave obviously with a typical shear-flexure deformation character corresponding to theoretical prediction. The maximum top-level displacements obtained by the experiments (Moehle1984) and by the analysis method proposed in this paper are summarized in Table 1. With respect to the maximum top-level displacements, the analytical results are in good agreement with the experimental results except for structure FW9, but are considered as an acceptable estimate. The correlation between the two methods suggests that the numerical method proposed in this paper is adequate for representing the dynamic response of the structures with shear wall cutoff.

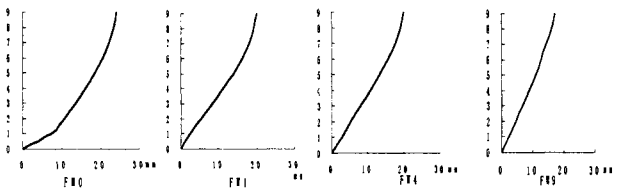

Figure 1: Computed displacements of the four structures

TABLE 1

THE MAXIMUM TOP-LEVEL DISPLACEMENTS (mm)

Structures	Measured d_m	Calculated d_c	d_c/d_m
FW0	26.3	24.2	0.92
FW1	22.4	20.2	0.90
FW4	23.2	20.1	0.87
FW9	26.1	17.1	0.66

The numerical analyses for the structures FW1, FW4 and FW9 use the same base motion having peak base accelerations of 0.41g, the resulting computed top-level displacements are as shown in Table 2. Comparison of the maximum top-displacement responses with simulated earthquake excitations (Table 2) does not show any significant variation between FW4 and FW9 under the strong earthquake but significant variation does exist between FW1 and FW9. What is clear, however, is that the shear wall should not be interrupted at the bottom of the structure. The values in parentheses in the table are ratios of quantities between the part height and the full height shear walls.

TABLE 2

EFFECT OF SHEAR WALL HEIGHT ON TOP-LEVEL DISPLACEMENTS (mm)

Structures	FW1	FW4	FW9
d_c	24.2 (1.18)	20.1 (0.98)	20.5

Storey Drifts

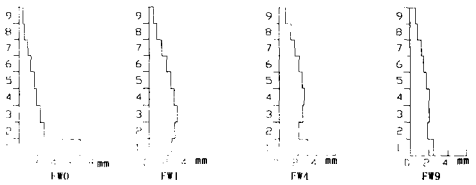

Figure 2: Computed storey drifts of the four structures

Distributions of computed storey drifts are plotted in Fig.2. For structure FW0, the discontinuity in the frame system in the first storey results in concentrations of interstorey drift and possible damage in that storey, interstorey drift in the first storey is many times that of the top-level drift. For structure FW9, the same irregularity as the frame FW0 is smoothed out by the shear wall that is continuous over the height of the structure. As a result, interstorey drifts for FW9 are nearly uniform over the full height. Structures FW1 and FW4 include shear walls to cover the first and fourth stories respectively, but a possible discontinuity is introduced at the locations of the wall cutoffs. Observed responses indicate that the larger drift is preset in the third storey for FW1. For the same shear wall cutoff in a different storey as in FW4, there is no apparent distress. Apparently, the location of the wall cutoffs affects the value of storey drift. It can be seen from Fig.2 that the drift shape of FW4 is almost the same as the drift shape of FW9 and the distributions of interstorey drifts for FW4 are more uniform over the entire height than for FW1. From Fig.2, it can also be seen that structures having the same stiffness cutoff, but occurring in different stories, do not perform equally. Using maximum drift as a criterion for comparison, terminating the wall at the midheight (as in FW4) does not affect response detrimentally. In contrast, terminating the same wall at a lower level of the structure FW1 results in behavior that is not significantly better than observed for the structure with no wall. It is means that a higher location of the wall cutoffs is better than a lower location for earthquake response. Drift distributions in FW4 do not reflect the apparent discontinuity in the lateral load resisting system. However, it should be noted that the drift at top level for FW4 is smaller than the drift for FW9 as shown in Fig.2. This means structure FW9 with the full height shear walls is subjected to more earthquake excitations than structure FW4. As mentioned above, the larger the stiffness of a structure, the more earthquake excitation (Wang 1991).

CONCLUSIONS

Four small-scale reinforced concrete frame-shear wall structures with and without shear wall cutoff, subjected to simulated earthquake excitations, have been studied and the analytical responses compared with experimentally measured responses. The study is aimed at determining analytically the effect of shear wall cutoff on storey drifts in the frame-shear wall structures with shear wall cutoff. Results from the shaking table are in agreement with the analytical results. Finally, it can be concluded that terminating a wall at midheight does not affect earthquake response detrimentally. If the shear wall is taller than that, the effect of the cutoff on the storey drifts is not significant. It is noted that these conclusions are based solely on the study reported in this paper, and further study of this topic is recommended.

HILBERT-HUANG TRANSFORM FOR DAMPING RATIO IDENTIFICATION OF STRUCTURES WITH CLOSELY SPACED MODES OF VIBRATION

J. Chen and Y. L. Xu
Department of Civil and Structural Engineering, The Hong Kong Polytechnic University
Hung Hom, Kowloon, HongKong

ABSTRACT:

This paper investigates the possibility of using the Hilbert-Huang transform method for modal damping ratios identification of the structure with closely spaced modal frequencies. A 2-story shear building under an impact excitation is studied for a wide range of dynamic properties from well-separated modal frequencies to very closely spaced modal frequencies. The damping ratio identification error by the HHT method as well as FFT method are compared with the theoretical value and then expressed as the function of normalized frequency space. The results show that the HHT method is superior to the FFT method in the identification of damping ratio of the structures with closely spaced modes of vibration. The HHT method seems to be a promising tool for parameter identification of linear structures.

System identification, closely spaced modal frequencies, modal damping ratio, the HHT method, the FFT method, random decrement technology

INTRODUCTION

The identification of damping ratios of a civil engineering structure is an important task toward the accurate dynamic response prediction and the reliable dynamic design of the structures. For a linear lightly-damped structure with well-separated modal frequencies, the Fast Fourier transform (FFT) method in conjunction with the bandwidth method are the most popular approach for identifying the modal damping ratios of the structure from the measured structural response time histories (Bendat and Piersol, 1993). This approach, however, may encounter difficulties when applied to structures with closely spaced modes of vibration.

Recently, a new data processing method named as Hilbert-Huang transform (HHT) has been proposed by Huang and his co-workers (1998), which consists mainly of empirical mode decomposition (EMD) and Hilbert transform (HT). Yang and Lei (1999, 2000) then successfully applied the HHT method to identify the modal parameters of linear structures based on the measured response data. They concluded that the HHT method offers a simple, effective and accurate tool for parametric

identification of linear structures. However, the example structures considered in their work are generally those with well-separated modal frequencies. The applicability of the HHT method to identify the structures with closely spaced modes of vibration has not been investigated yet.

Thus, the focus of this paper is to explore the possibility of using the HHT method to identify modal damping ratios of structure with closely spaced modes of vibration. The procedure suggested by Yang and Lei (1999) for modal damping ratio identification is adopted with some degrees of modification in respect of intermittency check. It is then applied to a 2-story building under impact load for a wide range of dynamic properties from well-separated modes of vibration to very closely spaced modes of vibration. The computed time-history of dynamic response of the system is first decomposed using the EMD with intermittency check to obtain the two modal free response time-histories of the system. The HT is then applied to each modal free response time history to estimate the natural frequency and modal damping ratio. The two modal damping ratios identified by the HHT method are finally expressed as the function of the function of the normalized frequency space and compared with those from the dynamic theory and those identified using the FFT method with the bandwidth method. These comparison show that the HHT method seems to be a promising tool for parameter identification of linear structures.

HHT FOR DAMPING RATIO IDENTIFICATION

Principle of HT for Parameters Identification of SDOF Structure

Application of Hilbert transform (HT) for modal parameters identification has been conducted for either linear or non-linear dynamic system (Feldman 1985, 1994; Hammond 1987). Considering a linear SDOF structure under the impulsive loading, for example, the impulse displacement response function of the structure is

$$v(t) = \begin{cases} 0, & t < 0 \\ A_0 e^{-\xi\omega_0 t} \sin \omega_d t, & t \geq 0 \end{cases} \tag{1}$$

where ω_0, ω_d =natural and damped circular frequency of the structure; ξ is the damping ratio; A_0 is a constant decided by the intensity of impulsive loading and the mass and frequency of the structure. To meet the requirement of applying the Hilbert transform, the impulse response function can be extended to the negative domain by considering its mirror image.

$$v(t) = A_0 e^{-\xi\omega_0|t|} \sin \omega_d t, \quad -\infty < t < \infty \tag{2}$$

The Hilbert transform of a real-valued function $y(t)$ in the range $-\infty < t < \infty$ is a real-valued function $\tilde{y}(t)$ defined by (Bendat and Piersol, 1986) as

$$\tilde{y}(t) = H[y(t)] = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{y(s)}{(t-s)} ds \tag{3}$$

where H denotes the Hilbert transform operator, P indicates Cauchy principal value. An analytic signal $Y(t)$ associated with $y(t)$ can then be defined as follows. An analytic signal means a signal having no negative frequency components with Fourier transform.

$$Y(t) = y(t) + i\tilde{y}(t) = A(t)e^{i\theta(t)} \tag{4}$$

$$A(t) = [y^2(t) + \tilde{y}^2(t)]^{1/2} \qquad \theta(t) = \tan^{-1}\left[\frac{\tilde{y}(t)}{y(t)}\right] \tag{5}$$

where $A(t)$ and $\theta(t)$ are defined as the amplitude and instantaneous phase angle of $y(t)$, respectively; and i is the imaginary unit. The instantaneous frequency $\omega(t)$ is then given by

$$\omega(t) = d\theta(t)/dt \tag{6}$$

Similarly, the corresponding analytic signal $z(t)$ for $v(t)$ of Eq. (2) can be obtained using Eq. (4) as

$$z(t) = v(t) + i\tilde{v}(t) = A(t)e^{-i\theta(t)} \tag{7}$$

For special case that ξ is small and ω_0 is fairly large, the amplitude $A(t)$ and the phase angle $\theta(t)$ for the SDOF system can be obtained as follows (Yang and Lei, 1999).

$$A(t) = A_0 e^{-\xi\omega_0 t} \tag{8}$$

$$\theta(t) = \omega_d t - \pi/2 \tag{9}$$

By introducing the logarithmic and differential operators to Eqs. (8) and (9) respectively, one obtains

$$\ln A(t) = -\xi\omega_0 t + \ln A_0 \tag{10}$$

$$\omega(t) = \frac{d\theta(t)}{dt} = \omega_d \tag{11}$$

Clearly, the damped natural circular frequency ω_d can be identified from the slope of instantaneous phase function $\theta(t)$. With the identified ω_d and the slope $-\xi\omega_0$ of the straight line of the decaying amplitude $A(t)$ in a semi-logarithmic scale, the damping ratio ξ can be identified from the function $\omega_d = \omega_0\sqrt{1-\xi^2}$. Considering that the instantaneous frequency may fluctuate around its mean value due to the amplitude variation of the signal (Huang, 1998) and that the requirement of small damping ratio may limit the application of the HT method, Yang and Lei (1999) suggested to determine the slope ω_d of the phase function $\theta(t)$ and the slope $-\xi\omega_0$ by applying the linear least-square fit technique to the linear function represented by Eq. (9) and Eq. (10).

Damping Ratio Identification Using HHT for MDOF Structure

For a linear MDOF system, its dynamic displacement response $v(t)$ caused by the external excitation $\boldsymbol{P}(t)$ can be expressed as the superposition of modal displacement responses.

$$v(t) = \sum_{j=1}^{N} v_j(t) = \sum_{j=1}^{N} \boldsymbol{\Phi}_j Y_j(t) \tag{12}$$

where N is the number of modes of vibration involved; $v_j(t)$ is the jth modal displacement response vector; $\boldsymbol{\Phi}_j$ is the jth mode shape; and $Y_j(t)$ is the jth modal response which can be computed from the following uncoupled modal equation.

$$\ddot{Y}_j(t) + 2\xi_j\omega_j\dot{Y}_j(t) + \omega_j^2 Y_j(t) = P_j(t)/M_j, \quad j = 1,2,...N \tag{13}$$

where ξ_j and ω_j are the jth modal damping ratio and natural circular frequency, respectively; and $P_j(t)$ and M_j are the jth modal force and modal mass, respectively.

It is seen from Eq. 12 that measured dynamic response time history of a MDOF consists of contributions from different vibration modes. Thus, directly application of the above mentioned identification procedure to MDOF structure can cause ambiguous meaning of instantaneous frequency as defined in Eq. (11). In general, band-pass filtering technology is necessary for the measured response in order to obtain a monocomponent signal that suitable for HT identification. Unfortunately, this filtering procedure may fail especially for structures with closely spaced modes of vibration (Staszewski, 1998). The EMD method is thus introduced to deal with this problem.

The empirical mode decomposition (EMD) is the key part of HHT method, which can decompose a complex signal into a series of intrinsic mode functions (IMF). This decomposition is based on the direct extraction of the energy associated with various intrinsic time scales of the time history itself (see detail in Huang et al, 1998). After EMD decomposition, the analyzed signal, e.g. $x(t)$ is finally expressed as the sum of the IMFs plus a final residue.

$$x(t) = \sum_{j=1}^{N} c_j(t) + r(t)_N \tag{14}$$

where N is the number of IMF components; and r_N is the final residue. An intrinsic mode function satisfies the following two conditions: (1) within the data range, the number of extrema and the number of zero-crossings are equal or differ by one only; and (2) the envelop defined by the local maxima and the envelop defined by the local minima are symmetric with respect to the mean.

Typically, different IMF has different time scale and the first IMF has the finest scale. However, when the analyzed data contain intermittency, directly application of EMD decomposition may cause mode mixing, which means that different time scales are contained in one IMF. Huang et al. (1999) then suggested a criterion called intermittency check to avoid mode mixing. The criterion works by specifying a cutting frequency ω_c for each IMF during EMD decomposition. Data having frequencies lower than ω_c will be removed from the resulting IMF.

It is pointed out by Huang et al. (1998) that the definition of instantaneous frequency for a signal has physical significance if it is an IMF. Thus we can use the EMD method to decompose the measured response of a MDOF structure into sum of IMF that admits well-behaved Hilbert transform. Therefore, the HHT method can be applied to identify ξ_j and ω_j ($j = 1, \cdots, N$) of a MDOF structure from the measured response time histories of the system under impulsive loading. The measured response time history is first decomposed into the IMFs using EMD method with intermittency check to obtain modal response time histories. The cutting frequencies used in EMD decomposition are determined from the power spectrum of the measured response time history. Then, for each of identified modal response time histories, the HT identification procedure for a SDOF system can be applied to identify the modal parameters ξ_j and ω_j.

NUMERICAL RESULTS

To explore the possibility of applying the aforementioned HHT method to identify the modal damping ratios of a structure with closely spaced modal frequencies, a 2-story shear building under an impulsive loading is studied for a wide range of dynamic properties from well-separated modal frequencies to very closely spaced modal frequencies. The equation of motion of the building can be expressed as follows:

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + (a \begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} + b \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix}) \begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ \delta(t) \end{Bmatrix} \tag{15}$$

where m_1 and m_2 are the two masses; k_1 and k_2 are the two stiffness coefficients; $\delta(t)$ is the impulsive load; it is equal to 1 when t=0 and equal to zero when $t \neq 0$; and the damping factors a and b are so decided that the two modal damping ratios are the same, which is

$$a = \frac{2 f_1 f_2}{f_1 + f_2} \xi \qquad b = \frac{2}{f_1 + f_2} \xi \tag{16}$$

Three typical levels of modal damping ratio of ξ=1%, 3% and 5% are considered in this investigation to see the effects of modal damping ratio on the applicability of the HHT method.

By changing the structural parameters m_1, k_1, m_2 and k_2 of the system, the difference (space) between the two natural frequencies are altered. To present a measure of the space (difference) between the two undamped natural frequencies f_1 and f_2, a space index (MSC NASTRAN, 1983) is adopted here.

$$\gamma = (f_2 - f_1)/(f_2 + f_1) \tag{17}$$

The index γ varies in a [0,1] range; a large value corresponds to well-separated modes of vibration while a small value denotes closely spaced modes of vibration. The maximum index considered in this application is 0.75 with f_1=1.10Hz and f_2=7.71, and the minimum index is 0.046 with f_1=3.39Hz and f_2=3.72Hz. The space index less than 0.046 is hardly achieved for the 2DOF structure investigated.

Fig.1 and Fig2 show the acceleration response time history of mass1 and its power spectrum for the case of structure with well-separated modal frequencies. In this case, the structural parameters are m_1=1 kg, m_2=2 kg, k_1=2256 N/m, and k_2=250 N/m. The two undamped natural frequencies are f_1=1.68Hz and f_2=7.99Hz with a corresponding space index of 0.66. The first two modal damping ratios are set as 5% using Eq. (16). From the power spectrum, the two natural frequencies and modal damping ratios can be easily identified using the FFT method in conjunction with the bandwidth method. The results are listed in Table 1. To identify the modal damping ratios of the system using the HHT method, the EMD method with the intermittency check is applied to the acceleration response time history of mass 1 with the cutting frequency of 4.39 Hz, which is the trough between two peaks of the spectrum. Since it is a 2DOF system, only one cutting frequency for the first IMF component is designed in the implementation of intermittency check during the EMD. A total of 5 IMF components are obtained by EMD. The first and second IMF components are plotted in Fig.3 and 4, respectively, together with the theoretical second and first modal responses of mass 1 of the system correspondingly.

It can be seen from Fig. 3 and Fig. 4 that the first IMF and second IMF component are nearly the same as the second and first modal response of mass 1 of the structure. Then, by applying the Hilbert transform to the first two IMF components, the instantaneous phase angle and amplitude of each IMF component can be obtained as the function of time. Shown in Fig. 5 and 6 are the instantaneous phase angle and amplitude of the first IMF component together with the fit lines using the linear least-square fit technique. The modal damping ratio and natural frequencies can then be identified from the slopes of the two fit lines, and the results are listed in Table 1. It is seen from Table 1 that the modal damping ratios identified by the FFT method are slightly smaller than the theoretical values, but the modal damping ratios identified by the HHT method are very close to the theoretical values.

TABLE 1 2-STORY STRUCTURE WITH WELL-SEPARATED MODAL FREQUENCIES

	Damped Frequency (Hz)			Damping ratio		
	Theoretical Value	FFT	HHT	Theoretical Value	Bandwidth Method	HHT
First Mode	1.68	1.71	1.68	5%	4.62%	5.02%
Second Mode	7.98	7.99	7.99	5%	4.81%	5.01%

For the case of structures with very closely spaced modes of vibration, acceleration response time history of mass 2 of the structure and its power spectrum are shown in Fig. 7 and Fig.8. Here, the structural parameters are selected as m_1=11.6 kg, m_2=0.1kg, k_1=3256 N/m, and k_2=30N/m. The two modal damping ratios are set as 5%. The two undamped natural frequencies are computed as f_1=2.58Hz and f_2=2.85Hz giving a space index of 0.050. It is seen from Fig. 8 that there are two peaks corresponding to the two damped natural frequencies. However, these two peaks are too close to each other to identify the two modal damping ratios using the bandwidth method. Thus, the HHT method is applied to the acceleration response time history of mass 2 to identify the modal damping ratios. The used cutting frequency in the EMD is 2.68 Hz. A total of 6 IMF components are obtained, the first and second IMF components are plotted in Figs. 9 and 10, respectively, together with the second and first modal responses of mass 2. It is seen that due to the closely spaced modes of vibration, the first two IMF components deviate from the theoretical modal responses to some extents. The instantaneous phase angles and amplitudes obtained by the HHT method and their linear least-square fits are shown in Figs 11 and 12 for the first IMF component. The identified natural frequencies and

modal damping ratios by the HHT method are listed in Table 2 together with the theoretical values. It is seen that the natural frequencies identified by the HHT method and the FFT method are quite close to the theoretical values. The two modal damping ratios identified by the HHT method are larger than the theoretical values but less than 10%. The FFT method together with the bandwidth method, however, fails to identify the modal damping ratios.

To examine further the applicability of the HHT method for the identification of modal damping ratios, the identified results of the first modal damping ratio using both HHT method and FFT method are shown, in terms of the relative damping ratio error against the space index, in Figs.13a, 13b, and 13c for the cases of the theoretical modal damping ratio of 1%, 3% and 5%, respectively. The relative damping ratio error is defined as the ratio of the absolute value of the difference between the identified damping ratio and the theoretical value to the theoretical value.

It is seen that for the case of 1% modal damping ratio, the modal damping ratio identified by the HHT method is almost the same as the theoretical value and independent of the space index. The relative damping ratio error caused by the FFT method, however, increases with the decrease of space index but the relative error is smaller than 0.7%. For the case of 3% modal damping ratio, the modal damping ratio identified by the HHT method is almost the same as the theoretical value if the space index is less than 0.13. Then, with the decrease of space index, the relative error increases but it is less than 3% within the concerned range. The deviation of the modal damping ratio identified by the FFT method increases with the decrease of space index but the maximum error in the concerned space index range is less than 7%. For the case of 5% modal damping ratio, the FFT method with the bandwidth method fails to identify the modal damping ratio when the space index γ becomes less than 0.053 but the HHT method is still workable. Though the relative damping ratio error becomes large for the case of 5% modal damping ratio, it is less than 10% when γ is larger than 0.05 when using the HHT method. The HHT method seems more robust than the FFT method for different levels of structural damping. The results clearly demonstrate that the HHT method is superior to the FFT method in the identification of modal damping ratios of the structure with closely spaced modes of vibration.

CONCLUDING REMARKS

This paper investigates the identification of modal damping ratio using Hilbert-Huang transform with emphasis on the structures with closely spaced modes of vibration. Application of the HHT method for damping ratio identification of a 2-DOF structure under impact load has been conducted for a wide range of dynamic properties from well-separated modal frequencies to very closely spaced modal frequencies. The identified results are compared with that obtained by FFT method, showing clearly that the HHT method is superior to the FFT method in the identification of damping ratio of the structures with closely spaced modes of vibration. The HHT method performing in the frequency-time domain seems to be a promising tool for system identification of linear structures. Further works are needed to investigate its practical application for noise-included measurements.

ABSTRACT

The wind and structural monitoring system installed in the Di Wang Building timely recorded wind and structural response data during Typhoon York in September 1999. The newly emerged Hilbert-Huang transform (HHT) method together with the random decrement technique (RDT) is applied in this paper to the measured data to identify dynamic characteristics of the building. A series of natural frequencies and modal damping ratios of the building under different wind speeds in different directions are identified and compared with those from the fast Fourier transform (FFT)-based method. The results show that the natural frequencies identified by the HHT method and the FFT method are almost the same, but the modal damping ratios identified by the two methods are different to some extent. The results also show that the total modal damping ratios increase with increasing wind speed and vibration amplitude but the situation is reversed for the natural frequency.

KEYWORDS: Di Wang Building, system identification, HHT, RDT, FFT method, comparison

INTRODUCTION

For tall buildings, the most popular approach for identifying natural frequency and modal damping ratio is to carry out ambient vibration measurement and then apply the fast Fourier transform (FFT)-based method to the measured building response time histories. However, this method often overestimates modal damping ratios due to bias errors involved in the spectral analysis (Litter and Ellis, 1995) though it can identify natural frequencies quite accurately. This approach will become more questionable to identify the modal damping ratios when the building response is non-stationary. The random decrement technique (RDT) may be an alternative to identify building modal damping ratios (Tamura 1996) but the same constraints on the data source (stationary, well separated modes of vibration) make it difficult to use effectively (Jeary, 1986).

Recently, Huang and his co-workers (1998) proposed the Hilbert-Huang transform (HHT) method, which consist of mainly the empirical mode decomposition (EMD) and the Hilbert transform (HT). The most powerful feature of the HHT method is capable of analyzing nonlinear and non-stationary time histories in the frequency-time domain. Yang and Lei (1999, 2000) successfully applied the HHT method together with the random decrement technique (RDT) to identify the modal parameters of linear

structures. They concluded that the HHT method offers a simple, effective and accurate tool for parametric identification of linear structures. However, this approach has not been examined yet using the field measurement data of real tall buildings under strong winds.

This paper thus applies the HHT method to the field measurement data of the Di Wang Building during Typhoon York to identify the dynamic characteristics of the building. The natural frequencies and modal damping ratios identified by the HHT method are then compared with those obtained by the FFT-based method to evaluate the applicability and superiority of the HHT method. The changes of natural frequencies and damping ratios with wind speed and building vibration amplitude are also investigated.

WIND AND STRUCTURAL RESPONSE DATA

The Di Wang Building, located in the downtown Shenzhen City of China, is one of the tallest composite buildings in the world. The height of the main structure is 310m and the width and depth of the building are 70 m and 37m respectively. On 16 September 1999, Typhoon York, which is the strongest typhoon since 1983 and the typhoon of longest duration on record, attacked Hong Kong and Shenzhen. The wind and structural monitoring system installed in Di Wang Building timely recorded both wind and structural response data. The detailed information on the Di Wang Building, Typhoon York and the monitoring system can be found in Xu and Zhan (2001).

The recorded time histories of 38 hours duration starting from 17:20 HKT, 15 September 1999 to 8:20HKT, 17 September 1999 are used for analysis in this paper. From the recorded wind speed and direction data at a height of 348m, it is found that the wind direction changes from the north-east to the south-west in clockwise and then remains almost constant. The high mean wind speeds occur during the transition period of wind direction, 4:00 to 19:00 on September 16. The maximum hourly mean wind speed is 33.80 m/s, which occurs between 6:00 to 7:00 HKT on September 16.

By averaging the signals from the north and south lateral displacement transducers, one may have the averaged lateral dynamic displacement response of the building with respect to its shear center, for these two transducers are symmetrically installed to the lateral axis on the 69th floor. The torsional dynamic displacement response can be obtained as the difference of the two lateral displacement responses divided by the distance between the two transducers. The longitudinal displacement response is taken directly from the channel installed on the longitudinal axis. The lateral, longitudinal, and torsional acceleration responses can be obtained n a similar way. Figs. 1 shows the lateral acceleration response time history of one hour duration from 16:00 to 17:00 HKT on 16 September 1999.

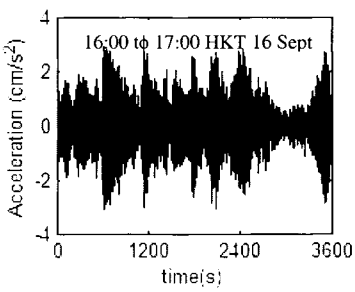

Fig. 1 Lateral Acceleration Response Time History

THE HHT METHOD FOR MODAL IDENTIFICATION

The Hilbert-Huang transform (HHT) method was proposed by Huang et.al. (1998). The basic procedure of using the HHT method to identify the natural frequencies and modal damping ratios from the measured response time histories can be followed in three steps. The measured structural response time history is first decomposed into the intrinsic mode functions (IMFs) using the empirical mode decomposition (EMD) method with the intermittency check to obtain modal response. The random decrement technique (RDT) is then applied to each of the modal response to extract the free modal response. Finally, the Hilbert transform (HT) is applied to each of the free modal response time histories to obtain the corresponding natural frequency and modal damping ratio.

Empirical Mode Decomposition (EMD)

By applying the EMD method, a complicated time history can be decomposed into a series of IMFs, $c_j(t)$, that admit well-behaved Hilbert transforms. The original time history $x(t)$ can be then expressed as the sum of the IMFs plus the final residue,

$$x(t) = \sum_{j=1}^{N} c_j(t) + r(t)_N \tag{1}$$

where N is the number of IMFs; and r_N is the final residue.

To avoid the mode mixing during the sifting process, a criterion was suggested by Huang et al. (1999) to separate the waves of different periods into different modes based on the modal frequencies. This criterion is named as the intermittency check, decided by the lower limit of the frequency ω_c that will be included in any given IMF component. The intermittency check, however, should be applied with care, for any additional criterion introduced in the sifting process implies an intervention with a subjective condition.

Random Decrement Technique(RDT)

When applying the random decrement technique (RDT) to each of the modal response time histories (Ibrahim, 1977), a threshold level should be selected to obtain N segments. The j^{th} free modal response $\ddot{x}_j^f(t)$ can be then obtained from the ensemble average of all segments as

$$\ddot{x}_j^f(i\Delta t) = \frac{1}{N}\sum_{k=1}^{N} \ddot{x}_j^t(t_k + i\Delta t); \quad i = 1,2,...,m \tag{2}$$

where $\ddot{x}_j^t(t)$ is the j^{th} modal response; t_k is the starting time for each segment; and $m\Delta t = t$ with t being the duration of each segment.

Hilbert Transform

The Hilbert transform (HT) has long been used to study linear and nonlinear dynamic systems and to identify their modal parameters in the frequency-time domain (Feldman 1985, 1994; Hammond 1987). The Hilbert transform of a real-valued function $v(t)$ in the range $-\infty < t < \infty$ is a real-valued function $\tilde{v}(t)$. By applying the HT method, the analytical signal $z(t)$ for $v(t)$ can thus be obtained as

$$z(t) = v(t) + i\tilde{v}(t) = A(t)e^{-i\theta(t)} \tag{3}$$

where $A(t)$ is the amplitude and $\theta(t)$ is the phase angle. The frequency-time distribution of the amplitude is designated as the Hilbert amplitude spectrum. Yang and Lei (1999) suggested the following procedures for the system identification of SDOF systems based on the HT method: (1) determine the damped frequency ω_d from the slope of the phase function $\theta(t)$ by the linear least-square fit technique; and (2) determine $\xi\omega$ by applying the linear least-square fit technique to the decaying amplitude $A(t)$ in a semi-logarithmic scale. After ω_d and $\xi\omega$ have been got, the natural frequency ω and damping ratio ξ can be obtained consequently.

COMPARISON OF MODAL FREQUENCIES AND DAMPING RATIOS

Data base

The time histories of acceleration response of one-hour duration are used to identify the first two natural frequencies and modal damping ratios. It is found that the structural response may vary considerably

within one-hour duration, which may affect the true change of natural frequency and modal damping ratio with hourly mean wind speed and hourly response standard deviation. To solve this problem, ten-minute standard deviations of structural displacement response in one-hour time history and the maximum difference between these six standard deviations are computed. If the maximum difference exceeds a specified value, the corresponding histories will not be included in the modal identification. As a result, a total of 14 one-hour time histories in different directions are selected for the subsequent modal identification. The time histories in lateral direction are listed in Tables 1. In the tables, "sep15" means "September 15" and "t19" denotes time "19:00 to 20:00 HKT" for instance.

Data analysis

The HHT method is applied to each selected acceleration response to obtain the Hilbert spectrum in the frequency-time domain. A typical Hilbert spectrum for the acceleration time history shown in Fig.1 is presented in Fig.2. From this Hilbert spectrum, the first two instantaneous frequencies can be easily found around 0.2 Hz and 0.7 Hz, respectively. The cutting frequencies required by the imtermittency check for the first two modal responses are then determined as 0.125 Hz, 0.25 Hz, and 0.9375 Hz. The first three-minute duration of the resulting first two modal response time histories are plotted in Fig.3 for the acceleration time history shown in Fig. 1. It is seen that each modal response is dominated by only one frequency and almost symmetric with respect to the horizontal line at zero level.

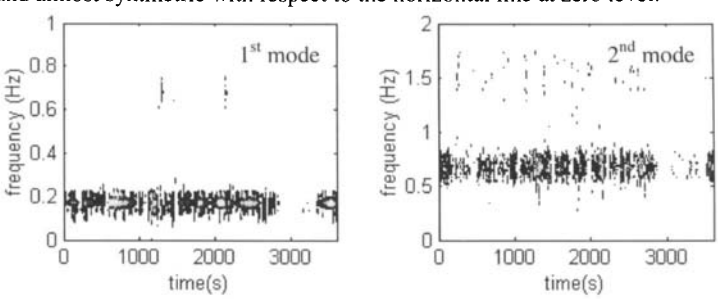

Fig. 2 Hilbert Spectra of Lateral Acceleration Response

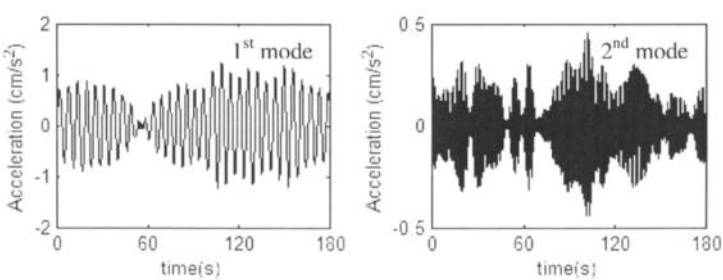

Fig. 3 First Two Total Modal Acceleration Response

Then random decrement technique (RDT) is the applied to the total modal responses to extract the free modal responses. The optimal threshold level used in the RDT would be in the range from 1.0σ to 1.5σ, where σ is the standard deviation of the time history. In this study, the threshold level is chosen as $1.5\ \sigma$. The duration of segment can be determined in such a way that the RDT function is fully decayed. The durations used in this study are 90 seconds and 25 seconds for the 1st and 2nd lateral modes of vibration, 100 seconds and 25 seconds for the 1st and 2nd longitudinal modes of vibration, and 60 seconds and 20 seconds for the 1st and 2nd torsional modes of vibration. The number of segments used in the RDT for each total modal response time history must be large enough. The number of segment used in this study is more than 270, 354, and 420 for the 1st lateral, longitudinal, and torsional mode of vibration. The number of segment for the 2nd lateral, longitudinal, and torsional mode of

vibration is more than 1103, 1127, and 1571, respectively. Fig. 4 depicts the 1st and 2nd free modal response time histories resulting from the 1st and 2nd total modal response time histories shown in Fig. 3 by the RDT.

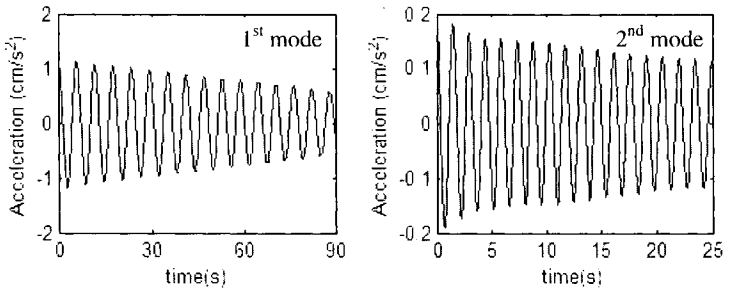

Fig. 4 First Free Total Modal Acceleration Response

The last step is to apply the HT method to each of the free modal response time histories to yield the instantaneous phase angle and amplitude functions and then the modal frequencies and modal damping ratios. Table 1 lists the first two natural frequencies and modal damping ratios of the Di Wang Building identified by the HHT method for different time periods in lateral direction. The results in longitudinal and torsional directions are omitted due to the space limitation.

To assess the applicability and superiority of the HHT method, the FFT method is also used to obtain the dynamic characteristics. The data number of each FFT is taken as 8192. The half-power bandwidth method is then applied to find the modal frequencies and modal damping ratios. The results identified by the FFT-based method for different time periods in lateral direction are shown in Table 1.

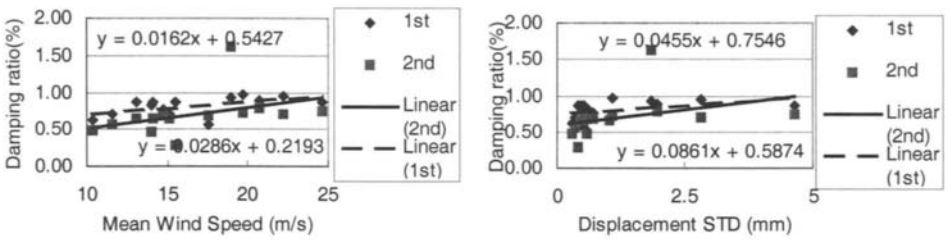
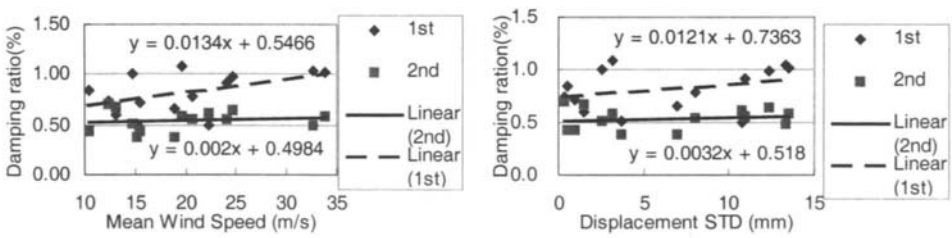
Comparison



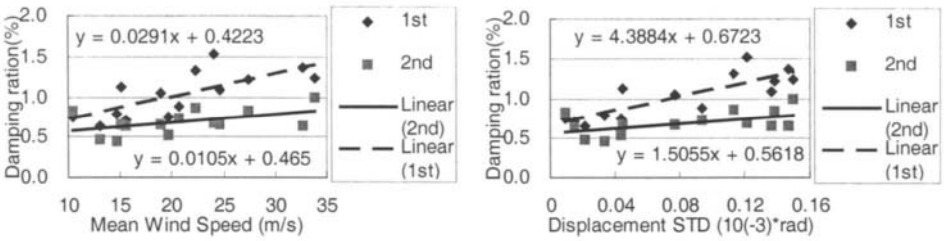
It is seen from the table that the modal frequencies identified by the HHT method are almost the same as those identified by the FFT method. In the lateral direction, the ratio of the 1st modal frequency identified by the FFT method to that identified by the HHT method ranges from 0.9925 to 1.0041, having a mean value of 0.9992. The ratio of the 2nd modal frequency ranges from 0.9987 to 1.0021, having a mean value of 1.0007. Similar frequency ratios are obtained in the longitudinal and torsional directions. However, the modal damping ratios by these two methods are different. The ratios of the modal damping ratio identified by the FFT method to that identified by the HHT method range from 1.02 to 2.95 for 1st mode and from 0.81 to 2.33 for the 2nd mode in the lateral direction. The corresponding mean values are 1.75 and 1.18 respectively. The FFT method seems to overestimate the modal damping ratio. Similar results have been obtained in the other two directions.

In consideration of the inherent drawback in the FFT-based half-power bandwidth method performed in the frequency domain and the adaptive nature of the HHT method performed in the frequency-time domain for modal damping ratio identification, the modal damping ratios identified by the HHT method may be more reliable than those by the FFT method. Thus, the investigation of the variations of modal frequency and damping ratio with vibration amplitude and wind speed are based on the results obtained from the HHT method.



VARIATIONS OF MODAL PROPERTIES WITH WIND SPEED AND RESPONSE AMPLITUDE

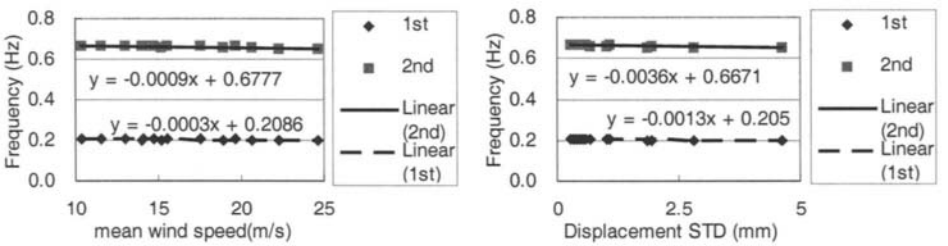
Variations of total modal damping ratio with wind speed and response amplitude



The variations of the first two total modal damping ratios with hourly mean wind speed and hourly standard deviation of displacement response in different directions are plotted in Fig 5. The linear least-square fits to these data are also plotted in the figure. It is seen that the total modal damping ratios increase with the increase of hourly mean wind speed and displacement standard deviation.

(a) Longitudinal

(b) Lateral



(c) Torsional

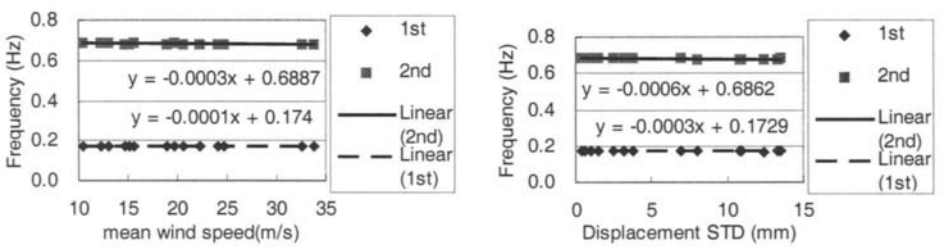


Fig. 5 First Two Total Modal Damping Ratios vs. Mean Wind Speed and Vibration Amplitude

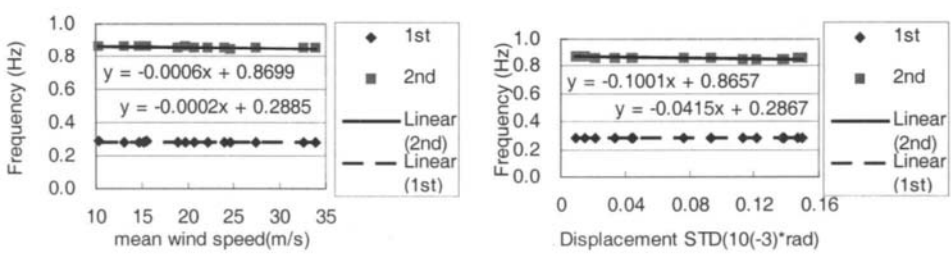
Variations of natural frequencies with wind speed and response amplitude



The changes of the first two natural frequencies with the hourly mean wind speed and the hourly standard deviation of displacement response, plus with their linear least-square fits are shown in Figs.6. It is seen that all the modal frequencies decrease very slightly with increasing hourly mean wind speed and the displacement standard deviation.

Fig. 6 First Two Modal Frequencies vs. Mean Wind Speed and Vibration Amplitude

CONCLUSIONS

The Hilbert-Huang transform (HHT) method has been applied to the measured wind and structural response data of the Di Wang Building to identify its dynamic characteristics. A series of natural frequencies and modal damping ratios of the building under different wind speeds in different directions have been identified and compared with those by the FFT-based method. The results show that the natural frequencies identified by the HHT and FFT method are almost the same. The modal damping ratios identified by the HHT method indicate that the FFT-based bandwidth method may significantly overestimate the modal damping ratios. The total structural modal damping ratio increases slightly with increasing wind speed and vibration amplitude but the situation is reversed for the natural frequency.

DISCUSSION ON DYNAMIC COEFFICIENTS FOR WIND-RESISTANT DESIGN IN SINGLE-LAYER RETICULATED SHELLS

Y. Q. Li

Department of Structural Engineering, Tongji University,
Shanghai 200092, People's Republic of China

ABSTRACT

Wind load is an important load in structural design of large-span single-layer reticulated shells. In order to consider the effects of fluctuating component of wind in a quasi-static wind-resistant design method, dynamic coefficients are usually used. In this paper, a method using artificial simulated wind load to estimate the coefficients has been presented. Based on wind load code of China, a Kiewitt type single-layer reticulated spherical shell was used as an example to investigate the dynamic coefficients, which is named wind-excited vibration coefficients in this code. Through a comparison between dynamic time-history analysis results and quasi-static analysis results, it is proved that the wind-excited vibration coefficients should be paid much attention to for wind-resistant design in large-span single-layer reticulated shells.

KEYWORDS

large-span single-layer reticulated shells, wind-excited vibration coefficient, artificial simulated wind load, *p*-order auto-regressive simulation technique

INTRODUCTION

The single-layer reticulated shell is an excellent large-span spatial structural system, which has been widely used. However, this system is very sensitive to the distribution of external load, and stability problem is dominant for structural safety. Considering the fluctuating and random characteristics of wind load, wind action becomes a very important load for the structural design of large-span single-layer reticulated shells, which should be paid more attention to than earthquake action in most cases. Therefore, it is necessary to estimate wind load more reasonable for this structure. In order to consider the effects of fluctuating components of wind in quasi-static wind-resistant design methods, dynamic coefficients are usually used. At present, a quasi-static method is used in GBJ 99-87 (1989), as the same as in wind-resistant design of other structures, such as tall buildings. Thus, the quasi-static wind load is estimated by following equation:

$$w_k = w_0 \mu_z \beta_z \mu_s \tag{1}$$

Where w_0 is the basic wind pressure in site, μ_z is the height coefficient, β_z the wind-excited vibration coefficient, and μ_s is the shape coefficient.

In Eq.(1), the result of ($\mu_z \mu_s w_0$) can be taken as the mean wind pressure for a corresponding point, where μ_z is a modifying coefficient for the height of the point and μ_s is another modifying coefficient for the place of the point on the surface of shell. Therefore, the wind-excited vibration coefficient β_z is a dynamic coefficient using to reflect the effect of fluctuating components of wind.

Up to now, widely accepted rules for estimating the values of wind-excited vibration coefficient in wind-resistant design of large-span single-layer reticulated shells do not exist in wind load code of China. Generally, empirical values for the coefficients were used for all the nodes of the structure. In fact, the coefficients will be different according to many parameters of single-layer reticulated shells, including the geometrical shape and flexibility of shell, the rise to span ratio, and even the spatial effects of wind load with the increase of span. Therefore, it is necessary to do further research on how to determine the suitable wind-excited vibration coefficients for such structural system. In this paper, considering the time and spatial correlation of natural wind, the artificial wind speed processes were simulated by an *p*-order autoregressive-type simulation method, and the super-relaxation iteration method was chosen to solve the large-scale matrix of regressive coefficients during the simulation. Through a comparison analysis on the characteristics of simulated wind, it was proved reasonable. Using the artificial simulated wind load, the wind-excited vibration responses of an single-layer reticulated spherical shell were investigated as an example with dynamic time-history analysis. Then, a statistic method was used to deal with the response variables including wind loads, displacements of nodes and internal forces of elements. At the same time, the quasi-static method suggested by wind load code was also used to analyze the same shell. Based on a comparison of the results from two methods, the suitable values of wind-excited dynamic coefficients were discussed.

SIMULATION OF WIND LOAD

Estimation of wind load is the first step for wind-resistant analysis. In this paper, time series of wind forces at each node of single-layer reticulated shells will be generated from artificial simulated wind. Many works have been done on how to simulate the spatial distribution of windspeed (Kareem, A. (1999)). Provided the windspeed processes abide by Gaussian distribution, mainly there are two kinds of simulation method, one is the spectral technique including CAWS (the Constant Amplitude Wave Superposition) and WAWA (Waves with Weighted Amplitude), the other is the time series methods including the autoregressive (AR) scheme, moving average (MA) scheme and their combination method ARMA. Anyways, for a practical project of large-span single-layer reticulated shells with so many degrees of freedom (DOFs), it's always a painstaking thing to simulate the windspeed at each joint. In this paper, the *p*-order auto-regressive filter technique is used to simulate the time series of windspeed, which was proved efficient for large DOFs problems (Li Y.Q. (2000)).

Brief introduction of the simulating process

In the *p*-order AR method, M multi-correlated random processes as $[u(t)] = [u^1(t) \quad \cdots \quad u^M(t)]^T$ can be generated by following equations (Iannuzzi, A.and Spinelli, P. (1987)):

$$[u(t)] = \sum_{k=1}^{p} [\Psi_k][u(t - k\Delta t)] + [N(t)] \tag{2}$$

Where, $[u(t-k\Delta t)]=[u^1(t-k\Delta t) \cdots u^M(t-k\Delta t)]^T$; $N(t)=[N^1(t) \cdots N^M(t)]^T$, $N^i(t)$ is a Gaussian white noise random process, $i=1,\cdots,M$; $[\Psi_k]$ is a $M\times M$ matrix of autoregressive coefficients, $k=1,\cdots,p$.

From Eq.(2), we can obtain the relationship between the covariance matrix $R_u(j\Delta t)$ and regressive coefficient matrix Ψ_k as follow:

$$[R]=[\overline{R}][\Psi] \tag{3}$$

Where,

$$[R]_{pM\times M}=\left[R_u{}^T(\Delta t),\cdots,R_u{}^T(p\Delta t)\right]^T \tag{4}$$

$$[\Psi]_{pM\times M}=\left[\Psi_1^T,\cdots,\Psi_p^T\right]^T \tag{5}$$

$$[\overline{R}]_{pM\times pM}=\begin{bmatrix} R_u(0) & R_u(\Delta t) & \cdots & R_u[(p-2)\Delta t] & R_u[(p-1)\Delta t] \\ R_u(\Delta t) & R_u(0) & \cdots & R_u[(p-3)\Delta t] & R_u[(p-2)\Delta t] \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ R_u[(p-2)\Delta t] & R_u[(p-3)\Delta t] & \cdots & R_u(0) & R_u(\Delta t) \\ R_u[(p-1)\Delta t] & R_u[(p-2)\Delta t] & \cdots & R_u(\Delta t) & R_u(0) \end{bmatrix} \tag{6}$$

$$[R_u(j\Delta t)]_{M\times M}=\begin{bmatrix} R_u^{11}(j\Delta t) & \cdots & R_u^{1M}(j\Delta t) \\ \vdots & \ddots & \vdots \\ R_u^{M1}(j\Delta t) & \cdots & R_u^{MM}(j\Delta t) \end{bmatrix}, j=1,\cdots,p \tag{7}$$

$$[\Psi_j]_{M\times M}=\begin{bmatrix} \Psi_j^{11} & \cdots & \Psi_j^{1M} \\ \vdots & \ddots & \vdots \\ \Psi_j^{M1} & \cdots & \Psi_j^{MM} \end{bmatrix}, j=1,\cdots,p \tag{8}$$

Based on Wiener- Khintchine Equation, the relationship between the covariance and power spectrum density can be obtained as

$$R_u^{ik}(j\Delta t)=\int_0^\infty S_u^{ik}(n)\cos(2\pi nj\Delta t)dn\ ,\quad i,k=1,\cdots,M \tag{9}$$

In order to resolve Eq. (3), A super-relaxation iteration method was chosen in the paper to solve the large-scale matrix equation group of regressive coefficients.

$$x_{ij}^{k+1}=\omega[(-\sum_{l=1}^{i-1}r_{il}x_{lj}^{k+1}-\sum_{l=i+1}^{N}r_{il}x_{lj}^{k}-y_{ij})/r_{ii}]+(1-\omega)x_{ij}^{k},\quad \begin{matrix} i=1,\cdots,N \\ j=1,\cdots,M \end{matrix} \tag{10}$$

Where ω is a relaxation factor. It has been proved that the calculation will be steadily convergent if $0<\omega<2$. Specially, if $\omega=1$, it become to the Gauss-seidel iteration method. For the super-relaxation iteration method, $1<\omega<2$.

Provided ε is the convergent limit, a convergent rule can be used as follow:

$$\left|\sum_{l=1}^{N}x_{lj}^{k+1}x_{lj}^{k+1}-\sum_{l=1}^{N}x_{lj}^{k}x_{lj}^{k}\right|\le\varepsilon\ ,\quad j=1,\cdots,M \tag{11}$$

As for $[N(t)]$, it can be calculated from a Cholesky's factorization, $[R_N]=[L][L]^T$, as follows:

$$[R_N] = [R_u(0)] - \sum_{k=1}^{p} [R_u(k\Delta t)] \tag{12}$$

$$[N(t)] = [L][n(t)] \tag{13}$$

Thus, we can obtain M spatially correlative discrete random processes with interval Δt and mean value of zero. Usually, windspeed at one point can be divided into two parts, the mean wind speed $\overline{V}$ and the fluctuating component $v(t)$. Here, the simulated random processes $u(t)$ can be taken as the fluctuating component $v(t)$ as follows

$$V(t) = \overline{V} + v(t) = \overline{V} + u(t) \tag{14}$$

Based on wind load code, we can obtain the basic wind pressure w_0. According to the relationship between wind speed and wind pressure, the basic mean windspeed can be calculated by

$$\overline{V} = \sqrt{2w_0 / \rho} \tag{15}$$

Where ρ is the density of air.

Examples of windspeed simulation

An example was used to check the reasonability of simulated results, as shown in Fig.1. Here, the mean windspeed $\overline{v}_{10}$=25m/s, the roughness length z_0=0.2m, the time interval Δt=0.1s, and the order p=4. Simulated time series of windspeed at Point A and B are given in Fig.2. Fig.3 gives a comparison of power spectrum density (PSD) of simulated results with target PSD, the well-established Von Karman spectrum formula (Von Karman, T.(1948)). It can be seen that the PSD of simulated processes are well consistent with the target PSD.

DYNAMIC ANALYSIS OF A SINGLE-LAYER RETICULATED SPHERICAL SHELL

As an example, a Kiewitt type (K6-12) single-layer reticulated spherical shell was used to investigate the wind-excited vibration coefficients, as shown in Fig.4. The span L is 100m and the rise f is 40m. The height of bottom is 40m. All the elements are 180mm diameter tubes with 5mm thickness. $\bar{v}_{10}$=25m/s, z_0=0.4m. Fig.5, 6, 7 and 8 gave a part results about the simulated time series of windspeed and wind force, the responses of node displacement and element internal force, respectively.

COMPARISON WITH QUASI-STATIC ANALYSIS RESULTS

Based on wind load code, a quasi-static method was used to analyze the same shell. According to Eq.(15), the basic wind pressure is 0.391 kN/m^2 at $\overline{V}$ =25 m/s. The wind-excited vibration coefficient β_z was equal to 2.0 temporarily. On the other hand, we can calculate the coefficients from dynamic results. To a variable u with a confidence interval [$\bar{u}$ - d, $\bar{u}$ + d] corresponding to a certain confidence level (1-α), a dynamic coefficient can be obtained as follows:

$$\beta = ((\bar{u})_d \pm d)/(\bar{u})_s \tag{16}$$

Where $(\bar{u})_d$ is the mean value of u from dynamic analysis, $(\bar{u})_s$ is the corresponding result from quasi-static analysis. α is the probability that the value of u is out of the confident interval [$\bar{u}$ - d, $\bar{u}$ + d], this is, $\alpha = P\{u < \bar{u} - d \quad or \quad u > \bar{u} + d\}$. If u is a response variable, β is called as the dynamic to static ratio of u, which is often used in structural analysis. While if u is the wind force, β will have the same function with the gust factor (Solari G. (1990)), although the calculation methods are different. Anyways, the value of β can be taken as an estimation of the wind-excited vibration coefficient.

According to Eq.(15), the values of β according to wind forces, displacement of node and axial force of element with a confidence level of 95% are given in Table 1, 2 and 3, respectively. It should be pointed out that in quasi-static analysis we had used a temporal dynamic coefficients of 2.0.

	Z	0.00057	0.00062	1.81	0.00067

TABLE 3: Dynamic coefficients of part elements according to axial force

Element No.	Dynamic analysis results (kN)		β	Quasi-static analysis results (kN)
	Mean axial force	σ of axial force		
4	49.73	11.40	1.76	57.47
10	25.61	10.68	1.65	31.86
23	52.74	10.75	1.58	67.72
24	18.37	12.34	1.71	22.41
37	19.05	9.70	1.68	23.41
59	48.72	9.37	1.70	58.06
60	10.24	6.14	1.69	12.57
82	12.66	7.41	1.80	14.57

From Table 1, we can find that with the confident level of 95%, the wind-excited vibration coefficients are about 1.7 according to wind force. If according to node displacement with the same confident level, the wind-excited vibration coefficients become a little larger, as shown in Table 2. While if based on the axial force of elements with the same confident level, the wind-excited vibration coefficients are varying between 1.58 and 1.80.

CONCLUSIONS

Wind-excited vibration coefficients are important in generating wind force of each node in wind-resistant design of large-span single layer reticulated shells. This paper just presents a simple ideal about how to obtain the coefficients. However, other factors, such as the effects of geometrical nonlinear characteristics, the interaction between wind and shells, are also necessary to be considered, especially with the increase of span or flexibility. Furthermore, wind tunnel model tests should be carried out to measure the simultaneous pressure distribution on the surface of shell with different rise to span ratios. On the other hand, such tests can be used to check the reasonability of simulated wind pressure distribution of shell surface, especially the spatial correlation. From the analysis results in this paper, the values of wind-excited vibration coefficients according to wind forces and wind-induced vibration responses are different. To the example shell used in this paper with a rise to span ratio of 0.4, the wind-excited vibration coefficients from wind force is about 1.7, while based on the response variables, it will become a little larger. From the point of view of a structural designer, it is better to consider the values of wind-excited vibration coefficients based on the responses of shells.

WIND MODELING IN *BLWT* AND DISCUSSION ON SEVERAL PROBLEMS

Y. Q. Li, Y. Tamura, A. Yoshida and A. Katsumura

Dept. of Architectural Engineering, Tokyo Institute of Polytechnics,
Atsugi, Kanagawa 243-0297, Japan

ABSTRACT

In this paper, wind modeling in the new boundary layer wind tunnel of Tokyo Institute of Polytechnics (TIP) was introduced briefly. Based on the test results, windspeed profiles and turbulence intensity profiles corresponding to different terrains defined by the loading code of Japan were simulated successfully. With comparative analysis of the measured data, the effects of blocks and spires on the profiles in this BLWT were presented. Several problems, including the optimal shape of spires, the consistency of power spectral density and the calculation methods for length scales were discussed. Finally, some advices about modeling wind in BLWT and processing the measured data were given for future reference.

KEYWORDS

boundary layer wind tunnel (BLWT), wind modeling, approach flow, windspeed profile, turbulence intensity profile, power spectral density, length scale

INTRODUCTION

At present, wind tunnel tests are widely used in many aspects, including obtaining overall or local wind load distribution of buildings, observing the wind-induced vibration responses of structures, evaluating pedestrian level winds, simulating the dispersion of pollutants, studying the characteristics of wind flow above special site, etc.. To structural engineering, it is a great help for wind-resistant design of some special structures vulnerable to wind load. In order to obtain the wind-effect data representative of full-scale conditions from a model test, the quality of the simulated approach flow in Boundary Layer Wind Tunnel (BLWT) is prerequisite. The simulated wind field should be approximate enough in basic characteristics to natural wind in the practical site, such as windspeed profiles, turbulence intensity profiles and power spectra density of windspeed with a certain length scale. In this paper, wind modeling of approach flow in the new boundary layer wind tunnel of Tokyo Institute of Polytechnics (TIP) was introduced briefly. Windspeed profiles and turbulence intensity profiles corresponding to four types of terrains defined by Architectural Institute of Japan (AIJ, 1996) were simulated successfully. With comparative analysis of the measured data, the effects of block size

and density, spire number and shape on windspeed profiles, turbulence intensity profiles, PSD and length scales in the BLWT were investigated. Several problems were discussed, including the optimal shape of spires, the consistency of power spectral density with existing spectrum models and the calculation methods for length scales. Finally, several advices about modeling wind in BLWT and processing the measured data were given for future reference.

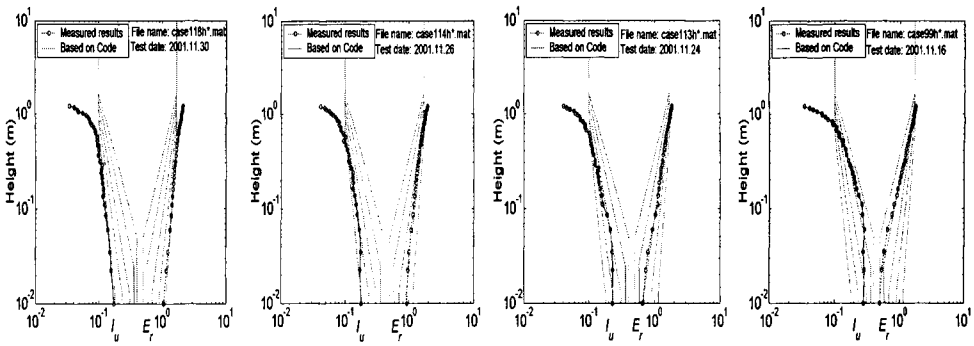
WIND MODELING

Brief introduction of the BLWT in TIP

The new wind tunnel of Tokyo Institute of Polytechnics is a closed low-speed boundary layer wind tunnel. The test section of the wind tunnel is 1.8m high and 2.2m wide, with a length of about 19m. The available windspeed is from 0.5m/s to 15.0m/s, the uniformity of windspeed distribution is more than 99% and the center turbulence intensities are less than 1%. The fluctuating pressure measuring system can be used to measure multi-point pressures simultaneously with a maximum of 128 channels. High frequency force balance techniques can be used in the BLWT.

Wind modeling for four types of terrains

The widely used spire-roughness technique is implemented to simulate the required four types of wind profiles. Four kinds of triangular spires are used: Type 1: 1.0 m high and 0.15m wide in base, Type 2: 1.0 m high and 0.25 m wide in base, Type 3: 1.5 m high and 0.20 m wide in base, and Type 4: 1.5 m high and 0.30 m wide in base. The roughness of floor was adjusted by cube blocks with different sizes and densities. The sizes of three kinds of cube blocks are 30×30×30 mm, 60×60×60 mm and 90×90×90 mm, respectively. As for the density of blocks, three kinds were used with intervals of 600×400 mm (sparsely), 400×400 mm (commonly) and 400×200 mm (densely), respectively.



Many cases were tested with different combinations between spires and blocks. Finally, four types of terrains defined by AIJ (1996) were simulated successfully by trial and error. The windspeed profiles and turbulence intensity profiles for these terrain types are given in Fig.1. In the figure, the continuous lines without marks are based on AIJ (1996), as described in Table 1. $E_r = U(z)/U_{10}^{\mathrm{II}}$, is the vertical distribution coefficient of windspeed in the flat uniformly rough (FUR) terrain, U_{10}^{II} is the windspeed at 10m high above Terrain type II. E_r, the turbulence intensity I_u, the length scale ${}^{x}L_u$, the corresponding roughness length Z_b, the gradient height Z_G and the exponent α for four types of terrains given by AIJ (1996) are also shown in Table 1. For the measured data in a case that does not belong to type II, there is no a corresponding value of U_{10}^{II} directly. Therefore, it is necessary to change U_{10}^{II} to U_{10}^{I}, U_{10}^{III} and U_{10}^{IV} respectively based on "the power law". Provided the actual scale is 1:L, the values of E_r can be calculated as

$$E_r(z) = \frac{U(z)}{U(10/L)} * \lambda \qquad (1)$$

Where λ is a coefficient between U_{10} on measured terrain type with U_{10}^{II}, which is equal to 1.232, 1.000, 0.794 and 0.576 corresponding to terrain type I, II, III and IV, respectively.

Figure 1: Windspeed and turbulence intensity profiles for four simulated terrain types

Fig.2 gives an example of the distribution of power spectral density (PSD) and length scale along height in a case that belongs to terrain type Ⅳ. The distributions of PSD in all the cases are well consistent with Von Karman spectrum model (Von Karman, 1948), which is widely used. The distribution of length scale along height in this case is well consistent with the formula recommended by AIJ (1996), as given in Table 1. It should be noted that not all the test cases have such well consistent results for length scale. All the results show that, as the exponent α decreases, the slope of distribution of length scale along height will increase gradually as well as the values of length scales near to the wind tunnel floor, as shown in Fig.3a and 3b.

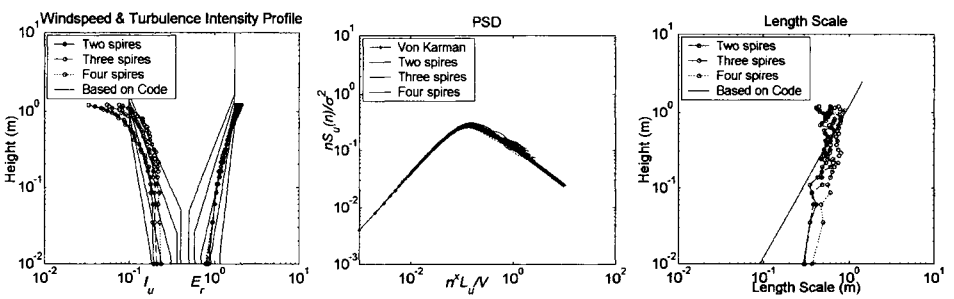
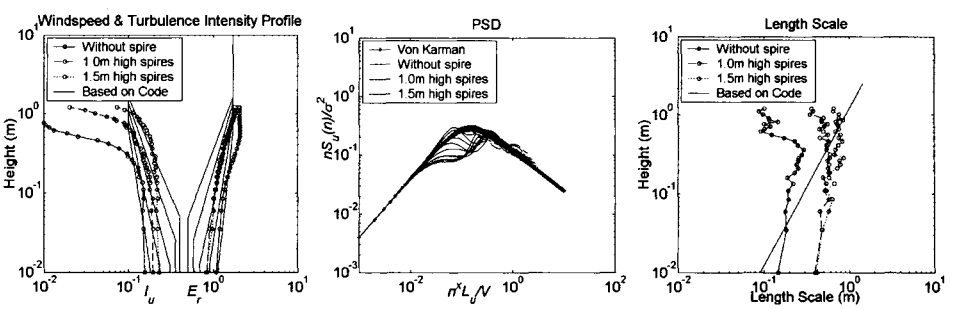
DISCUSSION ON SEVERAL PROBLEMS

Effects of Blocks and Spires



Many comparisons had been carried out to investigate the effects of blocks and spires in the wind tunnel, including the effects of block size and density, the effect of spire number and shape, etc.. A part of results is given in Fig.3. It should be pointed out that herein we used an autoregressive (AR) method to smooth the curves of PSD directly resulted from the multidimensional discrete fast Fourier translation (FFT) method shown in Fig.2a. The consequent difference in the results of length scales is shown in Fig.6 later on.



(a) Density effects of 60×60×60 mm blocks with four 1.5m high spires (Type 3)

(b) Size effects of Blocks placed densely with four 1.5m high spires (Type 3)

(c) 90×90×90 mm blocks placed commonly with two, three and four 1.5m spires (Type 4)

(d) Four spires (Type 4) with 60×60×60 mm blocks placed densely

Figure 3: Effects of blocks and spires

Based on the comparison, following results can be found: (1) With the same block size, the increase of block density gives obvious effects on windspeed profiles, turbulence intensity profiles and length scale near to the wind tunnel floor, but little on PSD. If the block size increases, the effects of block density will increase correspondingly. The same regularity can be seen for the effects of block density. (2) The difference between two and three spires is very small in the BLWT, but compared with four spires, there are obvious difference in the results of turbulence intensity profiles and length scale, and little to windspeed profiles and PSD. (3) The effects of spire height on the results of windspeed, turbulence intensity and length scale profiles are obvious. As the height of the spire increases, the gradient height of simulated wind field, or the thickness of boundary layer will increase, too.

Determination of the spire shape

The spire shape has a great effect on the measured results, which can be proved in Fig.3(c) and 3(d). Therefore, how to determine the shape of spires initially for a new BLWT is really a problem. One method for designing spires was presented by Irwin (1981). An empirical relation among the height of spires h, the thickness of boundary layer δ and the power-law exponent α was used as follow:

$$h = 1.39\frac{\delta}{1+\alpha/2} \tag{2}$$

Then, based on a momentum balance analysis, the base width to height ratio b/h of triangular spires can be estimated by the following equation:

$$\frac{b}{h} = 0.5[\frac{\psi(H/\delta)}{1+\psi}](1+\frac{\alpha}{2}) \tag{3}$$

Where, H is the height of test section. The coefficient ψ can be calculated by following equations:

$$\beta = (\frac{\delta}{H})(\frac{\alpha}{1+\alpha}) \tag{4}$$

$$\psi = \beta\frac{\frac{2}{1+2\alpha}+\beta-\frac{1.13\alpha}{(1+\alpha)(1+\alpha/2)}}{(1-\beta)^2} \tag{5}$$

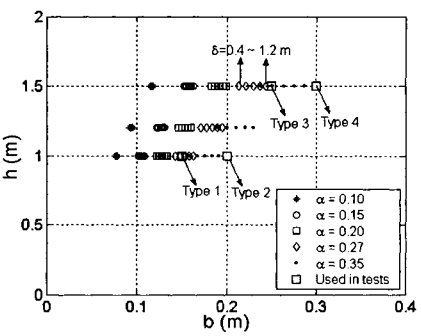


Figure 4: Optimal shape analysis of spires

According to above method, optimal base width of spire, b, corresponding to three kinds of spire height, 1.0m, 1.2m and 1.5m, for the BLWT are given in Fig.4, considering five different exponent α, 0.1, 0.15, 0.2, 0.2 and 0.35, respectively. To each kind of exponent, five kinds of thickness of boundary layer, δ, are analyzed, including 0.4 m, 0.6 m, 0.8 m, 1.0 m and 1.2 m. At the same time, four types of spires used in the tests are shown in the figure. From Fig.4, it can be found that the spires Type 2 and Type 4 are not suitable to our tests theoretically. That was proved by the test results, too.

Comparison on PSD

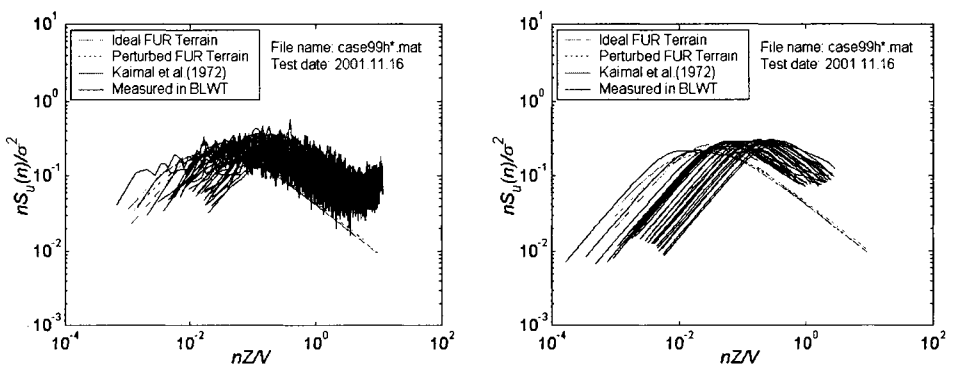
There are many different spectrum models used to describe the distribution of PSD. Based on the theory of isotropic turbulence, Von Karman (1948), presented a spectrum formula as follow:

$$\frac{nS_u(z,n)}{\sigma_u^2} = \frac{4n^x L_u/V}{[1+70.8(n^x L_u/V)^2]^{5/6}} \tag{6}$$

Where n is the frequency in Hertz, ${}^xL_u$ is the length scale of longitudinal turbulence in X direction, V is the mean windspeed of longitudinal component u and σ_u is the root mean square (RMS) value of V.

Another spectrum model proposed by Kaimal et al. (1972) with the reduced frequency $f = nz/V(z)$, as

$$\frac{nS_u(z,n)}{\sigma_u^2} = \frac{32.0f}{(1+50f)^{5/3}} \tag{7}$$



Tieleman (1992) developed spectral equations for the longitudinal component u as follows:
For the ideal flat uniformly rough (FUR) terrain:

$$\frac{nS_u(z,n)}{\sigma_u^2} = \frac{20.53f}{1+475.1f^{5/3}} \tag{8}$$

For the Perturbed FUR terrain:

$$\frac{nS_u(z,n)}{\sigma_u^2} = \frac{40.42f}{(1+60.62f)^{5/3}} \tag{9}$$

As an example, a comparison between above spectrum expressions and PSD distributions resulted from measured data in one case is shown in Fig.5. In Fig.5(a), the PSD is calculated directly with the FFT method, while the curves of PSD in Fig.5(b) are smoothed with the AR method. From Fig.2 and Fig.3, it can be found that the PSDs from measured data are well consistent with the distribution described by Von Karman expression. However, there are increasing errors with other expressions as the height increases, as shown in Fig.5. This reason is that the reduced frequency $f_m = nz/V(z)$ corresponding to the maximum of PSD increases along the height, which can be proved in Fig.5(b). In Eq.(6), such regularity has been considered, but neglected in Eq.(7) to Eq.(9).

(a) Without smoothed (b) Smoothed with the AR method

Figure 5: Comparison of PSD distributions with existing spectrum formulas

Estimation of Length Scale

The length scale ${}^xL_u$ is a measure of the most energetic gust size used widely in wind engineering practice. It is also a necessary value for designing the test model. The values of length scale will be different at different height or above different terrains. There are several methods can be used to calculate the values of length scale from measured data. Harris (1986) gave extensive discussions about the equations for calculating length scale deduced from existing spectrum formulas. However, these formulas have several parameters, which are not easy to be used for processing the measured data in wind tunnel tests. In this paper, three kinds of methods are chosen to estimate the values of length scale from the measured data.

The physical definition of length scale at a measured point is given as follow:

$$^{x}L_u(z) = \overline{V}\,^{x}T_u = \overline{V}\int_0^{\infty} R(\tau)d(\tau) \tag{10}$$

Where, $^{x}T_u = \int_0^{\infty} R(\tau)d(\tau)$, is the time scale of longitudinal turbulence in x direction, $\overline{V}$ is the mean windspeed, and $R(\tau)$ is the cross-correlation function of measured time history data.

Except for the definition, Length scale can be estimated based on the existing spectrum expressions. For example, An equation for estimating length scale can be obtained from the well-established Von Karman spectrum formula (Eq.(5)) at the frequency $n = 0$ as follow:

$$^{x}L_u(z) = \frac{V(z)S_u(z,0)}{\sigma_u^2(z)} \tag{11}$$

Where $S_u(z,0)$ is the value of power spectral density function at frequency $n = 0$ at height z. During the data processing, the first part of PSD was used as the representative value of $S_u(z,0)$.

In addition, simple empirical formulas also can be used to estimate of the values of $^{x}L_u$. An empirical is recommended to estimated the length scales in the Atmospheric Surface Layer (ASL) by American Society of Civil Engineers (ASCE, 1999) as follow:

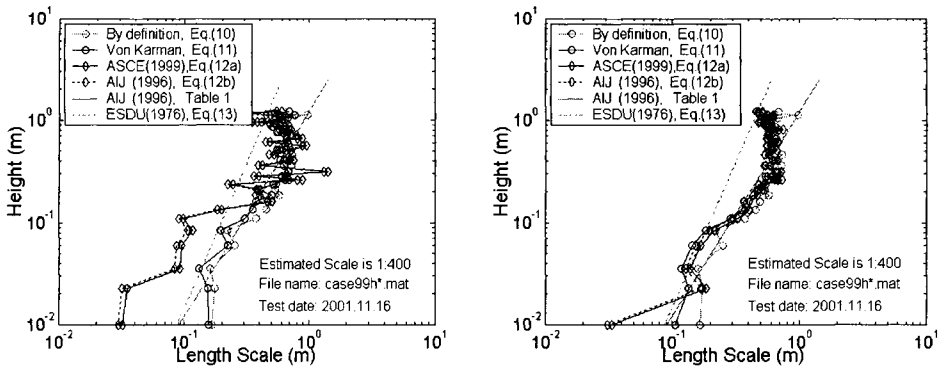
$$^{x}L_u(z) = \frac{z}{2\pi f_m} \tag{12a}$$

Where $f_m = nz/V(z)$ is the reduced frequency for which $nS_u(z)$ is a maximum.

Architectural Institute of Japan (AIJ, 1996) also gives an almost the same simple equation as follow:

$$^{x}L_u(z) = \frac{1}{6.87}(V/n)_{peak} \tag{12b}$$

Where $(V/n)_{peak}$ means the values of $V(z)/n$ for which $nS_u(z)$ is a maximum.



The difference between Eq.(12a) and Eq.(12b) is just a constant, the former is 2π and the latter is 6.87.

A comparison of the results of length scale calculated from above mentioned equations is given in Fig.6. In Fig.6(a), the values of length scale are based on the PSDs resulted directly from the FFT method, while in Fig.6(a), the values of PSD used are smoothed with the AR method. In Fig.6, the continuous lines without marks are based on AIJ (1996), as shown in Table 1; the dashed lines without marks are from E.S.D.U. (1976), as given by following equation:

$$^{x}L_u(z) = 25(z^{0.35}/Z_b{}^{0.063}) \tag{13}$$

From Fig.6, it can be found that the calculated results of length scale from Eq.(10) and Eq.(12) are very near to each other, and the difference becomes smaller and smaller as the height increases. Anyway, all of the results from above mentioned methods are approximate and acceptable.

Regarding to the lines recommended by codes, it should be noted that the formula proposed by AIJ (1996) does not consider the effect of terrain types on length scale. In fact, the slope of length scale data along height is different according to the roughness length, which can be observed from the measured results in the wind modeling tests.

(a) Using PSDs without smoothed (b) Using smoothed PSDs with the AR method

Figure 6: Estimation of length scales

CONCLUSIONS

Based on the test and discussion, several conclusions can be drawn as follows:
(1) The spire-roughness technique is efficient way for wind modeling in wind tunnel. However, it seems not easy to control the results with theoretical analysis. Trial and error is necessary for the test.
(2) The effect of spires to the characteristics of simulated wind is dominant, while the size and density of blocks have obvious effects on the wind flow near to the floor of wind tunnel. The method proposed by Irwin (1981) can be used as a reference to determine the shapes of spires initially.
(3) The peak of PSD to the reduced frequency moves with the increase of height obviously, so Van Karman spectrum model is better to describe the characteristics of simulated wind in the wind tunnels.
(4) Regarding the calculation of length scale, Both Eq.(10) Eq.(11) and Eq.(12) are simple and suitable with approximate results, especially based on the smoothed PSDs with the AR method.

ABSTRACT

This paper carries out comparative study of wind tunnel test and theoretical analysis on wind-induced responses and wind load factors for flexible roof structures with medium deformation. Flexible roof structures with medium deformation refer to a kind of roofs that the wind-structure-coupling effects can be neglected. Fluctuating wind pressure records from rigid model wind tunnel tests are taken as wind loads acting on roof structure, then wind-induced responses and wind load factors are analyzed in the time domain. For comparison, the spectral analysis based on quasi-steady theory is also used to predict wind responses of the same roof structure. It is found that the results predicted by the time domain method well agree with those obtained by the perfect aeroelastic model wind tunnel tests. On the other hand, the results predicted by spectral analysis based on quasi-steady theory are the same with test results only in tendency, but far more than test results in value. Hence, a modified coefficient is introduced when the spectral analysis method based on quasi-steady theory is used to estimate the wind effects on flexible roof structures with medium deformation.

Long-span roof structure, wind-induced response, wind load factor, wind effect factor, time domain method, quasi-steady theory; spectral analysis.

INTRODUCTION

The wind load has recently become a major concern in wind-resistant design of long-span roof

structures due to their characteristics: light, flexible, lightly damped, low natural frequency and so on. Furthermore, these kinds of structures are relatively low, located in the high turbulence intensity region of the atmospheric boundary layer where wind velocity varies widely with elevation. The roof shapes are generally so irregular that the airflow and aerodynamic effects are complicated. Consequently, the structures become quite sensitive to wind load, particularly to its dynamic effect.

The roof structures, in terms of their stiffness, can be divided into three categories: rigid roof structures, flexible roof structures with medium deformation and flexible roof structures with large deformation. For rigid roof structures, wind-induced dynamic response can be neglected. For flexible roof structures with large deformation (i.e. membrane structures), the coupling action between structure movement and approach flow should be considered. For flexible roof structures with medium deformation, on one hand, since the amplitude of vibration is on the small side, the coupling action between the structure and approach flow can be neglected; on the other hand, vibration-induced inertia force should be taken into account. As flexible roof structures with medium deformation are widely used in Civil Engineering, it is of particular importance to investigate wind effects on these structures.

Most of the previous investigations were made for the characteristics of the mean and fluctuating wind pressures acting on roofs with various shapes, such as hip roofs (Xu and Reardon,1998), gable roofs (Case and Isyumov,1998), flat roofs with parapets (Kareem and Lu, 1992) and stadium annular covering (Marighetti *et al.*, 2000). In their works, the roofs were reasonably regarded as rigid covers since the roof span is relatively small. However, as the roof span increases, the flexibility of roof and its dynamic effects have to be considered. Heretofore, several researches on wind response of flexible roof structures with medium deformation have been carried out by means of wind tunnel test combined with computer numerical analysis. For example, Yasui (1999), based on the data obtained from a stiff model wind tunnel test conducted for a long-span structure, simulated a multi-point fluctuating wind pressure time series by the Monte Carlo method. Then a time series response analysis was carried out using the wind pressure time series. Uematsu (1997) measured the modal force of the first vibration mode (i.e. the modal force is regard as a sum of the point pressures multiplied by weighting factors) through a rigid model wind tunnel test, and then, the gust loading factor or so-called wind effect factor, defined as the ratio of maximum peak displacement response to the mean displacement response in a time duration, was computed. Although this method enjoys a distinct advantage of simple and immediate computation, in this study, only the first modal force is considered for estimating the gust-loading factor; neither effects of high order mode of vibration nor the non-linear properties of structure are considered. The researches of China mainly adopt spectral analysis based on quasi-steady theory to analyze wind responses of long-span roof structures (Lou et al., 2000). But, since the wind pressure applied on the roof are chiefly generated by pneumatic separation and reattachment, whether the quasi-steady theory is still suitable should be further discussed and the expression of wind-induced force on the roof is also a problem. In the present study, wind-induced dynamic responses and wind load factors of roof structures are analyzed in the time domain based on wind pressure records from rigid model wind tunnel tests. For comparison, the spectral analysis based on quasi-steady theory is also used to predict wind responses of the same roof structure. It indicates that time domain method has high accuracy, but quasi-steady theory is not well suitable to predict wind-induced responses of roof structures.

SPECTRAL ANALYSIS BASED ON QUASI-STEADY THEORY

Based on quasi-steady theory, fluctuating component of the wind force acting on roof structure is expressed as (Simiu and Scanlan, 1986):

$$F_i(t) = \frac{1}{2}\rho V^2 A_i \left[C_{Li} \frac{2v(t)}{V} + \left(\frac{\mathrm{d}C_{Li}}{\mathrm{d}\alpha} + C_{Di} \right) \frac{w(t)}{V} \right] \tag{1}$$

where V and $v(t)$ are the horizontal mean wind speed and horizontal fluctuating wind speed at roof level respectively; $w(t)$ is the vertical fluctuating wind speed at roof level. In order to compare with the wind tunnel test results, in this study the vertical fluctuating wind speed $w(t)$ is neglected. The Eqn.1 then is simplified as

$$F_i(t) = \rho C_{Li} A_i V v(t) \tag{2}$$

in which ρ is air density; C_{Li} is the mean lift force coefficient of pressure pat i obtained from wind tunnel test; A_i is the roof surface area corresponding to node i.

A long-span flat roof subjected wind excitation vibrates like as elastic thin plate, and so can be divided into orthogonal elements. Using thin plate bending element stiffness and mass matrices, the finite element vibration equations of a long span roof structure under wind excitation are assembled as

$$[M]\{\ddot{X}\} + [C]\{\dot{X}\} + [K]\{X\} = \{F(t)\} \tag{3}$$

In similar as the spectral analysis of wind responses for high-rise building, the RMS displacement response of node q on roof is given by (Lou et al., 2000)

$$\sigma_{x_q}^2 = \sum_{j=1}^{n} \varphi_{qj}^2 \frac{\sum_{r=1}^{n}\sum_{k=1}^{n} \varphi_{rj}\varphi_{kj}\rho^2 V_r V_k C_r C_k A_r A_k}{M_j^2} \times \int_0^\infty \frac{\sqrt{S_v^r(\omega) S_v^k(\omega)} \cdot \mathrm{coh}(r,k,\omega)}{(\omega_j^2 - \omega^2)^2 + (2\beta_j \omega_j \omega)^2} \mathrm{d}\omega \tag{4}$$

and then the RMS acceleration is

$$\sigma_a = \sqrt{\sum_{j=1}^{n} \omega_j^4 \sigma_{xj}^2} \tag{5}$$

where, $S_v(\omega)$ and $\mathrm{coh}(r, k, \omega)$ are spectral density and coherence function of the horizontal fluctuating wind velocity respectively. Spectral density and coherence function reported by Davenport are adopted in this investigation.

TIME DOMAIN METHOD

Commonly, the analysis of wind response in the time domain is conducted in the following three steps. First, fluctuating wind speed time history is simulated from fluctuating wind speed spectrum by means of harmonic synthesis and linear filter; Next, the time history of fluctuating wind load acting on the structure is determined through transforming the time history of wind speed into that of wind load based on quasi-steady hypothesis. Third, the response is calculated by the time domain six-order Runge-Kutta method. However, the airflow sweeping past the roof structure will create complicated pneumatic separation and reattachment, and so it will bring about errors that the quasi-steady theory is adopted to describe the wind load acting on the long-span roof structure. Accordingly, in the present

study, dynamic wind pressure records obtained by stiff model wind tunnel tests through simultaneous technique are taken as wind loads applied on roof structure. And then, wind responses and wind load factors are analyzed by the time domain six-order Runge-Kutta method. The fluctuating wind load $F_i(t)$ acting on node i of roof structure can be ascertained by pressure tap i as follows:

$$F_i(t) = \frac{1}{2} C_{pi}(t) \rho V^2 A_i \tag{6}$$

where $C_{pi}(t)$ is the lift force coefficient time history of node i; A_i is the roof surface area corresponding to node i.

Combined Eqn.3 with Eqn.6, the wind-induced response time history of roof structures can be calculated by direct integral approach such as six order Runge-Kutte method. Then, the statistical information (maximum value, mean value and RMS) of responses and the wind load factor are easily obtained.

WIND-INDUCED DYNAMIC RESPONSE AND WIND LOAD FACTOR

In order to verify the accuracy of the above time domain method, a square flat roof, simply supported on a closed building, with ratio of height to span L/H = 3.0 and with 30m span, is selected as an example for numerical analysis, rigid model and perfect aeroelastic model wind tunnel tests. The computed first six natural frequencies of this prototype are 2.03Hz, 5.07Hz, 5.07Hz, 8.13Hz, 10.15Hz, and 10.15Hz. The rigid model was made with the geometry scale of 1/50. The perfect aeroelastic model was designed with the same geometry scale of 1/50. In order to satisfy Froude number similarity, Cauchy number similarity and mass distribution similarity requirements, the model is finally made of aluminum plate with 1.5mm thickness. In wind tunnel tests, the mean wind velocity reference height for the tests was set 20cm above the floor of the wind tunnel, just the height of roof surface. The reference wind velocity is 12m/s for fluctuating pressure measurement tests and varies from 8m/s to 12 m/s with 1m/s interval for acceleration measurement tests. Due to satisfaction of Froude number similarity, the accelerations of the aeroelastic model were just equal to those of the prototype roof.

RMS Acceleration Response

The roof RMS acceleration responses are obtained by three approaches: spectral analysis based on quasi-steady theory, time domain method and aeroelastic model wind tunnel tests respectively. In calculation, the damping ratio of the first mode is set to be 1.0% that is near to the aeroelastic model damping ratio. The wind pressure coefficients are obtained from the stiff model wind tunnel tests. The first six modes are taken into account in order to consider the effects of high order modes on acceleration responses of the roof when spectral analysis based on quasi-steady theory is used.

Fig. 1 and 2 show the RMS acceleration responses at quarter-span pints under different wind speeds and wind directions. The curves as shown in Fig. 1 and 2 are obtained by the above three approaches respectively. It is clear from the figures that the results predicted by the time domain method well agree with those obtained by the perfect aeroelastic model wind tunnel tests. It also found that the results predicted by spectral analysis based on quasi-steady theory are the same with test results only in tendency, but far more than test results in value. Consequently, spectral analysis based on quasi-steady theory is not well suitable to the analysis of the wind-induced responses of roof structures.

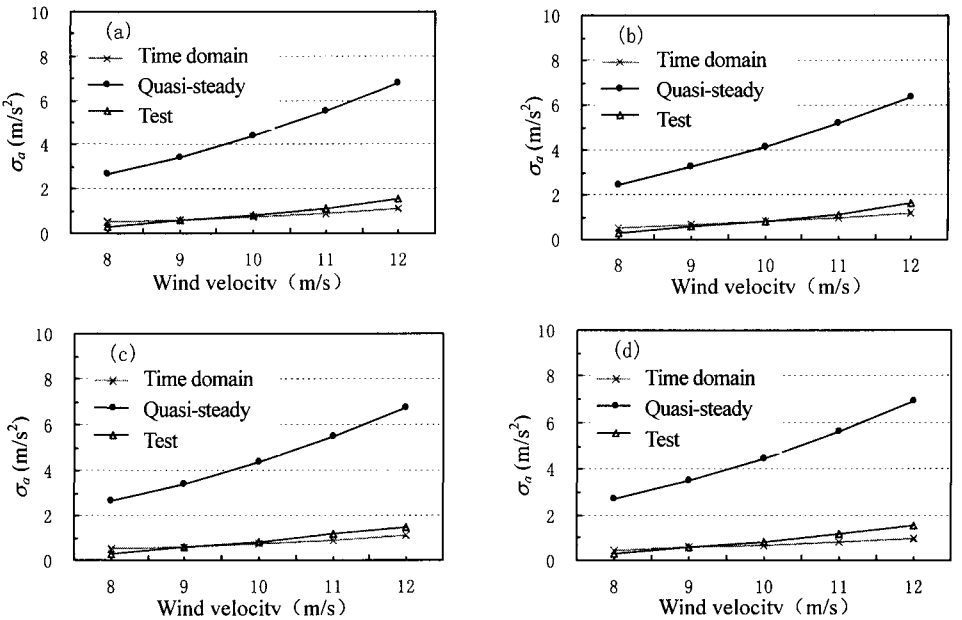

Figure1. RMS acceleration response of roof at left quarter span under different wind velocities:
(a) 0° wind direction ; (b) 15° wind direction ; (c) 30° wind direction; (d) 45° Wind direction

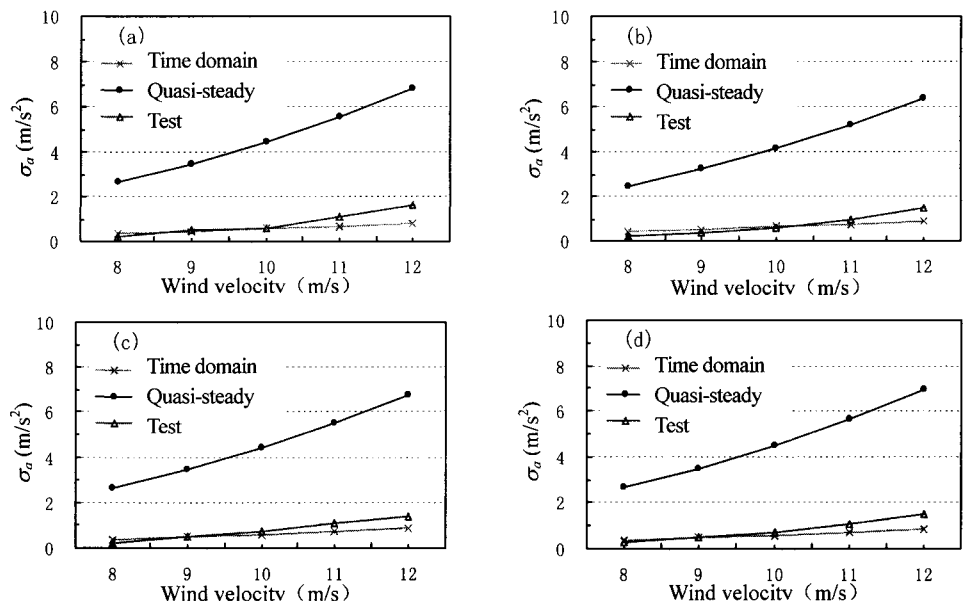

Figure2. RMS acceleration response of roof at right quarter span under different wind velocities:
(a) 0° wind direction ; (b) 15° wind direction ; (c) 30° wind direction; (d) 45° Wind direction

Wind Load Factor

It is common practice to evaluate wind effects on structures using an equivalent static wind load. The equivalent static wind load for a flexible roof may be expressed as the product of the mean wind pressure and a wind load factor. In China Building Load Code (GBJ9-87), wind load factor is specified as the ratio of maximum wind-induced force to static component of wind force acting on the roof. In the previous paper of authors (Lou et al., 2000), it has been pointed out that wind load factor significantly varies with positions on a roof. It indicated that the distribution of wind load factor on the whole roof is a curve surface similar to the first mode shape. Therefore, the wind load factor is not convenient to be used. In fact, if defining a coefficient as the ratio of maximum wind-induced effect (including static and dynamic effect) to wind-induced static effect, such as the ratio of maximum peak displacement response to the mean displacement response in a time duration, this coefficient is denoted as wind effect factor expressed as follows

$$\beta_D = 1 + \frac{U_D}{U_s} = 1 + \frac{\mu\sigma_x}{U_s} \tag{7}$$

where β_D is the wind effect factor of the roof; U_D and U_s are displacement response induced by dynamic component and static component of wind load respectively; σ_x is RMS displacement response of the roof; μ is the peak coefficient of response, inhere, μ is approximately set to be 3.0.

The computed results demonstrate that wind effect factor is almost uniform on the whole roof, and so wind effect factor is prior to wind load factor in estimating wind-induced response. Table 1 shows the wind effect factors of the example prototype roof at the wind velocity of 70.7m/s and under the different wind directions. In this table, the results predicted by time domain method and by spectral analysis based on quasi-steady theory respectively are listed. The following features can be seen: (1) The wind effect factors predicted by spectral analysis based on quasi-steady theory are far more than those predicted by time domain method, (2) The variation of wind effect factor with the wind direction is not significant.

TABLE 1

COMPARISON OF WIND EFFECT FACTORS

Wind direction		0°	15°	30°	45°
Wind load factor	Time domain method	1.30	1.32	1.31	1.30
	Spectral analysis	2.46	2.63	2.49	2.36

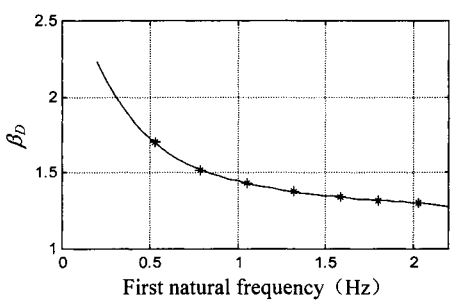

Figure 3: Wind effect factors at different first natural frequency

Further investigation suggests that the wind effect factor depend primarily on stiffness (or frequency) of roof structures. The variation of wind load factor of the example flat square roof with its first natural frequency is shown in Figure 3.

Modification of the Spectral Analysis Based on Quasi-Steady Theory

The spectral method based on quasi-steady theory is used to estimate wind-induced responses of tall buildings due to its simplicity. Can this method still estimate wind-induced responses of roof structures by introducing a modified coefficient to the result obtained by this method? Carefully comparing the curves shown in Fig.1 and Fig.2, it is seen that if the ratio of the result predicted by time domain method to that predicted by this method is near to a constant value, this constant value can be taken as the modified coefficient. For the convenience of practical application, the ratios of the wind effect factors by two methods under different wind velocities and roof stiffness are investigated. As shown in Table 2 and Table 3, the ratios in all cases are near to 0.6, and so the modified coefficient of wind effect factor can be approximately set to be 0.6 when the spectral analysis method based on quasi-steady theory is used to estimate the wind effects on flat roofs with medium deformation.

TABLE 2

MODIFIED COEFFICIENTS OF WIND EFFECT FACTOR UNDER DIFFERENT WIND SPEEDS IN THE CASE OF 2.03Hz ROOF FIRST FREQUENCY

Wind velocity (m/s)	56.6	63.6	70.7	77.8	84.9
Modified coefficient	0.57	0.55	0.53	0.52	0.50

TABLE 3

MODIFIED COEFFICIENTS OF WIND EFFECT FACTOR UNDER DIFFERENT ROOF FREQUENCYS IN THE CASE OF 30m/s WIND SPEED

First frequency (Hz)	0.53	0.79	1.05	1.58	2.03
Modified coefficient	0.593	0.615	0.628	0.634	0.635

CONCLUSIONS

The following conclusions are drawn from comparisons of analytical and test results: (1) The RMS accelerations of the roof under various wind speeds and directions predicted by time domain method well agree with those of the perfect aeroelastic model wind tunnel tests. On the other hand, the results predicted by spectral analysis based on quasi-steady theory are the same with test results only in tendency, but far more than test results in value; (2) A modified coefficient must be introduced for the purpose of that the spectral analysis method based on quasi-steady theory is suitable to estimating wind effects on roofs; (3) The modified coefficient of wind effect factor is approximately set to be 0.6 when the spectral analysis method based on quasi-steady theory is used to predict the wind effects on flat roofs with medium deformation.

ABSTRACT

Based on the characteristics of the wind load and response of membrane structures, the thin airfoil aerodynamic theory is applied to calculate air inertia load of the membrane structures for unsteady flows in the paper. Vortex method is used to derive the formula of added air mass of membrane and the theoretical results are gained at the first time. Some useful results are obtained through analyzing the effects of inertial load caused by the added air mass for dynamic response properties of membrane structures.

KEYWORDS

Membrane structures; Vortex method; Added air mass; Vortex-induced vibration

INTRODUCTION

Among the analyses of wind-induced dynamic responses of long-span roof structures, small deformation is often assumed and the added air mass induced by structural vibration in the unsteady flows is generally neglected. Because membrane structures belong to the light-flexible and small damping structures, large deformation will be produced under the action of wind load. Great turbulence in the boundary layer of atmosphere can cause the vortices to break off and the flows to convert in the process of viscosity diffusion and wake, and the turbulence-induced vibration in this process can't be neglected. Therefore, the added air mass on the membrane structures must be considered by the knowledge of unsteady flows, which is difficult to analyze and not settled well heretofore. In past decade, a few papers analyzed nonlinear wind-induced dynamic responses for membrane structures. But the added air mass is usually not considered in the their theoretical

calculation. Some studies(Harrod 1981, Zhang1990) suggested to use indiscriminately Morison Equation obtained from ocean building dynamics to solve the wind-induced dynamic responses of membrane structures.

In order to study this problem deeply, the thin airfoil aerodynamic theory(Arnold 1976) is applied to calculate added air mass of membrane structures. The vortex sheet of thin airfoil theory fitted to membrane structures in unsteady flows is established. The vortex filaments are used to calculate added mass action on membrane structures. These theoretical results are obtained by some techniques, such as coordinate mapping and Mathematical denotation integral, and the formulae of added air mass for the membrane structures are convenient to study the flexible roofs including long-span structures. Finally, the inertia loads induced by the added air mass are used to analyze the dynamic response of the membrane structures in time domain, and some important results of wind-induced vibration of the membrane structures are obtained.

VORTEX SHEET OF AIRFOIL AERODYNAMICS

The vortex sheet, shown schematically in Fig.1, may be thought of as an infinite number of vortex filaments, each has infinitesimal strength and extends to infinity or to boundary of the flow. The strength of the vortex sheet, γ_m, termed the circulation density, is defined as a limiting form of Stokes's theorem:

$$\gamma_m = \lim_{\Delta s \to 0} (\frac{1}{\Delta s} \int \vec{\mathbf{V}} d\vec{\mathbf{S}}) \tag{1}$$

Where Δs is the width of the sheet enclosed by the contour. If the circulation is clockwise, γ_m is a positive value.

No discontinuities occur anywhere in the velocity field except at the sheet itself. It could be proved (Arnold 1976) that the velocity component parallel to the vortex surface jumps by an amount equal to the strength of the sheet at the point where the contour crosses the sheet surface, i.e.:

$$\gamma_m(x,t) = u_2 - u_1 \tag{2}$$

Suppose a plane membrane is horizontally supported in a static state, the distance between the supports of the membrane is l, the mass per unit area is m. Membrane is assumed to be undergoing a natural vibration continuously in two-dimensional space. The maximum vibration amplitude is H, as shown in Fig.1, and the expression of the dynamic displacement $h(x,t)$ at any point x and time t is:

$$h(x,t) = 4H \frac{x(l-x)}{l^2} \cos \omega t \qquad (0<x<l) \tag{3}$$

The complex velocity potential Φ_z induced by a vortex filament at any position $z = x + iy$ $(i = \sqrt{-1})$ can be expressed as:

$$\Phi_z = i \frac{\gamma_m(\xi,t) d\xi}{2\pi} \ln(z - \xi) \tag{4}$$

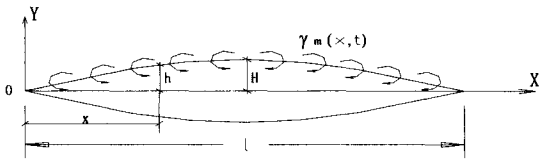

Fig.1 Deformation of membrane and model of vortex sheet schematically

The components of velocity in the x- and y-directions induced by the circulation density $\gamma_m(\xi,t)$ at any point on the membrane can be obtained from equation (4) as $\mathrm{Re}[\partial\Phi_z/\partial z]_{z=x}$ and $\mathrm{Im}[-\partial\Phi_z/\partial z]_{z=x}$, respectively. The total velocity components distributed along the whole membrane are given as follows:

$$\begin{cases} \dfrac{1}{2}(u_1+u_2)=[u]_{y=0}=0 \\ \dfrac{1}{2}(v_1+v_2)=[v]_{y=0}=\dfrac{1}{2\pi}\displaystyle\int_0^l \frac{\gamma_m(\xi,t)}{\xi-x}d\xi \end{cases} \quad (0<x<l) \tag{5}$$

Where u_1, u_2 are the vibration velocity components of the membrane in the x-direction and v_1, v_2 are vibration velocity components in the y-direction respectively, shown in Fig.2. Therefore, v_1, v_2 can be expressed as:

$$\begin{cases} v_1=\dfrac{\partial h}{\partial t}+u_1\dfrac{\partial h}{\partial x} \\ v_2=\dfrac{\partial h}{\partial t}+u_2\dfrac{\partial h}{\partial x} \end{cases} \tag{6}$$

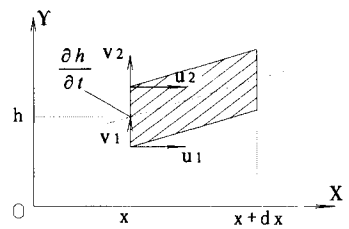

Fig.2 Speed amount of membrane

Applying equations (5) and (6), an integral equation can be obtained as follows:

$$\frac{\partial h}{\partial t}=\frac{1}{2\pi}\int_0^l \frac{\gamma_m(\xi,t)}{\xi-x}d\xi \qquad (0<x<l) \tag{7}$$

Now substituting equation (3) into the equation (7) and integrating, the solution $\gamma_m(x,t)$ will be:

$$\gamma_m(x,t)=-\frac{2H\omega}{\pi}\sin(\omega t)\left[\sqrt{\frac{l-x}{x}}\int_0^l\sqrt{\frac{\xi}{l-\xi}}\frac{4x(l-x)}{l^2}\frac{}{x-\xi}d\xi+\frac{Cl}{\sqrt{x(l-x)}}\right] \tag{8}$$

Where C is an integral constant. Introducing the coordinate transformation:

$$\begin{cases} x=\dfrac{l}{2}(1-\cos\theta_x) \\ \xi=\dfrac{l}{2}(1-\cos\theta_\xi) \end{cases} \tag{9}$$

and substituting equation (9) into equation (8), the solution γ_m becomes as:

$$\gamma_m = -\frac{2H\omega}{\pi}\sin\omega t\left[-\pi\sin\theta_x(1+\cos\theta_x)+\frac{2C}{\sin\theta_x}\right] \tag{10}$$

Because the flow pattern is symmetric with respect to $x = l/2$, the solution γ_m should satisfy a boundary condition:

$$\gamma_m(\frac{l}{2},t) = 0 \qquad or \qquad \gamma_m(\frac{\pi}{2},t) = 0 \tag{11}$$

The integral constant C, determined by above boundary condition, is $\pi/2$. Finally, we get the solution:

$$\gamma_m = 2H\cdot\omega\cdot\sin\omega t\cdot ctg\theta_x\cdot(\sin^2\theta_x - \cos\theta_x) \tag{12}$$

ADDED AIR MASS ON MEMBRANE

According to the definition of velocity potential Φ and generalized Bernoulli's equation, we have:

$$\left[\frac{\partial\Phi}{\partial t}\right]_1 + \frac{1}{2}(u_1^2+v_1^2) + \frac{p_1}{\rho} = \left[\frac{\partial\Phi}{\partial t}\right]_2 + \frac{1}{2}(u_2^2+v_2^2) + \frac{p_2}{\rho} \tag{13}$$

Then, the pressure difference Δp is as follows:

$$\Delta p = p_1 - p_2 = \rho\frac{\partial h}{\partial t}\frac{\partial h}{\partial x}\gamma_m(x,t) + \rho\frac{\partial}{\partial t}\int_0^x \gamma_m(\xi,t)d\xi \tag{14}$$

Where ρ is mass density of the airflow. Also, substituting equations (3) and (12) into the equation (14) and applying coordinate transformation equation (9), the pressure difference Δp can be expressed as:

$$\begin{aligned}\Delta p &= \rho\left(-H\omega\sin^2\theta\sin(\omega t)\right)\left(4H\frac{\cos\theta}{l}\cos(\omega t)\right)\left(2H\omega\sin(\omega t)ctg\theta(\sin^2\theta-\cos\theta)\right)\\ &\quad + 2\rho H\omega^2\cos(\omega t)\int_0^{\theta} ctg\theta_\xi\left(\sin^2\theta_\xi - \cos\theta_\xi\right)\left(\frac{l}{2}\sin\theta_\xi\right)d\theta_\xi\\ &= \frac{8\rho H^3\omega^2}{l}\sin^2(\omega t)\cos(\omega t)(\sin\theta\cos^3\theta - \sin^3\theta\cos^2\theta)\\ &\quad + \rho Hl\omega^2\cos(\omega t)(\frac{1}{3}\sin^3\theta - \frac{1}{2}\theta - \frac{1}{4}\sin 2\theta)\end{aligned} \tag{15}$$

Based on the energy conservation, the kinetic energy increment dT_f of the air should be equal to the work done on the whole membrane by the force corresponding to Δp during time period dt. This relation could be expressed as:

$$\begin{aligned}dT_f &= \int_0^l \Delta p ds\,\frac{\partial h}{\partial t}dt = \int_0^l \Delta p\sqrt{1+\left(\frac{\partial h}{\partial x}\right)^2}dx\,\frac{\partial h}{\partial t}dt \approx \int_0^l \Delta p\left[1+\frac{1}{2}\left(\frac{\partial h}{\partial x}\right)^2\right]dx\,\frac{\partial h}{\partial t}dt\\ &= \rho H^2 l^2\omega^3\sin(\omega t)\cos(\omega t)dt\left\{\frac{11\pi}{96}+0.674132\left(\frac{H}{l}\right)^2\cos^2(\omega t)+\frac{\pi}{64}\left(10+24\left(\frac{H}{l}\right)^2\cos^2(\omega t)\right)\left(\frac{H}{l}\right)^2\sin^2(\omega t)\right\}\end{aligned} \tag{16}$$

Denoting the added air mass per unit area of the membrane as m_a, the kinetic energy increment dT_f of the vibration membrane can be expressed as:

$$\begin{aligned} dT_f &= \frac{\partial}{\partial t}\left[\frac{1}{2}m_a\int_0^l\left(\frac{\partial h}{\partial t}\right)^2 dx\right]dt = m_a\int_0^l\frac{\partial h}{\partial t}\frac{\partial^2 h}{\partial t^2}dxdt \\ &= \frac{8}{15}H^2 l\omega^3\sin(\omega t)\cos(\omega t)dt\cdot m_a \end{aligned} \tag{17}$$

From the equation (16) and equation (17), we can obtain the added air mass per unit area m_a:

$$m_a = \rho l\left(\frac{55\pi}{256}+1.0922\left(\frac{H}{l}\right)^2+0.1718\left(\frac{H}{l}\right)^2\cos(2\omega t)+0.5522\left(\frac{H}{l}\right)^4\sin^2(\omega t)\right) \tag{18}$$

It is a theoretical formula of the added air mass for the membrane structures, which shows that the added air mass m_a depends on air density ρ, distance l between the supports, maximum vibration amplitude H, circular frequency ω and time t. Since H/l is less than 0.1 in most cases, the forth term of the equation (18) is the quartic small quantity and could be neglected. Also the third term is far less than the sum of the first and second terms in equation (18). So it is adequacy to hold the first two terms. Then equation (18) could be approximately expressed as:

$$m_a = \rho l\left(\frac{55\pi}{256}+1.0922\left(\frac{H}{l}\right)^2\right) \tag{19}$$

Thus, the added air mass m_a can be considered as independent on circular frequency ω and time t. The non-dimensional form of the equation (19) will be:

$$\overline{m}_a = \frac{55\pi}{256}+1.0922\overline{H}^2 \tag{20}$$

Where $\overline{m}_a$ and $\overline{H}$ are non-dimensional parameters and they are equal to $m_a/\rho l$ and H/l respectively.

From equation (20), it is shown that $\overline{m}_a$ is quadric function of $\overline{H}$. When $\overline{H}$=0, $\overline{m}_a$=0.6750, and $\overline{H}$=0.1, $\overline{m}_a$=0.6859, the $\overline{m}_a$ only increases a small value (1.6%). By the numerical integral calculation for some H、ω and t, Minami(1998) indicated that $\overline{m}_a$ does not depend on H、ω and t and suggested that $\overline{m}_a$ equal 0.68. But from the theoretical equations (18) and (20) obtained from present study, the non-dimensional added air mass $\overline{m}_a$ increases with the $\overline{H}$ as power function. Only when high-order small terms are neglected, m_a becomes independent on ω and t. When $\overline{m}_a$=0.68, $\overline{H}$ is equal to 0.068, which means that the amplitude of structure vibration reaches as high as 6.8% of the distance between the supports. Since varying range of $\overline{m}_a$ is small in general cases, the value of $\overline{m}_a$ could be taken as a constant, which corresponds to the numerical results by Minami(1998). In this case, the added air mass on membrane is directly proportional to the product of air density ρ and span l. The larger span between the supports of the membrane structures is, the greater added air mass and the air inertia loads on the structures, and more sensitive to fluctuation wind loads on the membrane structures.

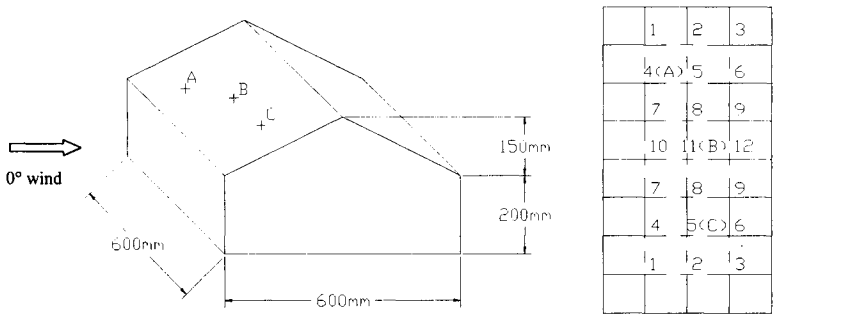
So how to reduce the distances between the local supports should be taken into account in resisting-wind design of membrane structures.

WIND LOADS OF THE MEMBRANE STRUCTURES

The wind loads of the membrane structures are composed of fluctuated wind loads and inertia loads induced by the added air mass. The general formula on a point i of the membrane structures is given by:

$$P_i(t) = \frac{1}{2}\mu_{si}\rho A_i V_i^2(t) - m_a A_i \frac{\partial^2 h}{\partial t^2}$$
$$= \frac{1}{2}\mu_{si}\rho A_i V_i^2(t) + \left(\frac{55\pi}{64} + 4.3688\left(\frac{H}{l}\right)^2\right)\rho A_i \frac{H}{l}\omega^2 x_i(l - x_i)\cos(\omega t) \tag{21}$$

Where the first term of right side of expression (21) is resistance force, i.e. the so-called general wind load, in which μ_{si} is the wind body-shape coefficient, ρ is the air density, A_i is the correlative area, $V_i(t)$ is the fluctuated wind speed and could be artificially generated by linearly filter method of self-regression model through application of Kaimal spectral density. In this paper, we selected the Kaimal constant is 0.4, the roughness length is 0.2m, the time step length is Δt=0.1061s, the time step numbers is N=1024 and self-regression step is p=4. The second term of equation (21) is the inertia loads of the added air mass on the membrane structures in unsteady vortices.



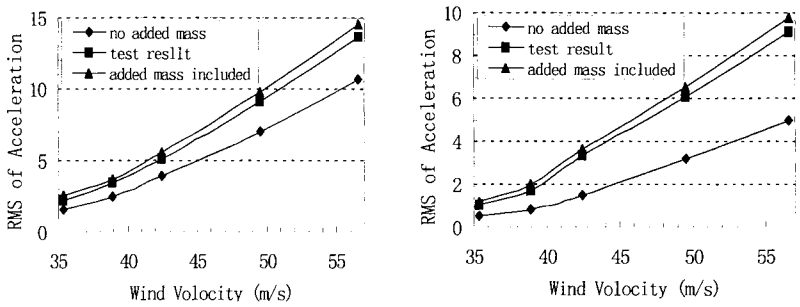
The equation (21) is the wind load equation for membrane structures in which the vortex-induced air inertia load is calculated when membrane structures vibrate in unsteady flows. From the equation we can see that the loads are related to air density ρ, span l, vibration amplitude H, the position x_i and circular frequency ω. But the air inertia loads acting on the cylinder in unsteady flows or from the Morison Equation are a constant in any position of the structures, that means independent of structural vibration. Generally, since the direction of inertia loads is not consistent with that of flows, the inertia loads of cylinder structures and from Morison equation can't be indiscriminately applied to the membrane structures. Here equation (21) indicates that the inertia loads vary with the point position of the structures, which truly reflects the basic characteristics of air inertia loads acting on the membrane structures.

ANALYSIS OF VORTEX-INDUCED VIBRATION IN THE TIME DOMAIN

The movement equation of the membrane structures is

$$\boldsymbol{M}\ddot{\boldsymbol{u}}(t) + \boldsymbol{C}\dot{\boldsymbol{u}}(t) + \boldsymbol{K}\boldsymbol{u}(t) = \boldsymbol{P}(t) \tag{22}$$

Where $\boldsymbol{M}$ and $\boldsymbol{K}$ is the mass and stiffness matrix respectively. Assuming damping matrix $\boldsymbol{C}$ is Rayleigh damping and the damping ratio is 0.055. $\boldsymbol{P(t)}$ is the wind loads acting on membrane structures and the equation (21) is taken as its expression.



(a) Calculation modal (b) Position number

Fig.3 Computation modal of membrane structures

Taking a double-slope roof membrane structures as an example, as shown in figure 3, the time domain analysis is applied to calculate dynamic responses of windward roof of membrane structures when the around walls of the structure are closed and wind angle is equal to 0°.

Figure 4(a) and 4(b) represent acceleration RMS at point A and B for different wind velocities and the analytical results are compared with that obtained from aeroelastic modal test(Wang 2001) when added air inertia is applied or not respectively. When the first term of equation (21) is only used to calculate structural response, i.e. does not include added air mass, acceleration RMS in time domain is evidently less than that obtained from wind tunnel test. Its calculated error is quite large, especially in lower positions of the structures, for example at point A. The reason is that Bernoulli Equation is based on hypothesis of quasi-steady flows, in which wind pressure fluctuation entirely is attributed to wind turbulence. From the knowledge of gradient wind, the wind velocity at point A is relatively small and its fluctuation is small too. Therefore, the corresponding wind pressure and its wind-induced vibration are small. When the added air mass is taken into account, the calculating acceleration RMS increases evidently and its value is close to or somewhat greater than result obtained from wind tunnel test.

When wind velocity is equal to 42.43m/s, wind angle is 0° and around walls of double-slop roof structure are closed, as shown in fig. 3, the added air mass is included to calculate displacement and acceleration RMS of windward roof for the structure. The results show that the influence of added air mass for displacement average of the structures is very small. But the influence of displacement RMS and acceleration RMS are evidently great. Taking the center point of the structure as an example, when added air mass is taken into account, the displacement RMS increases from 5.14cm to 8.32cm by 1.619 times. For the other positions, the displacement RMS also increase by 1.567~2.766 times. Also, the acceleration RMS of the structures evidently increases by 1.360~2.830. It is shown that the vortex-induced dynamic response is a main influence factor of membrane structural vibration and cannot be neglected in wind-resisting design.

Fig.4 Acceleration RMS on point A and B at different wind velocity

CONCLUSIONS

In the present study, the theoretical formulae of the added air mass for the membrane structures are derived and are applied to analyze the wind-induced dynamic response of large-span flexible roof. The FEM and time domain analysis is also applied to study vortex-induced vibration of the membrane structures. Some main conclusions are obtained as follow:

1. The added air mass is approximately independent on natural frequency of the membrane structures and time, but varies directly with the ratio of product $\rho \cdot l$.

2. The inertia loads caused by added air mass is related not only with air density ρ and span l, but also with the position x_i, vibration amplitude H and frequency ω.

3. The added air mass has little influence on displacement average, but has greatly influence on displacement RMS and acceleration RMS. It means that the added air mass is a main factor for increasing the response of membrane structures and can't be neglected in resisting-wind design.

PARAMETERIZATION STUDY ON THE OPERATING EFFICIENCY OF AIR-COOLED CHILLERS

K.T. Chan and F.W. Yu

Department of Building Services Engineering
The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT

The chiller plants for providing cooling in buildings in a dense urban environment, as is Hong Kong, often require heat rejection by air-cooled condensers. Improved efficiency of air-cooled reciprocating chillers requires knowledge of the behaviours of the operating parameters. A parameterization study aiming at exploring such behaviours was carried out with the hybrid use of the operating data from an installed chiller in an existing building and the predicted data by a validated chiller model. The chiller efficiency generally increases with the chiller part load ratio. A close relationship between the evaporator performance and the chiller part load ratio was observed, but varying the chilled water flowrate and the evaporating temperature shows a diverse effect on the evaporator performance. Multiple steps of capacity control would result in fluctuating compressor power input. Evaluation of the condenser performance indicates that the performance cannot be simply represented by any one of the control parameters: part load ratio, refrigerant mass flow, heat rejection airflow and condensing temperature. The opportunity of reducing the condensing temperature at below-design outdoor conditions for better efficiency and energy saving was exploited through the evaluation of the boundary and the means to achieve the lowest possible working condensing temperature.

KEYWORDS

Air-cooled chiller, reciprocating compressor, operating efficiency, condensing temperature

INTRODUCTION

The chiller plants for providing cooling in buildings in a dense urban environment, as is Hong Kong, often require heat rejection by air-cooled condensers. Energy consumption using different heat rejection methods has been reported, e.g. Yik, et al. (2001). The electricity consumption by chiller plants is large, and imposes a direct impact on the peak demand load on the power station. Improving the operating efficiency of the chillers would lead to less electricity consumption and hence less emission of global warming gases from power stations, which contributes to the overall scheme for building energy effectiveness.

The operating efficiency of a chiller can be expressed in kW/ton, which is the chiller consumption per ton of refrigeration output. Chan and Yu (2002) reported that the cooling effectiveness is penalized by the high electricity consumption by the chillers running at low efficiency as they work at a high condensing temperature of about 50°C based on the design outdoor condition of 33°C. Similar finding was stated by Smith and King (1998). Poor chiller efficiency also results from the oversized chillers running at part loads most of the time, and the inappropriate matching of operating chillers to the building cooling load based on the experience of the plant operators. Improving the chiller efficiency requires knowledge of the behavior of each operating parameter on the chiller consumption and the cooling output. Nevertheless, there is a lack of culture in keeping in-situ chiller operating parameters, which poses the difficulties in verifying the chiller performance over the manufacturer specification and developing optimum control strategies for improved chiller efficiency.

This parametric study explores the behaviors of the operating parameters of direct air-cooled chillers with reciprocating compressors from a local chiller plant. Study is made on the key operating parameters: evaporating and condensing pressures, chilled water flow rate, supply and return chilled water temperatures and entering and leaving condenser air temperatures, as well as the chiller power together with other predicted parameters from a chiller system model. It is intended to exploit further how the chiller efficiency can be improved by reducing the condensing temperatures under the local mild weather. Results of the parametric analysis will be useful in three ways. Firstly, the relative significance of each parameter on the chiller efficiency can be identified, which will provide a gateway for the chiller system simulation study and to verify the confidence levels on the prediction of the chiller component performances by simulation. Secondly, the understanding of the characteristic relations within the performance and operating parameters can help to trace out a set of chiller efficiency curves under different weather-load conditions for the optimal combinations of chillers and the evaluation of the year round consumption. Thirdly, the results support the need of developing control of lowering the condensing temperature by making full use of the below-design outdoor temperature conditions for maximizing the chiller efficiency, taking into account the likely effects and boundaries of other operating parameters.

THE STUDIED CHILLER PLANT AND THE CHILLER MODEL

The Studied Chiller Plant

The studied chiller plant consists of seven identical sets of air-cooled reciprocating chillers using refrigerant R-22 with rated capacity of 120 tons of refrigeration (420 kW). The loading and unloading of chillers are manually controlled with reference to the return chilled water temperature, chiller running ampere and outdoor air temperature. At a particular cooling demand, the chilled water flow rate through each chiller may be equal to or greater than the design flow rate by operating more pumps than necessary.

Each single chiller typically composes of three semi-hermetic reciprocating compressors with cylinder unloaders for capacity control, a thermostatic expansion valve for regulating the refrigerant feed to the evaporator, a shell-and-tube evaporator and an air-cooled condenser of finned coils with multiple condenser fans. There are six steps of capacity control with a minimum of 33% rated capacity by staging the three compressors with cylinder unloaders. Each operating compressor is interlocked with 3 constant-speed condenser fans. The required heat rejection when adopting head pressure control can be obtained by cycling the condenser fans.

Hourly operating parameters of the individual chillers were obtained from the manually recorded readings from the built-in instruments. The operating parameters include: evaporating and condensing pressures, P_{ev} and P_{cd} (kPa), chilled water flow rate m_w (kg/s), supply and return chilled water

temperatures, T_{chws} and T_{chwr} (°C), entering and leaving condenser air temperatures, T_{cdae} and T_{cdal} (°C) and chiller running ampere, I_{ch}. Field measurements using portable instruments for the running ampere, power factor and chilled water flow rate were also carried out to substantiate the accuracy and reliability of the recorded data.

The Chiller System Model and Parameter Evaluation

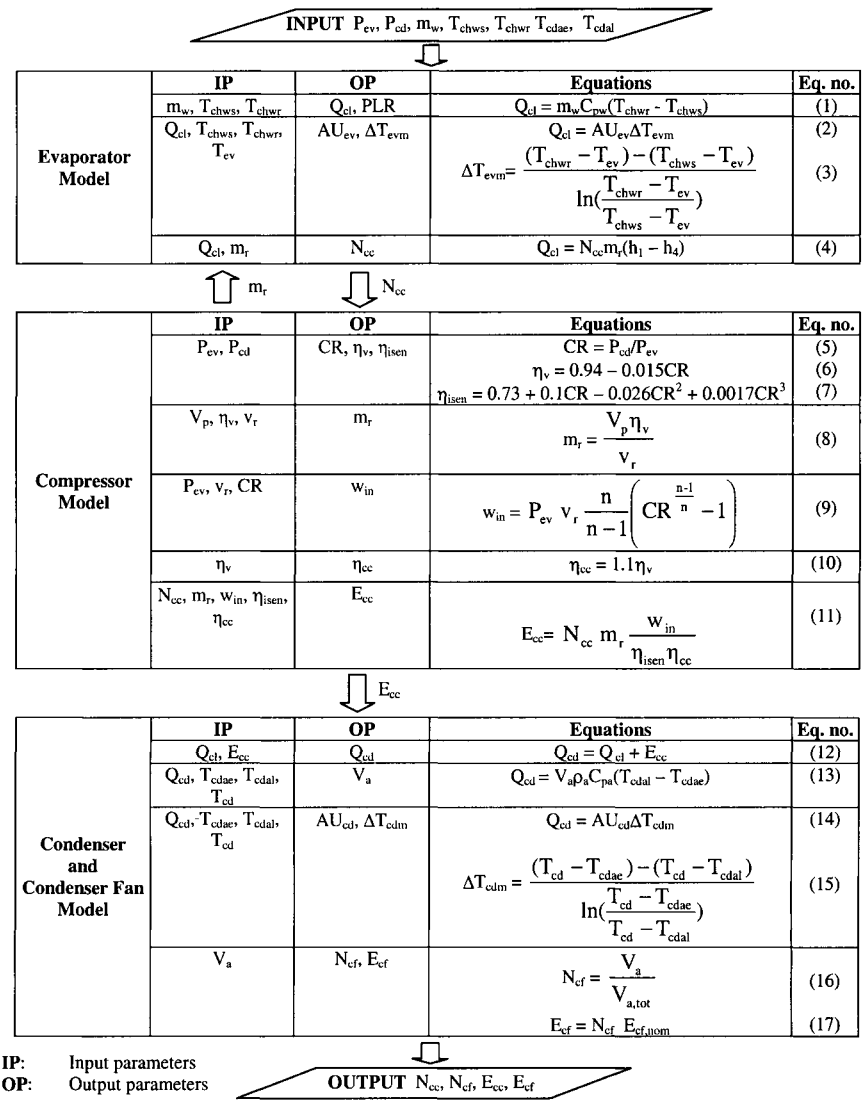

Figure 1: The chiller system model.

In the vapor compression cycle of chiller operation, the thermodynamic states of the refrigerant can be determined from the state equations of the refrigerant. Figure 1 shows the system model containing

different sets of empirical, mass and energy equations (1) to (17) within the chiller components. The hourly operating data (i.e. P_{ev}, P_{cd}, m_w, T_{chws}, T_{chwr} T_{cdae}, and T_{cdal}) constitute the independent input parameters to evaluate the predicted parameters that cannot be directly monitored but influencing the chiller consumption. It is expected that the predicted parameters would satisfy with real operating conditions as the range of the input parameters complies with the actual operating conditions. The chiller part load ratio, PLR was used to indicate the cooling load. The procedures and assumptions for the evaluation of the predicted parameters are described as below.

For the compressor model, the piston displacement of a compressor, V_p (m^3/s) in Eqn. (8) relating to the cylinder diameter, stoke of the piston, cylinder number per compressor and the revolution per second is regarded as a constant and can be evaluated by using the manufacturer data at the rated condition. For a typical reciprocating compressor, the volumetric efficiency, η_v is related to the compression ratio, CR by the empirical Eqn. (6) (Wang 2001). The refrigerant mass flow rate per capacity control step, m_r can be determined from the known parameters of η_v and the specific volume of refrigerant at the compressor suction state, v_r. The predicted m_r is then used to evaluate the required number of capacity control steps, N_{cc} for a certain cooling load using Eqn. (4) in the evaporator model.

The isentropic compression efficiency, η_{isen} is empirically governed by the compression ratio, CR in Eqn. (7) (Tassou, et al. 1998). Since there is no mathematical relation governing the compressor efficiency, η_{cc}, it is firstly approximated to be the volumetric efficiency with additional 10% to offset the power loss due to the mechanical friction in the compressor as given by Eqn. (9). Subsequent calibration to the η_{cc} can be carried out by comparing the results of the predicted output parameters with the operating data to give a derating factor as a function of the part load ratio.

For a specific cooling load the required heat rejection, Q_{cd} (kW) is readily calculated using Eqn. (12) upon the cooling load, Q_{cl} (kW) and the compressor power input, E_{cc} (kW) are evaluated from the evaporator and compressor models. The calculated Q_{cd} can then be used to find out the required condenser airflow, V_a (m^3/s) and the number of operating condenser fans and hence the fan power, E_{cf} (kW) based on the modeling equations in the condenser model.

The predicted power consumption of an operating chiller, E_{ch} by the system model is given by Eqn. (18), whereas the actual chiller power consumptions were obtained from the hourly recorded data.

$$E_{ch} = E_{cc} + E_{cf} \tag{18}$$

RESULTS AND DISCUSSION

Model Validation

Model validation can be accomplished by comparing the predicted data with the operating data and calibrating the empirical model equations so that the discrepancy falls within ±10% of the operating data. The chiller efficiency curve defined as a plot of the kW/ton against the chiller part load ratio was used here for the validation process. Figure 2 shows the existing data, the predicted data by the model after calibrating the compressor efficiency, the regression line of the existing data of chiller efficiency together with the ±10% boundary lines.

Nearly all the predicted values lie within the ±10% boundary lines. Parametric analysis can then be carried out based on the operating parameters and the predicted parameters from the validated model.

In the existing chiller plant studied the efficiency exceeded 1.3 kW/ton most of the time, indicating that the chiller operation cannot meet the minimum COP of 2.7 (i.e. 1.3 kW/ton) required for air-

cooled reciprocating chillers under the code of practice for energy efficiency of air-conditioning installations implemented by the government (EMSD, 1998). This low part-load efficiency of the air-cooled chiller deserves the exploration of optimum control strategies to minimize the compressor power at the below-design conditions.

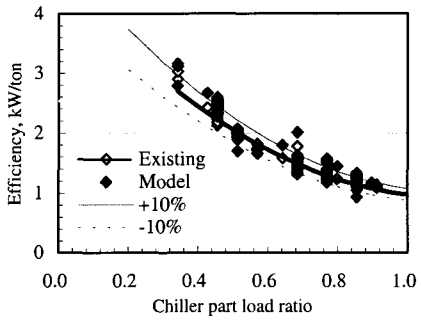

Figure 2: Chiller efficiency curve obtained from existing data (with modeled data for comparison)

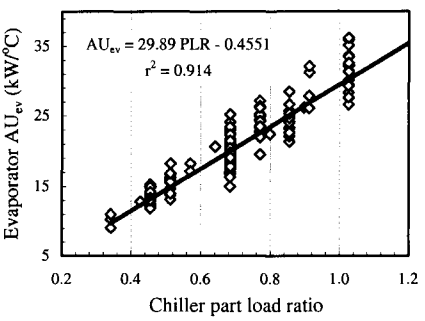

Figure 3: Correlation of the evaporator performance with the chiller part load ratio

Parametric Analysis

Having identified that the chiller efficiency is dependent on the part load ratio, it is necessary to exploit the change of the performance parameters of the chiller components in response to the part load ratio and the relative significance of the control parameters on the performance.

As can be seen in Figure 3, the evaporator performance parameter expressed by the heat transfer coefficient, AU_{ev} closely relates to the chiller part load ratio, with a coefficient of determination of 0.91. For a certain cooling capacity, the AU_{ev} can be explicitly predicted by the regression equation. Such explicit equation is preferable in developing the chiller system model for steady-state simulation when the ease of computation prioritizes over the accuracy. Precise prediction on the evaporator performance should resort to the mechanistic relations on the shell-and-tube heat exchanger involving the shell side and tube side heat transfer coefficients together with the specific parameters on the evaporator geometric and fluid properties. The coefficients associated with the chilled water mass flow, m_w and the cooling capacity, Q_{cl} would introduce implicit equations, under which all the parameters have to be solved by the iterative approach.

It is expected that the AU_{ev} of the evaporator and cooling capacity are enhanced with larger chilled water flowrate. The trade-off between the enhanced cooling capacity and the increased pump power incurred by larger water flow should be investigated, especially at the low part load condition when the pump power may outweigh the compressor power. Another operating strategy is to raise the evaporating temperature by setting the supply chilled water temperature at a higher value under the part load condition. Nevertheless, from the parametric analysis, appreciable improvement in the evaporator performance cannot be obtained by increasing the evaporating temperature during the part load operation. There exists a wide range of the AU_{ev} at a particular evaporating temperature and a clear trend between the two cannot be observed.

The results of the parametric analysis on the evaporator side indicates that varying the control parameters of chilled water flow and the evaporating temperature shows a diverse effect on the chiller operating efficiency, as they do not bear a close relationship with the evaporator heat transfer coefficient. It suggests that the mechanistic relation of chilled water flow rate on the AU_{ev} will be dominant at the tube side heat transfer coefficient, whereas it produces fluctuating effect on the shell

side heat transfer coefficient. The direct relation between the chiller efficiency and the part load ratio becomes justified if the operating chiller is maintained at constant chilled water flow.

Figure 4 depicts the capacity control steps by staging compressors and unloading cylinders in response to different part load ratios. Referring to Figure 5, at a constant part load ratio, the compressor power and work of compression exhibits a linear relationship. However, the compressor power values shift up and down with changes of part load ratio. This explains for the need of applying a derating factor as a function of part load ratio to the compressor efficiency in the prediction of actual compressor power. This modeling approach is common to mechanistic models in which the mechanistic relations employ empirical functions to predict performance of the modeled components and to simplify the required geometric parameters.

It is noted that fluctuating compressor power occurs at part load ratio of around 0.8 at which the 4th and 5th capacity control steps coexist, and higher compressor power occurs at lower part load ratios handled by half-load operating compressors. This situation can be improved by using variable compressor speed to modulate the refrigerant flow on continuous basis, but is not feasible for the reciprocating chillers where the refrigerant flow is intermittently controlled by unloading cylinders and staging of compressors.

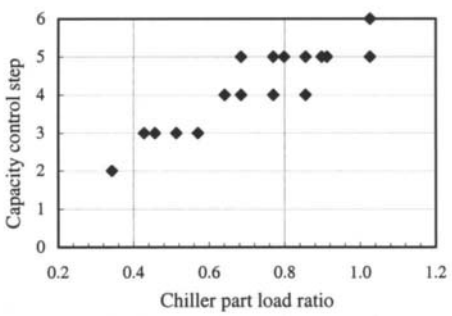

Figure 4: Required capacity control step for various chiller part load ratio

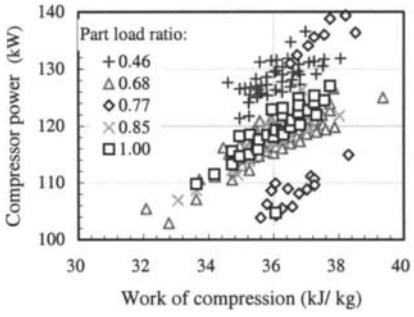

Figure 5: Compressor power vs. work of compression at various part load ratio

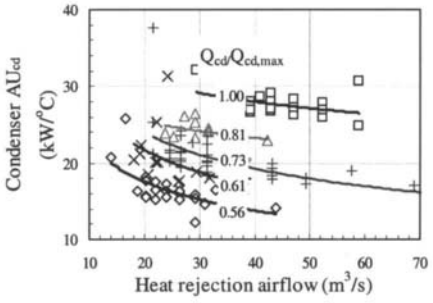

Figure 6: Effect of heat rejection airflow on the condenser performance

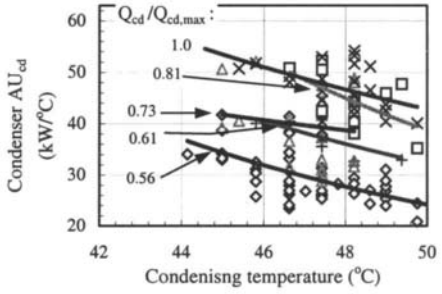

Figure 7: Effect of condensing temperature on the condenser performance

Similar to the behavior of the evaporator performance, the condenser performance in terms of the condenser heat transfer coefficient, AU_{cd} increases with the chiller part load ratio, but the correlation is much weaker than in the evaporator. Further parametric analysis illustrates that the condenser performance cannot be simply represented by any one of the control parameters: total refrigerant mass

flow, m_r, heat rejection airflow, V_a and condensing temperature, T_{cd}. As shown in Figure 6, the condenser performance increases with the normalized heat rejection ratio (i.e. $Q_{cd}/Q_{cd,max}$), but unexpectedly, the increase in condenser airflow would depress the condenser performance at any particular heat rejection ratios.

Since the refrigerant mass flow and the heat rejection airflow are constrained by the operating balances of the cooling load and the required heat rejection, they are not controllable for energy efficiency under varying weather-load conditions. As seen in Figures 7 and 8, the condenser performance and the chiller efficiency are improved with downward shift of condensing temperature at below-design outdoor temperature even though the operation is under head pressure control.

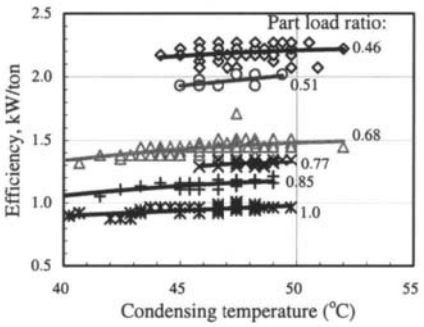

Figure 8: Relationship between the chiller efficiency and the condensing temperature

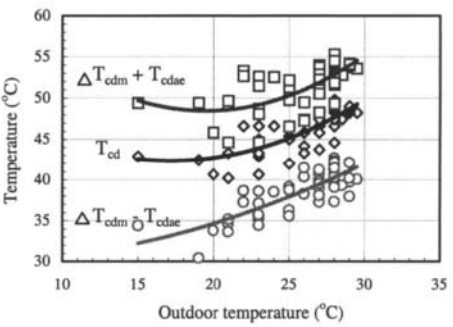

Figure 9: Boundaries for the condensing temperature at various outdoor temperatures

Opportunity of Reducing the Condensing Temperature

For a certain heat rejection, the condensing temperature can be reduced by cycling on more condenser fans to increase the heat rejection airflow. To exploit the likely boundary conditions experienced by the condensing temperature, two specific parameters: $\Delta T_{cdm} + T_{cdae}$ and $\Delta T_{cdm} + T_{cdal}$ are plotted together with the condensing temperature, T_{cd} against the outdoor temperature, T_{cdae} as shown in Figure 9. The condensing temperature data lie within the $\Delta T_{cdm} + T_{cdal}$ and the $\Delta T_{cdm} + T_{cdae}$ at any outdoor temperature. The two parameters form the upper and lower boundaries, and that the condensing temperature follows the inequality below:

$$\Delta T_{cdm} + T_{cdae} < T_{cd} < \Delta T_{cdm} + T_{cdal} \tag{19}$$

It is desirable to control the condensing temperature close to the lower boundary by making full use of the lower outdoor temperatures during the mild season. The condensing temperature tends to drop slightly with decreasing outdoor temperature under the head pressure control by cycling on more condenser fans to induce larger heat rejection airflow. But this drop of condensing temperature, as seen in Figure 9, is small. The potential of reducing the condensing temperature can be greater if the head pressure control method is discarded.

The constraint of lowering the condensing temperature lies on whether ΔT_{cdm} can be reduced, which can be achieved through the enhancement of the condenser heat transfer coefficient, AU_{cd}.The existing control makes the condenser operate at the ceiling of ΔT_{cdm} (i.e. 20°C) with the condensing temperature of above 50°C most of the time, which is undesirable for energy efficiency.

The maximized chiller efficiency occurs at the lowest possible condensing temperature governed by

the outdoor temperature and the condenser performance. However, the lower boundary for the condensing temperature is constrained by the requirement for lubrication oil return and for the thermostatic expansion valve to work properly. Further experimental and simulation studies are required to develop the control algorithm to achieve the lowest possible condensing temperature making use of the low outdoor temperatures available during the mild weather, and taking into account the operational constraints. Quantification of the improved chiller efficiency and the year round energy saving can then be made from a set of chiller efficiency curves generated by a chiller system simulation together with the anticipated weather-load conditions.

CONCLUSIONS

A parameterization study aiming at exploring the behaviors of the operating parameters of the air-cooled reciprocating chillers by the hybrid use of the operating data of an existing chiller and predicted data by a chiller system model has been carried out. A chiller system model taking into account the thermodynamic properties of the vapor compression cycle and the operating balances with the chiller components was developed and validated to predict other parameters influencing the chiller efficiency.

Increasing the chilled water flow and the evaporating temperature to enhance the evaporator performance is likely to be offset by the additional pump power and a trade off study between the two should be carried out. The constraints of the chilled water temperature reset control for improved efficiency lie on the limited enhancement on the evaporator performance and the additional pump power from the increased chilled water flow. The realistic compressor power performance can be predicted using an empirical expression of compressor efficiency relating to the part load ratio. Fluctuating compressor power and chiller efficiency by the multiple number of capacity control steps was identified.

Evaluation of the condenser performance indicates that the chiller efficiency as well as the condenser performance can be improved by reducing the condensing temperature. The analysis on two specific parameters: $\Delta T_{cdm} + T_{cdae}$ and $\Delta T_{cdm} + T_{cdal}$ from the operating data confirms that the condensing temperature is lower bounded by $\Delta T_{cdm} + T_{cdae}$ and upper bounded by $\Delta T_{cdm} + T_{cdal}$. The condensing temperature can be brought down by lowering the upper boundary through introducing additional heat rejection airflow by driving more numbers of condenser fans. It can also be reduced by lowering the ΔT_{cdm} through the enhancement of the heat transfer coefficient, AU_{cd}.

THE DESIGN OF HIGHLY GLAZED FACADES AND THEIR ENVIRONMENTAL IMPACT

Phil Jones

Welsh School of Architecture
Cardiff University, Cardiff CF10 3NB

ABSTRACT

Thermal comfort and energy use in modern office type spaces is closely related to the thermal performance of the glazed façade. The ability to provide shading and thermal insulation can influence the type of environmental system for cooling and ventilation. This paper will describe the use of computer modelling to predict glazing performance in relation to modern office environments. A combination of dynamic thermal modelling and spatial airflow modelling has been used in the design of a range of glazed facades. The paper will draw on experience of real façade design projects based on new and existing offices in Europe, involving different combinations of glazing treatments and internal environmental systems. The appropriateness for such systems in Hong Kong is discussed.

KEYWORDS

Facades, energy efficient design, thermal modelling, airflow modelling, chilled surface cooling.

INTRODUCTION

In recent years there have been interesting developments in façade design in Europe. This has largely been in response to the design of 'climate selecting' or 'passive' buildings that can provide comfort conditions with the efficient use of energy. Many such buildings have highly glazed facades to provide daylit spaces, visual contact between inside and outside, and to provide aesthetically pleasing elevations. However, thermal conditions and energy use in modern office type spaces is closely related to the performance of the glazed façade. Its ability to provide shading and thermal insulation can influence the type of environmental system for cooling and ventilation. The façade is increasingly becoming a major component of environmental design and its performance needs to be carefully assessed during design in relation to the heating and cooling loads on the space and the associated systems.

A well designed façade can significantly reduce the cooling load of a building. In Switzerland, for example, there is a tight control over the use of air-conditioning, and in most cases it is restricted to mechanical ventilation with some comfort cooling. Air conditioning is only allowed if the design can

demonstrate that the solar gains are minimised through the facade. Sometimes additional cooling may be provided through active cooled surfaces, such as chilled beams and ceilings. These new innovative combinations of façade design, low level ventilation and surface cooling, provide energy efficient thermally comfortable solutions for modern office environments. The question is, to what extent are these solutions appropriate to the Hong Kong environment, typified by, high levels of internal heat gains from people and processes, and high external temperatures, solar radiation and relative humidity.

THERMAL DESIGN OF FACADES

The aim of the thermal design of facades is to control heat gain and heat loss. The solar heat gain can be from direct and diffuse solar radiation. In hot weather, there will also be some transmission heat gains from high external temperatures. Controlling solar gains is more difficult for west and east facades where the sun angle is lower.

The problem of controlling solar gains can be addressed through innovative shading, often of a dynamic nature, moving into position only when the sun is incident on the façade. A typical European requirement could be that the internal air temperature does not exceed 26°C in summer and the internal glass surface temperature should be within 5°C of the space air temperature. Glazing g-values (that is, a coefficient that describes the total solar transmission through a facade) should be less than 0.15 and there must be an internal mass greater than 350kgm^{-2} of floor area. The facade has to be carefully designed to minimise solar heat gains, not only to the space but also to the glazing system and avoiding high glass temperatures. Even for facades with low g-values, there have been problems associated with excessive heat gains and high internal glass surface temperatures (greater than 40°C), making the internal glazing effectively a 'low temperature' radiator.

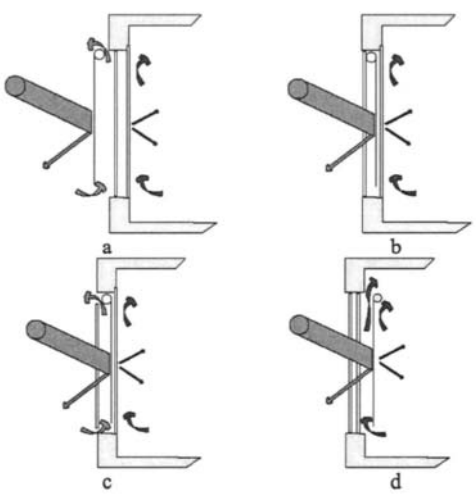

Figure 1: Illustration of different glazing shading strategies indicating convective and radiant heat exchange for, a) external shading, b) middle sealed shading, c) middle ventilated shading, and d) internal shading.

So, if large areas of glazing are to be used, some form of shading is required. This can be located (see figure 1):

- On the external façade: sometimes moving into position only when the sun is on the façade. This is usually considered the best approach, as the solar heat gains are kept external to the space and glazing system.
- In the middle: within the glazing system. If the system is sealed then the solar heat gains can be trapped within the glazing system and can result in high internal glass temperatures. If the glazing system is ventilated then the heat gains can be exhausted to outside, but still the glazing system is subject to some gains which can give high temperatures, especially if the ventilated glazing extends for a number of floors.
- On the inside: This is the worst case to control as the heat gains are allowed to enter the space. Although some are reflected back and absorbed by the shading system most of the heat will be contained in the space either as convective gains or long wave radiant gains.

COOLED SURFACES AND MECHANICAL VENTILATION

The façade design should be integrated as part of the overall environmental design. This will often include the ventilation and thermal capacity aspects of thermal design. The façade design should control solar gains and minimise external heat gains. This should be accompanied by measures to reduce internally generated heat gains from lights and small power. Ventilation can often be reduced to the minimum for occupation and where necessary, other means of cooling applied. A strategy is outlined in figure 2.

1. Reduce internal gains
   - Internal gains 25-35 W/m^2
2. Provide solar control façade
   - g-value less than 0.15
3. Reduce ventilation to minimum for occupancy. Expose thermal mass to stabilise heat gains (usually with night cooling).
   - Exposed mass cooling 5-10W/m^2
   - Ventilation rate 2-3ac/h at 18°C
4. If heat gains are higher, provide mass cooling with a water or air chilled slab
   - Chilled mass cooling 30-35W/m^2
5. If heat gains are higher provide cooling with chilled beams
   - Chilled beam cooling < 80W/m^2

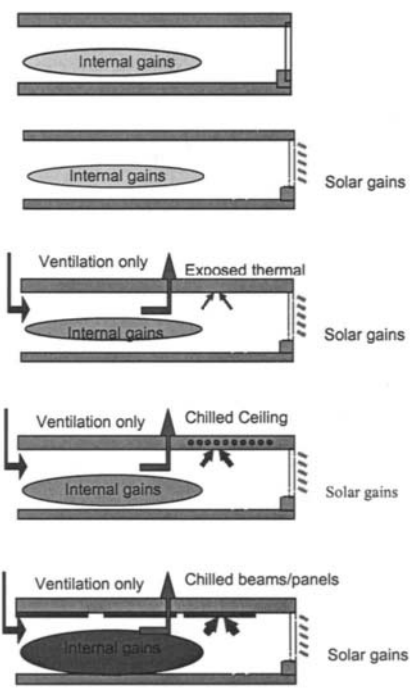

Figure 2: Chilled surface and mechanical ventilation options

Mechanical ventilation systems should have low pressure drop distribution to minimise fan power. In the UK, building regulations specify a specific fan power of 2W/l/s for new buildings [Part L2, UK Building Regulations 2002]. Ventilation systems are often of the displacement type, using floor delivery systems with extract at high level.

PREDICTIVE TOOLS

The accurate prediction of the performance of integrated environmental systems is needed for design. The glazing system performance must be integrated with other environmental aspects, such as passive or active cooled surfaces and displacement ventilation. There is therefore a need to be able to predict the time varying performance of facades under varying external conditions of temperature and solar radiation. This can be achieved using a dynamic energy model. The model HTB2 used in the work described here was developed at the Welsh School of Architecture (Alexander 1997) and is in use in a number of academic and industrial organisations. It can be used to predict internal space and glass surface temperatures (Lang et al 2000). It models the system as a set of nodes, each node associated with a space temperature or a surface (or 'finite difference' temperature within a construction). The only assumed information is the ventilation rate of the space and this has to be input to the model. Figure 3 presents the nodal description of a simple space with a blind on the inside.

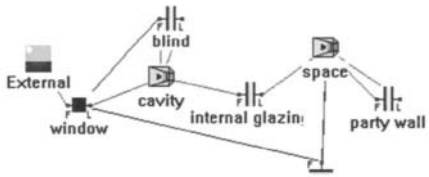

Figure 3: A nodal representation of an office space with an internal blind. The gap between the blind and the glazing is modelled as a separate space.

The ventilation rates associated with individual spaces and the spatial variation of temperatures and air movement can be predicted using an airflow model. The most widely used airflow models are now generally computational fluid dynamics (CFD) models. They can predict the spatial variation of temperatures and air movement. Airflow models are generally used to predict conditions at a point in time, often using surface temperature boundary conditions generated by dynamic models, which can account for thermal mass effects (Jones and Kippenburg 2000). Figure 4 presents an example of an airflow model predicting the airflow and internal temperatures for an internal blind system.

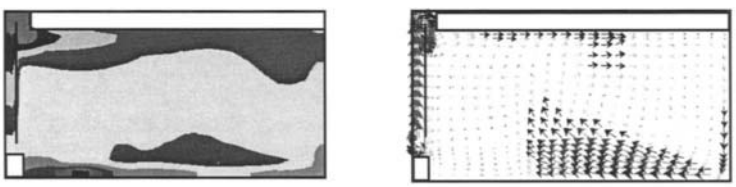

Figure 4: A vertical section through a space with an internal blind and displacement ventilation, showing the temperature contours and air velocity vectors.

APPLICATION TO SHADED GLAZED FACADES

The above tools have been used to predict the performance of the glazing systems shown in figure 1. In each case the system was approximated to a system of nodes, with the inside shading option indicated in figure 3. The ventilation rates associated with the three ventilated shading systems (cases 1a, 1c, and 1d in figure 1) were estimated from airflow prediction (similar to figure 4). The results are presented in figure 5 (a to d).

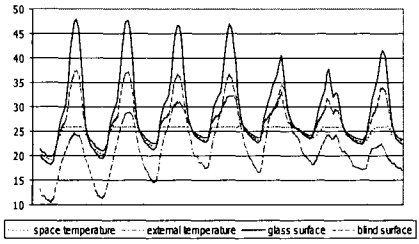

Figure 5a: Internal blind.

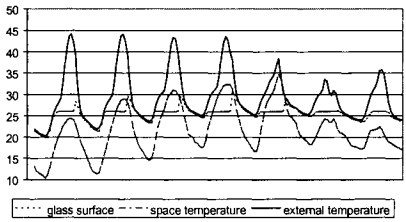

Figure 5b: Middle blind in sealed glazing system.

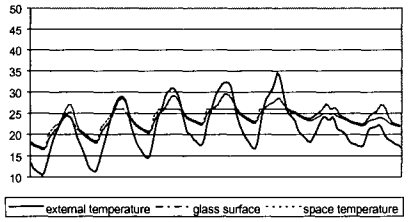

Figure 5c: Middle blind in ventilated glazing system

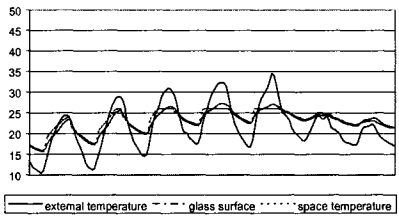

Figure 5d: External blind.

The results of the simulated blind performance indicate the internal glass (or blind in figure 5a) temperature for the different systems. For example, with the internal blind and middle sealed blind the internal glass surface temperature is relatively high, peaking at 36.5°C and 43.5°C respectively, which is well above the desired 5°C limit above the internal space temperature.

When considering these results it should be noted that they relate to specific window systems, with particular blind and glazing properties. They are therefore only indicative of the performance of these types of systems and should considered in this context.

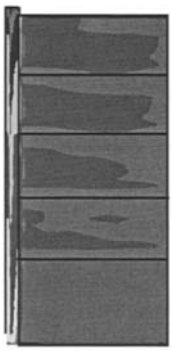

Figure 6: Double skin façade on five floors.

In some cases the blind system will extend over the whole façade and it will be necessary to predict the façade performance at this scale. In such cases the airflow model can be applied to predict peak or typical conditions. Figure 6 shows an example of a simulation of a double skin façade indicating the rise in air temperature with height, imposing an increasing cooling load and internal glass surface temperature on floors at higher level.

APPLICATION TO OTHER CLIMATES

The above discussion has related mainly to building designs in northern Europe. The application to other climates such as Hong Kong is considered below in relation to the main differences in climate.

- Higher external air temperatures: If the façade is well insulated and well sealed, in relation to air leakage, the increase in transmission heat gain should not give rise to a significant increase in the heat load on the space. The coolin load relating to the ventilation air supply will be higher but the supply air temperature and flow rates to the internal spaces need not change as they then only relate to the occupancy levels, internal heat gains and solar gains.
- Increased solar radiation: If a low g-value façade is used then the solar heat gain should be well controlled. For example a double skin ventilated façade with shading should provide sufficient solar control.
- Higher external humidity: The supply air must have humidity control, and the building should be well sealed to minimise air leakage and consequential effects on internal relative humidity levels. The internal sources of moisture in Hong Kong, that is, people, should be no different from other parts of the world.

So, the indication is that the integrated façade and environmental systems described in this paper can be used in Hong Kong without much alteration. The main differences for the Hong Kong situation will be in relation to increased cooling and dehumidifying of the external ventilation air supply.

CONCLUSION

The modelling of facades is important in relation to controlling solar gains. There is potentially a wide range in performance for different glazing shading systems. The main aspect of successful design is to exhaust the solar heat gains trapped by the glazing system. This is a problem for internal and sealed glazing blind systems.

The design of the integrated environmental system will depend on the level of internal heat gains. The system should aim to minimise ventilation cooling and provide chilled surface cooling as appropriate to the internal heat gains.

Such systems will work in Hong Kong provided the building is well sealed and the ventilation supply air has humidity control.

A combination of dynamic thermal modelling and CFD airflow modelling provides a means of predicting system performance and integrating the glazing system with other environmental systems, for example, thermal mass and ventilation.

LOCAL STUDY OF THE INFLUENCE OF A NUMERICAL THERMAL MANIKIN ON THE AIR FLOW PATTERN AND TEMPERATURE FIELD OF A SPACE

Kaja Kippenberg-Kretzer and Phil Jones
Welsh School of Architecture, Cardiff University, Wales, UK

ABSTRACT

This paper presents the first results of a numerical thermal manikin implemented into a Computational Fluid Dynamics (CFD) code whose position in the simulated space can be easily changed in successive steady-state calculations. The mobility allows for local studies of the influence of human heat release and body shape on the air flow pattern and temperature field of a space.

The body of the manikin consists of 14 segments, with a simple body shape. For the study presented here constant skin temperatures were assumed. A more refined thermo-physiological model is currently developed. The manikin is a simulation tool that can be run on a standard desk top computer or notebook with reasonable computation time.

Three different positions of the manikin were simulated: One with the manikin standing near the internal wall, one with the manikin in the centre of the space and one with the manikin standing near the window. For all three positions simulations for summer and winter conditions were performed, respectively. Thus, all in all 6 cases are presented. The simulations clearly show the influence of the position of the manikin on the air flow pattern and temperature field of the space, using a relatively course grid manikin.

INTRODUCTION

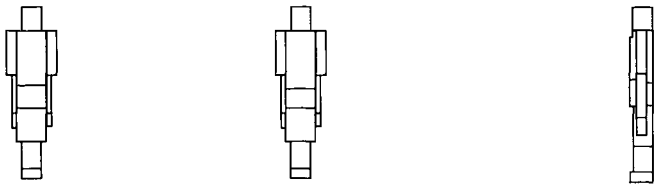
Heat release and shape of the human body influence the air flow pattern and the temperature field of a space. Depending on the purpose of a space occupants might move around or be more static. The less active people are, the more sensitive they usually are towards the thermal environment, (ASHRAE (1993)). Thus, the importance of the influence of their heat release on the thermal environment increases with decreasing activity levels, e.g. for sedentary activities in a typical office space.

Indoor thermal environments often are non-uniform throughout a space. Recent research of thermal comfort has investigated the ability of the human body to adapt to a wide range of thermal conditions as well as behavioral adaptation of occupants to their thermal environment (Brown & Jones (1993)), (Humphreys & Nicol (1988)). Recent studies showed that people might even prefer a thermal environment that varies in time and space (Xia, Zhao & Wu (2000)), (Conceicao (2000)), (Nakamura, Mizuno & Ida (2000)) to a static and uniform one.

When innovative low energy heating and cooling systems or passive building design, for which often no previous experiences of performance exist, are to be developed, the examination of the achieved thermal environment and adjustment of design during the design process is important. With advancing computer technology, numerical manikins are increasingly employed for the investigation of thermal comfort and indoor thermal environments. Several manikins with complex thermo-physiological models exist (Murakami, Kato & Zeng (2000)), (Huizenga, Hui & Arens (2001)), (Miyanage, Urabe & Nakano (2001)), and one of them is integrated into a CFD code (Murakami, Kato & Zeng (2000)). However, numerical manikins have been very detailed requiring large CFD grids and simulation times.

The manikin employed in this study is implemented within a CFD code (Jones & Waters (1993)) using a relatively course grid structure. Its position in the simulated space can be chosen at the start of each run of a steady-state simulation, whereby the geometry and layout of the simulated space are conserved. The mobility of the numerical manikin is of great advantage for the examination of non-uniform indoor thermal environments. The layout of the manikin and the simulated space is explained in detail below.

The aim of the work is the development of a numerical manikin simulation tool that can be used on a standard desktop computer or notebook with reasonable computation time. It should be possible to perform a study with different positions of the manikin quickly. Thus, the grid is rather coarse and the shape of the manikin very simple.



In this paper six case studies of a space similar to an office space are presented: The first one with the manikin standing near an internal wall, the second one with the manikin standing in the centre of the space and the third one with the manikin standing near the window. For all three positions simulations for summer and winter conditions were performed, respectively. The aim was to investigate the influence that the position of the manikin has on the air flow pattern and temperature field under varying thermal conditions.

THE MODEL

For the study presented here a standard CFD code was used (Jones & Waters (1993)) which has been adapted to incorporate a numerical manikin. The code employs finite volume method with hybrid differencing scheme. Turbulence is modelled with a constant eddy viscosity of 200 x laminar. Currently the model only deals with convective heat exchange but in the future a radiant component will be added.

The body of the manikin is displayed in Figure 1. The heat exchange with the environment is modelled by defining constant skin temperatures. Values were taken from an experimental physical manikin (Myers, Hosni & Jones (1998)) consisting of 16 body parts. For simplicity at this stage this study uses only 14 body parts; feet, calves and thighs are defined as blocks. For left and right body parts mean values of the

skin temperature values in (Myers, Hosni & Jones (1998)) were used. The constant skin temperatures are displayed in Table 1.

a) b) c)

Figure 1: Schematics of the manikin body segments: a) front, b) back, c) side

TABLE 1
SKIN TEMPERATURE OF THE DIFFERENT BODY SEGMENTS OF THE MANIKIN

Body Part	Skin Temperature [°C]
Feet	29.6
Calves	31.6
Thighs	31.5
Lap	32.9
Buttocks	32.3
Chest	30.6
Back	32.4
Head	28.3
Upper Arms	30.5
Lower Arms	30.8
Hands	29.5

Currently the shape of the manikin is very simple, with the arms attached to the torso and the legs being one rectangular block. The influence of this simplification on the air flow pattern will be investigated later, and necessary changes will then be made.

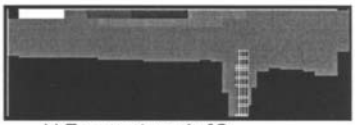
The whole simulated space including the body of the manikin is built of a rectangular grid with varying cell sizes. Around the manikin the grid is finer than in areas further away from the manikin that are of lesser interest. The grid lines extend through the whole space causing refinement of the grid not only at the position of the manikin but also in the extrapolation of the manikin body along the respective directions. The side lengths of cells around the manikin are 0.05m to 0.10m, those of cells further away are up to 0.20m. This grid is rather coarse and was chosen so to keep computation time low. The dimensions of the simulated space are 3m x 6m x 2.7m. The space has only one wall to external, the whole area of which is treated as a window. Mechanical ventilation was employed, with supply and

extract opening sizes of 0.2x0.2 m^2. The inlet opening is located in the upper centre of the 3m internal wall, opposing the window. The outlet is located in the ceiling, centred around the long axis with a distance of 2 m to the window. The u-value of the window was chosen to be 3W/m^2. All enclosures have differing surface temperatures as displayed in Table 2. Those temperatures were calculated by thermal dynamic simulation, employing HBT2, a thermal dynamic simulation computer program developed at the Welsh School of Architecture, (Alexander (1996)).

TABLE 2
SPACE SETUP

	Summer	Winter
Date	18/7; 16am	9/12; 8am
External Air Temperature [°C]	28.7	-1.6
Ventilation Rate [m^3/s; ac/hr]	0.0405; 3	0.027; 2
Supply Air Temperature [°C]	18.0	30.0
Floor/ Ceiling Surface Temperature [°C]	25.1	20.7
Wall Surface Temperature [°C]	25.6	20.5
Window Surface Temperature [°C]	28.4	13.0
Av. Space Air Temperature [°C]	24.9	20.8

At the start of a simulation the user first has to enter the location and size of the ventilation openings in multiples of the largest cell side length for each direction. If the geometry of the space does not allow a chosen opening the computer displays an error message and advice on choices of smallest possible modifications of either decreasing the size of the respective opening or changing its location. After the openings are accepted by the program the user is asked to enter the position of the manikin as distance to the origin, as well in multiples of the largest cell side length for each direction. The program then adjusts the grid accordingly. If the position of the manikin which constitutes the layout of the grid does not comply with the chosen geometry of the space (e.g. space dimensions or size and location of openings) the user will be advised on the nearest possible position of the manikin. With the current grid the correction of the manikin position is usually not larger than about 0.2m. To allow a large number of positions of the manikin variation of cell sizes is constrained to each cell size being an integer multiple of the next smaller one.



CASE STUDIES

The air flow patterns and temperature distributions of the case studies are displayed in figures 2.1 to 2.3. for the winter cases and figures 2.4 to 2.6 for the summer cases. The results show that the location of the manikin significantly affects both the distribution of air velocities and (in the case of the summer time) the air temperatures.

Figure 2.6: Manikin near internal wall, summer case

CONCLUSIONS

- The influence of the position of the manikin on the air flow pattern and temperature field of the simulated space can clearly be seen. The study shows the advantage of a mobile manikin over a static one in the examination of non-uniform thermal environments.
- It would be useful to construct a seated manikin and allow for the user to choose the posture of the manikin at the start of a simulation run since the heat release pattern and body shape of a seated manikin will be different from that of a standing one.
- A more refined thermo-physiological model of the manikin is currently developed and will be validated with experimentally measured data from a physical THERMAL MANIKIN used by a research group at Hong Kong Polytechnic University. The CFD code will be coupled with a radiation model, enabling a more accurate prediction of convective and radiant heat exchange. With the refined thermo-physiological model local predictions of thermal comfort that include several comfort parameters shall be performed for non-uniform thermal environments.
- The manikin shall be simple enough to allow the program to be run on a standard computer with reasonable calculation time so that local studies may be performed for everyday design processes. A systematic study needs to be performed to find out how much precision in each part of the model (e.g. grid, heat release) is needed in order for the results to be useful for the design process.
- The refined manikin model will allow the investigation of further questions of interest, among them the distinction of air-conditioned and passive design buildings from simulations point of view.

VALIDATION OF THE SIMULATION MODELS OF THE DOUBLE SKIN FACADE

W.J. Stec & A.H.C. van Paassen

Indoor Climate Technology, Sub Faculty of Mechanical Engineering, TU Delft,
Mekelweg 2, 2628 CD, Delft, The Netherlands. Email: w.j.stec@wbmt.tudelft.nl.

ABSTRACT

A mathematical model of the double skin façade (DSF) is validated with two test facilities.
A simplified version of the double skin façade was constructed in the laboratory. It is focused on defining its heat performance including convection (free or mixed), conduction, radiation and transportation heat transfer. Measurements and simulations were made at steady state conditions thus no real weather conditions were taken into account. The flow through the model is driven by the buoyancy effect and/or by fan.
Results from the laboratory test facility are used in modeling a test cell with a double façade situated outside the laboratory. This model is validated by experiments on this test cell under real weather conditions.
Validated model of the building with the double skin façade can be used to analyze the performance of different configurations of the double skin façade and related control.

KEYWORDS

Validation of thermal and airflow model of the double skin facade. Simulations.

INTRODUCTION

In the recent past several studies of the double skin façade (DSF) were done. Some of them were based purely on the simulations (Todorowic & Cvjetkovic 2001, Stec & Van Paassen 2001, Di Maio 2000, Mastrullo & Mazed & Vigo 1983, Moots & Benzin 1996). Some of the studies were also based on the experimental approach (Ziller 2000, Chic & Shako 2001, Spinnler 2002, Jones & Message & Li 2000, Sealens & Hens 2001). All those works introduce the heat and flow performance inside of the double skin facade (DSF) under steady state or unsteady conditions. None of these studies gives a validated thermal and air flow model of the double skin façade together with detailed analysis of its performance. In this work current result of the validation the simulation models of the double skin facade together with the building behind are presented.

Validation work is divided into two parts:

- Validation of the simulation model of the DSF with the laboratory test facility.
- Validation of the simulation model of the DSF together with the building done with the use of the test cell outside the laboratory

With a laboratory test facility thermal and airflow performance is tested under steady state conditions. That means that no changing outside weather conditions are taken into considerations. With this facility the buoyancy effect and free convection heat transfer are studied.
The results from the laboratory facility are used in simulation of the behavior of a full-scale test cell with DSF placed outside the laboratory. The performance of this test cell is monitored and compared with double skin facade and building is tested under real weather conditions.

SIMULATIONS OF THE LABORATORY TEST FACILITY

Measurements

The test facility is constructed out of the wood with steel frame and one glass wall (figure 1.). All walls apart from the glazed one are insulated with the 50 mm tick polystyrene. The back wall substitutes the basic wall of the building and the front glass plate simulate outside glass skin of the building. Back wall and glass skin create the air cavity in which a heating mat is situated. Heating mat gives up to 500 W/m^2 constant heat flux.
T-type thermocouples (36) were installed to examine temperature distribution. The temperatures of each surface and cavity on three heights are measured.

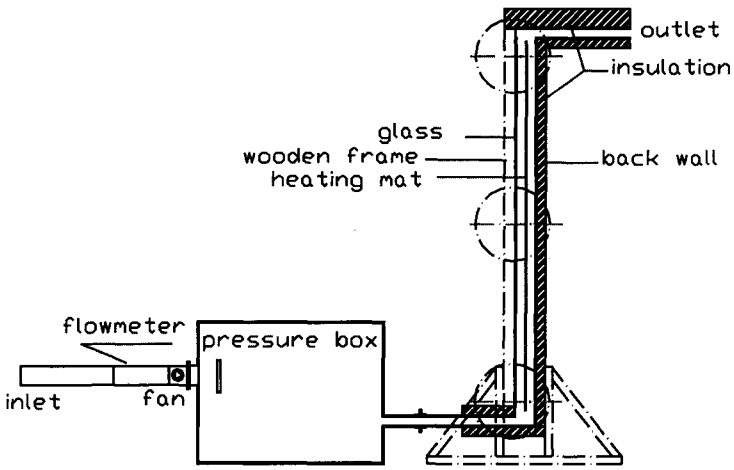

Figure 1. Test facility of the DSF at TU Delft

The flow measurement is realized with the use of the pressure box and flow meter connected to the inlet of the model. The pressure box supplies air to the cavity, which should be equal to that, induced by buoyancy effect. The flow meter installed on the inlet to the pressure box measure the total airflow through the system. Its accuracy is approximately 5%.
The fan connected with the pressure box compensates the resistance of the pressure box and flow meter (see figure 1). It can also be used for experiments with forced airflow through the cavity.

Simulations

The mathematical model consists of two parts: the airflow model and the thermal model.
These two models are simultaneously interacting one with each other.
The model was realized with the use of the MATLAB™. The model is static what in this case does not decrease its quality with comparison to the dynamic one (Di Maio 2001).
During the measurements the test facility was protected from any disturbances, so movements of the surrounding air are neglected and variations of temperature are very slow.
The airflow is driven by the buoyancy effect and is calculated according to Van Paassen &Voorden 2000. The average difference between calculated and measured flow shows to be 4.17% what is inside of the accuracy of the flow measurement.
The thermal model was built based on the network of heat exchange between each skin of the model (Stec 2002). The conduction, convection, radiation and transportation heat transfer was considered (see fig. 2). The problem that was to be solved was to select the solutions for the convection and transportation heat transfer.

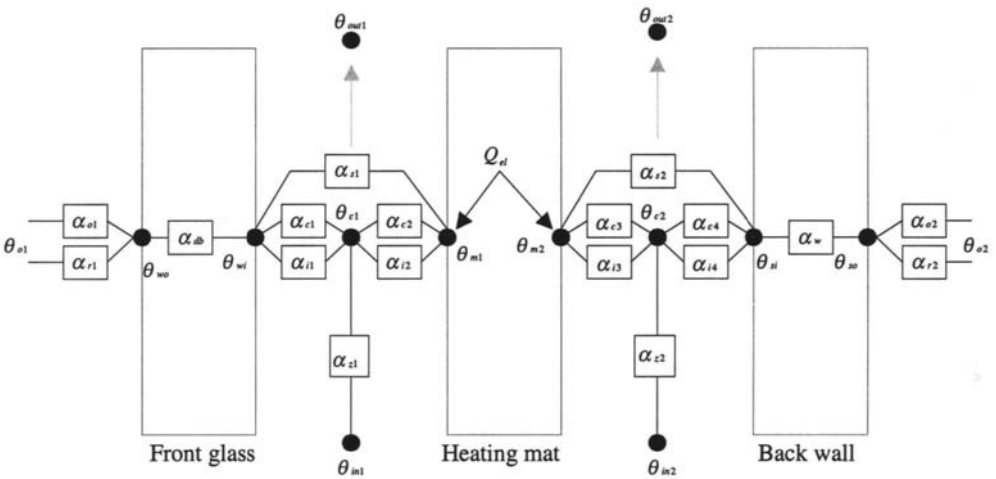

Figure 2. Network of heat exchange in the model of DSF.

Where,

$\alpha_{o(1,2)}$ -	Convection heat transfer coefficients between external surfaces of the model and outside air
$\alpha_{c(1,2,3,4)}$ -	Convection heat transfer coefficients between each skin and air inside of the model
$\alpha_{z(1,2)}$ -	Transportation heat transfer coefficients that represent the heat flow in the cavity from a lower to a higher node in the network.
$\alpha_{i(1,2,3,4),adb,w}$ -	Conduction heat transfer coefficients
$\alpha_{s(1,2),r(1,2)}$ -	Radiation heat transfer coefficients

By regression values of the transfer coefficients are defined giving the best fit with the measurements (table 1). Also ranges of values for each coefficient are given using the heat transfer relations found in literature.

Table 1. Values of specified heat transfer coefficients found by regression and with the formulas.

heat transfer coefficient	Values defined by regression	Final values defined with formulas
α_{o1}	8.80	8.20 – 8.50
α_{o2}	6.30 – 6.50	6.40 – 6.60
α_{c1}	5.00 – 5.80	4.90 – 5.90
α_{c2}	10.60 – 10.80	10.40 – 10.43
α_{c3}	6.70 – 6.80	6.50 – 6.60
α_{c4}	5.60 – 5.70	5.60 – 5.66
α_{z1}	10.90 – 11.25	11.20 – 11.40
α_{z2}	12.60 – 13.40	12.90 – 13.44

The formula of Knudsen & Katz for free convection along the vertical plate was selected as the one that gives the best fit of the calculations with measurements.

$$Nu = 0.52(Gr \cdot \Pr)^{0.25} \qquad [1]$$

The transportation heat transfer coefficient was defined analytically and is given by equation [2]

$$\alpha_z = \frac{\dot{m} \cdot c_p \cdot (\theta_{out} - \theta_{in})}{A_m \cdot (\theta_c - \theta_{in})}, \qquad [2]$$

where;

$A_m[m^2]$– Area of the heating mat,

$\dot{m}[kg/s]$– Mass flow through the cavity,

$\theta_{out}[C]$– Temperature of the air leaving the cavity

$\theta_{in}[C]$– Temperature of the air entering the cavity

$\theta_c[C]$– Temperature in the cavity (in the middle of the height),

$c_p\left[\frac{J}{kg \cdot K}\right]$- Specific heat of the air,

Results

With the simulation model the total performance of the double skin façade was simulated. The calculations and measurements were made for the following data:

H = 2 m. – Height of the DSF

B = 1 m. – Width of the DSF,

D = 0.1 m. – Distance between the back wall and front glass

Q_{el} = 500 W/m^2. – Power of the heating mat. It is placed in the middle between the back wall and front glass.

With these inputs the average difference on temperature between the air in the cavity and outside air is 14.78 °C.

Standard deviations between the temperatures (measured and calculated) are in range between 0.3879 and 0.1824.
Correlation coefficients are in range of 0.9184-0.9822. Comparison of the cavity temperature for the period of 6 days is shown in figure 3.

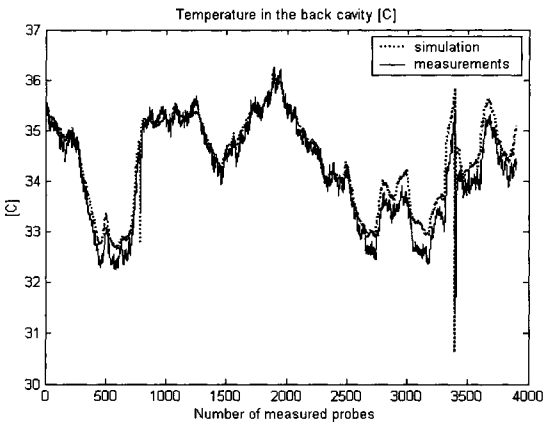

Figure 3. Comparison of the temperature (measured and simulated) in the back cavity

SIMULATIONS OF THE DOUBLE SKIN FAÇADE WITH THE BUILDING BEHIND UNDER THE REAL WEATHER CONDITIONS

Measurements

The measurements were done with the test cell at TU Delft (see figure 4). Test cell is equipped with following elements:

Figure 4. Test cell at TU Delft

- The double skin façade constructed from:
  - Basic wall with motorized windows
  - Additional glass skin on the outside of the wall

    - Venetian motorized blinds situated in the cavity between the wall and glass façade
    - Valves on the bottom of the façade
- Air handling split level unit
- Mechanical ventilation system with two modes of control: supply air or extract air from the cavity by making an over- or under pressure in the cell.
- Weather station and monitoring system with the measurements of:
    - Solar radiation (On the horizontal surface, the vertical inclined wall and inside of the test room)
    - Temperature. In total 48 thermocouples were placed outside and inside of the cell and in every layer and on different heights of the double skin façade.
    - Wind velocity and direction

With these measurements simulations of buildings with double skin facades can be tested.

Simulations

Simulation was made with Simulink^{tm} and it is divided into
- Simulations of the double skin façade
- Simulations of the building.

To build the model of the double skin façade results from the laboratory test facility are used. Additional components taken here into consideration are:
- Wind effect
- Airflow distribution in function of the position of the blinds, windows and valves controlling the airflow in the cavity
- Distribution of the solar radiation heat gains in the structure of the façade. This include also different properties of the blinds in function of the angle of the blades

The wind effect is considered based on the solutions proposed by Van Paassen & Voorden (2000) and Di Maio (2001). It is closely related with the airflow through the model. The airflow is calculated based on the network of flow exchange (Di Maio 2001). The influence of the construction of the façade and its components needs to be improved to reflect precisely the real behaviour of the façade. Calculations of the solar radiation and its distribution in the structure of the façade are carried out with the following steps:
- Calculating of the solar radiation falling on the vertical plate from the solar radiation falling on the horizontal plate
- Creating the network of the distribution of the solar radiation in the structure of the façade
- Defining the properties of each skin (absorption, reflection and transmission coefficient)
- Calculating ratios of the solar radiation absorbed on by each skin and transmitted to the inside of the building

Calculations of the vertical solar radiation from the horizontal solar radiation were made according to the Orgill 1977 and Brink 1987. The calculation results were compared with the relevant measurements. Calculations agree fairly well except the diffuse radiation at cloudy days.
The network of distribution of the solar radiation in the facade was build with double reflection of the rays inside of the façade. Properties of materials were defined based on tables found in literature and with the program WIS (Bakker 1996).
With such a constructed model of solar radiation final solar radiation transmitted through the façade to inside was calculated (Stec 2002). To improve the results more studies of the properties of materials

are necessary. Especially it is important with defining the properties of blinds as a function of the blades' angle.
The simulation model of the building behaviour was based on the models of Di Maio (2001) and Groninger (2000). All enclosing walls, one point air model, HVAC and internal heat gains are taken into account.

Results

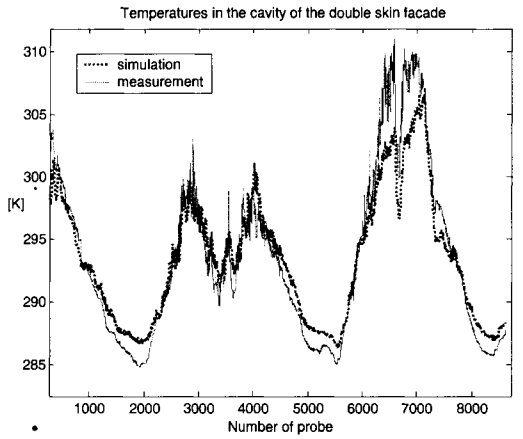

Figure 5. Comparison of the temperature (measured and simulated) in the cavity of the double skin façade

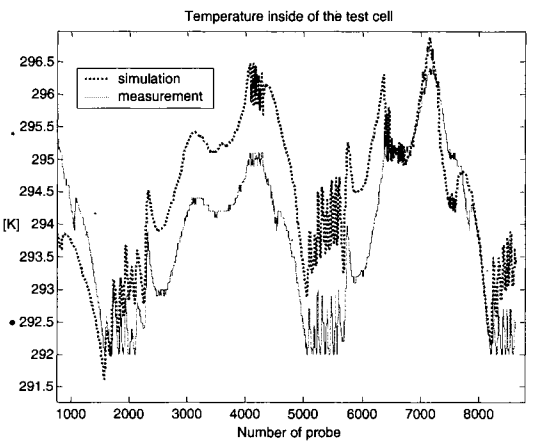

Figure 6. Comparison of the room air temperature (measured and simulated)

Calculations of the temperature in the cavity and inside the test cell are compared with the measurements (see figure 5 & 6). Both subsystems (DSF and room) have better correlations with measurements when the outside conditions are stabilized.
In general simulation model of the double skin façade shows a good fit. Nevertheless model needs some adjustments to be more flexible for different weather conditions and settings of the blinds and valves.
Thermal behaviour of the room shows to be correct. Still some adjustments are needed to simulate the influence of the window openings and HVAC system.

CONCLUSIONS

- Models of double skin façade (DSF) are validated using measurements of the laboratory test facility and the test cell under real weather conditions
- In general models of DSF agree quite well with the experiments
- After necessary improvements simulation model of the building with the double skin façade will be used to examine the thermal and airflow performance for different configurations of the building and DSF.

ACKNOWLEDGEMENT

Autors would like to thank to the several companies involved in the project: Novem (financial support), Unica (HVAC installation co.), Rollecate (facades design & construction), Klima Delft (consulting).

MODELLING OF A CLOSE-COUPLED PHOTOVOLTAIC HEAT PUMP

C. P. Underwood and A. D. Jones

School of the Built Environment & Sustainable Cities Research Institute,
Northumbria University, Newcastle upon Tyne NE1 8ST, UK

ABSTRACT

The close coupling of a conventional compression heat pump evaporator with photovoltaic modules is proposed, thus ensuring a higher power generating efficiency from the PV modules than would be the case in conventional installations. The power generated is used to power the heat pump compressor for the generation of domestic hot water in cool northern latitude climates. A mathematical model of the plant is described and the model is applied to a system scaled at 6kW – capable of generating all hot water needs of a large family home with a surplus available for space heating when needed. Results show that the plant is capable of generating all such energy needs in summer, with a significant power surplus, and about 40% of these needs on sunny winter days.

KEYWORDS

crit	Critical refrigerant state
f,fg,g	Refer to liquid, saturated vapour and gaseous phases respectively

INTRODUCTION

Several sources have identified substantial potential for power from photovoltaics (PV) within buildings (for a summary, see for example Gregory & McNelis (1994)). The performance of PV-cladding might be optimised through load targeting to particular loads within a building (Bailey et. al. (1993)). One area of particular promise lies in the integration of PV with heat pumps for space heating, principles of which have been identified by Underwood (1995).

The electrical conversion efficiency of a PV module is currently around 15%, most of the excess energy is converted to waste heat. The utilisation of this waste heat as heat pump source energy gives the additional benefit of lowering PV module temperature, leading to increased PV power conversion efficiency, which varies inversely with the temperature of the PV material by approximately $0.35\%K^{-1}$. Thus a reduction in PV material temperature of 30°C would improve power generation by 10%. In typical UK summer conditions, PV modules operate at around 30-40°C. Maintaining the module temperature at a reasonable frost margin (e.g. 5°C) ensures that this 10% improvement in power generation is a practical and feasible target.

In this work, a close-coupled PV compression heat pump is described as a basis for the sustainable generation of domestic hot water in cool northern latitude climates such as the UK. A dynamic thermal model for the system is developed and the model is applied to samples of UK weather data. Conclusions are drawn about the performance of the system in relation to the conventional heating of domestic hot water.

CLOSE-COUPLED PV HEAT PUMP

Figure 1 is a system diagram of the proposed close-coupled PV heat pump for domestic heating. The PV modules are mounted on the roof of a typical house. In normal daytime operation a combination of energy in surrounding ambient air plus solar radiation to the PV surface provides the necessary source energy to sustain the heat pump. The evaporated refrigerant is piped to the compressor from which superheated refrigerant enters the condenser where heat is given up to the hot water store. The fluid leaving the condenser then expands through a throttle before returning to the PV modules. Coincidentally, a low body temperature for the PV substrate will be maintained due to heat exchange with the evaporator (maintained at 5°C to give a frost margin) ensuring high power conversion efficiency.

The key target load for the system will be domestic hot water – increasingly becoming the dominant thermal energy load in modern airtight and well-insulated houses. However, by inter-connecting the house space heating through an annular heat exchanger and a two-position three way valve, the heat pump condenser can provide heat input to the space heating during those times in which the hot water thermal store is satisfied.

In the model described below, the hydrofluorocarbon working fluid R134a is adopted.

SYSTEM MODELLING

PV-Evaporator

The module energy balance was adapted from a model proposed by Jones (1999). Consequently, energy balances about the PV-evaporator give:

$$\frac{\mathrm{d}T_{\mathrm{mod}}}{\mathrm{d}t} = \left[Q_{\mathrm{mods}} - (Q_{\mathrm{modr}} + Q_{\mathrm{modc}} + Q_{\mathrm{er}} + W_{\mathrm{mod}})\right] / C_{\mathrm{mod}} \tag{1}$$

$$\frac{\mathrm{d}H_{\mathrm{ero}}}{\mathrm{d}t} = \left[m_{\mathrm{er}}(H_{\mathrm{eri}} - H_{\mathrm{ero}}) + Q_{\mathrm{er}}\right] / (V_{\mathrm{er}}\rho_{\mathrm{er}}) \tag{2}$$

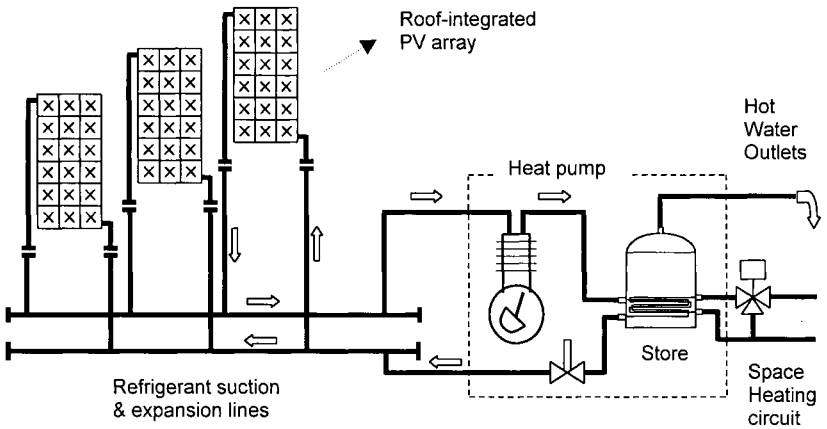

Figure 1: Conceptual system schematic

The various energy rates are:

$$Q_{\text{mods}} = A_{\text{mod}}\alpha_{\text{mod}}I_{\text{s}} \tag{3}$$

$$Q_{\text{modr}} = A_{\text{mod}}\sigma(\varepsilon_{\text{mod}}T_{\text{mod}}^4 - \varepsilon_{\text{sky}}(T_{\text{o}} - 20)^4) \tag{4}$$

$$Q_{\text{modc}} = A_{\text{mod}}h_{\text{c}}(T_{\text{mod}} - T_{\text{o}}) \tag{5}$$

$$Q_{\text{er}} = A_{\text{modi}}U_{\text{er}}(T_{\text{mod}} - T_{\text{er}}) \tag{6}$$

$$W_{\text{mod}} = C_{\text{FF}}I_{\text{s}}\ln(kI_{\text{s}})/T_{\text{mod}} \tag{7}$$

The refrigerant quality leaving the PV-evaporator will be:

$$x_{\text{ero}} = (H_{\text{ero}} - H_{\text{erf}})/H_{\text{erfg}} \tag{8}$$

$$\text{And when } x_{\text{ero}} > 1 \text{ then } T_{\text{ero}} = T_{\text{er}} + (H_{\text{ero}} - (H_{\text{erf}} + H_{\text{erfg}}))/c_{\text{erg}} \tag{9}$$

$$(\text{Otherwise } T_{\text{ero}} = T_{\text{er}})$$

Refrigerant properties were obtained from ICI (1996). In general:

$$H_{\text{erf}}, H_{\text{erfg}}, c_{\text{erg}} = \text{f}(T_{\text{er}}, T_{\text{crit}}) \tag{10}$$

It was assume that the evaporator, controlled to a constant pressure condition, would experience at all times:

$$P_{er}, T_{er}, \rho_{er} = \text{constant} \tag{11}$$

An algorithm was developed to calculate the boiling heat transfer coefficient within the PV-evaporator tubes based upon a method proposed by Collier & Thome (1999). However this proved computationally demanding and it was noted that the dominant independent variables were refrigerant mass flow rate and heat exchange surface temperature for the constant pressure (and temperature) conditions anticipated. A curve fit was therefore obtained based on results from the algorithm, giving a more convenient result with little loss of accuracy:

$$\begin{aligned} U_{er} &= 3.5237 + m_{er}(3.57892 - 0.34108T'_{mod} + 0.00756T'^2_{mod}) + \ldots \\ m^2_{er}&(-3.59294 + 0.36268T'_{mod} - 0.00833T'^2_{mod}) - 1.03174T'_{mod} + 0.08085T'^2_{mod} \end{aligned} \tag{12}$$

Compressor

The displacement, work transfer and leaving enthalpy can be expressed as follows based on the standard equations for a single stage reciprocating compressor (see for example McQuiston et. al. (2000)):

$$m_{pr} = V_{ps}\rho_{er}(1 - V_{pd}/V_{ps}) \times \left[(P_{cr}/P_{er})^{1/n} - 1 \right] \tag{13}$$

$$W_{pr} = m_{pr} R T_{ero} \left[n/(n-1) \right] \times \left[(P_{cr}/P_{er})^{(n-1)/n} - 1 \right] \tag{14}$$

$$W_p = W_{pr}/\eta_p \tag{15}$$

$$H_{pro} = H_{ero} + W_{pr}/m_{pr} \tag{16}$$

The dynamics of the refrigerant flow rate in the evaporator and compressor were neglected. Hence:

$$m_{er} = m_{pr} \tag{17}$$

Condenser and Accumulator

Energy and continuity balances about the condenser give:

$$\frac{dT_{cwo}}{dt} = \left[m_{cw} c_w (T_{cwi} - T_{cwo}) + Q_c \right] / C_c \tag{18}$$

$$\frac{d\rho_{cr}}{dt} = (m_{pr} - m_{cr})/V_{cr} \tag{19}$$

The refrigerant state leaving the condenser was assumed to be a saturated liquid at all times and the condensing rate dynamics were neglected. Hence by a steady-state energy balance on the refrigerant side:

$$m_{cr} = (Q_c + m_{pr} H_{pro}) / H_{cro} \tag{20}$$

Energy and continuity balances about the accumulator give:

$$\frac{dH_{aro}}{dt} = \left[m_{cr} H_{cro} - m_{pr} H_{aro} \right] / (V_{ar} \rho_{cr}) \tag{21}$$

$$\frac{dV_{ar}}{dt} = (m_{cr} - m_{er}) / \rho_{cr} \tag{22}$$

The condenser heat transfer rate was obtained from:

$$Q_c = A_c \left[1/U_{cr} + 1/U_{cw} \right]^{-1} \times (T_{cwo} - T_{cr}) \tag{23}$$

The condensing heat transfer coefficient was based on a correlation obtained from Collier and Thome (1999) for condensation outside tubes. Once again, in the interest of computational efficiency, a curve fit was obtained based on this method related to the two dominant independent variables involved; T_{cr} and m_{cr}:

$$\begin{aligned} U_{cr} &= 0.37081 - 0.0017 T_{cr} + m_{cr}(2.858878 - 0.01306 T_{cr}) + \ldots \\ & m_{cr}^2 (0.01093 T_{cr} - 2.39208) \end{aligned} \tag{24}$$

To close the equation set, an algorithm was written to calculate the refrigerant properties based on the extended Antoine equation (ICI (1996)), from which:

$$T_{cr} = f(\rho_{cr}) \tag{25}$$

$$P_{cr} = f(T_{cr}) \tag{26}$$

Finally, the heat pump coefficient of performance:

$$P_{HP} = m_{cw} c_w (T_{cwo} - T_{cwi}) / W_p \tag{27}$$

MODEL APPLICATION AND RESULTS

The model equations were assembled into blocks using Simulink in the Matlab environment. Four Matlab functions were written. Two of these were used to pre-process boiling and condensing heat transfer data (subsequently reduced into the simple correlations of equations (12) and (24)). The third Matlab function was used to calculate condensing refrigerant properties (equations (25) and (26)) and the fourth function was used to pre-process solar data. The latter was read from a file of global horizontal solar radiation measurements at 10-minute intervals. The global values were first split into direct and diffuse components, then corrected to equivalent surface-normal total solar radiation using a procedure described by Jones (1999). The measurements (including 10-minute external air temperatures) were taken in Newcastle upon Tyne during 1995-1997.

Model differential equations were solved using a 4th-order Runge-Kutta method and the model was applied to the input data set summarised in Table 1 which is based on a plant scaled to 6kW of condenser output at design. The plant would be capable of generating all hot water needs for a large family home with a surplus for space heating use at certain times. To service this load, 52 modules each of 0.63m^2 would be needed – sufficient to cover the south-facing pitch of the typical house referred to, thus forming part of the roof covering. The model was run during two daytime periods – a clear August day and a clear January day, for the daytime period 07:00-17:00hrs in order to demonstrate the potential of the plant during the main daytime hours of sunshine. Results are summarised in Figures 2 and 3.

DISCUSSION AND CONCLUSIONS

Figures 2 (c) & (d) show the simulated module power generation and corresponding compressor power use. In clear summer conditions, the module-generated power satisfies the compressor for most of the operating day with a significant excess available for other uses. In winter, the module-generated power satisfies about 40% of the compressor power requirement necessitating top-up power at other times of the day. The corresponding heat pump coefficient-of-performance profiles are shown in Figures 2 (a) & (b). Figures 3 (a) & (b) show that the module temperature remains fairly close to the constant evaporating conditions (5°C), ensuring high module power generating efficiencies at all times. With heat pump operation, the mean module temperature on a clear winter day is 5.06°C and the solar conversion power efficiency is 12.79%. This contrasts with 18.21°C and 12.21% without heat pump operation. However in summer, the corresponding module data are 7.16°C and 13.74% with heat pump operation and 46.67°C and 11.95% without. Clearly a significant module performance improvement can be expected with close-coupling especially in warmer weather conditions.

Figures 3 (c) & (d) indicate the temperature available for hot water heating. For all occasions in which the module power matches or exceeds the compressor power demand, heat is being generated "free" and in a sustainable manner. With the addition of a thermal store, it will be possible to achieve this sustainable heating of hot water throughout most of the operating year, except winter, though in winter a significant contribution can be expected. Further work needs to be done on the design of a thermal store and associated plant controls.

It is concluded that the close-coupling of PV modules with a conventional compression heat pump evaporator offers considerable potential for sustainable domestic hot water heating in the cooler northern latitude climates.

ANALYSIS OF NATURAL VENTILATION EFFECT FOR AN OFFICE BUILDING CONSIDERING MOISTURE ABSORPTION BY MATERIALS

Yoshida Harunori[1] and Kono Tetsuya[1]
[1]Department of Global Environment Engineering, Kyoto University,
Yoshida Honmachi, Sakyo-ku, Kyoto 606-8501, Japan.

ABSTRACT

Natural ventilation of buildings is becoming one of the major design approaches for sustainable buildings all over the world; however, the control strategies of vents or windows have not been well established especially when applied to hot and humid climate such as the Asian summer. In humid weather natural ventilation accelerates the absorption of water vapor by books, papers, materials used for furniture and furnishing, etc. This effect may increase the air-conditioning load when ventilation is performed intermittently in an air-conditioned building. Therefore it is important to determine ventilation control strategies on how and when vents or windows should be open and closed. For this analysis the authors developed a simulation code that can calculate air-conditioning load and room conditions by taking both natural ventilation and moisture flow analysis into account. In the present paper how much the vent schedules and quantities of moisture absorbing materials affects air-conditioning loads and room thermal conditions is evaluated and investigated. The results show that the natural ventilation controlled by temperature plus humidity ratio during nighttime is the best scenario among the considered scenarios, but enthalpy based control is not adequate contrary to expectation. Air-conditioning load is reduced by 37% in comparison to that for the no ventilation scenario.

KEY WORDS

Natural ventilation, Simulation, Moisture absorption, Air-conditioning load, Energy conservation, Asian climate

INTRODUCTION

Natural ventilation has come to international attention as a means to harmonize buildings with the natural environment and achieve energy conservation. Traditionally residential buildings relied deeply on natural ventilation for environmental control but other types of buildings depend mostly on HVAC systems. Recently however a number of naturally ventilated nonresidential buildings with a new concept can be found especially in European countries and the number of this type of project is increasing in Japan (Enomoto, Yoshida and Morita (1988) and Sako et. al. (1999)) and other countries as well. Most of the time in those buildings natural ventilation is achieved with the provision of specific features like vent shafts and automatically controlled vents instead of providing only manual opening/closing of windows.

Utilizing natural ventilation for controlling building environment and achieving energy conservation is a conventional technology but at the design stage comparing several design ideas and determining optimal control strategies for vents to maximize natural ventilation advantage is not an easy task. For the best design sophisticated computer simulation should be used to predict airflow rates and wind speed distributions in compartments. However the

research work related to determining an optimal control strategy is insufficient and the implications for different control strategies are not clarified. In addition, especially in a humid climate such as in Asia, natural ventilation may increase the absorption of water vapor by the books, papers, materials used for furniture and furnishing, etc. (Takahashi and Yoshida (2000)), and consequently air-conditioning load may increase when air-conditioning and ventilation take place alternately.

Since most available simulation codes are limited in performance, the authors developed a simulation tool that can calculate air-conditioning load and room conditions by incorporating the simultaneous analysis of natural ventilation and moisture absorption/desorption by materials. In this paper firstly the configuration of the tool is described. Then it is evaluated how moisture absorption/desorption and different control strategies affect air-conditioning loads and room thermal conditions using the tool, and a pseudo-optimal ventilation strategy is proposed.

SIMULATION CODE

The simulation code was developed by modifying the HASP/ACLD, Japanese heating/cooling load calculation program where the algorithm is based on the internationally used response factor method, by adding two major parts; 1) calculation of natural ventilation rates for a building with multiple compartments, and 2) calculation of heating and cooling loads considering simultaneous heat and moisture flow in building and existing materials in compartments.

Calculation of Airflow Rates

In most of the available codes to calculate natural ventilation for a multi compartment building, airflow through an opening between two compartments is calculated assuming the opening as a point orifice without size. This simplification implies that air flows always only one-way even though two-way airflow may occur along a vertical opening like a window and a door due to buoyancy effect. The governing equations used for evaluating the airflow through a vent opening are as follows by assuming a steady state (See Figure 1).

$$G_U = sign(\rho_b - \rho_a) \cdot \frac{2}{3} \cdot pq \cdot \sqrt{2g\rho_a |\rho_b - \rho_a|} \cdot \{h_2 - h_n\}^{3/2} \quad (1)$$

$$G_L = sign(\rho_b - \rho_a) \cdot \frac{2}{3} \cdot pq \cdot \sqrt{2g\rho_a |\rho_b - \rho_a|} \cdot \{h_n - h_1\}^{3/2} \quad (2)$$

$$G = G_U + G_L \quad (3)$$

$$h_n = (-P_a' + P_b')/\{(\rho_b - \rho_a)g\} \quad (4)$$

Where, G_U and G_L are the airflow rate of upper and lower part of the opening and G is the net airflow. ρ_a and ρ_b are the air density of the space A and B. h_1, h_2 and h_n are the height of the upper and lower ends of the opening, and the neutral pressure level from the reference floor height. g is the acceleration due to gravity. p, q are the height and width of the opening. *sign* is the sign of the term inside the parentheses. In Figure 1 P_a' and P_b' are the space pressures at the reference height.

Net airflow rate for a compartment or space must be zero because of the conservation of mass. i.e. $\sum G = 0$. When N compartments exist in a building N-th order nonlinear simultaneous equations are obtained (Eq. 5). In our study the equations are solved by applying a nonlinear programming approach known as the Gauss-Newton method with line-search , that is, by minimizing the objective function Eq. 6 regarding pressures P_1 through P_N.

$$\mathbf{G}(P_1, P_2 \cdots, P_N) = \mathbf{0} \quad (5)$$

$$\min_{\mathbf{P}} G_T = G_1^2 + G_2^2 + G_3^2 + \cdots + G_N^2 \quad (6)$$

Calculation of Air-conditioning Loads Considering Moisture Absorption and Desorption

Although simultaneous heat and moisture transport in building materials is not taken into account in most air-conditioning load calculation codes, it might have a large effect on the loads when natural ventilation is used

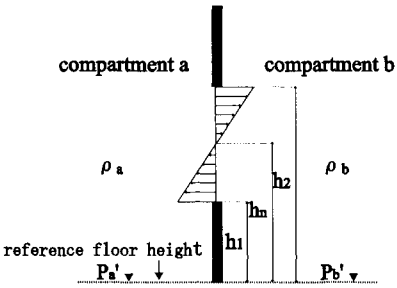

Figure 1: Model of airflow through an opening

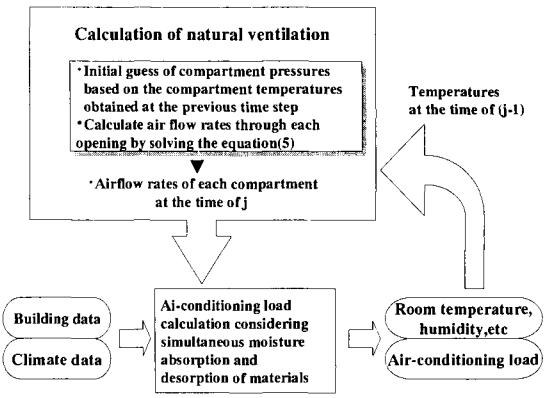

Figure 2: Configuration of the whole simulation

extensively and intermittently. One of the authors had developed a method for calculating transient responses considering the phenomenon of multi-layered construction based on discrete Fourier transform, Yoshida (1991) and Yoshida et al. (1994). For the present study a new simulation code incorporating this feature was developed. The method is briefly summarized as follows. The overall response of a multilayer construction is expressed by the equation (7), where $\mathbf{P} = (X\ \Theta)^T$, $\mathbf{F} = (W\ Q)^T$, and $X\ x\theta wq$, Θ, W and Q are the s-domain variables of humidity x, temperature θ, moisture flow w and heat flow q. $\mathbf{K}$ is called a 2 by 2 admittance matrix with the elements
of s-domain function $K(s)$. Inverse discrete Fourier transform is applied to obtain the time domain response $k(t)$ for a triangular input. Eight kinds of response $k(t)$ are defined as shown in Table.1. Using the $k(t)$ the equations governing heat and moisture balance of a room are formulated as equation (8) and they can be solved by differentiating them with respect to time.

$$\begin{Bmatrix} \mathbf{F}_1 \\ \mathbf{F}_2 \end{Bmatrix} = \begin{bmatrix} \mathbf{K}_{11} & \mathbf{K}_{12} \\ \mathbf{K}_{21} & \mathbf{K}_{22} \end{bmatrix} \cdot \begin{Bmatrix} \mathbf{P}_1 \\ \mathbf{P}_2 \end{Bmatrix} \tag{7}$$

$$m_r \frac{dx_r}{dt} = M_g + M_{ac} + m_v(x_o - x_r) + \sum_{L=1}^{L} A_L \sum_{j=0}^{\infty} k_{22,12}(j\Delta)\theta_o(t - j\Delta) - \sum_{I=1}^{I} A_I \sum_{j=0}^{\infty} \left\{ k_{22,11}(j\Delta)x_r(t - j\Delta) + k_{22,12}(j\Delta)\theta_r(t - j\Delta) \right\}$$

$$m_r c_p \frac{d\theta_r}{dt} = H_g + H_{ac} + m_v c_p(\theta_o - \theta_r) + \sum_{L=1}^{L} A_L \sum_{j=0}^{\infty} k_{21,22}(j\Delta)\theta_o(t - j\Delta) - \sum_{I=1}^{I} A_I \sum_{j=0}^{\infty} \left\{ k_{22,21}(j\Delta)x_r(t - j\Delta) + k_{22,22}(j\Delta)\theta_r(t - j\Delta) \right\} \tag{8}$$

compartments are fixed as those of the previous time when calculating airflow rates, then by using the airflow rates the air-conditioning loads and compartment temperatures at current time are calculated. For the exact calculation these two steps must be performed alternately until the airflow rates, the loads and the temperatures converge at the current time. However, to reduce of computation time this process is not performed. The effect of this simplification is not significant because compartment temperatures do not change drastically with time. The outline of the whole simulation process is schematically shown in Figure 2.

BUILDING MODEL FOR SIMULATION

For the present study a small office building shown in Figure 3 is used for simulation. Openings located below the windows and an atrium or a vent shaft with a top opening are provided enhancing natural ventilation. This feature is one of the typical ways for designing a naturally ventilated building. The wind pressure coefficients of each opening are determined according to the position of the opening and current outside wind direction. Attaining optimum utilization of natural ventilation all the openings are assumed to be controlled by Building Energy Management System (BEMS) based on a given scenario. Commonly used interior finishing such as gypsum and rock wool boards, carpets, etc. is put on ceilings, walls and floors and these materials are good moisture absorbing materials. Besides theses, hypothetical thick paper walls are located inside the room representing documents or books on bookshelves. The maximum size of the hypothetical wall is 7.2 by 2.8 m for each span and 8 rows are specified altogether. Other conditions of the building are summarized in Table 2. The weather data used are those

of the Reference Year of Osaka, Japan where the climate is hot and humid in summer.

Natural ventilation scenarios are abbreviated by combinations of letters. The first letter represents ventilation strategy: R means non-natural ventilation with daytime air-conditioning, D is for daytime ventilation only, N for nighttime only and air-conditioned during daytime, B for both night and daytime. The second letter represents the control strategy of opening/closing of the vents: N means no control, T for opening/closing vents control based on temperature, E for based on air enthalpy and H for based on air temperature in daytime and both temperature and humidity ratio in nighttime. The third letter is optional. If letter n is added no moisture absorption is taken into account in simulation, and if number 2 is used the paper wall area is 2/3 of the maximal area and number 1 is for the area of 1/3.

The strategy of vent control is as follows;

T is for controlling based on temperature. Daytime: open when $22 \le T_i \le 28°C$, $18 \le T_o \le 26°C$ and $T_o \le T_i$ are all satisfied. Nighttime: open when $20°C \le T_i$, $10 \le T_o \le 28°C$ and $T_o \le T_i$ are all satisfied. Where T_i is room temperature and T_o is outside air temperature.

E is for controlling based on enthalpy. Daytime open when $12.6 \le E_i \le 33.6\,J/g$, $8.2 \le E_i \le 29.4\,J/g$ and $E_o \le E_i$ are all satisfied. Nighttime: open when $16.8\,J/g \le E_i$ and $E_o \le E_i$ are satisfied. Where E_i is room air enthalpy and E_o is outside air enthalpy.

The above strategy is made by averaging the strategies applied for several real projects. At present there is no standardized and well established way of securing an optimal control strategy, therefore a real project is designed by rule of thumb and tuned at the operation stage. Rationally finding an optimal control strategy is an important future issue.

RESULTS AND DISCUSSIONS

The simulation results for each scenario are compared and analyzed below mainly by showing the total air-conditioning loads of three rooms. The duration of the simulation is the six months from June to October.

Effect on Air-conditioning Loads by Moisture Absorption

As previously stated simultaneous heat and moisture transfer is not taken into account in commonly used air-conditioning load calculation codes, and the effectiveness generated by natural ventilation enhancement is usually analyzed by similar codes. Therefore evaluating the difference caused by whether the effect into account is taken into account or not is necessary and gives valuable information. As seen in the Table 3 giving results for the scenario of RNn (non-simultaneous transfer) and RN, RN2 and RN1 (with simultaneous transfer), the total loads increase about 15% by taking the effect into account; more precisely 16%, 14% and 12 % for RN, RN2 and

TABLE 3 Seasonal Total Load for Scenario R (effect of simultaneous transfer)

Scenario	Cooling Load(GJ)	Ratio to RNn
RNn	62.8	1.00
RN	73.2	1.16
RN2	72.0	1.15
RN1	70.6	1.12

RN	73.2	1.00
DT	50.1	0.69
NT	53.6	0.73
BT	47.6	0.65

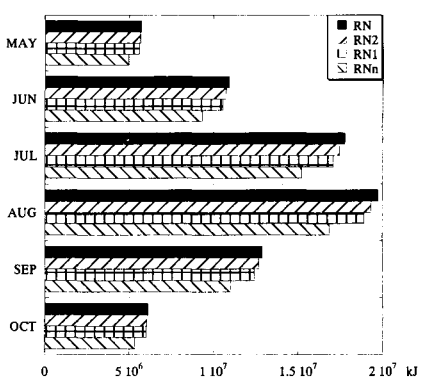

Figure 4: Monthly loads for scenario R

RN1 respectively. The differences caused by quantities of moisture absorbing materials are smaller than those caused by the consideration of the absorption effect. The reason for the increase is mainly due to the large latent load during the start-up period when the effect is considered. This is created by the stored moisture in materials due to moist air leakage in the nighttime. To investigate it more precisely the loads for each month are shown in Figure 4. However the increases are almost the same, roughly 17%, for all months. Buildings intended to enhance natural ventilation usually have many openable vents which tend to create large leakage area and to create much air leakage. Therefore, careful consideration must be taken to minimize the leakage area and a load calculation code that can handle the simultaneous transfer must be used.

Thermal Load Reduction by Temperature Based Natural Ventilation Control

The thermal load reduction by the temperature based natural ventilation control, which is abbreviated as T and defined previously, is evaluated. The results are shown in Table 4 by comparing to the reference operation RN, that is the non-natural ventilation scenario. The reduction of all the scenarios, DT, NT and BT, is approximately

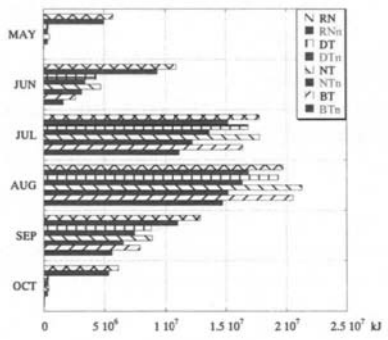

Figure 5: Monthly loads for scenario T

TABLE 5 Load comparison for scenario T and E

Scenario	Cooling Load(GJ)	Ratio to BT
BT	47.6	1.00
BE	51.0	1.07

DT	50.1	1.00
DE	55.3	1.10

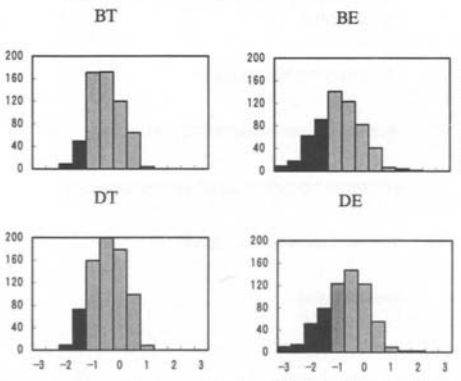

Figure 7: Distribution of PMV for scenario T and E (B: whole day ventilation, D: day time ventilation)

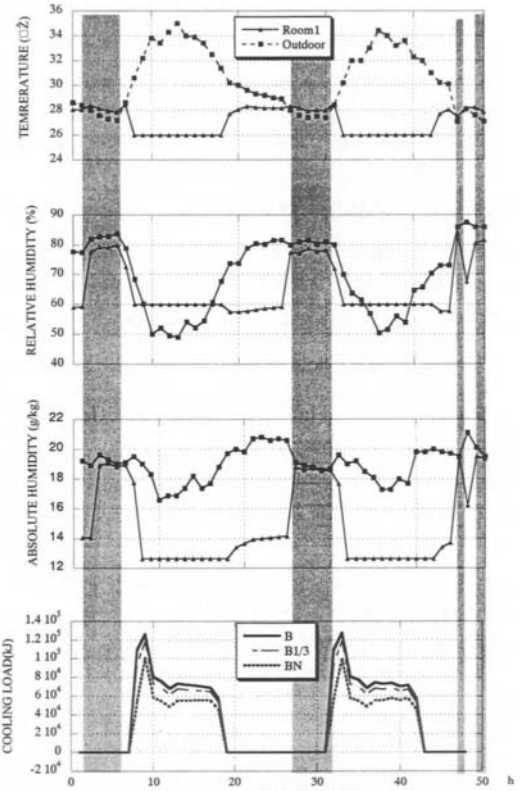

Figure 6: Example of adverse effect by nighttimeventilation

TABLE 5 Load comparison for scenario T and H

Scenario	Cooling Load(GJ)	Ratio to RN
RN	73.2	1.00
BT	47.6	0.65
BE	51.0	0.70
BH	45.9	0.63

30%. The best strategy in terms of load reduction is BT (35%), namely ventilation both for daytime and nighttime, followed by DT (31%); daytime ventilation only, and then NT (27%); nighttime only. It can be seen that the effectiveness of nighttime ventilation is not so significant. To investigate the reason, the monthly base loads are shown in Figure 5, and all the loads of scenario DT; daytime only, are smaller than those of RN; however the load in August of scenario NT; nighttime only, is only 8% larger. This adverse effect is generated because there is a higher possibility that outside temperature is lower than the room temperature, but outside humidity is quite high during the night, and this causes load increase. The specific and extreme example is shown in Figure 6: The halftone parts indicate naturally ventilated periods and during the times when the room air humidity becomes very high but the room is not well cooled.

Thermal Load Reduction by Enthalpy Base Natural Ventilation Control

As the air-conditioning load for processing air is directly related to enthalpy rather than dry bulb temperature, enthalpy based natural ventilation is more appropriate so that thermal load reduction should be improved. However determination of the thresholds is not straightforward because people cannot directly sense enthalpy. In the present study, therefore, the thresholds were determined by trial and error so as to make the opening time of vents as close as possible to that, about 30% opening duration per season, of the temperature based control scenario. The thresholds found are those explained previously. Simulation results for the whole day ventilation scenario, however, did not show improvement contrary to our expectation. Rather the load increased by 7% as shown in Table 5. This can still be due to moisture absorption. In addition, as the distribution PMV shows in the upper part of Figure 7, even the thermal condition of the rooms is worse than that for scenario BT. To avoid the problem a day time only scenario DE was investigate, but improvement was not achieved.

Additional Improvement on Temperature Base Control

To improve scenario T, additional control is added. That is, ventilation is activated only when the humidity ratio of the outside air is lower than that of room air to suppress moisture absorption. This scenario is named BH. By this modification additional a 2% load reduction can be attained. The improving effect is very small but large difference was found in total ventilation time, of about 60 % of the scenario BT. The comparisons of scenario RN, BT, BE and BH are shown in Table 6.

CONCLUSION

Many successful buildings with enhanced natural ventilation can be found especially in Europe and they represent one of the types known as green buildings. It is getting popular in Asian countries as well, but in a humid climate it may not always be adequate because moisture absorption by building materials when vented causes substantial additional thermal load when air-conditioning is in operation again after ventilation.

To investigate this issue the authors developed a computer program which combines the calculation of airflow rates by natural ventilation for a multiple compartment building and the calculation of intermittent air-conditioning loads and room temperatures considering simultaneous heat and moisture transfer. Applying this code to a naturally vented small office building several control strategies for ventilation ware investigated. Although the results are not necessarily universal to any building many general and important findings are obtained as follows.

1) By incorporating calculation of simultaneous moisture absorption and desorption into the simulation algorithm, it was found that air-conditioning load increases by about 15%. Although in common load calculation codes this effect is not considered.

2) As the basic and commonly applied ventilation strategy, a temperature based control strategy was investigated. Comparing three natural ventilation scenarios, namely daytime only,

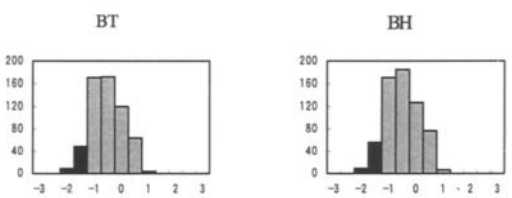

Figure 8: Distribution of PMV for scenario T and H (B: whole day ventilation, D: day time ventilation)

nighttime only and whole day, it was found that nighttime ventilation is not as effective as expected. This is because humid air is brought in by ventilation during the night and moisture accumulation takes place. In general it appears that the effectiveness of the whole day ventilation is not significant.

3) In order to improve ventilation effectiveness by avoiding moisture absorption issue, enthalpy based control was investigated. However, a load reduction was not attained. On the contrary the load increased and room environment evaluated by PMV became even worse. The result indicates that determination of the appropriate thresholds is difficult, even though this control strategy is used on some real projects of a naturally ventilated building.

4) Furthermore to improve the temperature based control strategy, humidity ratio based control, added during nighttime only, can decrease load by 5% over the purely temperature based control strategy.

ACKNOWLEDGMENT

The present study was supported by a grant-in-aid from the Ministry of Education and Science Japan. The authors are deeply grateful for this aid.

ABSTRACT:

At present, during the early design stage of a building, different options are assessed using simple tools (tables, graphs and software) that contain a large number of assumptions the very nature of which can bias choice or possibly lead to an inappropriate solution. It can be argued that the only way to provide a rational assessment of options is to use calculation methods that represent in detail the physical processes involved; this usually involves the use of dynamic thermal models. Furthermore if this tool is also used during detailed design it would introduce a consistency that is normally absent from the analytical design process. Many designers are of the opinion that, because not all details are known, then such tools are not suitable for application at early stages in the design. This view can be challenged because, even at the concept stage, a great deal is known about a building.

This project aims to show that a general description of the building can be used to generate sufficient data to drive a valid analysis using a detailed thermal model at the early sketch stage of the design process. The paper describes the philosophy, methodology and the interface developed to achieve this aim. The interface guides the user through the input process using a series of screens giving options for keywords used to describe the building; comprehensive default data built into the software are then attached to these keywords. The resulting data file is a building description that is the best possible interpretation of the design intent. This can then be used to assess options and guide towards a final design.

Whilst naturally ventilated buildings are currently considered to be the ideal solution to low energy design in the UK, there remain a large proportion of buildings for which air conditioning offers the

only practical solution. This project is intended to provide a means to assess design options for such buildings at a very early stage in the design and in particular address the selection of the most appropriate system. The form of the interface is still developing and while it has been demonstrated to designers no third party tests have yet been carried out.

KEYWORDS

Architecture, Engineering, Energy, Assessment, Sketch stage, Design process, Data transfer and XML.

1. INTRODUCTION

There have been a number of projects that aim to provide simple interfaces to assist the designer, for example:

- The 'NATVENT' project (Natural ventilation for Offices. BRECSU March 1999);
- The 'Office Design Tools' (Building Services Journal, December 1999);
- The 'Building Design Advisor (BDA)' (Papamichael, K. et al. Decision making through use of interoperable simulation software, Building Simulation '97. Fifth International IBIPSA Conference, Prague 1997).

The complex nature of ventilation, and the very uncertain nature of the boundary conditions (wind environment, pressure coefficients, for example) justify the simple nature of the analytical models used in the first two examples. The third is a way of using a detailed thermal model to analyse design options. The main difference between this proposal and the BDA lies in the interface. The BDA uses a graphical tool that requires each space to be specified in some detail. It is therefore close to a conventional analysis tool and as such is not suitable for studies at the sketch stage of the design. The method by which results are presented is however one example that will be examined during the project. Members of the *EnergySave* team have visited the Laurence Berkley Laboratory in California and are therefore fully aware of the strengths and weaknesses of the BDA.

The intention of the *EnergySave* project is to make use of available software and skills. In particular, whilst a detailed thermal model is necessary for the implementation of the method there is no intention to develop that model. It is however important that the source code of that model is available to the team. The model selected is ENERGY2. This program has been developed in Arup Research and Development and has been exposed to the International Simulation Community by means of the IEA Annex 21 (a task shared project related to quality assurance and validation of thermal models).

In order to facilitate energy calculations it was necessary to develop generic system models. These are based upon those described in the CIBSE Energy Code 2, 'Energy demands for air conditioned buildings'. Arup Research and Development were involved in the drafting of this code and made significant inputs into the building description application of climatic data and testing of early versions. Although these models are very simple they capture the essential features of the systems. This means that the major inefficiencies are accounted for.
At present, during the early design stage of a building, different options are assessed using simple tools (tables, graphs and software) that contain a large number of assumptions the very nature of which can bias choice or possibly lead to an inappropriate solution. It can be argued that the only way to provide a rational assessment of options is to use calculation methods that represent in detail the physical processes involved; this usually involves the use of dynamic thermal models. Many designers are of the opinion that, because not all details are known, then such tools are not suitable for application at early stages in the design. This view can be challenged because, even at the concept stage a great deal is known about the building, for example:

- Size;
- Number of floors;
- Occupancy;
- Preferred glazed areas;
- Insulation standards;
- Thermal mass;
- Required internal environmental conditions.

Not withstanding this there is still resistance to the application of simulation, typical reasons given are:

- Too time consuming to input the necessary data;
- The program is not user friendly;
- Manual methods are quite adequate;
- Programs cannot be trusted;
- Do not understand how the program works.

Arups had already recognized the need to address these issues and encourage the use of simulation throughout the life cycle of the building and so, at their own expense, joined the International Energy Agency (IEA), Building and Community Systems, Annex 30 (Bringing Simulation to Application). Arup Research and Development was the official UK Participant.

The IEA project demonstrated the value of simulation throughout the design process, the value of good quality default data and the need for software validation. However despite identifying user friendliness as an important issue in increasing the uptake of simulation throughout the construction industry, it did not make a serious attempt to address that issue. One objective of *EnergySave* is to redress this.

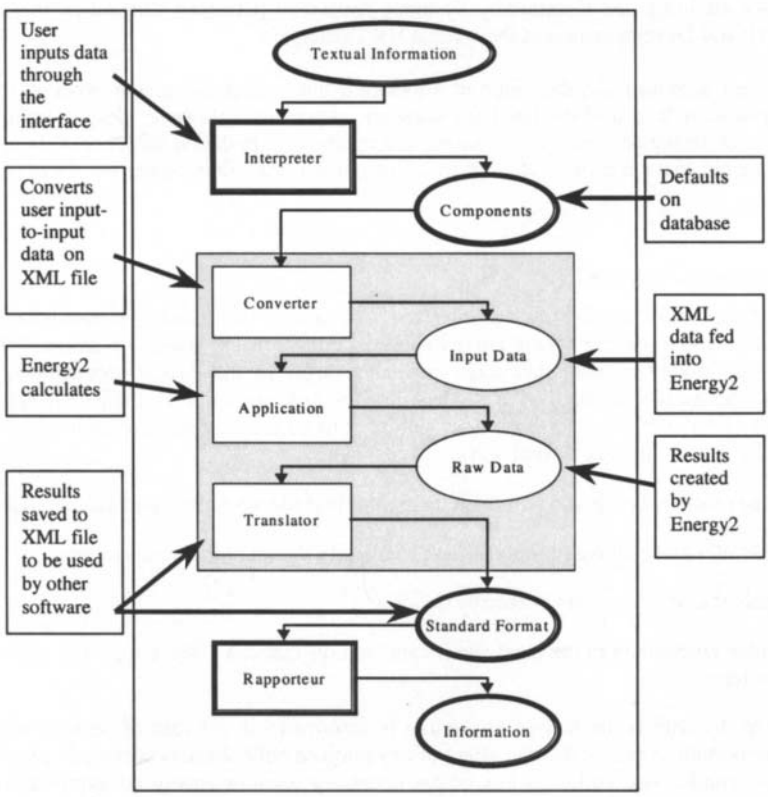
2. ENERGYSAVE CONCEPT

The second objective for the *EnergySave* interface is to capture the essential elements of a design in an unambiguous way to enable a valid energy analysis at the concept stage of a design. The use of a detailed thermal model[1] at both this stage and later stages in the design process would bring a consistency to the analysis through out design. A third and equally important objective is to provide a mechanism to bring simulation to those who believe it to be too complex for their needs and far to difficult to use. This is done in several ways:

- The use of extensive, intelligent defaults to minimise the amount of data that are required;
- The use of a pictorial based input system to identify the main input parameters;
- The use of minimum data to describe building;
- A critical assessment of the most significant features that can affect the energy consumption of the building.

An example of the later is the way solar shading is described. In the case of passive buildings it is particularly important to ensure that the effect of any purpose built shade is accurately represented. In the case of air-conditioned buildings this is less necessary because energy consumption is far more

[1] A detailed thermal model is usually a simulation program capable of calculating the performance of both building and HVAC systems at hourly intervals for the period of a year. In the UK context design programs based upon the CIBSE Admittance method are not considered to be detailed thermal models.



closely related to systems and controls. *EnergySave* does not ignore external shade but on the other hand does not encourage users to be obsessed with complex representations. The form of the building is simplified, at present to a rectangle. While this is recognised to be a limitation it is also felt that the majority of buildings can be adequately represented. *EnergySave* is intended to apply to the norm. Section 4 (Overview of the interface) demonstrates the principles described above.

A fundamental to the system is to use what is already available, thus the main database used is a commercial product chosen because the majority of PC users will have access to it. Intermediate data transfer uses an XML Schema taken from the public domain (Green Building Schema).

It is important to realise the *EnergySave* **does not** contain a calculation engine. It is intended that the XML file be described in sufficient detail to allow the use of third part 'engines'. This is in direct contrast to the development of public domain engines in the USA.

3. STRUCTURE

The following flow diagram shows the form of the system.

The interface between *EnergySave* and the application is the XML file. This Section briefly describes the system.

3.1 The Interpreter

The written descriptions are converted into components using rules developed from discussions with designers from the industrial partners, Amec, Ove Arup and RIBA, who have also provided default data based upon previous projects. These are combined with user specific data into building and system components and written to a standardised data file. The data structure produced by this process is to be specified in sufficient detail to allow any developer to use their model in conjunction with this system. One function of the interpreter is convert simple descriptions into physical layers that are suitable for use in a detailed thermal model. Examples are:

- Opaque walls. Input U value and response time – output layers in the construction and the physical properties of those layers.
- Glazing. Input shading coefficient – output layers and basic properties such as transmission and absorption at normal incidence for each.

The 'Interpreter' combines the default data taken from the database and combines that with the user input to write the XML file. It is important that a single XML file contains ALL options investigated. This can be done by specifying each as a new building on the same site (campus in the Green Building Schema).

3.2 The Converter

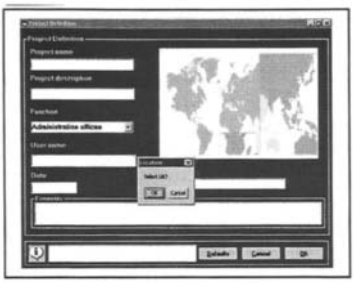
This is specific to the simulation model used and it would be written by the application vendor to convert the data on the XML file to that required by the program.

3.3 The Application

In this case the Arup ENERGY2 program will be used. It could however be any appropriate model.

3.4 The Translator

This is specific to the program used in the analysis and is used to convert the predictions (raw data) into a standard format. This format is specified in detail to allow the system to be used by other software developers. The output from the 'translator ' is to the XML file.

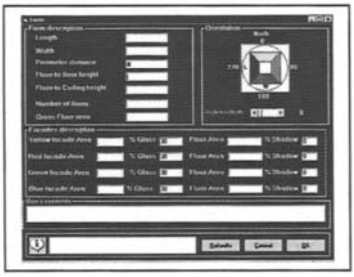


3.5 The Rapporteur

The nature of the output from an energy simulation requires specialist knowledge for a valid interpretation, in particular where comparisons are to be made. The rapporteur provides a facility to compare and interpret design options. It is hieratical in nature so the user is first offered overall energy (and CO_2 figures). It is then possible to delve deeper to looking order to develop an understanding of the performance indicated. Automatic comparison of options will be available. The 'Rapporteur' is currently under development.

4. THE INTERFACE

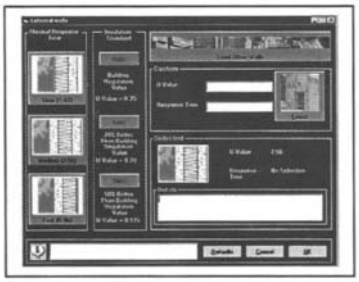
This Section shows some of the essential elements of the interface and where appropriate how they can be used to set defaults. It is intentional that the screens – or forms –presented to the user do not have the appearance of a conventional Windows interface. It is inappropriate to display the complete

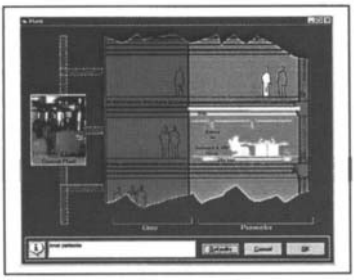


interface, the sample 'forms' presented here are intended to highlight the main principles behind *EnergySave*.

Project Definition
In addition to capturing the standard inputs such as project description and user, the location and function of the building are defined. Location sets insulation standards via local building regulations and occupancy patterns and internal gains are set by the function. A default building is generated.

Location
The country map is displayed. Each region contains a link to a climatic data file. Software vendors can enter their particular file names on the database. Exposure is also identified. Because this can be done in several ways, an advanced option allows an alternative definition, terrain type. This is intended to provide data for software that requires some means to describe wind shading for infiltration and ventilation calculations.





Building's form
A simple model of a building is created, using zones based on the façades. The user inputs the length, width, floor-to-floor height, and the number of floors. Simple solar shading is also set here, another input (not illustrated here) allows for individual window shade to be entered.

Internal Gains
Internal loads are defined by 'level', very high to very low. The defaults corresponding to these levels are displayed and it is possible for the user to make changes.

External Walls
Materials used in external walls can be selected. The variations are labelled by their U-Value and thermal response time (Admittance). The user can select the closest type of wall or alternatively create a custom wall using the advanced option. Similarly other input screens allow input of parameters for windows, partitions etc.

HVAC Systems

A side view cut out section of the building is split into the core, inner perimeter and outer perimeter. Each section can be "filled" with heating and cooling systems. This is shown in the green section with the under-floor VAV system. As the user enters data, options are limited for other sections so that inappropriate combinations cannot be selected.

5. CONCLUSION

The *EnergySave* project is intended to bring simulation to a wide range of building design professionals. To do this it has been necessary to make many simplifications to the description of a building and the associated HEVAC systems. These are based upon the relative importance of each element upon energy consumption. It is believed that the weightings used will result in meaningful predictions. *EnergySave* differs from other approaches to simplified energy analysis in that simplifications are made in the way data are described to the analytical engine and not in the engine.

6. ACKNOWLEDGEMENT

EnergySave is part funded by the United Kingdom Department of Trade and Industry.

THE DEVELOPMENT OF A PROTO-TYPE PV DECK-SHADING SYSTEM AS THERMAL BUFFER AND ELECTRICITY GENERATOR

J.Close[1], KH Lam[1] and YH Wong[1]

[1]Department of Architecture, University of Hong Kong, Pokfulam Rd, HK SAR China

ABSTRACT

A Copper Indium Diselenide (CIS) technology photovoltaic deck-shading system has been designed for the sub-tropical climate to generate electricity, act as a thermal buffer and provide naturally lit shaded recreation or teaching-space at deck level. The system has been designed for pre-wiring and pre-fabrication techniques to allow the increased quality control of factory production plus reduced site installation costs. The system has a wider range of applications but is customized to the 7.5m x 9.6m planning grid of Hong Kong (HK) Schools. The system is suited to 330x 1300mm dimensioned modules, and particularly the ST40 CIS module manufactured by Siemens Solar. The robust, lightweight and low-maintenance system is particularly designed for latitude 22° where high altitude sun permits close-spacing of the modules that can, with 33% increased module area, maximise summer electricity yield. Performance under high wind-load has been a critical factor in the design necessitating wind tunnel measurements and module wind-loading tests. The module supporting system consists of factory pre-fabricated stainless steel trusses supporting paired strings of modules. Each truss interlocks to the preceding truss through the hub containing the customized electrics junction box. The system and its electrical components are intended as starters to the development of a local PV components industry. Simulation studies for the new 36 class Ma Wa School, to be completed in 2003, indicate that a 6-bay system provides a modest 2.8% saving on the annual cooling load and the electricity yield contributes 9.79% to the estimated annual classroom electricity demand. Tendered costs indicate the total system construction at approximately US$681/m^2 with module costs representing about 61% of the system costs.

KEYWORDS

Copper Indium Diselenide (CIS) Photovoltaic (PV) deck-shading system, thermal buffer, electricity generator, pre-fabrication, low- maintenance

INTRODUCTION

Hong Kong (HK) is a vertical city but its schools are a building sector with a more pronounced horizontal than vertical character thus offering scope for optimizing PV applications with a generous area for PV arrays. New HK schools conform to a 7.5m x 9.6m planning grid providing the opportunity for product standardization and also PV commercialization due to the size of the Schools Construction Programme administered by the HK Government. A PV roof deck shading system has been designed for HK schools and six bays are to be included in the Ma Wan Primary School, a government/utility funded PV demonstration project currently under construction, Close (2001). The deck shading proto-type design is a self-supporting system that acts as a thermal buffer to the building envelope as well as generating electricity. It offers, at roof-deck level, additional sheltered space for equipment, recreation or teaching while its open north-light design ventilates the space and the PV modules.

Fig. 1 : Model of Ma Wan Primary School, Hong Kong Construction from January 2002-mid 2003

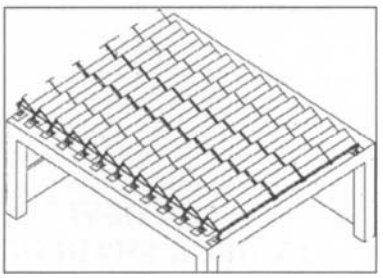

Fig. 2 : 7.5m x 9.6m bay of roof deck shading system with double module of Siemens Solar ST40 CIS technology

APPROACH

The design of the deck-shading system included these factors:

- Selection of PV technology (performance in sub-tropical climate), manufacturer & module
- Truss spacing + dimensional relationship to the 7.5m x 9.6m planning grid
- Wind-load capacity of selected module
- Detailed structural design for pre-fabrication, low-maintenance + long life
- Integration of the electrical sub-system.

1. PV TECHNOLOGY & MODULE SELECTION

Cost and relative efficiency are still the major factors in PV module selection. Performance monitoring in real outdoor conditions indicates the related effects of high ambient air temperature and high cell temperature on lowering PV module efficiency of mono & polycrystalline modules in the sub-tropical climate of Hong Kong. Their high cost also inhibits large area application for Building Integrated Photovoltaic (BIPV) applications. Amorphous Silicon (a-Si) technology is considerably lower cost but its long-term stability is still under review and improved efficiency above maximum 8% peak rate is not yet achieved. Copper Indium Diselenide (CIS) is a relatively new thin-film technology now coming into commercial production that has similar lower material/production costs as a-Si but a higher efficiency, Siemens Solar has produced the first production line CIS modules, independently tested and rated at 10.2% efficiency and warranted for 10years by the manufacturer. Siemens Solar advises the end-2002 price for ST40 (40watts peak) is US$120 per module which is comparable to US Utility electricity charge of US$3 per watt - the prevailing benchmark.

CIS PV technology appears to offer the potential of improved performance over amorphous silicon, yet without the efficiency losses in high temperature conditions of mono or poly-crystalline technologies or their higher cost. A recent paper by Durisch, Lam & Close, (2) records the performance in real outdoor conditions of an early production module of Siemens ST40 in temperate climate from which a general model for performance in all climate conditions was developed. Table1 adjacent, indicates the relatively small efficiency drop (2%) over cell temperature range of 35-85° C. This is particularly important in HK's high summer temperatures. At these cell temperatures, mono or polycrystalline cell efficiency can drop substantially, to 5% below rated efficiency for some products. Also, the relatively high efficiency is maintained for irradiance levels varying between 200-1000 W/m^2 at only 2% variation.

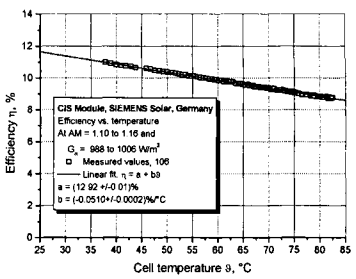

Table 1 : Siemens ST40 performance under high cell temperatures -HK conditions

2. SYSTEMS DESIGN : TRUSS SPACING + MODULE AREA

An open deck-shading system promotes ventilation, and, in the northern hemisphere, if correctly north/south orientated, provides indirect (cool) daylight. It also provides maximum solar access for south-facing modules. The opaque Siemens Solar module dimensions 329 x 1293mm, permitting 5 modules per 7.5m bay width. The design pairs them to form two adjacent strings. The 25 degrees truss design angle is best for all-year performance at HK's latitude. For the 9.6m bay length the closer spacing between truss centres of 800mm, compared with the initial 1066mm, permits 12 trusses per bay compared with 9, give an increased module area of 33%. During winter months, with sun angle below 40°, there will be mutual shading of the lower part of the truss but by-pass diodes limit the shading impact on the total electricity generated. Simulation with various programmes has estimated the annual yield, though only PVSYST allows for mutual shading losses. (The differences in the PVSYST annual yields results from the weather database range.) Yield and contribution to a school's annual electricity consumption as reported by Close, Wong, Chan & Kwok (3) is based on 6 bays of the deck-shading system and the 36 classroom, Ma Wan School design that also incorporates other PV installations and energy-saving School Building Energy Management System (BEMS).

Design: Open ventilated truss + maximum module area	Modules Per 6- bay	Module Area M^2	Total at peak rate kW	Estimated Annual Yield kWhrs
25 degree tilt at **1,066mm** ccs **double** module	540	231.6	21,600 kW	24,370kWhrs

3. WIND-LOAD

Hong Kong is a city subject to summer typhoons with high wind speeds. The HK Building Department imposes a wind-load code on all installations related to their exposure and building height. Additionally the context of low-rise Ma Wan School with high-rise surrounding buildings is known to produce turbulent and unexpected conditions. The extent of these conditions and likely loading on the PV deck system was

simulated in wind tunnel tests carried out at The Wind Tunnel Facility of the HK University of Science & Technology (HKUST) in December 2001. The wind pressure conditions were determined by carrying out both a wind tunnel topographical study of the Ma Wan island location and also the cladding pressure tests on a 1:100 scale model of the Ma Wan School (See Figure 7 below).

The Wind Tunnel tests simulated the loading under the extreme conditions of mean hourly gradient wind velocity of 64m/second as stipulated by the HK Practice Note (PNAP150). The wind pressure measurements on the 1:100 scale model were taken at pressure taps located through the six bays of deck-shading system and at 10 degree intervals of incident wind direction over the full 360 degrees. The suction, or negative pressure, measured greater than the positive pressure and the leading edge of the array received the brunt of the pressure. See diagram in Figure 8 below. The largest positive differential pressure measured 2.33kPa and the largest negative differential pressure measured -7.28kPa.

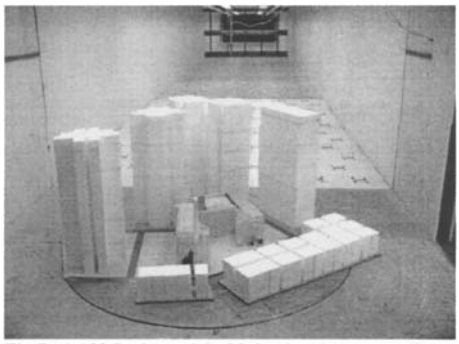

Fig 7 : 1:100 Scale model of School with surrounding high buildings in HKUST Wind Tunnel

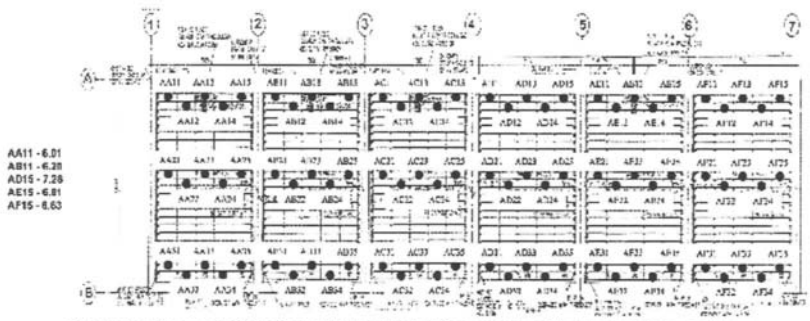

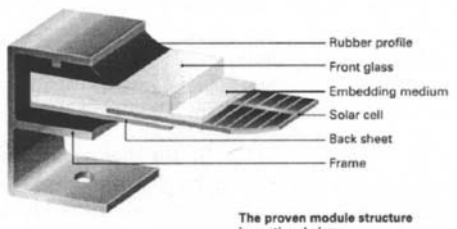

Figure 8 : Diagram of the 6-bay PV deck-shading system with pressure tap positions. Maximum negative pressure positions identified

4. MODULE STRENGTH

The selected module, the Siemens Solar ST40, is a standard module in the PowerMax range. The product literature gives insufficient construction detail for structural calculations , see brochure detail below, and the meaning of the various certificates, IEC 61215, UL 1703, TUV safety class II, etc, is not identified.

Reference to the manufacturer established the construction as

Cover glass – Tempered Solite glass 3.05-3.40mm thick
3 Sheets EVA encapsulate
Raw CIS module – Untempered glass 1.8-2.1mm thick
1 Sheet EVA encapsulate
1 Sheet TPAT (Tedlar Polyester Aluminium Tedlar)
34mm deep aluminium frame on all four sides

Figure 9 : Siemens Solar brochure image of the ST40 module construction with manufacturer's description adjacent

In view of the large negative pressures possible on the module in extreme conditions it was decided to test the module's wind-loading capacity at a Test Facility certified by the HK Government. A standard production module, ST40 was tested for a cyclic pressure test in accordance with HK Practice Note PNAP 106 incorporating a 1.25 safety factor at the Research Engineering Development Façade Consultants Ltd, Yuen Long, HK. The ST40 module maintained its structural integrity at +1.50kPa Positive Pressure and at -3.3kPa Negative Pressure. In view of the far higher pressures measured in the wind tunnel test, the module was next tested with a continuous negative loading in 0.50kPa increments from 1-8.0kPa, held for 10 seconds, and subsequently in 1kPa increments, held for 10 seconds. The module maintained its structural integrity up to -17kPa Negative Pressure, more than double the maximum wind pressure measured in the wind tunnel test, and no further tests were done. Subsequently, the same structurally tested module was electrically tested and found to be in working order and not electrically affected by the deflections of the pressure test.

5. STRUCTURAL SYSTEM DESIGN

Since the standard Siemens Solar ST40 module meets the wind-loading demands, the supporting system was then refined. The system is required to be robust yet also lightweight, low maintenance and with visual appeal. Further the system should be designed for wiring integration, factory pre-fabrication, easy transportation, resulting in a sensibly-priced final product with a long-life.

HK's extremely corrosive marine climate influenced the selection of stainless steel over galvanized steel, paint-protected steel or structural aluminium. The projected 50+ year life of school premises and low maintenance needs were major factors. The shading system consists of a standard truss design linking cast stainless steel circular sections and high tensile stainless steel rods. The trusses interlock at the hub with a specially designed gusset plate. The hub is bolted to the upstanding support suited to the Ma Wan school application but capable of modification for other conditions.

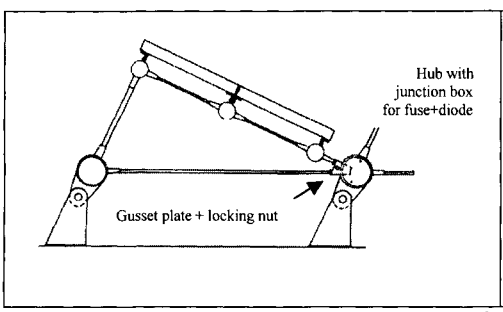

Figure 10 : Truss design with inter-locking gusset plate and hub

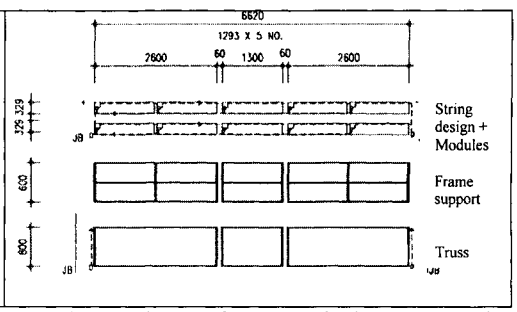

Fig 11 : Diagram of the prefabrication & wiring string

6 ELECTRICAL DESIGN

A further design aim was the integration of the electrical system wiring to minimize site labour and this resulted in the design of a customized junction-box. Upper and lower lines of modules each form a string. As shown in Figure 11. The modules being connected with pre-wired push-fit connectors. The hub that interlocks the trusses also houses the customised junction box. This incorporates two sets of connector, fuse and bypass diode, one set for each string of modules per truss as shown in Figure 12 below. For Ma Wan School the junction boxes will be linked via customised branch cables to the inverter sited on the wall below. The Centre for Advanced Product Development Technologies (CAPDT) at HKU assisted in the 3d solid modeling of the interlocking hub that links the trusses together and locks with the upstand support. The rapid tooling technique is the means of generating the proto-types of complex parts directly from 3D Computer Aided Design (CAD). Approaches are presently being made to electrical contractors in HK to collaborate on the detailed design and small-scale manufacture of the customized junction boxes

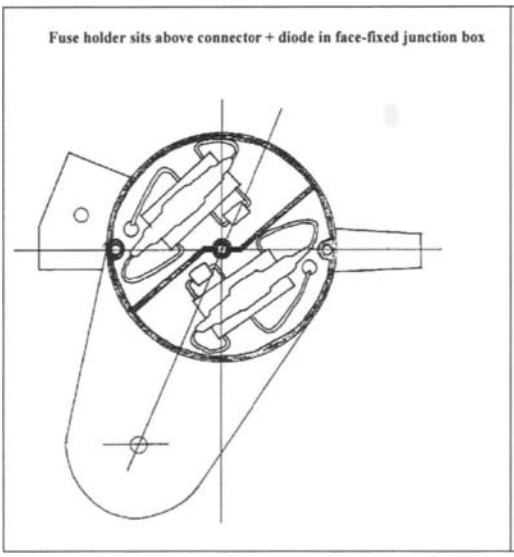

Fig 12 : Plan of the customised junction box with fuse & diode sets

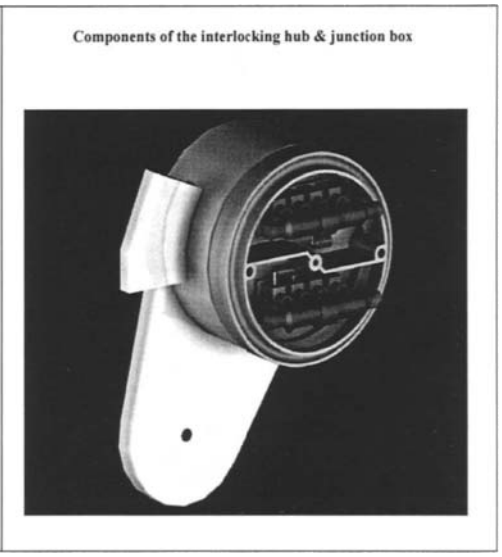

Fig.13 : Solid 3D modeling of the hub for rapid proto-typing

7 COSTS

The PV deck-shading system is one of four PV installations included in the new school at Ma Wan. Prices submitted in the tender procedures indicate the following costs:

Construction (no overheads)	%	Total %
General Contractor (GC)		
Modules	61	
Truss system	5.6	
GC's Building Services Interface	4.5	
Protection	2.5	
Wind-load test	3.3	
Struct/Elect. Design checks	2.6	
Extras	2.5	
Total GC		**82**
Electrical Contractor		
Inverter	11	
Junction boxes, isolators and cables etc	7	
Total Electric Contractor		**18**
Total		**100**

Fig 14 : Indicative percentage costs of the PV Deck-shading system

The truss support system is a relatively small proportion of the total cost despite the choice of stainless steel material. 7% total allowance for General Contractors' interface with the building services and extras indicates the lack of experience of contractors in this construction as does the additional 6% for wind-load tests and more particularly the structural design and electrical design checks. As is frequent in construction today, the contractor carries the 'Design and Build' responsibility. The electrical costs exclude monitoring system costs. The approximate total cost of both general contractor and electrical contractor's work is about HK$5316/m^2 (US$681.5/m^2).

8 SCIENTFIC INNOVATION & RELEVANCE

The outdoor testing in sub-tropical conditions (Hong Kong) indicates the suitability of CIS technology for our high ambient temperatures in summer and also the consistent conversion performance in lower solar radiation conditions. The Siemens Solar module's lightweight yet robust construction also suits the high

wind-load demands of typhoon regions. The lightness allows the supporting structure of the deck-shading system to be correspondingly lightweight. The stainless steel construction is low-maintenance and its construction easily pre-fabricated and pre-wired. The specially designed and integrated junction box includes by-bass diodes and fuses. No such junction box is presently commercially available to the knowledge of these authors. Local electrical industries are being encouraged to manufacture small quantity PV components for the PV industry. Although the system has been designed for schools it has wider applications as a shading structure for markets, car-parking, petrol stations, bus terminals etc. As a system, it can be easily reduced or extended. As a system design it has the potential, through greater familiarity and experience of PV integration, to lower initial manufacture and installation costs.

RESULTS & CONCLUSION

Priced at US$3 per watt and with performance in real conditions expected to be close to the rated STC efficiency, the Siemens Solar ST40 module offers good value. The module presently has a 10year limited manufacturer's warranty. At the time of writing, Siemens Solar has advised of their intention to modify the construction of the module from that tested by reducing the EVA sheet encapsulation of the raw module and also the backing sheet. Structural calculations based on the new construction details indicate the revised module would meet the wind-loading requirement. A proto-type truss, the width of a bay (7.5m) will be manufactured in preparation for the full test of the module plus supporting system required by the local building authority. A study of the production, construction and life-cycle analysis costs is underway. A local electrical components manufacturer has expressed interest in the junction box production. 6 bays of the system will be installed in the Ma Wan Primary School in the Spring of 2003 with 12 months monitoring to follow. The tendered construction costs include approximately 14% extra covering unknown work. This highlights the higher costs of work outside a contractor's normal building experience and the unknown shared scope of work with the electrical contractor identifying the need for construction professionals to be educated and trained in PV building integration.

INTEGRATION OF DOUBLE FACADES AND VENTILATION SYSTEMS IN BUILDINGS

F. Di Maio and A.H.C. van Paassen

Laboratory for Refrigeration Engineering and Indoor Climate Technology,
Delft University of Technology, Delft, The Netherlands.

ABSTRACT

Nowadays the awareness concerning the environmental pollution and the demand of transparent facades in architecture, lead research in finding new solutions to increase the energy performances of the building and the installations as well. Among those, different kind of Double Skin Facades have been studied and several laboratories are still working on them to find a suitable way to apply this technology in new buildings and in the restructuring of old ones. To find out how the constructive parameters affect the performances of the Second Skin Façade and for the purpose of energy saving in building this paper studies the modelling of systems made up by Double Façade coupled with a building. These interactions between the building, the Double Facade and the external environment have been simulated using the simulation code Simulink.
The model has been set up to answer questions about: (a) the gradient of pressure along the facades; (b) flow and temperature along the façade; (c) find out the necessity for control; (d) how to split up the Double Facades in compartments in order to have benefits without serious overheating problems. The effect of the depths of the cavity has been shown to influence the Double Façade's performances.
It has found that due to the pressure gradient, different airflow at different temperature enter the room facing the Double Skin Façade. A control system is then necessary to synchronize all the components involved.

KEYWORDS

Second Skin Façade, simulation, Simulink, pressure gradient, airflow, thermal balance, stack effect, wind pressure, overheating.

INTRODUCTION

The demand of transparent facades in architecture, has given new impulse in finding new way to improve the energy performance of the buildings. Among those, different kind of Double Skin Facades have been studied and several laboratories are still working on them to find a suitable way to apply this technology in new buildings and in the restructuring of old ones.

In traditional buildings the outdoor climate is considered as an enemy, whose influence must be controlled by the Heating, Ventilation and Air-Conditioning system. The technology of the Double Skin Façade coupled with an HVAC system is an attempt to achieve the opposite, namely to use the solar radiation and the wind, in an advantageous way to reduce the energy consumption and to improve the comfort at the same time. Actually the Double Skin Facades can reduce the solar gain in summer and provide thermal insulation in winter. Moreover, it can be used as a solar collector to preheat the ventilation air. The intelligent controlled façade tries to use outdoor climate as much as possible for all indoor climatic aspects. These aspects include cooling and heating to maintain a required indoor temperature, the supply of fresh air and the guarantee of a certain lighting level. The solar radiation is used in addition to heating and lighting and the natural ventilation can be used for fresh air supply and for cooling. Although this seems an attractive building philosophy, there are problems because the advantage of the outdoor climate is often not available at the right time or in the required amount. Consequently, the Double Skin Facades of the building should be equipped with components that can be controlled such that the best use is made of the outdoor climate. This requires intelligent controlled façades (Paassen, 1999).

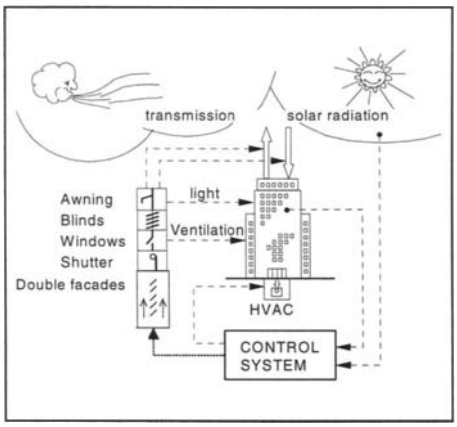

Figure 1 - Building with an intelligent façade.

Figure 1 shows in a schematic way the relation between the Double Facades, the building, the HVAC system and the weather conditions. In order to get a good integration the controlled facades should be equipped with the following components:

1) Shading devices. For the applications in the Double Skin Façade the more effective shading devices are the venetian blinds placed between the external glass element and the glass element facing the room. They act as solar collectors supplying the stack effect that is one of the main driving forces moving air inside the cavities. Exterior shading device (as awnings, rolling shutters and shades but no second skin) could show equivalent performance in summer and could therefore be used to prevent high cooling load. They have some disadvantages due to the risk they can be blown away by the wind especially in the high buildings.

2) Louvers with adjustable slats can also control sunlight entering the rooms. Consequently they can be used as well for shading as controlling daylight.

3) Adjustable vent windows for ventilation and cooling with outdoor air. Cool outside air, especially during the night, could be forced by wind and "chimney" effect would push warm air out so that built-up heat would be removed. All these components have the capability to influence the contribution of

the outdoor climate to the indoor climate aspects such as indoor air temperature, fresh air supply and lighting.
In case the indoor climate conditions cannot be maintained with the use of the passive components and the outdoor climate, the following active components should be available:
4) Auxiliary heater and/or cooler.
6) Artificial lighting.
The HVAC system should be equipped with heat recovery units connected with the double facades' cavities as well. The Double Skin Facades can be used as heat recovery for the HVAC system (Stec & van Paassen 2001).

MODELLING

The model used in these simulations is make up by many subsystems but as shown in figure 2 the main framework can be regarded as an interaction between the Second Skin Façade subsystem and the Thermal Model subsystem. As schematically shown in figure 2 the output variables of the Double Façade model are used as input of the Thermal Model of the Building.
The heat transfer coefficients related to external surfaces of the façade walls and the one related to the external surfaces of the double glasses are considered to be the same. They are implemented in the Alpha Generator subsystem inside the Double Façade model (Di Maio & van Paassen 2001).
The Thermal Model of the building uses these variables as inputs together with the weather data and the ventilation heat flows computed in the Ventilation Generator subsystem (see figure 2) to perform the calculations needed to calculate the air temperatures and the walls temperatures of the rooms. Iteratively the Double Façade model uses results of these calculations as inputs together with the weather data.
As an output of the coupled model, the air temperatures inside the rooms are stored in the Matlab workspace and can be plotted as shown later on.
The way the Second Skin Façade subsystem works can be found in literature Di Maio & van Paassen (2001).

The Thermal Model

The purpose of the model

The thermal model calculates the indoor temperatures and the wall's temperatures in all rooms of the building. The inputs necessary to perform these calculations are the weather data, the ventilation heat flows from the Ventilation Generator, the internal glass' temperatures and the average air temperatures in the cavity from the Double Facade subsystem. The Thermal Model of the rooms receive the airflows rate and their temperatures flowing in the cavities from the Double Façade model subsystem together with the temperatures of the glass panes facing the rooms. Convective heat exchanges take place between the glass' surfaces and the air in the rooms. Radiative heat exchanges take place between the glass' surfaces and the rooms' surfaces.
The Double Façade model receives the air and surfaces temperatures of the rooms from the Thermal Model of the rooms. The subsystems showed in figure receive the weather data from the Matlab workspace.

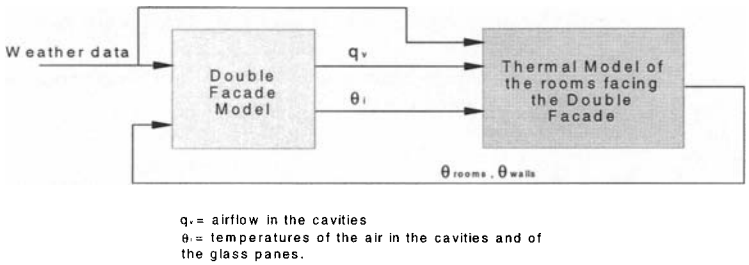

Figure 2 - Model of the rooms modelling the building's room and the Double Façade.

Model hypotheses

A network as shown in figure 3 can illustrate the heat transfer process occurring in a room. It represents the heat transfer in a room which is surrounded on both sides and above and below by identical rooms. This standard room has three interior walls in addition to the roof and the floor. The exterior wall is facing the double façade which is provided with a venetian blind as solar shading device.
Due to the complexity of the thermal network simplifications are necessary to build the model. It is assumed a good mixture of the air inside the rooms, so that only one temperature ("homogeneous temperature distribution" model usually called "One-point model") depicts the thermal response of the room to the heating and cooling loads caused by the internal sources and by the flows calculated in the Ventilation Model subsystem. Each interior surface of the room is depicted by one node. The latter assumption has been verified by Mitalas (1965). About the first one especially in unconditioned rooms, temperature gradients have been observed. These gradients depend strongly on the air circulation inside the room (Chen, 1988). Nevertheless this assumption has been accepted for the purpose of this thesis. A resistance network connecting the nodes represents the heat exchange by radiation between the various surfaces and the heat exchange between these surfaces and the room air. For each node a heat balance can be set up. These heat balances result in a set of differential equations that are solved simultaneously together with the others contained in the subsystem named Double Façade model (see fig. 3).
Three types of heat transfer are taken into consideration in the modelling process. There is convective heat transfer from the window's glass, the walls, the floor and the ceiling to the room air. There is a radiative heat transfer from the window's glass to each wall's surface, to the floor and the ceiling. There is conduction heat transfer inside the walls, floors and the ceilings of the building. The heat balances of all the surfaces in the room do not take into account the radiative heat transfer between the surfaces themselves but a virtual surface having the mean temperature of the surfaces inside the room and a view factor equal to $(1-F_{s,g})$ (where $F_{s,g}$ represents the view factor between the surface and the glass), exchanges radiative energy with the walls' surface. A ventilation heat flow from the Double Façade subsystem or from the air-handling unit is present in order to maintain the comfort condition inside the rooms. Moreover during the working time there is an internal load inside the rooms due to the people, the lightning and the equipments. Solar radiation falls on the Double Façade. Part of it enters the room through the glasses and the sunshine device and it is assumed to be evenly divided on the entire area of the room and it will be indicated by q_{si}. It was supposed that the entire surface facing the cavity is made by glass. Actually part of that surface ($1.1 \cdot 3.6$ m^2) is made by brick. Due to the shading device it does not receive a lot of solar radiation $(A3+A4) \cdot q_s$. Further investigations should be done in order to estimate the real approximation and its thermal influence on the system.
Each wall in the model is simulated according to the scheme shown in figure 4.

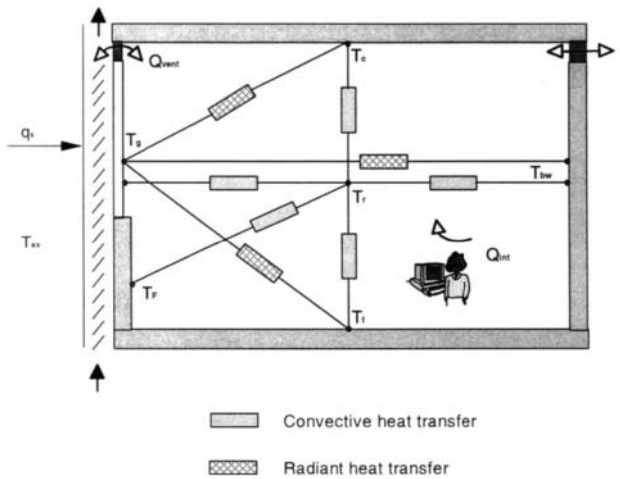

Figure 3 – Physical model of the thermal behaviour of the room

Lumped parameter assumption is adopted. This is realized by splitting the wall into some layers. In each layer, the parameters, like temperature, specific heat and conductivity, are the same. Since the parameters are actually different, the more layers the wall is split, and the closer the model is to the reality. However, too many layers make the models more complicated and lower simulation speed.
On both side of a wall there is a convection heat transfer to the air temperature (T_r), a radiant heat transfer to the surrounding surfaces and a solar load (q_{si}) depending on the surface that is taken into account. Conductive heat transfer is present inside the walls. Each wall itself is divided into three layers having its own conductivity *k*, density ρ, specific heat *c* and thickness Δx. It was assumed a good connection between the different surfaces of the wall so that no additional resistances the thermal energy has to meet through the wall. Running the simulation it is possible to know the temperatures in the four points in the wall.

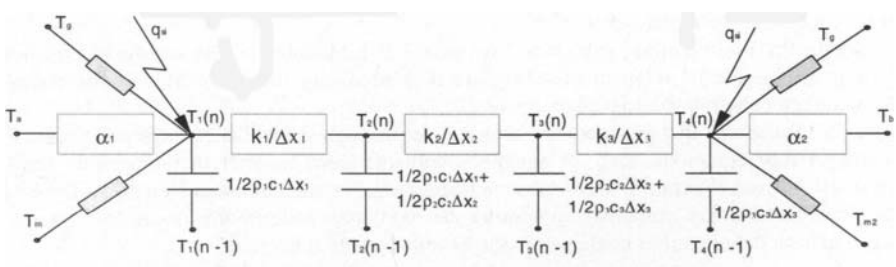

Figure 4 –Electrical R-C representation of the wall.

Where:

α_i = convective heat transfer; i = 1, 2	[W/m^2 K]
k_i = conductivity of the ith layer; i = 1, 2, 3	[W/m K]
ρ_i = density of the ith layer; i = 1, 2, 3	[kg/m^3]
c_i = specific heat of the ith layer; i = 1, 2, 3	[J/kg K]
Δx_i = thickness of the ith layer; i = 1, 2, 3	[m]

T_a = air temperature in the room and/or in the cavities [K]
T_b = air temperature in the room [K]
T_i = temperature inside the walls; i = 1, 2, 3 [K]
T_g = temperature of the glass [K]
T_m = mean temperature of the walls [K]

Decomposition into subsystems

The system is composed of a segment for each storey. Each of them has basically the following subsystem:

- The Wall, Floor, Ceiling subsystems
- The Alpha Generator subsystem
- The average Wall Temperature subsystem
- The Ventilation Generator subsystem
- The One Point Air Model subsystem

Because the subsystems are almost the same for each floor, only those ones concerning the second storey will be discussed in detail. Figure 6 shows the second storey subsystem.

The wall, floor, ceiling subsystems

There are 21 of these subsystems in the model. Each of them has to compute the temperature on both side of the layer (wall, floor or ceiling). The temperatures between the layers in which the wall, floor or ceiling are divided are monitored as well.
There are five *Floor-Ceiling subsystems* in the model. As far as the second storey subsystem is concerned, the subsystem designed to compute the temperature of the ceiling is the same as the one computing the temperature of the third storey's floor. The inputs are the weather data, the glass' temperatures of the windows on the third storey and on the second storey from the Double Façade subsystem, and the third and second room's air temperature from the One Point Air model subsystem. The small differences concerning the fourth storey ceiling and the first storey floor will be discussed later on.
The equations implemented in the Floor-Ceiling subsystem are derived from heat balances made on the system schematically shown in figure 4.
When data for the Floor-Ceiling subsystem (contained in a Matlab file) are substituted in these four equations it is possible to solve them. Therefore it is necessary to load a Matlab file contains the physical parameters before to run the simulation.
There are 21 subsystems that calculate the heat transfer through the walls, ceilings and floors. Each of them contains four equations, then 84 equations with the same number of temperature have to be simultaneously solved in order to know those temperatures. For each iteration step this is done together with the four heat balance equations computing the room's air temperature in the four rooms of the building, and with the equations contained in the Double Façade subsystem.

The One Point Air model

From a heat balance for the system showed in figure 3 it is possible to derive the differential equation 1 which calculates the air temperature in the room.

$$\rho_a c_a V_{r2} \frac{dT_{r2}}{dt} = Q_{int} A_{fl} + Q_{vent} + \alpha_{r2}(T_{g2} - T_{r2}) A_g + \alpha_{r2}(T_F - T_{r2}) A_F +$$
$$+\alpha_{r2}(T_{sw1} - T_{r2}) A_{sw1} + \alpha_{r2}(T_{sw2} - T_{r2}) A_{sw2} + \alpha_{r2}(T_{bw} - T_{r2}) A_{bw} + \alpha_{fl}(T_{fl} - T_{r2}) A_{fl} + \quad (1)$$
$$+\alpha_c (T_c - T_{r2}) A_c$$

Where:

A_g =	total glass area	[m^2]
A_F =	internal façade wall area	[m^2]
A_{sw1} =	internal side wall 1 area	[m^2]
A_{sw2} =	internal side wall 2 area	[m^2]
A_{sw2} =	internal back wall area	[m^2]
A_F =	floor area	[m^2]
A_c =	ceiling area	[m^2]
ρ_a =	air density in the room	[Kg/m^3]
c_a =	specific heat of air in the room	[J/Kg·K]
V_a =	volume of the room	[m^3]
Q_{vent} =	ventilation heat flow	[W]
Q_{int} =	internal heat load	[W/m^2]

Solving this equation the results are the air temperature in the rooms.

RESULTS

Several simulations have been carried out on the coupled model in order to investigate the usage of night cooling by opening the vents windows facing the Double Façade. The simulations have been carried out for a four-storey, west oriented building:

-Height 13.2 m;
-Width 3.6 m;
- Depth of the cavity 0.4 m;
- Ventilation opening area 3.2×0.155 m^2;
- Opening angle of vent windows 45°, 25°, 15°, 0°.
- Internal load 500W in each room;
- Pressure in the room –2 Pa;

Figure 5 shows the room temperatures at each floor together with the external temperature and the airflows through the ventilation openings (45 degree). After a four-day period with bright and warm weather eventually the temperature on the fourth floor reaches about 40 °C. With opening angles of vent windows 45° the temperature on the same floor could be reduced to about 30 °C.

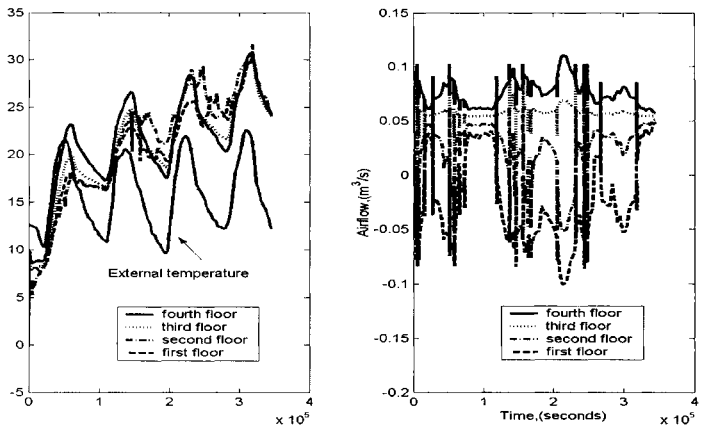

Figure 5 – Indoor and outdoor temperature. Opening angle 45°. Airflows through ventilation openings. Due to the pressure gradient along the façade, air is extracted from the rooms in the first and second storey and supplied into the above rooms.

The neutral zone of the façade is placed somewhere between the second and the third storey. Due to the pressure gradient along the cavity, air is extracted from the rooms in the first and in the second storey and supplied into the above rooms. The result is that the average indoor temperature are higher at the highest floor due to supply of warm air from the cavity, while in the first and second floor cooler air is supplied from the corridor and exhausted through the cavity.

CONCLUSIONS

The temperatures inside the rooms at different floors have been shown to be different. Highest floors have higher temperatures. Moreover, the pressure gradient and its effect on the ventilation rate through vent openings suggests a proper control of the ventilation openings and partitioning of the Double Façade to avoid overheating problems. The simulations shown that the Double Skin Facades can have a flexible use as (a) supply fan or exhaust fan; (b) preheating device for ventilation systems with natural supply through openings in the inner façade; (c) supplier of preheated fresh air for a central air handling unit.

MECHANICALLY VENTILATED DOUBLE SKIN FAÇADES

M. Kragh, PhD

Permasteelisa, Via Friuli 10, 31020 San Vendemiano (TV), Italy

ABSTRACT

With the growing interest in environmentally friendly architecture and transparency, the development has lead to still more advanced building envelope concepts. Double skin façades pose an interesting alternative as they allow large transparent areas without compromising occupant comfort and energy consumption. The paper introduces different mechanically ventilated double skin configurations in terms of engineering and performance characterisation. The two main concepts discussed are the Active Wall, a double skin façade mechanically ventilated with the return air from the indoor environment, and the Interactive Wall, which is ventilated with outdoor air by means of small fans incorporated in the façade. System performance characterisation becomes increasingly complex as the function of the building skin adapts to the environmental requirements. The paper discusses ways of characterising the façade in order to provide adequate input for HVAC system sizing, a field currently lacking guidelines and standardisation coverage. The way these advanced façade systems act as filters between indoor and outdoor environments allows for not only transparency and daylighting, but also implementation of soft cooling technology. Successful implementation, however, depends closely on an integrated design approach from the early, schematic phases of design, where the Architect should collaborate with both façade engineers and M&E engineers in order to create a truly synergetic overall building design scheme.

KEYWORDS

Multiple skin façades, double skin facades, transparent architecture, integrated building design, comfort, energy consumption, performance characterisation, financial implications.

BACKGROUND

The present paper deals with advanced façades for commercial buildings, but many of the considerations will apply to other applications as well. Growing awareness of environmental issues is currently leading to more sustainable architecture on a global level with local differences depending on climate, market trends and legislation. After having relied on HVAC to handle the indoor climate and to a much lesser extent designing *with* the climate, architects and engineers are now explicitly re-discovering fundamental principles and facing the challenge of realising sustainable architectural designs and indoor spaces with high levels of occupant comfort without inferring excessive energy consumption.

A current architectural trend – the pursuit of fully transparent buildings – are pushing the boundaries of design, in turn leading to innovative concepts and generally more adaptive and responsive façade configurations. Multiple skin façades can be conceived as a response to the demand for transparency and occupant comfort in a sustainable context. Whereas the present paper deals specifically with the façade configurations, it is noted that true design optimisation is only possible when local climatic conditions, building orientation and thermal mass are duly taken into account during schematic design.

All too often, the façade design is developed when fundamental decisions, for instance pertaining to HVAC system scheme, have already been taken. At this point, it can be too late to fully benefit from an advanced façade solution. If façade and environmental system are engineered as two parts of the same solution, not only will the performance most likely be superior – both initial and running costs may moreover be reduced significantly. Successful application of these systems depends closely on the adoption of an integrated design approach from the early, schematic phases of a given project. Moreover there is a pronounced need for a common language in order to characterise and communicate the performance of innovative systems such as the mechanically ventilated façades. Quantities such as U-value and solar heat gain coefficient are not readily applicable when the façade interacts with the ventilation system, and traditional ways of designing HVAC systems may not be adequate when assessing possible application of innovative solutions such as soft-cooling.

ADVANCED FAÇADE CONCEPTS

Façade Types

In order to introduce the adopted terminology, four fundamentally different façade categories are described briefly in the following.

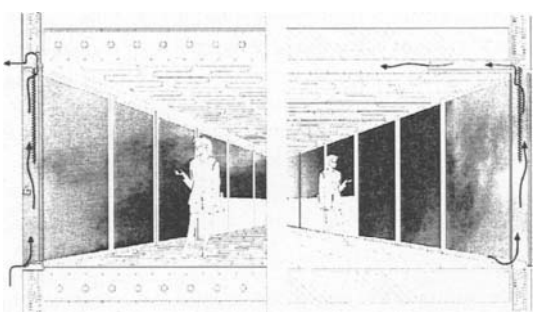

Figure 1: Schematic – Interactive Wall (left) and Active Wall (right)

Conventional, fully glazed, façade

In this context, the conventional façade is the base case, typically incorporating insulating glazing units and either external or internal shading devices. Coated glass is used to modify thermal and solar glazing performance.

Naturally ventilated façade (a.k.a. double skin façade or flue wall)

The glazing configuration is composed of an external single layer of glass and an internal insulating glazing unit. The cavity between the two skins is naturally ventilated with outdoor air through openings in the external skin. The cavity can be continuous over one or more floors.

Active Wall (a.k.a. airflow window or climate wall)

The glazing system is composed of an external insulating glazing unit and an internal single layer of glass. The cavity between the two skins is ventilated with return room air, which is extracted from the room at the base of the glazing and returned to the air-handling unit at the top. (Refer to the schematic in Figure 1). Figure 2 shows the Headquarters of ABN AMRO, a large-scale application of the Active Wall concept.

Interactive Wall

In this case the glazing configuration is composed of an external single layer of glass and an internal insulating glazing unit. The cavity between the two skins is ventilated with outdoor air, which is introduced at the base of the glazing and returned to the outside at the top by means of temperature-regulated micro-fans located in the façade itself (Refer to the schematic in Figure 1). The Interactive Wall is currently being adopted at the new headquarters of ST Microelectronics in Geneva (Figure 2).

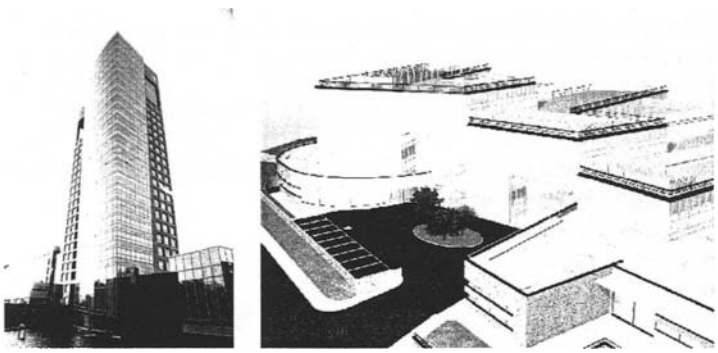

Figure 2: Left / ABN AMRO Headquarters, Amsterdam, Active Wall,
Right / ST Microelectronics, Geneva, Interactive Wall (in progress)

Smart façades

As the building envelope is increasingly acting as an adaptive filter it is also increasingly integrated with the environmental system of the building. The various components of the building envelope are connected to the building management system (BMS) for example as parts of the overall ventilation or daylighting strategies. Whereas smart systems as such are beyond the scope of the present paper it is noted that, whereas the term *Smart* denotes that the façade responds with a certain logic, the term *Intelligent* somehow implies a system with a learning capacity. Such systems are actually being developed, for instance control of shading devices can be engineered to adopt a certain occupant behavioural pattern, but there is a general tendency to ascribe more intelligence to products than what is actually justified given this terminology.

Comparison

Energy loads and occupant comfort are two determining factors in terms of both environmental quality and economy (directly in terms of reduced cooling/heating loads and indirectly in terms of increased occupant comfort and productivity). Comparing the performance of the different systems is complex, but can be summarised as follows:

The *Active* façade is preferred in climates where occupant comfort close to the façade during cold periods is a concern. Since the façade is integrated with the building ventilation system and ventilated with indoor air,

the indoor surface temperature is close to room air temperature, reducing downdraught and the sensation of 'cold radiation'. Moreover, the system allows for heat-recovery on sunny days in heating mode. The transmission heat loss is low due to the three layers of glass.

The *Interactive* façade, on the other hand, is preferred when cooling loads are the major concern. Its low solar heat gain coefficient is comparable to that obtained by means of external shading, yet without the potential drawbacks associated with these (aesthetics, cost, wind resistance, maintenance). The solar heat gain coefficient is a central parameter when dealing with large transparent areas in office buildings with high internal gains. The solar heat gain coefficient of the Interactive Façade is roughly half that of the Active Façade, which has a considerable impact on the solar gains. In cold periods with heating loads, the micro-fans in the façade are switched off and the façade has a low transmission heat loss. Another potential benefit is that the façade system is 'stand-alone', as there is no physical integration between façade and building ventilation system.

Due to the extra layer of glass, the acoustic insulation of the double skin façades is improved compared with conventional façades. However, special glazing configurations are usually employed in cases with strict requirement in terms of acoustic insulation.

The three main building physics parameters characterising a façade are the following:

g	the solar heat gain coefficient (SHGC) – the fraction of irradiant solar energy transmitted to the indoor environment	[-]
U	the thermal transmittance	[W/m²K]
τ_{vis}	the light transmittance	[-]

Besides the glazing configuration itself (Active/Interactive), the system performance depends closely on glass types, blinds setting and reflectance, airflow rates, panel dimensions and design details in general. Whereas g and τ_{vis} are usually specified for the glazing, U can be specified for the glazing and/or the whole system, including framing members and spandrel zones. Moreover, the *internal glazing surface temperature* is an important comfort parameter, which is frequently considered part of the system performance. In order to allow a rough comparison, a set of indicative performance parameters is given in the following table.

TABLE 1
INDICATIVE PERFORMANCE PARAMETERS (WHOLE FAÇADE)

Façade Type	Light Transmittance τ_{vis}	Solar Heat Gain coeff. g	Thermal Transmittance U	Acoustic Insulation R_w
Conventional fully glazed	0.50 – 0.60	0.30 – 0.40	2.0W/m²K	32 – 34dB(A)
Active Wall	0.60 – 0.70	0.15 – 0.25	1.4W/m²K	36 – 40dB(A)
Interactive Wall	0.60 – 0.70	0.10 – 0.20	1.2W/m²K	36 – 40dB(A)

Energy and comfort

It is important to note that any measure of energy performance should always be assessed in conjunction with a measure of the corresponding comfort performance. In other words: for a given set of project conditions, a given level of occupant comfort results in a certain energy consumption, depending on façade and HVAC system design.

ENGINEERING AND PERFORMANCE ASSESSMENT

Engineering of Advanced Façades

As façade designs become increasingly complex and façades tend to interact with environmental systems of buildings, a timely, well defined and adequate façade performance characterisation is still more instrumental to successful overall building design. Moreover, the façade characterisation should be communicated in time for M&E contractors to account for the façade performance in a sufficiently detailed way to consider alternative and potentially innovative schemes.

In the following it is assumed that structural integrity of the façade systems is secured. This is not to say that structural aspects are less important in any way, but the paper is deliberately focusing on concepts and building physics related aspects pertaining to energy and comfort.

Advanced façades act as filters between the outdoor environment and the controlled environment indoor, responding to combinations of occupant requirements and climatic situations, modifying their configuration and characteristics. Hence the static values applicable to conventional, passive building components are rendered obsolete if the true potential of advanced façades is to be taken into account. In less abstract terms this means that the performance of a ventilated façade incorporating solar shading depends on both *airflow rates* and the *setting of the shading device*, parameters which may change according to the requirements.

In the following, the approach currently adopted by Permasteelisa Research & Engineering is introduced in order to illustrate the need for thorough analysis and characterisation of double skin façades. The method is based on commercially available software and simplifications are introduced in recognition of the intrinsic complexity – the problems are essentially 3-dimensional and include airflow – which cannot be dealt with in an operational way as part of normal project engineering. However, the methods presented in the following are found to yield acceptable accuracy.

Framing and spandrel are modelled by means of 2-dimensional finite element methods. Permasteelisa is currently utilising the THERM software (THERM, 2000), but various similar tools are commercially available. A steady state analysis is carried out according to standards and/or project specifications. Heat fluxes and temperature distributions are determined on the basis of a relatively detailed model of a given section. Since the objective is always to assess system performance, the frames are modelled including the edge of the glazing taking 2-dimensional edge effects into account

Conventional glazing system characteristics are usually provided and certified by the glazing supplier. As mentioned, insulating glazing units – or single layers of glass – can be modelled by means of the Window software (Window, 1994). For more *complex glazing systems*, such as ventilated double skin façades incorporating solar shading, Permasteelisa is currently using the WIS software (WIS, 1996). Apart from the fundamental principles of the model, the main limitation of the tool is the availability of product data. Permasteelisa is currently part of the *WinDat* Thematic Network, funded in part by the European Commission, aiming at improving WIS product libraries and making the software available through the Internet (visit www.WinDat.org for information).

Theoretical Assessment Procedure: Thermal and Solar Performance

In the following, the estimation procedure is briefly introduced using an Active Wall as an example. The method can be divided into five steps as follows

I. Window modelling of glazing units

Glazing systems are combined of different layers stored in the Window glass library. Subsequently these

glazing systems can be imported into a given THERM model.

II. THERM modelling of frames/spandrel

A finite element model is created and thermal properties are assigned to the various elements (materials) of the section. The program calculates the U-values of different parts of the model and the temperature distribution depending on environmental conditions.

III. WIS modelling of the glazing centre

By means of the WIS software, the glazing system can be modelled including both solar shading and ventilated cavities. In order to adequately characterise the glazing performance, the systems are usually modelled, *varying both blind setting and airflow rates*. Moreover, *different environmental conditions* are modelled in order to determine U-value and solar heat gain coefficient as well as glazing surface temperatures for different design conditions. The nature of the airflow is not simulated as in computational fluid dynamics (CFD). Application of CFD is beyond the scope of normal performance assessment and poses a series of problems in terms of boundary conditions. Research is in progress and it is possible that future models will be based on CFD methods, but currently the WIS tool is found to yield acceptable approximations whilst being user- friendly and operational.

IV. Estimation of overall system performance

The *system overall U-value* (frame, spandrel, glazing centre) is estimated by area-weighting the component U-values. A series of U-values are computed for different airflow rates to enable M&E engineers to analyse different scenarios. For the glazing system, the performance is estimated for different façade cavity airflow rates, blind settings and environmental conditions. The U-value will usually be specified for night-time conditions without ventilation as well as daytime conditions with ventilation. The solar heat gain coefficient is specified for different airflow rates and blind settings as input for optimisation.

V. Condensation risk assessment

The *condensation risk* is assessed determining the minimum internal surface temperature under design conditions. If the indoor ambient temperature and the minimum internal surface temperature are known, the critical indoor relative humidity can be specified. In order to operate with a façade characterisation, which is independent of environmental conditions, the *Temperature Factor* is defined as follows (EN ISO 13788, 2001):

$$f_{Rsi} = \frac{\theta_{si} - \theta_e}{\theta_i - \theta_e}$$

Where

f_{Rsi}	is the temperature factor	[-]
θ_{si}	is the internal surface temperature	[°C]
θ_i	is the indoor temperature	[°C]
θ_e	is the outdoor temperature	[°C]

Façade / HVAC

When dealing with the Active Wall configuration (indoor/indoor ventilation), the integration with the building ventilation system is a central issue. Usually, the ventilation of the façade is based on the required air-change of the indoor environment, which under normal conditions corresponds roughly to the optimum façade airflow rate. In situations with cooling loads, which is the normal situation in commercial buildings with large transparent areas and low U-values, the air is expelled when extracted from the indoor

environment. In periods with heating loads, two situations are considered. When solar irradiation is heating up the air in the façade, the heat can be recovered by means of heat exchangers, whereas the air will be cooled in absence of solar irradiation. Thus, the overall energy performance depends on the overall building HVAC/façade scheme. Along with the U-value, the temperature of the air leaving the façade cavity is usually specified, enabling M&E engineers to account for enthalpy changes. The term *equivalent U-value (or apparent U-value)* is adopted to indicate that it applies to the façade when ventilated

Project-Specific Testing

Verification of project-specific design details is an essential part of the engineering process. Full-scale mock-up testing is used to secure correct airflow distribution - air velocities are measured and smoke is used to visualise the nature of the flow. The condensation risk may, moreover, be assessed in a climatic chamber as part of subsequent general performance testing.

Full-Scale Test Rooms

At Permasteelisa's Headquarters in Italy, a series of advanced façade solutions have been realised in conjunction with innovative HVAC systems. Currently, a total of 12 full-scale test rooms are operative and another 2 rooms are in progress. The measurements yield direct comparisons between different solutions exposed to identical climatic conditions and provide a basis for validation of both simplified and detailed engineering tools. The building envelope configurations comprise double skin façades (naturally ventilated, mechanically ventilated indoor-indoor and outdoor-outdoor). The environmental systems comprise variations of radiant systems as well as displacement ventilation. For comparison, the innovative systems are installed side-by-side with conventional systems adopting high performance glazing and fancoil cooling/heating. The rooms are continuously monitored in terms of energy consumption, ambient temperatures and humidity as well as surface temperatures across the façade and solar radiation transmitted through the façade. Moreovcr, daylight measurements can be carried out in one room at a time. A meteorological station records the climatic conditions from the roof of the building. A more detailed description of the test rooms can be found in (Kragh, 2001).

FINANCIAL IMPLICATIONS

First Costs and Running Costs (Energy and Maintenance)

Also in terms of *first costs*, the building should be analysed as a whole. When contemplating application of high-performance, advanced façade designs, decision makers should carefully analyse implications in terms of potentially reduced HVAC requirements. Downsizing ducting and air-handling units results in direct savings in terms of components and installation, and indirect savings in terms of an increasing net-lettable area. HVAC system downsizing and utilisation of radiant systems reduce the required equipment maintenance. Case studies such as the UCB Center in Brussels have demonstrated that innovative solutions can be realised at the same overall building cost as conventional solutions and result in increased comfort, reduced maintenance and 30% energy savings (Kragh, 2000 and 2001).

Productivity

Energy-efficient building and office design offers the possibility of significantly increased worker productivity. By improving lighting, heating, and cooling, workers can be made more comfortable and productive. The Rocky Mountain Institute has carried out a series of case studies of new buildings and retrofits, all demonstrating the correlation (Romm and Browning, 1998).

Tax Incentives and Building Codes

In the UK, Government initiatives to secure best value have lead to changes from normal development, making 'cost in use' a key factor in the design. The Authorities need to take into account whole life costing of the service or element. Both central and local government is thus undergoing significant change. Similar strategic changes are also taking place in the private sector. The purchase decision is moving away from the lowest tendered costs with the focus being more on the cost in use benefits whoever the tenant is going to be. This issue is particularly relevant in the selection of an appropriate façade design. The tax laws in the United Kingdom are uniquely favourable to technical development in environmental engineering generally and active façades in particular. UK tax relief is given by way of capital allowance on plant and machinery that writes off the capital value effectively within 8-9 years (Glanville, 2000).

Added Value

Summarising, it could be concluded that the integrated design of high performance building envelopes in conjunction with innovative HVAC systems can result in significant *added value at contained costs*. At present, energy savings may not be economically significant on all markets, but legislation and incentives will gradually lead to more sustainable designs from a political hold. However, the added value in terms of increased occupant comfort and productivity, downsizing of mechanical plant, increased net-lettable area, lower running costs and last, but not least, improved (corporate) image may well turn out to be far more powerful drivers in the future.

CASE STUDIES OF THE APPLICATION OF INNOVATIVE ENERGY-EFFICIENT EQUIPMENT IN BUILDINGS

C.K. Lee, K.K. Lam and Martin K.T. Wu

Energy Efficiency Office
Electrical & Mechanical Services Department
Government of the Hong Kong Special Administration Region

ABSTRACT

The Energy Efficiency Office (EEO) of Electrical and Mechanical Services Department is actively exploring means to reduce energy consumption in buildings and a series of initiatives are being implemented to achieve the goal. One of the initiatives is to investigate advanced and innovative energy saving equipment and technologies via series of pilot projects in government buildings with a view to promote the wider use of these technologies in public and private sectors of the construction industry. The investigation covers innovative equipment for lighting, air conditioning, lifts and escalators, etc. The paper will present details of two case studies of the pilot projects, one for lighting and one for air-conditioning, carried out by EEO in government buildings. The pilot lighting project involved the application of high output T5 lamps and luminaires in an indoor games hall. Aspects on both energy and visual performance will be presented for the new lighting system and comparison will also be made with the existing high bay lighting system using High Intensity Discharge (HID) lamps. For the case study in air-conditioning, focus will be on the application of indirect evaporating pre-cooling system for fresh air intake to building. The otherwise waste exhaust air and waste condensate water form the building air-conditioning system were used for heat reclaim through an integrated heat exchanging and evaporating unit in this pilot project. Significant energy saving have been recorded in both cases.

Energy Efficiency, High Output T5 Lamps, Games Hall Lighting, Indirect Evaporating Cooling.

PILOT T5 LIGHTING PROJECT AT EAST KAI TAK INDOOR GAMES HALL

As part of the Pilot Energy Management Opportunity (EMO) Implementation Programme using innovative energy efficient equipment, Energy Efficiency Office (EEO) of Electrical and Mechanical Services Department (EMSD) has completed a pilot lighting project at East Kai Tak (EKT) Indoor Games Hall. The new lighting system made use of the latest T5 lighting technology for illuminating the high ceiling games hall. As compared with the existing high-bay lighting using High Intensity Discharge (HID) lamps, the new high output T5 lighting system was found to be more energy

efficient and offered many other benefits which provide users of the games hall a more comfortable visual environment for their sporting activities. There were totally 48 high-bay HID luminaries existing in the game hall. Half of the lamps were 400W metal halide and the rests were 250W high pressure sodium (SON) lamps. The new T5 lighting system included 56 special impact resistant luminaries accommodating 3x49W high output T5 lamps and electronic ballasts (168 T5 lamps in total). Power consumption was 17.2kW for the existing lighting system. Measurement on site for the new T5 lighting system was 8.7kW, which represents a power reduction of almost 50% in lighting. The average illuminance measured at floor level was found to be 760 lux and 480 lux for the new T5 lighting system and the existing high-bay lighting system respectively. Other than the 58% increase in illumination level, improvement in the lighting quality in terms of glare, colour appearance and colour rendition were also recorded. Surveys were also carried out to collect users' opinion on the new lighting system. Majority of the users' feedback was in favour of the new T5 lighting system. General comments included brighter than before, more comfortable, less glare, softer visual environment and better colour appearance.

Existing Lighting System in EKT Indoor Games Hall

The existing lighting installation in EKT Indoor Games Hall consists of 24 numbers 400W metal halide lamps and 24 numbers 250W high pressure sodium (SON) lamps mounted inside the industrial type high-bay luminaries with parabolic reflectors. Fig. 1 shows the existing lighting layout plan and Fig. 2 shows a photograph of the existing lighting environment with HID lamps. The metal halide and SON luminaries were designed to mount in pair (Fig. 3) adjacent to each other for colour blending. All existing HID lamps were switched on for the whole opening hours of the game hall because these HID lamps need at least 5 minutes warming up period to start up and instant re-strike after switching off or a power interruption is also not possible. The colour appearance of metal halide lamp is typical cool white in colour (6000°K) and that for SON is yellow (2000°K). Neither metal halide lamps (too cool) nor SON lamps (too warm) are suitable to be used alone for indoor games halls lighting and they are therefore employed in pair for colour mixing and to create an appropriate visual environment for sporting purposes. Metal halide lamps are also characterised by their good colour rendering property (essential for live TV broadcasting) but less efficacy (76 lm/W). SON lamps have relatively poorer colour rendition (rich in yellow/orange spectrum) and possible shift of colour appearance in operation but much higher efficacy (100 lm/W).

Fig. 2: Existing lighting environment with HID lamps at EKT Indoor Games Hall

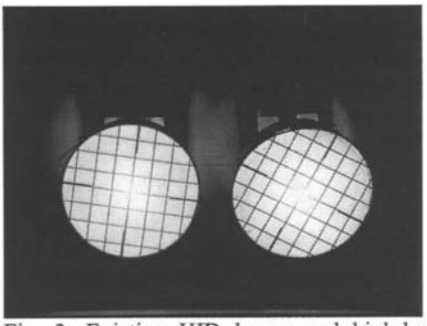

Fig. 3: Existing HID lamps and high-bay luminaries at EKT Indoor Games Hall

New High Output T5 Lighting System

The new pilot T5 fluorescent lighting system we used in EKT Indoor Games Hall consisted of 4 rows of 14 specially designed impact resistance luminaries complete with 3x49W high output T5 lamps and electronic ballasts (Fig. 4 and Fig. 5). The design illuminance was 500 lux at floor level as recommended by CIBSE Lighting Class II for indoor sports and mid-level competition such as regional or local club competition, which generally involved medium size spectators capacity with medium viewing distances. High-level training can also be included in this class.

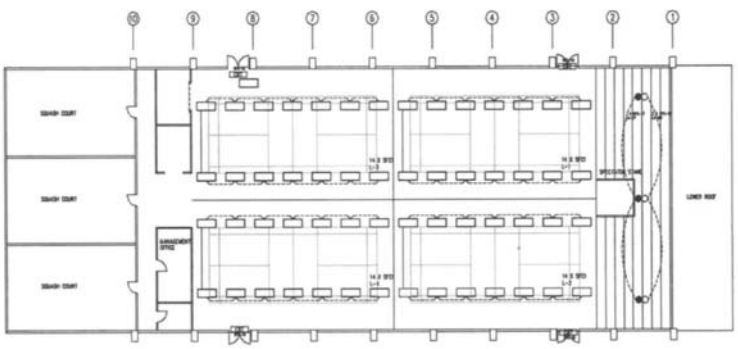

Fig. 4: Lighting layout of the new high output T5 lighting at EKT Indoor Games Hall

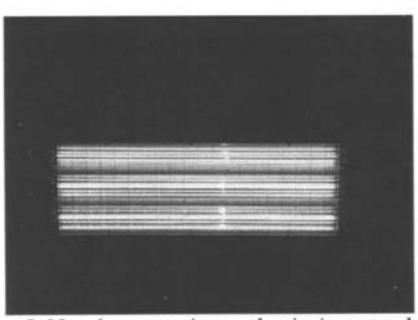

Fig. 5: New impact resistance luminaires complete with 3x49W T5 lamps and electronic ballasts at EKT Indoor Games Hall

Fig. 6: Visual environment of the new T5 lighting at EKT Indoor Games Hall

Unlike HID lamps, T5 fluorescent lamps could be switched on and off instantly without a long warming up period. Operation of the new T5 lighting system could then be arranged to suit the schedule of game hall booking and the switching circuits have also been arranged in 4 separate zones to tie in with the layout of the 4 badminton courts.

Energy Performance

Energy performance of the two lighting systems was measured on site on 23 July 2001. The measured results were summarised in Table 1. It was found that the total power reduction for the new T5 lighting system was 8.5kW (49%) and improvement in current THD was also very apparent (reduced from 23.6% to 4.7%). As the games hall is fully air conditioning, reduction in heat gain from lighting would also decrease cooling load of the AC plant. The estimate reduction in cooling load would be about 30% of the reduced lighting load (i.e. 2.5kW).

TABLE 1
ENERGY PERFORMANCE OF THE EXISTING HID AND NEW T5 LIGHTING SYSTEMS

	Existing HID Lighting System	New T5 Lighting System	% Difference
Active Power (kW)	17.2 kW	8.7 kW	- 49%
Power Factor.	0.97	0.99	+ 2%
Current THD	23.6%	4.7%	- 80%
Lighting Power Density	26.3 W/m^2	13.3 W/m^2	- 49%

Visual Performance

Illuminance in lux (i.e. lumen/m^2) of a point at a horizontal plane illuminated by a lighting system is one of the most important parameter defining the quantity of light received at the point. The horizontal illuminance at floor level was measured on 22 May 2001 with both HID and T5 lighting systems. Results of the measurements indicated that the average illuminance measured for the existing lighting system was 479 lux with a maximum of 642 lux occurred at the centre of the games hall. For the new T5 lighting system, the average measured illuminance was 760 lux and the maximum illuminance occurred at centre of the hall was 998 lux. There was an average increase of 58% in illumination when the games hall was lit by the new T5 lighting system. The uniformity found for both old and new lighting systems were 0.48 and 0.51 respectively. The minor improvement was due to the closer spacing of T5 luminaires at ceiling level.

Glare is a major concern in an indoor games hall for both players and spectators alike. The concentrated point source of HID lighting can cause problematic glare. The condition occurs whenever someone looks directly or very close to an HID lamp in the line of sight. When the eye "sees" the extremely bright light source, the pupil becomes very small. Then, when the eye looks elsewhere, it cannot focus properly for a few seconds. The situation is similar to your eye responses when a camera flash blinds your subjects during a photo shoot. The linear and diffused light source of T5 lamp does not create the same problem. Although they are quite bright, T5 lamps are not "blinding" like the HID lamps.

Glare caused by a light source is directly proportional to its brightness. Luminance in candela per square meter (cd/m^2) is a physical measure of a surface brightness caused by light emission or reflection. Luminance for both HID and T5 luminaries had been measured at various observation angles. Because of the parabolic effect, maximum luminance (1.160 x 10^5 cd/m^2) occurred at about 60° for 250W SON luminaries, which is almost 11 times brighter than the new T5 luminaire at the same

observation angle. As far as disability glare is concerned for players viewing upward in the game hall, HID luminaries would create more serious problem than T5 luminaires.

Other then the measurable parameters above for assessing the quality of the visual environments of the two lighting schemes, colour temperature and colour rendition properties could also play their parts in the appraisal. The light colour of a lamp is expressed as colour temperature in Kelvin (K). The T5 lamps used have a colour temperature of 4000°K (i.e. cool white) and could maintain the colour appearance throughout their lives. Metal halide and SON lamps have an initial colour temperature of 6000°K (daylight) and 2000°K (yellow) respectively and their colour appearance could deviate during their operation lives resulting in a non-consistent colour appearance among lamps.

Measured to a scale of 0 to 100, the colour rendering index (CRI) describes the capability of a light source to accurately render a sample of eight standard colours relative to a standard source. Light sources that exhibit higher CRIs render colour better than sources with low CRIs. The T5 fluorescent lamp used in this project has CRI above 80 and those for metal halide and SON lamps are 65 and 27 respectively. A CRI of at least 60 is recommended by CIBSE Lighting Guide 4 for multi-purpose sport halls to reveal the correct colour pitch markings.

The average rated life for HID lamp is about 20,000 hours and for T5 lamps is 16,000 hours. They lose some of their light output as they age. Expressed quantitatively, it is common for the output of HID sources to degrade by nearly 40 percent over their lifetime, whereas T5 lamps exhibit lumen depreciation as low as 5 percent. The T5 lighting scheme would therefore maintain a much more consistent lighting level throughout their lifetime than their HID counterparts. If the economic lamp life (i.e. 30% depreciation) were taken into account for bulk lamp replacement schedule, the advantage of longer lamp life for HID lamps would then be diminished.

INDIRECT EVAPORATING PRE-COOLING SYSTEM AT KOWLOON PARK

As one of the pilot projects using innovative energy efficient equipment, we have completed in September 2001, the installation of an indirect evaporative cooling (IEC) system at Kowloon Park Swimming Pool Complex. The IEC module is basically an indirect evaporating pre-cooling unit for fresh air intake to building. The otherwise waste exhaust air and waste condensate water form the building air-conditioning system are used for heat reclaim through this module.

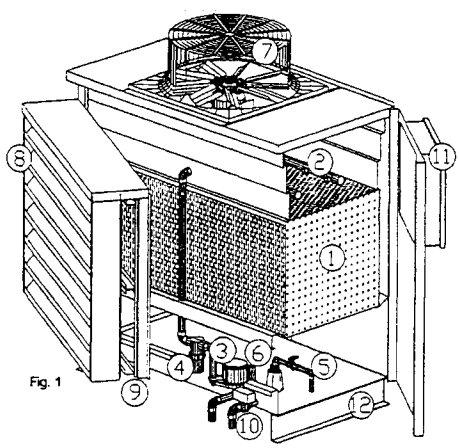

Fig. 7: Construction of the Indirect Evaporating Cooling Module

As shown in Fig. 7, the module consists of an extended surface cross-flow wet plate heat exchanger, nozzle sprays, an indirect pump, strainers, a vaporiser air fan, solenoid valves and control panel. The heat exchanger is constructed of non-corrosive polymeric materials. Exchanger plate spacing controlled by air turbulence spines is designed to enhance heat transfer, water distribution and efficiency. Primary and secondary airflows are separated by polymeric adhesive and rubber seals. Primary airflow is horizontal and vaporiser airflow is vertical in a cross-flow pattern.

System Description

The IEC module is originally designed for outdoor application using direct outdoor air and water mains as energy sources for pre-cooling fresh air. In our pilot project, the module was installed inside the Air Handling Unit (AHU) plant room in Kowloon Park Swimming Pool Complex. The existing exhaust and fresh air duct inside the plant room were modified and connected into the module for heat reclaim before leaving the building. The cool condensate water condensed from the AHUs are collected in a small tank and pumped into the IEC module via a small submersible pump for evaporating cooling. The ductwork and pipe work arrangement at the vicinity of the IEC module are shown in Fig. 8 with various temperature, humidity and flow sensors installed and connected to the computer for data logging.

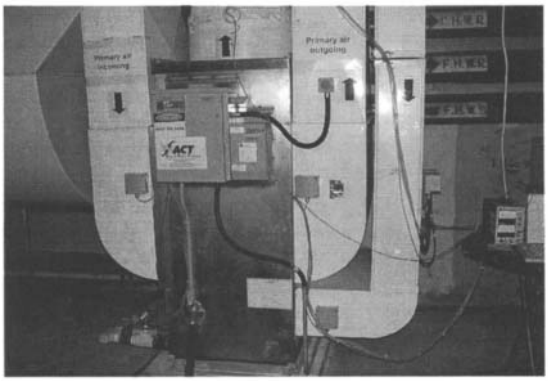

Fig. 8: Ductwork Connection to the Indirect Evaporating Cooling Module

Strategy for Testing

In order to accurately assess the energy performance of the IEC module installed in Kowloon Park Swimming Pool Complex for different climatic and weather conditions throughout the year, the following measurement instrument and testing equipment have been installed for collecting data and logged into a computer. The Department of Building Services Engineering of PolyU was appointed as consultant for the whole testing process including the installation of monitoring equipment.

1. Temperature and humidity sensors and transducers at inlet and outlet positions of the exhaust and primary/fresh air ducts.
2. Air flow sensors and transducers at intake air ducts of exhaust air and primary air.
3. Temperature sensors and transducers at inlet and outlet of the condensate water pipes.
4. Water flow sensors at flow of condensate water pipe.
5. A package of data logging system for collecting data every 10 minutes for 1 whole year starting from October 2001

The schematic line diagram of the complete testing system is shown in Fig. 9. The location of some

sensors and transducers could also be identified in Fig. 8. All instrument installed were calibrated in the laboratories of PolyU before installing on site.

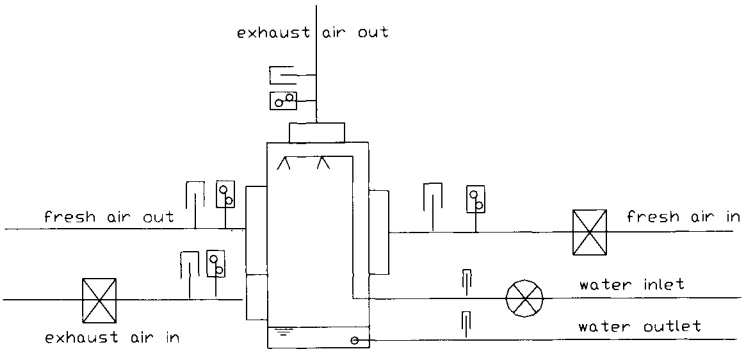

Fig. 9: Schematic Diagram of the Testing System

Preliminary Test Results

The basic mathematical model for the energy performance analysis of this IEC system is:

$$Q_p = Q_e + Q_c$$

Where Q_p, Q_e, and Q_c are the absolute values (sensible and latent heat) of the energy change for primary air, exhaust air and evaporation of the condensate water. These quantities could be calculated from the measured dry bulb temperature, relative humidity or wet bulb temperature and volume flow rate of the primary air and exhaust air before and after the heat exchanger together with evaporation of the condensate water. Test data have been collecting on site since October 2001. Data collected in November and December 2001 and January 2002 were not good enough due to very low primary air temperature. We are expecting good results in summer with a wider temperature differential of the primary and exhaust air.

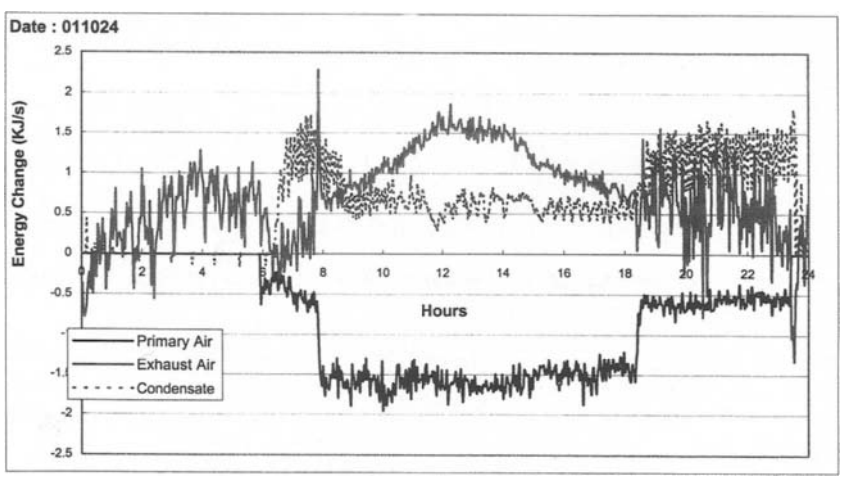

Fig. 10: Absolute Energy Changes measured on 24/10/2001

In order to demonstrate the effectiveness of the system, data collected on 24/10/2001 were used for analysis of energy transferred amount primary air, exhaust air and evaporating water. The absolute value of energy of the three items were plotted against time as shown in Fig. 10. From these data plot, the energy gain for the primary air is more or less equal to the total energy change for both exhaust air and condensate water. The measured values at 2:00 p.m. on 24/10/2001 were extracted from the data logger and highlighted in Table 2 below.

TABLE 2
EXTRACT OF DATA LOGGED AT 2:00 P.M. ON 24/10/2001

	Temp. IN	Temp. OUT	RH IN	RH OUT	Flow Rate
Primary Air	29°C	27°C	59.5%	65.5%	608 l/s
Exhaust Air	26.5°C	25°C	57.5%	71.5%	332 l/s
Condensate Water	17.5°C	20°C	--	--	4 l/min

The site measurements are still ongoing on site until end of summer in 2002. It is too early to draw any conclusion yet. The overall energy performance of the system will then be analysed for different weather conditions. Nevertheless, the use of exhaust air and condensate water, which are generally available free of charge in all air conditioned spaces, to pre-cool the outside primary air load is extremely beneficial for air conditioning systems in both existing or new buildings.

ACKNOWLEDGEMENT

The authors would like to thank Dr. T.M. Chung and Dr. H.X Yang of Department of Building Services Engineering, the Hong Kong Polytechnic University and their research students, in particular Mr. Kenneth Lo and Mr. An, for carrying out the measurements on sites.

A DYNAMIC MODEL OF COMMERCIAL GAS AND OIL BURNED BOILERS

Z. Liao and F. Parand
Building Research Establishment (BRE), Bucknalls Lane, Watford, WD25 9XX, UK

ABSTRACT

A dynamic model of commercial hot water boilers has been developed and integrated with other heating system component models to create a simulator of central heating systems. Detailed experimental data were obtained to validate the boiler model. The validation results indicate that the model can accurately simulate both transient and steady state performance of such boilers as installed in central heating systems. The model development was carried out under a European Commission project with the aim to improve the overall efficiency of water heating systems. The simulator was subsequently used to develop an innovative boiler controller that has been tested in simulation, emulation, a test building and field trials in real buildings with successful results. This paper presents the mathematical boiler model and its implementation in Simulink™. The validation of the model is also discussed.

KEYWORDS

Energy efficiency, boiler, control, model, simulation, validation, central heating systems.

INTRODUCTION

In common with many other types of building services plants, boilers in heat systems are often considerably oversized in order to provide a substantial margin of capacity [Gardner, 1984]. Therefore it is essential to operate such boilers under part load with high efficiency. Most boilers deliver hot water satisfactorily but in most cases do so under undetected inefficiency when managed by the presently installed control devices and systems [Liao and Parand, 2001]. This is because boilers in heating systems are normally controlled such that a certain temperature setpoint of the hot water supply, which may be fixed or compensated with the external temperature [Levermore, 1992], is maintained. The variation of heating load at the terminal is not considered comprehensively in most existing boiler control schemes. As a result, the overall energy performance is normally far below the level that would otherwise be obtained if the control of boilers could be optimised [Liao and Parand, 2001].

An European Union project, funded under the CRAFT programme, in which BRE and other research partners worked as the Research and Development arm of a number of industrial companies, investigated this problem and developed an innovative control technology for the optimal control of boilers in heating systems. The boilers investigated in this project are commercial gas or oil burned boilers with a normal heating capacity ranging from 20 kW to 300 kW, which are widely used in heating systems in Europe. The investigation was carried out in both simulation and field trials. A simulation platform of

central heating systems has been developed for this purpose, in which a dynamic model of gas or oil burned boilers found an important role to play. Over last 40 years a number of boiler models have been developed [Lu, 1993; Lang, 1992]. Some of these models have been integrated with some thermal simulation software packages well established. However, no model is suitable for the purpose of this project because:

- These models do not cover the type of boilers investigated.
- Rigorous validation is not exhibited therefore misleading may occur if these models or methods were directly employed in this project.

Therefore of fundamental importance to the reliability of the simulation platform is to develop a dynamic model of the targeted boilers and cross-validate the model using experimental data obtained from different sources.

METHODOLOGY

The methodology adapted for developing and validating the boiler model is briefly summarised as below:

- Survey study of gas or oil burned boilers used in heating systems in Europe. This study was carried out in three European countries, including UK, Germany and Italy. The objective is to collect technical information of the targeted boilers and to understand how they are installed and operated in the current practice. Through this study a number of typical boiler structures have been identified.
- Develop the mathematical model. The typical boilers were analysed to identify essential heat transfer processes. A simplified boiler model was developed.
- Implement the model in Simulink™ for validation and utilisation.
- Validate the model. The validation was carried out using experimental data obtained from different sources. These data sources include the operation data of real systems obtained through the survey study mentioned above, experiments carried out respectively in a test rig specially built in BRE, UK for this project and a testing facility in ICITE, Italy.

MATHEMATICAL MODEL

Figure 1 presents a simplified structure of targeted boilers.

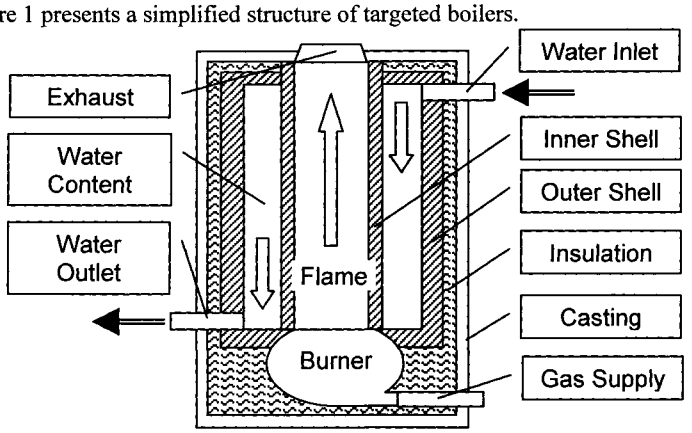

Figure 1 A simplified structure of gas or oil burned boilers

As shown in Figure 1, a gas or oil burned boiler consists of the following major components:

- A burner where fuel (gas or oil) is combusted to release heat.
- A flame tunnel along which flame loses heat energy and cools down to as low as 150°C at the exhaust.
- An inner shell that separates the flame and the water content.
- A water tunnel where water is heated.
- An outer shell.
- An insulation fabric.
- Casting shell.

The heat transfer within the boiler includes:

- Fuel is combusted in the burner to release heat that is transferred to the inner shell through both radiation and convection.
- Heat conducts through the inner shell and transfer to the water content through convection.
- Water enters the boiler at a lower temperature at the inlet and is heated while it flows through the water tunnel. Water discharges from the outlet at a higher temperature.
- Water loses heat to the outer shell that in turn transfer heat to the insulation layer. The heat lost from the insulation layer is then conducted through the casting shell and transferred into the ambient.

This can be translated to an electrical circuit as presented in Figure 2.

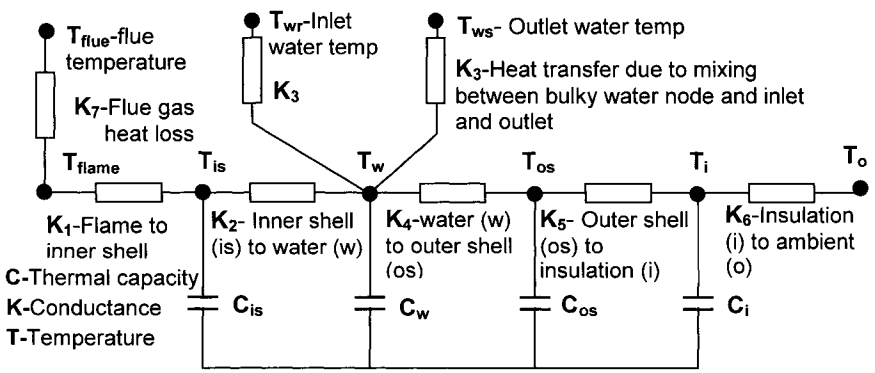

Figure 2 Electrical circuit model of a gas or oil burned boiler

The dynamics of the inner shell (T_{is}) is governed by:

$$C_{is} \cdot \frac{dT_{is}}{dt} = Q_{burner} - K_2 \cdot (T_{is} - T_w) \tag{1}$$

where:

Q_{burner} is the heat transfer from the flame to the inner shell.

Heat transfer between the flame and the inner shell is through both convection and radiation, therefore Q_{burner} can be calculated by:

$$Q_{burner} = E_c \cdot (T_{flame} - T_{is}) + E_r \cdot (T_{flame}^4 - T_{is}^4) \tag{2}$$

Alternatively, Q_{burner} can be treated as a constant determined by the normal heating capacity and efficiency of the boiler. In this paper, Q_{burner} is treated as a constant but of different values for different boiler operations. In general the cycle of boiler operation can be distinguished into three steps, as below:

- Idle: the burner is not firing and the ventilation fan is not running. During this period, the inner shell may lose heat to the air naturally ventilated through the combustion chamber and flame tunnel.
- Purge: the burner is not firing yet but the ventilation fan is running. During this period, the inner shell may lose heat to the air forcedly ventilated through the combustion channel and flame tunnel.
- Firing: the burner is firing and the ventilation fan is running. During this period, heat is transferred to the inner shell from the flame.

Therefore, Q_{burner} is given as:

$$Q_{burner} = \begin{cases} Q_{idle} & Idle \\ Q_{purge} & Purge \\ Q_{fire} & Firing \end{cases} \tag{3}$$

The dynamics of the water node (T_w) is governed by:

$$C_w \cdot \frac{dT_w}{dt} = K_2 \cdot (T_{is} - T_w) - K_4 \cdot (T_w - T_{os}) - \dot{m} \cdot (c\rho)_w \cdot (T_{ws} - T_{wr}) \tag{4}$$

The lumped water temperature (T_w) is related to the water temperature at the inlet (T_{wr}) and outlet (T_{ws}) of the boiler through the following equation [Niu, 1994]:

$$T_w = \alpha \cdot T_{wr} + (1-\alpha) \cdot T_{ws} \tag{5}$$

where α is a constant ranging from 0 to 1.0.

The dynamics of the outer shell (T_{os}) is governed by the following equation:

$$C_{os} \cdot \frac{dT_{os}}{dt} = K_4 \cdot (T_w - T_{os}) - K_5 \cdot (T_{os} - T_i) \tag{6}$$

Finally the dynamics of the insulation layer and the casting shell (T_i) is governed by:

$$C_i \cdot \frac{dT_i}{dt} = K_5 \cdot (T_{os} - T_i) - K_6 \cdot (T_i - T_o) \tag{7}$$

IMPLEMENTATION IN Simulink™

Two versions of the boiler models have been implemented in Simulink™ for investigation. In the first version, all components presented in Figure 1 and 2 are presented by a number of single lumped variables. For example, the water content is presented by a lumped water temperature (T_w) and a total thermal capacity of water content (C_w). In the second version, the boiler is equally divided into five sections and each section is treated in the same manner as how a whole boiler is treated in the first version. Therefore in this version, each component property is represented by five lumped variables. For example, the water temperature is represented by five sectional water temperature ($T_{w1}, T_{w2}, T_{w3}, T_{w4}, T_{w5}$). This is illustrated in Figure 3.

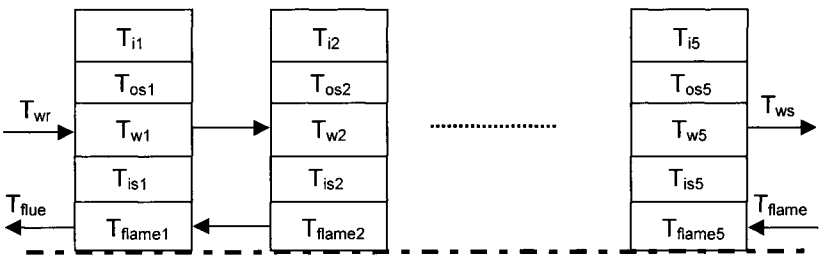

Figure 3 Sectional boiler model (5 sections)

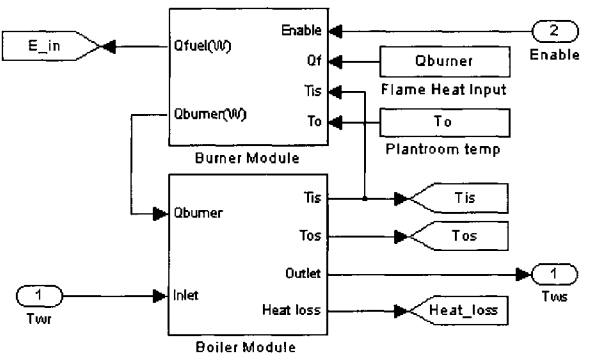

Figure 4 Simulink implementation of the boiler model

Figure 4 presents an overview of the Simulink implementation of the boiler mode. It shows that there are two essential modules, including a Burner Module and a Boiler Module. The Burner Module deals with the control of burner and calculates the heat energy transferred from the flame to the inner shell (Equation 3). The Boiler Modules accommodates the dynamic equations of the inner shell (Equation 1), water content (Equation 4), outer shell (Equation 6) and insulation layer (Equation 7). The constants presented in the model are calculated on the basis of the technical data of boilers. For each given boiler, a set of these constants are described in a data file. Different boilers can be simulated in this implementation by associating relevant boiler data file with it.

VALIDATION

The boiler model has been rigorously validated using experimental data obtained from different sources. These sources include:

- Survey study. During the survey study that was aimed to identify typical boilers used in heating systems in Europe, a number of site measurements have been made to produce the data related to the performance of selected boilers in real operation.
- Experiments carried out in a boiler test-rig in BRE, UK. This rig consists of three major parts, including two boilers with a total heating capacity of 100 kW, a hydraulic system simulating the heating load and a software simulated building.
- Long-term testing in ICITE (Italy). A commercial boiler with 40 kW of heating capacity was installed in a fully instrumented testing facility in ICITE to test the long-term performance of the boiler.

Figure 5 presents how the experimental data is used to validate the boiler model. It shows that the recorded data of the water parameters at the inlet of boiler (flow rate and temperature) and the boiler control signal are fed into the boiler model that in turn simulates the water parameters at the boiler outlet (Outlet_sim). The simulated outlet parameters are compared with the experimental data of the outlet water (Outlet_test). The comparison shows how accurate the model can simulate the dynamic performance of the boiler.

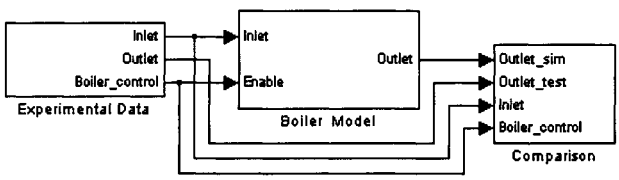

Figure 5 Validating the boiler model using experimental data

Figure 6 presents an example of validating the model using the experimental data monitored in a real installation (Building B14 in BRE) through the survey study. A good agreement can be observed between simulated and tested outlet water temperature.

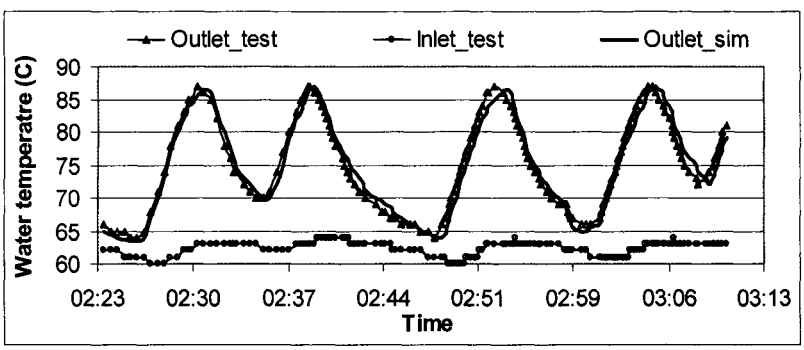

Figure 6 Validating the boiler model using experimental data monitored in a real installation

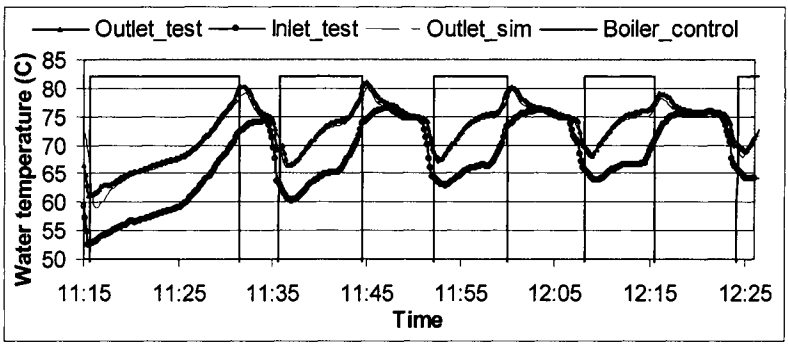

Figure 7 Validation by test-rig data (floating Inlet temperature)

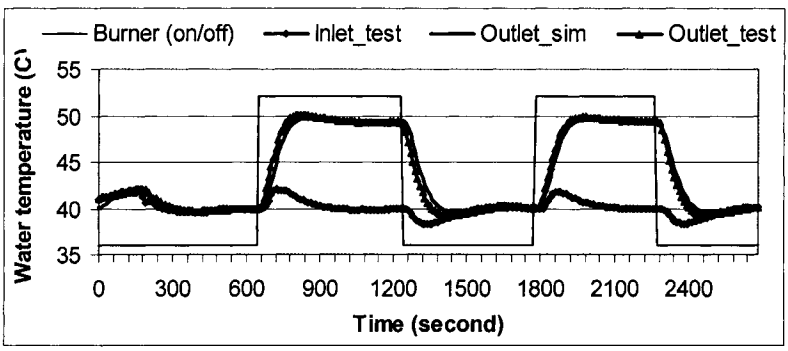

Figure 8 Validation by test-rig data (constant Inlet temperature)

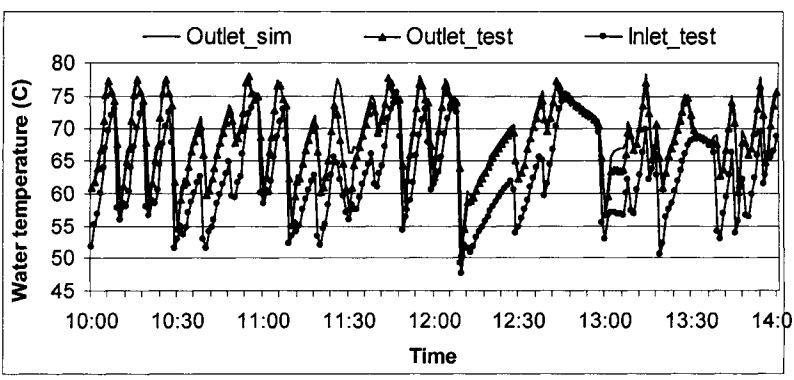

Figure 9 Validation by ICITE data (an example)

Figure 7 and 8 present the validation results using the data recorded in the test-rig experiments. Two scenarios were considered, including:

- The test rig is driven by the building simulator to mimic a real operation. In this case the Inlet water temperature varies as linked in the distribution loop (Figure 7).

- The Inlet water temperature is controlled at a constant value and the boiler is turned on and off to test the transient performance of the boilers (Figure 8).

Figure 7 and 8 indicates that the boiler model can accurately simulate the performance of the boilers installed in the test rig.

The test in ICITE lasted for two heating seasons and all recorded data was used to validate the boiler model as well as for other purposes. Figure 9 only presents a snapshot of this validation. A good agreement between the simulated and recorded outlet water temperature can be observed, consistently over the entire testing period.

CONCLUSION

A simplified model has been developed to simulate the dynamic performance of commercial gas or oil burned boilers that are commonly used in heating systems in Europe. Two versions of the model have been implemented in Simulink™. The model has been rigorously validated using experimental data obtained from different sources. The validation results show that the model can simulate the dynamic performance of the targeted boilers with high accuracy. This model had been integrated with a simulation package of central heating systems, which was used for the development of a novel boiler controller [Liao and Parand, 2001].

ACKNOWLEDGEMENTS

The work presented in this paper was financially supported by EU through Craft programme (contract number: JOE3-CT98-7010) and the participating industrial partners, including Brittech Controls (UK), ISC (Germany) and Digital Controls (Italy). The authors would like to thank Dr. John Crabb from University of Exeter, UK for his fundamental analysis of heat transfer processes in the targeted boilers, which makes the development of the model presented in this paper possible. Special thanks also go to ICITE (Italy) for carrying out the long-term testing that have provided the experimental data used to validate the model.

LOW ENERGY BUILDING MATERIALS: AN OVERVIEW

A. M. Omer

The School of Built Environment
University of Nottingham, University Park
Nottingham NG7 2RD, United Kingdom

ABSTRACT

Sustainability has acquired great importance due to the negative impact of various developments on the environment. The rapid growth during the last decade has been accompanied by active construction, which in some instances neglected the impact on the environment and human activities. The impact of developments on the traditional heritage has not been taken into consideration although the latter represents a rich resource for sustainable building practices.

KEYWORDS

Building materials, energy efficiency, sustainable development, environment impacts

INTRODUCTION

Within the last decade sustainable development and building practices have acquired great importance due to the negative impact of various development projects on the environment. In line with a sustainable development approach, it is critical for practitioners to create a healthy, sustainable built environment [1,2]. In Europe, 50% of material resources taken from nature are building-related, over 50% of national waste production comes from the building sector, and also 40% of energy consumption is building-related [3,4]. More attention should be directed towards establishing sustainable guidelines for practitioners. Furthermore, the rapid growth in population has active construction that, in some instances, neglected the impact on the environment and human activities. At the same time, the impact on the traditional heritage, an often-neglected issue of sustainability, has not been taken into consideration, despite representing a rich resource for sustainable building practices.

Sustainability has been defined as the extent to which progress and development should meet the need of the present without compromising the ability of the future generations to meet their own needs [5]. This encompasses a variety of levels and scales ranging from economic development, and agriculture, to the management of human settlements and building practices. This general definition was further development to include sustainable

building practices and management of human settlements. During the Rio Earth Summit in 1992 [6], the following issues were addressed:

- The use of local materials and indigenous building sources.
- Incentive to promote the continuation of traditional techniques, with regional resources and self-help strategies.
- Regulation of energy-efficient design principles.
- International information exchange on all aspects of construction related to the environment, among architects and contractors, particularly non-conventional resources.
- Exploration of methods to encourage and facilitate the recycling and reuse of building materials, especially those requiring intensive energy use during manufacturing, and the use of clean technologies.

This study investigates sustainable building practices. The objectives of the study aims to:

1. Develop a comprehensive definition of sustainability that includes socio-cultural, bio-climate, and technological aspects.
2. Establish guidelines for future sustainable architecture.
3. Predict the CO2 emissions in buildings.
4. The proper architectural measure for sustainability is efficient, energy use, waste control, population growth, carrying capacity, and resource efficiency.
5. Establish methods of design that conserve energy and natural resources.

A building inevitably consumes materials and energy resources, the technology is available to use methods and materials that reduce a building's environmental impacts, increase operating efficiency, and increase durability. Literature on green buildings reveals a number of principles that can be synthesised in the creation of the built environment that is sustainable. According to one source, these are: land development, building design and construction, occupant considerations, life cycle assessment, volunteer incentives and marketing programmes, facilitate reuse and remodelling, and final disposition of the structure [7]. These parameters and many more are essential for analysis, making them an important part of the design decision-making process. Today architects should prepare for this, but they have to deal with existing buildings with many unfavourable urban environmental factors: many spaces have no choice of orientation, and are often set in noisy streets, with their windows opening into dusty and polluted air and surrounding buildings overshadowing them.

BUILDING AND CO_2 EMISSION

To achieve urban dioxide (CO_2), emission targets more fundamental changes have been suggested [8]. The actual performance of buildings must also be improved to meet the emission targets, To that end, it has been suggested that the performance assessment should be introduced o ensure that the quality of construction, installation and commissioning achieve the design intent. Two key parameters, air-tightness and the commissioning of plant and controls, are the main elements of assessing CO_2 emission. Air-tightness is important as uncontrolled air leakage wastes energy. Uncertainties over infiltration rates are often the reason for excessive design margins that result in oversized and inefficient plants.

Commissioning to accepted procedures would significantly improve energy efficiency. The slow turnover in the building stock means that improved performance of new

buildings will only cut CO_2 emissions significantly in the long term. Consequently, the performance of existing buildings must be improved. For example, improving 3% of existing buildings would be more effective in cutting emissions than, say, improving the fabric standards for new non-domestic buildings and improving the efficiency of new air conditioning and ventilation systems.

BUILDINGS AND ENERGY USE

Buildings consume energy mainly for cooling, heating and lighting as shown in Table 1. The energy consumption must be based on the assumption that the building operates within ASHRAE-thermal comfort zone, during the cooling and heating periods [9]. Most of the buildings incorporate energy efficient passive cooling, solar control, photovoltaics, lighting and day lighting, and integrated energy systems. It is well known that thermal mass with night ventilation can reduce the maximum indoor temperature in buildings in summer [10]. Hence, comfort temperatures may be achieved by proper application of passive cooling systems. In addition, energy can be saved if an air conditioning unit is used [11]. The reason for this is that in summer, heavy external walls delay the heat transfer from the outside into the inside spaces. Moreover, if the building has a lot of internal mass the increase in the air temperature is slow. This is because the penetrating heat raises the air temperature as well as the temperature of the heavy thermal mass. The consequence is a slow heating of the building in summer and the maximal inside temperature is reached only during the late hours when the outside air temperature is already low. The heat flows from the heavy walls inside can be removed with good ventilation in the evening and night. The capacity to store energy also helps in winter, since energy can be stored in walls from one sunny winter day to the next cloudy one. Here defined four levels of thermal mass as follows:

1. Light building: no thermal mass, like a mobile home.
2. Medium-light building: light walls, but heavy floor, like cement tiles on concrete floor, and concrete ceiling.
3. Semi-heavy building: heavy floor, ceiling and external walls (20 cm concrete blocks) but light internal partitions (Gibsum boards).
4. Heavy building: heavy floor, ceiling, external and internal walls (10 cm concrete blocks, with plaster on the both sides).

The exact reduction in the maximum indoor temperature depends on the amount of thermal mass, the rate of night ventilation, and the temperature swing the site between day and night.

SUSTAINABLE PRACTICES

With increasing urbanisation in the world, cities are growing in number, population and complexity. At present 2% of the world's land surface is covered by cities and yet the people living in them 75% of the resources consumed by mankind. Economic and social imperatives often dictate that cities must become more concentrated, making it necessary to increase the density to accommodate the people, to reduce the cost of public services, and to achieve required social cohesiveness. Tabe 2 shows the effect of urban density on city's energy demand.

TABLE 1
ENERGY-SAVING IN BUILDINGS

Passive Comfort Measures	Active Comfort Measures	Climatic zones			
		Mediterranean	Subtropical	Tropical	Desert

* 0 = not important, 4 = important, and 7 = very important (importance is rated from 0 to 7).

TABLE 2
EFFECTS OF URBAN DENSITY ON CITY'S ENERGY DEMAND

Positive effects	Negative effects
Transport: • Promote public transport and reduce the need for, and length of, trips by private cars. Infrastructure: • Reduce street length needed to accommodate a given number of inhabitants. • Shorten the length of infrastructure facilities such as water supply and sewage lines, reducing the energy needed for pumping. Thermal performance: • Multi-storey, multiunit buildings could reduce the overall area of the building's envelope and heat loss from the buildings. • Shading among buildings could reduce solar exposure of buildings during the summer period. Natural lighting: Energy systems: District cooling and heating system, which is usually more energy efficiency, is more feasible as density is higher. Ventilation: • A desirable in flow pattern around buildings may be obtained by proper arrangement of high rise building blocks.	Transport: • Congestion in urban areas reduces fuel efficiency of vehicles. Vertical transportation: • High-rise buildings involve lifts, thus increasing the need for electricity for the vertical transportation. Ventilation: • A concentration of high-rise and large buildings may impede the urban ventilation conditions. Urban heat island: • Heat released and trapped in the urban areas may increase the need for air conditioning. • The potential for natural lighting is generally reduced in high-density areas, increasing the need for electric lighting and the load on air conditioning to remove the heat resulting from the electric lighting. Use of solar energy: • Roof and exposed areas for collection of solar energy are limited.

Buildings are significant users of energy and materials in a society and energy conservation in buildings plays an important role in urban environmental sustainability. A challenging task of architects and other building professionals today is to design and

promote low energy buildings in a cost effective and environmentally responsive way. Passive and low energy architecture has been proposed and investigated in different locations of the world [12,13]; design guides and handbooks were produced for promoting energy efficient buildings [14-17]. However, at present, little information is available for studying low energy building design in density populated areas. Designing low energy buildings in high-density areas requires special cure to the planning of urban structure, co-ordination of energy systems, integration of architectural elements, and utilisation of space. At the same time, the study of low energy buildings will lead to a better understanding of the environmental conditions and improved design practices. This may help people study and improve the quantity of built environment and living conditions.

MAJOR CONSIDERATIONS FOR LOW ENERGY BUILDINGS

1. Efficiency Use of Energy

- Climate responsiveness of buildings.
- Good urban planning and architectural design.
- Good house keeping and design practices.
- Passive design and natural ventilation.
- Use landscape as a means of thermal control.
- Energy efficiency lighting.
- Energy efficiency air conditioning.
- Energy efficiency household and office appliances.
- Heat pumps and energy recovery equipment.
- Combined cooling systems.
- Fuel cells development.

2. Utilise Renewable Energy

- Photovoltaics.
- Wind energy.
- Small hydros.
- Waste-to-energy.
- Landfill gas.
- Biomass energy.
- Biofuels.

3. Reduce Transport Energy

- Reduce the need to travel.
- Reduce the level of car reliance.
- Promote walking and cycling.
- Use efficient public mass transit.
- Alternative sources of energy and fuels.

4. Increase Awareness

- Promote awareness and education.
- Encourage good practices and environmentally sound technologies.
- Overcome institutional and economic barriers.

- Stimulate energy efficiency and renewable energy markets.

CONCLUSION

Many towns around the world are facing the problem of increasing urban density and energy demand. As towns represent a significant source of growth in global energy demand, their energy use, associated environmental impacts, and demand for transport services create great pressure to our planet. Low energy design of urban environment and buildings in densely populated areas requires consideration of a wide range of factors, including urban setting, transport planning, energy system design, and architectural and engineering details. It is found that densification of towns could have both positive and negative effects on the total energy demand. With suitable urban and building design details, population should and could be accommodated with minimum worsening of the environmental quality.

BUILDING HVAC SYSTEMS ECONOMIC PERFORMANCE EVALUATION USING NEURAL NETWORK METHOD AT BEGINNING OF DESIGN

Fulin Wang[1], Yi Jiang[2] and Harunori Yoshida[1]

[1]Department of Global Environment Engineering, Kyoto University,
Yoshida Honmachi, Sakyo-ku, Kyoto 606-8501, Japan

ABSTRACT

Two aspects need to be done to assess the performance of building Heating Ventilation and Air Conditioning (HVAC) systems. One is to evaluate the extent to which an HVAC scheme satisfies the air conditioning requirement. The other is to evaluate the economic characteristics of several HVAC schemes, all of which can satisfy the air conditioning demand. It is difficult to evaluate the economic performance of HVAC systems because economic evaluation involves some factors that frequently change and often unknown such as equipment price, especially at the beginning of the design stage. Furthermore, there is a conflict between the situation of knowing few information of HVAC system and the demand of detailed information to evaluate economic characteristics at design beginning stage. Neural network method can solve these problems for its self-adaptive ability and convenient multi-variable input-output function. ADLINE neural network model is analyzed and used to evaluate the economic characteristics of HVAC systems. The compare between the value predicted by ADLINE and the value calculated in detail shows that the relative error is less than 6% and the economic performance evaluation using ADLINE neural network model can satisfy the demand of actual HVAC project design.

KEYWORDS

Building HVAC Systems, Economic Performance, Evaluation, Prediction, Neural Network Method, ADLINE

INTRODUCTION

In order to assess the performance of building Heating Ventilation and Air Conditioning (HVAC) systems, actually two aspects need to be done, one of which is to evaluate the extent to which an HVAC scheme satisfies the air conditioning requirement and the other of which is to evaluate the economic characteristics of several HVAC schemes that can satisfy the air conditioning demand.

Many scholars have studied much about the assessment of the extent to which an HVAC scheme satisfies the air conditioning requirement. But there are few researches about evaluating the economic characteristics of the HVAC systems, especially combining the economic evaluation into design stages. It is difficult to evaluate the economic performance of HVAC systems because economic evaluation involves some factors that frequently change and often unknown such as equipment price, especially in the design beginning stage. However, at design beginning stage it is important to know the economic performance of several feasible schemes. Because some big decision, such as scheme of heating and cooling source, need to be decided before design. Only after determining the design content could the design be in progress. Reasonable economic evaluation can help the managers of a building and designers make good decision and prevent to repeat and waste work.

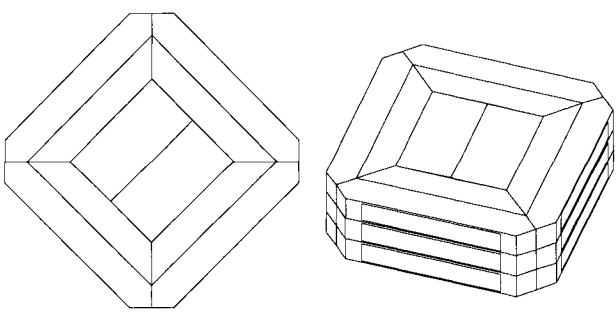
Design beginning stage is the beginning of the HVAC systems design. At this stage, the known information is about the building, such as building area, building use, building envelope parameter and so on. Besides these parameters, the HVAC scheme and refrigeration scheme can also influence the economic characteristic. But to calculate the economic parameters in detail, such as initial investment and operation cost, the information above is far from adequacy. In order to calculate the economic parameters in detail, at least the size and amount of the HVAC equipments and materials need to be known. However at the the beginning of the design stage this information is impossible to be obtained. So there is a conflict between the situation of knowing few information of HVAC system and the demand of detailed information to evaluate economic characteristics at the beginning of the design stage.

For the purpose of solving this conflict, some economic prediction method is needed other than detailed calculation. The prediction method should be able to process multi-variable problem because at the beginning of the design stage there are many variables that might influence the economic characteristic, such as building area, building use, building envelope parameters, the HVAC scheme and refrigeration scheme. Neural network method can solve this kind of problems for its self-adaptive ability and convenient multi-variable input-output function.

Neural network is 'a network of interacting simple units together with a rule to adjust the strength of the connections between these units in response to externally supplied data', Lisboa (1992). There are two phases to use a neural network:

(a) Training phase, which is to determine the weight of the connection between two neurons by inputting the parameters of training samples and comparing the output given by the neural network and the samples' output and adjusting the weight according to a certain study algorithm.
(b) Recall phase, which is to use the trained neural network to predict the value of an unknown object corresponding to its input parameters.

This paper will discuss how to apply neural network method to predict the economic parameters of a



building's HVAC systems at the beginning of the design stage.

NEURAL NETWORK TRAINING

The first step of using a neural network is to train it. For the sake of training a neural network, training samples need to be determined. The training samples are a series of data vectors, every of which is consisted of input vector and output vector. For the aspect of economic characteristics of a building 's HVAC systems, the input vector contains the parameters that can influence the economic characteristics, such as building area, building use, building envelope parameter, and the output vector is the economic parameters, i.e. initial investment and operation cost of the HVAC systems. Because there are too many variables that might influence the economic characteristics, sensitivity analysis needs to be implemented to determine the important variables and eliminate the variables that influence the economic characteristics very slightly.

Sensitivity Analysis

This article analyzed a building as shown in Figure 1 and studied the economic sensitivity to the change of building area, building use, building envelopment, rate of window to wall, shape factor (rate of length to width), opening hours, outside air supply scheme, cooling and heating source scheme, HVAC scheme. The initial investment and operation cost of the sample building at 25 kinds of different situation w ere calculated by changing the parameters mentioned above.

Plan Perspective

Figure 1: Sample building for sensitivity analysis

Building use is divided into three types according to the indoor heat generation: 1) hotel (including residential buildings), 2) office building (including library and hospital buildings), 3) shopping center (including restaurant, dancing hall, exhibition hall and gymnasium). Two kinds of window are analyzed, 1) single layer aluminum alloy window, 2) double layer aluminum alloy window. Two kinds of outside air supply scheme are analyzed, 1) constant outside air rate which is 0.1, 2) variable outside air rate which is from 0.1 to 1. Three kinds of regular HVAC scheme were analyzed: 1) FCU, 2) CAV, 3) VAV. Five kinds of regular cooling and heating source scheme were analyzed: 1) Compression refrigerator driven by electric power and water boiler burning gas, 2) Compression refrigerator driven by electric power and water boiler using electric power, 3) LiBr absorber driven by vapor and boiler burning gas, 4)

LiBr absorber burning gas, 5) Air source heating pump.

Sensitivity analysis of initial investment

The sensitivity analysis showed that building area has prevailing influence to HVAC initial investment. Rate of window to wall and length to width cause the same scale of influence to HVAC investment. The change of building use can change HVAC initial investment 40%. Different window type can make HVAC initial investment change 8% and the influence of window type can be ignored. HVAC scheme can change the initial investment 50%. Cooling and heating source can change the initial investment 30%.

Figure 2 shows the change of the HVAC initial investment caused by the changing of the factors mentioned above except building area which is prevailing, compared with the building in standard condition. The standard condition is a office building, whose rate of window to wall is 0.7, rate of length to width is 1, single layer aluminum alloy windows are used, HVAC sch eme is FCU, cooling and heating source is scheme (1).

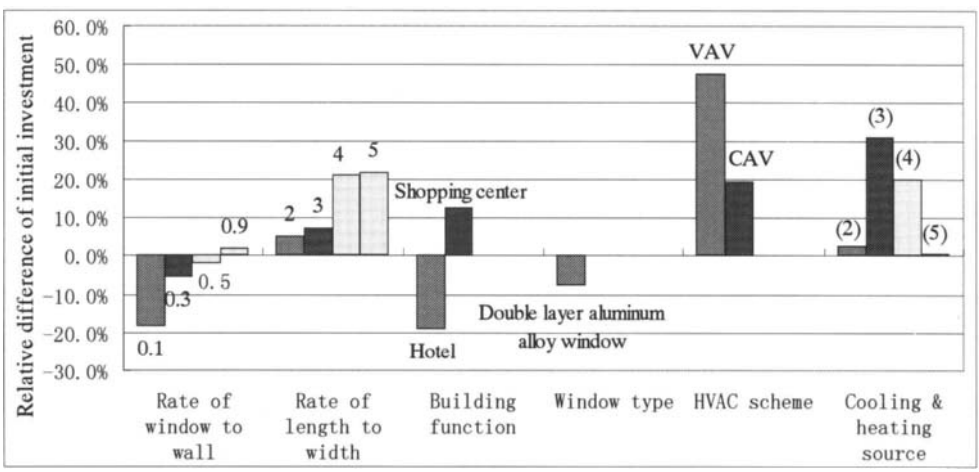


Figure 2: Change of initial investment caused by different factors

From the analysis above we can determine that the sensitive factors of initial investment are building area, building use, rate of window to wall, rate of length to width, HVAC scheme, cooling and heating source scheme. The change of window type cause little influences to the initial investment and can be ignored.

Sensitivity analysis of operation cost

Sensitivity analysis shows that the change of building area and opening hours overwhelmingly influence the operation cost of HVAC systems. The rate of window to wall and length to width can change the operation cost about 20%. Building use can change the operation cost 2~3 times. Window type can change the operation cost 6%. The operation cost of constant outside air rate system is 30% higher than that of variable outside air rate. HVAC scheme can change the operation cost change 50%~100%.

Cooling and heating source scheme can change the operation cost 20%.

Figure 3 shows the HVAC systems operation cost change caused by changing the factors mentioned above except building area and opening hours which are prevailing, compared with the building in standard condition.

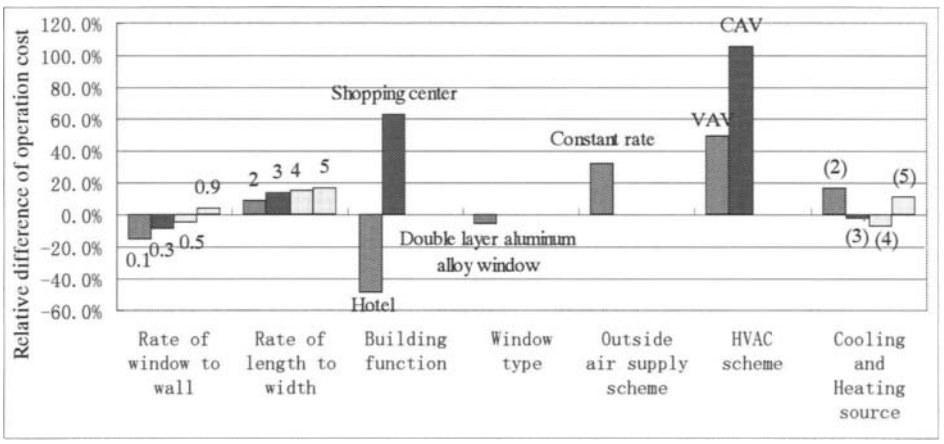

Figure 3: Change of operation cost caused by different factors

According the analysis above we can determine the sensitive factors of HVAC systems operation cost are building area, opening hours, building use, rate of window to wall, rate of length to width, HVAC scheme, cooling and heating source scheme. The change of window type has little influence to the operation cost and can be ignored.

Selection of Neural Network Model

There are near 60 different types of neural network depending on the structure and the algorithm u sed to define them, (Cai, 1998). Among these neural network models, Adaptive Linear Element (ADLINE) is proper to predict economic characteristics. One reason is that E. Shoneburg had successfully used ADLINE to predict the changing of several stocks (Hu, 1993). Another reason is that the initial investment and operation cost of HVAC systems have obviously linear relationship with the building area, which has the overwhelm influence to the economic characteristics according to the sensitivity analysis. The difference between ADLINE and linear regression method is that ADLINE uses iterative method to calculate the weight of every variable, which is convenient for calculating using computer. Furthermore, it is convenient to adjust weights when new samples are added to the sample set.

Figure 4 shows the structure of the ADLINE model. $(x_0, x_{1k}, x_{2k}, \cdots, x_{nk})^T$ is input vector. $(w_0, w_1, w_2, \cdots, w_n)^T$ is weight vector. The continuous output is

$$Y_k = X_k^T W = W^T X_k \tag{1}$$

During training phase, the Least Mean Square (LMS) algorithm is used to adjust the weight to adapt the

neural network to the characteristics of training samples. The error between neural network predicted value and expected value at time t is

$$E_k(t) = \frac{1}{2}[d_k - y_k(t)]^2 = \frac{1}{2}\varepsilon_k(t)^2 \tag{2}$$

The weight vector at time t+1 is

$$W(t+1) = W(t) - \eta \frac{\partial E_k(t)}{\partial W(t)} \tag{3}$$

Let $\eta = \dfrac{\alpha}{\|X_k\|_2^2}$, then

$$W(t+1) = W(t) + \frac{\alpha}{\|X_k\|_2^2}\varepsilon_k(t)X_k = W(t) + \frac{\alpha}{\sum_{i=0}^{n}|x_{ik}|^2}\varepsilon_k(t)X_k \tag{4}$$

Where,

W (t+1) — Weight vector at time t+1,

W (t) — Weight vector at time t,

α — Learning speed, when 0< α <2, the iterative computation is convergent, (Cai, 1998).

X_k — Input vector,

ε_k — Error between neural network predicted value and expected value, $\varepsilon_k = d_k - y_k = d_k - X_k^T W_k$

When the total error of all training samples is less than the preset least error, the training processing is finished.

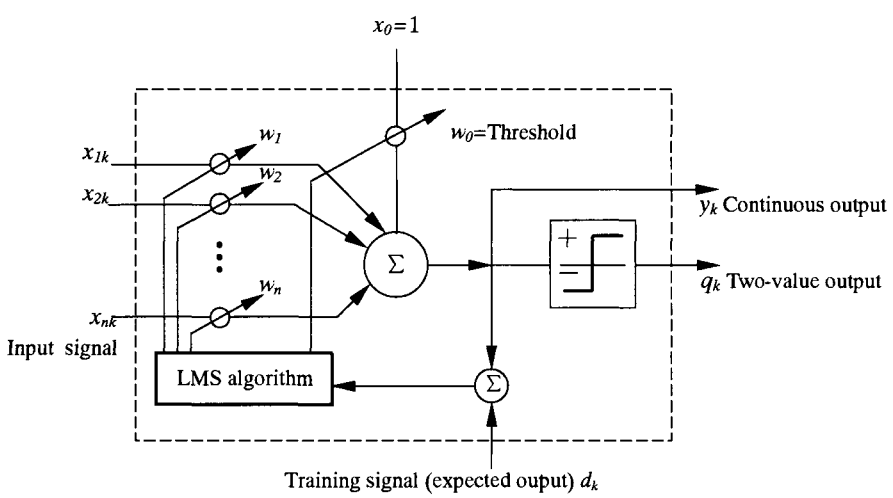

Figure 4: Structure of ADLINE

Because ADALINE is a linear model, the influence of inconsecutive variables, such as building use, HVAC scheme, cooling and heating source scheme, can only be reflected through using amending coefficient which is determined according to the sensitivity analysis. The consecutive variables are the input parameters of the neural network. Because the operation cost is in direct ratio to the opening hours, operation cost can be calculated through multiplying the predicted operation cost per hour and opening hours.

The training samples are 21 selected buildings. Firstly the initial investment and operation cost of these samples are calculated in detail. DeST (Chen, 1999), a simulation software developed by Tsinghua University is used to simulate the whole year performance of a HVAC design. Through simulation we can obtain the size and quantity of HVAC equipment and materials and the hourly operation parameters. So the initial investment and operation cost can be calculated according to the simulation results. Then economic parameters of these samples are used to train a neural network. Figure 5 shows the changing of relative error accompanying the iterative times.

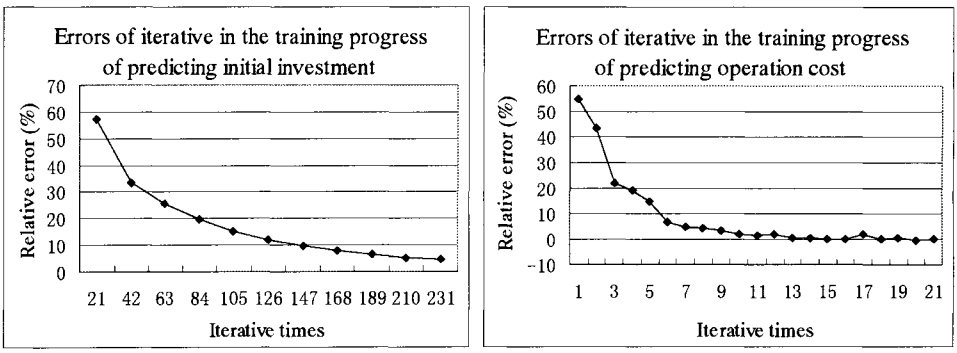

Figure 5: Relative error change along with iterative

NEURAL NETWORK PREDICTION

After the neural network training is finished, the characteristics of the samples are stored in the neural network. When we input the parameters of the building to be predicted, the neural network will output the HVAC systems' initial investment and operation cost as the prediction result according to the characteristics stored in it. Figure 6 shows the difference between the detailed calculation value and neural network prediction value of initial investment and operation cost of 5 real buildings, which are not the training sample buildings.

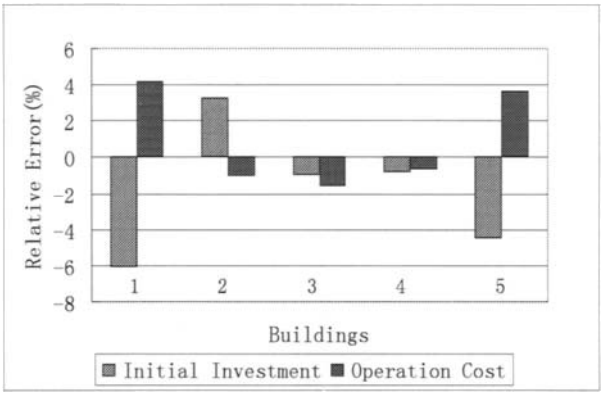

Figure 6: The difference between neural network prediction and detailed calculation value

DISCUSSION

The biggest predominance of prediction using neural network is the self-adaptive function, which make it can adapt to the change of some factor such as price.

Because the training of neural network is to adjust the weight between the nodes according to the input samples, the trained neural network reflects the mean character of the samples. If the deference among the samples is too big, the training process cannot converge to relatively high accuracy. Then more detailed input variables are needed to obtain high accuracy of training.

CONCLUSION

For the purpose of make good decision of HVAC scheme, it is important to evaluate the economic performance of several feasible HVAC schemes at the beginning of the design of a building's HVAC systems. Neural network method is suitable to predict the economic parameters at the beginning of the design stage for the lack of detailed information of HVAC equipments and materials. The analysis of this paper shows that the ADLINE neural network method can successfully predict the economic characteristics of HVAC systems at the the beginning of the design stage.

ABSTRACT

Phase Change Materials (PCMs) found considerable application in the 1980s and early 1990s in large air conditioning schemes. PCMs were primarily used to introduce capacitance within the system to enable it to take account of fluctuations in the daily cooling load. The main benefits of this are lower capital expenditure through smaller chiller size and lower revenue costs through greater use of off peak electricity. This paper reviews recent research into phase change materials applied to refrigeration and air conditioning (RAC). The specific research areas it addresses are methods for improving heat transfer within the PCM, optimum control techniques and novel methods of integration.

KEY WORDS: PCM, Cooling storage, Heat Transfer, Refrigeration, Air Conditioning, TES

INTRODUCTION

Thermal energy storage (TES) systems have played an important role in energy management, and have been used extensively in RAC systems. Water was commonly employed as a sensible energy storage material. In the early 1970s, they were used to produce capacitance within the cooling systems by minimizing the fluctuations in daily cooling load. TES systems are now developed as a demand side management (DSM) tool for electric load management and for supply side management (SSM) allowing efficient and economical power production. In buildings, DSM utilises smaller capacity cooling equipment resulting in smaller capital costs of plant and lower running costs through the greater use of off peak electricity. SSM allowed the existing national grid to be more efficient and effective, reducing the requirement for new capital intensive power stations. More efficient use of power stations also resulted in environmental benefits through reduced greenhouse gas emissions.

In the UK, buildings consume approximately 40% of the total energy used (Beggs, 1997), and a significant reduction of emissions from the building sector is a key Government priority in the fight against global warming (Kulkarni 1994). The incorporation of TES in building systems has been reported to directly result in 10-20% reductions of carbon dioxide emissions (Beggs, 1995, 1997). TES has also been integrated into renewable energy schemes allowing better use of intermittent natural energy sources and reducing the requirement for fossil fuel generated electricity and heat.

Phase Change Materials PCMs, which are an alternative to sensible storage, subsequently found considerable application in the last two decades in large air conditioning schemes. The main advantage of latent storage over sensible storage mechanisms is their ability to store large quantities of energy in

small volumes and to produce a constant source temperature. However, the literature suggests that PCMs, like sensible storage systems are not problem free. Common drawbacks of these storage designs are the low heat transfer rate within the phase change material partly due to the effect of super cooling. Despite these limitations, phase change materials have found application in a number of new building services technologies. This paper reviews the state of the art of PCM systems including difficulties in applying PCM in refrigeration and air conditioning, and the novel methods of application.

THE MAIN PROBLEMS AND RESEARCH FOR BETTER PCM APPLICATION

The main difficulties associated with the application of PCMs in RAC system reported in the literature are low heat transfer rate, the effect of super cooling and poor system design/ control. These difficulties and research to overcome them is discussed in the paper.

Other problems that have been cited are less generic and are not reported here in detail. These include the effect of incongruence on one type of PCM, salt hydrates, which result in a short life for the PCM (see EPSLtd design guide). Also problems of corrosion of heat exchanger surfaces with some PCM types is not reviewed but discussed elsewhere (ASHRAE 1997).

Low Heat Transfer Rate and Improvements

The low heat transfer rate within PCMs occurs for a number of reasons. Firstly as the solid/liquid boundary moves away from the heat transfer surface, the thermal resistance increases. Secondly, in the solid region, this is further increased by heat transfer being solely by conduction and this is low due to the low thermal conductivity of PCMs. Heat transfer enhancement techniques, include the following:

Larger heat exchanger surface

As a PCM heat exchanger, the main heat transfer resistance is on PCM side, the use of extended surfaces on this side can effectively reduce the thermal resistance. For the shell-and-tube type, a number of researchers reported their results. Lacroix (1993) implemented the investigation of the PCM around a finned tube in both radial and axial directions by numerical and experimental methods, the results showed that annular fins are most effective for moderate mass flow rate and small inlet temperatures of the heat transfer fluid. Choi et al. (1996) found that the enhancement of heat transfer by thin finned-tube over the unfinned-tube is negligible, the heat transfer coefficient in the thick finned-tube system is approximately two times higher than that in the unfinned-tube system. Sadasuke (1991) investigated the performance of a finned flat wall in contact with Paraffin wax under solidification, a mathematical model showed good agreement with the test results. The numerically study on fins can also be found in Velraj (1997) and Costa et al. (1998) work.

Thermal conductivity enhancement

A) *By using metal matrix* Hoogendoorn and Bart (1992) have reported that the low value of the thermal conductivity of the PCMs could be greatly improved by embedding a metal matrix structure in them. Tong et al (1996) numerically investigated increasing the heat transfer rate during ice melting and freezing by inserting a metal matrix into water. They concluded that inserting an aluminium matrix into a low thermal conductivity PCMs could achieve an exponential increase in the inner wall heat flux and similar decrease in the total melting and freezing time. The parameter dominating heat transfer enhancement is the metal matrix volume fraction, while geometric sizes play minor roles.

B) *By using heat pipes* The heat pipe is a passive heat transfer device with a thermal conductivity equivalent to approximately 500 times that of copper (Reay 1995). Heat pipes can help the PCM charging and discharging with in short time, and make the storage system controllable, which helps to

improve the system efficiency. In 1987 a new air-conditioning system using a heat pipe ice storage system was installed in Yokohama in Japan, the new system achieved a COP equivalent to a water chiller system (CADDET). In 1994, a heat-pipe ice thermal storage system for air conditioning was installed by another Japanese company, which showed a coefficient of performance for cooling of 2.79 for ice storage and 3.08 for space cooling. These COPs are equivalent to water storage systems (Kawamaki, 1996). A mathematical model based on a heat pipe latent heat storage system was developed by Horbaniue et al.(1996,1999).

C) *By using high conductivity materials combined with PCMs* Seigel (1977) studied the improvement in solidification rate in molten salt dispersed with high conductivity particles. For a reasonable fraction (20% by volume) of these particles in PCM, moderate improvement (17%) in heat transfer rate is achieved. Chow and Zhong (1996) proposed two thermal-conductivity enhancement techniques, the first technique focused on placing encapsulated PCMs of various shapes in a liquid metal medium. The second technique involves a metal/phase-change material composite. Specifically, 5%Ni was added uniformly to the PCM (LiH), the later method gave a better enhancement in thermal conductivity. Compared to the pure PCM, the melting time was halved. Velray et al. (1999) reported three methods of improving the thermal conductivity in PCM, of which both the numerical solution and test results showed that using lessing rings can enhance the thermal conductivity by several times but it also reduces the PCMs storage capacity.

Using PCMs with different melting temperature- Big temperature difference

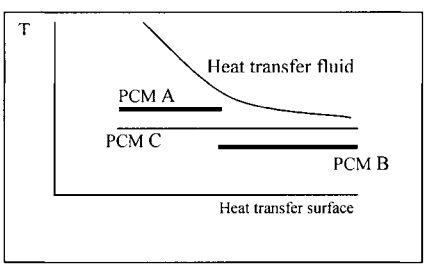

Figure 1 The temperature distribution along heat transfer surface with different PCM

The mechanism to enhance heat transfer rate by using different melting PCM can be explained by figure 1. Using PCMs A and B instead of PCM C, there is a great improvement in temperature difference along the whole heat transfer surface, and then a better heat transfer rate achieved. Farid was the first to use this method of enhancing heat transfer in thermal storage capsules containing paraffin waxes (Farid et al 1990)

Farid (1994) tested his theory on a system employing direct contact latent heat storage method, and chose $Na_2S_2O_3 \bullet 5H_2O$ and $Na_2CO_3 \bullet 10H_2O$ as PCMs, which have different phase change temperatures. Heat transfer fluid flowed from the first $Na_2S_2O_3 \bullet 5H_2O$ solution to the second $Na_2CO_3 \bullet 10H_2O$ during heat charging process. The use of two columns connected in series for heat storage gave higher rates of heat transfer during heat charge and discharge, when compared to a single column. Gong et al. (1996, 1997) through numerical investigation, found that the heat transfer rate could be increased by 30%-35% using five PCMs than using a single PCM. Domanski and Fellah (1996) found that by using two PCMs in the same storage tank could improve the second-law efficiency of the system significantly (31.4% for two PCMs system compared to 22.4% for a single PCM system). Wang et al (1999) also found that the phase change time of composite PCMs with the optimum linear phase change temperature distributions used in thermal storage systems can be decreased by as much as 25-40% by selecting the segmented numbers of composite PCMs as compared with that of single PCMs.

Direct contact

Etherington was thought (Farid et al 1994) the first to introduce the idea of using direct contact heat transfer between an immiscible heat transfer fluid and solution of hydrated salt. Light mineral oil as a heat transfer fluid was bubbled through a solution of sodium phosphate dodecahydrate. Heat was exchanged between the bubbles and the solution efficiently without the requirement of expensive

metallic heat transfer surface. Subbaiyer et al. (1990) showed a simulated result of a refrigeration unit with a direct contact evaporator. The unit consumed only 50-60% of electrical energy compared with a cooling coil ice generator. Kiatsiriroat et al.(1998) developed a direct contact evaporator system, which uses an injection of R12 refrigerant into the water tank to exchange heat with water directly, cooled the water to freezing point and ice was formed, the ice was used for producing chilled water for air conditioning, the coefficient of performance was about 3.4-3.6 which is higher than that of conventional system. Kiatsiriroat et al (2000) also investigated a sodium thiosulphate pentahydrate storage exchanging heat directly with heat transfer oil during discharging process; high heat transfer was obtained with direct contact heat exchange method.

Royon et al. (1997) first presented a new material, formed from two solutions, the first was a solution of acrylamid and bisacrylamid and the other was a starting-solution (potassium persulphate), the mixture is maintained at 313K, and the polymerization is complete after about 12 hours. The material has two contradictory constraints: maximum water for high thermal capacity and maximum polymer for better rigidity, which can contact directly with heat transfer materials, and does not need any envelope. It also can include other PCMs in a tridimensional network of polymer by using the polymerising process. They found that the new material appears to be very promising for practical applications involving the recovery of low level thermal energy.

Electrohydrodynamics (EHD)

Crystallization which occurs during phase change processes, consists of two separate processes, namely, nucleation and crystal growth. Based on diffusion-reaction theories, the rate of crystallization from a liquid depends on the rate of heat transfer from the crystal surface to the bulk of the liquid, and the growth rate of crystallization then depends on the rate of mass transfer. When an electric field is present in a dielectric crystal-melt system, the bulk liquid is be polarised. The force acting on the dipole by electric field will have a strong effect on the stagnant or effective film in the bulk melt. This will result in instability in the film and reduce the thickness so that the film coefficient is increased; as a result, the rate of crystallisation from the liquid is significantly increased. Yan et al (1997) found that the time for appearance of crystals reduced by 50% at 15KV than that at zero fields, and more stable crystals appear earlier under the action of an electric field. It means that heat and mass transferred from the crystal surface to the bulk mixture is enhanced than without an electric field

Super Cooling and Improvements

A further factor that results in lower system efficiency is the phenomenon of super cooling. This is the presence of liquid below freezing point. System efficiency is reduced with super cooling since it causes the effective temperature difference between the phase change material and the heat transfer temperature to be reduced, and prolongs the charging and discharging time.

The addition of nucleating agents to the PCM (for example ice), iron ore, iron chips and silver iodide can effectively improve the probability of nucleation (Chen et al 1998). Different materials have different nucleating agents. Saito et al. (1990) thought Vonnegutwas was the first to report the use of AgI and PbI_2 as the nucleating agents for super cooled water droplets in the atmosphere, and found that these agents greatly improved the super cooling phenomenon of small water droplets. They later found that in ice storage systems, the surface roughness affected the degree of super cooling (for ice formation). The super cooling state can be minimised by applying a certain roughness on the surface such as the electrolytically polished surface or the porous surface.

Super cooling does not occur with organic compounds, such as paraffin wax which presents no super cooling. However, they have a disadvantage of low thermal conductivity.

System Design and Control

Due to the complexity of the phase change process, few software are available which can precisely predict the behavior of PCM systems. Hence, contemporary designers faced great difficulty in the design and control of systems. This led to oversized or undersized PCM storage systems of which the former were uneconomical and inefficient due to long charging and discharging times, hence were hard to control. This also reflected on the smaller sized PCM storage systems, which did not offset the output load.

Knebel (1995) believes that with total shifting type PCM schemes storing the optimum quantity of energy at night to satisfy the following days demand is very important in terms of operating efficiency. As the building load varies depending on the time of year occupancy pattern etc, however, accurate predication of demand is complex. Keeney (1994) used an intelligent control system based upon weather forecast and utility tariffs to optimise operational performance of a PCM cooling scheme. Rupanagunta et al. (1995) developed a 24-hour load-forecast model to achieve dynamic system response to the variations in the ambient weather conditions. They designed an optimal controller for the storage system's operating cycle to minimise the running costs of the storage facility. The saving of the control storage system under optimal control was 4.3% over an alternative ice-priority control strategy when perfect foresight is assumed.

NOVEL APPLICATION OF PCM IN AIR CONDITIONING AND REFRIGERATION

The review of the literature has made it apparent that the problems with PCM applications, in particular the low effectiveness needs to be resolved. To improve the energy saving potential of PCMs, recent research has reported novel methods of applying phase change materials in cooling systems. These techniques consist of evaporative cooling, night radiation cooling and direct integration of PCM heat exchanger, which are discussed below.

Evaporative Combined PCM in HRAC System

Asrael et al (2000) reported a scheme where thermal storage was incorporated into the cooling tower circuit as shown in figure 2, this enabled the system to charge the thermal store at night when there are lower wet bulb temperatures. The stored cold energy is released into the heat rejection circuit during the day, which produces lower condensing temperatures and higher efficiency. According to Asrael this method can reduce both peak energy and power use by as much as 35%.

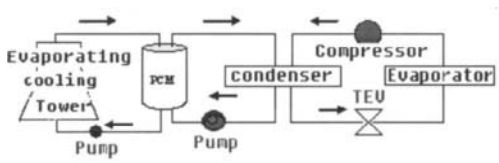

Figure 2: Night evaporative cool with PCM system

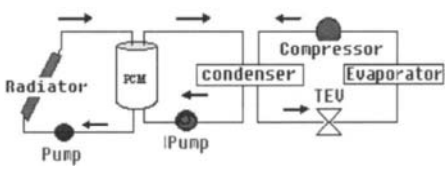

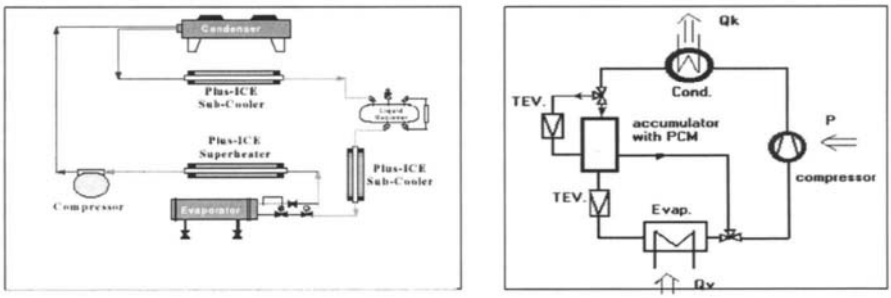

Figure 3: Night sky radiation cool with PCM system

Night-sky Radiant Cooling Combined PCM in HRAC System

A number of papers reported schemes which use night sky radiant cooling within the heat rejection water circuit as shown in Fig 3. The lower effective temperature of the night sky is used as a heat sink with long wave radiation taking place between the condenser water and the night sky. With the use of thermal storage cold energy can be released during daytime hours to improve energy efficiency. CADDET reported a case in USA on night sky radiant cooling system combined the PCM storage

system, the net annual cooling energy savings are over 50%.

(a) (b)

Figure 4 PCM integrated directly into refrigeration system

PCM Integrated Directly in Refrigeration System

Ure (1997) reported (Fig4 (a)) refrigeration system incorporating phase change material heat exchangers in contact with the suction and liquid lines. The purpose of the liquid line PCM exchanger is to enable the refrigeration system to benefit from lower night-time ambient conditions. At night lower temperatures generate lower condenser pressures as well as increased liquid sub-cooling. The use of a PCM in the liquid line provides an artificial load on the condenser, which often avoids the necessity for inefficient condenser control, as well as allowing the night-time cold energy to be stored for release during daytime operation. Ure does not qualify the benefit of this technology when applied to a real system, but states that a 15K increase in sub-cooling levels leads to a 10% improvement in peak plant efficiency. The purpose of the suction line PCM exchanger is to limit the superheat in the suction line by providing thermal capacitance. Again Ure gives a peak efficiency improvement of 15% for a 5K reduction in superheat, but this is not quantified under applied condition.

HAVELSKÝ (2001) (fig.4 b) numerically investigated another system shown in Fig.4(b), which uses a PCM integrated directly in a heat pump cycle. By controlling the three way valves, the accumulator with PCM stored energy from refrigerant coming through the condenser will act as an evaporator when the outside temperature is less than the balance point temperature. With this system, the numerical results showed that the average energy saving was nearly 20%.

PCM Integrated into Thermoelectric Cooling (TEC) System

Omer et al (2001) studied the application of PCM integrated with a TEC system. They found that heat sink with large heat storage is crucial to the performance of TEC system. They employed an encapsulated PCM as a cold sink in thermoelectric system, and integrated the PCM with heat pipes, which prevented the heat flow back to the cold space during off power periods as shown in Fig 5. It was found that the COP of the new system with PCM increased by a factor of two than without PCM.

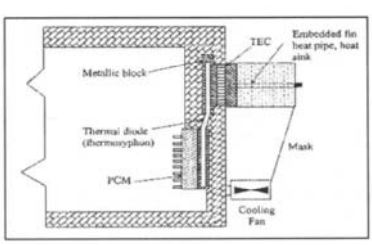

Figure5 PCM integrated into thermoelectric refrigeration system

CONCLUSIONS

A comprehensive literature has been reviewed in this paper. New PCM materials, heat transfer enhancement technology, nucleating and super cooling preventing techniques, combined new technology and system optimal control technology have been developed progressively.

Low heat transfer rate, as a main drawback of PCMs, has been recognized. Many heat transfer enhancement methods are investigated extensively and summarized in this paper. These methods provide effective ways of overcoming heat transfer problems in practice. Meanwhile system design requires sophisticated software to help designers with efficiency system in design stage. It is necessary to build a mathematical model to predicate and optimise the behavior of the systems. In order to increase the energy saving potential of PCMs in system, the novel use PCMs in RAC systems is also discussed in this paper.

Water and Energy Conservation of Rainwater Collection Systems on Building Roofs

H. X. Yang, W.H. Chow and J. Burnett

Department of Building Services Engineering,
The Hong Kong Polytechnic University, Hong Kong

ABSTRACT

In this study, an investigation on the rainwater catchment systems for domestic supply and commercial supply were conducted for Hong Kong Conditions. The focus of this study is the water and energy conservation of rainwater collection on building roofs in Hong Kong. The amount of rainwater supply mainly depends on the amount of rainfall, the collection area (i.e. normally roof area), runoff coefficient and the size of collection tank. The main parameters and their relationships have been established to estimate the amount of rainwater collected in different roof areas and different sizes of tanks based on the amount of rainfall recorded by the Hong Kong Observatory. The investigations of the supply and utilization of rainwater for different types of buildings such as residential, commercial and other developments were made. The results of the investigations such as supply, the demand of flushing, feasibility, reliability and energy saving of using rainwater supply are summarised in this paper.

1. INTRODUCTION

Water conservation is regarded as more important than energy conservation on earth nowadays. Water

shortage occurs in a lot of areas in the world. Significant amount of fresh water in Hong Kong is supplied from Shenzhen as well. The necessity for water conservation is obvious. One of the methods which can save water as well as energy is the rainwater collection technique on building roofs. The collected rainwater can be used for different purposes, such as drinking, cooking, cleansing, irrigation, toilet flushing and heat rejection of refrigeration systems in buildings.

In Hong Kong, the Government makes use of reservoirs for collection and storage of rainwater. After sterilization and purification process, the water collected by reservoirs can be provided as fresh water to people. Nowadays, water supply from solely the collection of rainwater is insufficient compared to the increasing demand. Therefore, another water source is the water pipe transportation supply from Guangdong, which accounts for a capacity of 1,100 million cubic metres per year [1]. Beside fresh water supply, the Water Supply Department (WSD) also provides seawater for flushing toilets for about 70% of the total area in Hong Kong [2]. It means that fresh water is also used for flushing toilets in some rural areas. In this paper, a case study of rainwater collection is investigated for different types of building to find the feasibility and reliability of using rainwater for flushing toilet and other possible areas.

Energy could be saved if rainwater is used in a building as the energy use for water transportation could be reduced and energy saving for water-cooling refrigeration systems can also be achieved. Thus, the energy saving due to rainwater application is also studied in this paper.

2. THE RAINWATER COLLECTION SYSTEM IN KFBG

The new reception building of the Kadoorie Farm and Botanic Garden (KFBG) in the New Territory has been built. A number of environmental-friendly and energy saving techniques are applied in the design, such as solar energy application, rainwater collection and grass roof. Rainwater is collected on the roof of the building and is used for flushing toilet. There is no city water supply in the farm as the farm locates in the rural area of Hong Kong. Spring water is used for all the activities so that water saving is very important. The schematic diagram of the rainwater collection and flushing water supply system in KFBG is shown in Figure 1. A rainwater tank of $1m^3$ on the roof is provided to collect rainwater by the roof catchment as shown in Figure 2. A break tank is used for toilet flushing, which consists of two numbers of ball float valves, one for rainwater and another for fresh water. The ball float valve level setting for rainwater supply is higher than the ball float valve for fresh water. If the rainwater supply

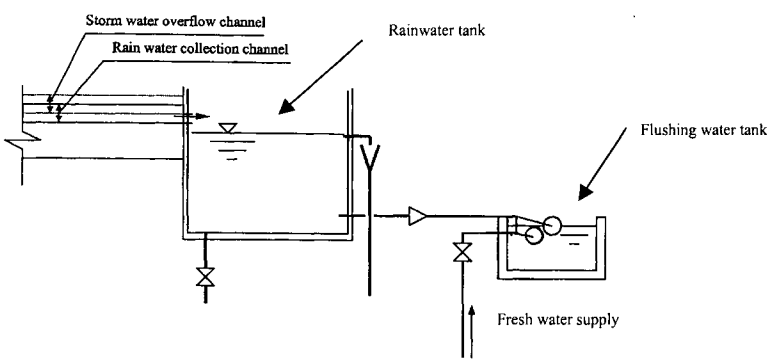

Fig.1 Schematic diagram of the rainwater collection system at KFBG

is not sufficient or the rainwater tank is empty, fresh water supply will fill up the tank for toilet flushing. If the supply of rainwater is greater than the demand of flushing, the rainwater collection tank will become full and then overflow. The excess rainwater will be drained to the traditional rainwater drainage system.

Fig.2 The rainwater collection tank on the building roof in KFBG

3. RAINWATER COLLECTION IN HONG KONG

Hong Kong is characterized as a sub-tropical weather. The mean annual rainfall is around 2215mm, which is based on the recorded data from the Hong Kong Observatory from 1961 to 1990. The wettest month is August and the driest month is January. In August, rain occurs about four days in seven days and the average monthly rainfall is 391.4mm. In January, the average monthly rainfall is only 23.4mm and rain occurs only for about six days in a month [2]. Figure 3 shows the five-day normal mean rainfall (1961 to 1990) in a year. These data can be used for calculating the potential amount of rainwater collected on building roofs.

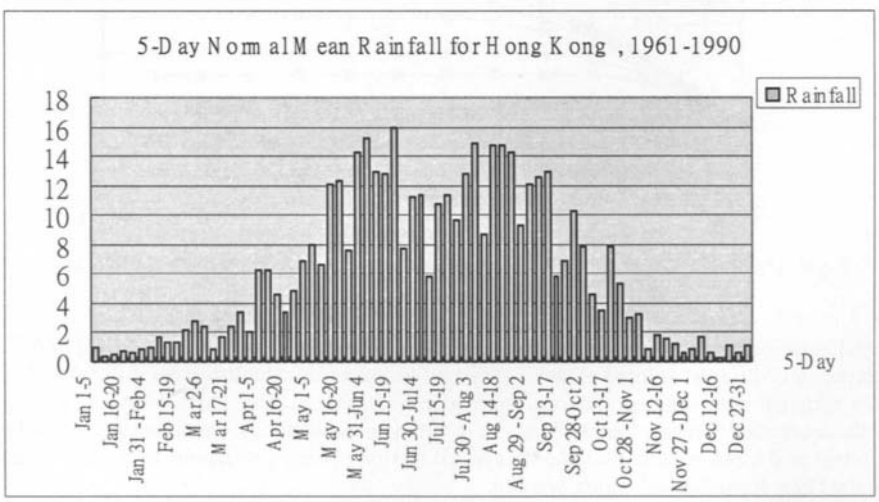

Fig.3 Five day normal mean rainfall in Hong Kong (1961-1990)

The amount of rainwater supply depends on the amount of rainfall, the collection area and the run off coefficient. Equation 1 gives the potential supply of rainwater. The runoff coefficient (Cr) is the ratio of the volume of water runs off a surface to the volume of rainfall that falls on the surface as shown in Equation 2. Due to the losses from leakage, evaporation and overflow, Cr is normally taken as 0.8 for a well-constructed roof harvesting system [4].

$$S = R \times A \times Cr \tag{1}$$

$$\text{Run off coefficient (Cr)} = \frac{\textit{Volume of runoff}}{\textit{Volume of rainwater}} \tag{2}$$

where S = Mean rainwater supply, i.e. the amount of rainwater collected, m^3;
R = Mean rainfall, (mm);
A = Collection area, m^2;
Cr = Run off coefficient.

Since the rainfall in Hong Kong varies and is not evenly distributed throughout a year, the rainwater collection tank is required to store the rainwater for daily use. If a small tank is chosen, the tank is easily fully charged and then overflows quickly during heavy rainfall. This leads to a result of water loss and decrease of catching efficiency. If the tank size is large, of course, rainwater can be collected close to or even the same as the potential rainwater supply amount. However, it will occupy a large space and also high construction cost will be involved. As a result, choosing suitable size of rainwater storage tank is very important. The amount of rainwater collected against different collection areas based on runoff coefficient 0.8 is calculated and presented in Figure 4. It shows that the maximum amount of rainwater collected is directly proportional to the collection area.

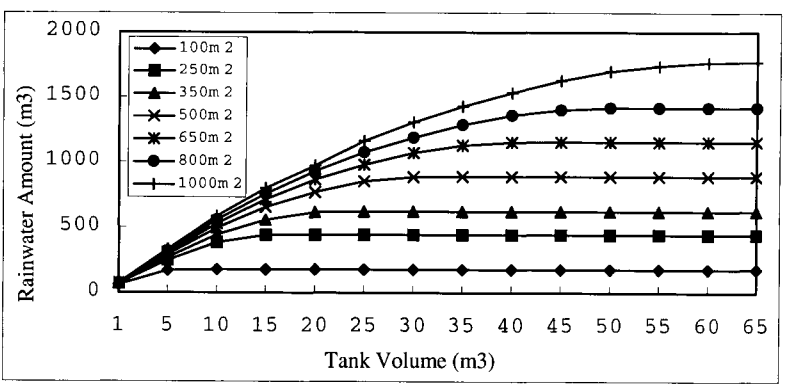

Fig.4 The amount of rainwater collected for different size of tanks and roof areas

The general equations have been established to estimate the amount of rainwater collected in different collection area and different volume of tanks. Different formulas are established for different collection areas with different conditions, which are summarized in Table 1. Those equations can be used to estimate the amount of rainwater quickly and easily with two assumptions. One is assumed that the run off coefficient is 0.8 and another one is only applied to Hong Kong's situations because the data are based on the Hong Kong historic rainfall record.

Table 1 Summary of equations to estimate the amount of rainwater

Collection Area (m^2)	General Equation	Condition
100	$Y = -51.98X^2 + 267.14X - 156.44$	$1 \leqq V \leqq 10$ and $0 \leqq Y \leqq 177.16$
250	$Y = -30.86X^2 + 279.48X - 182.34$	$1 \leqq V \leqq 20$ and $0 \leqq Y \leqq 442.90$
350	$Y = -25.47X^2 + 298.56X - 198.32$	$1 \leqq V \leqq 25$ and $0 \leqq Y \leqq 620.06$
500	$Y = -19.33X^2 + 291.10X - 204.95$	$1 \leqq V \leqq 35$ and $0 \leqq Y \leqq 885.80$
650	$Y = -15.52X^2 + 209.59X - 205.26$	$1 \leqq V \leqq 45$ and $0 \leqq Y \leqq$ 1151.54
800	$Y = -12.93X^2 + 289.71X - 202.41$	$1 \leqq V \leqq 55$ and $0 \leqq Y \leqq$ 1417.28
1000	$Y = -10.56X^2 + 288.40X - 198.30$	$1 \leqq V \leqq 65$ and $0 \leqq Y \leqq$ 1771.60

where : Y = Amount of rainwater (m^3), V = Volume of collection tank (m^3)

($V = 5(X-1)$ for X=2, V = 1 when X=1 and V=5 for X=2)

4. RAINWATER CONSUMPTION

The supply of the rainwater collected on different roof areas with different sizes of tanks for several locations were investigated for three major categories: residential high-rise buildings, commercial buildings, industrial buildings and small houses. According to the Plumbing Engineering Services Design Guide[7, the demands of flushing for different buildings were investigated and summarized in Table 2. It is found that the supply of rainwater is insufficient for toilet flushing demand especially for residential high rise buildings. Most of them have only less than 10% of demand. The insufficient rainwater supply is due to the limited roof area. It is also not practicable to use large collection tank such as $65m^3$ tank to collect more water due to the space consumption, increase of structure loading and cost. Therefore, suitable and reasonable sizes of collection tank should be selected.

The reliability for commercial and small houses is much better than that of residential high-rise buildings. The rainwater supply and consumption is illustrated in Figure 5 for commercial buildings. The reliability of supply for commercial, small house and other places are listed in Table 3.

5. COST ANALYSIS

According to the information from WSD, the cost for supplying fresh water is around HK\$8/m^3 including the purchasing cost from Guangdong, operation, maintenance (O&M) and administration costs. The cost for supplying seawater is around HK\$1.68/m^3. The annual saving for using rainwater supply is shown in Table 3. The figures in brackets in table 3 show the costs or savings when the fresh water charge is \$4.58/ m^3. The government subsides users for fresh water and seawater supply (the sea water supply for toilet flushing is free of charge). Therefore, the end users pay less than the real cost.

The payback is also estimated s shown in the table. Due to the amount of saving was not significant, longer payback period was found. The construction cost is much greater than the cost of water saved due to the limited roof area.

Table 2 Summary of investigations

A) High-rise residential buildings

Estate	Tse Man Est. Phase 2	Un Chau Estate Phase 3	New Kwai Fong Gardens	Kwai Chung Plaza
Roof area (m^2)	674	1019	410	506

6. ENERGY CONSERVATION

Energy can also be saved from rain water collection as shown in Table 3. If rainwater is used for irrigation or cleansing, the same amount of fresh water must be saved. According to the information given by the Water Services Department of the HKSAR, the energy consumption for treatment and transportation of fresh water is 0.4 kWh/m^3. On the other hand, if the collected rainwater is used for flushing purpose and the energy consumption for treatment and pumping sea water for flushing is 0.44 kWh/m^3, the annual energy saved for treatment and transportation of water for different purposes were presented in Table 3. The energy saving was only for treatment and transportation of the water from source to users.

7. CONCLUSIONS

The supply and demand of using collected rainwater for toilet flushing were investigated for different

type of buildings in Hong Kong. It was found that the collected rainwater is insufficient for the demand of toilet flushing for the high rise buildings. The supply might only cover 10% of the demand because the rainwater catching area (i.e. roof area) is limited for high-rise residential buildings. For commercial buildings of fifteen to twenty-five storeys, the reliability of supply was found better than the high rise domestic buildings. It is because the supply increases and the demand decreases compared with high rise domestic buildings. However, the reliability of rainwater supply for small houses or buildings with large floor areas is very good.

Although using larger rainwater collection tank can collect much water, it would not be practicable as it will occupy more space and increase structure loading and construction cost. The flushing or irrigation system in a building cannot just rely on rainwater, but also on fresh water supply as well.

THE INFLUENCE OF ENVELOPE CHARACTERISTICS TO THE ENERGY BEHAVIOUR OF HIGH-RISE RESIDENTIAL BUILDINGS

Yik, F., Bojic, M., Wan, K.

Research Centre for Building Environmental Performance, Department of Building Services Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong SAR, China

ABSTRACT

This paper presents the results of several studies on the influence of different envelope characteristics to the energy behaviour of flats in high-rise residential buildings in Hong Kong. These studies investigated into the effects of various conventional façade treatments, including variations in the wall thickness, the window-to-wall area ratio and the shading coefficient of window glass, and the provision of shading devices, such as overhang and side-fins. In addition, the effects of applying thermal insulation at different positions within walls, partitions and doors, and of insulated walls and doors in different parts of the building fabric were investigated. The impacts of these factors on the yearly cooling load were evaluated using the software HTB2, which is a detailed building heat transfer model. These studies showed that the use of glazing of better performance would be the most effective in reducing the yearly cooling load in a residential building, by up to 13%, and applying thermal insulation could lead to a reduction in this load by up to 10%. Key considerations to be given in determining where to put insulation are described and areas for further investigations are outlined.

KEYWORDS: High-rise residential, Envelope design, Thermal insulation, Annual cooling load, Simulations

INTRODUCTION

The residential sector is responsible for about a quarter of the annual electricity use in Hong Kong, which is equivalent to about one-sixth of the total primary energy requirement of the city. To cope with the projected housing demand, tens of thousands of new public and private residential units are produced each year (HKHA, 1995). This will further increase the electricity use of the residential sector, and the associated green house gas emissions, in the coming years. It is therefore important to also target for a higher level of building energy performance while attempting to realise the quantity target.

Energy use in high-rise commercial buildings in Hong Kong has been actively researched into (Chau et al, 2000), but much less so for residential buildings. In the past, the majority of residential flats were not equipped with air-conditioners but the situation is now reversed – air-conditioning has become the

dominant energy end-use in residential buildings and the major cause for the rapid rise in electricity consumption of the residential sector in the past decade. Therefore, more active research studies into means for enhancing the energy performance of residential building design is needed. Simulation predictions showed that the annual cooling requirement in residential buildings, which is proportional to the electricity consumption, is dominated by the heat gains through the building envelope (Yik et al, 2000). Careful consideration should, therefore, be given to the energy performance of the building envelope in designing energy efficient residential buildings.

This paper presents the results of several simulation studies on high-rise residential buildings in Hong Kong that were undertaken at the Hong Kong Polytechnic University. These studies investigated into the influence to the space cooling load when the building envelope was incorporated with different characteristics. The studied characteristics include a range of conventional façade treatments and the less conventional method of applying thermal insulation to walls and doors in buildings in subtropical climate.

THE SIMULATION SOFTWARE HTB2

The simulation tool used in the study was HTB2, which is a dynamic building energy model that can predict the heating and cooling loads and the environmental conditions in a building. In HTB2, the dynamic heat conduction through the building envelope is modelled using an explicit finite difference numerical scheme (Lomas et al, 1997; Jones & Alexander 1999). HTB2 can model dynamic heat transfer through multi-layered walls, roofs and partitions and through glazing taking into account variations in the solar transmittance and absorptance with different solar incident angles. The model can predict the thermal performance of a building when it is subject to the influence of outdoor temperature, solar gain, shading, and ventilation and infiltration. It also allows the user to define complex cooling and heating schedules, occupancy, lighting and internal load intensity patterns, and to vary control settings during run-time, to mimic realistic occupation conditions.

THE MODEL BUILDING

Figure 1 shows the layout of an intermediate floor in a typical high-rise residential building in Hong Kong, which comprises eight apartments per storey. Unlike commercial buildings, few residential buildings are equipped with central air-conditioning systems. In residential buildings, window-type and split-type air-conditioners are widely used. Within a residential apartment, air-conditioners would be provided for some rooms, such as living rooms and bedrooms, but some other rooms, such as bathrooms and kitchens, would not be equipped with air-conditioners. The common lobby on each floor is also not air-conditioned. Survey studies showed that the operation pattern of air-conditioners in residential buildings would basically follow the occupation pattern of the rooms (Lam, 1993; Leung, 2002). Air-conditioners serving living and dining rooms would be turned on most often in the evenings, sometimes during daytime as well, but would be switched off at night. Those serving bedrooms, however, would be run starting from late evening till early in the morning in the next day.

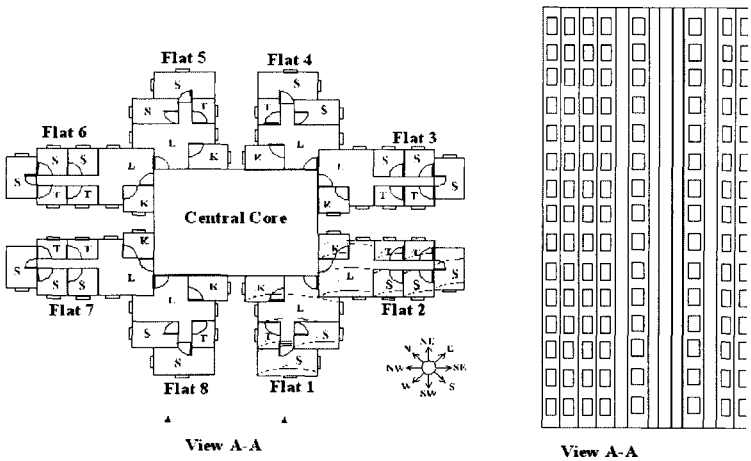

Figure 1: Floor plan and elevation of the model residential building

CONVENTIONAL FAÇADE TREATMENTS

Some of the results obtained from studies on the effects of varying individual features of the building envelope design are summarised below. In these studies, the model building was assumed to comprise 40 storeys of residential flats with a floor layout as shown in Figure 1.

Table 1 summarises the values of the parameters assigned to the envelope design of the model building that were chosen as the reference case (Case 0), and the value of the parameter varied in each of the additional cases studied (Cases 1 to 6). The parameters varied include the wall thickness (Case 1); the window-to-wall area ratio (Case 2); the shading coefficient of window glass (Case 3); inclusion of an overhang at each window (Case 4); and inclusion of a side-fin at the left-hand side (Case 5) and the right-hand side (Case 6) of each window. The side-fin dimensions were denoted by the parameter called external shading multiplier, which was calculated according to the standard method defined in the Handbook for overall thermal transfer value (OTTV) calculations (Building Authority, 1995).

TABLE 1
BUILDING FAÇADE FEATURES VARIED IN THE PARAMETRIC STUDY (IN BOLD FACE)

Case	0	1	2	3	4	5	6
Wall thickness (mm)	100	**300**	100	100	100	100	100
Window to wall area ratio	0.65	0.65	**0.25**	0.65	0.65	0.65	0.65
Shading coefficient of window glass	0.95	0.95	0.95	**0.25**	0.95	0.95	0.95
Shading (external shading multiplier)	0	0	0	0	**OH 0.5**	**LF 0.5**	**RF 0.5**

Notes: OH 0.5 denotes overhang with an external shading multiplier of 0.5; LF 0.5 denotes side-fin at the left-hand side with an external shading multiplier of 0.5; and RF 0.5 denotes side-fin at the right-hand side with an external shading multiplier of 0.5.

Figure 2 shows a comparison of the annual cooling loads of the building pertaining to the cases studied. As can be seem from this figure, replacing clear glass with a shading coefficient of 0.95 by reflective glass with a shading coefficient of 0.25 (Case 3) would result in a rather significant

reduction in the annual cooling load of the residential building, by 13%. Each of the other features studied would contribute to a reduction in the annual cooling load by several percent.

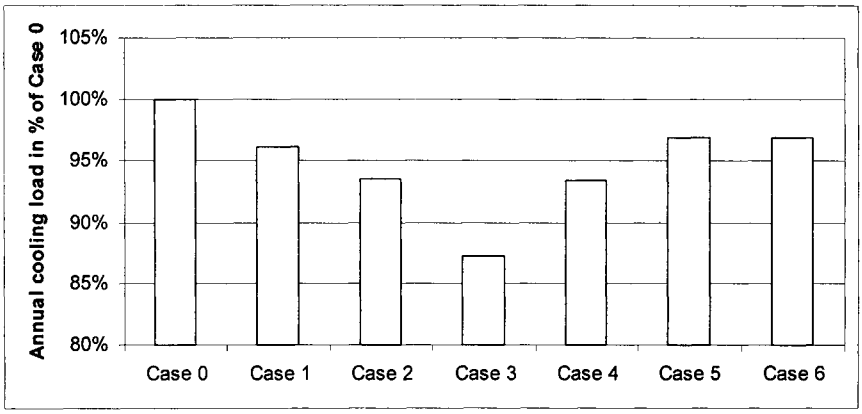

Figure 2: Comparison of the effect on the annual cooling load of the residential block due to different façade treatments (refer to Table 1 for details of the Cases shown)

THERMAL INSULATION

At present walls and doors in residential buildings in Hong Kong are not thermally insulated at all. Studies have been performed to investigate if providing thermal insulation to the building fabric would be effective in improving the energy performance of residential building designs. In these studies, the flats, as shown in Figure 1, with their original construction design were taken as the base-case model. Modifications to the base-case model were then made on the walls and doors, which included inserting a layer of thermal insulation into different locations within the walls, and applying these modified walls to different parts of the fabric.

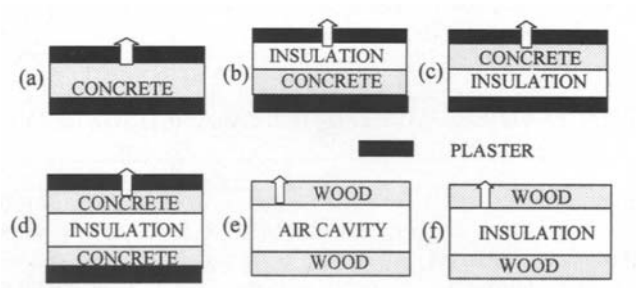

Figure 3: Thermal insulation position in a wall and a door: (a) wall without thermal insulation; (b) wall with thermal insulation at the outer side; (c) wall with thermal insulation at the inner side; (d) wall with thermal insulation in the middle; (e) door without thermal insulation; and (f) door with thermal insulation. The arrows designate the outside face of slabs

Since the layout of each pair of apartments is simply a mirror image of the other pairs of apartments on the same floor (Figure 1), the simulation study was based on the layout of Flats 1 and 2 only. The

thermal insulation material for the walls was assumed to be polystyrene (thermal conductivity, k, = 0.034W/Km) and the study investigated into having this insulation layer inserted into three different locations in a wall slab, as shown in Figure 3. The thermal insulation material for the doors was assumed to be mineral wool (k = 0.053W/Km), which would form the middle layer in a door (Figure 3).

The effects of applying thermal insulation to different combinations of the walls and doors enclosing the two flats were also studied. Figure 4 shows four cases of walls and doors arrangements: F, W, L, and B. In the F arrangement, the thermal insulation layer was inserted at the outer side of the walls, and all the external walls as well as the walls and the main entrance doors that separate the flats from the common lobby were insulated. In the W arrangement, all walls between air-conditioned rooms and non-air-conditions rooms were insulated. In the L arrangement, the walls circumscribing the living room and the connected corridors were insulated. In the B arrangement, only walls enclosing the bedrooms were applied with thermal insulation.

Details about the study on the influence of the arrangement of the thermally insulated walls and doors on the space cooling load in the two modelled residential units have been reported in Bojic et al (2002c). In that study, the walls were applied with a 50mm thick thermal insulation, at the outer side of the concrete layer, and a range of thickness of the concrete layer in the walls, up to 400mm, was covered. The thickness of the thermal insulation layer applied to the modified doors was 38mm. The yearly cooling load (Q) of the two flats, when incorporated with the base-case design and when having the building fabric design modified according to each of the four wall and door arrangements F, W, L & B (Figure 4), and with different combinations of the thickness of the concrete layer in the walls, were predicted using HTB2.

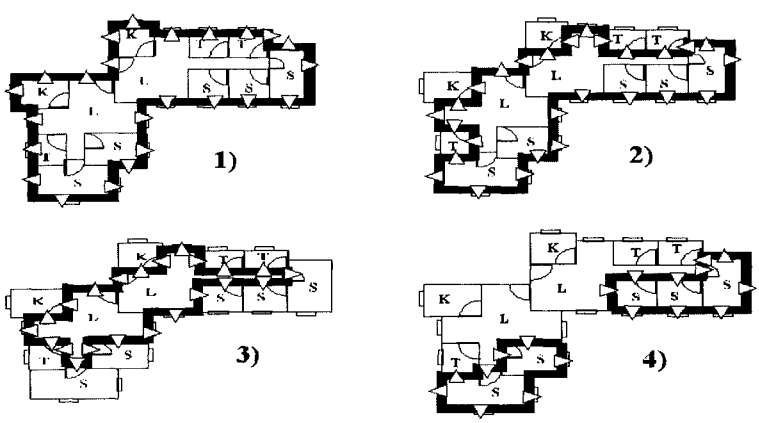

Figure 4: Walls and doors arrangements: 1) F, 2) W, 3) L, and 4) B. Here, S denotes a bedroom, L a living and dining room, K a kitchen, and T a toilet. The tip of each arrow indicates the side of concrete where the insulation layer was placed.

Figure 5 shows one set of the results, including the difference between the yearly cooling loads of the modified cases from that for the base-base. The simulation predictions indicated that the optimal insulation arrangement would be to apply insulation only to those walls circumscribing the living room and the connected corridors (arrangement L). A reduction in the yearly cooling load of the two flats by up to 8% could be achieved for this arrangement.

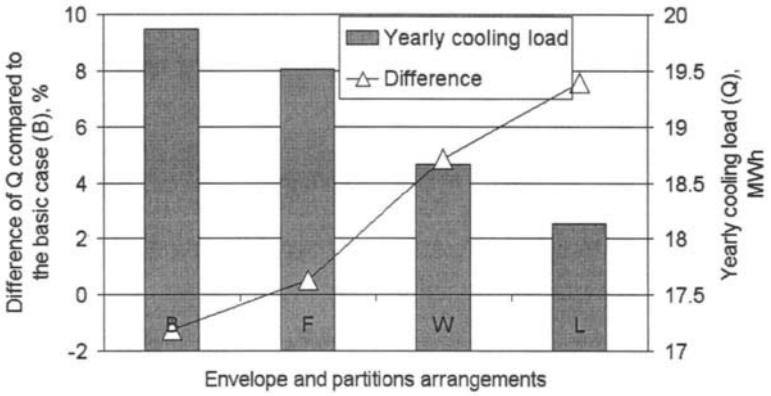

Figure 5: Yearly cooling load and cooling load difference as functions of the arrangement of thermally insulated walls and doors. Difference of cooling load is compared to that of the basic case. Here, modified walls have 50mm of thermal insulation, and 400mm of concrete.

The effect of varying the location of the insulation layer within the wall has been studied based on arrangement F (Bojic et al, 2001; 2002a). In that study, the thermal insulation layer, up to 150mm thick, was placed either at the inner side, or at the outer side, or at the middle of the walls (Figure 3). The thickness of the concrete layer covered in the study was up to 400mm. Some of the simulation results are shown in Figure 6, which shows the variation in the yearly cooling load (Q) with the thickness and position of the thermal insulation layer for Flat 1, when its windows were facing southeast. It can be seen that inserting the thermal insulation layer at the outer side and in the middle could lead to an increase in the cooling load; the location of the insulation layer in the walls of this flat should, therefore, be at the inner side of the concrete layer in order that a reduction in the cooling load could be achieved. Other results obtained in the study showed that placing the insulation layer at the outer and middle positions could still lead to a reduction in the cooling load if the windows were oriented toward a different direction, but still less significant than placing the insulation at the inner surface. Moreover, further increasing the insulation layer thickness beyond 50mm would lead to virtually intangible incremental effects, which was a general observation among the cases studied. A reduction in the yearly cooling load by up to 7% could be achieved when the 50mm thick thermal insulation layer was inserted at the inner side of the concrete layer.

Other observations made from the simulation study results include:

- For a residential building in hot climate regions, which is air-conditioned primarily in the evening and in the night-time, adding thermal insulation and thermal mass to external walls could lead to counteracting effects. Adding thermal mass would increase the heat storage in the fabric leading to an increased cooling load in the evening. The cooling load could be reduced by also increasing the thermal insulation to reduce the heat transfers into the walls through the outdoor surface, which would be effective when the thickness of the wall is around 250mm. However, increasing the thermal insulation of a thin wall would reduce the rate that the stored heat could be dissipated back to the outdoor, leading to an increase in the cooling load.
- The best strategy of providing thermal insulation in the building fabric of residential buildings would be to insulate the partitions so as to minimise heat transfer from non-air-conditioned spaces into the living room, which would be cooled in the evening, as for arrangement L

(Figure 4). However, for bedrooms, which would be cooled in the late evening and overnight, adding insulation, as for arrangement B (Figure 4) would lead to the opposite effect.

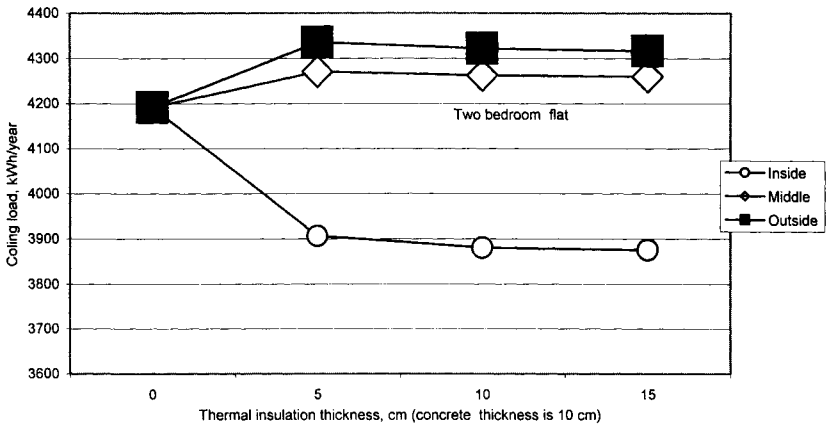

Figure 6: Cooling Load as a function of the thermal insulation thickness and the position of thermal insulation inside the F-walls (thickness of concrete is 100mm).

CONCLUSION

In this paper, a summary is given of the findings of several investigations performed on the thermal performance of the envelope design of high-rise residential buildings in Hong Kong when the building envelope was incorporated with different characteristics. These investigations were based on the yearly cooling load predicted using the detailed building heat transfer simulation program HTB2.

The results presented include the effects of several conventional treatments at the façade for improving the energy performance of the envelope of a residential building, including increasing the wall thickness, reducing the window-to-wall area ratio, reducing the shading coefficient of the window glass and inclusion of overhangs and side-fins at windows. Simulation predictions showed that the use of a glazing type of better thermal performance would be effective in reducing the yearly cooling load in the air-conditioned spaces. Other treatments at the façade could each yield a reduction in the yearly cooling load by several percent.

The simulation studies on the effects of applying thermal insulation to the building fabric elements showed that the insulation layer to be applied would lead to a significant effect up to thickness of 50mm, but further increasing its thickness would lead to intangible incremental benefit. Among the results for the investigated scenarios of applying thermal insulation to different elements of the building fabric, the maximum reduction in the yearly cooling load was found to be about 8%. The best strategy of applying thermal insulation would be to insulate those partitions between spaces that would be air-conditioned in different periods and between air-conditioned and non-air-conditioned spaces. Inserting the insulation layer at the inner surface of the concrete layer would, in general, lead to beneficial results. Inserting the layer at other positions, e.g. the inner side or at the middle of the wall could lead to the opposite effect depending on the exposure direction of windows and external walls in the flat.

As the yearly cooling load of a flat would be proportional to the annual electricity use for air-conditioning the flat, a reduction in the yearly cooling load means a reduction in the electricity consumption of a similar order, which will be accompanied also by a reduction in the primary energy consumption and in environmental impact.

Further studies should be made into how the building envelope design could be optimised, taking into account of the trade offs among cooling energy use, lighting energy use, availability of daylight and natural ventilation, and economic viability of the improvement measures.

ACKNOWLEDGEMENTS

ABSTRACT

Operation of building systems after occupancy is getting to be recognized as a key issue for substantial reduction of energy use and CO_2 emission. Especially optimal operation of HVAC systems is very important because of their large energy consumption. Many methodologies for the purpose have been proposed, however most of the reported results are based on the simulation with the assumption that the performance of each component and subsystem is known or prescribed. In this paper an optimal operation scheme of HVAC systems for existing buildings is proposed and the test results of applying the scheme in a real office building are shown and investigated. The scheme is divided into two steps: the first is to identify the parameters of the mathematical model of each component such as a fan, a pump and a heat pump, and the second is to optimize total energy consumption of HVAC system operation. Mathematically the second step is a non-linear optimization process which is to be embedded into a BEM system.

Optimization, Identification, Simulation, HVAC, BEM system, Energy saving, Methodology test.

MODEL IDENTIFICATION

Operation of building systems is increasingly to be recognized as a key issue for substantial reduction of energy

use and CO_2 emission, especially the operation of HVAC systems because of their large energy consumption. So it is important to determine proper HVAC systems' models to optimize the operation. We would suggest the way to get good models using real operation data of system components, which we give the name of 'model identification'. Figure 1 shows a HVAC system. This system has energy storage, one heat pump unit, one secondary pump, and four air handling units which have two fans (but energy storage and four constant speed fans in air handling unit are not considered in optimization). The following parts of this paper will discuss how to identify the models of these equipments.

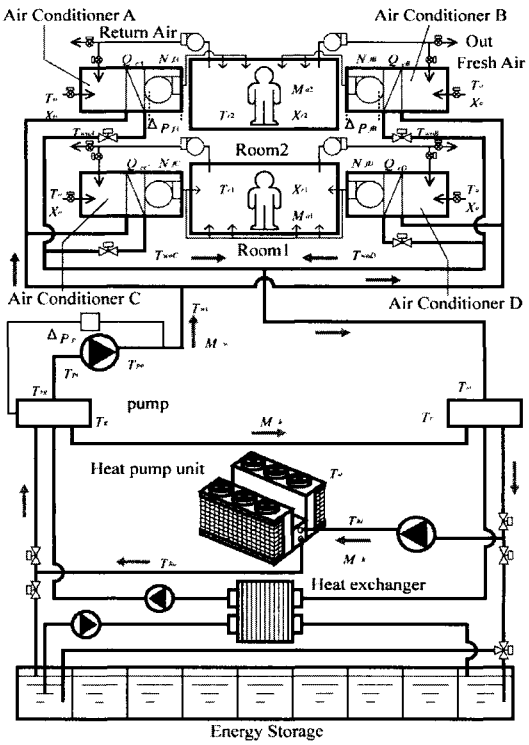

Figure 1 : HVAC system assumed in the research

Secondary Pump and Fan in AHU

Pump and fan model is composed of following equations.

$$C_f = \frac{M}{\rho N D^3} \tag{1}$$

$$C_h = \frac{1000 \times \Delta P}{\rho N^2 D^2} \tag{2}$$

$$C_h = a_0 + a_1 C_f + a_2 C_f^{\,2} + a_3 C_f^{\,3} + a_4 C_f^{\,4} \tag{3}$$

$$\eta = b_0 + b_1 C_f + b_2 C_f^{\,2} + b_3 C_f^{\,3} + b_4 C_f^{\,4} \tag{4}$$

$$E = \frac{M \Delta P}{\eta \rho} \tag{5}$$

C_f :dimensionless coefficient of water or air flow rate, C_h :dimensionless coefficient of pressure difference, D :equivalent diameter, M :water or air flow rate, ρ :water or air density, N :revolution speed, ΔP :pressure difference, E :electric energy consumption, η :efficiency of a pump or fan. Model identification of pump and fan are to decide the values of parameters a_i and b_i in equation (3) and (4) using Least Square Approximation method. First, these parameters were decided according to specification data supplied by the manufacture. Second, water or air flow rate , pressure difference ΔP , revolution speed , and electric energy consumption were to be measured, then parameters were corrected to minimize the difference between measured data and simulation data. Electric energy consumption of pump and fan of measured data and simulation data are shown in TABLE 1 and 2. The ratios of error of mean square to designed energy consumption are shown, too.

TABLE 1
ELECTRIC ENERGY CONSUMPTION OF SECONDARY SUPPLY PUMP

	mean of electric energy consumption[kW]	error of mean square of electric energy consumption[kW^2]
measured data	0.90	-
simulation data before corrected	1.15	0.484 (22.0%)
simulation data after corrected	0.96	0.264 (12.0%)

TABLE 2
ELECTRIC ENERGY CONSUMPTION OF SUPPLY AND RETURN FAN

	mean of electric energy consumption [kW]	error of mean square of electric energy consumption [kW^2]		mean of electric energy consumption [kW]	error of mean square of electric energy consumption [kW^2]
measured data of supply / return fan A	0.96 / 0.55	-	measured data of supply / return fan B	1.34 / 0.67	-
simulation data of supply / return fan A before corrected	0.53 / 0.19	0.488(22.2%) / 0.393(26.2%)	simulation data of supply / return fan B before corrected	0.85 / 0.30	0.521(23.7%) / 0.377(25.2%)
simulation data of supply / return fan A after corrected	0.96 / 0.55	0.148(6.74%) / 0.066(4.38%)	simulation data of supply / return fan B after corrected	1.34 / 0.67	0.087(3.95%) / 0.035(2.34%)

Heat Pump

Heat pump model is composed of the following equations.

$$\frac{Q_h'}{Q_{hd}} = \left(e_0 + e_1 T_{hi} + e_2 T_{hi}^2\right)\left(e_3 + e_4 T_o + e_5 T_o^2\right) + e_6 \tag{6}$$

$$\frac{E_h'}{E_{hd}} = \left(g_0 + g_1 T_{hi} + g_2 T_{hi}^2\right)\left(g_3 + g_4 T_o + g_5 T_o^2\right) + g_6 \tag{7}$$

$$r_q = \frac{Q_h}{Q_h'} \tag{8}$$

$$E_h = r_e \cdot E_h' \tag{9}$$

$$T_{ho} = T_{hi} - \frac{Q_h}{M_h c_w} \tag{10}$$

M_h :water flow rate in heat pump cycle, Q_h :cooling load, Q_{hd} :rated value of cooling capacity, T_{hi} :inlet water temperature, T_{ho} :outlet water temperature, T_o :outdoor air temperature, E_{hd} :rated value of electric energy consumption, and c_w :water specific heat capacity, Q_h' :the maximum cooling capacity, E_h' :the maximum energy consumption, r_q :a rate of partial load, r_e :a rate of real electric energy consumption, and r_q :supposed to be equal to r_e .

Heat pump model identification is to decide parameters e_i , g_i in equation (6) and (7). Basically, the method of identification is same as pump and fan. Errors between before and after models corrected are shown in TABLE 3. Rated value of cooling capacity Q_{hd} and rated value of electric energy consumption E_{hd} are constant. Where outdoor temperature T_o and cooling load Q_h are measured by the BEM system and known.

TABLE 3
ELCTRIC ENERGY CONSUMPTION OF HEAT PUMP

	mean of electric energy consumption[kW]	error of mean square of electric energy consumption[kW^2]
measured data	20.8	-
simulation data before corrected	22.0	1.64(5.7%)
simulation data after corrected	20.8	1.08(3.8%)

Cooling Coil

Cooling coil model is composed of the following equations.

$$Q_c = Q_d + Q_w \tag{11}$$

$$Q_d = U_d A_d T_{md} \tag{12}$$

$$Q_w = U_w A_w h_{mw} \tag{13}$$

$$\frac{1}{U_d A_d} = K_{od} + K_{td} + K_{id} + \frac{F}{A_{id}} \tag{14}$$

$$\frac{1}{U_w A_w} = K_{ow} + K_{tw} + K_{iw} + \frac{F}{A_{iw}} \tag{15}$$

$$T_{wo} = f_{two}(X_{ai}, M_w, T_{wi}, T_{ai}, M_a) \tag{16}$$

Equation (16) is refered to coil model in the paper, reference 3).

Q_i :cooling load, U_i :total heat transfer rate, A_i :surface area of coil, K_{od}, K_{ow}, K_{td}, K_{tw}, K_{id}, K_{iw} :terms related to heat transfer, X_{ai} :inlet air humidity ratio, M_a :outlet air flow rate, M_w :water flow rate through coil,

T_{ai} :inlet air dry bulb temperature, T_{wi} :inlet water temperature.

Coil model identification is to decide a coefficient F which is dirty ratio of coil in equation (14) and (15). The method of identification of coil is same as other equipments. Then a numerical subscript d means dry part, w means wet part. Errors between before and after cooling coil models corrected are shown in TABLE 4.

TABLE 4

LOAD OF COOLING COIL

	cooling load[kW]		cooling load[kW]
AHU A before corrected	1.72(5.47%)	AHU C before corrected	4.07(12.1%)

TOTAL OPTIMAL OPERATION

In Total Optimal Operation, optimal set points, which are water flow rate of secondary pump, air flow rate of supply fan in AHU, and outlet water temperature from heat pump are determined by solving an optimal problem of which the objective function is energy consumption of whole HVAC system shown as follows.

$$E = E_f + E_p + E_h \tag{17}$$

E:total energy consumption, E_f:consumption of fan, E_p:consumption of pump, E_h:consumption of heat pump unit. E_f:the function of supply air flow rate M_a, E_p is of M_w, and E_h is of M_a, M_w, and T_{sg}. T_{sg} is secondary supply water temprature, and is assumed to be equal to T_{ho}. Therefore E is the function of M_a, M_w, and T_{sg}. There are following four conditions and constraints in the optimization.

1) To satisfy cooling demand.
2) HVAC system operation is proper.
3) HVAC system operation and loads are at a steady state.
4) There is no heat loss from pipes and ducts.

Applying Total Optimal Operation to the real system is tested. The outdoor temperature, outdoor humidity, and cooling load of the test day are shown in Figure 2 and 3, in which case N1 and N2 is normal operation, case O1 and O2 is Total Optimal Operation. In the test, real time cooling load, outdoor temperature, outdoor humidity, and room temperature, room humidity are substituted into the equations of HVAC model. Then the equations are solved to find the each setpoint. The system is controlled based on the setpoints. The results are shown in TABLE 5. From TABLE 5, the comparing of case O1 and case N2, both of which have the same cooling load, shows that Total Optimal Operation can reduce 30.3% of the energy

consumption of case N2.

RESULTS AND DISCUSSION

Total Optimal Operation was tested in 27/10/2001, when cooling load was small. The percentage of reducing energy consumption can be expected to be lower when it is in a peak load season. Because the optimal operation cuts down the excessive energy consumed by normal operation. When it is in peak load season, the excessive energy is not as much as in low load season. So the expected energy saving effect of optimal operation is not as much as that in low load season. To investigate this point, optimal operation in a high load season is compared with normal operation in the season by using simulation models.

Comparison in a High Load Season

A high cooling load given by simulation, outdoor temperature and humidity on 23rd Aug in 2001 are shown in Figure 4 and 5. The results of simulation are in TABLE 6. From TABLE 6, it is found that the rate of reducing energy consumption by Total Optimal Operation on the high load day is 7.4%, much smaller and about one fourth of 30.3%, which is that of the test day. However, the amount of reducing energy consumption by Total Optimal Operation on the high load day is 1.51kW, about one half of 3.39kW, which is that of 27/10/2001. The result is that even on the high load day, the reduction of energy consumption is about one half of that on a low load day. Considering an operation on high load days, middle and low load days suitable to optimal operation, considerable energy consumption is to be reduced by Total Optimal Operation. The result of simulation, on the assumption that the number of days of high, middle, and low load is same, shows that 8.76% of energy consumption can be reduced through July, Augusy, and Septem-

ber.

CONCLUSION

The feasibility of the proposed method was tested in a real HVAC system of an office building and the following results were obtained: 1) Parameter identification can be performed successfully by using mathematical models used in common simulation software such as TRNSYS, HVACSIM+ and HASP/ACLD. 2) No small errors in the model performance were found at some operating points. however, about 13.3% energy conservation was able to be attained by the optimal operation method as a whole.

ABSTRACT

Energy comsumption in Building Heating, Ventilation and Air-Conditioning (HVAC) systems is growing quickly. Fault detection and diagnosis (FDD) is necessary for the modern office building since it can be used to trace the cause of the decrease of energy efficiency in an HVAC system or the decrease of the thermal comfort level in the rooms. This paper studies a model-based FDD on an office room. By analyzing the physical relations between all the parts of an office room, the models for the room are built with Simulink®. Two types of fault are studied in this paper: an opening window and a jammed radiator valve. By introducing a characteristic parameter, these two faults are able to be detected and diagnosed.

KEYWORDS Model-based; Fault detection and diagnosis; Simulink; HVAC system; office building

INTRODUCTION

As a result of economic, business and population growth, energy use in buildings has grown quickly in the recent decades. More and more residential and commercial buildings have been built and have contributed increasing service demands, e.g. more air-conditioning, more computers, larger rooms.

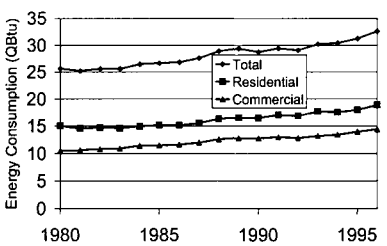

Figure 1: Building Energy Use, 1980-96, U.S.

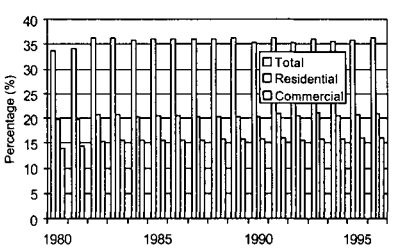

Figure 2: Percentage of Buildings Energy Consumption to the Total Energy Consumption, 1980-96, U.S.

Some useful information can be acquired from statistics for the United States. As shown in Figure 1, according to the review of U.S. Department of Energy (1999) from 1980 to 1996, the energy use of buildings increased about 27%. Therein, the increased amount for residential building is about 25% and for commercial building is about 36%. It is shown in Figure 2 that building energy use in the U.S. accounts for over one-third of U.S. total energy consumption. Therein, residential building accounts for one-fifth and commercial building accounts for one-sixth of U.S. total energy consumption. For the energy use in EU, similar conclusion also can be drawn (Vreuls, 1998). As an energy crisis approaches rapidly, research into energy saving for buildings is quite significant and is being developed from different point of view.

In order to achieve a comfortable working environment, thanks to the rapid development of computers and information & communication technology, modern office buildings increasingly supply integrated, complicated and intelligent services. People want better indoor climate quality and network facilities. Therefore, Heating Ventilation and Air-Conditioning (HVAC) system, automatic control systems and Building Energy Management Systems (BEMS) have been gradually installed in buildings. Since the building control system and HVAC system could not run under optimal condition and sometimes faults or disturbances appear in the different stage of design, commissioning and operation, this increases the complaints level from tenants and the energy consumption level. Hence fault detection and diagnosis (FDD) is necessary.

Model-based FDD has been studied for the past twenty years. It shows good results in some applications. Usoro et al. (1985) presented a nonlinear mathematical model of HVAC system plus an extended Kalman filter to detect faults. A computer program that implements this method was successfully used to detect various simulated faults in the HVAC system. Vaezi-Nejad et al. (1992) used ARX models to diagnosis energy abnormal consumption as a window left opened in a building. Because the opening of a window in a room results in a quick transient variation of the internal temperature, the paper used a model following the behaviour of the inner temperature. Dexter et al. (1996) described two model-based schemes for detecting and diagnosing faults in HVAC system. The first scheme uses a "first principles" model and a rule-based classifier to identify the faults. The second scheme uses a set of fuzzy models and a classifier based on fuzzy matching for fault diagnosis. Peitsman et al. (1994, 1996) presented a black-box model to build an FDD system for a reciprocating chiller. Wang and Wang (1999) presented a law-based sensor fault diagnosis and validation on a central chiiling system. They use a validated dynamic simulation package to evaluate their FDD method. Peitsman (1997) discusses black-box-model-based diagnosis for real-time systems. The diagnosis tool can perform a fast evaluation of a given situation, provided that conflict detection and diagnosis are both performed on the same level of detail. However, the diagnosis tool lacks some robustness. This is caused by the uncertainty in some of the ARX models. Benouarets et al. (1994), Dexter et al. (1997), Ngo and Dexter (1998) introduce fuzzy reference model-based FDD. It is a semi-qualitative method. The feasibility of FDD based on semi qualitative generic reference models has been demonstrated. No training on the actual plant is needed and the faults in a simulated AHU can be successfully identified. Diagnosis based on generic fuzzy models will be slightly less sensitive than diagnosis based on fuzzy models of an individual design.

Model-based FDD is applied on an office room. The simulation model is first built and validated. (Yu and van Paassen, 2001). The physical model calculates the reference value for the room temperature.

The procedure for model-based FDD system is simply shown as figure 3. The system uses residuals to realize the FDD process. Residuals come from the difference between real system output and model output.

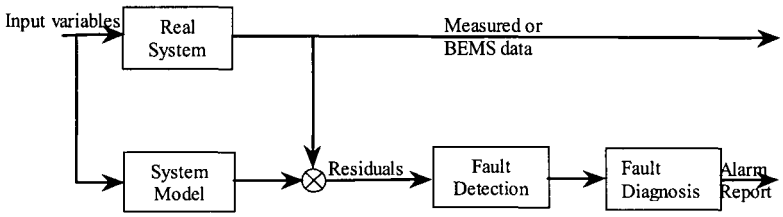

Figure 3: Procedure for model-based FDD system

Two faults are studied on this model-based FDD system. They are: 1) an open window; and 2) a jammed radiator valve. In order to simulate and test the FDD system and physical model, a room is chosen in the office building of the Kropman company in Rijswijk (Netherlands).

SYSTEM ANALYSIS

Modeling Structure

The structure of the model-based FDD for the office room is shown as Figure 4.

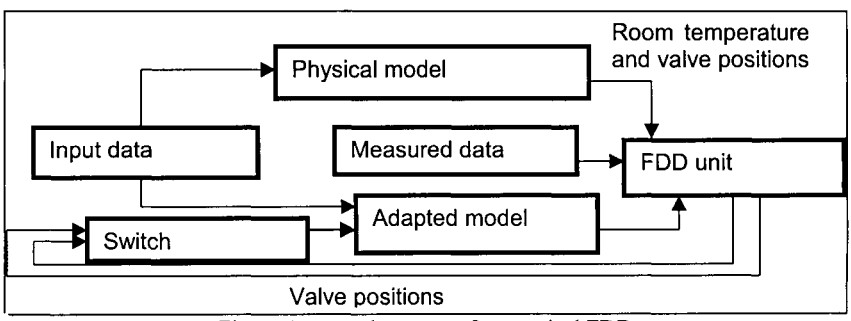

Figure 4: general structure for practical FDD

The components in the stucture are

1. Physical model; predicts the correct room temperature as a result of the dynamic simulation of the thermodynamic behavior of the air in the room.
2. Real state; gives the measured air temperature in the room
3. Adapted model; gives a prediction of the air temperature when the radiator valve jams.
4. Input data; consists of the weather data and technical data from the air-conditioning unit, such as the temperatures of warm and cold water supply.
5. Switch; it has the task, when necessary, to switch over from the theoretical valve position (calculated by physical model), to an estimated valve opening. This happens when FDD suspects the presence of a fault. Doing this, we can simulate a faulty situation

Fault type

With regard to faults in the air temperature, we classify into two types.

1. Fault type I causes an increase in the room temperature.
2. Fault type II causes a drop in the room temperature.

The first step in the FDD process is identifying these two types of faults. The difference has to do with the weather condition, e.g. during a hot summer day an open window results in a fault type I whereas in the wintertime it results in a fault of type II.

In this paper the winter situation with the following two faulty conditions are considered:
1. an open window
2. a jammed radiator valve

Effects of the fault on air temperature

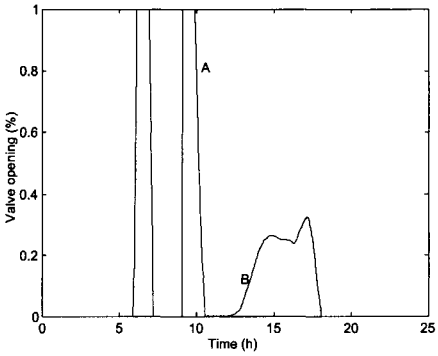

Figure 5: variation of valve opening for one day

For the raditors valve case, the effects are mostly dependent on the direction of the valve movement (closing/ opening). The variation of the valve opening in a workday in November is shown in figure 5.

Points A and B are two points with different characteristics. On point A the valve is closing and on point B the valve is opening. Jamming the valve on point A results in a fault type I and jamming on B results in a fault type II.

With the assumption that during the winter the outside temperature is most of the time below the indoor comfort temperature, it is concluded that an open window will results in a fault type II. The designed FDD component takes account of the type of the fault and activates different criteria.

For the sake of fault detection, information acquired from the measurement plays an important role. In an office building, usually the room temperature is the only measurement, which is directly available for fault detection. Another valuable variable is the output of the controller present in the room. In a faultless situation, it is assumed that the radiator valve position (X) is equal to the normalized value of the output signal (x) from the controller (thermostat), for example, $x = 50\% \Rightarrow X = 0.5$.

X is not a measured value, but a system parameter. Th physical model calculates both room temperature and the output of the controller. The phsysical model creates the diagram in Figure 5. Because of the inaccuracy of the model, some differences arise between calculated room temperature results, $T_{air,model}$ (Tm) and valve position X_{model} (Xm) and their real values of them, $T_{air,real}$ (Tr) and X_{real} (Xr).

$$r\ (\text{residuals}) = (Tr) - (Tm) \tag{1}$$

$$\Delta X = (Xr) - (Xm) \tag{2}$$

Variations of these two variables are shown in figures 6 and 7 for a test period of 11 days on November. Figure 8 shows the variation of Xr for the same day as in figure 5.

Figures 6 and 7 show how the calculated results of Tm and Xm deviate from their real values. Fault detection algorithm should consider these deviations in such a way that fewer false alarms happen. From the result in Figure 4, it can be concluded that the physical model gives a reasonable approximation of the real room temperature. The differences between real and calculated values for

room temperature are mostly limited between ±1 degree Kelvin. In this case, a threshold of 1 degree can be taken to be one indication of a faulty condition.

$$\left.\begin{array}{l} r > 1 \\ r < -1 \end{array}\right\} \quad \text{faulty condition} \tag{4}$$

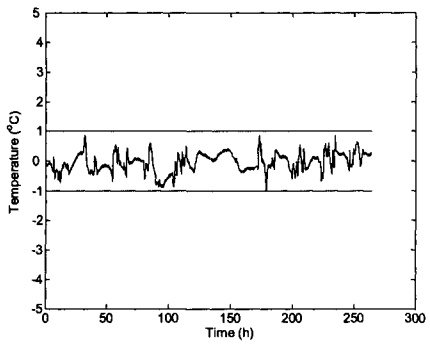

Figure 6: variation of residue during 11 days

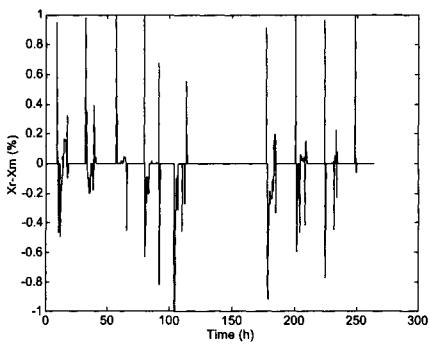

Figure 7: variation of ΔX during 11 days

However, it seems this variable is not a complete detection parameter from the simulation results for the following reasons:

1. Temperature drop caused by an open window could be compensated by an increase in the radiator valve opening.
2. In practice, the threshold to trigger the alarm has to be at least equal to 1.5 degrees. Smaller values of threshold increases the possibility of false alarm due to the natural fluctuation in the room. It is remarkable that the order of magnitude of faults is the same as that due to disturbances.
3. Heat capacity of the walls strongly delays the effect of a fault type II on room temperature.

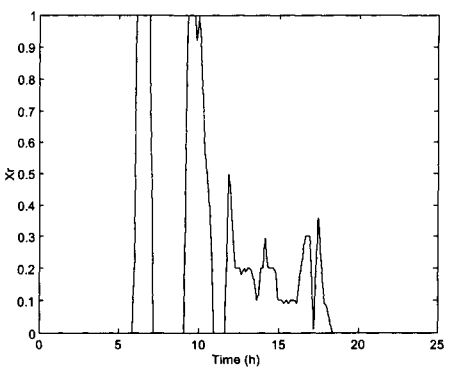

Figure 8: variation of controller output for one day

The simulation results show that only using condition (4) for fault detection will lead to big delays between the occurence of a fault and its detection. This can affect the online character of the FDD system in a bad way. To make the detection happen earlier, another characteristic parameter is needed. This parameter not only uses the r variable as a detection criterion, but also make use of the differences between valve positions calculated by physical model (Xm) and output of the controller in the real condition (Xr). This parameter should be insensitive to the within tolerance deviations between the valve positions. The tolerable deviations are those fluctuations as a result of uncertainties and inaccuracies in the physical model (Figure 5).

FAULT DETECTION ANALYSIS

Type 1:

When a fault occurs which results in a temperature drop in the room (fault type II), the difference

between Xr and Xm or ΔX, will grow quickly. After occurrence of a fault type II the controller tries to compensate for the temperature drop by an increase in the output signal to the radiator. In the mean time the valve position calculated by the model follows a direction leading to the faultless situation. Integration of ΔX over time is considered as one the characteristic parameter. Another variable, which also reflect the effect of fault type II, is the fraction Toutside/Tinside. A temperature drop caused by a fault type II makes the value of the fraction increase. A characteristic parameter which is a combination of above two effect is introduced as:

$$P = \left|\frac{T_{outside}}{T_{inside}}\right| \int |X_r - X_m| \, dt \tag{5}$$

if $|T_{outside}| < 1$, then $\left|\frac{T_{outside}}{T_{inside}}\right| = \left|\frac{1}{T_{inside}}\right|$

The parameter P for a faultless situation is shown in Figure 9. P is made by an integrator, which undergoes a reset every morning at 4 o'clock. Doing this the value of P is set to zero at 4 o'clock every morning. When a fault type II happens, P begins to grow quickly. Passing a limit ε, which P does not exceed in a healthy (faultless) situation, indicates a fault. Figure 10 shows the P values when a window is open with 100m^3/h airflow after 13.5hour.

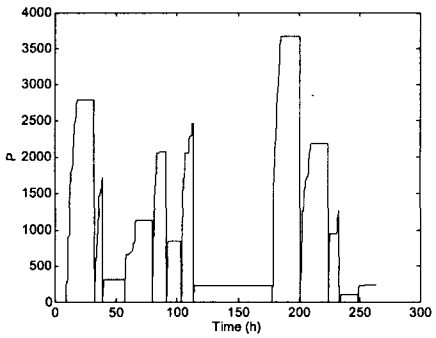

Figure 9: variation of variable P during a test period of 11 days

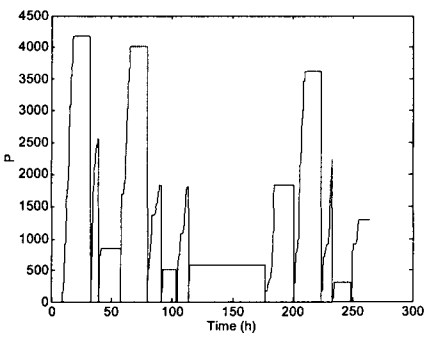

Figure 10: Variation of parameter P when a window open 100m^3/h after 13.5hour

From Figure 9, the cautious threshold is 3500 but this could introduce a longer delay in detection. Choosing a smaller threshold will improve the speed of detection but a lower value enlarges the chance of false alarms. An optimum value for ε is chosen as 3000. Although by this choice the chance of false alarm still exists, we will try to reduce this possibility by using redundant conditions during detection and diagnosis. One of these conditions is the residual of room temperature. When a fault type II arise, the residued (Tr-Tm) is smaller than –0.5 and in the case of a fault type I, it is greater than 0.7 degree. This condition prevents a false alarm on the 8th day of the test period where P>3000.

Type 2:

When the result of a fault is a temperature increase in the room (fault type I), our conclusion can be a jammed radiator valve during getting closing. Detection of a fault type I occurs by establishing a remarkable increase in the residual. Considering the available heat power of the radiators, a (during closing period) jammed radiator valve results almost immediately (1-2 hours) in a increase of more than 1.5 degree in residual. This is the case when the valve position has been bigger than 50%.

When residue reaches a value bigger than 1.5 degree, an alarm report shall occur. It is obvious that in this case, detection and diagnosis happen at the same time.

Type 3:

There is another type II fault which can be detected quickly by the criterion 'residual has crossed the limit of −1.5 degree'.
This is the case when in the early morning the valve refuses to open. Because of the compensation heat from the radiators, this limit can hardly be crossed by another faulty condition, open window.

DIAGNOSIS

A fault type II can be a result of 1) a radiator valve that is jammed during opening; or 2) an open window.

When a fault type II occurs, the characteristic parameter P increases and the detection threshold (ε=3000) will be crossed. The next step is to diagnose of the fault source. Here an open window and a jammed valve are considered as condidates. An adapted model is used to for the diagnosis (Figure 4). This model calculates a fictitious room temperature (Ta), as soon as the variable P crosses the limit of ε = 3000.

When P > 3000, a sample and hold action is started by which the theoretical position of the radiator valve (Xm) gets sampled and held. This value is considered as the manipulated valve position (Xa), which will be sent to the adapted model via the switch. Switch changes from Xm over to Xa when P > ε. The room temperature calculated by adapted model is an indicative temperature for the real case wherein the radiator valve is jammed on (Xr). Because of the delay between the fault arising and crossing the limit of e > 3000, it is not possible to calculate the exact position of the jammed valve by sample and hold. Actually the average of the valve position is used. The average period is 30 min and the estimated Xa is

$$X_a = X_{n+1} = \frac{X_n + X_r}{2} \tag{6}$$

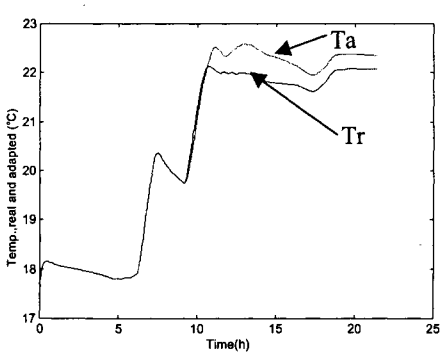

Figure 11: Curve of Treal & Tadapted when a jammed valve fault

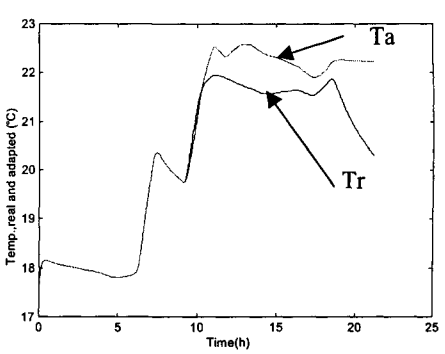

Figure 12: Curve of Treal & Tadapted when a open window fault

By means of the adapted model the faulty behavior of the room temperature as a result of a jammed radiator valve is simulated. Fiugre 11 and Figure 12 are two different results when the P overshot the threshold to indicate a fault.

- When a jammed valve causes a temperature drop in the room, Tr and Ta will develop in a parallel way. This is shown in Figure 11. The shift is due to the difference between Xavr. and Xr. The difference remains smaller than 1 degree.
- When the temperature drop comes from an open window, the difference between Tr and Ta will keep growing as shown in Figure 12. It will continue to grow until it become bigger than 1.5 degree, which results in an alarm.

CONCLUSION

Energy comsumption in office building is growing quickly in recent decades. Faults which appear in a building HVAC system lead to more energy comsumption and worse thermal comfort. Model-based fault detection and diagnosis has been studied for an airconditioned room in one office building. The effects of two types of fault, an open window and a jammed radiator valve, have been explored. A characteristic parameter P which allows for the compensation effect of the radiator and the influence of outside temperature has been presented. When the above two types of fault appear, P can be used as the fault detection criterion and the adapted model is used for the fault diagnosis. The results achieved are good.

The Applications of Solar Heat Transfer & Solar Electricity Transfer in Building

Zhang Wei[1]and Yuan Huizhou[1]

[1] Department of Building Engineering, Shenzhen Polytechnic,
Shahe Road West, Shenzhen, 518055,China

ABSTRACT:

The fossil energy (e.g. fossil oil, natural gas, coal) in the world is limited. It would be unavailable if fossil energy is consumed in the same increasing rate as that of today. In our country, the possession of fossil energy per person is only one-third of its world average, and 95% of energy is imported to the Taiwan area. One of the major environmental problems, at present, is green-house effect in the whole globe, which results from a large amount of carbon dioxide. The more fossil energy is used, the more carbon dioxide is given off. In many cities in North China, the concentration of aerosol is 9.6 times as much as the Acceptable Concentration Level set by the World Health Organization(WHO), and acid rain has been found in many areas. Solar energy is a new power source with a long history, which is characterized by large quantity, easy to obtain, safety, cleanness. Therefore, it has little effect in destroying the ecology balance. Thus world exploitation and utilization of solar energy is an urgent solution to the green-house problem. Solar energy can be used in many fields, including such as in electric power generation, but still today there is relatively mature commercial technology usage except in solar heat transfer. Consequently, this paper inquires into not only solar heat transfer but solar electricity transfer.

KEYWORDS:

ONE: CONTEMPORARY APPLICATION IN SOLAR HEAT TRANSFER

As solar energy research & utilization is taken seriously by international society , in the National

Development Planning Program of 1995-2010 for new energy and heat reuse applications , China raised a government policy of " enterprise should be up to a larger scale; technology should be up to higher level; quality should be up to higher grade and market should be up to better standards." Since 1987, when Professor Yin Zhiqiang, of Tsinghua University, obtained the vacuum heat-transfer tube patent, the quality and technology level of our solar products have reached international advanced level. The solar heater industry has become a new business with good prospects.

In the mainland, the number of solar heaters is about ten million, family utilization ratio is 4%, among which Yunnan has more than 20%. Our solar heater products are of the full-automatic type, hold-pressure type, balcony-hanging style and slope-roof style since 1992. They are also exported to Japan, Korea, Singapore, Malaysia and other places. During the six years from 1985 to 1992, the method of reward was carried out in order to popularize solar heating systems. During these years, the area of solar heat collector in use was increased with 80,000 m^2 in 1992 compared with 40,000 m^2 to 50,000 m^2 for earlier years, furthermore, the figure was over 90,000 m^2 in 1995. During these more than ten years, the total output value for solar heaters was up to nearly $10,000,000,000, the total area of heat collector was as much as 870,000 m^2 and the utilization ratio was about 3.1%. Hence thousands of employment opportunities were created in the solar industry.

As indicated in table 1-1, the total area of heat collector in the mainland and Taiwan still has large latent capacity compared with that of relative advanced nations and states. In Taiwan, the area of installed heat collector system (both family heater and industry heater) is up to 18,000,000 m^2. It is estimated that 116,300 equivalent litres of fossil energy has been saved every year and 4204,000 tons less of carbon dioxide has been output.

TWO:PRINCIPLES AND INTEGRATED SYSTEM OF SOLAR-HEAT TRANSFER & SOLAR ELECTRICITY TRANSFER

Put simply, the principle of solar-heat transfer is to collect heat through a heat collector and conducting that heat to water. The system is mainly made up of a heat collector, a hot-water box, a auto-controlled auxiliary calorifier and a temperature-control pump.(See Fig 2-1)

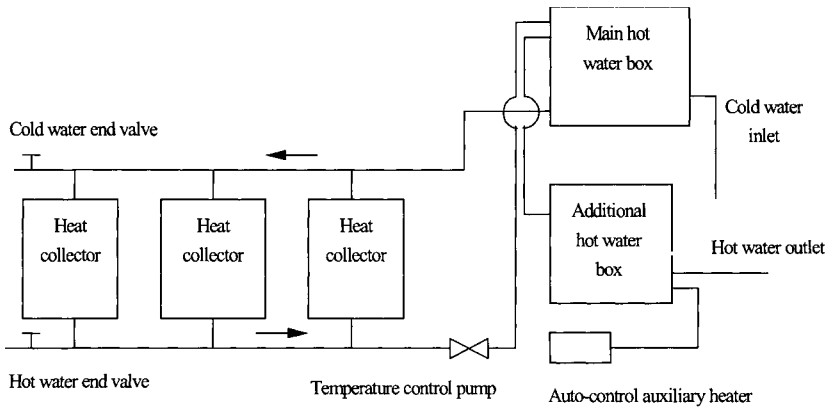

Figure 2-1 The principle of solar heat transfer

The heat collector is in the core position and the key technology of solar-heat transfer. It can be divided into the flat style and the vacuum tube style according to the difference of structure.(See Fig 2-2 and Fig 2-3). The flat style is composed of many copper-aluminum cores, characterized by simple manufacture and with low cost of construction. However, with low outside temperature, when the heat collected by the copper plate is conducted to water, part of the heat is lost to air. Therefore, the heat efficiency drops in the cold season. The outside tube is high of boron-silica glass which can resist heat and can resist hail stones. The inside tube is glass or metal. The exterior of the inside tube is made by a magnetron spatter vacuum plating process, the plating having a higher absorption rate and lower radiation rate. The reflection plate is able to gather solar energy between the tubes. Thus the solar utilization ratio is improved. The temperature of the tubes can be raised to over 200°C when they are exposed to the sun without water. The temperature of water in box can go up to 70°C-90°C, the average thermal efficiency is over 40% and the heat dissipation value is below 3 $W/m^2 \cdot °C$.

There is a temperature controller in the auto-controlled auxiliary heater. When the temperature of hot water is below the demand on a cloudy day or rainy day, the auto-controlled auxiliary heater will heat water in the box, in the usual way with electricity, liquefied gas or diesel oil. Which way is used depends on the customer's circumstances.

The temperature-control pump will open automatically when the temperature of water on one side of the heat-collector is higher than that of the hot water box, the water is pumped into the water box from the heat-collector, and so the water's temperature in the box is rising. This cycling will not be stopped until the temperatures of the two sides are equal.

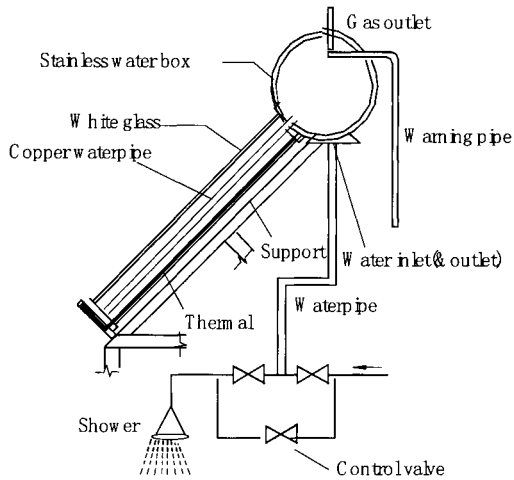

Figure 2-2 Flat style solar collector

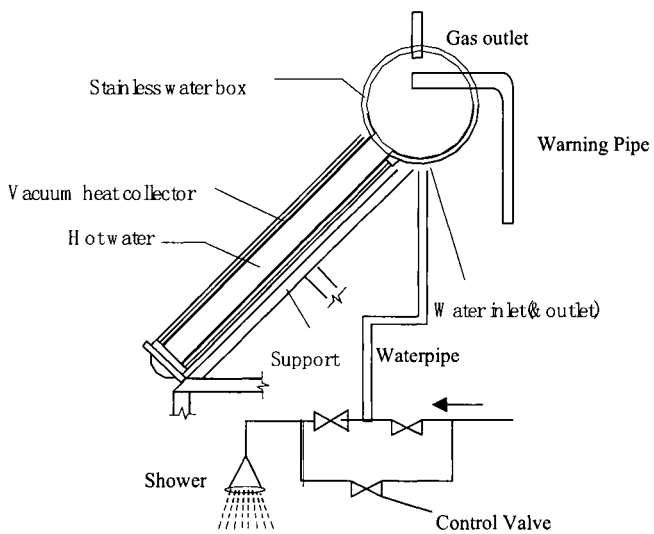

Figure 2-3 Vacuum tube style solar collector

The solar battery was invented in 1954 by an American scientist, Pearson et al.. At first America used it to power an artificial satellite, Vanguard. At that time, because it was very expensive, it was limited to sea-islands or remote places where laying a cable was really difficult. Then, along with the invention of non-crystal solar battery, it became possible for solar energy to generate electricity in building.

The solar battery uses the principle of photoelectricity. An electron is created when the surface of a

semiconductor is subjected to solar radiation. Described in more detail, the solar batter contains overlay P-model semiconductors and N-model semiconductors. This combination will create negative electrons and positive electrons when radiated. The negative electron is absorbed by its N-model semiconductor and the positive by its P-model and a voltage comes into being between the two surfaces of those two kinds of semiconductor. The current emerges when they are wire connected.

Several kinds of semiconductors are used in producing solar batteries, the most common is silicon, the rest are cadmium sulphide, gallium arsenide, etc. If a silicon semiconductor is employed, it can be made into a monocrystal, polycrystal and non-crystal by different manufacture methods.

Solar electricity is coming in at a high level and a large scale, among which PV technology applications are the main popular aera at present. From the report of the international energy institution, solar building will become the most important new industry. As to integrating buildings and PV, the Building Integrating PV(BIPV) can be divided into two kinds: one is a PV system integrating building, the other is a PV device integrating building. These two kinds have their own characteristics respectively.

THREE:EXAMPLES IN ENGINEERING

One college in Shenzhen has ten student-dormitories(500 students in each). These buildings adopted solar-heat systems of the copper-aluminia flat style. The design hot water consumption is 50 kiloliters per student every day. According to the meteorological data of Shenzhen in the last ten years, the sunny days are 210 a year, while the cloudy days and rainy days are only 155 per year. On a sunny day, one square meter of heat-collector can heat at least 100 kiloliters water from 20°C to 50°C. If it was done by liquefied gas, it would consume 0.3 kilograms and give off 0.9 kilograms carbon dioxide. The cost of construction and the discharged volume of carbon dioxide by solar and liquefied gas each dormitory are reported in table 3-1.

TABLE 3-1
THE COMPARISON OF THE COST OF CONSTRUCTION

	Solar collector area(Water heater)	Unit price (YuanRMB)	Cost of equipement($\times 10^4$Yuan RMB)	Operation cost per year ($\times 10^4$Yuan RMB)	Amount of carbon dioxide discharge(Tons)	Total cost(equipemeng and operation 15years) ($\times 10^4$ Yuan RMB)
Solar	250 (m^2)	1000	25	1	0	40
Liquefied gas	100	2000	20	3	47.25	65

As table 3-1 indicates, the primary cost of a solar system(about 250,000 Yuan RMB) is a little higher than that of a liquefied gas system(about 200,000 Yuan RMB), but if calculated over 15 years, the former's total cost for ten dormitories will be 2,500,000 Yuan RMB less than the latter's, and what is more, the solar system will not discharge 472.5 tons carbon dioxide a year, favourable to reducing the green-house effect.

FOUR: PROBLEMS TO SOLVE

Even though solar-heat transfer has been applied widely, there are still some problems to be solved urgently:

1.There are many enterprises in this industry, but there are less than 10 enterprises with a large scale production and over 50,000,000 Yuan RMB output value a year. However, there are over 500 enterprises whose output is less than 1,000,000 Yuan RMB. Accordingly, there are too many products varieties and this is not good for establishing a good service system.

2.The government must build up products test centers and in addition work out product quality levels and engineering acceptance quality regulations, which will enhance enterprise healthy development.

3.During the design of most buildings, the solar-heat systems are not considered as an integral part of the buildings, but are only treated as equipments for later installation. Thus the installation of solar-heat systems will damage the construction of the building outside to some extent. If installed on a roof, it may cause the roof to leak. Therefore, it is important that architects understand the nature of solar-heat systems, which will lead them to consider their standard water proofing integration during the design.(for example, for protection of a balcony, the heat conservation of a roof, etc) This also will lead to installing the solar systems more extensively in a building.

4.Need legislation. It is necessary that solar systems should be designed and installed compulsorily as part of residential architecture for the purpose of reducing carbon dioxide discharge.

CONCLUSION

Along with the appearance of higher efficiency vacuum heat tubes and the usage of auto-controlled auxiliary calorifiers, solar-heat transfer systems can be used in practice on a large scale. This is not only technologically feasibile, but brings better economic benefits than conventional fossil energy systems. The most important additional function is reduction CO_2 discharge. Energy is in short supply in the mainland, especially electricity. At present, over 20 countries still have no electricity supply, where many people live. Taiwan is so short of energy that over 95% is imported, which not only consumes a large amount of foreign exchange but also affects the economy stability. We have abundant solar resources for two-third of the area with sunshine for over 2000 hours a year and the amount of radiation is also over 5,020,000 KJ/m^2 a year. The development and utilization of solar energy not only reduces the green-house effect but also reduces the energy gap between supply and demand. It is beneficial to both the economy and the environment protection if the cleanness of solar energy is widely used, the legislation is strengthened by government, and the quality of solar products and their installation quality are supervised.

INTUMESCENT FIRE PROTECTION COATING THICKNESS FOR SHALLOW FLOOR BEAMS

W. Sha and T. M. Chan

Metals Research Group, School of Civil Engineering, The Queen's University of Belfast, Belfast BT7 1NN, UK

ABSTRACT

To design for fire protection required for universal beams and columns the British Standard provides a formula relating the protection thickness to section factors, thermal conductivity, fire resistance and limiting temperature. However, this formula does not apply to the shallow floor beams, which are almost totally contained within the concrete slab. This paper is to derive an alternative relationship for determining the thickness of intumescent fire protection coating required for shallow floor beams, using existing fire test data. The results clearly show that the required thickness of fire protection to the shallow floor beams is thinner than to the regular steel beams. The formula derived can be used for quick, simple design calculation for the required thickness of fire protection. For safety reason in design there should be a safety factor used in conjunction with the formula. The analysis based on fire test data is supplemented with calculations based on beam temperature obtained from heat transfer models.

KEYWORDS

Intumescent coating, fire protection, shallow floor, fire engineering, fire test, asymmetric beam, thermoconductivity, steel structure, section factor.

INTRODUCTION

Providing adequate fire protection to steel structure (columns and beams) is the traditional way to prevent failure and to ensure that the structural steel member can meet the required fire resistance standard. The most common types of fire protection in building structures are board protection, concrete encasement and intumescent coating. However, these protections can increase the cost of construction by about 50% of the structural section member and the depth of the section by up to some 6-cm [Todd (1996)]. Sometimes different types of fire protection can be used together to achieve a better fire resistance.

The development of shallow floor construction is an excellent example of the use together of different concepts of fire protection to give a better performance of fire resistance. In this type of construction,

a beam is contained almost totally within the depth of a concrete floor. Only the bottom flange or a plate welded to the bottom flange is exposed outside of the concrete floor. Therefore, intumescent coating can be applied on the exposure area at the bottom flange.

In the recent years, Corus (formerly British Steel) with the collaboration of the Steel Construction Institute (SCI) in England has developed two types of new shallow floor beams, the fabricated SLIMFLOR beam and the ASYMMETRIC SLIMFLOR beam. In addition, TOPHAT beam was developed in Scandinavia [Sha (1997a,b), (1998), (2001), Sha & Lau (2001), Ngu (1999)].

Shallow floor construction provides a solid, flat-slab appearance similar to reinforced concrete construction. The fabricated SLIMFLOR beam is based on a Universal Column section, with a single horizontal plate welded to its bottom flange, shown in Figure 1. The ASYMMETRIC SLIMFLOR beam (ASB) does not require welding of an additional plate and achieves optimum properties for design. The TOPHAT beam is formed by four plates welded together to make a shape like a hat. The floor can be constructed of pre-cast concrete units or long span composite slabs with deep profiled steel decks.

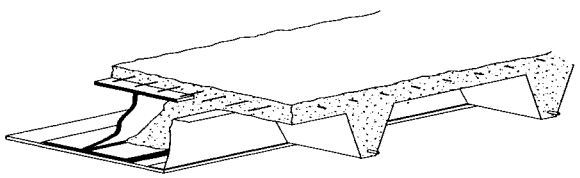

Figure 1: Fabricated Slimflor beam

Because the beams are almost totally contained within the floor slab, they have inherently good performance in fire and in most cases can achieve 60 minutes fire resistance without applied protection. However, if the fire resistance requirement is more than 60 minutes then protection must be applied to the bottom plate. Thin film intumescent coatings are ideal in this respect because they add a negligible amount to the depth of the section. Typically, thickness of about 1 mm is used for protecting conventional steelwork. For shallow floor beams, the required thickness is expected to be lower due to the intrinsically good fire resistance of the construction.

In the British Standard, a formula is given to calculate the required thickness of fire protection to regular steel section depending on the fire resistance rating and on the limiting temperature of the member. However, this formula does not apply to the three new shallow floor beams. The aim of this work is to derive a new formula to calculate the required thickness of fire protection for the new shallow floor beams from fire test data.

Intumescent coatings are paint-like materials which are inert at normal temperature but, when subjected to heat, swell to form an insulating char, stable over a limited period of time in fire conditions. Their thermoconductivity value varies with temperature, and is estimated at around 0.5 W/m°C. These materials provide thermal protection to the underlying surface through the absorption of heat by endothermic chemical reactions and through the insulating properties of the final char [Butler (1997)]. The two commonly used intumescent coatings manufactured by Nullifire Ltd., England are S605 and S607. S605 has been marketed by Nullifire for a number of years and is a hydrocarbon solvent-based system. It contains 10–25% xylene, 2.5–10% C9 alkylbenzenes and 50–75% proprietary resins, pigments and fillers. It has been fully assessed for conventional beams and columns using the procedures of the Association of Specialist Fire Protection (ASFP) [Fire (1992)]. Specifically, it has been fire tested utilising structural sections after extensive accelerated and natural ageing. The assessment of S605 for shallow floor systems can therefore gain confidence from the

earlier assessment. S607 is a newer water based product developed from S605. Is contains proprietary resins, water and fillers. It does not have the same level of test evidence on conventional steelwork to support the assessment but it has been tested in Norway on a shallow floor system and performed in a very similar manner.

PROCEDURE

The three types of shallow floor beams used in previous fire tests are the Slimflor beam, Asymmetric Slimflor beam and Top-Hat beam. By using the previous fire tests result data [Sha (1997a,b), Sha & Lau (2001), Ngu (1999)] a formula can be derived to calculate the required thickness of fire protection for these beams. The previous fire tests data include the sizes of the shallow floor beams tested, the coating thickness, the testing time and the temperatures measured at the bottom flange or at the plate welded to the bottom flange. The important data from the fire tests are shown in Table 1. This contains all the fire test data.

TABLE 1
FIRE TEST DATA FOR THE FIVE TESTS AT NULLIFIRE, THREE TESTS AT SINTEF AND THE WARRINGTON TEST

Beam	H_p (m)	A (m^2)	Coating	Thickness (mm)	Temperature (°C)		
					60 min	90 min	120 min
Slimflor	0.436	0.01372	S607	0.166	687	802	903
	0.436	0.01372	S605	0.343	559	714	818

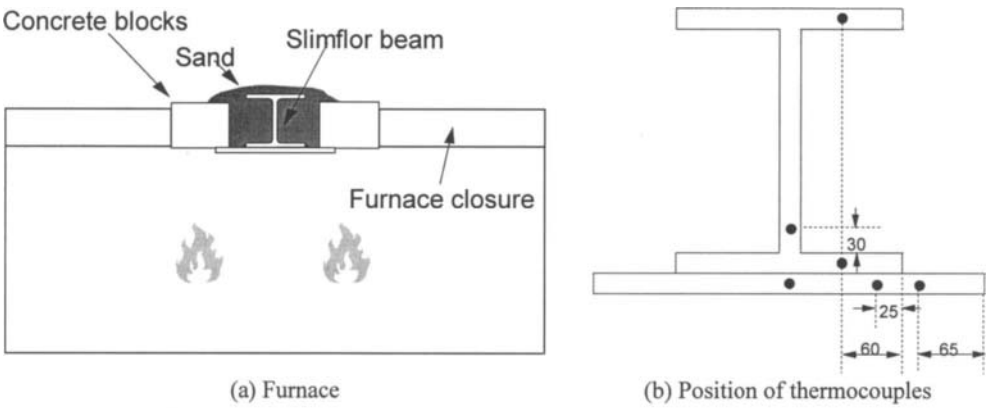
ASB	0.316	0.01267	S605	0.285	469	630	717
	0.316	0.01267	S605	0.774	-	462	587
Top-Hat	0.470	0.01104	S607	0.179	721	823	915
	0.470	0.01104	S607	0.179	718	811	868
	0.470	0.01104	S607	0.537	532	673	747
	0.420	0.00893	S607	0.418	-	-	800

Nullifire Ltd. carried out fire tests on four unloaded Slimflor beams and a Top-Hat beam protected using S605 and S607 intumescent coatings manufactured by the same company. The test furnace was approximately 1-m cube. Protection was only applied on the plate welded to the bottom flange (Slimflor) or the bottom flange (Top-Hat). This was directly exposed to fire and the rest of the section was buried in sand, Figure 2 [Sha (1997a), Sha & Lau (2001)]. Temperatures were measured along the beams at two sections, each approximately one third of the exposed beam length (approximately 1 metre) from the end of the beams. "K" type thermocouples were used, with a diameter of 1.5 mm, in a sheath. The variation in the coating thickness was within about 7.5 μm.

In Table 1 the last three Top-Hat beams were tested at Norwegian Fire Research Laboratory (SINTEF) [Task (1993)]. All tested Top-Hat beams have a lower-flange thickness of 10 mm. The bottom face of the beams was protected using the S607 intumescent coating. The furnace temperature was measured with thermocouples of shielded type as described in Figure 4 of International Maritime Organization

(IMO) Resolution A.754 (18) Section 7.2.1 [FTP (1998)]. The diameter of the thermocouples was 6 mm.



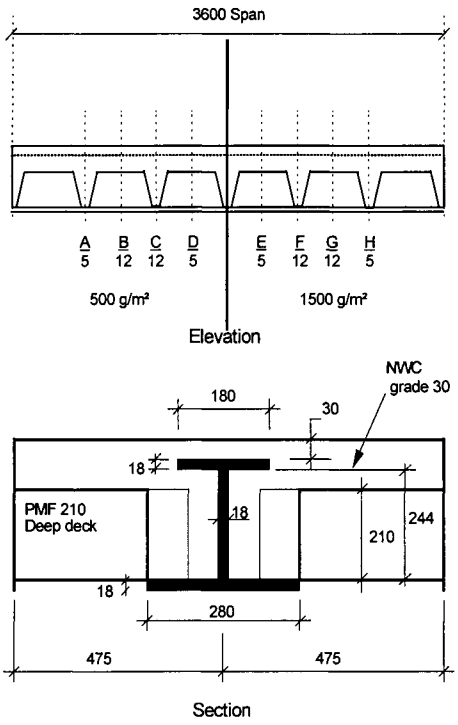


Figure 2: Test at Nullifire Ltd.

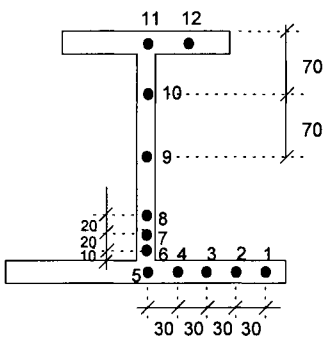

An unloaded asymmetric Slimflor beams was tested at Warrington Fire Research Centre, England. The bottom face of the beams was protected using the S605 intumescent coating. In the test, only the bottom flange was directly exposed to fire, and the rest of the section was surrounded by concrete. Half of the beam on the left-hand side was coated with a relatively thin layer of S605 coating, at a density of 500 g/m^2 (thickness = 0.285 mm). The coating for the right-hand side was relatively thick, 1500 g/m^2 (thickness = 0.774 mm). The furnace at Warrington Fire Research Centre was much larger than the one used in Nullifire Ltd. The furnace was 3.6 m long and 0.95 m wide. Figure 3 shows the elevation and section views of the test assembly [Sha (1997b)]. 3 mm diameter mineral insulated "K" type thermocouples, Ni-Cr/Ni-Al, with insulated hot junctions and Inconel sheaths were used. The Warrington data were also used in the paper (Table 1), undistinguished from the Nullifire data. It is difficult to directly compare the results with the tests at Nullifire in a smaller furnace as the beams were different, but earlier work has demonstrated that tests at the two laboratories give comparable outcome [Sha (2001a)].

As mentioned above, these beams are almost contained within the floor slab. They have very good performance in fire and in most cases can achieve 60 minutes fire resistance without applied protection. For more than 60 minutes fire resistance, protection must be applied to the bottom flange or the plate welded to the bottom flange. Therefore the fire test data at 60 minutes are not used for this paper.

The required thickness of fire protection to the steel section depends on the rate of heating of the section and on the limiting temperature of the member. For enclosed members with box or profile protection the heat flow depends on the section factor (H_p/A) of the member and on the properties of the fire protection material. The introduction of the section factor concept enables a broader use of fire test data to be made, leading to economy while maintaining the required performance standard. A steel section with a large perimeter (H_p) will receive more heat than one with a smaller perimeter. In addition, the greater the cross-sectional area (A) of the section, the greater is the heat sink. It follows therefore that the increase in temperature for a small thick section will be slower than for a large thin one. Section factor is thus a measure of the rate at which a section will heat up in a fire. The higher its value the greater will be the protection thickness required.

(a) Elevation and section views

(b) Position of thermocouples

Figure 3: The ASB test beam

According to BS 5950: Part 8, the thickness of fire protection for the regular beams, d_i, is determined from the formula [Newman & Lawson (1991)]:

$$d_i = (H_p/A)\,\lambda_i\,[t_e/(40(\theta_s - 140))]^{1.3}\,F_w \qquad (1)$$

where λ_i = thermal conductivity of the fire protection material; t_e = fire resistance (min); θ_s = limiting temperature of the section; F_w = modification factor (<1) due to the density of the protection material; H_p = perimeter of section exposed to fire (m); and A = cross sectional area of the steel member (m^2).

Because the shallow floor beams have a different cross sectional shape compared to the regular steel section the thickness of fire protection required might be different from what is obtained using the above formula. To derive the formula for shallow floor beams the first task is to calculate the section factors of the shallow floor beams used in the previous fire tests. Now rearranging the formula like the following:

$$d_i/(H_p/A) = \lambda_i [t_e/(40(\theta_s - 140))]^{1.3} F_w \quad (2)$$

As the d_i, H_p, A, θ_s and t_e are known the plot of $d_i/(H_p/A)$ against $[t_e/(\theta_s - 140)]^{1.3}$ should yield a linear relationship. θ_s is the section temperature measured at time t_e in the fire test, t_e being 90 and 120 minutes. The values of these and the other parameters are listed in Table 1. From this the combined coefficients of λ_i, F_w and $40^{-1.3}$ can be found.

RESULTS AND DISCUSSION

Table 1 includes the values of d_i, H_p and A calculated with the beam condition used in the fire tests. Figure 4 shows the graph of $d_i/(H_p/A)$ against $[t_e/(\theta_s - 140)]^{1.3}$. The 19 data points in the figure are from the 19 temperature values in the last two columns of Table 1. It may be noted that in the last row of Table 1, there is no datum collected in the fire test corresponding to 90 minutes, resulting in the odd number of the total data points. Both coatings, from the three test facilities, are shown in the figure, as little difference was found in their performance. The figure also displays a best-fit line, which has a coefficient of determination (R^2) of 0.89. As mentioned before, these shallow floor beams are almost contained within the floor slab. They have very good performance in fire and in most cases can achieve 60 minutes fire resistance without applied protection. The graph in Figure 4 only includes the values of $d_i/(H_p/A)$ plotted against the values of $[t_e/(\theta_s - 140)]^{1.3}$ at 90 and 120 minutes fire resistance. The equation for the best-fit line represents the required thickness of fire protection to the shallow floor beams:

$$d_i/(H_p/A) = 0.263 [t_e/(\theta_s - 140)]^{1.3} - 0.016 \quad (3)$$

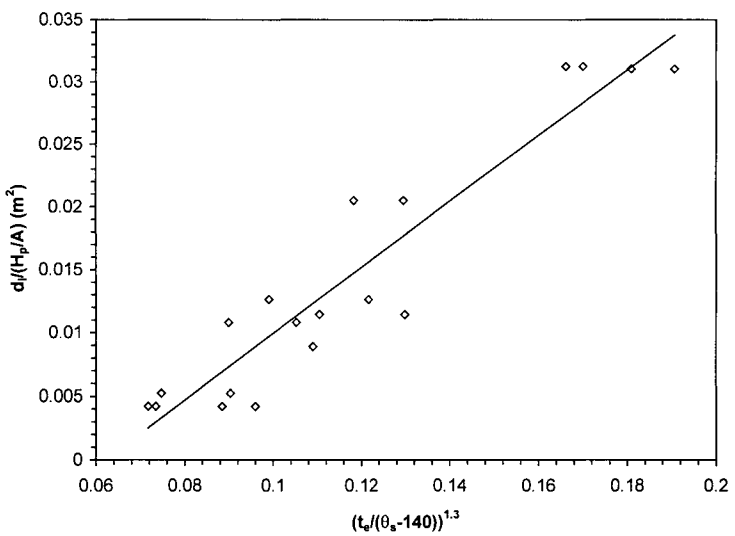

Figure 4: $d_i/(H_p/A)$ against $[t_e/(\theta_s - 140)]^{1.3}$ from fire test data

Obviously the combined coefficients of λ_i, F_w and $40^{-1.3}$ are represented in 0.263. The significant difference between this formula and the original formula for the regular section (Eqns. 1 and 2) is that this formula has a negative constant (–0.016) added into it. This indicates that the required thickness of fire protection for the shallow floor beams is thinner than for the regular steel beams. This formula is useful for the engineers for quick determination of the required thickness of fire protection.

The steel temperatures at various parts of a shallow floor beam can also be calculated from heat transfer models [Sha (2001b)]. This was carried out with a Slimflor beam of the same dimension as used in the fire tests [Sha & Lau (2001)]. Figure 5 shows the calculation results, in the form of the plot of $d_i/(H_p/A)$ versus $[t_e/(\theta_s - 140)]^{1.3}$. The thermoconductivity of the intumescent coating used in the calculations was 420 W/m°C. The typical variance in the thermal conductivity (λ) of steel is included in the program, in the form of $\lambda = 54 - 0.033\ (T - 20)$ where T is the steel temperature in Celsius. When T is greater than 829°C, λ remains at 27.3 W/m°C. The relationship between $d_i/(H_p/A)$ and $[t_e/(\theta_s - 140)]^{1.3}$ for plate is:

$$d_i/(H_p/A) = 0.186\ [t_e/(\theta_s - 140)]^{1.3} - 0.021 \tag{4}$$

and for flange:

$$d_i/(H_p/A) = 0.345\ [t_e/(\theta_s - 140)]^{1.3} - 0.031 \tag{5}$$

The coefficients of determination (R^2) are 0.9997 and 0.995 for plate and flange, respectively. The value 140, embedded in Eqns. 4 and 5, is an assumption.

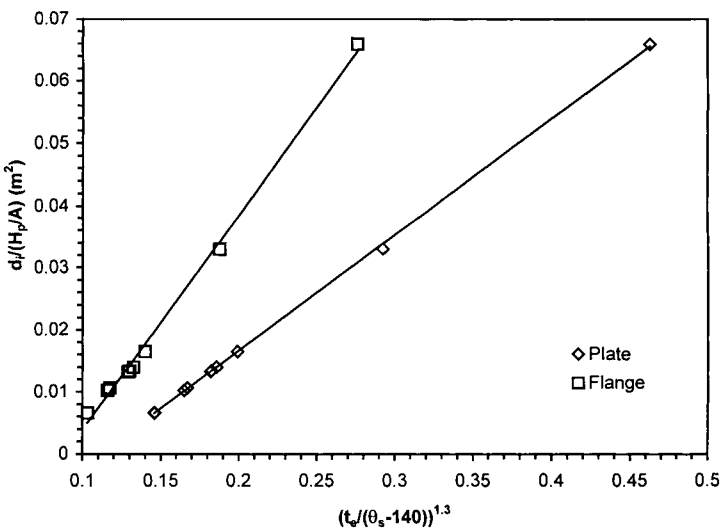

Figure 5: $d_i/(H_p/A)$ against $[t_e/(\theta_s - 140)]^{1.3}$ from heat transfer model calculation

SUMMARY

From fire test data the required thickness of intumescent coating for fire protection of shallow floor beams is derived. The thickness is thinner than for regular steel beams because of a negative constant. The formula can be used for quick, simple design calculation for the required thickness of fire protection. For design purposes there should be a safety factor used in conjunction with the formula.

THE AIRFLOW AROUND AND INSIDE HIGH-RISE RESIDENTIAL BUILDINGS IN HONG KONG

Bojic, M., Yik, F., Burnett, J.,

Research Centre for Building Environmental Performance, Department of Building Services Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong SAR, China

ABSTRACT

The airflow around and inside high-rise residential buildings in Hong Kong has been studied, with focus put on four major aspects: pedestrian wind environment, air-conditioner heat rejection, natural ventilation, and indoor air movement. The pedestrian wind studies showed that CFD simulation is an appropriate and effective method essential to designs of estate layouts to avoid excessive wind amplification and stagnant regions. The heat rejection studies showed that the dimension of recessed spaces should be checked taking account of the positions of window-type air conditioners and the amount of the rejected heat to avoid energy wastage and cooling capacity loss. Methods have been proposed to mitigate the problem. The natural ventilation studies assessed availability of natural ventilation in a typical building design. The indoor air movement studies looked into the impacts of the installed location of a window-type air conditioner on the indoor air movement pattern and thermal comfort of occupants.

KEYWORDS

CFD, pedestrian wind, recessed spaces, air-conditioner performance, natural ventilation, indoor air movement

INTRODUCTION

Good environmental performance of high-rise residential buildings is of vital importance to Hong Kong because an enormous number of residential units already exist and tens of thousands of new units are developed each year. To enhance their performance, we should evaluate and improve new designs of rooms, flats, entire buildings, and entire estates. The Hong Kong Building Environmental Assessment Method (HK-BEAM), which is a voluntary assessment scheme available in Hong Kong, provides good practice guides, including a list of issues of importance and benchmarks of building environmental performance (BEC, 1999). Research studies are ongoing in support of further development and enhancement of these guidelines, and to provide advice on improved new designs to ensure good thermal comfort and air quality inside and outside the residences, and to minimise adverse impacts on the environment in the global, local and indoor scales.

One of the major areas being pursued has been on the airflow around and inside high-rise residential buildings. The study on indoor and outdoor airflows were performed primarily using computational fluid dynamics (CFD) simulation, with the use of software packages such as FLUENT 5.0, FLOVENT, and a multi-zone airflow model COMIS. The research studies on airflow around buildings concerned with wind flow within an entire estate and the buoyant flow inside recessed spaces immediately outside high-rise buildings due to heat rejection by air conditioners. The aims of the studies include to ensure comfort of pedestrians and users of amenities; and to minimise impact of the confined recessed space on the electricity consumption of air conditioners. Research has also been done on airflow inside buildings, looking into utilisation of natural ventilation in residences for enhancing indoor air quality and minimising energy use for comfort control, and into airflow inside rooms for enhancing thermal comfort. This paper reviews these studies, summarizing their results, drawing some conclusions, and giving recommendations for their use in practice. For details of these studies and applied techniques, the reader is directed to recent papers dealing with specific topics.

FLOW AROUD A BUILDING

Airflow on Pedestrian Level (Lee, 2001)

Wind induced airflow within an estate on the pedestrian level should provide pedestrians and users of amenities with both thermal comfort and quality air. When channelled to flow around a group of buildings, the wind will accelerate or decelerate to an extent that depends on the layout of building blocks in the estate and the shape of the buildings. High wind speeds cause thermal discomfort to pedestrians and in the extreme cases could be dangerous to them whereas stagnant air causes pollution problem and deposition of debris in amenities areas.

The results of the CFD study on an existing high-rise estate in Tseung Kwan O of Hong Kong are presented here (Lee, 2001). The estate is shown in Fig. 1. In the CFD study, the flow was computed by using roughly 500,000 cells in the 3D meshes (shown in Fig.2). Then, the software FLUENT 5.0 was used in conjunction with the standard k-ε model. The velocity vectors and wind amplification factor distributions for the case with Northeasterly wind on the horizontal plane 2m above ground, as obtained from the CFD simulation, are shown in Fig.3 and Fig. 4. With these results, areas exposed to high and low-speed wind can be clearly seen. These CFD predictions agreed well with the results from an erosion test in a wind tunnel (CU, 2000). They also agreed in an order of magnitude with measurements at the actual site. Note, that the boundary conditions set at CFD simulations were the same as that set in the wind tunnel.

Air-Conditioner Heat Rejection in Recessed Spaces (Bojic et al, 2001a&b, 2002 a-f)

The heat discharged by condenser units of window-type air conditioners into a recessed space may lead to excessive use of electricity by air conditioners at higher levels, which should be avoided. Some typical locations of these air conditioners inside the recessed spaces are shown schematically in Fig.5. A photo of one recessed space containing four window-type air-conditioners per storey is shown in Fig.6. The CFD code FLUENT 5.0 and the k-ε model were used to predict the temperature and flow fields inside different recessed spaces. The results show that there would be powerful rising hot air streams inside these spaces. A velocity field on a horizontal plane inside the recessed space is shown in Fig.7. This figure has been selected as the cover page figure for the journal *Energy and Buildings*. The velocity and temperature field on a vertical plane is shown in Fig.8.

The effects of varying the height (Bojic et al, 2001a), depth (Bojic et al, 2002a), locations of air conditioners (Bojic et al, 2001a), and the amount of rejected heat (Bojic et al, 2002a,b) in a recessed

space were studied. The results show that condenser units of air-conditioners at the top levels would draw less air at an elevated temperature, and, therefore, would consume much more electricity than

Figure 1: Tseung Kwan O Site

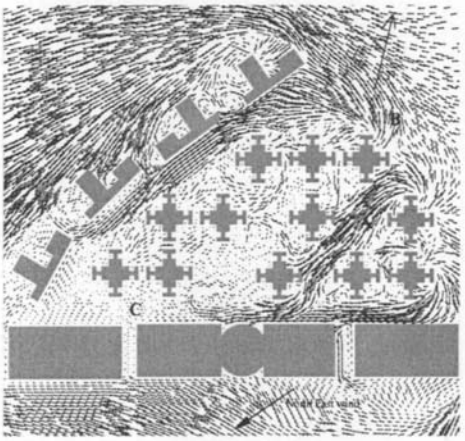

Figure 3: The velocity vector plot based on the CFD results of a 3D simulation.

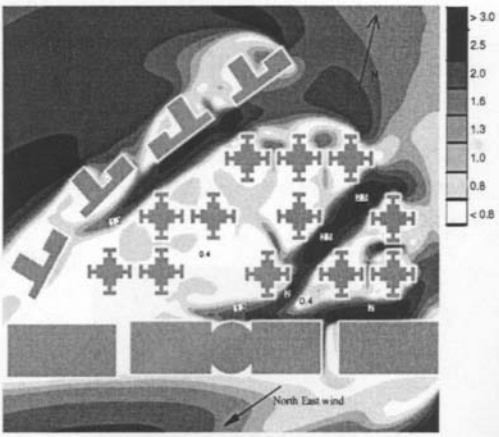

Figure 4: The contour of the wind amplification factor predicted by a 3D simulation.

they should, and would at the same time suffer from reduced output capacity. The energy consumption of the topmost units could be reduced by around 10% with a reduction in the height of the recessed space by five stories, or a reduction in the rejected heat by 5%, or an increase in the air conditioner distance from the corner wall by 1.1m. However, the energy consumption would not change with a variation in the depth of the recessed space.

Furthermore, the provision of horizontal plates inside the recessed space has been proposed as a mitigation measure, which would divert the hot air plume from below to flow outside the recessed space and thus allow air-conditioners above the plate to draw in cool outdoor air for condenser heat removal. The effects of installing one plate (Bojic et al, 2002c) and several plates (Bojic et al, 20002d) have been studied. Provision of one plate inside the recessed space would on average lower the electricity consumption of the topmost air conditioners by 15%, and provision of two plates by 48%. These results would inform design for the avoidance of excessive use of electricity by air conditioners in recessed spaces.

FLOW INSIDE A BUILDING

Natural Ventilation (Chan, 2001)

Ventilation provision in residential units is essential, for dilution of indoor air pollutants, such as radon, odours, and moisture, so as to ensure acceptable indoor air quality. For minimising the

associated energy use, sufficient ventilation should, as far as possible, be achieved by natural ventilation, although mechanical ventilation or air-conditioning would still be required for quick purging of pollutants at high concentration levels or for thermal comfort control in hot summer days.

As an example, the result of applying the multi-cell airflow simulation program COMIS to modelling the airflows in the flats on one floor of a typical residential building is presented here. This study was performed for summer and winter and for several wind speeds that may be expected at the building site. The floor plan of the studied building is shown in Fig. 9. Wind pressure coefficients were first determined from a CFD simulation of the outdoor airflow using FLUENT, as shown in Fig. 10. The air movements between indoors and outdoors and from room to room inside the flats on the 10^{th} floor of the building, as predicted by COMIS, are shown in Fig. 9. The result shown was pertaining to a wind speed of 4m/s and an indoor/outdoor temperature difference of 12°C. The result shows that in the four building wings, Flats 3 and 4 would enjoy good natural ventilation, while Flats 1 and 2 would be poorly ventilated. However, Flats 3 and 4 of wings A and B would have ventilation air ingression from the lobby, which would not be fresh outdoor air but could have already been partially polluted as the air passed through other flats.

The COMIS simulation results also allowed the cumulative time of occurrence of various rates of infiltration in a room to be determined. Fig. 11 shows the result for one of the living rooms in the studied building. As the ventilation requirement for this room was $5m^3/h$, it can be seen that this requirement would be satisfied only for 50% of time in the year, meaning that infiltration alone would not provide adequate ventilation for that room throughout the year. This suggests that changes to the floor layout design, or the use of devices for enhancing natural ventilation (e.g. trickle vents) or mechanical ventilation, would be required.

Room Cooling (Bojic et al, 2001b, 2002f)

For rooms equipped with air-conditioners, the location for installation of the air conditioners should be carefully chosen in relation to the room and furniture layout and the position of the occupants to avoid poor air circulation and draft, which affect thermal comfort of the residents. This would be critical to relatively small rooms.
This issue has been investigated into by the application of the CFD software FLOVENT and the k-ε turbulence model to model the airflow and temperature fields in a bedroom for three positions of an air-conditioner. The room layout studied was as shown in Fig. 12. A plan view of the 80,000 cells used for the simulation domain is shown in Fig. 13. Fig.14 shows the air velocity and temperature distributions on a vertical plane inside the room obtained in the simulation study. Such results would inform building designer of the optimal location for installing the air-conditioner for providing the maximum degree of thermal comfort for the occupant.

CONCLUSION

This paper presented the results of several studies done at the Hong Kong Polytechnic University on the airflows around and inside high-rise residential buildings in Hong Kong. These studies were on airflow by using CFD; first on pedestrian level due to wind; second, inside recessed spaces due to air conditioner heat rejection; third, inside high-rise buildings due to natural ventilation; and finally inside a room due to operation of the air-conditioner. As CFD approach is restricted due to limited computer memory and speed, problems of scaling, and that of turbulence modelling, CFD and multi zone analysis used at design stage would give order of magnitude values that are consequences of such a design.

For a new estate design, a CFD analysis of the layout of building blocks would help to avoid exceedingly high wind amplifications or stagnant zones. The results of such a study will provide a

visualisation of the wind environment, allowing the master layout design of a new estate to be fine-tuned.

For a new building design, a CFD analysis of the recessed space would help to avoid excessive use of electricity and decrease in cooling capacity when the residential flats are cooled. Next, for a new building design, a COMIS and CFD analyses on assisting of natural ventilation in dwellings would help to enhance indoor air quality and minimize energy use for comfort control. Finally, for a new building design, a CFD analysis on adequate provisions for installation of air-conditioners taking into account possible locations of furniture in a room would help to enhance thermal comfort control.

Generally, the results from such studies would inform design of estate, building, residences, and interior of rooms leading to better indoor and outdoor environmental conditions and more environmentally sustainable housing development.

BUILDING VENTILATION 'HEALTH' CHECKS

Phil Jones
Welsh School of Architecture,
Cardiff University

ABSTRACT

This paper describes the production of a Ventilation Check Technical Memorandum produced by the Chartered Institute of Building Services Engineers (CIBSE) through a UK government funded Partners in Innovation (PII) project. The procedure comprises a checklist and standard method that outlines the tasks and procedures necessary to maintain a ventilation system in good working order. It is designed to highlight areas of inefficient performance of a system to enable remedial action to be taken. The tool provides a standardised approach to ventilation system maintenance that is applicable to the non-domestic building stock, and supports the adoption of good practice across the building services profession.

KEYWORDS

Ventilation, check-list, non-domestic buildings, performance testing.

INTRODUCTION

This paper describes a new CIBSE Technical Memorandum (TM) for carrying out regular checks on ventilation systems in non-domestic buildings. Most buildings require ventilation, whether by natural means through purpose made openings, or with mechanical assistance. Regular inspection and maintenance of a ventilation system is essential to ensure that it is operating effectively and efficiently. It should provide good air quality for the health, comfort and productivity of the occupants, or appropriate to any process, whilst optimising energy efficiency.

The concept of ventilation checks is not new. Compulsory ventilation performance checks have been undertaken in Sweden since 1991 and are based mainly on two Swedish law acts; the Swedish Planning and Building Act (PBA 1987:10) and the Swedish Work Environment Act (1977:1160). Both apply to a good indoor climate and the owner of the building is responsible for ensuring this

The TM provides guidance for building owners or operators and facilities managers to carry out a regular performance check of a building ventilation system with reference to health and safety, and energy use. It is designed as a guide to check that the ventilation system installed in the building is

clean and delivers the correct volume and reasonable quality of air into the spaces where it is required..

The TM outlines a range of measures for inspecting a building and its ventilation system. These are selected to highlight areas where systems may be performing poorly and require remedial action. These measures are set out in checklists that are applicable to any non-domestic building. The anticipated benefits through using the TM include:

- Identification of poorly performing systems
- Validation of properly performing systems
- Enhanced occupant satisfaction.
- Improved productivity due to effective operation of ventilation systems
- Reduced energy costs

BACKGROUND

The technical knowledge and professional experience needed to maintain ventilation systems are widely available. However, owners and operators of buildings do not always appreciate the need for regular maintenance and the negative impact that poorly maintained systems has on energy efficiency and the indoor environment.

Poor indoor air quality may adversely affect productivity (CIBSE TM24, 2001) and inefficient operation will waste energy. Even well designed buildings may be compromised throughout their working life by poor and inefficient operation. Problems may also arise if the function of the ventilation system is not properly considered when buildings undergo a change of use or layout. Also, it is generally recognised that air-conditioned buildings require high levels of maintenance to maintain efficient operation and, for example, reduce the risk of sick building syndrome (Ventilation and health in non-industrial Environments, 2001).

The use of the TM relates directly to satisfying the requirements of UK Health and safety at work legislation, which requires the provision of effective and suitable ventilation, and that systems should be regularly and properly cleaned, tested and maintained (Workplace health, safety and welfare, 1992). They should deliver minimum recommended ventilation rates (CIBSE Guide B2 2001) should not cause uncomfortable draughts for occupants and within reason remove odours.

In addition the TM responds to new requirements from Part L (Building Regulations Approved Document Part L2, 2002) of the UK Building Regulations, and proposed European legislation on energy performance in buildings. Approved Document L2 of the Building Regulations introduces a requirement that 'the owner/occupier of a building should be provided with details of the installed building services plant and controls, their method of operation and maintenance, and other details that collectively enable energy consumption to be controlled.' These details include the basic information about the building that is required to undertake this ventilation system check. Approved Document L2 also allows for air leakage tests be carried out on certain building types, and sets new requirements for specific fan power in new and refurbished buildings.

The proposed Directive of the European Parliament and of the Council on the energy performance of buildings (Directive of the European Parliament and of the Council on the energy performance of buildings, 2001) will cover *'specific inspection and assessment of boilers and heating/cooling installations'*. It includes installed equipment for air-conditioning and ventilation and regular maintenance of air conditioning systems

THE VENTILATION CHECK

The procedure contains two levels of survey (Figure 1). Before these are carried out it is advised that base data on the building, its installations and usage in the form of a building log book is compiled.

Building Description

The new Part L2 introduces a requirement that 'the owner/occupier of a building should be provided with details of the installed building services plant and controls, their method of operation and maintenance, and other details that collectively enable energy consumption to be controlled.' These details will almost always include the basic information about the building that is required to undertake a ventilation system check. The log book is only required for new buildings granted planning consent after 1st April 2002. It is also likely to be provided for some refurbishment works approved after that date. In all other cases the basic information for the ventilation checklist will have to be assembled. Ideally this will be made available by the client prior to any visit to the site. Details of the building for inclusion in the building log book should be collected under the following headings:

- The building
- Ventilation system
- Occupancy and building use

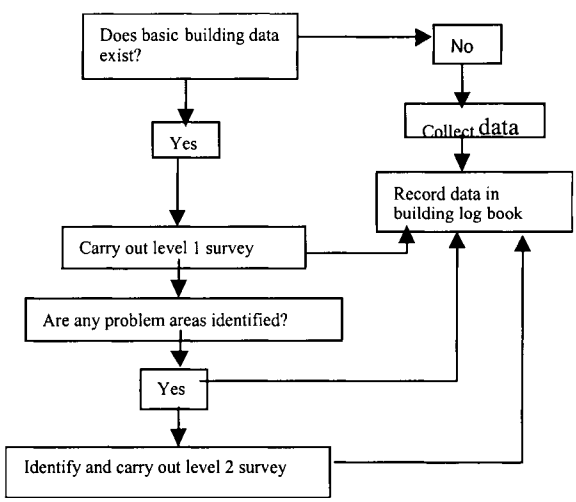

Figure 1: Diagram of survey procedure

Level 1 survey

This survey provides a basic assessment of performance. It is of the form of an annual 'walk-through' survey using observation and instantaneous measurements. On most buildings it should be possible to carry out a Level 1 survey within one working day, providing the building log book information is available and good access is provided. This survey provides a basic assessment of performance.

The use of a camera to record any relevant issues is advisable. Simple spot check measurements may be used to validate performance where appropriate, for example, to check temperatures, RH, CO_2 levels, air velocities, static pressure etc.

The survey will provide the following information:

- Indoor Air Quality
    - *Occupancy Satisfaction:*
    - *Fresh air supply:*
    - *Pollutant audit:*
- Comfort
- Air Leakage
- Room Air Delivery
- Cooling and Heating
- Energy Efficiency
- Equipment
- Cleanliness

The building should be ranked as follows:

1) needs major remedial action immediately
2) certain areas need attention without delay
3) system satisfactory

Factors that need to be addressed at a level 2 survey should be identified.

- An update information in the building log book,
- A report on the effectiveness building ventilation system,
- Any recommendations for remedial or repair work,
- The need for more detailed surveys where appropriate.

Level 2 surveys

These involve more detailed surveys that may be undertaken as a matter of routine or may be identified as required under the Level 1 survey to address specific problem areas or dealing with complex ventilation systems. Level 2 surveys include a more detailed survey of the performance of the ventilation system, which might include monitoring conditions over a period of time and undertaking occupancy surveys. Actions that might be carried out under a Level 2 survey might include:

- Comfort and air quality measurements:
    - *Occupant surveys*
    - *Carbon Dioxide Monitoring*
    - *Gaseous sampling –*
    - *TVOC's*
    - *Formaldehyde*
    - *Microbial sampling*
    - *Particulate measurement -*
    - *Cleaning*
- Energy measurement:
    - *Specific fan power*
    - *Energy audit*

- Check on Control Equipment

BENCHMARK INFORMATION

The ventilation system can be checked against:
- current good practice
- current best practice

For older buildings that may not be designed to current good practice, the survey will identify what action is needed to bring them to current good practice standards. This may be targeted to take place during a programme of refurbishment.

The benchmark data relating to current good and best practice is listed below in Table 1 for the test criteria.

TABLE 1
BENCHMARK DATA

Criteria	**Benchmark**	**Good practice**	**Best practice**
Indoor Air Quality	Carbon Dioxide (CO_2) (ppm)	1000	< 600
	Occupant Dissatisfaction	10-20%	5-10%
	Fresh Air Supply (l/s)	8 l/s	12 l/s
Criteria	**Benchmark**	**Good practice**	**Best practice**
Comfort	Air Velocity (m/s)	<0.15 (80%)	0.15 m/s (100%)
Air Leakage	Refer to CIBSE TM 23	/	/
Room Air Delivery	Ventilation Effectiveness		
	Mixing system	>80%	>90%
	Displacement system	>100%	>110%
Energy Efficiency	Specific Fan Power $kW/(m^3/s)$	<3	<2
Cleanliness	Cleanliness of system	no visible dust	regular cleaning & filter changes

Application of Titanium Dioxide in Refuse Collection Point

K.F. LAU, Andy M.T. SUEN, Arthur C.C. TANG

Building Services Branch, Architectural Services Department,
Government of the Hong Kong Special Administrative Region

ABSTRACT

Photo-catalysis is an advanced oxidation process for decomposing organic pollutants in water and air. Titanium Dioxide (TiO_2) is a semiconductor and it has been proved to be the best among the other semiconductor materials tested for photo-catalysis due to its strong oxidizing power under UV illumination and also its chemical stability. Extensive scientific studies on photo-catalytic chemistry of Titanium Dioxide have been carried out over the past 25 years. The studies done so far have proved that Titanium Dioxide is very effective in the removal of organic and inorganic compounds from contaminated water and air. Recently, the Architectural Services Department of the HKSAR Government has carried out a pilot project on the application of Titanium Dioxide where the internal wall surfaces of a newly completed Refuse Collection Point (RCP) were coated with this material. The indoor air quality (IAQ) of this RCP was then measured and the results were compared to the indoor air quality of another RCP of similar construction and locality but without Titanium Dioxide wall coating. This paper presented the measured IAQ data of the two RCPs and the data are also compared and discussed. The paper also looked at the way forward for the application of Titanium Dioxide in the construction industry.

KEYWORDS

Photo-catalysis, Semiconductor, Titanium Dioxide (TiO_2), Air Pollutants, IAQ.

INTRODUCTION

Global environmental pollution has long been an undeniable social problem that needs to be addressed imminently. According to researchers, Titanium Dioxide (TiO_2) has the ability to combat pollution due to its photo-catalytic property and this technology is becoming more and more appealing to the industry today.

When TiO_2 is applied to a surface, the surface will have the effects of self-sterilizing, anti-bacteria, anti-virus, anti-fungi, self-cleaning, anti-fogging, stain-proof and easy cleaning. Experiments also showed that when TiO_2 is used, the low-intensity UV radiation from various types of indoor lighting fixtures such as fluorescent lamps is already sufficient to photo-catalytically decompose nearly all

pollutants in indoor environments. If the pollutants are carbon compounds like aldehydes, they will be completely decomposed to carbon dioxide and leaving nothing behind. If the pollutants are those containing nitrogen and sulphur, their products such as nitric acid and sulphuric acid would stay on the TiO_2 surface [1].

Titanium Dioxide

Titanium Dioxide is a solid semiconductor. It is a colourless material and begins to melt at over 1800 ^0C [2]. It is one of the most basic materials in our daily life. Due to its high refractive index, durability, strength, non-toxicity, dispersion, tinting, and chemically inert nature, it has been widely used for coatings, enamels, paints, lacquers, inks, leather finishes and ceramics. Normally, it has to be developed to a particle size of about 0.3 microns so that one may realize its special properties. It has also been proved to be the best among the other semiconductor materials tested for photo-catalysis due to its strong oxidizing power under UV illumination and also its chemical stability.

Photo-catalytic Action

Photo-catalysis is an advanced oxidation process for decomposing organic pollutants in water and air. Extensive scientific studies on photo-catalytic chemistry of TiO_2 have been carried out over the past 25 years. The studies done so far have proved that TiO_2 is a very effective photo-catalyst in the removal of organic and inorganic compounds from contaminated water and air.

There are three prerequisite conditions for the photo-catalytic action to function satisfactorily. Firstly, the decomposition reaction only occurs when light energy (ultra-violet portion) is utilized by the catalytic action of TiO_2. Secondly, the photo-catalytic reaction will not take place unless a substance of interest is brought into contact with the surface of TiO_2. Thirdly, which is also most important, the reactions only take place when UV light reaches the TiO_2 surface. When all these three conditions are satisfied, the photo-catalytic activity of TiO_2 plays a positive role which decomposes organic materials such as dirt, grime, malodorous chemicals, irritants, toxic chemicals, smoke residues, bacteria, etc. that come into contact with it. This effect gives rise to the well-known phenomenon of paint chalking, where the organic components of paint break down as a result of photo-catalytic action [3].

Due to the complexity of the chemical reaction involved in the photo-catalytic mechanisms, the details of the chemical reactions will not be covered in this report. In essence, a photo-catalyst is a substance that would be activated by a photon. Activation of the chemical reaction of a semiconductor photo-catalyst is achieved through the absorption of a photon of ultra-band energy, which results in the promotion of electrons from the filled level to the vacant level, generating an electron-hole pair. This electron-hole pair is the primary photoproduct formed upon the excitation of a semiconductor and has a finite lifetime to allow a separate site for the oxidative and reductive half-reactions to occur [4].

PILOT TiO_2 PROJECT

The Architectural Services Department is responsible for the design and construction supervision of Refuse Collection Points (RCPs) for the Food and Environmental Hygiene Department. As there are staff/workers who would stay inside the RCPs for a long period of time everyday, the indoor air quality (IAQ) inside RCPs has always been one of our main concerns. As such, sufficient mechanical ventilation as well as various types of air purification equipment such as water scrubbers, electrostatic filters, UV sterilizers and bio-oxygen generators, etc. are provided at these RCPs to improve the indoor air quality.

To further enhance the IAQ of RCPs, we have carried out a pilot project recently on the application of TiO_2 where the internal wall surfaces of a newly completed RCP were coated with this material. The air pollutants concentration in this RCP was then measured and the results were compared to the air pollutants concentration of another RCP of similar construction and locality but without TiO_2 wall coating.

The Refuse Collection Points

A Refuse Collection Point (RCP-1) located at Kowloon Tong is a newly completed two-storeyed building and consists of a refuse collection chamber on ground floor and offices and plantrooms on the upper floor. The refuse collection chamber has a floor area of $160m^2$ approximately. Ducted mechanical ventilation system is provided inside the refuse collection chamber which is connected to a water scrubber system. The water scrubber system is provided to ensure that smelly exhaust air from the RCP will not cause nuisance to the residents nearby. As the indoor air quality inside the refuse collection chamber is one of our main concerns, electrostatic air filter, UV sterilizer and bio-oxygen generator are installed inside the refuse collection chamber. In addition, all the internal wall surfaces of the refuse collection chamber were applied with TiO_2 coating.

In order for the photo-catalytic action to take place, presence of UV light is vital. High intensity discharge (HID) lamps are installed at ceiling level of the refuse collection chamber and the UV contents from these discharge lamps would provide the necessary light energy for the photo-catalytic action of TiO_2.

A second Refuse Collection Point (RCP-2) that was used for comparison is located at Tai Kok Tsui and its construction and M&E provisions are similar to the previous RCP-1 except that there is no TiO_2 coating on the wall surfaces of the refuse collection chamber.

Application of TiO_2 Coatings

The use of correct method and procedures for applying TiO_2 coating is very important as it will directly affect the durability of the coating as well as its effectiveness of air pollutants removal. In this pilot project, TiO_2 solution was used and the solution was prepared in the factory and then delivered to site by the supplier. First of all, the wall tiles where TiO_2 coating would be applied were washed and cleaned with fresh water to remove all grease and dust particles. The walls were then let to dry thoroughly before the TiO_2 coating was applied. A pressurized airbrush using compressed air was used to spray the TiO_2 solution onto the surface of the wall tiles. When the first layer of TiO_2 solution was dried a second layer was then applied and all together three layers of TiO_2 solution were applied. The solution was then left to dry for 24 hours so as to achieve a rigid attachment of the TiO_2 coating on the wall surfaces.

Measurement Instrumentations

Carbon Monoxide Measurement - An Air Quality Monitor for continuous and simultaneous monitoring of 5 primary IAQ parameters including CO was used. The instrument has an electro-chemical sensor for the measurement of CO. This sensor, coupled with microprocessor and proprietary software, provide reliable, reproducible and accurate data for evaluation, assessment and control of air quality parameters.

TVOC Measurement - A ppbRAE monitor is used for the measurement and monitoring of TVOC. This equipment is installed with a microprocessor control and uses photo-ionization detector to detect a

wide range of organic vapors. Organic vapours passing through a UV lamp are photo-ionized and the ejected electrons are detected as current. The default calibration gas is Isobutylene.

On-Site Measurements

The on-site measurements at the two RCPs include two main parts, i.e. visual inspection and pollutants measurements. Before conducting on-site measurements at the RCPs, the indoor environments of the RCPs were visually inspected with great care to search for stains and blots on wall tiles. A walk through of RCP-1 and RCP-2 were carried out and locations where dirt accumulated were noted. In particular, the locations inspected included wall surfaces above drainage channels, wall surfaces close to exhaust duct air inlets and areas where garbage containers were located. The staff/workers inside the RCPs were also interviewed and their views recorded.

On-site measurement of pollutants concentration was then conducted. Due to resources constraints, the measured parameters included only carbon monoxide (CO) and Total Volatile Organic Compound (TVOC) and using culture-based sampling method. It was realized that samplings by culture-based method have their limitations it does not provide a continuous profile of monitoring [5]. However, due to time and resources constraints, culture-based methods were considered to be the most practical approach for this exercise. A measuring period of 10 minutes for each location and a logging interval of 1 minute were used.

RESULTS

Visual Inspection

For the two premises investigated, tiles on walls of RCP-1 were white in colour and were maintained in a rather clean condition even after being put into operation for almost a year. The wall surfaces appeared to have no mould growth or stain. From the interview with the staff/workers of RCP-1, it was also noted that the wall tiles required little cleaning.

On the contrary, the overall impression of RCP-2 was less favourable. Walls of this RCP were not as clean as RCP-1 and stains and blots could be seen in many wall surfaces inside the RCP even though the RCP had just been cleaned before our site measurement.

Pollutants Measurements

Several on-site measurements for CO and TVOC concentrations including indoor and outdoor locations at RCP-1 and RCP-2 were taken and recorded. The concentration profiles of CO at four measurement points of RCP-1 and RCP-2 and the concentration profiles of TVOC at three measurement points of RCP-1 and RCP-2 are taken and recorded. A comparison between the averaged air pollutants concentration data for RCP-1 and RCP-2 is summarized in table 1 below:

TABLE 1
COMPARISON OF INDOOR AND OUTDOOR AIR POLLUTANTS CONCENTRATION FOR RCP-1 AND RCP-2

	Types of Indoor Air Pollutants	Average Indoor Concentration (A)	Average Outdoor Concentration (B)	Percentage Increase at Indoor (C)
RCP-1	Carbon Monoxide	0.98ppm / (1136.5ug/m^3)	0.92ppm / (1066.9ug/m^3)	6.5%
RCP-2	Carbon Monoxide	1.24ppm / (1438.0ug/m^3)	1.07ppm / (1240.9ug/m^3)	15.9%
RCP-1	TVOC	177ppb / (409.1ug/m^3)	150ppb / (346.7ug/m^3)	18%
RCP-2	TVOC	320ppb / (739.7ug/m^3)	262ppb / (605.6ug/m^3)	22%

FINDINGS AND DISCUSSIONS

Less Stains and Easy Cleaning

As both RCPs had been put into operation for a certain period of time, it was reasonable to find dirt or stain on wall surfaces inside such an operational environment. However, from the visual inspections, wall tiles of RCP-1 where TiO_2 was applied were found to be in a better condition than those in RCP-2. Therefore, 2-fold effects could have been resulted from the TiO_2 coating. Firstly, dirt or other matters that reached the surface of the coating oxidized to become gaseous compounds and left nothing behind on the wall surfaces. Secondly, substances left behind on the coating surface had been cleaned and washed away easily.

Removal of Air Pollutants

From the data as summarized in Table 1 above, the increases in average indoor CO concentration for RCP-1 and RCP-2 are 6.5% and 15.9% respectively and the differences between the two are quite substantial. The smaller increase in average indoor CO concentration level in RCP-1 could have been resulted from the application of TiO_2 coating on the wall surfaces which removed some of the air pollutants.

As for TVOC, the increases in average indoor TVOC concentration for RCP-1 and RCP-2 are 18% and 22% respectively. Although only a small difference was observed between the two RCPs, TiO_2 could have induced some effects on the reduction of TVOC content of RCP-1.

Shortfall of this Investigation

As the two measured RCPs are not exactly identical in terms of locations as well as operational conditions, it is in fact not appropriate to have direct comparison on the measured data for RCP-1 and RCP-2. It would be more meaningful if the investigation could have been carried out at one single RCP where the site measurements could be taken at the RCP before and after the application of TiO_2 wall coating. However, due to technical and operational constraints, this was not possible at the time of this pilot project. As such, in this investigation, we can only discuss the effect of TiO_2 on the removal of indoor air pollutants with respect to the concurrent outdoor conditions for the RCPs.

THE WAY FORWARD

As a matter of fact, the effectiveness of TiO_2 in the removal of air and water pollutants has been proved and verified in many scientific researches and laboratory tests. Apparently, the pilot project carried out by the Architectural Services Department as mentioned above has also indicated that TiO_2 could have some effects in the removal of indoor air pollutants. However, it would be useful if more extensive and in-depth investigations could be carried out in future to verify the effectiveness of TiO_2 in practical applications. Incidentally, other possible applications of TiO_2 in the Building Services Industry could also be explored. The following are some of the suggested areas where such applications can be further investigated:

Ductwork and PipeWork

TiO_2 coating can be applied on the internal surfaces of air ducts or water pipes provided that the ducting or piping system has equipped with appropriate UV light source to enable the photo-catalytic reaction to take place. With TiO_2 coating, the formation of dirt or scale on the internal surfaces of the ductwork or pipework would be reduced and the frequency of ductwork or pipe work cleaning required would thus be reduced. As for water pipework system, reduced scaling on internal pipe surfaces would also reduce the necessary pump power required which means savings in electricity operating cost.

Lighting Fittings

In lighting design and installation, the maintenance factor is one of the main factors that would affect the number of light fittings to be provided and thus the electricity operating cost. When TiO_2 is applied to the internal surfaces of a luminaire and/or the external surface of a light bulb, the amount of dirt/dust that would attached to the surfaces of these lighting equipment would be greatly reduced. The maintenance factor of the luminaire would thus be improved and subsequently the number of light fittings required to achieve the same illumination level would then be reduced. This would result in savings in not only initial equipment cost but also in electricity operating cost. One obvious example would be the application in vehicle tunnels. If TiO_2 were applied to the lighting fittings (or even to all internal surfaces) of a tunnel, it would not only increase the maintenance factor of the luminaries but also help removing some of the air pollutants and thus improving the indoor air quality inside the tunnel.

THE MEASUREMENT OF SURFACE MASS TRANSFER COEFFICIENTS IN A STANDARD FLEC

J. L. Niu, L. Z. Zhang, T. K. Wan

Department of building services engineering, the Hong Kong Polytechnic University, Hunghom, Kowloon, Hong Kong, China

ABSTRACT

FLEC (field and laboratory emission chamber) is becoming a standard method to characterize pollutant emissions from building materials. Up until now, only the emission rate profiles are obtained, which are useful for the comparison and ranking of emission strength from different materials. However, to use the chamber emission test data to model pollutant concentrations in real buildings, and also to evaluate the effects of various control strategies, mass transfer model is required. As the first step, surface convective mass transfer coefficients are essential. In this study, a first series of direct measurements of surface mass transfer coefficients using distilled water at 5 air flow conditions ranging from 186ml/min to 509ml/min in a standard Flec is conducted. Mass transfer data inside the Flec is correlated by a dimensionless equation.

INTRODUCTION

There is an increasing awareness regarding the potential impact of indoor air pollution on health and comfort, in particular, the emission of volatile organic compounds (VOCs) from building materials and products. This has resulted in various technical guides for emission testing. The current state-of-the-art involves two types of devices: emission test chamber and emission cell. The emission test chamber is defined as an enclosure with operational parameters for the determination of VOCs emitted from building products. Typical chamber volumes cover a range from 20 L to 1m^3 (Spiker, Hosker, and Corner et al., 1992). In case of the emission cell, the surface of the test specimen itself becomes the integral part of the cell and it has a high sensitivity due to large loading ratio (surface area/volume). To-day, the best described and most frequently used tool is the so-called Field and Laboratory Emission Cell-FLEC (Wolkoff, 1996). The emission cell is portable and user-friendly, therefore, FLEC has become a standard for emission testing in Europe (CEC, 1998; Uhde, Borgschulte and Salthammer, 1998).

There have been many tests with FLEC involving various building materials. ClenΦ and co-workers (Clenϕ, Clausen, and Weschler et al., 2001) measured the ozone removal rates by selected building products. Wolkoff and Nielsen (Wolkoff and Nielsen, 1996) obtained the diffusion profiles of trans-2-nonenal with Flec data from carpet and hexane from sealing material, to name but a few. In these researches, emission rate profiles are obtained for a given air volumetric flow rate. These results are test-specific. However, to use these emission test data to model pollutant concentrations in real buildings, and also to evaluate the effects of various control strategies, more detailed mass transfer model is needed. A complete emission model should include three mechanisms: convective mass transfer on surfaces, diffusion in solids, and sorption-desorption with building materials. As the first step, in this study, the surface convective mass transfer coefficients in a standard FLEC are obtained experimentally. Such work has not been found in the open literature. Correlations are summarized to estimate the mean and local Sherwood numbers using dimensionless parameters governing the transfer and flow properties.

EXPERIMENTAL PROCEDURE

The Flec cell is circular and made of stainless steel with a diameter of 150mm and a maximum height of 18mm. The flow geometry is shown in Fig.1. The cell in our experiment is composed of two parts: cap and lower cavity. The deepness of the lower cavity is 10mm. When testing, the material is placed on the bottom surface of the lower cavity and becomes an integral part of the emission cell. The air is supplied through the cap. It is introduced through two diametrically positioned inlets (symmetrically placed) into a circular-shaped channel at the perimeter from where the air is distributed over the test surface through the circular air slit. The flow geometry of the cell is shown in Fig.1 and the pictures of the Flec in Fig.2. The cell is supplied with clean and humidified air from air supply unit. After mass transfer, the air leaves the cell at the top of its center. A more detailed description of the structure and parameters of the cell can be found in (CEC, 1998). The complete test rig is shown in Fig.3.

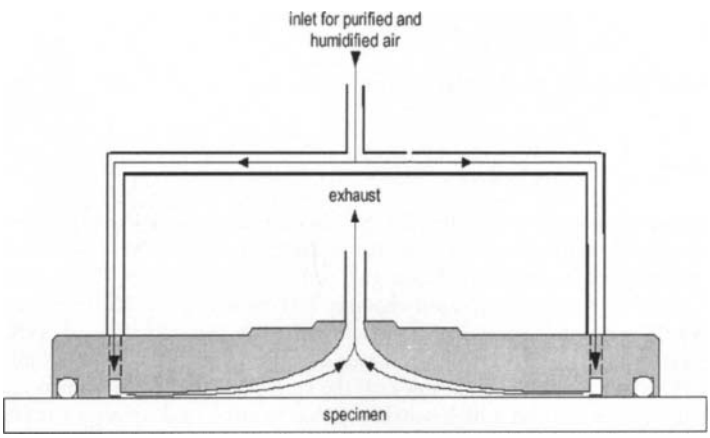

Figure 1: A schematic showing the flow geometry of the Flec

The supply air flows from a compressed air bottle and is divided into two streams. One of them is humidified through a bubbler immersed in a bottle of water and subsequently it is mixed with the other dry air stream. The humidity of the mixed air stream is controlled to the set points by adjusting the proportions of air mixing. The air-flow rates are controlled by two air pumps/controllers at the inlet and outlet of the Flec. To prevent outside air from infiltrating into the Flec, a manometer is installed to monitor the pressure inside the Flec and ensure the inside pressure positive. The humidities and temperatures in and out the Flec are measured by the built-in RH and temperature sensors in the pumps/controllers. The measuring accuracies are respectively 2% for relative humidity and 0.2°C for temperature and 2.5% for air flow rate.

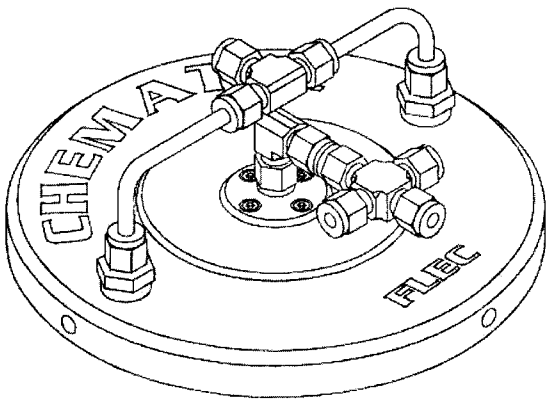

Figure 2: Pictures of the Flec, showing the cap

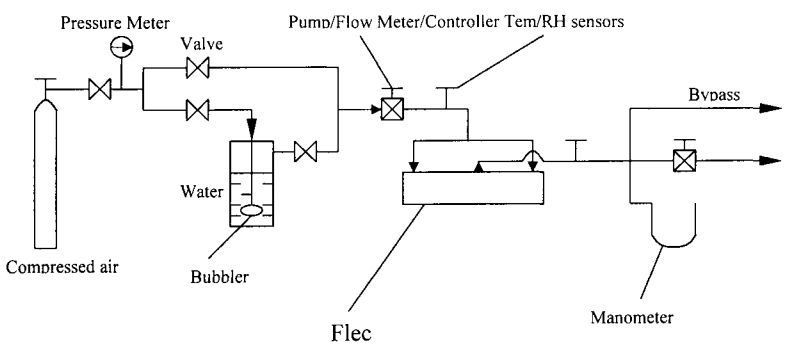

Figure 3: The set-up of the test apparatus

In this experiment, distilled water is used as the loading material. Rather than directly measuring emission rate profiles of VOCs from building materials, convective surface mass transfer coefficients are calculated by measuring the humidity differences between the inlet and outlet of an air stream, which flows through the Flec and exchanges moisture with water on the lower surface. To investigate the mean and local mass transfer coefficients at different Flec radius, five glass discs with thickness of 10mm and diameters ranging from 130 to 148mm are prepared. In each test, a disc is placed onto the bottom surface and distilled water is filled in the space between the cell wall and the disc. Special care is given to ensure the water has the same height with the disc and doesn't wet the disc's upper surface. When the air is pumped, it exchanges moisture with the water and is humidified. Since the RH of water on water surface is 100%, by calculating the humidity differences, the mean convective mass transfer coefficients across the water surface can be calculated. Different discs provide the mean mass transfer coefficients at various Flec radius. To investigate the influences of different gases, both air and N_2 are used in the experiment.

Once the humidity differences are measured, the mean mass transfer coefficient is calculated by

$$Sh_m = \frac{2k_m\delta}{D_v} = \frac{V\Delta\omega}{A_t(\omega_s - \bar{\omega})} \tag{1}$$

where V is the volumetric air flow rate to the Flec (m^3/s), $\Delta\omega$ is the humidity ratio differences between air inlet and outlet (kg/kg), A_t is the transfer area between air and water surface (m^2), ω_s is humidity ratio on the water surface (kg/kg), and $\bar{\omega}$ is the mean humidity ratio of air in Flec (kg/kg), D_v is vapor diffusivity in air mixture (m^2/s), Sh is Sherwood number and k_m is the mean mass transfer coefficient (m/s). The Reynolds number used to characterize the airflow rate is based on the height of the air inlet slit, δ, and given by

$$\mathrm{Re} = \frac{2u_m\delta}{\nu} \tag{2}$$

where ν is the kinematic viscosity (m^2/s) and u_m is the mean air velocity at the slit, and it is calculated by

$$u_m = \frac{V}{2\pi r_0\delta} \tag{3}$$

where r_0 is the maximum radius of the emission surface (m).

RESULTS AND DISCUSSION

Table 1 lists the experimentally obtained mean Sherwood numbers with different radius glass discs. Two types of gases, air and nitrogen, are available. Seven diameter discs are used. A correlation has been summarized to calculate the mean Sherwood numbers from the experimental data with regression techniques as following:

$$Sh_m = 0.8171\mathrm{Re}^{0.8578}Sc^{0.6790}\left(\frac{r_0 - r}{2\delta}\right)^{-0.6761} \tag{4}$$

where Sc is the Schmidt number.

The comparisons between the experimentally obtained and the calculated Sh numbers are plotted in Flg.4. It is seen that the correlation fits the experimental data well. The largest deviation happens when the Sh is very large, namely, in the position near air slit. This phenomenon may result from the influences of inlet flow conditions. Generally speaking, the correlation can be used to represent the

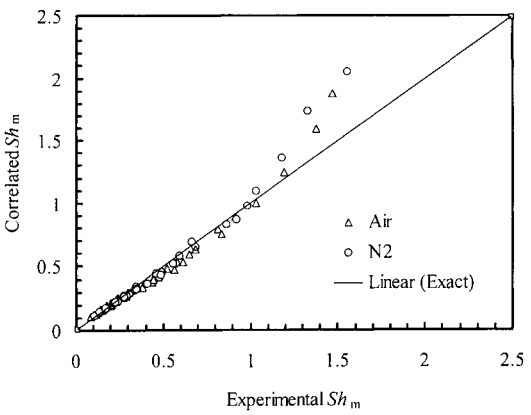

Figure 4: Comparisons of Sh numbers correlated and experimentally obtained

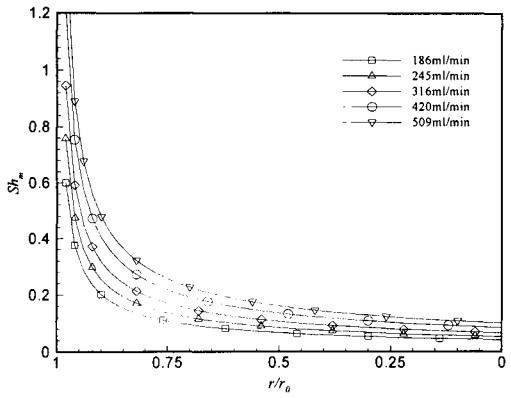

Figure 5: Mean Sherwood numbers in relation to Flec radius

mean Sherwood numbers. The calculated mean Sh numbers from the above equation in relation to Flec radius are shown in Fig.5 for air. It is disclosed that the Sherwood numbers decrease with the flow progressing. The higher the air flow rates, the larger the Sh numbers. For air flow rate ranging from 186 to 509ml/min, the mean Sherwood numbers on the whole Flec emission surface change from 0.05 to 0.2.

CONCLUSIONS

In this experiment, the mean mass transfer coefficients in a standard Flec cell are measured. A correlation is summarized to calculate the Sherwood numbers along the chamber radius. The results indicate that the mean Sherwood numbers on the whole emission surface change from 0.05 to 0.2, depending on the air volumetric flow rates. Locally, the mean Sh numbers decrease with radius decreasing.

COMPARISON OF SUMMER AND WINTER THERMAL ENVIRONMENT IN TRADITIONAL VERNACULAR HOUSES IN SEVERAL AREAS OF NEPAL

H. B. Rijal[1] and H. Yoshida[1]

[1]Department of Global Environment Engineering, Kyoto University,
Yoshida Honmachi, Sakyo-ku, Kyoto 606-8501, Japan

ABSTRACT

To evaluate and improve the thermal environment in traditional vernacular houses of the Banke, Bhaktapur, Dhading, Kaski and Solukhumbu districts of Nepal, an indoor thermal investigation and a questionnaire survey were conducted in the summer and winter. They were analyzed in terms of 1) the mitigation of thermal environment by residents, 2) the relation between living-space temperature and climate, 3) the temperature control effects by building materials, 4) the relation between indoor and outdoor temperature difference and altitude, and 5) a comparison of indoor and outdoor temperature difference in existing studies.

The findings on the thermal environment of investigated houses are as follows. 1) Residents mitigate the thermal environment by moving between indoor, semi-open and front yard spaces. 2) Living-space temperature was found to be very high in the sub-tropical climate in the summer (32.0 °C) and very low in cool climate in winter (6.5 °C). It is different according to climatic zones and seasons, which suggests that people have adapted to live with their natural environment. 3) The room temperature was 3.2K lower than the outdoor temperature during summer daytime, and 3.8-5.5K higher during winter nighttime. This is due to the effect of cool radiation in summer and heat storage in winter by the earth floor, stone walls and brick walls of the houses. 4) The indoor and outdoor temperature difference (T_{in}-T_{out}) was small in the low altitude location and large in the high altitude location. This is due to presence of open-type houses in low altitude locations and closed-type houses in high altitude locations. 5) Compared to Japanese houses, Nepalese houses are similar in T_{in}-T_{out}. This could be due to limitations of local building materials and the construction methods of traditional houses. The T_{in}-T_{out} of Nepalese and Japanese houses was 1.2K in summer which is 1K smaller than in winter. The reason for this could be that residents open the openings in summer and shut them in the winter.

INTRODUCTION

Nepal is a small country with a 147,181km^2 land area, but the climate varies from sub-tropical to frigid due to the wide altitude difference of 60m to 8848m. Therefore, different types of traditional houses, which have a variety of ideas to mitigate inside thermal conditions can be found. The examples are, 1) eaves or roofs cutting down sunshine, 2) effective ventilation, 3) semi-open spaces, and 4) thermal mass by using materials such as stone and soil. However, problems can also be found. For example, neither the windows nor doors have glass and, as a result, excessive openness effects the winter room conditions. In addition, a gradual increase of modern building materials are being used, such as corrugated iron, which make the indoor environment worse.

A qualitative understanding can easily be made from the information above, however, a quantitative analysis is necessary to improve the indoor thermal conditions by using modification or renovation methods. But, no such study can be found, therefore this study focuses on the thermal environment in traditional houses in Nepal. Summer and winter measurements were analyzed and summarized based on indoor and outdoor thermal environments and the regional differences. The objectives of this study are as follows. 1) To clarify the mitigation of the thermal environment of residences, such as use of space and duration of time spent in them. 2) To quantify the relation between living-space temperature and climate. 3) To find out the temperature control effect of houses, such as indoor and outdoor temperature difference. 4) To identify the house types according to altitude in terms of indoor and outdoor temperature difference. 5) To evaluate the thermal characteristics of traditional houses by comparing with them existing research.

THE STUDY AREA

The study areas are located in the Banke (A), Bhaktapur (B), Dhading (C), Kaski (D) and the Solukhumbu (E) districts of Nepal (Figure 1, Pandy, 1995). The climatic zone of A is sub-tropical (S). B, C and D are temperate (T), and E is cool (C). These are abbreviated as S_A, T_B, T_C, T_D and C_E. Study areas are chosen according to the altitude, climate, topography, ethnicity, energy, and housing conditions in Nepal (Table 1).

In Nepal, summer is in May and winter is in January (Figure 2). Because of the landlocked nature of the country, the climate is dry and hot in summer. Nepal lies in low latitudes (26°-30° north), therefore the solar radiation is high in winter. Bhaktapur is an urban area and the other districts are rural areas. In rural areas, agriculture is the main occupation and firewood is used for cooking and heating. Table 2 shows the outline of investigated houses. The types of houses are: one-story mud houses in S_A, 4-5 story brick houses in T_B, 2-3 story stone houses in T_C, T_D and C_E. The thickness of mud, brick and stone walls are approximately 10cm, 50cm and 50cm respectively. The typical house spaces are as follows. 1) S_A has kitchen, bed room, prayer room and veranda (semi-open) in 1F. 2) T_B has shop, water space and toilet in 1F, bed and store room in 2F, bed and living in 3F, kitchen in 4F, and store and terrace in 5F. 3) T_C has veranda, kitchen and bed in 1F, storage, bed room and balcony in 2F, and store in 3F. 4) T_D has veranda, kitchen and bed in 1F, and storage in 2F. 5) C_E has cattle shed in 1F, kitchen, bed room and prayer room in 2F, and store and bed room in 3F. The house is constructed by natural material which is available in the village. But, recently, because of modernization, the thatched roof is being changed to a corrugated iron roof. In the temperate climate (T_C, T_D), the kitchen room is used not only for cooking but also for living, dining, sleeping, etc. But, in other climates the kitchen is not used for sleeping. In the cool climate (C_E), because of low temperatures, people spend most of their time in the kitchen burning firewood.

INVESTIGATIONS

Investigations were conducted in summer (April to May 2000) and in winter (December 2000 to January 2001). Air temperature, relative humidity, globe temperature, surface temperature, solar radiation, wind velocity and direction were measured. The main outdoor and indoor measurement points were 1.5m above the ground level (in T_B 1.5m above the roof level) and 0.6m above the floor level respectively. Air temperature was also measured at 0.1m above the floor level and 0.1m below the ceiling level. Surface temperature was measured in the middle of the floor, wall, ceiling and roof. All data were measured in 5 minutes intervals and recorded by a data logger. Measured data were calibrated. Questionnaire survey related to thermal mitigation was conducted with 10(S_A), 12(T_B), 17(T_C), 19(T_D) and 9(C_E) subjects.

RESULTS AND DISCUSSION

Mitigation of Thermal Environment by Residents

Figure 3 shows the percentage of space used and duration of time spend in indoor, semi-open, front yard and outdoor spaces in a day. It can be divided into a) S_A, b) T_B, C_E and c) T_C, T_D. In summer, people spend most of their time in the semi-open spaces and front yard to feel cool atmosphere in S_A, T_C and T_D. Conversely, T_B and C_E have no semi-open spaces and people spend time mostly indoors. The T_B is a city area and people do more activity indoors. The C_E is a cool climate, and people have a habit of living indoors even in the summer. Because of low temperatures in winter, people spend more time indoors than they do in the summer (Table 2). Duration of time spent indoors in summer and winter is similar in the T_B and C_E areas, while a difference of 3.2-9.2h in other districts. During winter nights, residents of T_C sleep in the semi-open spaces, where very little indoor and outdoor temperature difference exists.

TABLE 2
OUTLINE OF INVESTIGATED HOUSES AND DURATION OF TIME SPEND IN EACH SPACE

District	No. of story	Wall types	Roof types	Roof material	Duration of time spend (summer/winter) [h/day]

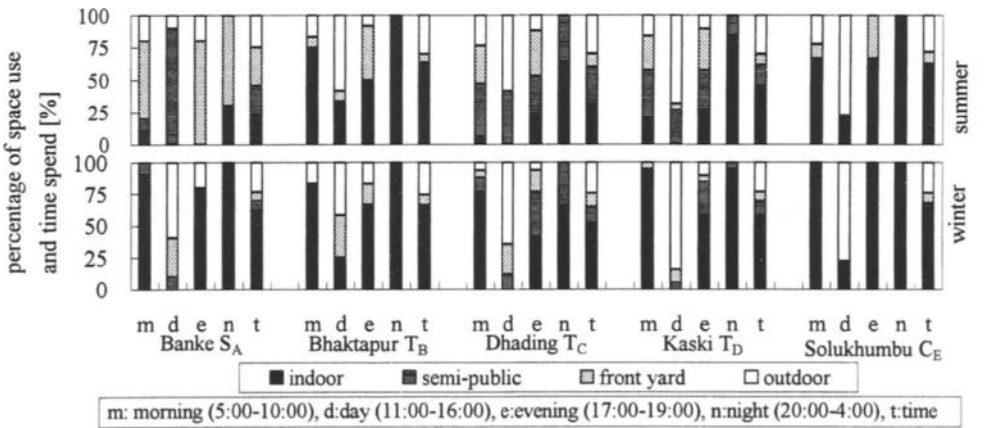

Figure 3: Percentage of space use and duration of time spend in each space in a day

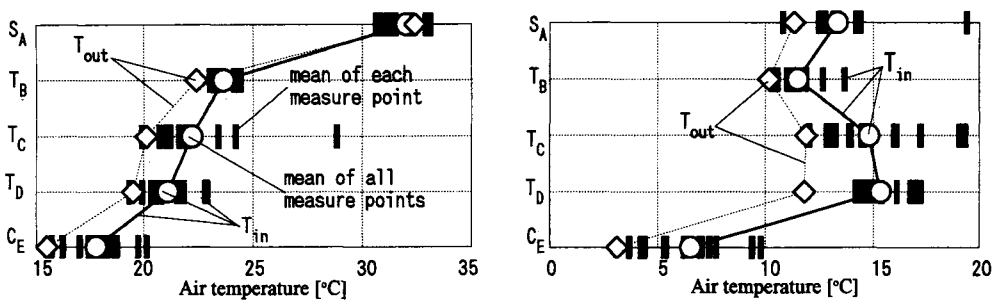
Because of their habit to live in nature, their thermal sensation is different from thermal comfort standard. This hypothesis can be described by summer lifestyle, where residents of S_A sleep in the front yard to feel the cool atmosphere at night. It can be said that people mitigate the summer and winter thermal environment by moving in indoor, semi-open and front yard areas, and by considering the period of time spent in each space.



Living Space Temperature and Climate

Table 3 shows the mean thermal environment of investigated houses. Figure 4 shows the daily mean outdoor (T_{out}) and indoor (T_{in}) air temperature in summer and winter. The indoor air temperature i.e. living-space temperature was found to be very high in the sub-tropical climate in the summer (32.0 °C), medium in the temperate climate (11.5-23.6 °C) and very low in the cool climate areas in the winter (6.5 °C). It is an uncomfortable thermal environment from the thermal comfort point of view, but people have accustomed themselves to these environments. The summer and winter living-space temperature difference was 5.8°C (T_D) to 18.7°C (S_A), which showed a big seasonal difference. T_C and T_D have less seasonal difference in living-space temperature, because people burn firewood year around for cooking and heating on the ground floor and heat rise to all upper floor of the house. It can be concluded that living-space temperature is found to be different according to climatic zones and seasons, which suggests that people have adapted to live with their natural environments.

Figure 4: Indoor and outdoor air temperature

(a) Summer (day mean) (b) Winter (night mean)

Figure 5: Indoor and outdoor air temperature difference

Temperature Control Effect by Building Materials

Figure 5 shows the indoor and outdoor temperature difference (T_{in}-T_{out}) in summer daytime and winter nighttime. The indoor air temperature was 3.2K (S_A) lower than outdoors in the summer daytime and 3.8K (T_C) to 5.5 K (T_D) higher than outdoors in the winter nighttime (Table 3). The ratio of daily range of indoor and outdoor air temperature (r) was small (0.3-0.7) in summer and winter. Compared to indoor air temperature, the daily mean floor and wall temperature was 3.6K (T_C) and 2.8K (T_C) lower in summer and 3.4K (C_E) and 7.4K (C_E) higher in winter respectively. The results showed that earth and wooden floors, mud, brick and stone walls are effective in keeping houses cool in summer and warm in winter.

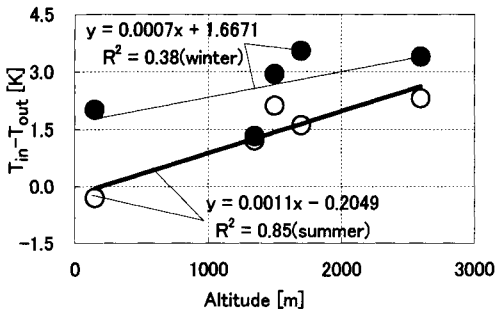

Figure 6: Relation between indoor and outdoor temp. difference and altitude

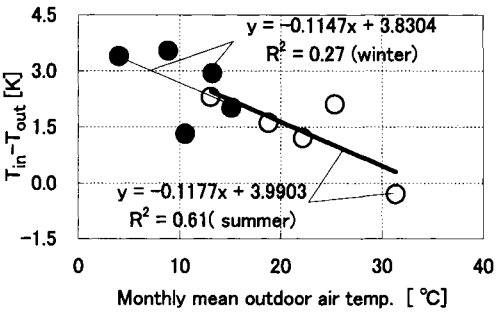

Figure 7: Relation between indoor and outdoor temp. difference and monthly mean outdoor air temp.

Relation between Indoor and Outdoor Temperature Difference and Altitude

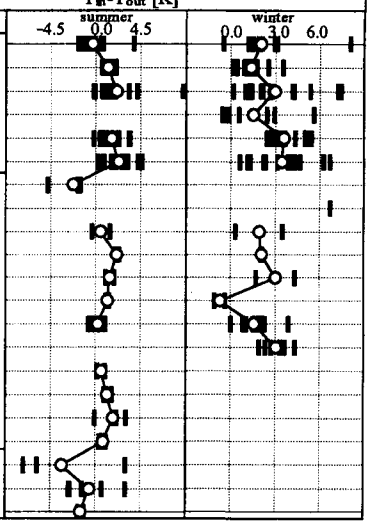

Figure 6 shows the relation between daily mean indoor and outdoor temperature difference (T_{in}-T_{out}) and altitude. Figure 7 shows the relation between T_{in}-T_{out} and the monthly mean outdoor air temperature. In summer, T_{in}-T_{out} was small (-0.3K) in the low altitude area (S_A, 150m) and large (2.3K) in the high altitude area (C_E, 2600m) (Table 4). T_{in}-T_{out} were highly correlated with the altitude and monthly mean outdoor air temperature. In winter, T_{in}-T_{out} was higher than in summer. However, a summer and winter both recorded similar trends in regards to altitude and monthly mean outdoor air temperature (see figure 6 and 7). Because of different methods of firewood usage for heating, the correlation coefficient is weaker in winter than summer. In the T_B (1350m), people do not burn the firewood for heating, therefore it has a smaller T_{in}-T_{out} than in the low altitude areas (S_A). The results showed that T_{in}-T_{out} is different according to altitude. The reasons could be that in the low altitude areas (sub-tropical climate), the open-type houses are suitable for high summer temperatures. In contrast, in the high altitude areas (cool climate), the closed-type houses are more suitable for low winter temperatures. In the medium altitude areas (temperate climate), the semi-open (veranda) and semi-closed (a window without a door) type houses are suitable in summer and winter.

Comparison of Indoor and Outdoor Temperature Difference

Table 4 shows the comparison of indoor and outdoor temperature difference (T_{in}-T_{out}) in Nepal, Japan and China. Nepalese houses are compared with Japanese houses because the latitudinal climatic variations of Japan is similar to the altitudinal climatic variations of Nepal. For reference, Chinese underground houses are also included. Traditional houses share a common point in their use of local materials and construction methods, therefore they can be compared in different areas. In Nepal, T_{in}-T_{out} was -0.3 to 2.3K in summer and 1.3 to 3.5K in winter. Compared to an existing study, T_{in}-T_{out} was lower in study areas 1, 13, 14, 15 (summer) and 6 (winter) than in this study (Table 4). If these values are excluded, the indoor and outdoor temperature difference of Japanese houses are in the range of Nepalese houses. It shows that the thermal characteristic of Nepalese and Japanese traditional houses are similar. This could be due to limitations in local building materials and construction methods of traditional houses. However, it should be noted that as we explained above, traditional houses have a high temperature control effect in summer daytime and winter nighttime. Focusing in microclimate, T_{in}-T_{out} is also different according to altitudes.

TABLE 4
COMPARISON OF INDOOR AND OUTDOOR TEMPERATURE DIFFERENCE

Country	Study area	No. of house	Measure points	T_{out} [°C] s	w	T_{in}-T_{out} [K] s+	w+

T_{out} & T_{in}: outdoor & indoor air temp., s: summer, w: winter, *: mean of two days, Matsue meteorological station, △: 1 measure point, 1: mean of each measure point, +, ○: mean of all measure points, a)-e): This study, cc): Rijal et al.(2001), 1): Ichikawa et al.(1970), 2): Kubota et al.(1989), 3)-6): Miyano et al.(1990), 7): Yanase et al.(1969), 8): Igarashi et al.(1971), 9): name in Japanese(1969), 10): Akamatsu et al.(1972), 11): Oshiyama et al.(1972), 12): Morita et al.(1972), 13)-15): name in Japanese (1987).

To find the summer and winter difference of Nepalese and Japanese houses, the average of T_{in}-T_{out} is taken in summer and winter. The results were 1.2K in summer and 2.2K in winter, which is 1K greater in winter. The reason could be that residents adjust the opening, for example doors and windows are opened in summer and shut in winter.

CONCLUSION

In this study an indoor thermal investigation and a questionnaire survey were conducted in summer and winter for the traditional houses in the Banke, Bhaktapur, Dhading, Kaski and Solukhumbu districts of Nepal. The results are as follows.

1) Residents mitigate the thermal environment by moving between indoor, semi-open and front yard spaces.
2) Living temperature is found to be different according to climatic zones and seasons.
3) The room temperature was 3.2K lower than the outdoor temperature in summer daytime, and 3.8-5.5K higher in winter nighttime. The results showed that earth and wooden floors, mud, brick and stone walls are effective in keeping houses cool in summer and warm in winter.
4) The indoor and outdoor temperature difference was small in the low altitude location and large in the high altitude location.
5) Compared with Japanese houses in existing studies, Nepalese houses had similar indoor and outdoor temperature differences. The indoor and outdoor temperature difference of Nepalese and Japanese houses was 1.2K in summer which is 1K smaller than in winter.

MAXIMIZING THE VENTILATION RATE FOR COOLING ENERGY REDUCTION

M. Udagawa[1] and H. Roh[2]

ABSTRACT

It is widely recognized that to minimize the ventilation rate will reduce the energy consumption of air conditioning systems in both heating and cooling seasons. However, the temperature difference between indoor and outdoor air temperatures in the cooling season is not so large in comparison with that in the heating season. In addition, there are many hours when the outdoor air temperature in the cooling season is lower than the design space air temperature.

Therefore, to minimize the ventilation rate may not be important for energy reduction in cooling with air conditioning systems. Better indoor air quality may be provided without increasing the energy requirements by increasing the ventilation rate during the cooling operation. Energy reduction in air conditioning system operation can be also expected depending on the temperature and humidity conditions required in the cooling season.

Appropriate ventilation rates and a basic control strategy are discussed using simulation results of a typical office building with the climatic conditions of Japan where the space cooling consumes larger amount of energy than the space heating in most major cities. The simulation results of the model office building in Tokyo show that the energy requirements for the cooling are almost the same wheather the ventilation rate is set to a minimum outdoor air requirement or to a maximum ventilation rate for all outdoor air without mixing with the return air from conditioned space. This simulation results show the potential of the outdoor air as a cooling source in the cooling season. Control strategies of the ventilation rate in practical design and operation of the air conditioning systems are discussed using the energy requirements obtained by the system simulation.

Cooling, office building, simulation, ventilation, energy conservation, air conditioning, heat load

INTRODUCTION

Ventilation rate and heat loads in cooling system is discussed from the view point of possibility of maximizing the ventilation rate including an all fresh air system without return air. It is widely recognized to minimize ventilation rate for reducing the energy consumption of air conditioning systems in both heating and cooling season. However, the difference between indoor and outdoor air temperatures in the cooling season is not so large in comparison with that in the heating season. In addition, there are many hours when the outdoor air temperature in the cooling season is lower than the design space air temperature required.

Therefore, to minimize the ventilation rate may not be important for energy reduction in the cooling operation of air conditioning systems. Better indoor air quality may be provided without increasing the energy requirements by increasing the ventilation rate in cooling operation.

Using the system simulation tool, this study examined the possibility of a cooling system to use outdoor air for cooling source as well as for better indoor air quality.

COOLING SYSTEM WITH MAXIMUM VENTILATION RATE

For example, in Tokyo the average outdoor air temperature of six months, from May to October when mechanical cooling is necessary, is 22.2 °C which is lower than the room set air temperature of 26.0 °C. Due to room heat load of office buildings in Tokyo, space cooling is required throughout the year caused by internal heat generation from lighting, office equipment and occupants in the space. Except for midsummer, the outdoor air temperature is lower than the room set point temperature. In such conditions, an all fresh air

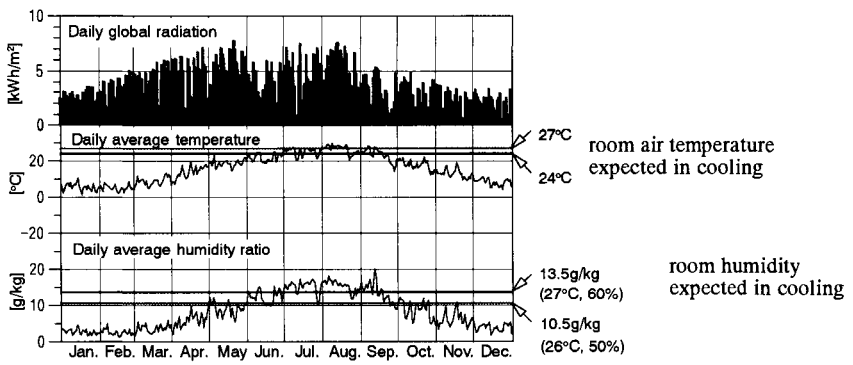

Figure 1: Annual variation of weather data and room thermal environment expected in cooling

system, in which 100% of cooling air supply from outdoors may be more advantageous than the cooling operation with minimum ventilation rate.

Figure 1 shows the year round variation of the weather data in Tokyo. The temperature difference between the expected conditioned room air temperature range in summer is small in comparison with the temperature difference in winter. This means that the sensible heat load of the cooling coil caused by ventilation air is not expected to be large, while the latent heat should be carefully considered as shown in Figure 1 in which the difference of the humidity ratios between outside air and the room conditions is rather large.

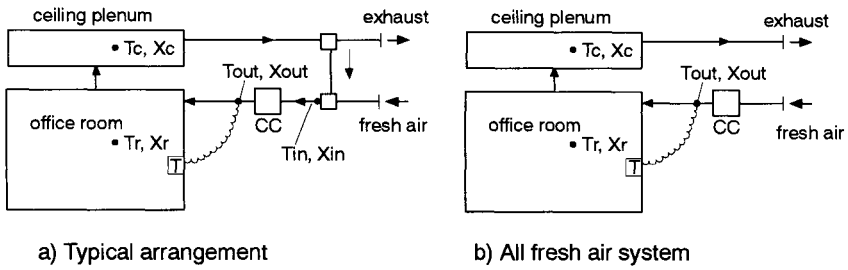

Figure 2: Office room cooling system schematic diagram

Figure 2a shows an example of a usual system with the return path making use of recirculation of the excess room air after exhausting the ventilated air. In this case, the ventilation rate is considered to be minimum or an appropriate value and the mixture of the ventilation outdoor air and the return air is introduced to the cooling coil. To examine the cooling coil load of the air conditioner including the ventilation cooling load at the extreme conditioned, the cooling system with all fresh air system shown in Figure 2b is assumed. The system is very simple, since there is no return path from the conditioned room to the air conditioner.

SIMULATION PROCESS

The system simulation of the cooling coil load of the air conditioner for three Cases was carried out for the model building shown in Figure 3. The simulated building had been designed as a typical office building for the simulation studies related to the room heat load and energy consumption by the air conditioning systems proposed by Takizawa(1985). For the typical floor, two office spaces are separated each other with the core space in the center. The floor area of each office space is 303m ^{2} and the volume is 787 m ^{3} with 2.6 m ceiling height.

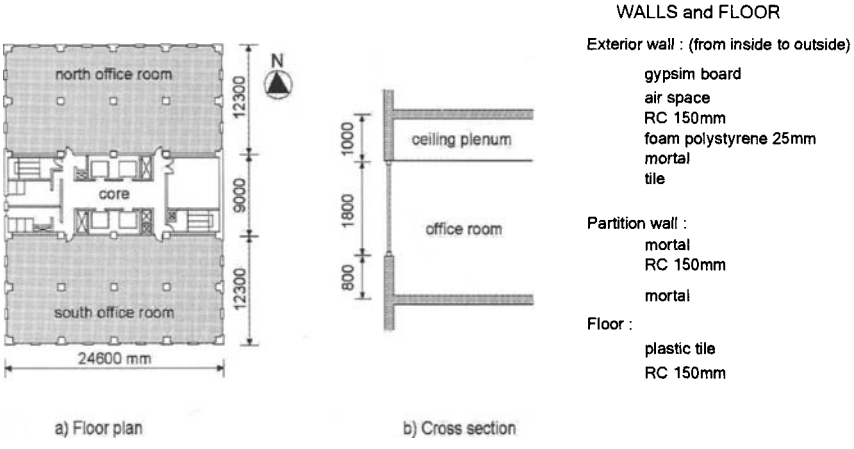

Figure 3: Model office building

TABLE 1
DESCRIPTION OF SIMULATION CASES

Case		Ventilation air ratio	Ventilation rate [m^3/h]	Cooling air supply[m^3/h]
Case 1	Base case(Fig. 2a)	25%	1200	4800
Case 2	Increased case(Fig. 2a)	50%	2400	
Case 3	All fresh air (Fig. 2b)	100%	4800	

The south room was used to discuss the simulated results, while the whole typical floor had been used as the simulation model. Since the tendency of the simulation results of the south room and the north room showed very similar.

The air conditioning systems of Figure 2 are assumed with the ventilation rate of the three cases. TABLE 1 shows the combination of ventilation rates. The supply air flow rate from the air conditioner, 1.6 kg/s (4800 m^3/h) was determined using the room sensible cooling load at the peak condition. Case 1 in Table 1 is the minimum outdoor air case. The ventilation rate of the minimum out door air case is 0.4 kg/s (1200 m^3/h) calculated from the recommended minimum ventilation rate for the office building in Japan based on 4 m^2/h per floor area which implies 20 m^3/h per person. In this case 25% of the supply air rate is the ventilation rate. Case 3 shows the all fresh air case in which 100% of supply air is outdoor air. In Case 2, 50% of supply air is outdoor air.

The building envelopes are considered as typical designs used in the Tokyo area. Light colored internal blinds are supposed to be used for shading direct solar radiation to the office space. The room internal heat generation from lights and appliances are 20 W/m^2 and 10 W/m^2, respectively and 0.2 person/m^2 of space are assumed. The internal heat generation as well as cooling operation from 8:00 to 18:00 is assumed. The room temperature set point is 26 °C throughout the cooling season. The room air humidity is free floating, as the constant outlet humidity model is used in the simulation model of cooling coils in the simulation tool EESLISM. The typical year weather data of Tokyo edited from AMeDas weather data set were used. Whereas the cooling period can be considered as lasting a whole year for the office building in Tokyo, it is assumed in this study that a cooling period of six months from May to October ia a sufficient period for mechanical cooling and summer weather conditions.

The simulation was carried out using a generalized simulation tool EESLISM developed by Udagawa(1990 and 1999). EESLISM can be used to simulate the whole building thermal system consisting of building thermal models and mechanical heating and cooling systems. The authors have used EESLISM for the simulation study of office buildings as well as residential houses(2001). The rooms to be simulated and the heating and cooling systems are defined as system components and the air flow path is used to connect the related system components. Using the information of each system component and their relationship, a set of simultaneous equations for the temperature and humidity ratios describing heat and mass balance of whole system components is set up and solved at each time step of the simulation process.

COOLING COIL LOAD AND ROOM THERMAL ENVIRONMENT

The results of the simulation are shown in Figures 4 through 7. Because of the internal heat generation and solar radiation through the envelopes, the room heat load shows the requirement for cooling as shown in Figure 4. As the room cooling loads are the same for the three Cases, Figure 4 can be used to examine the tendency of the room cooling loads commonly for all simulation cases. The daily coil cooling loads for the three Cases can be compared using Figure 5. The coil load is normalized for the room floor area. While Case 1, the minimum ventilation rate case shows the smallest daily loads among the three Cases in midsummer from early July to middle of September, Case 3, all fresh air case shows the smallest in June and late

September. It is very obvious that the latent cooling load for Case 3 in midsummer is very large in comparison with the base case, Case 1, whereas the sensible cooling coil loads of the three Cases show only small differences. Except for midsummer both sensible and latent cooling loads show smaller differences in spite of the large difference in the ventilation rate.

Figures 6 and 7 show the hourly simulation results for a week in midsummer, from end of July to beginning of August. The room thermal environment are also shown in Figure 6. The air temperature and humidity variations of the room air and the coil inlet air are similar for all cases, since the room air temperature is kept to the set point and the coil outlet air temperature is controlled to keep the room set point temperature. As the constant outlet relative humidity model is used in the simulation, the room humidity can not be kept to a constant value even in the air conditioned hours. The relative humidity of the cooling coil of the outlet air was assumed to be 90%. Under the controlled outlet air temperature with CAV control scheme,

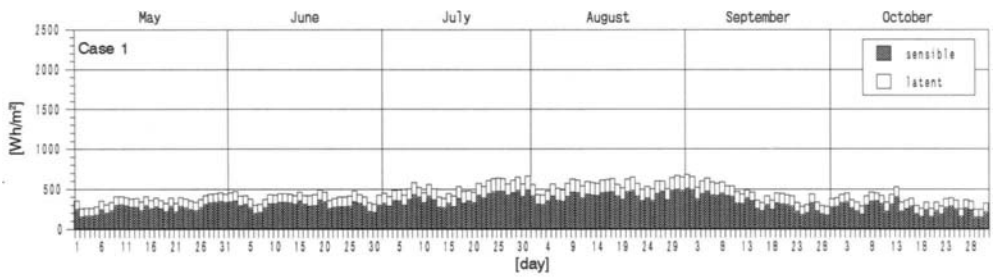

Figure 4: Variation of daily room cooling load of Case 1

Figiure 6: Hourly variation of room air temperature and humidity
(Case 1, from July 26 to August 1)

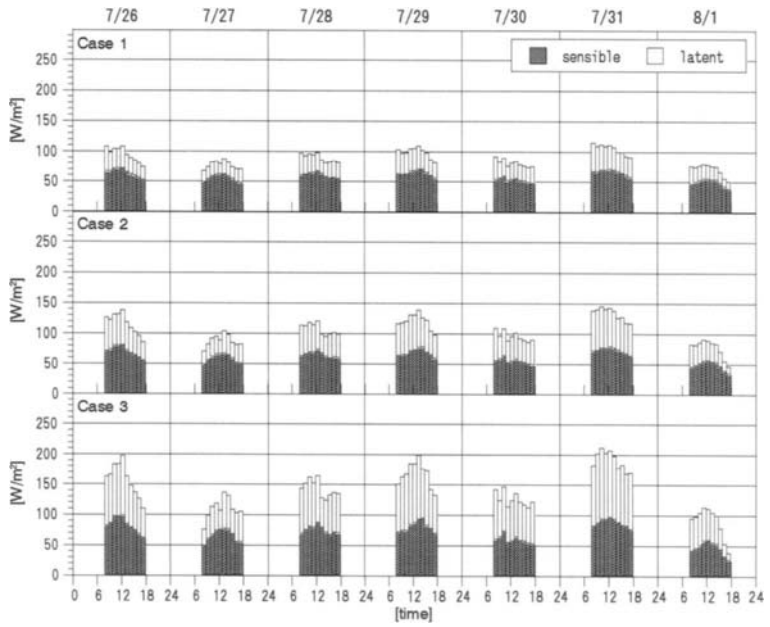

Figure 7: Comparison of hourly cooling coil loads in midsummer
(from July 26 to August 1)

the room air humidity is around 60% in the air conditioning hours for all Cases.

The peak coil load is observed on July 31 with the maximum outdoor air temperature of 34.4 °C. The hourly coil loads are shown in Figures 7 for the comparison of Cases 1 to 3. Figure 7 shows almost twice

TABLE 2
COMPARISON OF MONTHLY AVERAGE COOLING COIL LOADS (kWh/㎡month)

	Cooling season May - October			Midsummer July and August		
	sensible	latent	total	sensible	latent	total
Case 1	10.1	3.3	13.4	15.0	7.3	22.3
Case 2	9.3	4.3	13.6	15.6	10.0	25.6
Case 3	8.5	6.6	15.1	16.6	15.6	32.2

the latent cooling coil load when comparing Cases 1 and 3. When comparing Cases 1 and 2 the latent load of Case 2 is larger than that of Case 1 by 20%. For the sensible coil loads, only small differences are shown, while Case 3 shows the largest load.

DISCUSSION ON VENTILATION RATE IN COOLING

Comparison of coil cooling loads for the entire cooling season is shown in TABLE 2. The total seasonal cooling loads consisting of sensible and latent loads express small differences considering the large difference in ventilation rate. The seasonal total cooling load is almost the same comparing Case 1 with Case 2, while a 13% increase exists comparing Case 1 with Case 3. However, increase of the latent heat load is remarkably close to increase of the ventilation rate especially in midsummer, July and August. The difference of the latent load between Case 1 and Case 2 is 37% of Case 1 in the midsummer. As shown in Figure 5, even in June and September, monthly heat loads of the three Cases do not show significant differences. Even in winter, cooling is often required for room heat load base in many office buildings in Tokyo. The difference in the total annual cooling coil load due to the increased ventilation rate is considered to be very small.

When increasing the ventilation rate during the cooling operation, the increase of the latent coil load to remove moisture from outdoor air is an important problem in midsummer. In considering the hourly cooling load, this tendency is emphasized as shown in Figure 7. For the cooling system, the ventilation rate is not necessary to be set at a minimum value for energy conservation even in midsummer, if the latent heat is removed effectively. The effect of the ventilation rate strongly depends on the difference in indoor and outdoor air humidity ratios. As shown in the results for June and September, the applications to the office building might be expected during a climate of low humidity in midsummer or when the buildings require cooling at night.

The all fresh air system using a heat recovery component using total heat exchanger with high effective latent heat exchange may be considered as a possible technology to reduce the latent heat load in midsummer. A latent heat exchanger with an efficiency of 75% can reduce the latent load of Case 3 to that of Case 1.

It is a well known practical way to use a minimum ventilation rate in the peak hours in midsummer and a maximized appropriate ventilation rate for the free cooling or the economizer cycle. Nevertheless, an all fresh air system has the possibility for the design of a simple duct system since the return duct system can be neglected. An all fresh air system may also be extended to examine the possibility of hybrid ventilation system combine with natural ventilation and a mechanical cooling system.

CONCLUSION

The effect of ventilation rate on the cooling coil load was examined for an office building assumed to be built in Tokyo to study the possibility for using outdoor air as a cooling source as well as for the preservation of better indoor air quality.

The simulation results for three Cases using three different levels of ventilation rate from the minimum to an all fresh air input showed that the total seasonal cooling coil loads are almost same. From the view point of energy consumption in cooling, the all fresh air system has a possibility to be used as a simple system and would provide better indoor air quality compared with the minimum ventilation case.

The latent coil load significantly increases corresponding to the ventilation rate in midsummer, July and August, while there is no significant difference for the sensible cooling coil loads. Therefore, dehumidification is very important when examining the relationship between cooling energy and ventilation rate during the hot and humid summer period.

Advantageous applications should be examined considering the factors influencing the cooling coil load. Latent heat recovery systems, climatic conditions, types of building and required room environment in cooling operation are the key variables to be balanced in designing effective applications.

THERMAL INDOOR CLIMATE AS A BUILDING PERFORMANCE

Proposal for new criteria, design aids and assessment methods in The Netherlands

ABSTRACT

In the assessment of thermal indoor climate in the Netherlands, the directives commonly used, are the ones given in 1979 and 1991 by the Government Buildings Agency (GBA). The criteria formulated in 1991, expressed in 'weighted excess hours' were a subject for debate. This paper treats these directives and their backgrounds, but above all, a proposal for new guidelines is presented. It incorporates the new notions about desired comfort temperature as described by "adaptive models" as given by De Dear and Brager.

KEYWORDS

Indoor climate, thermal comfort, thermal comfort performance criteria, building thermal performance, performance assessment, adaptive models.

INTRODUCTION AND BACKGROUND

One of the main characteristic performances of a building is its thermal indoor climate. The indoor climate should optimally support the activities of the people within the building. In The Netherlands more than 20 years of experience exist with performance specifications on Thermal Indoor Climate, formulated by the Dutch Government Buildings Agency (GBA), Van der Linden et al. (2002). Using Fanger's Predicted Mean Vote (PMV), these specifications are based on the central starting point that a in a "good" building the thermal climate exceeds at most 10% of the working time the limits of $-0,5 < PMV < 0,5$, Rijksgebouwendienst (1979). In computer simulations on a yearly bases, the hours that the indoor climate exceeds these limits are counted and the hours are weighted in relation to the extend the climate exceeds the limits. The design value is 150 weighted hours. For an average office building i.e. this means that the indoor operative temperature exceeds a limit of 25°C for at most 100 hours a year (about 10% of the working time in the summer period of about six months).
Weighing the hours the climate exceeds the desired limits was considered necessary regarding the difference in thermal capacity of different buildings. This can be plainly noticed: in the case of a small thermal capacity, the mean temperature of a room during the *excess hours* will be definitely higher

than in that of a heavy building. It can also be assumed without further argumentation, that in such situations the thermal load experienced by people will also be higher. Fanger's Predicted Percentage of Dissatisfied (PPD) was applied as a criterion to calculate the extent of excess temperatures. During the period in which it exceeds a PMV = +0.5 (PPD = 10%), a weighting directly proportional to the PPD is applied. In other words, 1 hour with 20% 'dissatisfied' counts twice as heavily as 1 hour with 10% 'dissatisfied'.
The weighting hours method also provides the possibility to consider the way in which people adjust to higher indoor temperatures, whether by modifying their clothing or increasing the air circulation (opening windows). These changes and the influence of different building types and building services, are automatically included in the input data for the execution of computer simulation calculations.
However consultants and designers widely apply the GBA-method in practice, in combination with other criteria. The debate that is taking place about the method shows the difficulty of optimally communicating its content with occupants and owners of the building.
Furthermore the method works very well in assessing buildings in the design stage by using temperature simulation programs. Assessing buildings in use is much more complicated because it is hardly possible to have temperatures measured during the complete six months summer period. So measurements of two days or two weeks periods have to be used.
Members of the Dutch construction industry and the research world came together to discuss some of these items during a workshop in Delft. The workshop report, De Wit et al. (1999), which includes a bibliography and interviews, constitutes the basis for a new project. The Technical University of Delft in collaboration with BBA/HPB (see authors) and ISSO (Dutch Institution for Study and Research in the field of Building services) is carrying out this project with the support of NOVEM (Dutch Organisation on Energy and Environment) and the Government Buildings Agency. This project will re-examine the current criteria, taking into account the recent research results on adaptive models and will develop new design and assessment instruments for practical use, Van der Linden (2000).

INTERNATIONAL DEVELOPMENTS; ADAPTIVE MODELS

The indoor climate criteria discussed up to now are based on steady state comfort models based on work with large groups of individuals in a laboratory situation.
In the Netherlands, people's adaptive behaviour in practice - changing clothing or physical conditions i.e. increase the air velocity by opening windows - has been taken into account for over 10 years now, Brouwers (1989). In indoor climate computer simulations at higher indoor temperatures (Ti > 25 °C) the summer value of $I_{clo} = 0.7$ is reduced by 0.2 points to $I_{clo} = 0.5$ and v_{air} is set to 0.25 m/s. As a matter of comparison, these actions cause the limit temperature to shift from 25.5°C to above 27°C.
The chosen values are plausible, but have not been validated by serious research.

Besides the effects of adjusting the physical conditions, new findings based on field studies gathered by Brager and De Dear (1998) show another additional effect which indicates a psychological adaptation to a higher indoor temperature in relation to the one outdoors in a preceding period and to people's expectations. This effect counts especially for naturally ventilated buildings, situations in which people have a stronger relation to the outdoor climate and, to certain extent, are able to influence their own thermal indoor climate.
These findings provide well-founded information on the magnitude of the combined effects. They form the basis for an adaptive model in which de indoor comfort temperature is given in relation to the mean outdoor effective temperature in the preceding (one month) period.
Figures 1 shows the results that are already familiar to people working in this field.
In buildings with natural ventilation and options for individual control of the indoor climate, the comfort temperature in relation to the outdoor temperature varies to a larger extent than the PMV-model can explain. The adaptation of the clo-value and the increase in air circulation during periods with higher temperatures, represent only half of the observed difference.

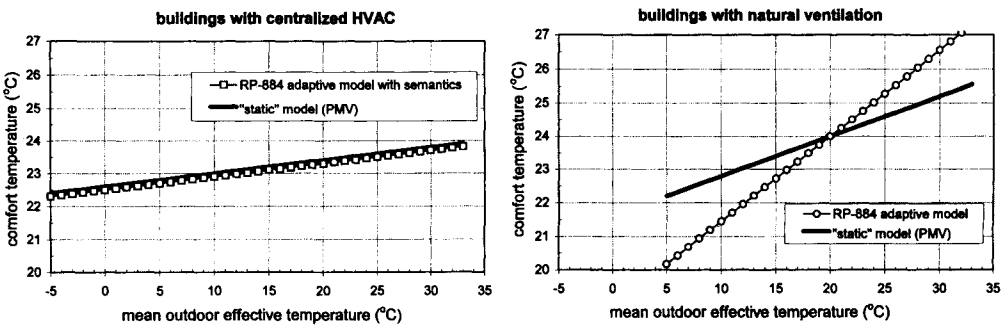

Figure 1: Comfort temperature in relation to the mean outdoor temperature in buildings without operable windows and with centralised temperature control and buildings with natural ventilation and with individual possibilities to influence the indoor climate, De Dear (1998).

In their article De Dear and Brager suggest that the other half of the difference is related to people's psychological adaptation to an indoor climate that follows the outdoor climate to a much higher degree than in an air-conditioned building. This leads to the conclusion that people's recent thermal experiences, together with their expectations concerning the premises concerned, play an important part in their assessment.

Recent analysis, Kurvers et al. (2001), of data found in 61 buildings in the Netherlands some 10 years ago, Preller et al. (1990), shows that a higher percentage of satisfied people is found in buildings with operable windows and natural or mechanical ventilation but without mechanical cooling, than in HVAC buildings, figure 2.

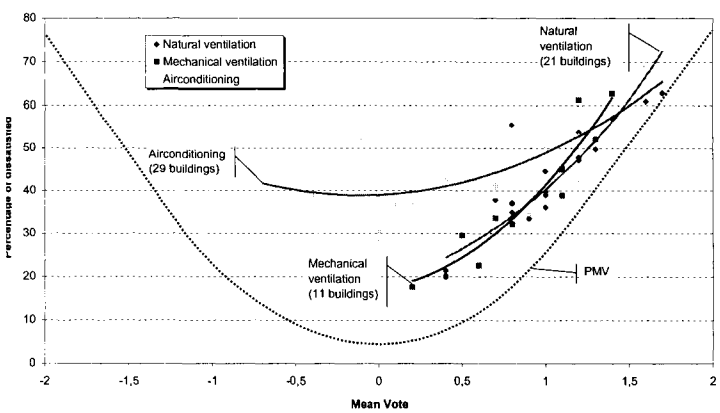

Figure 2: Relation between MV and PD in summer, Kurvers et al. (2001)

Figure 3 (next page) shows that the satisfaction in non air conditioned buildings, expressed in the percentage of satisfied people, is greater - although these people experience the climate as hotter (MV = +0.97 and +0.91) - than of people in air conditioned buildings (MV = +0.51).
This means that the statistical distribution of the votes is quite different in the two situations.
It is important to know that the percentage of dissatisfied people is fixed by counting the people that vote +2 and +3. Furthermore, the votes were not asked for instantaneously. The questions about summertime experiences were put in the context of a broader Sick Building Survey, carried out in

January and February. So the respondends' reactions were based on long-term experience and expectations. The results are consistent with Brager and De Dear's findings and illustrate the necessity for an adjustment of the current Dutch guidelines.

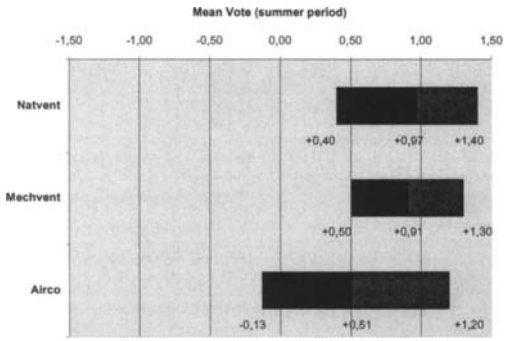

Figure 3: Mean Vote in summer as found in three building categories, Kurvers et al. (2001-1)
The values given represents P10, average and P90; number of buildings see figure 2.

PROPOSAL FOR A NEW DUTCH GUIDELINE ON THERMAL INDOOR CLIMATE

Based on a extensive literature review, Kurvers et al. (2001-2) a proposal for a new thermal comfort guideline is made. Note that this is just a proposal under discussion in the Dutch research group working on the subject. The thermal comfort model used, is the adaptive model developed by Aucliciems et al (Oseland & Humpfreys, 1994).
Basis for the assessment of the quality of the indoor thermal climate in practice are the lines given in figure 4. The quantitative data that these comfort limits are based upon are derived from De Dear et al (1997). These lines represent the upper limit of the 90% satisfaction area. Exceeding these lines means PPD > 10%. Following the work of De Dear et al. the comfort temperature varies with the outdoor temperature. This outdoor temperature is described by RMOT*, see intermezzo.

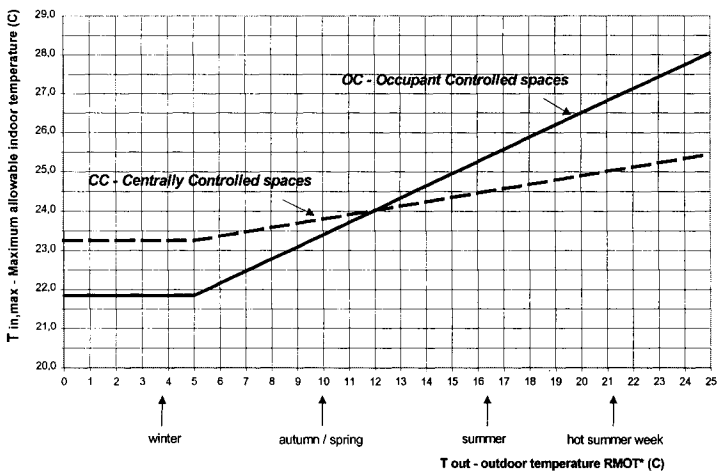

Figure 4: Upper comfort limits for the effective indoor temperature (based on the PPD=10% lines of De Dear et al, 1997) for occupant controlled and centrally controlled spaces in relation to outdoor temperature (see also Intermezzo RMOT*).

The comfort criterion for occupant controlled building spaces is less severe than the criterion for centrally controlled indoor climate and also less severe than the existing criteria as given by the Dutch GBA for both occupant controlled and centrally controlled buildings. This means less need for mechanical cooling (less complicated building services) and less energy use. But there is a strong need to give a very clear definition on "when a building space can be considered as occupant controlled".

Building performance with respect to thermal indoor climate

To assess the performance of a building with respect to the thermal indoor climate the response of the building (a room in the building) to the outdoor climate of a whole year is considered. In designing new buildings this is common practice; the use of thermal simulation computer models is wide spread. It is important to use the same basis. In The Netherlands the outdoor Climate of the year 1964/65 is used as a reference. To assess buildings in use is quite another topic. This is treated shortly further on in this paper

In a computer simulation, the hours (during working time) that the comfort limit of figure 4 is exceeded are counted. This is more or less the same as was done in the GBA-method, described before. The great difference is the basis of the criterion for the momentary comfort in which people adaptive behaviour is now taken into account.

To take into account the difference in thermal behaviour of buildings with different thermal mass and different types of building services, resulting in a stable or a more fluctuating indoor climate, also the extend to which the limit is exceeded is counted and the average is calculated. In this way a classification of building performance with respect to indoor thermal climate as given in table 1 can be made.

TABLE 1
PERFORMANCE CLASSIFICATION PROPOSAL

classification	% of time limit is exceeded	exceeded with (avg.)
excellent	0%	-
good	0-10%	<1 °C
moderate	0-10%	>1 °C
poor	>10%	-

Optimising communication

Nowadays it is quite normal for a consultant to translate the employer/client's functional requirements, often formulated in abstract terms, into quantitative ones; subsequently, the consultant will suggest one or more solutions that comply with the quantitative requirements. The client may then make a decision based on other preconditions and performances.

Even if the account is rendered to the client in quantitative terms, the actual communication takes place in the domain of (non-quantified) functional requirements. The client has to rely completely on the consultant for a translation into technical solutions.

To achieve proper communication regarding the thermal indoor climate, a qualification as given in table 1, will be of great help. Because these qualifications are still formulated in a rather abstract way, it probably will be necessary to translate them into figures that can be more intuitively comprehended.

Assessing buildings in use

Work is to be done on an instrument that can directly assess buildings, based on measurements of indoor and outside temperatures during a limited period of time (one or two days and up to a week).

Once the indoor climate quality during a shorter period will be related to the indoor climate for the whole year for different building prototypes and for a number of outdoor climate prototypes during one or two weeks, this should be possible. This relation may be found by means of large number of computer simulation calculations.

Intermezzo: RMOT*

Analysis of field studies (e.g. De Dear, 2001; Oseland & Humpfreys, 1994) showed that the amount of clothing people wear inside correlates strongly with the Running Mean Outside Temperature (RMOT), which is an 'artificial' outdoor temperature that can be described as an integrated temperature over the day of exposure and a couple of days before. It was assumed that in general the time-dimension of thermal adaptability is of the same order as the time-dimension of clothing adaptation. For practical reasons a numerical simplification of the RMOT is introduced, called RMOT*. In formula:

$$RMOT^* = \frac{1 \times T_{out,\ today} + 0.80 \times T_{out,\ yesterday} + 0.4 \times T_{out,\ day\ before\ yesterday} + 0.2 \times T_{out,\ 2\ days\ before\ yest}}{1 + 0.8 + 0.4 + 0.2}$$

With the remark that as 'outdoor temperature' on a certain day (today, yesterday etc.) once should calculate the average from the maximum and minimum outdoor temperature that can be collected from weather stations.

OCCUPANT CONTROLLED BUILDING SPACES

Because of the great difference between the two comfort limits it is very important to develop a clear definition to judge whether a building space can be considered occupant controlled.
Windows that can be opened (natural ventilation) are very important, but are of no use when the building occupants can not use them the way they want to. About the same can be said of individual control of building services. One of the parameters that limit the extend to what individual control can be practiced is the number of people in a room. A field study in 13 Dutch office buildings (about 12000 occupants in total) shows a big difference in the number of complaints in relation to the number of people in a room (figure 5), Kurvers et al. (2001-1).

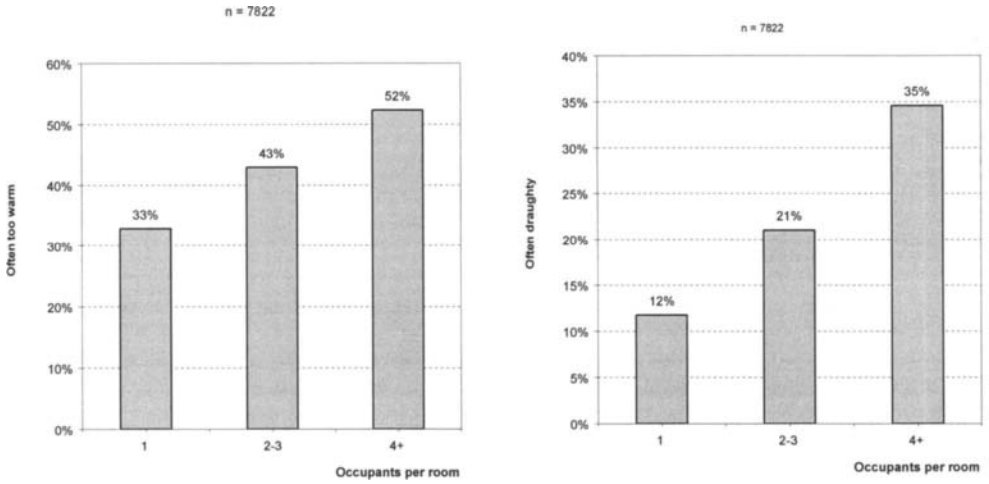

Figure 5: Relation between number of occupants per room and the percentage of occupants perceiving their workplace as "often too warm" (left) or "often draughty" (right) in 13 Dutch office buildings.

Perception of health, air quality, acoustical and visual comfort shows the same effect. Office rooms for 4 occupants or more lead to 1.5 – 3 times more complaints compared with the situation that rooms are occupied by just one person.

A part of the population was also asked about their perception of the possibilities of individual temperature control and the possibility of opening windows. Figure 6 shows 3.5 times more occupants in larger office rooms don't have the opportunity to open a window compared to single person rooms. About 4 times more occupants judge the possibility of individual temperature control insufficient.

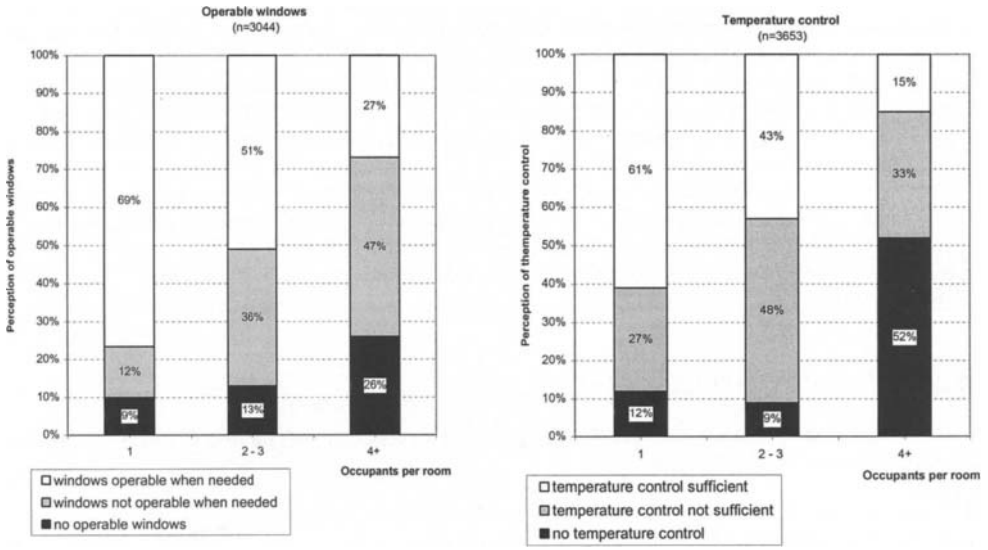

Figure 6: Number of occupants per room and the perception of the effect of operable windows (left) and the perception of the effect of temperature control (right) in 8 Dutch office buildings.

DISCUSSION

Based on a thorough review of the literature, Kurvers et al. (2001) and workshops with Dutch IEQ experts, a proposal for a new Dutch guideline for thermal comfort performance of indoor spaces is presented. Some aspects of the proposal are still 'under discussion', e.g. the RMOT* concept. Another question is: what requirements to use when outside air temperatures are below 5 °C, and what to do with the 5-12 °C range where requirements for occupant controlled spaces are now more stringent than those for centrally controlled and often artificially cooled spaces?

Furthermore lot of work has to be done on developing a good definition of "occupied controlled building space".

The final version of the guideline will be established the second half of the year 2002. This final version will present guidance on *how* to use the new requirements, not just in a design context (computer simulations), but also for evaluation purposes (measurement analysis).

In addition to the new guideline a format for field studies will be presented to evaluate the new guideline during the coming years.

ACKNOWLEDGEMENTS

This paper is based on the outcomes of a study carried out by Delft University of Technology and ISSO, the Dutch institution for the Study and Research in the field of Building Services in co-operation with BBA Environmental Consultants and High Performance Buildings.

The project is funded by NOVEM, the Dutch organisation on Energy and Environment and the Rijksgebouwendienst, the Government Buildings Agency of the Netherlands.

CONCLUSION AND IMPLICATIONS

A draft guideline for thermal comfort performance evaluation is presented. It's properties:

- The new guideline distinguishes between requirements for centrally controlled and for occupant controlled indoor environments, following De Dear's meta-analysis results.
- The new guideline will define 'suitable occupant control': e.g. requirements for effective operable windows, clothing policies, group size per room, etc.
- The upper temperature limits are set in terms of maximum allowable operative indoor temperatures. These increase with increasing outside temperature (RMOT*). Thus anticipating on adaptive effects (both behavioural and psychological) in relation to season and weather conditions. See figure 4 and Intermezzo RMOT*.
- The building's performance is characterized by the 'percentage of occupancy time that the allowable maximum indoor temperature is exceeded' and the 'average amount of degrees that the upper-limit is exceeded during these hours of excess'.
- It defines different levels of thermal performance quality in 4 categories. See table 1.
- Once established, the new guideline will be evaluated on the basis of well defined field research

IMPROVEMENTS OF INDOOR HUMIDITY PERFORMANCE BY A NOVEL AIR-CONDITIONING SCHEME: CHILLED-CEILING COMBINED WITH DESICCANT COOLING

L. Z. Zhang, J. L. Niu

Department of Building Services Engineering,
The Hong Kong Polytechnic University, Kowloon, Hong Kong, China

ABSTRACT

A novel HVAC system, chilled-ceiling combined with desiccant cooling is proposed for an office room in hot and humid climates in Hong Kong. Studies found that improved indoor humidity performance can be obtained in comparison with a traditional all-air conditioning system. Actually, for conventional constant volume all air system, the minimum RH is in July and the RHs are well controlled to around 50% in summer season. In winter and transient seasons, the RHs rise up. RHs bigger than 70% occasionally occur in these seasons. In contrast, the chilled ceiling combined with desiccant cooling system controls indoor temperature and humidity independently. The variations of monthly averaged RH are relatively small and they are in phase with outside humidity fluctuations: maximum in August and minimum in February.

KEYWORDS

Radiant cooling, Humidity, Desiccant cooling, all-air system.

INTRODUCTION

There have been increased interests of radiant cooling in North America and Asian countries due to its inherent advantages of increased thermal comfort with reduced energy use (Feustel and Stetiu, 1995; Stetiu 1992; Niu, Kooi Ree 1995). However, up until now, most of the works concerning radiant cooling are focused on its thermal analysis, while indoor humidity, which is equally important as thermal performance, is neglected. The scarcity of knowledge in this area has limited the applications of chilled-ceiling systems to hot and humid regions, where the risk of condensation on the chilled ceiling surfaces represents a significant problem. This is understandable considering Hong Kong has a hot and humid summer with an average dew point exceeding 22°C. Consequently, indoor moisture levels need to be carefully controlled in this climate, not only for thermal comfort purposes, but also for condensation reasons. It is inevitable that air dehumidification and ventilation must be well combined with chilled ceiling panels and the resulting indoor humidity performance should be evaluated, in addition to building thermal performance analysis.

In this paper, the indoor humidity behaviors associated with a system combining chilled-ceiling and desiccant cooling (CC+DC) are investigated and compared with a traditional constant volume all-air system (CAV). Some operational measures to prevent water condensations on ceiling panels are recommended.

SYSTEM DESCRIPTIONS

Traditional air-conditioning system is constant volume all-air system. In such a system, both the sensible and latent load is treated by coiling coils in an AHU (Air Handling Units). To use the concept of radiant cooling, a new system, namely, a system combi ıing chilled-ceiling with desiccant cooling, is proposed, as shown in Fig.1 for schematics and Fig.2 for psychrometrics, respectively. With this system, the latent load is treated by the desiccant cooling system and most of the sensible load is treated by ceiling panels. The water flow rate to ceiling panels is kept fixed, while the inlet water temperature is controlled instead to maintain a pre-fixed indoor environment.

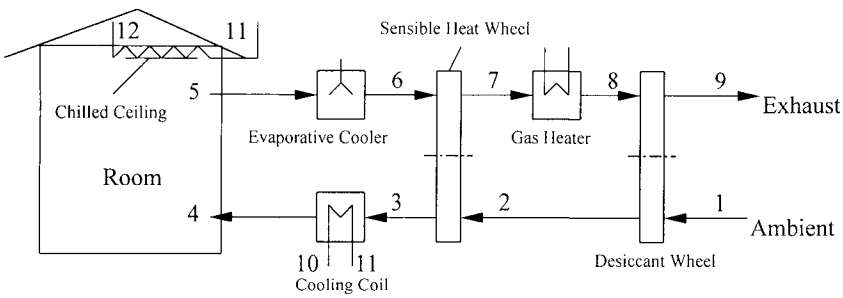

Figure 1: Schematics of the system combining chilled-ceiling with desiccant cooling.

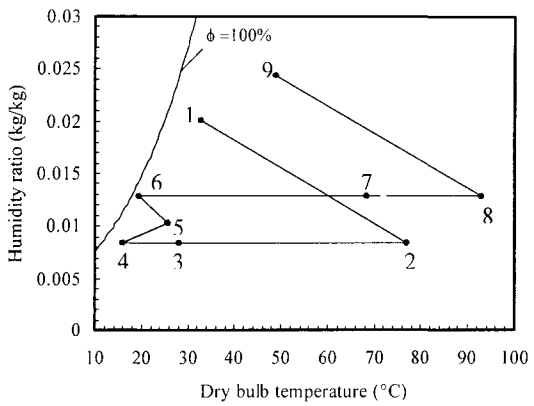

Figure 2: Psychrometrics of air handling in desiccant cooling.

The main purpose of desiccant cooling is for fresh air ventilation and dehumidification. Ambient outdoor air at state 1 enters the supply air duct. This air passes through a desiccant wheel and hot, dry air exits at state 2. This increase in temperature is due to the heat of sorption and some sensible heat transfer. The hot, dry supply air transfers much of this heat to the return air stream in process 2 to 3 involving a sensible heat wheel. Unlike a commonly used desiccant cooling, where air at state 3 is evaporatively cooled to state 4, in this system, the warm, dry air at state 3 is cooled by a cooling coil to around 18°C, to keep the dryness of supply air at state 4. The cool, dry air at state 4 is then distributed to the room. After accepting the building latent load and a small amount of sensible load, the air then returns to the desiccant system through return air ducting. This is the state of the air which corresponds to state 5. This somewhat cool, fairly dry air is evaporatively cooled to as low a temperature as possible at state 6. This cold, damp air is then preheated by the rotary sensible wheel to state 7 while cooling the supply air stream. State 7 is the state of the moist air as it enters the heating coil. Hot, humid air exits at state 8 and regenerates the desiccant wheel. Warm, very humid air at state 9 is then exhausted to the surroundings. In this combined system, εn evaporating temperature as high as 15°C is needed for the water-chiller, which means a much raised *COP*.

METHODS

Thermal performance is evaluated by a special cooling load program for cooled ceiling systems ACCURACY (Niu and Kooi 1994) which is developed and validated previously at Delft University of Technology in Netherlands. The program calculates not only the cooling load, but also the required supply water or air temperatures for different panel installation areas. The program also works out the respective convective and radiant heat extractions by cooling panels, and the radiant and convective heat from all the window and wall surfaces. Adopting such building dynamics simulation techniques, year round simulation of rooms with or without chilled-ceilings provides hour-by-hour data of cooling/heating loads, and temperatures of room air and other components.

Moisture balance in the room is calculated by,

$$\frac{V_r \rho_r dw_r}{d\tau} = -\dot{v}_s \rho_s (w_r - w_s) + ACH \cdot V_r \rho_o (w_o - w_r) + \dot{m}_s - \dot{m}_{ad/de} \quad (1)$$

where V_r is the room volume (m^3), ρ is air density (kg/m^3), w is humidity ratio (kg/kg), τ is time (hr), $\dot{v}_s$ is supply air volumetric flow rate (m^3/h), ACH is air infiltration rate (h^{-1}), $\dot{m}_s$ is indoor moisture generation rate (kg/h), subscripts "r", "o", "s" refer to "room", "outside", and "supply" respectively. The last term $\dot{m}_{ad/dc}$ is moisture adsorption and absorption by room surfaces and furniture (kg/h). In general, the moisture adsorption/absorption properties of building materials are less understood, therefore, overall, precision of moisture prediction lags behind that for thermal prediction. In this study, the indoor surface and furniture adsorption and desorption effects are not included. In reality, such effects may help smooth the RH fluctuations, but will not significantly affect the hourly averages (Niu and Burnett 1998). In simulations, thermal analysis is coupled with moisture analysis to take into account the interactions between thermal and moisture performance. The performance of the desiccant cooling system is predicted with a model proposed by (Jurinak, Mitchell, and Beckman 1983)

A typical office room in a south-facing high-rise building in Hong Kong (22°N, 114°E) is simulated in this study. The office is 5.1m long, 3.6m wide, and 2.6m high. The thickness of the envelope is 260mm and the resulting heat transmission coefficient U for the opaque part of the facade is $2.91 W/m^2K$. The glazing area is $2.88m^2$ with double-pane windows of which center-of-glass U value is 1.31 W/m^2K. Louver curtain is installed behind windows. It is determined that about 70% of the

ceiling is covered by radiant ceiling panels when the radiant ceiling panel system is applied. An occupancy pattern of 2 persons with a schedule from 9 to 18h is simulated in the office. When present, each person generates 75W sensible heat and 57.6g/h moisture. Of the sensible heat generated, 50W is radiative and 25W is convective. Besides, constant loads of 459W of equipment and lighting with a schedule from 9 to 18h are modeled in the room. Half of these loads are considered as radiative and half convective. The operating hours of the ceiling panels and ventilation systems are also from 9 to 18h. However, as will be discussed later, dehumidification/ventilation prior to the operation of chilled-ceilings would be required in summer to prevent condensation on panel surfaces. Air infiltration rates ranging from 0.05 to 0.4 ACH are modeled during the time when the ventilation system was switched off and the building is not pressurized.

The supplied chilled water flow rate to the ceiling panels is 0.5t/h, resulting a temperature rise of about 1.6°C through the panels. The ventilation fresh air is supplied at a rate of $67m^3/h$, which complies with ASHRAE standard 62 (ASHRAE 1999). For all-air systems, the ratio of return/fresh air is 3.4, resulting a supply air flow rate of $300m^3/h$. The operative temperature is set to 25°C in summer and 23°C in winter.

RESULTS AND DISCUSSION

The distribution of indoor relative humidity during working hours are shown in Fig.3 for CAV and CC+DC. The optimum zone is from 40% to 60%RH and 50% RH is ideal for building occupants to avoid the hazards of fungi, bacteria, viruses, and respiratory difficulties. The figure shows that the all-air system has the least annual hours in the comfort region, and has the most hours in either the dry (<40%) or the humid (>60%) regions. The chilled-ceiling combined with desiccant cooling controls the indoor humidity best: 90% of annual operating hours is in the optimum region.

The monthly averaged relative humidity is illustrated in Fig.4 for CAV and CC+Dc. For conventional constant volume all air system, the minimum RH is in July and the RHs are well controlled to around 50% in summer season. In winter and transient seasons, the RHs rise up. RHs higher than 70% occasionally occur in these seasons. This phenomenon is due to the fact that in a conventional all air system, temperature is intentionally controlled, while the humidity is passively controlled, because the supply air state is determined by the sensible load. In winter and transient seasons, sensible load becomes smaller and air is not sufficiently dehumidified. The result of this approach is a loss of humidity control while the temperature is maintained at set point. In contrast, in a CC+DC system, both the temperature and the indoor humidity are well controlled around set points, since they are decoupled and intentionally controlled independently. The variations of monthly averaged RH are relatively small and they are in phase with outside humidity fluctuations: maximum in August and minimum in February. It can be concluded that chilled-ceiling systems have better indoor humidity controls with reduced energy use than their all-air counterparts.

Even though chilled-ceiling systems realize independent humidity control with reduced energy use, when used in hot and humid regions, condensation on ceiling panels remains a troublesome issue. To prevent condensation, room air needs to be dehumidified prior to the operation of ceiling panels. A one-hour in advance dehumidification/ventilation strategy is simulated in which ceiling panels are operated from 9:00-18:00 and the AHU is operated from 8:00-18:00. The room moisture levels are substantially pulled down during the first dehumidification hour, and when the ceiling panels begin to operate, the maximum RHs are below 90%. Therefore, water condensation is prevented. The larger the air infiltration rates at night, the earlier it requires for air dehumidification, to prevent condensation. Generally speaking, a one hour in advance dehumidification could prevent condensation for most buildings except those that have very high air infiltration rates. On the other hand, if a building is well enclosed and the air infiltration rate is less than 0.05 at night, no condensation occurs

even for simultaneous dehumidification and ceiling cooling. The condensations with desiccant cooling are similar to those with AHU.

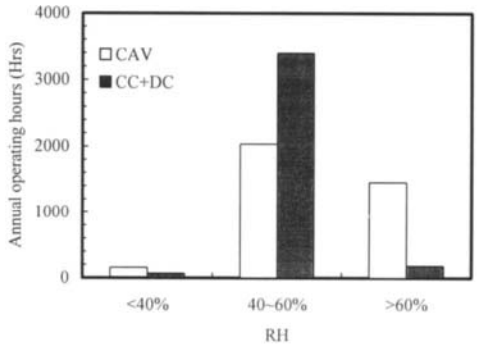

Figure 3: Indoor humidity distributions of two systems: CAV and CC+DC.

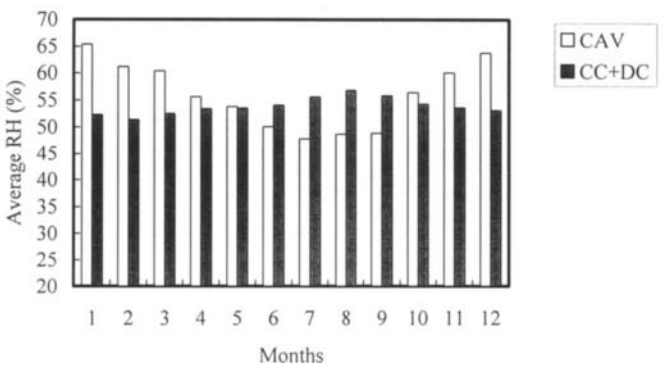

Figure 4: Monthly averaged relative humidity: CAV and CC +DC

CONCLUSIONS

The conventional constant volume all air system passively controls the indoor humidity. The result of this approach is a loss of humidity control while the temperature is maintained at set point in transient seasons. In contrast, in a system combining chilled-ceiling with air dehumidification, the temperature and the indoor humidity are decoupled and intentionally controlled independently. As a result, more annual hours are in the comfort region.

Air dehumidification and ventilation system should be operated at least one hour earlier than the operation of ceiling panels. Otherwise, condensation may occur. However, if a building is well sealed and the air infiltration rate is less than 0.05 at night, no condensation occurs even without in advance dehumidification.

THE ECO-COSTS/VALUE-RATIO

Ch.F. Hendriks, Mrs. ir. Gabriëlla M.T. Janssen and J. Vogtländer

ABSTRACT

The basic idea of the EVR (Eco-costs/Value Ratio) model is to link the 'value chain' (Porter, 1985) to the ecological 'product chain'. In the value chain, the added value (in terms of money) and the added costs are determined for each step of the product 'from cradle to grave'. Similarly, the ecological impact of each step in the product chain is expressed in terms of money, the so-called eco-costs.
The eco-costs are 'virtual' costs: these costs are related to measures which have to be taken to make (and recycle) a product *'in line with earth's estimated carrying capacity'*. These costs have been estimated on the basis of technical measures to prevent pollution and resource depletion to a level which is sufficient to make our society sustainable. The ratio of eco-cost and value, the so-called Eco-costs/Value Ratio, EVR, is defined in each step in the chain as:

$$EVR = \frac{eco\text{-}costs}{value} \tag{1}$$

The five components of the eco-costs have been defined as 3 'direct' components plus 2 'indirect' components:

- virtual pollution prevention costs, being the costs required to reduce the emissions of the production processes to a sustainable level (Vogtländer et al., 2000);
- eco-costs of *energy*, being the price for renewable energy sources;
- *materials* depletion costs, being (costs of raw materials) * (1-α), where α is the recycled fraction;
- eco-costs of *depreciation*, being the eco-costs related to the use of equipment, buildings, etc.;
- eco-costs of *labour*, being the eco-costs related to labour, such as commuting and the use of the office (building, heating, lighting, electricity for computers, paper, office products, etc.).

Based on a detailed cost-structure of the product, the eco-costs can be calculated by multiplying each cost element with its specific Eco-costs/Value Ratio, the EVR. These specific EVRs have been calculated on the bases of LCAs.

KEYWORDS

eco-costs, value, recycling, prevention, land use, materials, pollution

1 INTRODUCTION

In the Preface of 'Our common future' of the World Commission on Environment and Development, G.H. Brundtland wrote in 1987:
'The downward spiral of poverty and environmental degradation is waste of opportunities and of resources. In particular it is a waste of human resources. These links between poverty, inequality, and environmental degradation formed a major theme in our analysis and recommendations. What is needed now is a new era of economic growth – growth that is forceful and at the same time socially and environmentally sustainable.'(Brundtland, 1987).

But what do these rather philosophical definitions of our future aim mean to governmental authorities business managers, designers and engineers in terms of the practical decisions they take?
There is a need to resolve simple questions like: What is the best architectural design in terms of ecological impact? What is the best concept of buildings in a city in terms of sustainability? What is the best spatial planning?

For that reason, the Delft University of Technology developed the eco-costs/value model as a practical tool for decision-making, based on the LCA methodology, and comprising the following features:

- one single indicator for the 3 major groups of environmental impacts (materials depletion, fossil energy consumption, toxic emissions) and land-use;
- a relatively simple and well defined allocation model to cope with the typical LCA difficulties in the building industry (in the building industry LCAs are characterized by many 'indirect' environmental impacts, like the environmental impact of the manufacturing of building equipment which are shared by many other external systems);
- an indicator which shows the degree of delinking of economy and ecology (eco-costs) of a product, which can be applied when a designer is asked to design a product (a house, a road, a city) within a given budget; the issue is then to create maximum value for the end-user at a minimum of environmental burden (eco-costs).

The basic idea of the model is to link the 'value chain' (Porter, 1985) to the ecological 'product chain'. In the value chain, the added market value (in terms of money) and the added costs are determined for each step of the product 'from cradle to grave'. Similarly, the ecological impacts of each step in the product chain are expressed in terms of money as well: the so called eco-costs. See Figure 1.

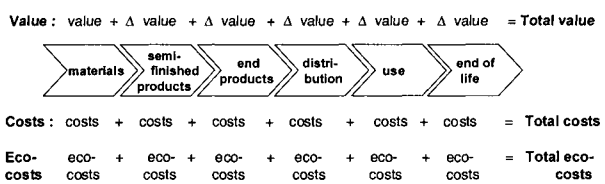

Figure 1: The basic idea of combining the economic and ecological chain: 'the EVR chain'.

The eco-costs are 'virtual' costs: these costs are related to measures which have to be taken to make (and recycle) a product *'in line with the earth's estimated carrying capacity'*. These eco-costs are the sum of the 'marginal prevention costs' of each 'class' (type) of pollution, see chapter 3.1, and the costs of measures for prevention of material and energy depletion, see chapter 3.2 and 3.3.
Since our society is yet far from sustainable, the eco-costs are 'virtual': they have been estimated on a 'what if' basis. The costs of the required prevention measures are not yet fully integrated in the current costs of the product chain (the current Life Cycle Costs). It is expected that, *in future,* the eco-costs

will become part of the product costs (by means of 'eco-tax', 'tradable emission rights', or other governmental measures), since our society will not continue to accept consequences unsustainable situations in the long term.

2 THE VALUE, COSTS AND ECO-COSTS OF A PRODUCT

Now we look into one step of the production chain.
The value ('fair price') of a product is determined by:

- product quality;
- service quality;
- image.

These 3 components of value are described in more detail by the 'eight dimensions' of Garvin (Garvin, 1988).

The cost-structure of a product comprises:

- the purchased materials (or components);
- the required energy;
- depreciation (of equipment, buildings, etc.);
- labour.

For each company in the production chain, the tax + profit equals the value minus the costs.

The direct eco-costs have been defined as sum of the following elements:

- virtual pollution prevention costs, being the costs required to reduce the emissions in the product chain (from cradle to grave) to a sustainable level;
- eco-costs of energy, being the price for sustainable energy sources;
- eco-costs of materials depletion, being (costs of raw materials)x(1-α), where α is the recycled fraction of materials to *make* a product (for details on the 'end of life' and recycling phase, see Section 4).

The indirect eco-costs are:

- eco-costs of depreciation, being the eco-costs related to the use of equipment, buildings, etc.;
- eco-costs of labour, being the eco-costs related to commuting and the use of the office (building, heating, lighting, electricity for computers, paper, office products, etc.).

This is depicted in Figure 2.

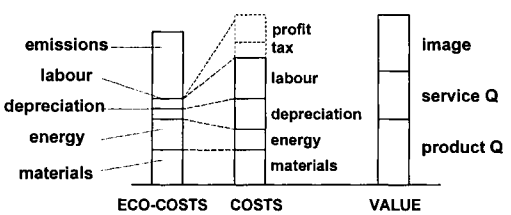

Figure 2: The decomposition of 'virtual eco-costs', costs and value of a product

Along the production chain the value, the costs and the eco-costs can be added up, as depicted in Figure 3.

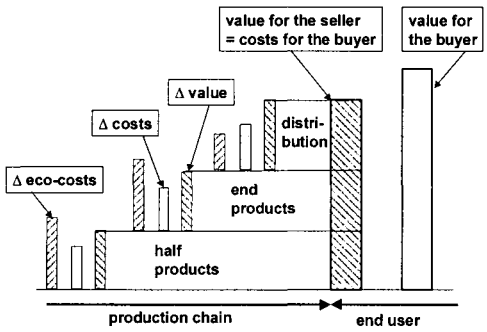

Figure 3: The decomposition of the value in the chain

Characteristic for each process, product or service is the ratio of the value and the eco-costs.
We can define this Eco-costs/Value Ratio, EVR, at every aggregation level of the production chain:
EVR = eco-costs/value.

A low EVR indicates that the product is fit for use in a future sustainable society. A high EVR indicates that the value/costs ratio of a product might become 'less than one' in future (since 'external' costs will become part of the 'internal' cost-structure), so there is no market for such a product in future.
Later in this article we will show how we might apply the EVR model for economic allocation in the LCA of a complex product-service system, but first we will define and describe the eco-costs.

3 THE COMPONENTS OF THE ECO-COSTS

As mentioned in Chapter 2, we define the eco-costs as the sum of 3 direct (toxic emissions, energy and materials depletion) and 2 indirect elements (depreciation and labour).
All these elements are calculated according to the LCA method, as defined in ISO 14041, as described hereafter.

3.1 The virtual pollution prevention costs

For toxic emissions, the marginal prevention costs are assessed for seven emission effect classes on the basis of prevention measures which are based on readily available technologies. The costs of the required marginal prevention measures are based on current West European price levels:
6.40 Euro/kg SO_x equivalent for acidification;
3.05 Euro/kg PO_4 equivalent for eutrophication;
50.0 Euro/kg VOC equivalent for summer smog;
12.3 Euro/kg fine dust for winter smog;
680 Euro/kg Zn equivalent for heavy metals;
12.3 Euro/kg PAH equivalent for carcinogenics;
114 Euro/1000 kg CO_2 equivalent for global warming.

3.2 The eco-costs of energy

The calculation method to determine the eco-costs of energy is based on the assumption that fossil fuels have to be replaced by sustainable energy sources. For details see (Vogtländer, 2001). The 'eco-costs of energy' is equal to the costs of the renewable energy system which has to replace the current system.

3.3 The eco-costs of materials depletion

With regard to the depletion of materials, the main approach in the model is:
- the eco-costs of materials depletion are set equal to the market value of the raw materials when the materials are not recycled;
- when a fraction α of the sourced material is recycled, a factor $(1-\alpha)$ is applied to the market value of the raw material for the new product to calculate the eco-costs of materials (for the general concept and its details see Section 4),

therefore

$$\textit{eco-costs of materials depletion} = \textit{'market value of the raw material'} \times (1-\alpha) \qquad (2)$$

The underlying assumption is that the (average) market value of the virgin material for *metals* reflects the fact whether the material is scarce or hard to find and/or mine (e.g. platinum, gold, silver), or whether that will happen in the foreseeable future.

For *plastics* however, the situation is different, since the source of it is crude oil.
It is more in line with the general philosophy of this model to avoid the use of fossil fuels and use biomass instead as source material for plastics. Therefore, in the EVR model the price of feedstock for plastics based on biomass has been chosen for the eco-costs of materials depletion. This price is estimated at 0.6 Euro/kg.
The fraction α has to be applied to the materials used for the new product (and *not* as a fraction of materials from the old product at the End of Life), *after* the upgrading process (if applicable).

3.4 Indirect eco-cost: the eco-costs of labour

The eco-costs of labour are indirect eco-costs, since labour as such is hardly causing any environmental burden. However, there is some environmental burden related to labour, such as the environmental impacts of heating, lighting, computers, commuting, etc.
The calculations of these eco-costs are specific for the type of labour.
A good guess for in offices is that the eco-costs for labour are approx. 10% of the costs. Calculations on labour outside offices (shop floor personnel in factories, sales people, truck drivers, etc. show that the eco-costs will vary in a range of 5% - 15% of the costs, where the eco-costs of commuting and use of electricity play a rather dominant role. Therefore it is recommended to make an LCA assessment in each typical case.

3.5 Indirect eco-costs: the eco-costs of depreciation of production facilities

The eco-costs related to the fact that fixed assets are used to make a product, are indirect eco-costs.
The calculations on the eco-costs of the use of fixed assets have the same characteristics as cost estimates for investments: for each individual situation, calculations have to be made on the applied materials and the required manpower.

The basic idea behind the 'eco-costs of depreciation' is that the eco-costs of the production equipment (or production facilities) have to be allocated to the products which are made by means of this equipment or in these facilities. The standard procedure is:

1. Calculate the eco-costs of the equipment or facility.
2. Divide the eco-costs of step 1 by the lifetime T (in years) of equipment or facility. In the EVR model the 'economic lifetime' has to be applied instead of the 'technical lifetime', which is 'safe side' since the economic lifetime is usually shorter than the technical lifetime.
3. Divide the outcome of step 2 by the quantity of products N which are produced per year.

In formula:

$$\textit{eco-costs of depreciation} = (\textit{eco-costs of the production facility})/T/N \tag{3}$$

It is obvious how to apply equation [3] to a production facility for prefab floor slabs, doors, prefab walls and other components for buildings.
But this equation is also applied to determine in more complex situations. As an example, this allocation procedure is applied to the use of an office building per m^2 per annum. Note that different facilities or different subsystems of facilities might have a different lifetime, T.
The same methodology can be used to analyse whether it is better to renovate specific old office buildings, rather than demolish these buildings and build new ones.
Since the EVR model applies the economic lifetime of the facility, equation [3] has a high similarity with the normal, linear equation for production costs related to depreciation:

$$\textit{costs of depreciation} = (\textit{value of the production facility})/T/N \tag{4}$$

Combining equation [3] and [3]:

$$\textit{eco-costs of depreciation} = (\textit{costs of depreciation}) \times (\textit{eco-costs/value})_{\textit{production value}} \tag{5}$$

The meaning for equation [5] is that the eco-costs of depreciation can be derived from the normal costs of depreciation by multiplying it with the EVR of the production facility. In situations where more than one type of product is produced in a complex production system, and where a 'cost break down structure' of the product is available, equation [5] can provide an easy way out of a rather complex allocation problem.
Calculations show the following characteristics for the eco-cost/value ratio:

- complex machines 0.3
- luxurious buildings (offices) 0.3
- low cost offices 0.4
- processes in stainless steel 0.4
- refineries 0.5
- steel structures 0.6
- warehouses 0.6

In general:

- the use of steel (and other metals) is related to a high EVR (because of high pollution prevention costs);
- complex systems have a low EVR (because of a high labour content).

4. THE ISSUE OF LAND-USE

The increasing use of land (urban areas, industrial areas, road infrastructure, etc.) is a major cause of degradation of our environment. In the last decades there is a growing concern about this negative aspect of a growing population and a growing economic wealth. So, most of the designers feel the need for incorporating the negative aspects of 'land-use' in spatial planning. But how?

The so called 'eco-costs of land conversion' is proposed as a single indicator, being the marginal costs of prevention (or compensation) of the negative environmental effects of change of land-use. These 'eco-costs of land conversion' are based on four sustainability characteristics of land (before and after the conversion):

1. the botanical aspects (the species richness and the rarity of ecosystems and vascular plants);
2. the aspect of 'scenic beauty';
3. the aspect of production of food and biomass;
4. the aspect of the H_2O cycle.

For the situation of The Netherlands (and the Western part of Europe), the eco-costs of the aspects 1 and 2 appear to be dominating.

4.1 The botanical aspects

'Habitat for plants, animals and other species' is one of the two major aspects with regard to conversion of land. The issue here is that 'biodiversity' is degraded by the expansion of urban areas. Although both flora and fauna are effected, flora has been widely accepted to classify the subject of land-use (Lindeijer, 2000), since it is easier to characterize than fauna (indicators for fauna are still under development), and since it is argued that there is a link between both types of biodiversity.

Species richness is characterized by the number of species of vascular plants at a certain area, S. It is one of the most applied measures of characterizing the botanical aspects of land in LCAs (Lindeijer, 2000).
For many Western European countries, data on S are available. For The Netherlands field data are available on a grid of 1 km^2.

In the EVR model, land-use is expressed in terms of 'actual m^2 'x' quality factor' of land before and after the change. The quality factor is defined as the counted total number of vascular plant species, S, divided by the quality norm for it, $S_{ref.}$, where $S_{ref.}$ is the number of species for 1 km^2 of nature.
The category indicator for species richness of land, *SRI* ('Species richness Indicator') is introduced, which is expressed in terms of the area, A (m^2), multiplied by the quality factor for it, $S/S_{ref.}$.

$$SRI = A \times S/S_{ref.} \tag{6}$$

So *SRI* is expressed in terms of 'equivalent m^2 of nature'.
The environmental effect of the change of land-use is described now as

$$\Delta SRI \times A \times AS/S_{ref.} \tag{7}$$

where Δ denotes the difference of S and *SRI* before and after the change.

For the quality norm of S in The Netherlands, $S_{ref.}$, a value of 250 vascular plants species for 1 km^2 is proposed. S is more than 250 for 9% of the total area of The Netherlands. (Areas above 300 are very scarce: 3.5% , areas above 200 are quite common: 21%).

For Germany, England and the northern part of France, the same quality norm of 250 species for 1 km^2 is proposed, since the species richness in these countries is in the same order of magnitude as in The Netherlands (Barthlott et al.,1998). For species richness of other countries, see (Vogtländer, 2001).

The total costs of compensation, the eco-costs of species richness, are:

$$eco\text{-}costs\ of\ species\ richness = \Delta SRI \times 4 \quad (Euro) \tag{8}$$

Where Δ *SRI* is the difference between *SRI* before and after the conversion.
A much more subtle methodology of botanical characterization on the basis of counting of species (vascular plants), is a methodology developed by Witte (Witte, 1998). This methodology takes the rarity of plants and ecosystems into account.
Although species richness is an indicator for botanical value ('when there are many species, there are normally valuable species as well'), it is a logical step forward to distinguish between species which are important and species which are less important. In this system, 'rarity of eco-systems' is the main measure of importance.
Since this method has been operationalised for The Netherlands only, the method is not described in this article. For a description of the methodology, see (Vogtländer et al., 2001) and (Vogtländer, 2001).

SUSTAINABLE USE OF RECYCLED MATERIALS IN BUILDING CONSTRUCTION

Mrs. ir. Gabriëlla M.T. Janssen and Ch.F. Hendriks

Faculty of Civil Engineering and Geosciences, Delft University of Technology,
PO Box 5048 2600 GA Delft, The Netherlands

ABSTRACT

This contribution focuses on the importance of sustainability in the building sector. The underlying idea being that sustainability and durability must be considered jointly. Different models are presented to determine the degree of sustainability, focussing on: the degradation factor, life cycle assessment, the Delft ladder of priorities, high-grade applications, design for recycling, design for disassembly, and the ecocost-value ratio. Examples are given of case studies in which these models have been applied successfully.

KEYWORDS

materials, recycling, life cycle assessment, high grade application, degradation, ecocosts

INTRODUCTION

The term 'sustainability' was introduced in the UN report *Our Common Future* (Brundlandt). The NEPP describes sustainable development as that which meets the needs of the current generation, without endangering the opportunities for future generations to meet their particular needs. The concept encompasses not only the environment, but also social and economic interests such as health and wellbeing, safety, care for living space, prosperity, sufficient employment and a fair distribution of resources. To ensure real sustainable development, these interests must be combined at all levels. Sustainable construction could therefore be described as a way of designing and constructing buildings that support human health (physical, psychological, and social) and which is in harmony with nature, both animate and inanimate.
For the importance of sustainability the model of factor 20 is proposed.
The so-called 'Factor 20' is a metaphor, a guideline for sustainable development and to make specific steps forwards. The metaphor can also be used for sustainable construction. Factor 20 refers to the aim to have the environmental impact per unit of prosperity reduced by a factor of 20, thus meeting social needs 20 times as environmentally efficiently – in this case building housing and other property. There are also a number of variants to this factor, e.g. using the less stringent factors 4 and 10. Assuming

that both the population and worldwide economic developments will continue increasing, it is quite some challenge to reduce the environmental pressure. To answer the question 'how great is the environmental load that mankind is asserting on the environmental capacity?', the American biologist and environmental expert Barry Commoner (1972) described the environmental load using the following formula:

$$EL = P \times PP \times E \quad (1)$$

where:

EL	=	environmental load
P	=	population size
PP	=	average prosperity per person
E	=	environmental load per unit of prosperity

Let us assume the (not unreal) scenario that in 50 years time the world's population will have doubled, the average prosperity per person will be fivefold (the poor countries have a lot of catching up to do), and we want to halve the total environmental pressure. This means that the environmental impact per unit of prosperity must be reduced by a factor of 20. To implement changes of this size, a number of trends will have to be reversed. However, such reductions cannot easily be achieved by (improving) existing systems and technologies. In addition to technological innovations, people's behaviour and perceptions will also have to change. Technological solutions can only succeed if they fit in with social and cultural developments.

What is sustainable and what is sustainable construction?

There are many descriptions of the term 'sustainable', but there is no single definitive meaning. Most descriptions also provide a very limited view of the subject. We should not think that 'sustainable' merely focuses only on the environment. The processing industry understood this far earlier: environmental aspects should not be placed alongside or opposite other aspects or interests, but should be 'part of the concept as a whole', or as part of an integral approach. Here we should note that, in relation to the word 'construction', the term 'sustainable' has two meanings, i.e. both durable and sustainable.
Durable refers to the property of a material, building section or construction that can resist any unacceptable deterioration of relevant functional characteristics through specific chemical, physical and mechanical loads, over a certain period of time.
Sustainable refers to the general property of a material, building section or construction that indicates whether or not specific demands are met for affecting the air, water and soil qualities, for influencing the health and wellbeing of living organisms, for use of raw materials and energy, and even for scenic and spatial aspects, as well as for creating waste and nuisance.

Errors often occur when only one of these meanings is taken into consideration for sustainable construction or, worse still, if one meaning has priority over the other. Such errors can and must be prevented by integrating both aspects into the development and knowledge transfer with regard to sustainability.

Starting points

Decisions concerning integral sustainability, which include both meanings of the term, should be based on the following three starting points.
- An integral approach to (raw) material use in the construction industry should be based durability as well as sustainability.

- The application should be optimised based on the entire life cycle, including several life cycles for reused material.
- The application should be such that recycled material is used for the next best purpose possible within the building chain. This means that these materials must be used in such a way that they can be easily recognised and separated.

Degree of sustainability

Various instruments have been developed to measure or calculate the sustainability of materials.

Degradation factor (DF)
Using the design specifications as starting point and taking into account (variants for) material use and the required lifespan, including repair and maintenance scenarios, an image can be formed of the expected degradation, as a function of time and conditions of application. This is also important in the decision-making process when considering possible variants for reuse and recycling once the end of the lifespan has been reached.

Life-cycle thinking (LCA method)
Life cycle thinking is based on the fact that decisions taken in one phase (design, implementation, management, maintenance, demolition and reuse) should always be set against the background of the consequences for the following phases. The intention is to minimise the environmental interventions over the entire life cycle. The most suitable method for this is the life-cycle analysis (LCA), which has now received both national and international (ISO: International Organisation for Standardisation) recognition.

TABLE 1
OVERVIEW OF ENVIRONMENTAL PROBLEMS IN THE LCA METHOD

Depletion	Pollution	Deterioration
Depletion of raw materials	Greenhouse effect	Deterioration of landscape
Abiotic and biotic depletion	Deterioration of ozone layer	Deterioration of ecosystems
	Human toxicity	Deterioration of habitats
	Ecotoxicity	Victims
	Smog	Dehydration
	Acidification	Fragmentation
	Eutrophication	
	Radiation	
	Rejected heat	
	Odour	
	Noise	
	Working conditions	

Waste management
Until recently, the Dutch approach was based on the so-called 'Lansink's ladder', i.e. prevention – reuse of building elements – reuse of materials, incineration with energy recovery – incineration – disposal.

Lansink's ladder dates back to the end of the 1970s, when the legislation concerning waste products was first being written. However, looking back with hindsight, we notice several things. Firstly, the number of opportunities has increased, i.e. the scale of these opportunities (construction, building elements and materials) and there are new insights regarding immobilisation (using chemical or physical methods to prevent the spread of contaminants). Secondly, Lansink's ladder includes a clear order of preference. Methods are now available concerning life-cycle analysis (LCA), eco-costs (costs of ensuring a system or process meets sustainability criteria, including the so-called hidden costs) and value assessment. In particular, the results of the LCA methods and the EVR (eco-costs/value ratio) are applicable for making the best choice as to which rung on the ladder should be used in a specific situation. The result is thus an 'eco-ladder' or 'sustainability ladder' for the building sector, in which the order up the steps is 'tailor made'. This new dynamic ladder is depicted below, under the name 'Delft's ladder'.

TABLE 2
THE 'DELFT'S LADDER'

The 10 steps	Consequences
Prevention	'Design for recycling' (DFR), recovery, based on remaining lifespan (technical and economic)
Reuse of constructions	DFR, oversizing, selective dismantling, remaining lifespan
Reuse of building elements	DFR, selective dismantling, reprocessing, return system
Reuse of materials	DFR, selective dismantling, reprocessing, return system, leaching and content of contaminants
Useful application as residue	Quality equal to reference (with regard to leaching)
Immobilisation with useful application	Leaching and content of contaminants
Immobilisation without useful application	Dumping conditions
Incineration with energy generation	Emission limitation
Incineration	Emission limitation
Dumping	Dumping conditions

The return system refers to building elements or building materials that are returned to the original supplier and are processed (cleaned, repaired etc.), thus allowing them to be reused for the same purpose.

The Dutch Building Materials Decree specifies acceptable compositions and leaching, while the Dumping Decree defines the regime with which dumping sites must comply. Immobilisation means that the dosage rate for leaching (leaching rate) must be drastically reduced once the material has been treated (thermally, chemically or by adding a binder).

High-grade

The term 'high-grade reuse' is becoming clearer. It is often said that, although a lot of construction and demolition waste is reused, this is mostly low-grade waste that is only suitable for building roads. High-grade therefore means reuse in concrete or other building products, as the economic return is much higher for roads than for concrete buildings.

Based on the Delft's ladder, and with the exception of the most desired option, how can the high-grade level be defined? The key can be found by answering the following 10 questions as accurately as possible. By performing this exercise for all recycling options, the results can be easily compared. However, just as when using the life-cycle analysis to select a material, we see that none of the options receives a perfect score, but weighing the criteria further usually leads to the desired choice.

TABLE 3
HIGH-GRADE LEVELS FOR REUSE

High-grade applications: definition of the functional unit as per the LCA	Choices or actions
Applications meet all existing requirements, according to both private and public law	Yes or no
Technical lifespan is greater than economic lifespan	Yes or no
Applications require little maintenance	Express in mass quantities of maintenance materials per functional unit
Maximum potential for future reuse	State the various opportunities for reuse
Minimum degradation during the usage phase	No longer usable due to degradation
Applications are material-extensive	Materials required per functional unit
Applications are energy efficient	Energy required per functional unit
Applications have minimum harmful emissions	Emissions per functional unit
Applications have minimum non-reusable residual waste	Amount of unusable waste in kg per functional unit
Applications conform to market standards	Yes or no

Design for recycling (DFR)

Most primary raw materials are natural substances and are homogeneous, e.g. sand, gravel, clay, oil (including the production of plastics), wool, cotton and wood (for various applications in the building sector, but also for paper), and ores (for metal production). This homogeneity often makes it possible, with relatively simple preparation, to use these raw materials in the production process.

However, this is not true for secondary raw materials, i.e. mainly discarded products, mostly material conglomerates the composition of which is often so complex that reuse is only possible after extensive processing.
Recycling secondary raw materials generally requires a series of processes, of which recognition, sorting, size reduction, and separating are the most important.
Housing or construction demolition rubble must first have the iron, wood, mastic, bitumen, cardboard, chipboard, plastics, aluminium, zinc, copper etc. removed before the aggregate from the rubble crusher is suitable for use as secondary material. Asphalt and concrete from broken-up road pavings is also contaminated with road dirt, salt and oil residues etc. that must be removed before the recycling process can begin.
During the past decades, mechanical 'reprocessing' systems have largely replaced manual processes, primarily in the metal sector but also for construction and demolition waste (CDW), so that CDW can now be used on a large scale in the construction sector.
Not only the recycling sector, but also the government, came under increasing pressure to implement 'design for recycling' (DFR), i.e. designing items in such a way that they can be recycled. DFR means:
- using fewer materials;
- using parts that can be easily dismantled;
- marking all the plastic parts used so that they can be readily identified during dismantling and can be easily separated for further processing.

Governments, both in the Netherlands and elsewhere, are promoting DFR through certification, subsidies, 'return to supplier' obligations and levies on non-recyclable materials or scarce primary raw materials.

For a definite DFR design the following categories of materials must be capable of being recycled and separated.

Concrete
- according to VBT concrete specifications (meets national standards)
- non-standard compositions (for use in concrete)

Masonry
- bricks, sand-lime brick and concrete brick with mortar (for use in roads or concrete)
- aerated concrete
- crushed brick used as such or in brick (without mortar)
- crushed sand-lime brick for use in sand-lime brick
- crushed concrete brick for use in concrete brick

Bituminous materials
- asphalt without modified binders
- asphalt with modified binders
- roofing materials

Wood
- hardwood
- unpreserved wood
- preserved wood

Plastics
- thermosetting and thermoplastic agents should be used separately

Design for disassembly (DFD)
When using constructions and materials the criterion applies that, regardless of whether or not materials can be disassembled in an economic fashion, they can be separated for later reuse, if necessary. The following provides a basis for this strategy.
- Inspection and sampling.
- Specifications.
- Maintenance inventory.
- Conditions of use.

Some elements and materials should have been previously removed: flue pipes, gypsum blocks, gypsum walls, aerated concrete, bituminous roofing containing tar, asbestos and materials mixed with dangerous waste.
Mixing with (contaminated) soil should be avoided where possible.
With regard to the various categories of materials that should be recycled and separated, the comments in the section 'Design for recycling (DFR)' concerning concrete, masonry, metals and wood, also apply here.
Glass should be separated independently or in combination with concrete or masonry.
Plastics should be split into thermosetting and thermoplastic agents.

When demolishing roads and hydraulic engineering constructions the DFD method is fairly simple as the various materials are usually applied in layers.

Eco-costs/Value Ratio (the EVR model)
This model describes 'sustainability' (in the ecological sense) from a management systems approach, in which sustainability means the strive for eco-efficiency, as defined by the World Council for Sustainable Development: 'the delivery of competitively priced goods and services that satisfy human needs and bring quality of life while progressively reducing ecological impacts and resource intensity through the life cycle, to a level at least in line with earth's estimated carrying capacity' (WTCSD, 1993).

This business-oriented definition connects the thinking of the modern manager ('the delivery of competitively priced goods and services ... ... quality of life') to the need for a sustainable society ('while progressively reducing ... ... to ... ... earth's carrying capacity'). But what does this definition mean in practice for managers and designers, with regard to the many decisions taken daily? This is why a numeric model has been designed that is based on this definition, whereby well-founded choices can be made during the design phase with respect to the sustainability of the design, which is then used as a basis for setting out an entrepreneurial strategy.

The first section of the definition describes the 'value' of a product, the second section describes the impact on the environment, or 'eco-costs'. The basic idea behind the model is to couple the 'value chain' (Porter, 1985) to the 'product chain' as defined in the life cycle assessment. The added value and the costs are defined in the value chain for every step (from raw material to client, the usage phase and the 'end-of-life' phase). The environmental impact is also defined in monetary terms for each step in the chain, i.e. the eco-costs. If the usage phase and 'end-of-life' phase are also added to the chain, this gives the 'Total Costs of Ownership' (this approach is common in the car industry and for structural and civil-engineering and civil projects). The 'Total Eco-costs of Ownership' are therefore defined in a similar way in the model.

The eco-costs are 'virtual' costs, i.e. the hidden costs required to manufacture and use a product in a sustainable manner, or 'in line with earth's carrying capacity'. These costs are estimated based on the costs of technical measures to prevent undesired emissions and based on depletion of fossil energy and raw materials. As our society is nowhere near sustainable, the eco-costs are 'virtual', or not yet integrated into existing costs of the product chain (the existing life cycle costs). The eco-costs therefore consist of costs that have yet to be made to reduce the environmental impact (emissions and depletion) to a sustainable level. The eco-costs/value ratio (EVR) is defined as: EVR=eco-costs/value. The composition of eco-costs, costs and value is shown in Figure 1.

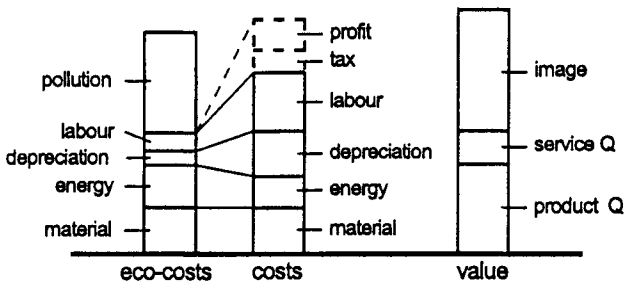

Figure 1: The value, costs and eco-costs of a product

A low EVR means that a product is suitable for a future sustainable society. A high EVR means that the economic value/cost ratio will worsen along the road to a sustainable society (and may even drop below 1.0) due to the required prevention measures, so that there will be no market for these goods in a future sustainable society.

STRENGTH OF CONCRETES PREPARED WITH NATURAL AND RECYCLED AGGREGATES AT DIFFERENT MOISTURE CONDITIONS

C.S. Poon, Z. H. Shui and L. Lam

Department of Civil and Structural Engineering,
The Hong Kong Polytechnic University, Kowloon, Hong Kong, China

ABSTRACT

The influence of moisture conditions of natural and recycled aggregates on the properties of the strength of the hardened concretes was highlighted in this study. Natural and recycled aggregates were incorporated into concrete in different combinations. The aggregates were controlled at air-dried, oven-dried and saturated-surface dried (SSD) states respectively prior to use. The results show that replacements of up to 50% of natural aggregates by recycled aggregates do not have significant detrimental events on the strength of the concrete produced. The effect of the moisture states of the aggregates on the strength of the concretes prepared with oven-dried and SSD-state aggregates at early age (i.e. 3 and 7 days) was noticeable. The concrete prepared with the air-dried aggregates achieved the highest average strength values at various ages. For the concrete prepared with recycled aggregates at the SSD condition, the increase in proportion of recycled aggregates significantly reduced the splitting tensile strength. The results suggested that an air-dried aggregate that contains not more than 50% recycled aggregate is optimum for producing normal strength recycled aggregate concrete.

KEYWORDS

Concrete, recycled aggregates, moisture state, strength development

1. Introduction

In Hong Kong, the construction industry produces about 37,000 tonnes of construction and demolition (C&D) waste everyday, which is roughly four times higher than that of municipal solid waste. But the shortage of land for new landfills and the end of major land reclamation projects in the near future have setup alarm in Hong Kong to find alternative uses of the C&D waste [1]. The government has adopted a policy to support innovative programmes that will promote the reuse of recycled aggregates. Recently, a few open storage-sites have been set up for temporary storing C&D waste and producing recycled aggregates, such as in Tseung Kwan O and at the old Kai Tak airport site. A development is being made to produce bricks and blocks with recycled C&D wastes [2]. To further develop the use of recycled aggregates in concrete production in Hong Kong, a systematic research programme is being carrying out at The Hong Kong Polytechnic University.

A number of past research has studied the properties of concrete made with recycled aggregates [3-5]. Hendriks and Pietersen [6] and Hendriks and Nijkerk [7] outlined the application issues of recycled aggregates in Europe, and described the main processes and equipment. Travakoli and Soroushian [8] highlighted the key factors that influence the strength characteristics of recycled aggregate concrete, such as the strength, size distribution and water absorption of the original concrete. Larbi et al [9] tried a thermal treatment method to improve the quality of recycled aggregate, and they found that after thermal treatment at 800°C, the recycled aggregate was reasonably comparable to conventionally used river-dredged aggregates.

Due to the high water absorption capacity of recycled concrete aggregates, the influence of the moisture states of the recycled aggregates on the properties of the fresh and hardened concrete prepared with recycled aggregates has received some research interest. Pre-wetted and saturated recycled aggregates were used in several studies [3, 10] in order to prevent a rapid decrease in concrete workability. These studies concluded that there was no obvious impact of the pre-wetted recycled aggregates on the mechanical properties of concrete. And this pre-wetting method has been recommended by several researchers [3]. However, Fleisher and Ruby [11] indicated that wet processing (i.e. pre-spraying) is not necessary for technological reasons, as long as the natural moisture of the aggregates is taken into account during the mix design. Also, it is suggested that it is hardly possible to pre-spray the recycled aggregate uniformly at a level of work that can still be justified. Oliveira and Vazquz [12] found that the compressive strength of the concrete made from dry and saturated recycled aggregates was slightly lower than the reference concrete. The decrease was especially noticeable in flexural strength of the concrete prepared with the saturated aggregates. And the concrete prepared with saturated and dry recycled aggregates exhibited poorer freeze thaw resistance whereas better results were obtained from the concrete made with the semi-saturated aggregates.

This study aims to increase the insight of the effects of the moisture states of the recycled aggregates on compressive and splitting tensile strength of the hardened concrete so as to promote the practical application of recycled aggregates in concrete production.

2. Experiments

2.1 Materials

Cement and fine aggregate

The cement used in this study was a locally produced Ordinary Portland cement equivalent to ASTM Type I Portland cement. The density of the cement was 3.16 g/cm^3 and the specific surface was 3,519 cm^2/g. The chemical composition of the cement is shown in Table 1. No chemical and mineral admixture was used in this study. The fine aggregate used was a natural river-sand with a fineness modulus of 2.11.

Coarse aggregates

Both natural and recycled aggregates were used in this study. The natural aggregate was a crushed granite with nominal sizes of 10 mm and 20 mm. The recycled aggregate was a crushed and graded unwashed recycled concrete aggregate obtained from a single source at the old Kai Tak airport in Hong Kong. The recycled aggregate was generated by the demolition activity of a number of reinforced concrete buildings and the concrete runway. The recycled aggregate was divided into two types in terms of their maximum nominal sizes,

i.e. 10 mm and 20 mm. The physical and mechanical properties of the recycled aggregate are shown in Table 2, where the porosity of the aggregates was determined using mercury intrusion porosimetry (MIP). In the concrete mixtures, the 10 mm and 20 mm coarse aggregates were used in a proportion of 1: 2.

2.2 Preparation of concrete mixtures

The concrete mixes were prepared with the use of natural and recycled coarse aggregates in four combinations; i.e., 100% natural, 80% natural + 20% recycled, 50% natural + 50% recycled and 100% recycled. These proportions of the concrete mixes were designed using the absolute volume method by assuming the aggregates were at a saturated surface-dried (SSD) condition. Adjustments were sequentially made according to the moisture contents and water absorption capacity of the respective aggregates. All the mixes had a free water content of 205 kg/m^3, a free water-to-cement ratio (w/c) of 0.57, and a fine aggregate to total aggregate ratio of 0.375. As the densities of the natural and recycled coarse aggregates were different, the actual amounts of fine and coarse aggregates in the mixes were slightly different.

In the study, the moisture states of the natural or recycled coarse aggregates were controlled at three states, i.e., air-dried (AD), oven-dried (OD), and SSD, while the fine aggregate was used at the as- received moisture state. Thus, in total, twelve concrete mixes were prepared with different combinations of natural and recycled aggregates in different moisture states. The oven-dried aggregates were prepared by drying them in an 105°C oven for 24 hrs, and they were cooled down to room temperature prior to mixing in the mixer. SSD aggregates were prepared by removing the surface moisture from the aggregates with a moistened cloth after immersing the aggregates in water for 24 hrs. The detached cement mortar during the soaking process was carefully collected and returned into the mixture.

To maintain the designed mix proportioning unchanged, the amounts of water and aggregates used in mixing were adjusted according to the actual moisture contents of the aggregates. When the air-dried and the oven-dried aggregates were used, an additional amount of water was needed to saturate the aggregates. Also, as the recycled aggregate had a higher water absorption capacity, the amount of water added to the mix increased as the percentage of recycled aggregate increased when they were used in the AD and OD states. The actual amounts of water and materials used in these twelve mixes are given in Table 3, and the moisture contents of the aggregates used in these mixes are given in Table 4. All the concrete mixtures were mixed for about 5 minutes in a Croker concrete mixer before casting into moulds and compaction on a vibrating table.

2.3 **Tests**

The compressive strength of the hardened concrete was determined at the ages of 3, 7, 28 and 90 days on 100mm cubes. The splitting tensile strength of these concretes were determined at the same ages on ϕ100×200mm cylindrical specimens. These specimens were removed from the moulds after 1 day and were cured in water at 27°C before testing.

3. Results and discussions

The compressive strengths of the concrete mixes are shown in Figure 1. It can be observed that all the concrete mixes achieved the target compressive strength of 35 MPa at the age of 28 days. However, the effects of the moisture states of the coarse aggregates on the compressive strength of the concrete were quite different for different combinations of coarse

aggregates. When only crushed granite was used as the coarse aggregate, the mixes prepared with the coarse aggregate in the AD and SSD states had similar compressive strength values at all tested ages, while the strength of the mix prepared with the coarse aggregate in the OD state was much lower. The use of recycled aggregate as a replacement of the crushed granite seemed to have a positive effect on the mixes prepared with the coarse aggregates in the OD state but a negative effect on those prepared with the coarse aggregates in the SSD state. Fig. 1 shows that while the strength of the AD mixes almost maintained unchanged as the percentage of recycled aggregate increased, the strength of the OD mixes increased, but the strength of the SSD mixes decreased. As a result, the OD mix showed a higher compressive strength than the SSD mix at all tested ages when all the crushed granite was replaced by the recycled aggregate. It can be seen that the 90-days compressive strength of concrete prepared with 50% and 100% SSD-recycled aggregate was lower than that of the others. It is interesting that the 28 days strength of AD-aggregate concrete at various recycled aggregate contents were higher than the strengths of the OD-aggregate concrete at the age of 90 days. And the 90 days strength of 50% recycled aggregate concrete prepared at the SSD state was lower than that of 28 days strength of 50% AD-recycled aggregate concrete. For the concretes prepared with 100% recycled aggregate, the 90 days strength of SSD aggregate concrete was lower than that of 28 days strength of AD- and OD-aggregate concretes.

The splitting tensile strength data are shown in Fig.2. The development of splitting tensile strength of concretes with various aggregate combinations up to 28 days was similar to that of the compressive strength. However, at the age of 90 days, the difference between the SSD series of concretes and the other two series of concretes become more significant. The splitting strength of the AD and OD series concretes was more or less similar to each other whereas the splitting strength of the SSD series concretes was obviously lower. The value further decreased with increasing percentages of recycled aggregate replacement. This result is consistent with the study described in Ref. [12].

It is well known that the strength of concrete depends on the strength of the cement matrix, the aggregates, and the interfacial bond between the cement matrix and the aggregates. For concrete prepared with crushed granite, the difference in strength development between the OD mix and the SSD mix might be related to the development of the interfacial bond strength. Wong et al [13] found that saturated-surface dried granite had a better bond with cement than the dried one in the initial period of curing. This may account for the lower strength of the concrete prepared with the OD granite than that with the SSD granite, although the high initial w/c ratio in the OD mix may also reduce the strength of the cement matrix.

The situation in the concrete prepared with recycled aggregates is different. The results of the present study reveals that compared with the crushed granite, the moisture states of the recycled aggregate had an opposite effect on the strength development of the concrete, and the use of the recycled aggregate in the SSD state is not preferred. The low compressive strength of the concrete prepared with the SSD recycled aggregate may be attributed to the bleeding of concrete, which was observed during compaction of the concrete cubes on the vibrating table. During vibration, the water inside the recycled aggregate particles may tend to move toward the cement matrix, creating a relatively high local W/C in the vicinity of the particles. This process can weaken the bond between the recycled aggregate and the cement matrix. On the contrary, when the recycled aggregate is used in the OD state, water and may tend to move from the bulk cement matrix toward the recycled aggregate particles, and cement particles may accumulate around the recycled aggregate particles. As a result, a

stronger bond may be formed between the cement matrix and the aggregate particles particularly at the early age.

Conclusion

1. For the concrete mixtures prepared with the incorporation of recycled aggregates, the air-dried aggregate concretes exhibited the highest compressive strength. The SSD recycled aggregates seemed to impose the largest negative effect on the concrete strength, which might be attributed to "bleeding" of excess water in the pre-wetted aggregates in the fresh concrete.
2. The long-term splitting tensile strength of concrete with 50% or more SSD-recycled aggregate was considerably lower than that of the other concretes.
3. Based on the results of this study, aggregates in the air-dried (as-received) state and contain not more than 50% recycled aggregate should be optimum for normal strength recycled aggregate concrete production.

CLAY-BRICK RECOVERY FROM MASONRY DEBRIS BY MEANS OF A THERMAL PROCESS

ABSTRACT
In the Netherlands more than 95 percent of all stony fraction of building demolition debris is being reused as a road building material. Twelve million tons on yearly base and each year the amount is growing. To avoid problems in future, alternatives should be created for future recycling of building materials. For masonry debris, clay-bricks should be recovered and reused for future brick laying. A thermal process might be a possibility of recovering clay-bricks from masonry. In this research first a model is made, which can calculate the forces in masonry and the shear stress on the clay-brick mortar interface. Then laboratory experiments are performed in which pieces of masonry are thermally treated in order to determine the required temperature. In the next laboratory research the strength of the clay-brick mortar interface is being measured. The research project is being evaluated by doing a full scale test in the clay-brick factory. The research shows that clay-brick recovery can be very successful, but it strongly depends on the way of dismantling the masonry from the building.

KEYWORDS
Masonry, building demolition debris, recycling, clay-bricks, recovery, thermal process, the Netherlands

INTRODUCTION

Clay-bricks from masonry constructions are reused on a very small scale in the Netherlands. The mortar is chipped from the bricks, which is a very labor intensive job. To make clay-brick recovery on larger scale possible a new technology should be introduced.

A thermal process might be a suitable technology to recycle clay-bricks. Clay-brick mortar separation can be achieved by heating to a temperature of 850 °C. At this temperature cement mortar decomposes. Lime decomposes at a temperature of 400 °C. In this laboratory research the quality of clay-brick that are

recovered from masonry debris by giving it a thermal treatment is determined. The effect of a temperature treatment on the properties of the clay-brick will also be determined.

The recovered clay-brick must be checked on internal cracking. Internal cracking will influence the mechanical properties of the clay-brick, which can be checked by measuring the tensile and compressive strength.

The difference in linear expansion coefficient between mortar and clay-brick causes shear stresses on the clay-brick mortar interface. The mortar is compressed and in the clay-brick there are tensile stresses, if there is still a bond between the two components. The mortar clay-brick interface is the weakest part of masonry and therefore might break by shear stresses. The temperature for collapsing of the interface depends on the properties of the clay-brick related tot the properties of the mortar and the resistance of the interface for shear stresses.

When the temperature in the oven is increasing, water in the open pores starts to evaporate. It is possible that cracking occurs by thermal strains in the clay-brick. This will decrease the mechanical quality of the clay-brick. It is also possible that the cracking already occurred during technical life span of the masonry. The strains in the product can reach a maximum caused by frost/thaw loads or mechanical loads during the technical life span. This can cause damage to the clay-brick and make it unsuitable for reuse.

THEORETIC MODEL

The situation of strains caused by thermal loads is modeled as a composite material, consisting of a layer of mortar and a layer of clay-brick. The difference in expansion coefficient between clay-brick and mortar introduces tensile and compressive stresses when thermally loaded. At the clay-brick mortar interface a shear stress is introduced (figure 1).

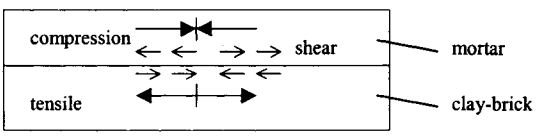

figure 1: Schematic view of strains in the clay-brick mortar interface caused by a temperature load

Now the boundary conditions for this loading situation can be made up. The total expansion (formula 1) of a material is the sum of thermal expansion and expansion caused by strains. The tensile or compressive load can be written as a function of expansion. The strain (formula 2) the thirst derivative of the change in length in a certain direction.

$$\varepsilon = \alpha T + \frac{N}{EA} \qquad (1)$$

$$\varepsilon = \frac{\partial u}{\partial x} \qquad (2)$$

This results in an equilibrium with a main force, which is a function of the expansion coefficient (ε) and the thermal expansion coefficient (α). The shear stress (q) is the thirst derivative of the main force in the x direction.

$$q = -\frac{\partial N}{\partial x} \qquad (3)$$

Figure 2: Material model of the clay-brick and mortar interface

In figure 2 the material model of clay-brick - mortar interfacial zone is shown. Both layers have a Youngs modulus, surface area and thermal expansion coefficient. The effective thickness of the mortar layer is 8 millimeters and for the clay-brick it is 50 millimeters.
Until the clay-brick mortar interface is broken, there is an internal equilibrium. The compression force in the mortar layer is equal to the tensile force in the clay-brick. The expansion for both materials is equal. For this loading situation a parallel system is valid, which means that the stiffness of both materials must be summed. Using formula 1 together with the second boundary condition results in formula 4.

Boundary conditions:

$$N_I + N_{II} = 0$$
$$\varepsilon_1 = \varepsilon_2 = \varepsilon \qquad \frac{N_1}{EA_1} + \alpha_1 T = \frac{N_2}{EA_2} + \alpha_2 T \qquad (4)$$
$$EA = EA_1 + EA_2$$

The solution is found by using boundary condition 1 and 3 with formula 4.

$$N_1 = -N_2 = \frac{EA_1 \cdot EA_2}{EA}(\alpha_2 - \alpha_1) \cdot T \qquad \text{and} \qquad \varepsilon = \frac{EA_1\alpha_1 + EA_2\alpha_2}{EA} \cdot T$$

Resulting in a total thermal expansion coefficient: $\alpha = \frac{EA_1\alpha_1 + EA_2\alpha_2}{EA}$

The shear stress (q) is the thirst derivative of the main force in the x direction. Because the main force N is undependable of x, the shear stress on the clay-brick mortar interface must be constant. From literature values can be found for the thermal expansion coefficient and Youngs modulus both for clay-bricks and mortar.

Clay-brick: $\alpha_1 = 3 - 9 \cdot 10^{-6} K^{-1}$ and $E_1 = 10 - 20 \cdot 10^9 Pa$

Mortar: $\alpha_2 = 10 - 12 \cdot 10^{-6} K^{-1}$ and $E_2 = 20 - 40 \cdot 10^9 Pa$

The huge variation in values for different clay-bricks and mortars results in a big range in shearing stress at certain temperatures. For example, when the temperature is 540°C than the shearing stress ranges between 0,35 and 5,60 N/mm^2 for the extreme values of the thermal expansion coefficient and the Youngs modulus.

LABORATORY EXPERIMENTS

Description samples

The masonry pieces came from a recycling plant. The demolition companies deliver their building demolition debris to the plant and the stony fraction is being crushed in order to produce granulate for building road foundations. Different types of masonry pieces are being collected, which came from different buildings, that were being demolished by different demolition companies. The masonry pieces, consisting 3 or 4 whole clay-bricks are being transported to the laboratory. In the laboratory both a gas heated chamber kiln and a electric heated kiln are being used for clay-brick recovery tests.

Temperature treatment

For the first experiment an electric heated kiln is been used. With the electric heated kiln it is impossible to use a forced cooling. The real temperature development during cooling is not measured. The gas heated kiln is suddenly heated when the burning gas is flowing in. The difference in temperature in the beginning of the temperature treatment is about 70°C.

TABLE 1: Experiments on clay-brick recovery

Experiment	Heating time	Max temperature/time	Cooling time	Sample	Results:
1	0:30	600 / 2:00	Non forced	softmud clay-brick red + Portland cement mortar	clay-bricks are cracked in two pieces, with a size of half a clay-brick
				hand molded clay-brick + lime mortar	lots of cracks in the clay-bricks
				plastered masonry	clay-bricks are broken in two pieces, the cracks on the mortar clay-brick interface can be seen clearly
2	0:30	400 / 1:00	Non forced	softmud clay-bricks red + Portland cement mortar	no visible cracks, clay-brick recovery is not successful even with mechanical force
				hand molded clay-brick + lime mortar	cracks are visible on clay-brick mortar interface, the clay-bricks can be recovered after a soft hit with a hammer
				plastered masonry	cracks on clay-brick mortar interface
3	2:00	600 / 1:00	Non forced	softmud clay-bricks red + Portland cement mortar	masonry part falls apart, the clay-bricks are totally cracked
				hand molded clay-brick + lime mortar	idem
				plastered masonry	idem
4	2:00	500 / 2:00	Non forced	softmud clay-bricks red + Portland cement mortar	the clay-brick can not be recovered
				hand molded clay-brick + lime mortar	the clay-brick mortar interface is cracked, the clay-bricks are recovered
				plastered masonry	the clay-brick mortar interface is cracked, the clay-bricks are recovered
Gas heated kiln					
5	2:00	540 / 1:00	Non forced	softmud clay-bricks red + Portland cement mortar	the clay-brick mortar interface is cracked, some clay-bricks are broken in two, some pieces of mortar are still stuck to the clay-brick
				hand molded clay-brick + Portland cement mortar	same result, some clay-bricks are recovered
6	2:00	540 / 1:00	Non forced	softmud clay-bricks red + Portland cement mortar	Cracks on clay-brick mortar interface, recovered
				hand molded clay-bricks red + Portland cement mortar	Cracks on clay-brick mortar interface, recovered
Electric kiln					
7	2:00	540 / 1:00	Non forced	softmud clay-bricks red + Portland cement mortar	The clay-bricks are totally cracked

Table 1 shows the results of the experiments that are done. In the first experiment the electric heated kiln is used to heat the clay-bricks to 600°C in half an hour. Then the temperature is stabilized during two hours. The cooling time depends on the heat capacity of the kiln, but is not measured. When the clay-brick mortar interface is cracked, the clay-bricks can be recovered easily, without damage. Both hand molded clay-bricks, which have a rough surface and softmud clay-bricks, which have a smooth surface are easily recovered.

Conclusions

The most effective clay-brick recovery can be realized at a temperature of 540°C. A higher temperature than 570°C results in damage to the clay-bricks. The clay-bricks are cracked, because of the sudden expansion during the quartz phase transformation.
The firing time is one hour at 540°C, the total firing time including heating and cooling down takes 5 hours. The firing time might be decreased, especially during cooling. The heating phase is more critical, because of the tensile forces in the clay-brick.
It can be concluded that the recovery of clay-bricks from masonry with Portland cement is more effective than with lime mortar. Less mortar is stuck to the surface of the clay-bricks. The Youngs modulus and thermal expansion coefficient are higher and therefore the shear stress in the clay-brick mortar interface will also be higher.

The results of the gas heated kiln, were better than for the electric heated kiln. This might be a result of the heating process. In an electric kiln the masonry is heated by radiation. In the gas heated kiln, the masonry is heated in the flames. Electric heating might result in a higher temperature coefficient in the masonry, as a result of which the clay-bricks crack.

Measuring the strength of the mortar clay-brick interface

Description of the research

Different mortars are made consisting of Portland cement CEM I 32,5. The mortars are being prepared with the same consistence by using the vibration table (according to the standard NEN 3534). The composition of the mortars is shown in TABLE 2.

TABLE 2: composition off the mortars

	p.c. A.	sand	lime	water	other substitutes
1	1	4	0.6	1.2	none
2	1	4	0	1.15	0.6 fly ash (EFA)
3	1	4	0	1	a.e. water reducing agent (30 cc/50kg cement)
4	1	4	0	0.9	a.e. water reducing agent (90 cc/50kg cement)
5	1	4	0	0.75	a.e. water reducing agent (300 cc/50kg cement)

For every type of mortar samples are being made in order to measure the strength of the mortar. The samples have a standard size of 40.40.160 mm^3. The samples are being stored for 28 days and then the three point bending test and compression test is being performed.

For two clay-brick types ('klinker' and 'hardgrauw') three 'shear stress' samples are being made for all the mortar types. The clay-bricks have a sanded site that was in the mold and an unsanded site. This layer of sand will have influence on water suction of the clay-brick and therefore differences are made in sample preparations.

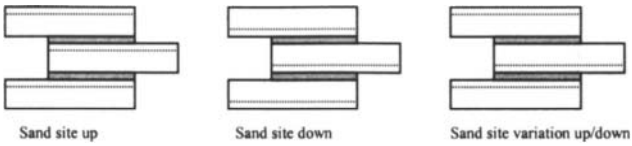

Figure 3: samples for shear stress measurements

After 28 days of hardening the samples are being tested. The mortar clay-brick interface will be loaded on shear stress. The load is increased slowly, until one of the interfaces brakes. Then the load is increased until the other interface also collapses.

The shear stress in the clay-brick mortar interface is: $\tau = \frac{P}{2 \cdot b \cdot l}[N/mm^2]$

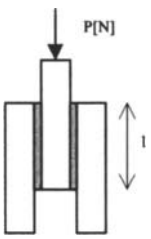

Figure 4: loading situation of the samples

TABLE 3: Strength of the mortars and of the clay-brick mortar interface

			clinker	hardgrauw	Air [%]
mortar	Compressive strength	3 p.b. strength	shear stress	shear stress	
1	12.5	3.4	0.9	1.2	7.8
	0.6	0.4	0.2	0.3	
2	14.6	4.3	1.4	1.4	3.0
	1.9	0.3	0.5	0.2	
3	4.8	2	0.7	0.8	17.5
	0.5	0.2	0.3	0.4	
4	5.3	2	0.4	0.3	24.5
	1.2	0.1	0.2	0.1	
5	4.3	1.9	0.5	0.2	20.3
	0.7	0.2	0.1	0.1	

The density of the mortars is calculated by measuring the volume and the weight of the mortar bars. With the mixture composition the 'real' volume of cement, water and sand can be calculated. Also the percentage of water can be calculated.

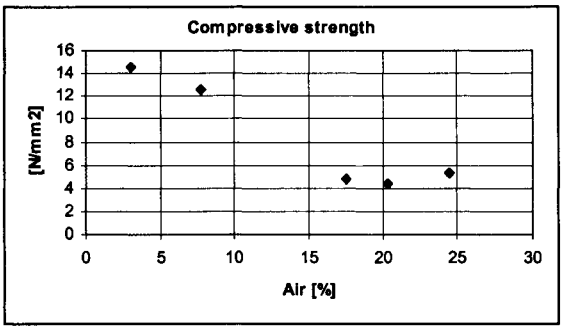

Figure 5: Compressive strength of the mortar samples

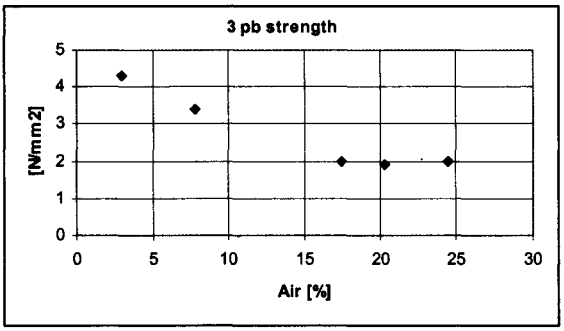

Figure 6: 3 pb strength of the mortar samples

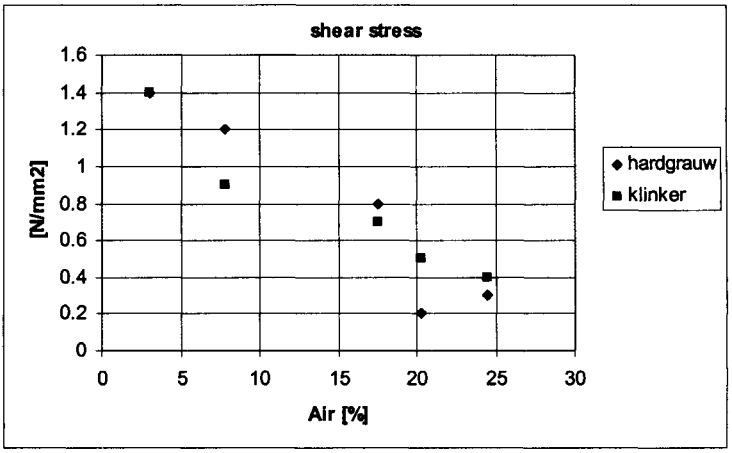

Figure 7: Shear stress of the masonry samples

From the theoretic model (figure 1) was concluded that the compression force in the mortar is equal to the tensile force in the clay-brick. The shear stress is the first derivative in x direction. It can be concluded that the clay-brick mortar interface is the weakest part, no values were found higher than 1,4 N/mm^2. The shear stress can vary between 0,35 and 5,60 N/mm^2, according to the model.

Conclusions

Mortars with fly ash require less water. The density is higher and the compressive strength, 3pb strength and strength of the clay-brick mortar interface are higher. A higher air content results in a lower density and a lower strength. The strongest type of mortars have a shear strength of 1.4 N/mm^2. The hardness of the clay-brick does not influence the strength of the clay-brick mortar interface. Some values for the shear strength were higher for the harder type of clay-brick and some values for the softer clay-brick. The lowest value (0.2 N/mm^2) was found for mortar type 5, with the harder type of clay-brick.
To evaluate the results from the laboratory research, a test has been performed in a clay-brick factory. The masonry has been selectively deconstructed from a building in Rotterdam.

Photo 1: Demolition of the railway building 'de Boezembocht' in Rotterdam

The interior and exterior walls are connected by anchors, therefore it is hardly impossible recover big parts of masonry from the walls. The pieces of masonry break before being recovered from the demolition object. In total 2,500 kg of masonry is collected and being transported to the factory. In the factory the masonry is put on wagons and transported to the chamber kiln. In the chamber kiln the masonry is thermally treated, in 10 hours to 540°C than 20 hours constant and then 10 hours cooling. The result is:

- 900 kg clay-bricks are recovered
- 900 kg clay-bricks are damaged
- 220 kg clay-bricks are broken
- 505 kg of mortar

The recovery rate is about 45 percent of the input, but this result strongly depends on the way of dismantling the masonry.

EFFECTIVE WASTEWATER TREATMENT / RECYCLING TECHNOLOGIES FOR CONSTRUCTION INDUSTRY – A LOCAL EXPERIENCE

Kenny S. W. Wong

Environmental Management Division, Hong Kong Productivity Council,
EMD, HKPC Building, 78 Tat Chee Avenue, Kowloon Tong, Hong Kong

ABSTRACT

During the construction / demolition period of a site, various types of wastewater will be generated and discharged. These various types of wastewater are, but not limited to, water from bore piling operation, rain water and ground water collected, spray water for dust removal, truck cleaning water, sewage and kitchen wastewater, etc. In most of the construction sites, government foul sewers will not be connected to the site premises during the construction period, hence the wastewater will have to be discharged to storm water drain, inland and coastal waters, etc. In this regard, the quality of discharged effluent will be controlled to very stringent limits, such as suspended solids (SS) to 30mg/L, oil and grease (O&G) to 20mg/L, biochemical oxygen demands (BOD_5) to 20mg/L, chemical oxygen demands (COD) to 80mg/L, etc. Without proper treatment, the discharged wastewater will exceed the discharge limits, resulting from not only polluting the environment, but also leading to heavy penalty to the construction companies.

This paper will focus on presenting appropriate technologies to tackle different types of wastewater from construction sites. They are:

1. Effective chemical coagulation and sedimentation system for treating high solids content construction runoff / wastewater from construction activities;
2. Biological wastewater treatment system in continuous operation for treating organic waste bearing wastewater from site office toilets, etc;
3. Biological wastewater treatment system in batch operation for treating highly polluted organic waste bearing wastewater from kitchens and canteens;
4. Automatic wheels washing machine for cost effective management of truck wheels cleaning process.

Construction wastewater, recycling, coagulation, sedimentation, biological treatment, anaerobic and aerobic treatment, sequencing batch reactor, automatic wheel washing machine

INTRODUCTION

Construction Industry is one of the largest industries in Hong Kong. The trade has been contributing to Hong Kong's success into one of the World's most famous cities by building effective transportation & communication networks, constructing landmark buildings and forming large infrastructures, such as the Chep Lap Kok International Airport, Disneyland, CyperPort, Science Parks, etc. However, during the construction period of a site, various types of construction operations will discharge potential environmental pollutants creating air, noise, waste, wastewater pollution, etc. Without proper handling and treatment methodologies, the discharged pollutants will exceed HKSAR Government's discharge standards, thus resulting from not only polluting the environment, but also leading to heavy penalty to the construction companies and interruption of construction activities. This paper will concentrate on the presentation of appropriate technologies which are utilized locally in dealing with the discharged wastewater from various types of construction operations.

Local Legislation - Water Pollution Control Ordinance (WPCO)

The Water Pollution Control Ordinance (Chapter 358) was enacted in 1980 and amended in 1990 and 1993. It provides the main statutory framework for the declaration of water control zones to cover the whole Hong Kong Territories. The whole Hong Kong territories are divided into 10 water control zones and the last control zone was declared on 1995. Within each control zone, all discharges or deposits are controlled by a licensing system. The Environmental Protection Department (EPD) of the HKSAR Government is responsible for the issuance of licence as well as enforcement of the licensing conditions. Depending on the water receiving bodies of the discharged premises, EPD will set discharge limits to the potential pollutants of the effluent that make acceptable to foul sewer, storm

drain, inland and coastal waters, etc. Upon issuance of the discharge licence, the licence holder is responsible to meet the effluent discharge standards, which are set out according to the Technical Memorandum (TM) issued under the WPCO. The TM is a guide issued by EPD in determining standards for effluents. It sets standards that differ in different areas and between surface waters and sewers. The standards also vary with the rate of effluent flow and the standard in the higher flow ranges are normally more stringent than those in the lower flow ranges.

Over the entire period of a typical construction site, especially in those new development areas, foul sewers are not normally connected until the very late stage of the project. The effluent will be discharged to storm drain, inland and coastal waters, etc. without subsequent treatment by the authority. Hence the quality of the discharged effluent from a construction site is controlled to very stringent limits, in most of the areas, suspended solids to 30mg/L, oil and grease to 20mg/L, biochemical oxygen demands to 20mg/L, chemical oxygen demands to 80mg/L, etc.

All effluent discharged from a construction site is subject to control, and the maximum penalties are:

(a) For illegal discharges : 6 months imprisonment, and
   - for a first offence, a fine of HK$200,000;
   - for a second of subsequent offence, a fine of HK$400,000;

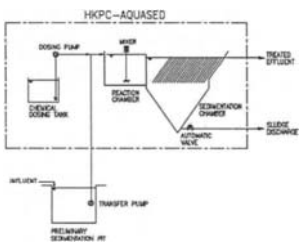
   in addition, if the offence is continuing offence, a fine of HK$10,000 is applicable for each day.

(b) For discharges of poisonous or noxious matter :
   - for a first offence, a fine of $400,000 and imprisonment for 1 year;
   - for a second or subsequent offence, a fine of HK$1,000,000 and imprisonment of 2 years;

   in addition, if the offence is a continuing offence, a fine of HK$40,000 is applicable for each day.

(c) For contravention of the conditions of a licence :
   - a fine of HK$200,000 and imprisonment for 6 months

Construction runoff / wastewater discharged from construction activities



The largest amount of wastewater discharged from a typical construction site is highly turbid muddy wastewater. The wastewater sources are generally classified as construction runoff, rainwater or ground water collected within the site, spray water for dust suppression, equipment or vehicle cleaning water, and wastewater generated from construction activities, such as air lifting process of bore piling. The discharged quantity can be ranged from only $10m^3$/day (superstructure) up to over $100m^3$/hr (foundation – bore piling process). The concentration of suspended solids in the wastewater can be ranged from 100mg/L (normal runoff) to over 30,000mg/L (bore piling wastewater). In the past, the construction companies used plain sedimentation tanks to treat the muddy wastewater. Some of the sites even add gravity sand filters for improving the solids removal efficiency. However the performance of those sedimentation tanks and filters were far from satisfactory because of poor design and low hydraulic retention time (HRT) which was insufficient to allow sedimentation of suspended particles. From the past experience, a HRT of more than 10 hours is required to settle the majority of

solid particles from the wastewater. Moreover, it is quite normal that the wastewater discharged from a typical construction site is slit-clay laden and therefore it cannot be separated effectively even for long HRT. It is because most of the fine suspended particles carry the same polarity of charge making them very difficult to combine into larger particles of settleable sizes. In order to overcome the problem, chemical agent which carries an opposite charge should be applied to agglomerate with the suspended particles for enhancing the effectiveness of sedimentation and a carefully designed tilted plate / tube settler should be put in place to separate the flocculated particles from the cleared wastewater. As many construction sites in Hong Kong are very congested and there is lack of space for the installation of huge sedimentation tanks for long HRT, it is necessary to design a fully automatic and self-contained system comprising the above features to treat the discharged wastewater in compliance with the government's discharge standards.

AquaSed

A self-contained wastewater treatment system for the construction site (herein after named as AquaSed) was developed by the Hong Kong Productivity Council and its flow schematic diagram is presented on the right. Untreated wastewater is pumped into the preliminary sedimentation pit from some low points within the construction site premises. In addition to acting as the centralized wastewater collection tank within the site, the main purpose of the preliminary sedimentation pit is to allow the settlement of relatively large and heavy particles (e.g. sand, grit, etc.) from the wastewater inside the pit, thus reducing the loading as well as the chemical consumption of AquaSed. The transfer pump is mounted at the middle level of the pit so that the settled solids will not be pumped up. When the wastewater is pumped into AquaSed, the system is turned on automatically. The mechanical mixer in the reaction chamber turns at an optimum speed to facilitate effective coagulation of the chemical with the suspended particles to form larger size flocs. Then all the wastewater is transferred into the sedimentation chamber, where the large flocs are settled at the bottom of the chamber and the cleared water is discharged through the V-notch weir at the top of the sedimentation chamber. A carefully designed tube settler is placed in the sedimentation chamber to enhance sedimentation of relatively smaller flocs. The design of the V-notch weir is to facilitate even distribution of wastewater rising up to the entire surface of the sedimentation chamber. Through measuring the height of water above the bottom of the V-notch weir, the flow rate of the wastewater pumped into AquaSed is easily monitored. After treatment, the concentration of suspended particles in the discharged effluent would be reduced to below 30mg/L.

Apart from suspended solids, the pH value is also an important parameter that is easy to exceed the discharge limit, especially when concreting process is being executed within the site. Because of the properties of the concreting agents, the pH value of the wastewater is usually very high, and sometimes up to 13. A specially designed Neutralization Unit can be adopted to adjust the pH value of the wastewater discharged from the AquaSed into acceptable range. Through proportional dosage

controlling mechanism, when the pH value of the wastewater is far beyond the set point, alkali or acid will be dosed at full speed to bring up or down the pH value respectively. When the pH value approaches the set point, the dosing rate will be reduced automatically so as to reduce the consumption of acid or alkali and to prevent overshooting of the effluent pH value. After treatment, the pH value of the effluent will be within the range of 6-9.

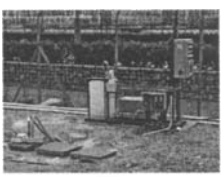
By the combination of AquaSed and Neutralization Unit, the suspended solids concentration and the pH value of the effluent can be treated to below 30mg/L and within the range of 6-9 respectively, which complies to the very stringent government discharge standards. In fact the system can be readily accommodated in construction sites of various sizes. The compact design of the AquaSed and Neutralization Unit enhance mobility of the system and it can be transported easily to different locations by standard trailer. However, the compact design does not affect the treatment capacity, standard models of AquaSed can handle continuous wastewater inflow rate from $10m^3$/hr to $120m^3$/hr.

With the superb quality of treated effluent, many construction sites are recycling the effluent for various types of construction activities, such as air lifting process for bore piling, equipment & truck wheels cleaning, dust suppression etc. The recycling of treated effluent will help the construction companies to achieve huge saving of water charge. Our experience revealed that some of the construction sites can recycle about 50% of the wastewater, and the monetary saving can be as high as HK$5,000 a day (i.e. monthly saving of HK$130,000, assuming 26 working days a month). Hence the payback period on the capital cost of AquaSed can be less than 3 months.

The incredible design of the system has been widely accepted by the construction industry. In addition it has gained important professional recognition. The AquaSed has won the CMA Certificate of Merit Award in the 2000 Hong Kong Awards for Industry and its has got one Hong Kong Short Term Patent approved and two other international patents pending approval.

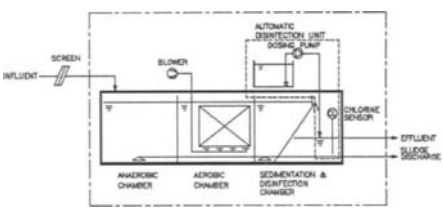
Wastewater discharged from site toilets

The wastewater discharged from site toilets generally is part of normal sewage from household activities. Unlike sewage from household activities that can discharge directly to government foul sewer without treatment, the quality of toilet wastewater from construction sites will have to meet the stringent government discharge standards on storm drain, inland and coastal waters if they are discharged. It is because foul sewer is normally not connected until the end of the construction project. The wastewater has high concentration of pollutants, normally BOD_5 at 150-250mg/L, SS at 200-400mg/L, COD at 200-400mg/L and E-coli at over 100,000count/100ml respectively.



Traditionally the wastewater discharged from the site toilets was handled by two different ways:

- Build a septic tank to collect and treat the toilet wastewater and then discharge through a soak away pit. However, the septic tank is not effective enough to treat the wastewater to acceptable



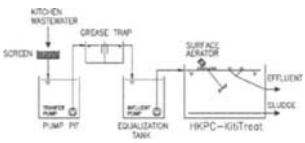
level for discharge. Due to the fluctuation of soil properties from one site to another, in many occasions the discharged wastewater from the septic tank cannot be penetrated away through the soak away pit. Overflow of septic tank is more likely to occur during rainy reason.

- Collect all the toilet wastewater into collection tanks and arrange tanker to pump the waste away from site periodically. Although no on-site treatment is required, the pump-away cost is very high and the construction company has to ensure that the collection tank does not overflow before calling upon the tanker.

To provide a more cost effective choice against the above methods, a self-contained package sewage treatment system (herein after named as STS) was developed for handling wastewater generated from construction site toilets. STS consists of an anaerobic chamber, an aerobic chamber and a sedimentation & disinfection chamber. Through different stages of continuous biological treatment, the BOD_5, SS, COD and E-coli can be reduced significantly to a level that complies to the discharged limits. A copy of the flow schematic diagram of STS is shown on the right. The wastewater from the toilets is firstly discharged into the anaerobic chamber for digestion and decomposition. After that, wastewater will be overflowed into the aerobic chamber for the aerobic treatment process. In the aerobic chamber, soluble and suspended organic matters in the wastewater are absorbed and assimilated by the microorganisms growing on the surface of fill media. After aerobic treatment, the wastewater enters into the sedimentation and disinfection chamber in which sedimentation will take place and then disinfecting agent will be dosed automatically to the treated effluent before discharge. The discharged effluent will be able to achieve acceptable concentrations of 20mg/L, 30mg/L, 80mg/L and 1,000count/100ml on BOD_5, SS, COD and E-coli respectively. Apart from the excellent treatment performance, STS generates very little sludge. Normal desludging frequency will be about 1-2 times a year. This will assist the construction companies to save a lot of money from an average of weekly tanker away of untreated sewage from the site.

STS

To enhance operation efficiency and effectiveness, STS can be floor mounted, buried wholly or half-submerged. The reactor is made of Fibre Reinforced Plastic (FRP) and it is light weight, high strength, anti-corrosion and highly durable, such that it can withstand very harsh environment on a construction site.



Wastewater discharged from site kitchens and canteens

Wastewater discharged from the site kitchens and canteens contains high oil and grease content and high concentration of other organic pollutants, normally O&G at over 300mg/L, BOD_5 at

150-500mg/L, SS at 80-150mg/L and COD at 500-1300mg/L respectively. Similar to the management of wastewater from other construction activities and site toilet wastewater, the quality of the kitchen and canteen wastewater from construction sites will have to meet the stringent government discharge standards on storm drain, inland and coastal waters. Normally the site kitchens and canteens will install in-situ grease trap to remove O&G and other insoluble pollutants. However, it is ineffective because of low hydraulic retention time and the standard design of the grease trap is unable to meet the discharge standards of storm drain, inland and coastal waters.

KitiTreat

Since the organic content of the kitchen and canteen wastewater is much higher than those of toilet wastewater, a batchwise biological treatment system (herein after named as KitiTreat) was developed for handling wastewater generated from construction site kitchens and canteens. KitiTreat employs the latest Sequencing Batch Reactor (SBR) technology in which the wastewater will be fed batchwise into the system at where the biological removal of pollutants will be taken place under optimum operating conditions and in fully automatic fashion. By batchwise operation, KitiTreat operates one or two cycles a day for removing O&G, BOD_5, SS and COD to a level that complies to the discharged limits. A copy of the flow schematic diagram of KitiTreat is shown on the right. After passing through the standard designed grease trap, the wastewater is stored in the equalization tank. The operating cycle of KitiTreat begins with automatic control of fill action. Through the control of programmable logic controller (PLC), the wastewater is fed into KitiTreat reactor and aeration will be carried out simultaneously. The organic matters in the wastewater are absorbed and assimilated by the microorganisms inside the reactor. After the aeration process, aeration stops and allows the activated sludge to settle. Then the clean supernatant will be discharged from the floating discharge weir. The discharged effluent will be able to achieve acceptable concentrations of 20mg/L, 20mg/L, 30mg/L, 80mg/L on O&G, BOD_5, SS and COD respectively. The KitiTreat is operated in fully automatic fashion and no chemical is required for normal operation. In addition it can be easily transported from one site to another by standard trailer.

Truck cleaning wastewater

Traditionally manual cleaning of truck wheels by using water hose was performed at the exit of a construction site. By doing so, extensive labour force and huge amount of fresh water were consumed. In many occasions, the mud and grit adhered to the base chassis and the inner wheels of the trucks could not be removed effectively. By manual cleaning, the cleaning time for the wheels of a dirty truck would take approximately 8-10 minutes. For some very heavy traffic site, the truck cleaning process will become the bottleneck of the construction operations, which sometimes resulted in a truck queue waiting for cleaning before exiting the site.

EnviroWash

In order to provide a cost effective way to manage the truck wheel cleaning operation on construction sites, a specially designed truck wheel washing machine (herein after named as EnviroWash) was developed. By using EnviroWash, the wheels cleaning operation for a vehicle on exiting the construction site can be performed automatically and the vehicles can be cleaned thoroughly from outside, inside and below the wheels. As the cleaning operation is very efficient, the typical cleaning time for a standard truck is only 1-2 minutes. Hence the cleaning time is greatly reduced and at the same time the cleaning performance is much better when comparing to manual cleaning. After cleaning, the water can be collected, treated and recycled thus reducing the water consumption and eliminating the effluent disposal problem. Because of the fully automatic operation of EnviroWash, the labour force for manual cleaning can also be eliminated. By eliminating the labour force and achieving significant saving in water charge on using EnviroWash, a typical construction site can easily save for HK$14,000 per month. Hence the payback period on the capital cost of EnviroWash is only about 8 months. Apart from noticeable financial savings, the special features of EnviroWash indeed assisted the construction industry to better manage their truck wheels cleaning process. Examples of the special features are, but not limited to, its high performance water jets offers superb cleansing effect; it has equipped with smart inducation lamps to provide user friendly instruction of operation; its specially designed weight activated mechanical sensor safeguards transiting personnel from high pressure jet; its highly effective coagulation unit to remove the solid particles from the recycling water.

Similar to the AquaSed wastewater treatment system, the genius design of the EnviroWash has also gained important professional recognition. The EnviroWash has won the CMA Certificate of Merit Award in the 2001 Hong Kong Awards for Industry and its has got one Hong Kong Short Term Patent approved and another China patent pending approval.

CONCLUSION

With the above 4 systems in place, the construction companies will not only be able to compile with the most stringent environmental requirements, but also can achieve huge monetary savings and improvement of company's corporate image by devoting more efforts on environmental protection.

BALANCE THEORY FOR RECYCLING OF CONSTRUCTION AND DEMOLITION WASTES

E.O.W. Wong and R.C.P. Yip

School of Professional and Continuing Education, The University of Hong Kong, Pokfulam Road, Hong Kong

ABSTRACT

The key to reduce construction and demolition wastes (C&D wastes) lies in finding a way to make them valuable. Recycling of C&D wastes into profitable commodities is one of the effective means.

Balance of the supply of C&D wastes and the demand of recycled C&D waste products (Balance Theory) is recommended in new developments. The maturity of Balance Theory requires gradual establishment of recycling facilities. These facilities are capable to accept and handle not only inert materials but also other C&D wastes like wood and wood products, cardboard, metal, plastics etc. The Balance Theory rouses construction workers to adopt the idea of reduction of wastes. They are educated to clean their working places constantly and collect all construction wastes they generated into separate collection spots within the construction site. The site management personnel is required to establish site facilities and set up conditions in employment contracts and subcontracts for workers and subcontractors to follow. The culture of separating wastes at sources must be established and widely adopted so that Balance Theory could be realised.

All in all, Balance Theory advocates the amount of wastes generated from a construction project and sent for recycling process must be equivalent (or proportional) to the amount of the recycled C&D products imported and used as construction materials for that project. Evaluation of the Balance Theory can be extended to a group of developments within a district or even augmented to a city as a whole. Zero C&D wastes sent to landfill may be too idealistic, however, minimisation of C&D wastes could be realised if Balance Theory is enforced.

Appropriate actions taken by the Government may be needed to encourage the execution of the Balance Theory when recycling facilities and the green working culture of construction participants are well developed. Balance Theory can be first carried out in government projects as pilot scheme. The proportion of imported and exported amount of C&D wastes be reviewed and adjusted to suit the adoption and development of the Balance Theory.

KEYWORDS

Recycling, Sustainable Development, Construction & Demolition Waste, Balance Theory, Waste Management, Material Management.

BACKGROUND

Since 1987, the notion of "Sustainable development" was introduced in the Brundtland Report. Sustainable development or sustainability is generally defined as a constraint on present consumption to ensure that future generations will inherit a resource base no less than the previous generation inherited. In meeting this intergenerational goal, sustainability is concerned with two types of limits the environment imposes on growth or development – source limits and sink limits. Source limits refer to the environment's finite capacity to provide resources – both renewable and nonrenewable, and both mere production inputs and essential, non-substitutable "natural" services. The sink limit refers to the environment's capacity to assimilate the wastes that economic growth and development cause.

Environmental Protection Department of the Hong Kong Special Administrative Region (EPD 1998) defined construction and demolition (C&D) materials as a mixture of surplus materials arising from any excavation, civil/building construction, site clearance, demolition activities, road works and building renovation. Statistical information from the EPD 2000 showed that the average daily C&D materials produced was 4 times as much as that of municipal solid waste. This reflected that the construction industry generated a substantial high proportion of solid waste in Hong Kong.

The aim of this article is to arouse the significance of sustainable development in the culture of the construction industry. On national level, sustainability is a resource management and pollution control problem. On the global level, sustainability is concerned with intragenerational equity, cross-boundary pollution, the loss of biodiversity, and the aesthetic value of nature. Although definitions of sustainability vary, there are some important common themes: a concern for the environment, an appreciation of the crucial difference between development and growth, and most importantly, a concern for both inter- and intra-generational equity. In order to achieve the global aim, there are several ways that have to be achieved in the construction industry:

- to minimise the amount of construction & demolition wastes through better planning and design;
- to recover those unavoidable C&D wastes into secondary material;
- to employ the secondary materials in construction projects.

ESTABLISHMENT OF BALANCE THEORY

The composition of C&D waste materials disposed at landfill sites in Hong Kong in 1995 is shown in Table 1 (Source: EPD 1995). It is noted that the asterisked inert materials can be easily recyclable into secondary materials if they are properly sorted and re-employed in construction site as temporary works and permanent works. The other C&D waste, except the ferrous metals, being sent to landfills can also be re-used if they are properly handled through recycling processes. Recent research indicated that the recycled inert materials of the C&D wastes were largely re-used for reclamation, road sub-base, bituminous macadam, and concrete of lower structural grade. Demolished ferrous metal can be sent to steel mill for processing as recycled steel. The scrap metal market in Hong Kong has successfully collected and recovered over 90% of ferrous metal wastes

from construction site. This scrap metal was largely shipped aboard for reproduction as other metal products and partially recycled locally as reinforcement bar, and in turn being used in local construction projects. Wood wastes in construction site include wood products, bamboo, trees and vegetation (mainly obtain from over-site activities in civil engineering works). If wood wastes are properly handled, the recycled products are basically cellulose products in chip and powder form. These recycled products can be used as raw material for chipboard, paper pulp, daily cover in landfill and mulch for moisture retention in landscaping works. Hence, though the construction industry produces quite significant amount of C&D wastes, we could recover them and re-use them into construction projects and benefit the community as a whole.

TABLE 1

COMPOSITION OF CONSTRUCTION & DEMOLITION WASTE DISPOSED OF AT LANDFILLS IN 1995 (SOURCE: EPD 1995)

Component	Composition of each category of construction & demolition waste received at landfill sites (% by weight)				
	Road work material	Excavated soil	Demolition waste	Site Clearance	Renovation Waste
Soil/Sand*	23.0	73.8	21.5	33.0	19.4
Concrete/Mortar*	16.9	1.2	10.8	4.6	7.4
Rock/Rubble*	14.4	12.5	27.7	15.0	38.8
Reinforced concrete*	14.2	0.4	5.8	0.9	7.0
Brick/Tiles*	0.8	0.4	12.1	1.4	9.6
Sub-total	**69.3**	**88.3**	**77.9**	**54.9**	**82.2**
Slurry & mud	1.8	9.7	1.5	1.0	3.1
Asphalt	24.7	0.0	0.0	0.2	0.0
Cement contaminated	1.7	0.4	3.2	15.6	3.3
Wood	0.6	0.9	10.5	13.3	7.1
Ferrous metals	0.5	0.0	0.6	1.0	1.3
Non-ferrous metals	0.0	0.0	0.7	0.2	0.1
Others (include bamboo, trees, glass, plastics, bulky wastes /fixtures, organics & garbage	1.4	0.7	5.6	13.8	2.9
Total	**100.0**	**100.0**	**100.0**	**100.0**	**100.0**
Percentage of total quantity of C&D waste landfilled	5.2	59.4	8.5	14.6	12.3

Note: * Inert materials which are considered suitable for public filling areas
The above figures are estimated by visual inspection of 3060 trucks loads delivering construction & demolition waste in 1995. They should be regarded as indicative only rather than actual composition of construction & demolition waste during the year.

The basic principle of Balance Theory is to acquire the equilibrium between the supply of the C&D wastes and the demand of the recycled C&D secondary materials. The Theory requires gradual achievement in Balance Ratio as defined:

$$\text{Balance Ratio (BR)} = \frac{\text{C\&D Secondary Materials Employed (by weight)}}{\text{C\&D Wastes Produced (by weight)}}$$

If a construction project acquires a high Balance Ratio (BR), that means it does not produce too much C&D wastes. Even if it produces much wastes, it is able to absorb quite a high proportion of the secondary materials.

From Table 1, it reflects that quite a high amount of C&D materials can be re-used or recycled into construction secondary materials even in different natures of projects. Hence, if a project can achieve 70% BR, it arrives a satisfactory level. If a project can achieve 80% or higher, it acquires at commentary level.

PLANNING & DESIGN

Balance Theory advocates that the amount of C&D wastes generated from a construction project is equivalent (or proportional) to the use of recycled C&D products. In order to obtain a commentary level, reduction of wastage is a fundamental step to achieve this purpose.

Waste minimisation can be greatly achieved at design stage. A good design saves considerable amount of wastages. Considerations of the dimension in design approach in one way complies with the functional requirements and on the other way focuses on minimising the cutting wastage of materials. Minimisation of discrepancies in construction information by careful coordination of all design components enables reduction of unnecessary abortive and redundant works. Standardisation of building elements allows repeated use of standard components such as system formwork, pre-fabricated units and precast units. Selection of environmental friendly materials and environmental friendly construction methods will be determinants of sustainability.

Largely adoption of recycled materials in temporary works and permanent works is another essential step to increase the balance ratio. EPD 2000 revealed that 80% of C&D inert materials were sent to public filling area as reclamation material. However, if better sorting process is undertaken, some of these materials could be retrieved to re-use or recycle as usable materials for construction aspects. It is, for instance, concrete fragments of smaller size in C&D wastes are treated by crushing and sieving processes. They can be used as aggregate in road formation, bituminous macadam, concrete blocks or lower structural grade concrete (RILEM recommendation 1992). The other 20% of C&D wastes which were sent to landfill can also be retrieved to a large extent by better sorting process for re-use through recycling. Wood waste can be re-used in producing wood chip products and paper pulp products. Gypsum board wastes can be reproduced as gypsum board or other gypsum products. Plastic wastes can be turned out as plastic raw materials. Consideration should be given to the cost, energy consumption and waste generation during the process of sorting, retrieval and recycling of these wastes. Cost-benefit analysis approach to evaluate the actual financial and environmental benefits must be taken into account. Selection of recycled materials in the design of temporary and permanent works enhances the achievement of a higher Balance Ratio. Preference should be given to recycled materials in design stage to ensure a certain amount of recycled materials is used in the proposed project. When new materials must be used, consideration should be given to the selection of material that is recyclable and re-usable after demolition.

WASTE MANAGEMENT AT WORK

Recent study of construction wastes (Poon et al 2001) revealed that public housing projects generated less construction wastes when compared to private residential projects. Table 2 shows the significance of wastes by trade in these two categories of projects.

From the figures, it reflected that standardised public housing project, due to its repetitive nature, provides better condition for site management which enhances reduction of construction wastes. It is evident that the design and conscious waste reduction implementation affects greatly the outcome of waste management. Other than the nature of project, adoption of a stringent waste management plan on site will greatly reduce the level of wastage and in turn reduces the resources require to handle the wasted materials.

TABLE 2
WASTE PERCENTAGE IN DIFFERENT TRADES FOR PUBLIC HOUSING PROJECT VS. PRIVATE RESIDENTIAL PROJECT

		Public Housing Project	Private Residential Project
Trade	**Material**	**Percentage Wastage**	**Percentage Wastage**
Concrete	Concrete	3-5%	4-5%
Formwork	Timber board	5%	15%
Reinforcement	Steel bars	3-5%	1-8%
Masonry	Brick & Block	6%	4-8%
Dry wall	Fine aggregates	5%	6-10%
Wall screeding	Ready mixed concrete	7%	4-20%
Floor screeding	Ready mixed concrete	1%	4-20%
Wall plastering	Plaster	2%	4-20%
Ceiling plastering	Plaster	2%	4-20%
Floor tiling	Tiles	6%	4-10%
Wall tiling	Tiles	8%	4-10%
Installation of bathroom fittings	Sanitary fittings	2%	1-5%
Installation of kitchen fittings	Kitchen fittings	1%	1-5%

Waste Management Plan can be categorised into three assertions:

a) Waste Preventive and Reduction Action at Design Stage

   i) Coordinate with designer to ensure dimension of material is well considered to avoid cutting wastage;
   ii) Adoption of pre-fabricated precast building components;
   iii) Design to suit system formwork or large panel formwork to reduce the use of timber formwork;
   iv) Designer and specification writer to willfully adopt recycled secondary materials in new development.

b) Waste Preventive and Reduction Action during Site Operations

This plays an important role to minimise unnecessary waste and fulfill recycling. It requires full devotion of site management and supervisory staff to propel all kind of waste preventive and reduction plans to push workers and subcontractors to implement. These plans are not limited to:

i) carefully plan ahead of all works to avoid mistakes, abortive works and double handling;
ii) establish site facilities for collection and sorting of C&D wastes;
iii) centralise material cutting and storage areas so that reusable pieces can be easily located;
iv) educate workers to be "green" construction consciousness by reducing unnecessary cutting of materials, cleaning working spots constantly, collect and sort all their construction wastes into the designated collection spots;

c) Material Management to Avoid Unnecessary Wastage

Material management to avoid unnecessary wastage should be the joint effort of site management and head office policy.

i) Adopt just-in-time material ordering and consumption system to manage material to avoid unnecessary wastage due to stockpile and transportation damage within site areas;
ii) Consider environmental friendly alternatives like cut-to-size, and/or pre-mixed materials to avoid in-situ cutting and mixing;
iii) Adopt to use as much recycled materials when condition permits;
iv) Establish corporate policy to enforce waste management plan and enforce its implementation by means of incentive or penalty system.

CULTURE AND EDUCATION

The strategy in setting up a successful waste management plan to achieve high Balance Ratio, relies much on the partnership between government, industry and consumers and on shared responsibilities among the main actors. Economic constraints, lacking technical specifications for the recycled materials as well as unclear legislation with respect to secondary materials constitute obvious barriers in the development of the use of recycled materials. Hence, specific actions have to be undertaken in order to give the evident opportunities a chance:

Information and sensibilisation of all the parties involved is a necessary. Responsibilities have to be refined. On site, the site manager is "a king" who also decides whether the waste is separated or not. Up to now, even the economical benefits have not made them start separation and few even consider starting it for environmental reasons. To start source separation on a large scale seems to require an order from waste officials.

Economic bottle necks have to be relaxed. Indeed, how strong the social concern about the environment may ever be, the final motivation for using recycled materials will always stay an economic one. As long as there is no real economic interest in using recycled materials instead of virgin raw materials the use of the former will last marginal.

The sustainability paradigm presents challenges as well as opportunities for the construction industry. It will mean higher costs for polluting materials, disposal methods, and processes. It will put a

premium on recycling. Sustainability also opens up new markets for those firms willing to take the initiative and gain the expertise. As business becomes aware that reducing waste and pollution means more profits, new markets are created for the industry. These opportunities include: installing more efficient, less polluting energy systems in power plants; providing environmental upgrades for existing factories; incorporating new more efficient, less polluting technologies into new facilities; and making buildings more energy efficient. Firms with this expertise, particularly those emphasising at the source reduction, will be in demand.

Specifications which relied thus far for a great extent on past experience with virgin materials of well known geological origin have to be reviewed and adapted. Moreover, the standard forms of building contracts are recommended to be revised to address environmental issues and that building professionals need to become aware of the importance of sustainable construction and tailor their professional services accordingly.

GOVERNMENT ENACTMENT AND ENCOURAGEMENT

Support and encouragement from the Government is essential to stimulate a new industry – sustainability development. There are mainly twofold of functions that the Government should play for the initiation and the subsequent growing industry. First and most essential encouragement the Government could give is to provide project funding in developing recycling facilities and the employment of the recycled secondary materials. Bonus can be awarded to those projects achieving commentary or even satisfactory level of the Balance Ratio. It could support private enterprises to enter into the recycling businesses like sorting, classification of wastes, processing and transportation.

On the other fold, the Government can legitimate more stringent rules to enforce the use of recycled materials as well as set up codes of practice for construction participants to carry out the Environmental Management Systems (EMS). In Ontario, the new waste management regulation enforces source separation to be part of the demolition projects over 2000 square metres. The EMS aims to provide a comprehensive framework for achieving sustainability during the construction stage of projects. Similar codes are published by the South African Bureau of Standards (SABS 1993). In the preface to this Code of Practice, the SABS acknowledges the valuable assistance derived from "Specification for Environmental Management Systems", published by the British Standard Institution (BSI 1992). In South Africa, most formal EMS have been implemented by large industrial and business organisations. It provides a comprehensive checklist which should improve the practice of environmental management of construction.

CONCLUSION

Construction industry must inevitably change its historic methods of operating with little regard for environmental impacts to a new mode that makes environmental concerns a centerpiece of its efforts. A proactive, involved industry that addresses environmental effects squarely will have a far better chance of addressing issues and finding solutions prior to government involvement on a scale that has negative consequences for the industry. The Balance Theory as well as the proposed Balance Ratio can be used as a means for establishing the goals of sustainable or green construction. The era of sustainability, perhaps more than anything else, is establishing that we need to synthesize and integrate information to provide future generations with their own sustainable environment.

IMPROVE THE QUALITY OF CONSTRUCTION AND DEMOLITION WASTE BY SEPARATION TECHNIQUES

W. Xing, H. Pietersen, Ch. Hendriks, and P. Rem

Faculty of Civil Engineering & Geo-sciences, Delft University of Technology,
P. O. Box 5048 2600 GA Delft, The Netherlands

ABSTRACT

In the Netherlands, each year about 16 million tons of construction and demolition waste (CDW) is produced, which locally is the largest solid waste stream. Nowadays, about 90% (by weight) of construction and demolition waste is being reused. However, most of it is reused in road foundations, embankments, and so on. Therefore, construction and demolition waste is still recycled in relatively low technical applications. In order to recycle CDW at a high technical level, the two main materials from CDW—concrete rubble and brick (masonry) rubble—should be recycled/reused in the concrete industry and in the brick industry respectively, and proper quality control is an important step to ensure qualified products without environmental risks. This study focuses on effective separation techniques to improve the quality of CDW, based on differences in physical properties and chemical compositions between concrete/mortar and brick. In the laboratory study, both dry and wet separation techniques were used to obtain concentrates of concrete/mortar rubble and brick rubble. The results show that magnetic separation, jigging, spiral separation, and color separation can be successfully applied for treating construction and demolition waste, and clean products can be obtained of satisfactory.

Construction and demolition waste, quality improvement, separation techniques, recycling, concrete rubble, brick rubble, physical behavior, chemical composition

INTRODUCTION

In the Netherlands, each year around 16 million tons of construction and demolition waste (CDW) is produced. It is one of the solid wastes with large quantities in the Netherlands. Because of the limited natural raw materials resources and high population density, the reuse and recycling of secondary materials is strongly encouraged by Dutch authorities and industry. In 1994, Dutch government published the "Environmental Management Act" and stipulated an order of preference for waste treatment that was referred to as "Lansink's ladder". After several years, the "Delft ladder" was put forward by Delft University of Technology. The Delft ladder covers all options of waste treatment.

Current practice of most CDW processing plants in the Netherlands is to reuse CDW in useful applications. Since it has been forbidden to dump recyclable CDW by the Dutch Construction and Demolition Waste Dumping Ban in 1997, more and more CDW is reused. Nowadays, about 90% (by weight) of CDW is being reused. Dutch government aims to further increase the percentage of CDW recycling in the next few years.

In order to reuse or recycle waste materials without environmental risks, the Dutch Building Materials Decree (BMD) gives the maximum acceptable risk for soil and ground water contamination in terms of the leaching values of building materials for inorganic compounds, and chemical composition for organic compounds. When CDW is reused as a building material, its environmental quality should meet the requirements of the Building Materials Decree. In addition, for the sake of the labor health, dangerous substances in CDW, like asbestos, polycyclic aromatic hydrocarbons (PAH), are governed by specific regulations. For example, according to the "asbestos safety module", asbestos must be removed selectively by certified companies in the building before it is demolished. All regulations ensure a minimum of environment and health risks with the recycling of CDW in construction.

The construction and demolition waste can be reused/recycled in three ways, recycling, up cycling, and down cycling. When a material from one chain is reused in the same chain, it is called recycling. When a material is reused in another chain, if it is for a lower-grade application, it is called down cycling; if it is for a higher-grade application than its original one, it is called up cycling. At present, the construction and demolition waste is mostly reused as road foundation and embankment materials. This means that the recycling of CDW is still in a relatively lower technical level. In order to reuse CDW as building materials and avoid down cycling, the quality of the materials must be improved to meet the requirements of quality standards. For this purpose, the separation techniques that have being applied in the mining industry can be used to treat CDW.

The largest fraction of CDW consists of hard stony material such as concrete and masonry/ clay brick; a minor part consists of wood, metals, paper, plastics, and so on. In order to reuse the two main materials from CDW, concrete rubble and brick rubble, respectively, suitable techniques were chosen according to the differences between the two materials. After separation, concrete rubble and brick rubble concentrates were obtained with high purity.

CONSTRUCTION AND DEMOLITION WASTE

Construction and demolition waste can be considered as two parts, reusable materials and waste material. The reusable materials can be divided into two different groups, i.e., stony materials and non-stony materials. Stony materials, like concrete and masonry/clay brick, constitute the majority of CDW (see Table 1). Non-stony materials include wood, plastics, paper, metals and so on. The waste includes harmful materials for the environment or people's health like asbestos, tar, organics, chlorides, and the materials containing these contaminants. The stony materials are usually reused as secondary aggregates in construction.

TABLE 1
COMPOSITION OF CDW (WEIGHT PERCENTAGE)

Composition	Concrete	Brickwork	Asphalt	Wood	Gravel	Metal	Packaging	Other
Percentage (%)	41	29	20	2	2	1	1	4

In the Netherlands, there are three main types of recycled aggregates: concrete aggregates, masonry aggregates, and mixed aggregates. Only a very small amount of the recycled aggregates is used in its own chain cycle again. From the point of view of "life cycle management", treated products from

CDW should be reused/recycled for their original application, this means that concrete rubble should be reused in concrete, and masonry/brick rubble should be reused in brick. In other words, CDW is desired to be recycled at a high technical level. The aim of this study is to improve the quality of the stony materials in order to reuse them in their original applications as qualified products.

In this study, two types of materials were used. One was actual construction and demolition waste taken from a Dutch CDW processing plant of "Theo Pouw" (Utrecht, the Netherlands); another was a mixture of brick and Portland cement mortar/lime mortar that was prepared in the laboratory.

Actual Construction and Demolition Waste

The construction and demolition waste was crushed in the processing plant, and the fraction with particle size smaller than 4mm was removed. After treating in the plant, the material contains concrete, clay brick, and a very small amount of pollutants like lime, asphalt, and wood.

By sieving analysis according to Dutch standard NEN2560, it is found that about 50 percent of the material is bigger than 8mm and about 10 percent is smaller than 4mm. The material was wet sieved into five fractions: 2 to 5mm, 5 to 10mm, 10 to 19mm and larger than 19mm. Samples were taken from each fraction and sorted by hand sorting into two fractions, namely the brick fraction and concrete fraction. The results are shown in Figure 1.

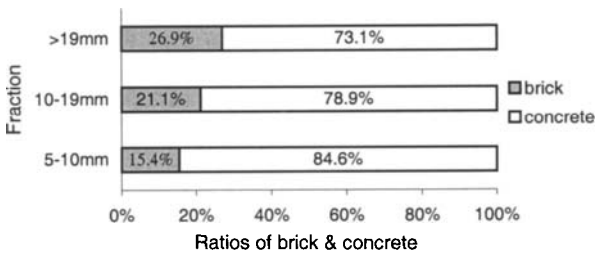

Figure 1: Proportions of brick and concrete with different particle sizes

From the above analysis, it is known that the amount of concrete in this material is about 80%, and the amount of masonry around 20%.

Mixtures of Brick and Mortar

Samples were made by mixing Portland cement mortar that had been hardened for 28 days with clay bricks in different ratios. In order to know the influence of the type of material, lime mortar was also used to make the mixture. In addition, three kinds of bricks were used, normal brick with a red color, brick with a yellow color, and hard fired brick with a dark red color. Mortar and brick were crushed and sieved respectively, then they were mixed in the different weight ratios of 50% to 50%, 30% to 70%, and 70% to 30% with the particle size between 0.15 to 2.36mm.

Properties of Concrete/mortar and Brick

The concrete rubble and brick rubble are the two main components in CDW. In order to recycle them respectively, the mixed granulate that was obtained from the plant must be further treated, and the two materials must be separated from each other to ensure qualified products. How to choose a suitable

separation technique? The differences of physical or chemical properties between the two materials are the basis. These differences are described in Table 2.

TABLE 2
DIFFERENCES BETWEEN CONCRETE AND BRICK & SUITABLE TECHNIQUES

Property	Brick	Concrete /Mortar	Techniques
Magnetic behavior	3 to 4% of Fe_2O_3	0 to 1% of Fe_2O_3	Magnetic separation
Density	1.6 to 1.8 g/cm^3	2.3 to 2.5 g/cm^3	Jigging, fluidized bed method, spiral separation
Color	Red or yellow	Grey	Color separation

A separation technique that works based on material density difference, or magnetic behavior, or color difference can be applied to separate concrete/mortar and brick from each other. The possible techniques are also shown in Table 2.

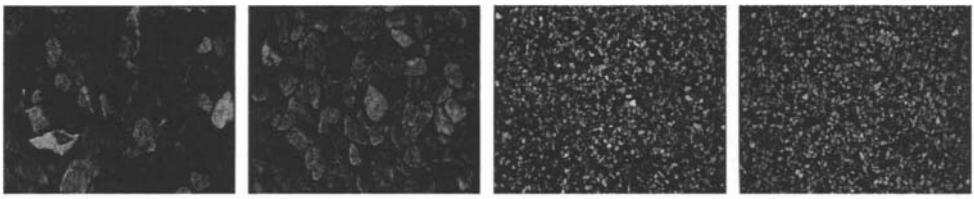
QUALITY UPGRADING AND DISCUSSION

The samples from actual CDW were separated by jigging, Humphrey spiral separation, and color separation techniques. The laboratory prepared samples were tested by a magnetic separator.

For bricks that are bound by mortar, a thermal process can be used to break mortar off brick. Applying a temperature of about 400°C for five minutes, mortar was removed from brick completely.

Separation of Actual CDW

Jigging



The ratio of the apparent densities in water for concrete and clay brick is bigger than that in air. Therefore, gravity separation will be more effective in water. Jigging is such a method. In a jig, the separation of materials with different densities is accomplished in a bed which is rendered fluid by a pulsating current of water. When water is put under pressure by a plunger, the particles fall with different speeds to the bottom, depending on their densities. The heavy fraction will sink first and be discharged from the bottom of the apparatus.

Four fractions, with particle sizes of 2 to 5mm, 5 to 10mm, 10 to 19mm, and >19mm, were separated by a jig. For each fraction, two concentrates were obtained, i.e., one on the top of the container and another on the bottom of the bed. The upper concentrate is the brick fraction and the lower is the concrete fraction. A good separation is easily obtained with larger particle size. For the fraction with particle size larger than 19mm, both brick fraction purity and concrete fraction purity are high (with similar color). This can be seen in Figure 2. For the fraction with the smallest particle size (2 to 5mm), a good separation is obtained by an asymmetric stole at lower frequency. The results show that jigging is an effective wet method to separate light and heavy stony fractions from CDW, especially for coarse particles. After jigging, the concrete fraction can be cleaned enough and recycled as concrete aggregates directly, but the brick fraction should be dried before recycling.

Humphy spiral separation

The fraction with a particle size smaller than 2.5mm was tested using the Humphrey spiral. The principle of the spiral technique is based on the gradient that exists when particles with different densities are transported by a water stream. The separation result depends on the difference in density,

particle size, particle shape and porosity. From this test, it is known that concrete fraction can be separated from soil and fine sand fraction successfully. Figure 3 shows the separation result.

Brick fraction | Concrete fraction | Brick fraction | Concrete fraction

Figure 2-a: Particle size > 19mm

Figure 2-b: 2mm < particle size <5mm

Figure 2: Separation by jigging

Figure 3: Separation by Humphrey spiral

Color separation

There is a clear difference between the colors of concrete and brick. Figure 4 shows the result of color analyzing by a computer. This is an effective method. However, it is expensive, and it is only effective when the material is cleaned, all particles are in their original colors.

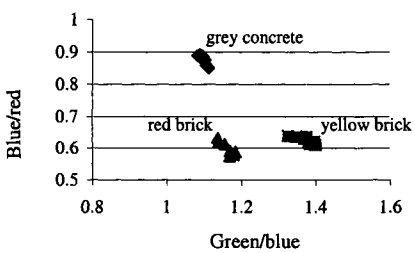


Figure 4: Color separation

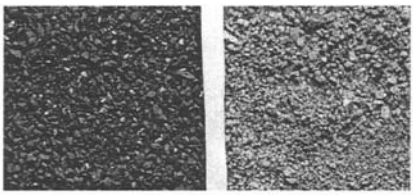
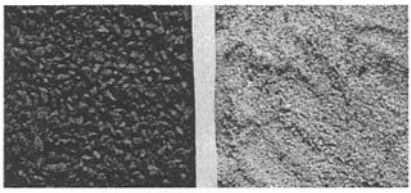
Separation of Mortar and Brick by Magnetic Separation

The content of Fe_2O_3 in brick is higher than that in concrete/mortar as shown in Table 2. In the case that brick is considered as a magnetic material, concrete/mortar can be considered as a non- or weakly magnetic material. Ideally, the particles of brick should end up in the magnetic fraction and the particles of mortar end up in the non-magnetic fraction. Table 3 shows the separation results. The



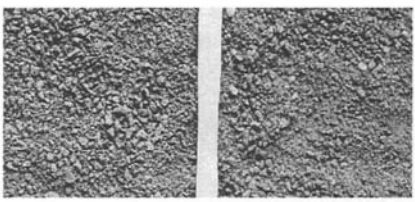
results show that when the ratio of brick to mortar is 1:1 at the machine angles of 15° and 17° with 1.2A current, good separations can be obtained. For the mixture of brick and mortar with ratio of 3:7, a good separation can be obtained at 17°, while for the mixture of brick and mortar with ratio of 7:3, a good separation can be obtained at 15°.

TABLE 3
MAGNETIC SEPARATION WITH THE MIXTURES OF BRICK AND MORTAR



Sample	Current I (A)	Machine angle α	Percentage of brick (%)	Purity of brick	Purity of Mortar
hard red brick : mortar = 50% : 50%	1.5	15	63.51	Pure	Purest
	1.5	17	55.67	Pure	Purest
	1.2	12	67.68	Non-pure	Pure
	1.2	15	54.91	Pure	Purest
	1.2	17	53.62	Pure	Purest
	1.0	9	73.18	None	Non-pure
hard red brick : mortar = 30% : 70%	1.5	15	41.45	None	Purest
	1.5	17	37.55	Non-pure	Pure
	1.2	15	35.40	Non-pure	Purest
	1.2	17	33.37	Pure	Pure
hard red brick : mortar = 70% : 30%	1.5	15	72.46	Non-pure	Pure
	1.5	17	70.28	Pure	Pure
	1.2	15	70.65	Purest	Purest
	1.2	17	67.34	Pure	Non-pure
red brick : mortar = 50% : 50%	1.2	17	56.62	Purest	Purest
	1.2	15	55.62	Pure	Purest
red brick : mortar = 30% : 70%	1.2	17	36.22	Pure	Purest
	1.2	15	36.30	Pure	Purest
red brick : mortar = 70% : 30%	1.2	15	70.6	Purest	Purest
yellow brick : mortar = 50% : 50%	1.2	15	56.22	Pure	Purest
yellow brick : mortar = 30% : 70%	1.2	15	40.50	Pure	Purest
yellow brick : mortar = 70% : 30%	1.2	15	72.83	Purest	Purest
red brick : lime mortar = 50% : 50%	1.2	15	48.94	Purest	Purest
red brick : lime mortar = 30% : 70%	1.2	15	29.71	Purest	Purest
red brick :lime mortar = 70% : 30%	1.2	15	66.17	Purest	Purest

The purity of produced product was checked by visual examination of color. There are four cases: "purest" means that all particles are in their own colors; "pure" means that the color is mixed with a few pieces of other color particles; "non-pure" means that the color is mixed with some pieces of other color particles; and "none" means the color is mixed with other particles.



In order to know how pure the separated brick or mortar/lime mortar fraction is, the separated brick fraction and mortar fraction were compared with the mixtures that were prepared in the laboratory according to their colors. In Figures 6-b and 7-b, the separated brick fraction and mortar fraction are the same as those in Figure 5-a. The color of prepared mixture (Figure 6-a) is similar to that of the separated brick (Figure 6-b). Hence, the purity of the separated brick is around 93%. Similarly, the purity of the separated mortar is around 87% (Figure 7). From this experiment, it is clear that magnetic separation is an effective method to separate brick and mortar from each other.

CONCLUSIONS

The only way to recycle CDW to a higher technical level is to improve the quality, especially to improve the quality of stony materials from CDW. From the laboratory study, it is known that magnetic separation, jigging, Humphrey spiral and color separation are suitable to treat construction and demolition waste. For the coarse fraction, a good separation of concrete and brick from each other can be obtained by jigging. For the fraction with particle size smaller than 3mm, a good separation can be obtained by either using Humphrey spiral or using magnetic separator. For color separation, a good separation can be obtained only with clean materials. The costs of color separation are higher than for the other three methods. Both jigging and Humphrey spiral are wet separation methods. The advantage of a wet method is that concrete rubble is washed at the same time so that it can be reused directly. However, it costs money to dispose of the slurry.

ABSTRACT

Aiming at a factor 20 reduction of the environmental load of buildings in 2040, it is necessary and logical to start by reducing the environmental load of the most important aspects of a building. The bearing structure is responsible for the second largest part of the environmental load of the building; the energy consumption is responsible for the greater part, assuming the life span of a building is 75 years (van den Dobbelsteen & van der Linden, 2000). The bearing structure consists of the foundation, columns, beams, floor and roof structure, and sometimes walls and facades. The horizontal elements of the bearing structure, consisting of the floor and roof structure and beams, are causing about 80% of the environmental load of the total bearing structure. Especially the floor and roof structure play a very important role (Arets, 2000). Therefore, optimisation of the floor structure will lead to an important environmental improvement of the whole office building. The question which structural material is ecologically or economically best, depends on the span the building design needs. For each floor type, for structural spans between 4.8 and 16.8 m, the environmental load and cost have been determined, resulting in a clear overview of best solutions for different spans.
Besides using the best floor types from an environmental point of view, given a certain building span, there are three other possibilities of diminishing the environmental load of the bearing structure:

- using the right material for the right function
- use of new materials for bearing structures
- innovative solutions for bearing structures

This paper describes how to determine the most sustainable floor types and how these other three possibilities contribute to diminishment of the environmental load of the bearing structure.

KEYWORDS

Sustainability, factor 20, environmental assessment, environmental impact, environmental load, environmental cost, innovation, sustainable building, bearing structure, floors, building materials.

1. INTRODUCTION

1.1 Factor 20 improvement

In 1987 the 'Brundtland Commission' released the report 'Our Common Future' in which the definition of sustainable development was an important topic. This definition made a connection between environmental and social goals in the world. In the year 1990 Ehrlich & Ehrlich and Speth re-introduced a formula, which makes it possible to quantify this connection between both goals:

$$\mathbf{EP = P \times W \times E}$$

In this formula EP stands for environmental pressure, which was said to be too high and had to be halved in 50 years from 1990. P stands for the world population, which is predicted to double within 50 years. W stands for the average welfare rate of a world citizen, which is predicted to improve with factor 5 in 50 years. Therefore E, the environmental impact by welfare per citizen, equals:

$$\mathbf{½ = 2 \times 5 \times \underline{1/20}}$$

The calculation shows that by the year 2040 the environmental load has to decrease by 95%, a factor 20. This factor 20 can be used as a goal and guiding line for the environmental performance of for instance buildings.

1.2 The environmental importance of the bearing structure

When analysing the environmental load of (office) buildings it turns out that the greater part of the environmental load is caused by energy consumption during the lifespan of the building (assuming the lifespan of a building is 75 years). The bearing structure is responsible for the second largest part of the environmental load of the building (van den Dobbelsteen & van der Linden, 2000).
Buildings often don't achieve a lifespan of 75 years; offices are functionally obsolete after 25-35 years. The shorter the lifespan the bigger the share of the bearing structure in the environmental load of buildings.
If we want to achieve a factor 20 improvement in 2040, a focus on the parts that contribute the most to the environmental load is necessary. Therefore, sustainability in building technology should be concentrated on improving the bearing structure and energy consumption. In this paper environmental improvement of the bearing structure is elaborated.

1.3 Four steps to improve the bearing structure

There are four ways to improve the environmental load of the bearing structure, in order of impact:

1. Finding the best materials given a certain bearing structure span
2. Making optimal combinations of bearing materials
3. Finding new materials for bearing structures
4. Developing innovative solutions for bearing structures

In the next four chapters these four principles are elaborated.

2. THE BEST MATERIALS GIVEN A CERTAIN BEARING STRUCTURE SPAN

2.1 The functional unity

In order to find the best material or structure variant a functional unity has to be defined. This functional unity forms the basis for comparison of different materials, without it a proper comparison isn't possible.
The functional unity consists of structural, safety and comfort requirements;

- load
- deformation
- dimensions
- fire safety (of the construction)
- thermal isolation
- sound isolation

Before comparing the alternatives, the requirements have to be quantified and the alternatives have to be designed in a way they meet all the requirements.

2.2 Horizontal elements of the bearing structure

When improving the bearing structure, consisting of the foundation, columns, beams, floor and roof structure and sometimes walls and facades, the first question is which part of the bearing structure is determining the greater share of the environmental load of the bearing structure. It turns out that the horizontal elements of the bearing structure (beams, floor and roof structure) determine about 80% of the environmental load caused by the bearing structure. Especially the floors (including roof, ground-floor and storey floors) are an important part of the environmental load (Arets, 2001).

2.3 Different floor types and their environmental load

Floors play an important role in the environmental load of the bearing structure. Therefore the environmental load of different floor types at different spans has been determined. These floors are:

- hollow core slab
- composite floor-plate (reinforced)
- composite floor-plate (pre-stressed)
- TT-slab
- steelplate-concrete floor
- bubbledeck floor
- wooden floor

In order to compare these floors, the functional unity is defined:

- load: 2,5 kN/m^2 (excl. construction weight)
- deformation: in conformance with the Dutch standards
- fire safety: 120 minutes
- sound isolation: in conformance with the Dutch standards for dwellings
- span: 4,8 to 16,8 m (with steps of 0,6 m), without intermediate beams

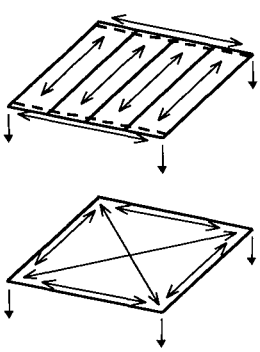

Figure 1: Load bearing capacity of floors in one and two directions

An important difference between the bubbledeck floor and the other floors is that the bubbledeck floor has a load bearing capacity in two directions. The other floors have a bearing capacity in one direction and beams are necessary to lead the load to the columns, this is shown in figure 1. These beams are not taken into account while determining the environmental load and cost.

For different spans the dimensions of the floors have been calculated meeting the requirements as defined in the functional unity. The wooden floor is equipped with plaster slabs to improve its fire safety up to 120 minutes. All floors have finishing.
Knowing the dimensions of the floors, the environmental load of the different floor types at different spans have been calculated. Therefore the database of GreenCalc (a Dutch computer program which calculates the environmental load of buildings; GreenCalc is LCA-based) is used. GreenCalc expresses the environmental load as environmental cost, making it possible to compare the economic and the ecological cost. The environmental cost are the cost necessary to prevent environmental effects and to restore the damage caused by the environmental effects.
The results are shown in figure 2. This graphic shows that the wooden floor and the hollow core slab have the lowest environmental cost for short spans and for lager spans the concrete TT-slab has the lowest environmental cost. This indicates that, based on the mentioned requirements, from an environmental point of view these floor types are the best for these spans.

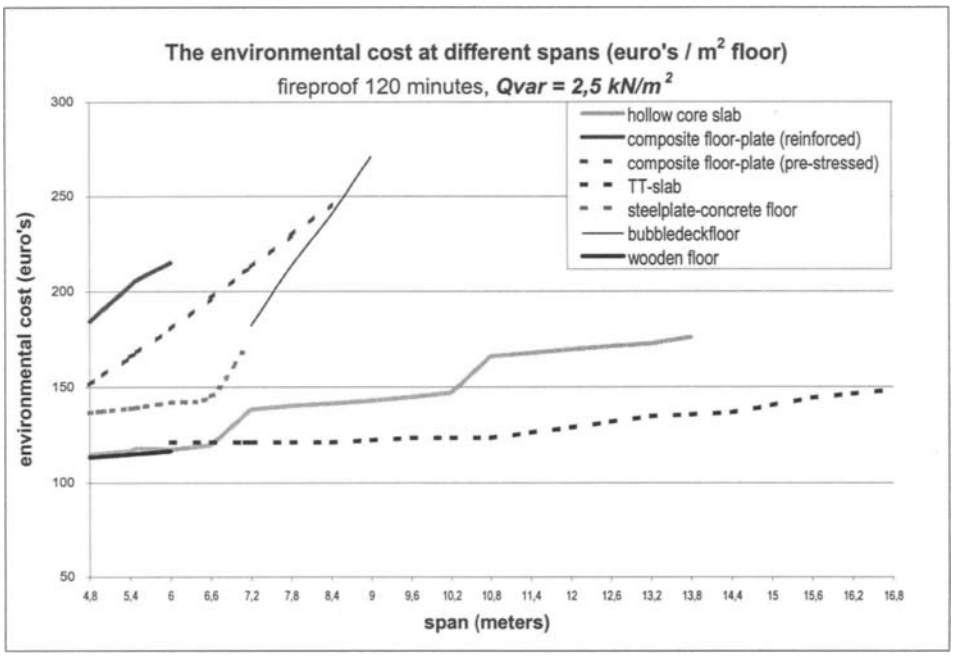

Figure 2: The environmental cost of different floor types

But not only the environmental cost is interesting, the economic cost of the different floor types play an important role in the decision making. Therefore the economic cost of these floors at the different spans has been calculated and added to the environmental cost, leading to the integral cost. The integral cost of the different floors is shown in figure 3. When looking at this graphic it's obvious that from environmental and economic point of view for short spans the hollow core slab is the most profitable and for larger spans the TT-slab is the most profitable (Arets, 2001).
There are a few things to keep in mind:

- these conclusions are only valid for the functional unity as mentioned earlier
- the economic and environmental cost are calculated for the Netherlands
- the cost (environmental and economic) is influenced by made assumptions; therefore it's more important too look at the difference in cost between the floor types than too look at the value of the cost.

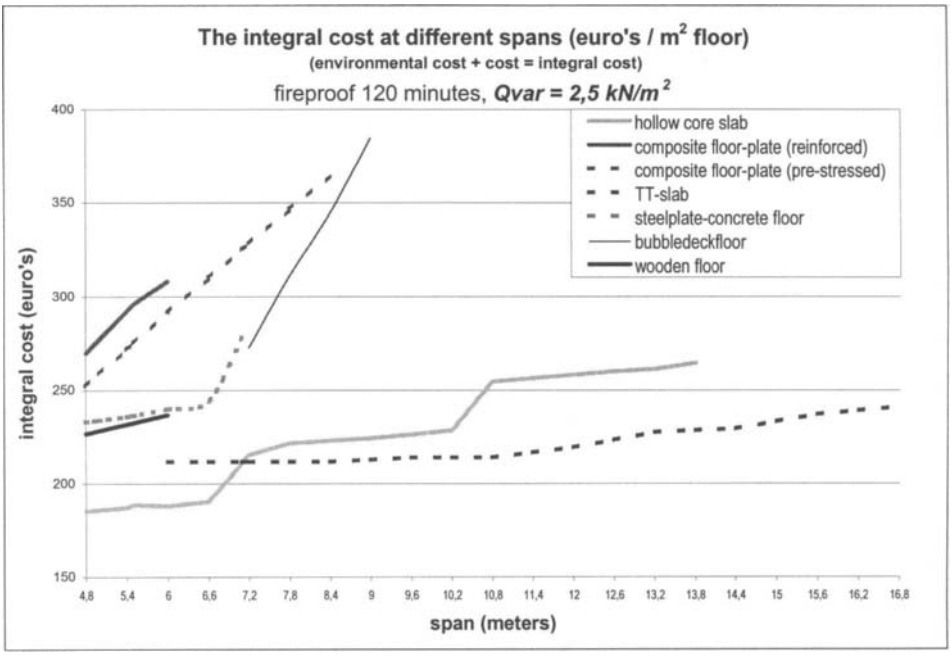

Figure 3: The integral cost of different floor types

3. THE RIGHT MATERIAL FOR THE RIGHT FUNCTION

Concrete, steel and timber are mostly used for the bearing structure. These materials have different qualities with respect to tensile-strength, compression-strength, bending-strength, shear-strength and so on. In order to use as less material as possible it's logical to use a material of which the qualities fit the appearing strain. But to diminish the environmental load there is more then just minimizing the use of materials. It's also important that one uses materials with a low environmental impact. The combination of using less material and materials with low environmental impact should lead to the use of the right material for the right function. In order to find out which material should be used from an ecological point of view the environmental cost of concrete, steel and timber have been calculated for a different manner of loading. The premises are:

Concrete: -B35 (tensile-strength: 1,4 N/mm^2; compression-strength: 21 N/mm^2; modulus of elasticity: 31000 N/mm^2)
-B65, precast (tensile-strength: 2,15 N/mm^2; compression-strength: 39 N/mm^2; modulus of elasticity: 38500 N/mm^2)

Steel: -Fe E 235 (tensile-strength: 235 N/mm^2; compression-strength: 235 N/mm^2; modulus of elasticity: 210000 N/mm^2)

Timber: -K24 (tensile-strength: 8,17 N/mm^2; compression-strength: 12,25 N/mm^2; modulus of elasticity: 7400 N/mm^2)
-K24, glulam (tensile-strength: 10,2 N/mm^2; compression-strength: 15,3 N/mm^2; modulus of elasticity: 9250 N/mm^2)

The environmental cost for the mentioned materials is calculated en indexed. The material with the lowest environmental cost get index 100. In table 1 the results are shown. Looking at the table it's clear that steel has high environmental cost. Although, for example the compression-strength of steel is much better than the compression-strength of concrete and timber, the environmental cost are so big that the index is 5 times higher than the environmental cost of the 'best choice'.

TABLE 1
ENVIRONMENTAL COST (INDEXED) - FOR DIFFERENT MANNERS OF LOADING

		weight	volume	compression-strength	tensile-strength	deformation by compression	deformation by tension
Concrete	B35	100	200	186	--	124	--
	B65	100	200	100	--	100	--
Steel	Fe E 235	964	620	515	217	571	327
Timber	K24	261	100	160	101	261	101
	K24, glulam	324	124	158	100	259	100

Concrete without any reinforcement metal is almost never put into practise. With reinforcing metal the compression-strength and the tensile-strength of concrete get better, but due to the high environmental cost of steel the environmental cost of reinforced concrete rise. If the concrete is pre-stressed, the material qualities will improve more than if it's reinforced, meaning that the environmental cost of pre-stressed concrete is lower then of reinforced concrete (Arets, 2001).

When applying the materials as construction, the shape of construction elements is also important. To get an impression of the environmental cost and the integral cost of beams, made of different materials and applying the most common shape for that material, the dimensions of the beams are calculated (Hogeslag, 1995). The span is 8 meter with one intermediate point of support; the load (without construction weight) is 15 kN/m. Knowing the dimensions, it's possible to calculate the environmental cost and the integral cost (in euro's). The results are shown in table 2.

TABLE 2
ENVIRONMENTAL COST FOR DIFFERENT BEAMS

Material	Dimensions	Environmal cost / meter	Index
reinforced concrete	250 mm x 490 mm	88	251
prestressed concrete	200 mm x 450 mm	65	186
steel	HE 260 A	190	543
timber (glulam)	100 mm x 800 mm	35	100
aluminium	HE 240 A + 4 studs (15x30)	193	553
Material	**Dimensions**	**Integral cost / meter**	**Index**
reinforced concrete	250 mm x 490 mm	114	114
prestressed concrete	200 mm x 450 mm	106	105
steel	HE 260 A	231	229
timber (glulam)	100 mm x 800 mm	101	100
aluminium	HE 240 A + 4 studs (15x30)	284	282

The results in table 2 show that from economical and environmental point of view timber (glulam) is the best solution and pre-stressed concrete is just a little bit worse.

Analysis of the relation between material qualities and their environmental cost leads to these conclusions:

- ⇨ High strength concrete (like B65) has the lowest environmental cost with regard to compression-strength.
- ⇨ Timber (especially glulam) has the lowest environmental cost with regard to tensile-strength.
- ⇨ For short spans timber (glulam) has the lowest environmental and integral cost; pre-stressed concrete is just a little bit worse.

Important for the environmental load of elements of the bearing structure is the shape of the element. As is well know an I-profile is much more effective (for bending, buckling, etc.) then a massive cross-section with the same amount of material.

4. NEW MATERIALS FOR BEARING STRUCTURES

4.1 Diminishing the environmental load of materials

In order to achieve the factor 20, the environmental load of the bearing structure has to decrease. Two ways have been mentioned, but there are more possibilities:

- ⇨ decrease material use with 95%
- ⇨ use material with 95% less environmental load
- ⇨ prolonging the lifespan by factor 20

An example of decreasing the amount of material are the concrete floor slabs. Using hollow core slabs or bubbledeck floors instead of massive floors, the amount of concrete is decreased from about 20% up to 45%. Decrease of material use can also be achieved by using the right material for the right function. Note that one has to be careful; although some materials are more suited for a function then others, the environmental load can be much higher.
Recycled materials and 'natural' materials have less environmental load than 'standard' materials. Note that when using these recycled or 'natural' materials, they have to meet the same requirements as 'standard' materials.
Prolonging the lifespan is possible on different levels. First of all the lifespan of the whole bearing structure (whole building) can be prolonged. Second the lifespan of elements of the bearing structure can be prolonged. This requires elements that are demountable and not polluted and that they are re-used in a sustainable way. Third the lifespan of the materials can be prolonged.
The greatest step towards the factor 20 is combining the three mentioned principles. Use less material and make sure that the used materials have a low environmental load and that they have a long lifespan (Arets, 2001).

4.2 'New' materials

As said before, in the western world concrete, steel and timber are commonly used materials for bearing structures. There are also other materials with specific qualities like glass, synthetic materials, bamboo and all kinds of other natural materials, for instance round timber from young trees.
It will take time to find out what the exact qualities of these materials are and how to use them in a way their qualities are utilised.
The search for 'new' materials which meet the same requirements and have a less environmental impact goes on.

5. EXAMPLES OF INNOVATIVE SOLUTIONS FOR BEARING STRUCTURES

Prefab demountable concrete constructions could be a solution for the shortening lifespan of buildings. The bearing structure consists of prefab pre-stressed concrete elements, put together at the construction site. The connections are mostly bolted and therefore demountable. Examples of these constructions are: the SMT system, the CD-20 system and the Bestcon system (Straatman, 2000).
A similar kind of construction is developed by Prof. van Herwijnen. It consists of specially developed TT-slabs, steel-concrete beams and concrete columns. All the elements are prefab and all connections are bolted and demountable (van Herwijnen, 2000).
One of the problems with this kind of construction is the question who is willing to take the used elements back, approve of them and use them in another building.

An example of an innovative solutions for floors is the IXO-floor. This floor consists of a three dimensional steel frame, with plates on both sides as ceiling and floor. The service-pipes can run through the frame. The floor construction can be demounted as far as cubic elements from about 600 mm and these elements can be demounted further (IXO Sustainable Technology, 2001).

The last example comes from 'historical' constructions, it's an 'under-stressed construction'. In these constructions the occurring tension and compression while bending is disengaged, and a large lever arm is created. Through this large lever arm the construction is very resistant for bending. And because of the disengaging different materials can be used; where there is tension, for instance timber, where there is compression, for instance concrete. Applying this principle in new constructions, floors could be under-stressed as well.

Just like the innovation in materials, the innovation in bearing structure needs to continue. More research of the whole bearing structure is needed. Also research on other building elements, on prolonging the lifespan and more efficient use of the building is necessary.

DELIVERING SUSTAINABILITY THROUGHOUT THE BUILDING PROCESS: A STUDY OF THE UK CEMENT AND CONCRETE SECTOR

J. Glass [1] and D.N. Pocklington [2]

[1] Oxford Centre for Sustainable Development, Oxford Brookes University, Gipsy Lane, Oxford, OX3 0BP, UK
[2] British Cement Association, Century House, Telford Avenue, Crowthorne, Berkshire, RG45 6YS, UK.

ABSTRACT

Sustainability is becoming an increasing influence on the way buildings and infrastructure are designed, constructed and occupied. With its emphasis on the 'triple bottom line' issues of environmental protection, economic growth and social progress, the principle of sustainability forms the basis of an increasing number of mandatory and voluntary initiatives within the EC and its Member States. Within the UK, sustainable development, (and its implications for energy use, materials, resources and social equity), is encouraged by government through the use of sectoral strategies and its incorporation in government policy relating to construction.

Within this policy context, this paper will consider the UK cement and concrete sector on a number of levels from compliance with European and national legislation to voluntary improvements to manufacturing performance. For example, the industry has been proactive in its early uptake of environmental management systems such as EMAS and ISO 14000 and its development of life cycle assessment of products. More recently, these have been extended to the inclusion of sustainability, and the development of company and sectoral sustainability strategies. However, with the construction industry producing almost 20% of the UK's waste and the occupation of buildings accounting for about 50% of UK CO_2, this paper will also focus on efforts to reduce the burden on UK plc via good practice using cement and concrete in construction. There will be a discussion of the use of fabric energy storage capacity of concrete to reduce or remove the need for air conditioning in buildings, recycled or waste materials within concrete and various methods to reduce waste.

INTRODUCTION

Sustainability is becoming an increasing influence on the way buildings and infrastructure are designed, constructed and occupied. With its emphasis on the 'triple bottom line' issues of environmental protection, economic growth and social progress, the principle of sustainability forms the basis of an increasing number of mandatory and voluntary initiatives within the European Community and its Member States. This development of EU legislation has reflected the growing environmental awareness within the Community, and the early reliance on 'command and control' has now been supplemented with 'producer responsibility' legislation, economic instruments and voluntary agreements (Pocklington, 1995; 2000). Within the UK, sustainable development, (and its implications for energy use, materials, resources and social equity), is encouraged by government through sectoral strategies and its incorporation in government policy relating to construction (DETR 1999a; 1999b; 2000a). Many of the European and UK directives in this area are related to the global issue of climate change and the targets determined within the Kyoto Protocol, which has resulted in more stringent controls, measures and taxation on 'energy intensive' industries. The UK cement and concrete industry is considered to be energy intensive (it produces approximately 2% of UK CO_2) and as such is subject to environmental legislation. It is also part of the £58bn construction industry in the UK, which is said to account for almost 20% of all waste. At first glance, these statistics indicate why this sector has been a key target for improvement, if the UK is to meet its commitments to the Kyoto Protocol. However with the construction and occupation of buildings accounting for about 50% of UK CO_2, it is clear that there are perhaps more significant results to be gained elsewhere. Perhaps by combining legislation invoking producer/manufacturer responsibility with a much more concerted effort to reduce the burden on UK plc by good practice in design and construction, this imbalance can be redressed.

This paper outlines the policy context associated with the manufacture of cement and the production of concrete. It will show that, in addition to compliance with European and national legislation in this area, the UK cement and concrete industry has been proactive in the improvement of its own performance and diligent in investing in energy efficiency improvements. Adoption of environmental management systems (i.e. EMAS, ISO 14000) has been accompanied by the development of life-cycle product assessment and the development of company and sectoral initiatives. However, there are also significant benefits to be gained in sustainability terms by better employing cementitious materials within the built environment to reduce the operational energy burdens associated with buildings. This issue will be examined in relation to property development, procurement and design, construction and building use. In particular, there will be a discussion of the use of fabric energy storage capacity of concrete to reduce or remove the need for air conditioning in buildings, recycled or waste materials within concrete and various methods to reduce waste (in terms of materials, time and energy).

RESPONSES TO GLOBAL ENVIRONMENTAL ISSUES – POLICY AND PRACTICE

As a consequence of the 5th EU Environmental Action Programme, sustainability is now one of the objectives of the Community, being incorporated formally into its legislative regime in the early 1990s. Further features of the Programme were the concept of shared responsibility between all stakeholders and the switch in emphasis from environmental protection by control of the environmental media (air, water, and land) to a consideration of the effects of all the environmental implications on various sectors of the economy. These provided the stimulus for broadening the scope from purely legislative controls to 'horizontal measures' (i.e. market-based instruments, horizontal, supporting instruments, and financial support measures). These measures have been imposed (in addition to statutory legislation) and the UK cement industry has been obliged to invest significant sums (c. £500M) to ensure its compliance, notably in relation to Integrated Pollution Prevention and Control (IPPC). In addition, there are a number of major instruments and measures that are currently affecting the UK cement and concrete industry related directly to environmental sustainability. These tend to be climate

change/CO_2-focused measures, as the UK strives towards honouring its commitments under the Kyoto Protocol. Global warming is the most significant environmental issue to be addressed, and the control of greenhouse gas emissions is an area that has been subject to the development of 'horizontal measures'. The UK has provided leadership in this area with the development of its Climate Change Programme, including the innovative combination of fiscal measures and negotiated agreements within the Climate Change Levy (CCL) and the market mechanism of the Emissions Trading Scheme (ETS) (Pocklington, 2001a).

Cement production is regarded as an energy intensive process, being associated with the generation of large quantities of carbon dioxide through the burning of fossil fuels within the kiln, and from the decomposition of limestone. Globally, these sources account for 5% of man-made CO_2 emissions, although in Europe the figure is closer to 2%. Under the UK CCL scheme, a levy is imposed on the industrial use of energy (although there are a number of excluded energy uses, exempted fuels, and activities subject to half-rate levy). An 80% reduction in CCL payments is available to companies whose sectors make commitments to energy efficiency improvements or reductions in CO_2 emissions. This discount is limited to 'energy intensive industries' falling within the IPPC regime and is conditional on the establishment of negotiated agreements with government. The UK cement industry is committed to improve energy efficiency by 25.6% from 1990 to 2010. This exceeds the government's aspirational target of 20%, its legally binding Kyoto commitment of 12.5%, and is substantially higher than a number of comparable sectors. Whilst the CCL scheme may be regarded as a technical success (set to achieve 2.56 MtC of carbon savings, DETR, 2000b). However, when viewed in terms of its equitability to business, a different conclusion is reached: the scheme is complex and there are significant discrepancies between the contributions of different sectors (Pocklington, 2001a; 2001b).

Details of the UK Emissions Trading Scheme were announced shortly after the CCL became effective, and it started in Spring 2002. In addition to CO_2, the ETS includes five more greenhouse gases (methane, CH_4; nitrous oxide, N_2O; hydrofluorocarbons, HFCs; perfluorocarbons, PFCs; sulphur hexafluoride, SF_6) providing that suitable protocols for measuring and verifying emissions can be developed. The ETS is expected to yield a minimum of 2.0MtC, i.e. of a similar order to the CCL, however, it is a simpler, more flexible system, in which there are no limits on who may trade and so commentators are more optimistic about its success. The Scheme is open to those already in the CCL regime and voluntary 'Direct Entrants', which must bid for part of an annual incentive of £30M, available over five years and are given 'allowances' permitting the holder to emit given quantity of greenhouse gases. Participants will trade these allowances ('cap and trade'), on 31st December 2002, compliance with targets will be assessed, and incentive payments made in April 2003. The process will be repeated annually.

Another recent economic instrument is the UK's Aggregates Tax, the objectives of which are to address the environmental impact associated with quarrying operations, to reduce the demand for virgin aggregate, and encourage the use of recycled materials. From April 2002, a tax of £1.60/tonne was imposed on sand, gravel and crushed rock subjected to commercial exploitation in the UK. The formal basis of the taxation includes a comprehensive range of exemptions (for other quarried or mined products such as coal, metal ores, industrial minerals etc. and for limestone used in the production of lime and cement). Despite this, the tax is expected to generate approx. £385m revenue in its first year, all of which will be returned to business through a cut in employer National Insurance Contributions and a new Sustainability Fund to deliver environmental benefits, similar to that within the Landfill Tax (Pocklington, 1998). The Aggregates Tax has attracted significant criticism from certain sections of the industry regarding its introduction, applicability and likely effectiveness at delivering the stated objectives. It is not yet clear to what extent it will result in genuine environmental improvements or to what degree it will effectively promote imports to the UK of materials not subject to the tax.

Indeed, there are two aspects to consider when assessing the effects of such environmental taxation. First, its efficiency in generating an environmental benefit and secondly, its overall environmental effectiveness (in terms of the alternatives available (e.g. Emissions Trading *vs.* CCL), the scope of the measure (e.g. addressing CO_2 emissions during manufacture when majority are associated with use); and other 'knock-on' effects of the measure (Oxford Economic Reporting, 2001; Centre for Economics and Business Research, 2001). This is well demonstrated by the CCL; although it is expected to result in a significant reduction in CO_2, the scheme is inefficient in its bureaucratic, restricted nature and pundits suggest that a similar result could have been produced through the ETS alone. In sum, cement and related concrete materials are subject to both the CCL and the Aggregates Tax. In addition to the likely impact on jobs and materials prices, it is anticipated that there will be an adverse effect on the UK infrastructure, where products are sold into areas with fixed budget allocations (e.g. local authorities). The impact will be significantly greater in areas such as Northern Ireland and the South East, where the locations favour imports from counties/countries not subject to the additional taxation.

Although the UK cement and concrete industry has been subject to an increasing number of fiscal and legislative environmental controls, it has nevertheless been proactive in the improvement of its environmental performance through voluntary initiatives. Initially introduced on the basis of ensuring environmental compliance, environmental management systems (EMSs) are now viewed in terms to their potential benefits to the company in areas such as stakeholder involvement, ethical investments, insurance, and purchasers of their goods or services. There is a strong business case for good environmental performance, and all cement plants within the UK have ISO 14000, and over 65% additionally have EMAS, with its commitment to public reporting. Concomitant with the uptake of EMSs has been company involvement in areas beyond their direct control, both upstream and downstream from their operations. In addition to controlling their interfaces with third parties, as required for most EMSs, organisations have developed expertise in supply chain management and life cycle assessment. The latter is of particular relevance, for it provides the basis for linking the costs and impacts of the production of cement to the use of concrete products. Recent work in this area has demonstrated that the 'use' phase of buildings and structures has a much greater environmental impact than that of the preceding processes associated with their provision. This confirms that greater benefits can be achieved via improvements in planning and design of buildings.

The cement and concrete sector has also been approached by government, with a view to develop and publish a 'sector sustainability strategy'. Since the sustainability of cement is strongly linked to its use in concrete products, buildings and structures, it was decided that a strategy for concrete in construction would be more appropriate than one for the cement industry in isolation. An inaugural meeting of the sector group was held in July 2001, following which representatives of interested parties met to draw up a programme of work. The British Cement Association are providing project management, and are sponsoring a supporting R&D programme at the University of Surrey. Additional inputs will include life cycle data on a range of concrete products, from a programme undertaken by Cembureau, and information from the ambitious two-year programme, 'Toward A Sustainable Cement Industry', undertaken by the World Business Council on Sustainable Development.

Having examined the cement and concrete sector, as an example of an 'energy intensive' industry that forms a major part of the UK construction industry, the next section of this paper considers the realms of the various actors and organisations involved in the realisation of the built environment. This will show that the onus to implement change (e.g. responding to climate change) has been, to date, placed squarely with the production side of the construction industry and how the procurement and design side is yet to be as significantly affected. However, it will also demonstrate that change is afoot, particularly within the UK context.

TOWARDS SUSTAINABLE DEVELOPMENT – THE ROLE OF DECISION MAKERS

The issue of how to use land sustainably is becoming more important in European and UK policy and is a matter of concern for planners and property investors (Williams et al, 2000). At the level of planning policy, sustainability is being woven carefully into the content of key documents, but for the layperson this may be a difficult trend to distinguish because it affects and interlinks so many diverse aspects of policy. One response to these issues has been the development of 'sustainable site selection' methods, which are being used by local authorities and private companies. As sustainability is addressed more comprehensively by policy, it will become clear that sustainability-linked EIA methodologies and in-use assessment methods will need to be developed and adopted as standard. This may require a significant effort to integrate social aspects of sustainability sufficiently. For sustainable property development, 'behind the scenes' characters are at least as important as the government and its regulatory building and planning framework in producing more sustainable buildings. Individuals and institutions that invest in property on a regular basis (i.e. not owner-occupiers) effectively control the location, nature and (sustainability) value of development. Institutional investors, such as pension funds, dominate property investment and long term financial performance is the single most important criteria against which they judge success.

Research within the London property investment industry suggests that 'environmental' factors will be a greater matter for concern for tomorrow's investors, but never for today's[1]. In the meantime such investors' decisions will continue to be based almost solely on the basis of long-term rental returns. This is unproductive as regards sustainability and singularly unhelpful in terms of operational efficiency to reduce CO_2 emissions, for example the highest rental returns in commercial office properties are associated with buildings featuring air conditioning as standard. This unwillingness to take a lead, forcibly or voluntarily, on sustainable property development is unlikely to change unless the government proffers a fiscal 'carrot' and a tax 'stick' to alter the situation in the same way as it has implemented appropriate measures affecting the production of building materials. With about 50% of the UK's CO_2 emissions arising mainly from the occupancy of buildings, designers, clients, building users, materials suppliers and contractors have major parts to play in the responsible design, construction and use of the built environment. Therefore, it has been suggested that development decisions for buildings should actually be based on the following 'rules' (Institution of Structural Engineers, 1999):

- Refurbish, adapt and re-use existing buildings (in preference to greenfield development). If not, design and construct new buildings that are adaptable to different users and functions and therefore offer longer life.
- Use recycled components and materials or those from sustainable sources.
- Minimise energy needed to operate buildings by essentially passive design.
- Use or recycle waste produced during construction, operation and deconstruction.

This list supports the notion that a discussion of the need to build should always be preceded by a discussion of the re-use/refurbishment options. Rehabilitation of existing buildings and structures is a very worthwhile option as is examining design life expectancy and maintenance/ replacement cycles in more detail. Within the sustainability debate there is also much discussion about the relative merits of re-use versus new build. There is no clear answer – as for most issues in the sustainability remit, it is a matter of balance. That said, research on the re-use and rehabilitation of older concrete frame buildings has revealed the inherent benefits of a structural frame with longevity, enabling creative refurbishment to buildings in high value, prestigious city centre locations (Gold & Martin, 1999).

---

[1] Keeping, M.: Oxford Centre for Real Estate Management, Oxford Brookes University, including Parnell, P. & Sayce, S. (1999) Attitudes towards financial incentives for green buildings, Drivers Jonas, London, UK.

Despite calls for change, sustainable methods of property valuation have yet to emerge within the mainstay of the traditional real estate sector. Until such conventions are overturned, then the sector's environmental credentials are unlikely to improve.

EVALUATING THE ALTERNATIVES – THE NEED FOR ECO-ACCOUNTING

The use of partnering and non-competitive forms of procurement is becoming more popular in building construction. There is an increasing incidence of 'blue chip' companies and regular construction clients choosing to establish long term contractual arrangements (and relationships) to create a more stable, trusting and ultimately productive working environment. There are several major benefits to this type of approach that impact positively in sustainability terms, not least the eradication of lengthy and intensive tendering routines. In addition, the establishment of long term working relationships facilitates better compilation and analysis of project data on the 'triple bottom line' factors. For example, the project partners can engage in 'continuous improvement' more easily where they have a series of ongoing projects and can work together to improve performance (e.g. by reducing construction waste or improving site standards), linking sustainability with good business practice.

There is a powerful tendency for the UK construction industry at large to rely on a 'first-cost culture'. This stems from a traditional approach to building procurement whereby one-off clients sought the lowest price for their one-off building and valued this criterion above most others. There is now growing concern that the short-term attitude to costing is undermining long-term sustainability for both the procurers and the occupiers of buildings. A more equitable and integrated approach is required, which does not simply presume at the outset that "green buildings cost 10-20% more to build, so we won't build green". However, there has not yet been significant growth in the use of whole-life costing (i.e. life-cycle costing, LCC). Life-cycle costing is a step forward in better eco-accounting, but it is still not sufficient on its own. At a slightly different level, eco-accounting in the form of life-cycle assessment (LCA) of a building and its component parts is becoming an increasingly appropriate means to measure and compare the environmental impacts caused by all aspects of production, design, construction, use, recycling and demolition. By the same token, the methods for appraising the practical aspects of construction are also under development.

The UK government has launched a strategy for sustainable construction, which was intended to give appropriate guidance to the various actors within the sector. The strategy aimed 'to provide a catalyst for change' by promoting awareness and stimulating action, in particular to reduce waste (the construction industry produces almost 20% of all UK waste). One example from the concrete sector was the Princess Margaret Hospital in Swindon, a major new building built on (cement) remediated land, designed to use 30% less energy during occupation than a conventional hospital, which generated 50% less waste during construction than typical sites (Glass, 2001). The in-situ concrete frame structure and precast concrete cladding were designed and built within a tight project framework (devised by a specialist sustainability consultant) to prove beyond doubt that all the triple bottom line issues could be addressed on a major public sector project. Indeed, the ability to measure and compare performance via appropriate indicators is an increasingly popular means of expressing tangible progress. A number of indicators have been taken forward under the Movement for Innovation (M4i) initiative in the form of environmental performance indicators (EPIs) for sustainable construction (Movement for Innovation, 2001):

- Operational carbon dioxide emission (kg CO_2/m^2/year)
- Embodied carbon dioxide (kg CO_2/m^2)
- Water (m^3/person (equivalent)/year)
- Waste in the construction process (measured in $m^3/100m^2$ floor area)
- Biodiversity (TBC; possibly area of habitat preserved or change in species index)
- Transport (TBC; possibly transport km or number of movements)

Having agreed on the most appropriate indicators, the effective comparison of live project data to industry benchmarks will now be possible – given that project managers are able to facilitate the collection and manipulation of such data.

DELIVERING RESULTS – FABRIC ENERGY STORAGE WITH CONCRETE

Indicators are a measurement tool, that is agreed, but it is the relative weighting or ranking associated with those indicators that will determine how success is to be judged on a project-by-project basis. To demonstrate this and relate it to global warming, take CO_2 amongst a basket of other key environmental indicators associated with climate change – doing so, a clear hierarchy emerges (in order of increasing magnitude):

- Initial construction impacts
- Refurbishment impacts
- In-use impacts: energy use and maintenance
- Urban development and infrastructure
- Society: people and their activities (including car travel)

The impacts from buildings are mainly from their use and the CO_2 associated with the generation of energy for heating, lighting and cooling. Only about 10% of operational (in-use) impacts are from the energy notionally embodied within building materials. The dominance of operational impacts means that designers, planners and constructors must keep in perspective the fact that sustainability is a matter of balance, and as such their efforts should be squarely on the long-term aspects of building performance. For instance, recent changes to UK Building Regulations are in direct response to global targets in terms of reductions in CO_2 and other greenhouse gas emissions. Operational energy efficiency in buildings is of the highest concern to UK government, and this is why such aspects of building construction are held up as the industry's most significant problem in terms of sustainability. One of the greatest concerns is the increasing use of air conditioning, which is very energy intensive and requires regular maintenance and short-term replacement cycles. This is in direct contrast to natural ventilation (passive) design strategies that are designed for long-life and minimal expenditure in terms of upkeep.

This is one area where concrete construction can make a very significant contribution (Glass et al, 1999). The use of concrete's thermal mass (called fabric energy storage) can result in 50% lower operational energy consumption and 20% lower capital construction costs, compared to 'comfort cooling'. Examples of major buildings throughout the UK demonstrate that building owners and occupiers can reap long term savings by exposing the undersides of the concrete floor slab (and other elements) to reduce and delay the onset of peak internal air temperatures. The building construction cost can be reduced by 5% simply on the basis of removing suspended ceiling systems. Exposed concrete offers a stunning example of the architectural opportunities for the building client. To give an indication of the scale of cost savings involved, a 32,000m^2 public sector building in Scotland was designed to achieve a £185,000 energy saving per annum by using concrete's fabric energy storage properties. As a dense material for floor and wall surfaces, concrete also offers a major benefit in terms of building health. The inert nature of concrete provides a better level of indoor air quality (IAQ). In combination with good natural ventilation and natural daylight, productivity improvements of at least 10-15% have been documented, and with the UK's current figure of £600m worth of days lost due to the symptoms of sick building syndrome, there is a clear business case. A simple ratio (1:5-10:200)[2] can be used to describe the orders of magnitude involved, for example in commercial office developments, where 1 = the cost of construction; 5-10 = the operational cost to run the building, and 200 = the salaries of people within it.

[2] After Peter Rogers (Stanhope) and Robin Nicholson (Construction Industry Council).

CONCLUSIONS

Despite the environmental importance of energy consumption and CO_2 emissions, the legislative and fiscal measures introduced to date have been restricted in their efficiency and effectiveness, and have tended to focus on production-related issues – a relatively small contribution in relation to emissions during use. The cement and concrete sector is making major inroads towards the practical and measurable delivery of sustainability throughout the building process, but it is no longer only within the realm of the 'energy intensive' industries to provide tangible results. Having complied with new economic instruments and voluntarily adopted environmental management systems, the sector is quickly reaching the limits of a 'reasonable response'. Rather, the time has come for sweeping changes to practice; to overhaul what in sustainability terms is an antiquated way of producing the built environment, but the onus must now be placed downstream of manufacturing activities.

An holistic approach involving whole-life assessments must be central to any future measure, and the construction industry has a vital role to play in providing such an analysis. Such an approach will be one outcome of the sectoral sustainability initiative on concrete in construction, which will build upon existing industry expertise in life-cycle analysis and supply chain management, and other sustainability initiatives. However, these must be complemented by a re-assessment of other drivers including the whole issue of material standards, Building Regulations, and initiatives relating to the operational energy associated with building use. Improvement to the long-term energy performance of buildings is a key part of sustainability and there is a clear business case for specifying concrete. However, the UK construction industry currently lacks tools with sufficient breadth of functionality and data to best evaluate and appraise the economic, social and environmental aspects of sustainable construction. It is unreasonable to expect the design team for a building project to be able to weigh up (unaided) the myriad pieces of evidence relating to sustainability indicators. An integrated eco-accounting methodology that is able to balance the 'triple bottom line' business case and compare it with 'business as usual' in an equitable fashion is vital to move the industry forward. These tools are being developed by some major construction firms, to provide the best response to the government's sustainable development and sustainable construction strategies. However, they will not be sufficient in their own right to deliver the changes deemed necessary – these will be effected only by major fiscal 'carrots' and tax 'sticks' to drive change forward. Indeed, it has been suggested that the magnitude of incentive necessary may be of an unprecedented order, for example with energy costs needing to be set at 40 times their current levels to fundamentally affect decision making processes.

SERVICE LIFE PLANNING: DEFINITION OF CLIENT REQUIREMENTS

Rebecca Hooper[1], Kathryn Bourke[1], Josephine Prior[1] and David Richardson[1]

Building Research Establishment Ltd., Watford, WD25 9XX, UK

ABSTRACT

The paper aims to provide architects, designers, engineers, specifiers and contractors with an understanding of the information they need from clients in order to deliver functional, durable buildings and infrastructure that provide value for money. Service life planning is the mechanism by which the design and construction process sets out to achieve a required service life. Achieving a pre-defined service life is one indicator of the value provided by the facility and service life planning offers a mechanism to achieve the goals of value from construction procurement.

The recent UK Government reviews of the construction industry have highlighted the need for improvements in the construction process to ensure efficient delivery of effective facilities. By understanding and defining service life and performance requirements clients can greatly increase the likelihood of achieving the value that they need from the final facility. Considering the service life of a facility at an early stage of the construction procurement process can lead to:

- improved understanding and definition of expectations of the facility in use;
- increased likelihood of continuity of function over time;
- reduced risk of failure and consequent loss of business value;
- optimal capital and operational expenditure.

Factors that are important to the achievement of required service life and need to be considered by the client are:

- the purpose of the facility;
- demands placed upon the design (*must-haves*) such as corporate policies, aesthetic considerations, sustainability credentials and so on;
- the need for flexibility;
- the required service life and the effects of service life failure;
- the levels of repair and maintenance;
- project expenditure and whole life costing.

KEYWORDS

Service life; client; whole life cost; value, briefing.

INTRODUCTION

This paper introduces the principles behind the *Service Life Checklist for Clients* (BRE 2002). The *Checklist* has been developed as the first stage in the service life design process, under the project *Service life design to minimise whole life costs and promote sustainable construction*, funded by the Construction Industry Directorate of the UK Department of Trade and Industry. This paper aims to provide architects, designers, engineers, specifiers and contractors with an understanding of the information they need from clients in order to deliver functional, durable buildings and infrastructure (referred to as facilities in this paper) that provide value for money.

What is Service Life and Why is it Important?

BS ISO 15868-Part 1 (BSI 2000) defines service life as "*the period of time after installation during which a building or its parts meets or exceeds the performance requirements*". Achieving a pre-defined service life is, therefore, one indicator of the value provided by the building. Service life planning is the mechanism by which the design and construction process sets out to achieve the required service life. The planning process begins with the definition, by the client, users or other stakeholders, of the service life required for the final facility and any performance requirements that it is expected to meet or exceed. Yet, the client does not always provide the information required by the design/construction team to match their expectations. A recent consultation exercise demonstrated that where service life information is included in the client brief, designers check their designs against this information (Hooper and Rizzi 2001). Clearly, where this information is missing, these checks cannot be made.

The Changing Attitude of Construction Clients

The sole purpose of construction project is to fulfil a business or aspirational need. The success of a facility depends on how well it meets a client's needs and interests. Construction should not only be an answer to basic client requirements, but it should also enhance and facilitate the activities that it accommodates (Prior and Rizzi 2002).

Recent changes in client attitudes to construction are reflected in an increasing interest in through-life costs, that is, not only the capital costs but also the operational costs associated with delivery of functional performance for a defined life span (Kernohan et al 1996, RAE 1998). The client has a significant opportunity to improve the delivery of their facilities, though the definition of required service life and performance at the start of the construction procurement process. Clear vision and direction are important elements for success. By understanding and defining service life and performance requirements clients can greatly increase the likelihood of achieving the value that they need from the final facility.

UK construction initiatives, such as Rethinking Construction (Egan 1998), Constructing the Team (Latham 1994) and The Building Down Barriers Programme (Cain 2000) demonstrate that repeat construction clients have paid "*unnecessarily high costs for an inefficient process which all too often delivered functionally inefficient buildings and facilities*" (Cain 2000). The UK Government Construction Clients' Panel has committed to *Achieving Excellence* through (GCCP 1999):

- Procurement decisions based on value for money,
- Using risk and value management,
- Performance specifications,
- Whole life costing,
- Use of information technology and standardised document handling,
- Use of innovative procurement strategies based on integration of the supply chain.

Inefficiencies in procurement and management of construction projects can cost up to £600 million per year for the UK Government (NAO 2001) leading to innovative procurement mechanisms finding favour. These mechanisms include (NAO 2001):

- *Private Public Partnerships* (HM Treasury 1999), particularly *Private Finance Initiative* projects (HM Treasury 2000). The supplier is contracted to construct and then deliver the services that the facility is intended to provide.
- *Design and Build* (HM Treasury 1999). A single supplier is responsible for both the design and construction of the facility.
- *Prime Contracting* (Holti et al 1999). A form of design and build where the prime contractor is expected to have an established supply chain to encourage the provision of value for money and quality.

These changes in UK Government attitude, and the focus upon achieving value from construction over a defined lifetime, are reflected internationally. For example, The Construction 21 Report of the Singapore Government encourages increased construction procurement through Design and Build (Ministry of Manpower 1999). In the USA, it is Federal policy to use performance-based acquisition wherever practicable and the *Seven steps to performance-based services acquisition*, provides a web-guide to assist procurement stakeholders apply this policy (DOC 2002). All of these Government policies support the idea that efficiency and value gains can be made through improved procurement, particularly construction procurement. And yet there is very little direct consideration of service life in these performance related procurement routes.

CURRENT PRACTICES IN CLIENT BRIEFING

The Royal Institute of British Architects (RIBA 2000) defines *Appraisal* as the first stage in construction procurement. *Appraisal* is conducted by (or on behalf of) the client and includes *"Identification of client's requirements and of possible constraints on development."* It is at this stage of the procurement process that the service life of the building needs to be considered and information relating to service life identified so that it is available to form boundaries to the design and construction process as procurement progresses. Factors that might be considered during *Appraisal* include (RIBA 2000):

- *"Functional performance*
- *Programme for operational use*
- *Value for money"*
- *Quality, architectural profile, corporate image*
- *Available finance*

Of these factors, functional performance, architectural profile, corporate image, programme for operational use and available finance, all have service life implications. However, to use this information effectively, fundamental questions should be considered, such as, *how long will the facility be expected to last, how will it be looked after, how will it accommodate change?* The need for this critical information was highlighted in BS 7543:1992 (BSI 1992), *"The building owner should specify the required service life of the building in the initial brief"*. However, recent industry consultation demonstrates this is often not the case (Hooper 2001). The *Service Life Checklist for Clients* aims to facilitate the inclusion of service life information in the briefing process. Factors, important to service life, that need to be considered by the client are:

- the purpose of the facility;
- demands placed upon the design (*must-haves*) such as corporate policies, aesthetic considerations, sustainability credentials and so on;
- the need for flexibility;
- the required service life and the effects of service life failure;
- the levels of repair and maintenance;
- project expenditure and whole life costing.

THE PURPOSE OF THE FACILITY

Defining the purpose of the facility assists the design/construction team to focus their efforts on making sure the facility achieves its objectives over its required lifetime. Clients need to consider why the facility is important to them, what it needs to achieve and if it needs to do (or avoid doing) anything particularly special.

Example

- The client wants a new corporate headquarters (HQ) to house 500 office staff who use the latest IT equipment that is regularly upgraded. The building should reflect their high-tech corporate image. This could lead the design/construction team towards a design that not only allows for easy upgrading of IT equipment but also of interior finishes to maintain a modern look. The team may consider specifying finishes that are inexpensive, easy to replace and that are only intended to last a short life span.

MUST-HAVES

The client may have specific desires or be subject to particular obligations. This information is essential to the design/construction team, as it will constrain the design and construction process. These *must-haves* can include an already purchased site, a particular feature and business policies that have design implications. Only by clearly identifying these limits can the design/construction team work within them.

For example, sustainability is becoming an increasingly important facet of construction. From the client's perspective there may be corporate policy obligations to maximise the sustainability of the facility. Such obligations can include energy efficiency, the use of the materials generated from the site clearance in the construction, or a predominance of recycled materials in the facility. It is important that the client considers these aspects and makes any relevant sections of policy documents available to the design/construction team.

Example

- The client of the corporate HQ is a banking / investment house and therefore requires fail safe power supplies and back-up to computer systems, together with expensive security measures and archiving facilities.
- The client has already purchased a site in a major town. This location will influence the design as, in this case, materials and a suitably trained workforce will be readily available for construction and inspection, maintenance, repair and replacement activities.
- As the client is a major consumer of electricity there is a corporate policy to maximise energy efficiency of buildings to minimise the electricity costs. This relevant corporate policy needs to be made available to the design/construction team.

FLEXIBILITY

The risks of obsolescence within the required service life are difficult to foresee, but it is possible for the design to include flexibility. The client is better placed than the design/construction team to foresee future changes. The client needs to consider if there are likely to be any changes in the purpose of the facility over its lifetime or if there are likely to be major changes to the facility contents. Describing the potential changes assists the design/construction team to address the level

of flexibility of the facility, which helps to maximise the likelihood of continued function over the service life.

Example

- As the corporate HQ is for a growing company, allowances should be made for increasing staff numbers during the service life. This could be as simple as orientating the building to allow for further construction on the site. Additionally, consideration is given to the potential need for increased car parking to accommodate additional staff, again through careful consideration of the building orientation on the site.
- Equally, there are likely to be significant changes in the computing servers during the lifetime of the building. Hence, these pieces of equipment should be accessible for replacement without significant disruption to the business value of the building, probably on the ground floor close to a parking area.

THE REQUIRED SERVICE LIFE

In addition to assessing how long the facility needs to last to serve their own purpose, the client needs to consider if they will want to sell the facility on and if they intend to offer a warranty or achieve a premium price for it. All of these factors will affect the service life they require from the facility. Knowing the required service life will help the design/construction team to design, specify and build the parts of the facility that need to last its life-time. It is important for clients to remember that the required service life is related to the overall facility not to individual components and that some maintenance, repair or replacement should be expected.

Example

- The building of the HQ is a substantial investment expected to provide business value to the company for a period of 50 years. In this case, the structural elements and underground structures such as sewerage pipes would be expected to last the required service life. However, the client has determined that the interior of the HQ needs to echo a high-tech corporate image. A suggested mechanism is a design allowing for the regular replacement of internal finishes. Hence the required service life of the building typically exceeds the lifetime of the internal finishes.

THE EFFECTS OF SERVICE LIFE FAILURE

The client needs to consider how the facility might stop being of value. Highlighting factors that would lead to service life failure, and would have significant implications for the client, allows the design/construction team to minimise the risk of these happening during the required service life. Service life failure and the end of service life are often related to uneconomic function of the building (Hooper 2001), when the building is not cost-effective to run, or is too costly, to maintain, repair and operate. This indicates that maintaining function within commercial limits is important to meeting or exceeding the performance required over the service life.

Example

- The failure of internal finishes in the corporate HQ will not affect the business value of the building since routine replacement is anticipated and can be budgeted for. However, failure of the power supply to a central computer server would mean money lost in staff time or customer losses as well as the repair costs. Understanding the critical importance to the

business of maintaining the power supply should lead the design team to make all the necessary arrangements to ensure of the continuity and quality of the electricity supply.

INSPECTION, MAINTENANCE, REPAIR AND REPLACEMENT

Only with very temporary facilities is it likely that no inspection, maintenance, repair or replacement of components will be necessary. The strategies to conduct these operations will depend on many factors such as facility purpose, location and the intended facility management arrangements. Firstly, clients need to make a choice between a proactive or reactive approach. Essentially, do they want to keep the facility running smoothly (proactive) or fix it if it breaks (reactive)? Also, there may be specific requirements concerning the scheduling of repair and replacements. Knowing the approach to be adopted, and details of required scheduling, allows the design/construction team to create a facility that fits the client's needs.

Example

- Since the client intends to maintain a modern interior to the HQ building, the design accommodates this by regular replacement of internal finishes. However, the client also requires that any internal routine maintenance and replacement activities take place during the night or at weekends so that the business is not disrupted. Thus, the interior finishes need to be easy to replace in very short time scales. This leads designers away from specifying painted finishes which take time to apply, dry and cause a lingering odour. Instead the design team suggests covering the walls with a readily demountable patent partitioning system or dry board finish fixed with cups and screws. In this way, the internal wall finishes can be replaced in a phased sequence throughout the offices without disruption, odour or wet paint.

PROJECT EXPENDITURE

An initial budget may have been allocated for the construction in advance of the developed construction brief, but this will often be on a capital cost basis using typical historic square metre costs. Equally, unless specifically requested in the briefing document the design team will not necessarily conduct whole life cost analysis. Whole life costing (WLC) has been identified as a mechanism to deliver improved value for money and predictability of expenditure (CCC 1999).

Clients need to identify if the available budget is for capital costs only and if consideration of operating costs is required. The design/construction team can assess if the client requirements can be met within the initial budget. If WLC analysis is requested they can use the service life information to develop and select the most whole life cost-effective option by balancing the capital and operating costs within the boundaries placed upon the design.

Example

The corporate HQ is to have a prestigious entrance hall. Two options are under consideration are:

a) A stone floor that is hard wearing and would last the life of the building but has an increased risk of accidental damage which is expensive to repair and the potential for increased slip hazards in wet weather. Additionally, the floor is likely to allow dirt to be carried through the entrance hall to the interior offices.
b) A high quality carpet that would be less expensive initially but would require daily cleaning and regular replacement throughout the lifetime of the building, and thus would be associated with higher operational costs.

One optimised solution might be to provide replaceable entrance matting which would minimise the slip hazard on the stone floor but avoid dirt being tracked into the building and thus reduce cleaning costs in other areas beyond the entrance hall. This solution would partially offset the increased capital costs of the stone flooring by reducing operational costs elsewhere in the building.

SUMMARY

Considering the service life of a facility at an early stage of the construction procurement process can lead to:

- improved understanding and definition of expectations of the facility in use;
- increased likelihood of continuity of function over time;
- reduced risk of failure and consequent loss of business value;
- optimal capital and operational expenditure.

The key areas for consideration by the client are:

- The purpose of the facility:
  - Why are you considering a construction project?
  - What do you want the facility to achieve?
  - Why is the facility important to you or your business?
  - Do you want anything special?
- The *must-haves*:
  - Has a site been selected/purchased?
  - Do you want a particular feature?
  - Do you have any business policies that might affect the design or construction?
- The need for flexibility:
  - Can you foresee any changes in the purpose of the facility over its lifetime?
  - Will you want to make major changes to the facility contents during its lifetime?
- The required service life:
  - How long do you want the facility to last?
  - Will you want to sell it on?
  - Will you be offering a warranty?
- The effects of service life failure:
  - How might the facility stop being of value to you or your business?
  - Are you responsible for the facility throughout its service life?
- The levels of repair and maintenance:
  - Do you want to keep the facility running smoothly or fix it if it breaks?
  - Do you have specific requirements of the inspection, maintenance, repair or replacement?
- Project expenditure and whole life costing:
  - Is the budget just for capital costs?
  - Are you considering the whole life cost?

INNOVATIONS IN THE DESIGN OF HOUSING DEVELOPMENTS IN HONG KONG

Horsfield J.N.[1], Gibbons C.[1], Yau R.M.H.[1], Ip T.F.C.[2]

[1]Ove Arup and Partners (HK) Ltd, Hong Kong

[2]Tom Ip and Partners, Hong Kong

ABSTRACT

This paper presents recent developments in the design of high rise residential accommodation in Hong Kong. The role of government, and the business community is reviewed to explore how innovative design is being encouraged within the sector. There then follows a case study of the design of a Home Ownership Scheme public housing development, which incorporates innovative features aimed at addressing many of the problems associated with high density living in an urban environment. The case study demonstrates the strong emphasis that has been placed by Hong Kong people on providing affordable, environmentally responsible, and socially sustainable housing and how this can be realised through an innovative and integrated approach to architectural and engineering planning and design.

KEY WORDS

Community, Efficiency, Energy, Environmentally responsible, Innovation, Life-cycle cost, Multidisciplinary, Optimisation, Natural ventilation, Prefabrication, Stakeholder participation, Value

INTRODUCTION

Buildings are among the largest consumers of natural resources, generators of waste and consumers of energy. In 2000 Hong Kong's construction industry consumed more than HK$50 billion worth of materials, energy and water and was responsible for approximately 40% of all municipal waste flows (EPD, 2002). Completed buildings place an even greater demand on the environment. Lighting, ventilating and cooling Hong Kong's residential and commercial buildings consumes around 50% of all electricity produced for the territory (EMSD, 2001). Economic efficiency and environmental protection, if not yet synonymous, are certainly being seen as strongly linked as the quest for sustainable development gathers momentum. The building industry has a significant contribution to make as it begins to reflect on its current practices and seeks to implement processes of change that lead to more sustainable patterns of production and consumption. The term ecological modernisation has been used to describe the process by which markets re-orientate to capitalise on trends in more environmentally responsible behaviour (Mol, 1997). An essential feature of this trend is for governments to provide impetus through appropriate market intervention. It is then the purview of industry to seek out innovative ways of creating and capturing market share in the ensuing

environmentally responsible approaches to economic growth. Environmental and economic interests are therefore not necessarily mutually exclusive and benefits are best achieved through a multi-disciplinary approach to the development process. A strong emphasis must be placed on stakeholder participation throughout the process of design, construction and operation of buildings.

The Hong Kong construction industry is beginning to recognise these opportunities and a number of initiatives have been instigated by the government to promote more environmentally responsible behaviour. These initiatives are being supported by the local business community and are establishing a niche, which has the potential to change the way construction professionals approach their work.

THE ROLE OF GOVERNMENT, BUSINESS AND THE COMMUNITY

In his policy address of 1999 the Chief Executive of Hong Kong made a commitment to improve working practices in the construction industry and established the construction industry review committee. In March 2001 the committee issued its report Construct for Excellence which identifies key areas in the construction industry which need to be addressed by industry professionals and government in order to improve quality, safety, foster innovation and reduce environmental degradation.

In March 2001 and March 2002 the government, through the Planning Department, Buildings Department and the Land's Department, issued Joint Practice Notes No.1 and No.2 respectively. The practice notes aim to encourage construction professionals to adopt principles of design that lead to more liveable space in residential developments. Balconies for apartments, larger lifts and lift lobby areas, the introduction of sky gardens, natural ventilation of apartments and the use of prefabricated construction elements are all featured in the practice notes. The practice notes offer various incentives in the form of gross floor area (GFA) concessions to encourage developers to incorporate the features.

Non-government organisations (NGOs) also have a role to play. Traditionally, NGOs have taken a critical stance from outside of industry. More recently, however, NGOs are becoming involved with industry. In Hong Kong the non-profit making NGO BEC (Business Environment Council) administers the HK-BEAM (Hong Kong Building Environmental Assessment Method) scheme. This voluntary scheme rewards environmentally responsible design, construction and operation of buildings. Covering global, local and indoor issues the scheme awards credits based on exceeding legislative requirements for buildings. Depending on the number of credits achieved a building can gain a rating of fair, good, very good or excellent. While the scheme is currently voluntary, it is gathering momentum and many developers now require their buildings to be assessed. This clearly demonstrates that the construction industry is beginning to place value on environmentally responsible behaviour.

CASE STUDY - PUBLIC HOUSING DEVELOPMENT, HONG KONG

Introduction

This section presents a case study of a residential development in Hong Kong, which is planned to incorporate many of the initiatives discussed. The innovative use of architecture in the context of Hong Kong housing has led to a hierarchy of space aimed at creating a more liveable environment for the residents of the development. This has been further enhanced through the incorporation of the government GFA incentives. Innovative engineering has been incorporated into the design process in order to improve resource use efficiency, reduce waste generation and improve energy use efficiency. The entire design process has been conducted in an open manner, drawing on the expertise of the many different stakeholders and professional disciplines required to bring a project of this nature to fruition.

In Autumn 2000 the Hong Kong Housing Authority invited entries for a two stage architectural competition. The aim of the competition was to promote an environmentally responsible approach to the production of subsidised housing in Hong Kong. The Shui Chuen O Home Ownership Scheme development was chosen for the competition. Hong Kong based architect Tom Ip and Partners won the competition and design commenced in March 2001. The Shui Chuen O development will provide 2500 units in 7 domestic tower blocks with associated car parking, landscaping and non-domestic facilities. In keeping with the environmentally responsible theme of the competition the winning scheme incorporates many innovative architectural and engineering features, which continue the drive toward sustainable development.

Architecture

The architecture of the Shui Chuen O residential project develops a hierarchy of space, which seeks to create a living environment where residents can feel a sense of community. The layout of the spaces focuses around three main plazas that are ecologically themed with a high degree of variety in the landscaping and provides barrier free community space for all residents to enjoy. The main public entrance plaza (Sun Plaza) leads to the two semi-public plazas (Forest and Water) and onto covered bridges linking to the domestic entrance lobbies of each individual tower block. The edges of the plazas clearly define the pedestrian system and covered walkways running around the perimeter and interconnect to the semi-private spaces that offer a diversity of outdoor amenities while encouraging communication and leisure activities.

Figure 1 Proposed Home Ownership Scheme public housing development at Shui Chuen 0, Shatin.

The scheme incorporates sky gardens, balconies, urban-windows and integrates innovative architecture and engineering in an holistic manner which epitomises many of the principles of sustainable development.

The seven domestic blocks are arranged in an intelligent tri-modular form, which maximizes the view potential of the development and follows the natural topography of the site. A "Green Core" is positioned at the centre of each block, while the centre of each of the three wings contains a "Social Hub" linking the four apartments in each wing. Accessed directly from the lift lobby through a straight but short corridor, the hub spaces provide a departure from the conventional corridor approach to unit entrances with direct visual contact with the lift lobby. The green core contains the lifts and main service arteries for each block and is arranged such that every third level is a full floor with two levels of mezzanine above before another full floor is reached. These lofty, environmentally conscious and naturalistic spaces are enhanced by natural ventilation, day light and greenery and create a sense of neighbourhood within the blocks, which would otherwise become simply an access to a dwelling.

The development takes full advantage of the plot ratio and GFA incentives recently promoted by the Hong Kong Government. Additional social space, aimed at enhancing the neighbourhood concept, is provided in the form of the "Urban Window", the "Green Sky Walk" and "Sky Garden". The sky walks and gardens are located at the 18th Floor and on the roof of each block and are accessible to all residents of the tower blocks. The urban windows add interest to the architectural elevation and break up the visual impact of the development, providing visual cues to the mountain landscape beyond. Every apartment has a private balcony leading from the main living area. The balconies not only provide a high quality indoor environment but they also play a crucial role in improving the acoustic properties of the development, in particular attenuation of traffic noise from adjacent roads.

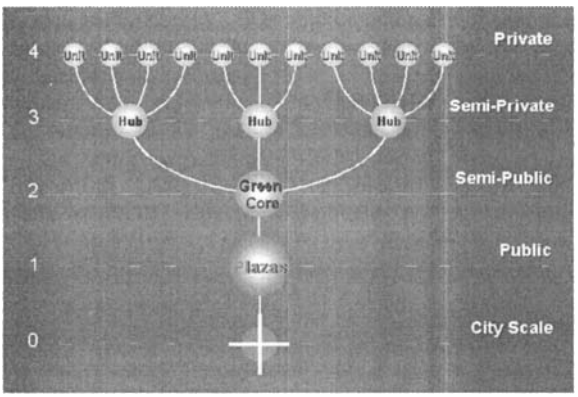

Figure 2 Spatial planning of the Shui Chuen O. Public Housing Project.

The diagram illustrates how the spatial planning hierarchy is conceptualised. Residents travel from the City Scale, urban space though the Public spaces and ultimately into the Private spaces.

Engineering

The engineering design for the Shui Chuen O development has proceeded in parallel with the architectural design. This approach has, as far as possible, allowed the engineering to "inform" the architecture, a process that has proceeded on two fronts. First a series of site specific engineering studies have been undertaken which have influenced the architectural planning. These studies have assisted in realising a design that has the potential to work in harmony with, rather than create a barrier against, the environment. Included are: natural ventilation and natural lighting studies which focus on reducing energy consumption; a traffic and acoustic study aimed at assisting with the architectural planning and arrangement of the domestic blocks; and an environmental wind study to assist in the development of a landscaping scheme that optimises human comfort in the common external areas. Second, engineering systems have been developed, which have the potential to increase efficiencies in resource use, energy use and waste handling. These include: an efficient structural system developed using innovative wind engineering and advanced structural optimisation techniques; the use of architectural precast concrete to capitalise on the dual function of material as structure and architectural finish; a photovoltaic system for the on-site generation of electrical power; a grey water recycling system for cleansing and irrigating common areas; and an automated refuse system to facilitate more efficient and hygienic refuse collection.

Engineering Studies

Natural Ventilation Study

In order to reduce the energy consumption of the development's mechanical ventilation systems, extensive use of natural ventilation has been promoted for the apartment units. Computational fluid dynamic analysis techniques were used to evaluate the innovative architectural design and recommendations made for areas where adjustments could be made to improve the natural ventilation characteristics of the development. Architectural features incorporated to improve the natural

ventilation of the common areas include the ventilated hubs, sky-walks and urban windows. The inclusion of wind wing walls and strategic positioning of operable windows will encourage natural ventilation within apartment units.

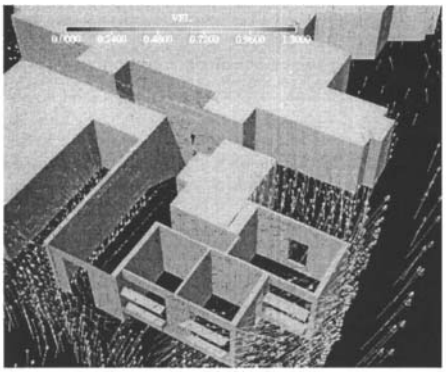

Figure 3. Natural Ventilation CFD Analysis

Natural ventilation is one of the most effective methods for reducing building energy consumption and the build up of indoor air pollutants. Computational Fluid Dynamics modelling has been used to analyse the effectiveness of natural ventilation within the development. By evaluating the specific architectural design and the meteorological condition, environmental benefits of the naturally ventilated indoor environment can be realised.

Natural Light Study

A computer modelling technique was employed to simulate the natural light penetration/reflection into each apartment unit. This process was able to inform the architecture in terms of window location and development of the detail of the facade to achieve optimum natural light performance in the context of other architectural constraints. Through these studies, it was possible to demonstrate compliance with the highest requirements of the sustainability tool HK Beam.

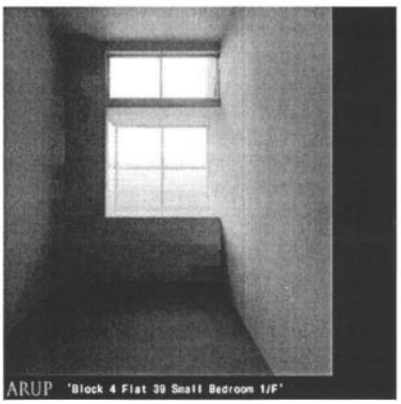

Figure 4. Radiance daylight simulation

Daylight is an energy efficient means of enabling appropriate room function. The requirements of HK-BEAM are set as the target for performance and by undertaking a daylight simulation daylight penetration within the rooms has been assessed. The daylight simulation is also used to access visual comfort and lumen distribution assisting in window and artificial lighting design.

Traffic Noise Study

The need for noise barriers around the development has been eliminated. This has been made possible through the close coordination of the environmental engineering, traffic engineering and architectural disciplines. By studying traffic flow data within the vicinity of the development it has been possible to determine those noise sensitive receivers that would be adversely affected by traffic noise. The arrangement of the affected apartments has been reviewed and adjustments made to the planning to reduce noise impact. Through the incorporation of balconies and bay windows into the noise impact assessment analysis it has been demonstrated that no apartment will experience noise levels in excess of 70dB(A).

Environmental Wind Comfort Study

The success of the outdoor areas of any residential development is in part dependent on the level of comfort associated with the wind environment. An environmental wind climate investigation demonstrated that pedestrian safety is maintained throughout the development. In addition to the safety criteria it has been possible to demonstrate that wind comfort levels appropriate to the activities to which the various areas are intended can be met. In those areas where wind comfort levels are not satisfactory, the environmental wind tunnel testing has furnished data allowing the location, form and function of the architecture and landscaping to be adjusted such that appropriate comfort levels can be achieved.

Engineering Systems

Structural Optimisation

Structural optimisation is an essential process in the design of building structures. The concept is not new, as structural engineers have traditionally sought to make the most efficient use of structural materials. The Shui Chuen O project has made use of advances in engineering technology to realise significant benefits in the efficiency of resource use. The use of computer aided structural optimisation and advanced wind engineering techniques have been instrumental in the realisation of these benefits.

The effects of local wind climate were established by testing a small-scale model of the surrounding topography in a wind tunnel. The data from this topographical test were then matched with a larger scale model of the buildings which was subsequently tested using an innovative multiple force balance technique to determine the wind loads to be used in the structural design. The wind loads predicted from the wind engineering study were found to be less than those predicted from a prescriptive code approach.

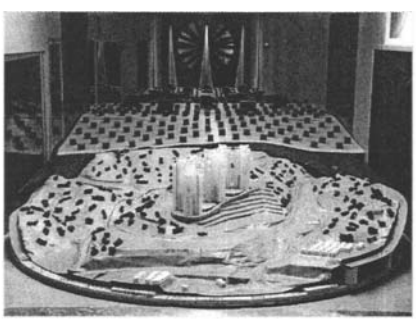

Figure 5. 1:400 scale model in wind tunnel.

The most common method of predicting structural wind loads is the high frequency force balance technique (HFFB). The testing of the Shui Chuen O model involved the simultaneous use of multiple HFFBs to measure loads and load distributions on the linked towers.

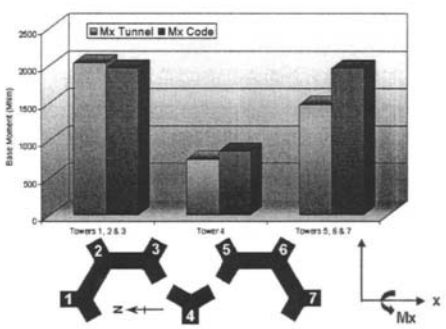

Figure 6. Comparison of wind tunnel test and code results.

The towers of the Shui Chuen O development are architecturally similar. However, due to topography and shielding they each experience different wind loads. Although there were some local increases in wind load compared with the code significant overall savings were achieved.

The loading derived from the wind tunnel testing was used to develop the structural design. Using computer aided structural optimisation technology the contribution of each element of the building to the overall stiffness of the structure is identified. Advanced algorithms determine the amount of structural material that can be redistributed such that the more efficient elements are increased in size while the less efficient elements are reduced. This optimisation process is controlled by a set of input parameters, which in the case of the Shui Chuen O project was based on structural material cost and value of useable floor space.

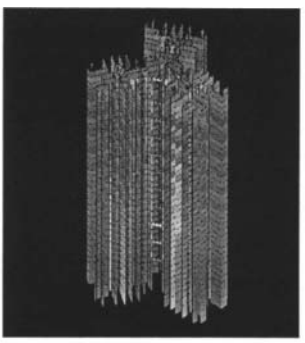

Figure 7. Identification of efficient elements

The relative cost efficiency of one of the towers of the Shui Chuen O development is illustrated graphically with the "hotter", lighter colours representing elements of higher efficiency and the "cooler", darker colours representing the less efficient elements.

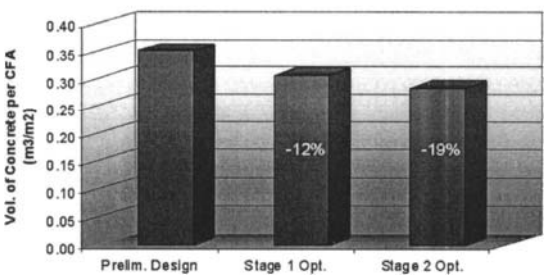

Figure 8. Savings in concrete volume through the optimisation process.

The process involves an initial preliminary optimisation based on code determined wind loads followed by a second optimisation using the wind loads generated by the wind tunnel testing. Significant savings in concrete volume have been realised.

The structural optimisation process has improved the cost efficiency of the structure while maintaining the overall structural performance (Horsfield etal, 2002). The potential value and environmental significance of these design processes is well illustrated through examination of the Hong Kong residential sector. In 1999 some 86,500 residential units were completed in Hong Kong (Hong Kong Housing Authority, 2001), with the primary construction material being reinforced concrete. If a 10% reduction in the use of these materials could be achieved, this would equate to the structural component of 25 no. 35 storey towers. The total volume of structural material in these towers would be approximately 700,000 tonnes. If one considers that construction today is a waste disposal problem of the future then initiatives that reduce construction material stored in current building stock should be encouraged.

Precast Facades

The Shui Chuen O project will adopt architectural precast facades. These façade units are prefabricated under factory conditions and delivered to site ready for immediate installation into the permanent works. The façade finish is achieved through the use of pigmented concrete and the application of specific surface treatments, which include acid etching a colourless surface sealant. This solution is particularly efficient in terms of material use as the structural substrate of the façade

performs the dual functions of structure and aesthetics. More significantly the need for finishing tiles is eliminated.

The elimination of traditional tiled finishes offers significant benefits in terms of future maintenance. A typical future maintenance regime for a building utilising tiled facades would include the need for local replacement of tiles that become de-bonded. There are also issues of safety as de-bonded tiles fall from building facades. Therefore, in addition to material use efficiency, and the potential to reduce capital costs, a life cycle cost approach yields additional benefits through the potential for reduced maintenance costs during operation.

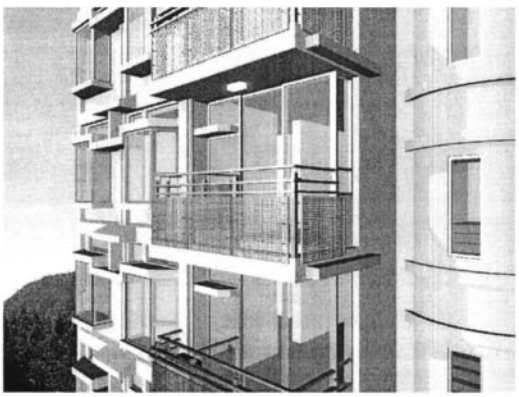

Figure 9. Precast façade.

Economic and environmental benefits derived through the efficient use of construction material

The structural concrete performs a dual role in providing strength and stiffness of the panel and the architectural finish.

A life cycle cost approach yields added benefits in terms of future maintenance effort.

Photovoltaic System

The most abundant form of energy on Earth is Solar energy from the Sun. While this source of energy is freely available it has also been traditionally difficult to collect in sufficient quantity to be of any commercial use. However, improvements in solar collector technology are beginning to have an impact on the power generation sector and commercially viable formats are now available. The Shui Chuen O development will to incorporate a system of photovoltaic (PV) cells to generate a portion of the electricity required for communal lighting within the green core areas. The PV cells are made almost entirely of silicon, which is one of the most abundant elements on Earth. The PV cells convert short-wave radiation from the sun into electricity in a thin layer of semiconductor material. By linking many PV cells together sufficient energy can be "harvested" to generate useful power.

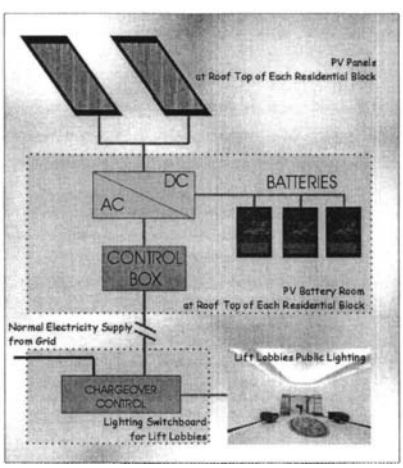

Figure 10. Schematic of the proposed photovoltaic system

Photovoltaic (PV) panels mounted at the roof level allowing greatest exposure to sunlight. Energy generated during the day is used to charge storage batteries for night-time discharge to power feature lighting within the Green Core.

The Shui Chuen O project will accommodate arrays of PV cells on the roof of each domestic block. The power generated from these arrays will run the communal, feature lighting within the green core of the lower 8 stories of each block.

The environmental benefits associated with implementation of the PV system are primarily associated with reduced emissions of so-called "green house" gases associated with more traditional methods of power generation. Such gases may contribute to global warming and climate change. Added benefits arise from the promotion of renewable energy systems, which foster further advancement of the associated technology and improvements in the economic viability of such systems.

Grey Water Recycling System

Estimates of the amount of fresh water available on Earth for human consumption range from 3 to 10 times current consumption levels (Tietenberg, 2002). These estimates combined with a world with expanding population and an uneven distribution of available water highlights the need to treat freshwater as a scarce resource and conserve its use where possible.

In order to reduce fresh water consumption the Shui Chuen O development will utilise a grey water recycling system. This system will collect and recycle grey water from baths, showers and wash basins from domestic bathrooms and utilise it for cleansing and irrigation purposes. It has been calculated that the grey water collected from all of the bathrooms of one block of the development will provide sufficient water to meet the entire development irrigation requirements for podium landscaping and all of the cleansing demand for the non-domestic areas at and below podium.

Water quality is a principle concern in the development of a water recycling facility. In Hong Kong there are currently no Government standards or codes of practice regulating the recycling of waste water from buildings. Water recycling regulations have, however, been developed in China and in some states in the USA. Regulations are based on the expected degree of human contact with and the intended use of the recycled water. The water quality levels adopted for the Shui Chuen O development exceed those recommended in the Chinese Standard GJ 25.1-89 (National Standard of the People's Republic of China, 1989).

Automated Refuse Collection System

The hygienic disposal of municipal waste is a common problem in modern living. This problem is magnified in the case of a high density, city development such as Shui Chuen O. To minimise the problem of odour and to create a controlled, low maintenance environment for the disposal of municipal waste an Automated Refuse Collection System will be implemented in the development. The system comprises a single refuse chute in each block with inlet doors on each floor. An underground network of pipes connects each building to a central collection station where refuse is compacted and stored in sealed containers. Residents dispose of refuse at a chute at each level of the residential block from where it is transferred to the central processing station via the underground pipe network controlled by a vacuum system. Therefore, once placed in the chute refuse is contained in a sealed environment for removal from site.

CONCLUSIONS

This paper has set out to illustrate some of the innovations that are being implemented in Public Housing developments in Hong Kong. Emphasis is also placed on the importance of adopting a multidisciplinary approach toward this kind of development. This is by no means a new idea, indeed project collaboration has been around for as long as projects. However, this paper has examined the role that government can play in encouraging and empowering the private sector to make more

environmentally responsible decisions in the development process. The paper has also examined how non-government organisations can exert pressure on industry to effect changes that contribute to this process. Finally this paper has presented a case study which illustrates the response of the construction industry to these pressures. The result is clearly a move in the direction of a more innovative and ultimately more sustainable construction industry.

ACKNOWLEDGEMENTS

The authors wish to give special thanks to Hong Kong Housing Authority and Tom Ip and Partners Architects for supporting the use of the innovative engineering technologies on the Shui Chuen O project. Also thanks to Man-Wah Chui of Ove Arup and Partners Hong Kong Ltd knowledge centre for assisting with data research and thanks to CM Chan of Hong Kong University of Science and Technology and Roy Denoon of Ove Arup and Partners Hong Ltd for their technical contribution.

Life-Cycle Analysis and Environmental Impact Assessment of Heating and Air-Conditioning Systems

M. Prek

University of Ljubljana, Faculty of Mechanical Engineering,
Askerceva 6, SI-1000 Ljubljana, Slovenia

ABSTRACT

During the design process of heating and air conditioning systems, the designer must analyse various factors in order to determine the best design options. Therefore, the environmental aspects of a product should be included in the analysis and selection of design options if an environmentally - aware design is to be produced. If one wishes to assess a product's environmental impact, its whole life cycle must be studied. The Life Cycle Assessment (or LCA) methodology is an example of one kind of environmental analysis which included the entire life-cycle of a product. However, this method has some limitations. It is unable to tackle the total environmental impact on a number of different levels (e.g. materials, energy, waste) at the same time. To overcome some problems in the LCA method, an alternative method, the so-called Eco-Indicator method has been proposed. Since it is based on a weighting method, only a single score for the total environmental impact is calculated. The application of this method for the optimisation of heating and air-conditioning systems is presented in this paper.

KEYWORDS

Environmental management, Environmental impact, Weighting method, Heating, Heating system, Air-conditioning, LCA method

INTRODUCTION

Life Cycle Assessment (LCA) is defined by ISO 14 series standards, e.g. ISO 14040 (1997), ISO 14041 (1998). They do not, however, give all the necessary information required for carrying out an LCA. The main phases of LCA are goal and scope definition, inventory, impact assessment and interpretation. The various applications of LCA are not regulated by the standard. The implementation of environmental assessment tools is complicated at all levels. It must, nevertheless, be an essential part of all the process, since every product impacts on the environment to some extent. Raw materials have to be extracted, the product has to be manufactured, distributed and packaged and ultimately it

must be disposed of. If we wish to assess a product's environmental impact, all its life cycle phases must therefore be studied; a life cycle assessment can be used in two ways:

1. To determine the total environmental impact of products or design alternatives with the aim of comparing them. For a designer an LCA can provide a solution if he has to choose between design alternatives or between different components or materials
2. To determine the most important causes of one product's environmental impact and a designer can then concentrate on these to achieve improvements here first.

A designer using a LCA in the design process has been faced by two major problems. The result of LCA is difficult to interpret. Within a life cycle assessment it is possible to determine the contribution of a product life cycle to the greenhouse effect, acidification and other environmental problems, while the total environmental impact remains unknown. The reason is the lack of mutual weighting of the environmental effects. In general, the careful collection of all the environmental data in a product's life cycle is complex and time-consuming. As a result extensive LCA usually cannot be carried out during a design process. Life Cycle Cost (LCC) calculations are an application of investment calculations which have been used in planning and design of products. These calculations are used as a routine for equipment comparison. It enables the purchase price and an estimate of the present value of the life cycle operating costs. In LCA calculations the present value of total costs (investment and operation) is calculated. In this case, the equation is as follows from ISO/DIS 14042 (1998):

$$\text{LCC(total)} = \text{Investment} + \text{Energy cost} + \text{Maintenance cost} + \text{Disposal cost} \tag{1}$$

LCC calculations are based on an equation of present values. Depending on the case, the calculations can be sensitive to the interest rate and the time of the calculation period (utilisation time or the life cycle of the device). In order to be able to optimise environmental performance, we need to weight different impacts to a common number. In LCA terminology, this is called weighting. In order to make weighting possible, we need to express environmental impacts via indicators that can be compared to some reference or valued. These indicators are called impact category indicators and may be chosen early or late in a cause-effect chain, but existing weighting methods today either use emissions or transformed emissions and compare with emission goals or use monetary valuation of damages. The Eco-indicator method, introduced by Goedekoop (1993) has resolved these problems as follows. The LCA method has been expanded to include a weighting method. This has enabled one single score to be calculated for the total environmental impact based on the calculated effects, as is shown by Goedekoop et al. (1993). During the development of the weighting method for the Eco-indicator much attention was given to defining the environmental impact. Into the account are taken the following environmental effects, as shown in Figure 1. The problem lies in determining the weighting factors. In this method, the so-called Distance-to-Target principle was chosen. This principle has been in use for some years in the Swiss Ecopoints weighting system Kortman et al. (1994). The procedure for determining the indicator value I can be expressed by the following equation:

$$I = \sum_i W_i \cdot \frac{E_i}{T_i} \tag{2}$$

where is W_i subjective weighting factor which expresses the seriousness of effect i, E_i is the contribution of the product life cycle to an effect i_i and T_i target value for effect i. In more general terms, the effect of a number of impacts can be written as:

$$I = D_k \cdot \sum_i \frac{E_i}{T_i} \tag{3}$$

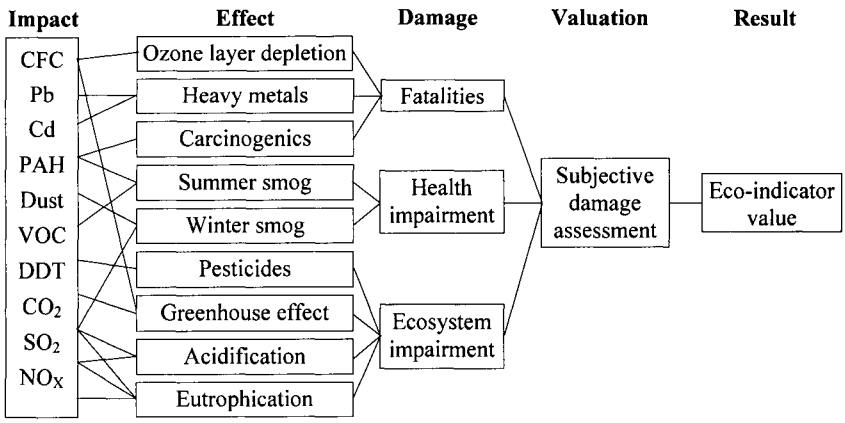

Figure 1: Eco-indicator weighting principle

In order to assess the overall impacts of trade-offs, the relative importance of various environmental problems must be determined. Following are criteria recommended to develop a weighted set of environmental problems, given in Table 1.

TABLE 1
WEIGHTING FACTORS FOR ENVIRONMENTAL EFFECTS

Environmental effect	Weighting factor	Criteria
Greenhouse effect	2,5	0,1 °C rise every 10 years, 5% ecosystem degradation
Ozone layer depletion	100	Probability of 1 fatality per year per million inhabitants
Acidification	10	5% ecosystem degradation
Eutrophication	5	Rivers and lakes, degradation of an unknown number of aquatic ecosystems (5% degradation)
Summer smog	2,5	Occurrence of smog periods, health complaints, particularly among asthma patients and the elderly, prevention of agricultural damage
Winter smog	5	Occurrence of smog periods, health complaints, particularly among asthma patients and elderly
Pesticides	25	5% ecosystem degradation
Airborne heavy metals	5	Lead content in children's blood, reduced life expectancy and learning performance in an unknown number of people
Waterborne heavy metals	5	Cadmium content in rivers, ultimately also impacts on people
Carcinogenic substances	10	Probability of 1 fatality per year per million people

The target level still embodies a major problem - what is a good target level and how can such a level be defined? To ensure that the target level is equivalent for different effects, a correlation must be established with the damage caused by the effect. The premise is that the target level for each effect yields uniformly serious damage. The following damage levels are assumed to be equivalent as defined by Goedekoop et al. (1993):

- the number of fatalities as a consequence of environmental effects (as acceptable, the chosen level is 1 fatality per million inhabitants per year)
- the number of people who become ill as a consequence of environmental effects. This refers in particular in winter and summer smog. (the acceptable level is that smog periods should hardly ever occur again).
- ecosystem degradation (a target level has been chosen at which only 5% ecosystem degradation will still occur over several decades).

To establish a correlation between damage levels and the effects, a detailed study was carried out of the actual state of the environmental in Europe. These data, given by Kortman et al. (1994) were used to determine the current level of an environmental problem and by what factor the problem must be reduced to reach an acceptable level. Table 1 lists the weighting factors and criteria applied. This table reveals that high priority must be given to limiting substances causing ozone layer damage and the use of pesticides. Furthermore, a great deal of consideration must be given to the diffusion of acidifying and carcinogenic substances.

There can be little doubt that buildings are important contributors to environmental deterioration. Buildings contribute 15% to 45% of the total environmental burden for each of the eight major LCA inventory categories. In any design, trade-offs must be made among solutions aimed to optimise building performance for various objectives. Environmental objectives are diverse, complex, interconnected, and frequently conflicted. Decision-making tools such as multiple attribute decision analysis can assist designers and their clients resolve conflicting project goals that normally are part of any project. Systematic analysis based on empirical data has provided the tools necessary for designers and other decision-makers to evaluate the trade-offs they must make between environmentally-friendly building features.

CASE STUDY

The purpose of the calculation is to establish priorities, or in other words - where can the designer best to achieve the greatest possible environmental profit? In the first instance it is possible to make fairly rough calculations and simplifications are permissible. In a life cycle perspective there is an optimum, where the incremental increase of impact from environmental performance and from equipment construction demands equals the incremental decrease of impacts from increasing efficiency – see Figure 2.

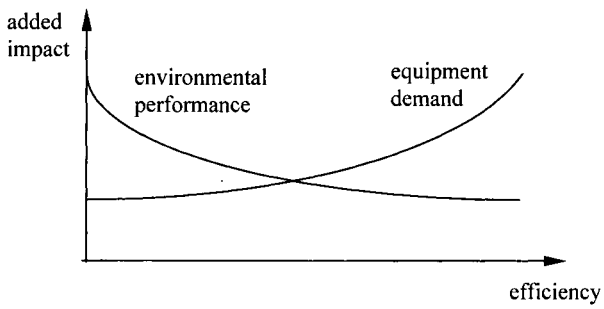

Figure 2: Optimisation of environmental performance of heating and air conditioning systems

Figure 3 shows ground plan of one building floor for heating or air conditioning system. In continuation of article it is shown the comparison between three different heating systems. For all these three different heating systems we took the same building floor for case study. Hence this the required heating/cooling power (11,8 kW) is the same for all heating systems.

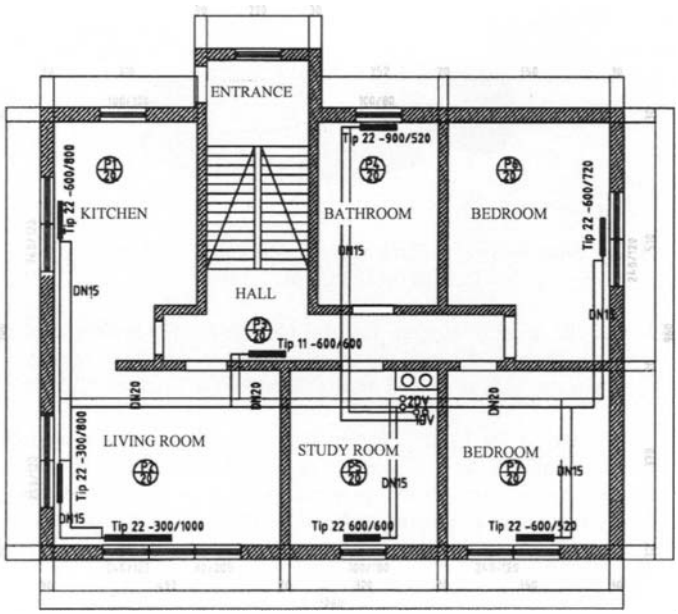

Figure 3: Simplified ground plan of one building floor for heating or air conditioning system

A simplified life cycle of heating or/and air-conditioning systems is given in Figure 4. Such a process tree provides a useful insight in further analysis.

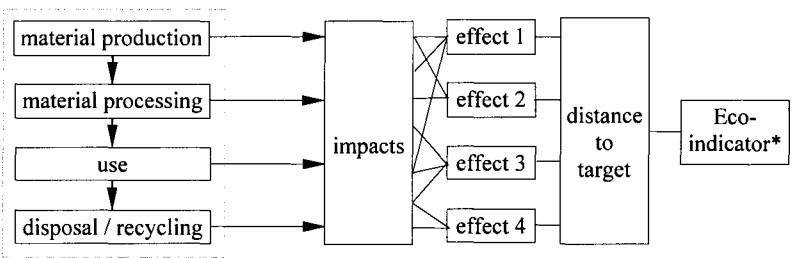

Figure 4: Example of simplified life cycle for heating and air conditioning system. The use phase determines the overall functional unit of a product. *The result is given in milli Eco-indicator point (mPt)

Radiator heating

In the case of radiator heating system, two different systems are analysed. The main difference was the chosen material for piping system (steel/copper) and for radiators – heating panels (steel/aluminium).

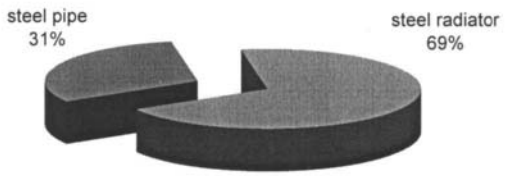

Figure 5: Eco-indicator value for steel radiator heating; pipe length 78,4 m, material for radiator 0,927 Pt, pipe 0,412 Pt, total 1,339 Pt

In Figure 5 is presented the result of analysis for steel radiator heating system with steel pipes, made by Eco-indicator method. The results reveal the great importance of radiator (greater mass of radiator than pipes) which presents the 70 % of overall impact. Total Eco-indicator is 1,339 Pt.

The results of similar analysis for heating system with aluminium radiators and copper pipes (as alternative) are shown in Figure 6. As it is seen in Figure 6, the copper pipes for aluminium radiator heating are dominant among the materials for environmental impact. Copper pipes represents 56 % of overall impact for the given example, despite smaller dimensions. Total Eco-indicator is 4,0 Pt, and is much more as for the steel system.

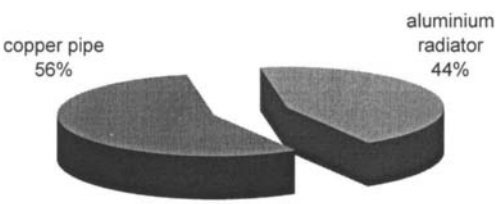

Figure 6: Eco-indicator value for aluminium radiator heating; pipe length 78,4 m, material for radiator 1,774 Pt, pipe 2,234 Pt, total 4,0 Pt

Floor heating

Eco-indicator value for polyethylene pipes, dimension 14×2, is 0,089 Pt and for polybutene pipes, dimension 16×2,2, is 0,111 Pt. Pipe length was 291 m and was the same for both systems. Difference was only in pipe material, while all other parameter were the same. While the heating demand is the same regardless the heating system, analysis results are comparable to other systems, since they are expressed in the form of Eco-indicator points. Smaller (better) eco-value for floor heating system is also the consequence of the fact that the extra building construction was not considered.

Fan coil convector

For the analysis, the exposed floor fan coil convector unit was chosen with average parts (valves, fittings etc). The base unit is made of 1,0 mm thick galvanized steel plate. Cold panels are insulated. The fan section is composed of a cross-flow tangential fan and special air discharge sections that ensures a uniform distribution of the airflow. The three-speed motor is mounted on flexible supports. Cabinet is made in five separate pieces, a front panel in 1 mm thick galvanized steel and painted with a durable baked polyester powder coating. Pipe coil is a copper tube and lanced aluminium fin construction. The convectors were chosen in accordance with heating power. The convectors are substitute for radiators, as is shown in Figure 3. For piping system, one could assume the same conditions as for the radiator heating system. Since the fan coil unit consists from various parts, we could determine the Eco-value for different part. In Figure 7 is shown the Eco-indicator value for different materials and in Figure 8 for different parts. From these figures the influence of different materials in different parts of unit is obvious.

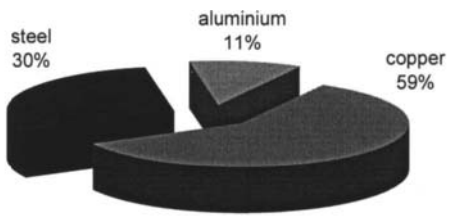

Figure 7: Eco-indicator value for fan coils (convector heating / cooling), by materials, total 3,126 Pt

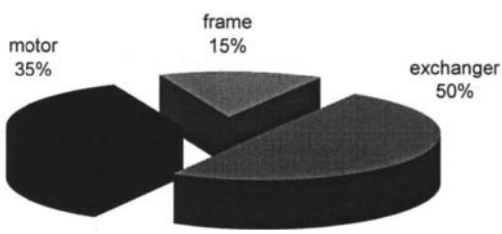

Figure 8: Eco-indicator value for fan coils (convector heating / cooling), by elements

In Figure 8 is presented the result of analysis for fan coil units. Heat exchanger is made of aluminium plates and copper pipes, which contributes the greater Eco-indicator (50 % of the whole unit). Total Eco-indicator is 3,126 Pt.

CONCLUSIONS

The Eco-indicator method has been used for the analysis and optimisation of heating and air conditioning systems. This method enables environmentally-aware design and is open working method with a platform on which both industry and science can integrate the environmental aspects into the design process. These design alternatives can be calculated in the same way with this method. The result permits the user or the designer to see how much environmental impact of these design alternatives will have. The designer can analyse the consequences of an idea quickly and effectively and establish clear selection criteria for an idea.

Prerequisites for a fair comparison of environmental characteristics of different heating and air conditioning systems are that the systems compared are equal and fulfil the functional requirements, the limits of the systems are drawn up by the same principles, technical characteristics and material data of the systems and equipment are reliable, environmental profiles of energies and materials used in the comparison are comparable. The weighting factors, used by the analysis, expresses the relation between an impact and the amount of damage either to human health or ecosystem quality. In used methodology they based on a combination of distance to target and damage function approach. Environmental impacts from production processes of products and materials are taken into account.

This research showed that three different concepts of heating systems with different construction materials varies the Eco-indicator value. We can see that for radiator heating system the Eco-indicator value is far superlative than for floor or fan coil convector heating system. Copper pipes and other copper parts contributes to the greatest environmental impact. Radiator heating Eco-indicator (1,339 Pt – steel pipes and 4,0 Pt – copper pipes) showed three times higher value for copper pipes than for the steel pipes despite smaller dimensions. The lowest values are obtained for floor heating systems, but no extra building construction was considered. Reasonable values are obtained for fan coil units (convector heating/cooling) with Eco-indicator value 3,126 Pt. Analysis show up, that heat exchanger (copper pipes) contributes the main part of the value. Nevertheless, the environmental aspect is only one of the evaluation criteria in addition to cost, aspects of use and standards.

ABSTRACT

This paper attempts to place proper emphasis on the role of urban courtyards in passive cooling. The article is a part of a larger study in preparation on the sustainability design of urban streets and courtyards on passive cooling in the urban canopy layer (UCL). The passive design control elements studied are the courtyard's geometry and the density of shade trees. The study presents the case of attached canyon-type courtyards in residential buildings, using summer data in the Tel-Aviv metropolitan area near the Mediterranean sea coast, characterized by hot and humid climate during the summer season. Measurements of air temperature were taken hourly at 9:00, 15:00,and 18:00 h in two courtyards, situated in the same locality in Tel-Aviv. Both courtyards consist of a 20 – 25 meter open space enclosed between two stretches of buildings of about 12 m high. Simulations were conducted for each courtyard, with and without trees, using an analytical model, the "Green CTTC model", developed recently by the authors. The simulations provide quantitative evaluation of a courtyard's diurnal air temperature pattern over the course of 24 hours. The effects of changes in the courtyard's geometry and the density of shade trees were studied by simulations. The simulated values were compared with measurements in situ. The combined cooling effect of the two studied courtyards due to trees and deepening is found to reach 4.5 K at noon out of 9 K rise of air temperature from sunrise to noon in August. The illustrations of the simulations carried out on the two studied courtyards further the importance of sustainability consideration in courtyard designs, and thus show the potentially in AC energy saving. The Green CTTC model applied to urban courtyards provides a practical tool for this purpose.

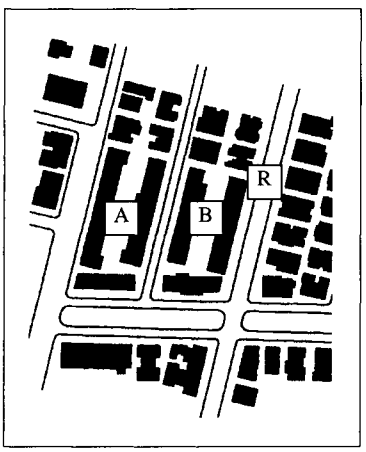
1. INTRODUCTION

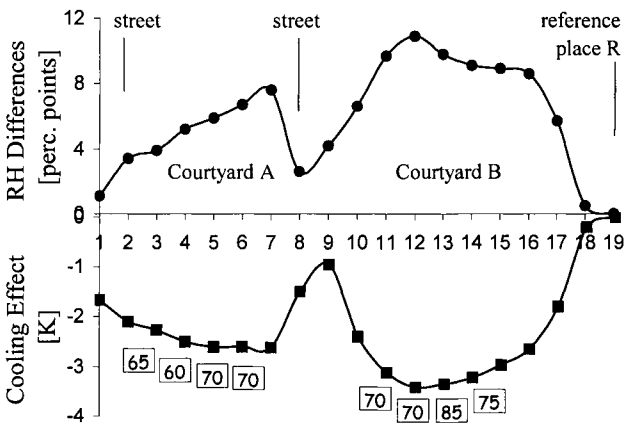
Open spaces usually cover more than two thirds of the urban area in modern architecture, hence their microclimate dominantely affects the urban canopy layer (UCL) climate. The case study presented here is a part of a study in preparation on the sustainability of different urban typologies on passive cooling. The typology presented in this paper is attached canyon-type courtyards in residential buildings. The control elements in passive design evaluated quantitatively in this study are the thermal effects of the courtyard's geometry and the density of shade trees. The latter is becoming an important issue as private courtyards are in the course of being converted for parking purposes due to urbanization and population growth [Rosenfeld et al. (1995), Wilmers (1988)].

Field observations were conducted in two canyon-type courtyards in Tel-Aviv city near the Mediterranean sea coast. The two courtyards are similar in geometry but slightly differ in tree density. The canyon-type courtyard is an urban open space enclosed between two stretches of buildings. It can be viewed as a connected unit of several typical single outdoor courtyards attached to apartment house buildings. The microclimate in such single courtyards is strongly influenced by background conditions, especially by the conditions prevailing in neighbouring courtyards such as vegetation, built-up geometry and albedo. The canyon-type is chosen here for analytical analysis in order to estimate the impact of design parameters on the microclimate of outdoor open courtyards.

The courtyard's diurnal air temperature pattern is evaluated quantitatively using an analytical model, the "Green CTTC model", developed recently by the authors [Shashua-Bar & Hoffman (2002)]. The model is based on the same principles as the Cluster Thermal Time Constant (CTTC) model, developed formerly by M. E. Hoffman and colleagues [Sharlin & Hoffman (1984), Swaid & Hoffman (1990/1)] and on the CC model - a modified CTTC model for enclosed courtyards [Mosseri (1990), Hoffman & Mosseri et al. (1994)], with additional effects of adjoining walls and shade trees. Simulations were conducted for each courtyard, with and without trees. The simulations provide prediction of air temperature pattern over the course of 24 hours including the diurnal thermal effect of the trees. The simulated cooling effects are compared with actual measurements in situ at 9:00, 15:00 and 18:00 h. In addition, simulations were conducted to assess the thermal effect of deepening the courtyards by raising the building height.



2. SITES AND EXPERIMENTAL DATA ANALYSIS



Data used in this paper are taken from a field study [Shashua-Bar & Hoffman (2000)] carried out by the authors on calm days in summer (July-August , 1996) on eleven green sites located in the Tel-Aviv metropolitan area. Two of the studied sites are canyon-type courtyards with trees. The Tel-Aviv metropolitan area is characterized by a hot and humid climate during the summer season with an average air temperature at noon about 29.7 °C and a relative humidity of 65.8%, as recorded in August 1996 at Sde-Dov , a near-by Meteorological station.

Nineteen observation places spaced at about 10 m were chosen along the two sites. Dry and wet bulb temperatures were measured at 9:00, 15:00, and 18:00 h, approximately at the height of 1.80 m. Besides the climatic variables, the partial shaded area (PSA) around each observation place in the site was also determined at 15:00 h (14:10 solar time), the time at which air temperature reaches its maximum in summer in the studied region.

The two courtyards are situated in Tel-Aviv in the same neighbourhood. Both sites consist of a 20-25 meter open space enclosed between two stretches of a 4-floor buildings of about 12 m high. Courtyards A and B are planted with a variety of shade trees of Olives, Poinciana and well-developed Ficus predominating. The PSA in courtyard A is about 66% and in B about 75%. The axis of both sites

are oriented close to North-South. The sites' map is given in Fig. 1, together with the patterns of the maximum cooling and humidity effects at noon.
The cooling effect of trees at each observation place, as determined by measurements in situ, was defined as the difference between the measured air temperature at the site and that at a nearby reference place, outside the site. The reference place was chosen to represent the sites' background microclimate, close to the site (50 to 100 m from it) with no trees. The humidity effect of the trees is evaluated in the same way, as the difference between the humidity (absolute or relative) of the site and that of its reference (op. cit. [Shashua-Bar & Hoffman (2000)]).

Length of the sites : courtyard A = 75 m , courtyard B = 67 m

Figure 1: Site maps, obs. plans and patterns of the maximum cooling effects [K] and humidity differences RH [percentage points] . Data : August 11-13 , 1996 . Time : 15:00 h (14:30-15:30)

In Fig. 1, the patterns of the cooling and relative humidity (RH) effects at 15:00 h indicate significant variations among the observation values. Statistical analysis indicates:

1st)An inverse relationship exists between the cooling and relative humidity effects. The relationship is strong (correlation r = -0.884). For every 1 K cooling, a rise of 3.1 percentage points in the relative humidity is expected at noon (the regression slope b = -3.1) .

2nd) The variation in the cooling effects along the site is explained mainly by the trees shade coverage. The relationship is highly significant (r = 0.830 , b = -3.37).

Daily average cooling and relative humidity effects in the two courtyards during the period of measurements (11-13, August 1996) are summarized in Tables 1 and 2. The air temperature and relative humidity at the reference place represent the daily background values.

At sunrise (6:00 h) and at midnight (24:00 h), no noticeable effects in air temperature and relative humidity were found in eleven green sites in the authors field study (op. cit. [Shashua-Bar & Hoffman (2000)]). The average temperature at sunrise (06:00 h), was 24.7 °C and the relative humidity 84%.

3. ANALYTICAL ANALYSIS

3.1. *Outline of the Green CTTC model*

The quantitative evaluation of the courtyard's diurnal air temperature is obtained by simulations using the analytical Green CTTC model (op. cit. [Shashua-Bar & Hoffman (2002)]). It is based on the same principles as the Cluster Thermal Time Constant (CTTC) model, developed earlier by M. E. Hoffman and colleagues (op. cit. [Sharlin & Hoffman (1984), Swaid & Hoffman (1990/1), Mosseri (1990)]), with the additional effects of adjoining walls and shade trees.

The CTTC model incorporates design parameters related directly to the physical structure and properties of built-up forms (building density, shade areas, the cluster's open space geometry, etc.). It was validated against observed data gathered in the Mediterranean coastal region of Tel-Aviv [Sharlin & Hoffman (1984), Aizenberg & Hoffman (1992)] and of Jerusalem and Essen in Germany [Swaid & Hoffman (1990/1)].

In the CTTC model, the predicted air temperature of a cluster is calculated through the contribution of the heat received from external sources, mainly net solar radiation and anthropogenic heat-release. The Green CTTC model includes the additional effect of vegetation. Conceptually, the predicting equation of the cluster's air temperature at time t is :

$$T(t) = T_0 + \Delta T_{SOLAR}(t) - \Delta T_{NLWR}(t) - \Delta T_{GREEN}(t) + \Delta T_{AHR}(t) \quad (1)$$

where:

T_0 is the regional base (or background) temperature, which was found to be equal to the mean daily air temperature measured at a representative rural Meteorological station (op. cit. [Swaid & Hoffman (1990/1)]).

$\Delta T_{SOLAR}(t)$ is the contribution of solar radiation (direct and diffused) to air temperature variations.

$\Delta T_{NLWR}(t)$ is the contribution of net outgoing long-wave radiation flux to air cooling.

$\Delta T_{GREEN}(t)$ is the cooling contribution to air temperature by vegetation in the cluster.

$\Delta T_{AHR}(t)$ is the anthropogenic contribution to air temperature including effects of man-made nature such as heat release owing to transportation, fuel consumption for domestic use and so forth.

The thermal effect of shade trees, in $\Delta T_{GREEN}(t)$, is estimated considering the effect of solar radiation penetration and the intensity of evapotranspiration. For well developed Ficus trees, the reduction of insolation by the presence of shade trees was estimated in this study for the summer period to be about 40% of the global solar radiation intensity incident on the tree canopy (op. cit.[Shashua-Bar & Hoffman (2002)]). In other words, complete shade coverage by trees (PSA = 1), would still allow the cluster to receive 60% of the global solar radiation.

3.2. *Estimating the cooling effect of trees*

The Green CTTC model is applied to simulate the diurnal air temperature of the two courtyards, with and without trees, using the cluster's parameter values as follows:
The solar radiation absorptivity, *m*, was 0.7 for ground and 0.5 for walls in both sites.
The overall heat transfer coefficient of surface *h*, which is related to wind velocity, was on the average 12 [W / m^2 K] in both sites.
The Brunt number (effective atmosphere emissivity), Br which is related to vapour pressure and cloudiness of the climatic region was on the average 0.74 for both sites.
The ground surface thermal emissivity , e , was 0.92 for both sites.
Cluster Thermal Time Constant , CTTC [hours], was 8 for ground and 6 for walls, in both sites.
The tree shade coverage represented by the partial shaded area, PSA Tr, was 0.66 for courtyard A and 0.75 for courtyard B.

The simulated diurnal patterns of air temperature for the two studied courtyards, using the Green CTTC model, are shown in Figure 2. In each courtyard, the higher curve indicates the diurnal estimates of air temperature in the absence of trees, and the lower one the values in the presence of trees. The difference of air temperature between the levels of the two curves in each courtyard gives the estimated cooling effect of the trees. The measured air temperature values in situ at 9:00, 15:00 and 18:00 h, are indicated for comparison.

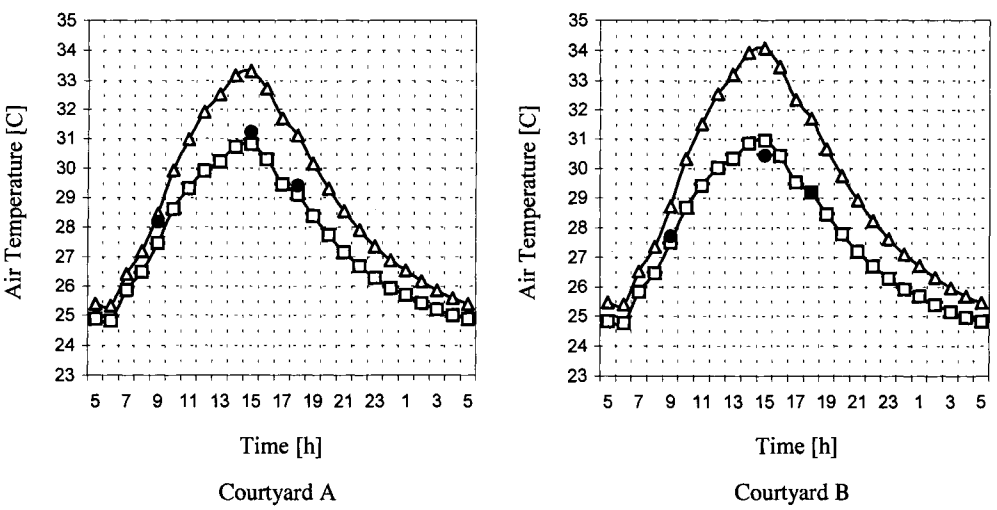

Figure 2 : Simulated patterns and measured in situ values of diurnal air temperature in courtyards A (H / W = 0.60) and B (H / W = 0.48) . Data : 11-13 August 1996
Δ Cluster without trees ◘ Cluster with trees ● Measured values in each courtyard

Table 3 shows the comparison between the measured values of cooling effects by trees and the simulated ones. A close fit was found between the measured and the simulated values. The bias at 15:00 and 18:00 h is less than 0.25 K, and at 9:00 h less than 0.5 K.

TABLE 3
COMPARISON BETWEEN MEASURED AND SIMULATED ESTIMATES OF COOLING EFFECTS ; [K]

Site	09:00 h	15:00 h	18:00 h
Courtyard A			
Measured	-1.31	-2.47	-2.29
Simulated	-0.97	-2.50	-2.00
Courtyard B			
Measured	-1.78	-3.26	-2.50
Simulated	-1.22	-3.12	-2.51

3.3. *Estimating the effect of courtyard deepening*

Vernacular architecture made much use of deep courtyards (high H / W ratio) and narrow open urban spaces to enhance cooling in hot and dry regions. Modern technology and traffic circulation led to reverse this trend. Lately, however, the need for residential housings is leading to high buildings on existing open spaces, thus to deepening but not necessarily on narrow spaces. Municipality ordinance are allowing increase in buildings' height from 3-4 floors to 6-8 floors in several streets in Tel-Aviv. The effect of this deepening process can be evaluated by simulations, using the Green CTTC model.
Figure 3 shows the simulated diurnal air temperature values for the two deepened canyon-type courtyards, by increasing their buildings' height to 20 m, from a 4 floor building to a 6 floor building, leaving the courtyard width unchanged (20-25 m).

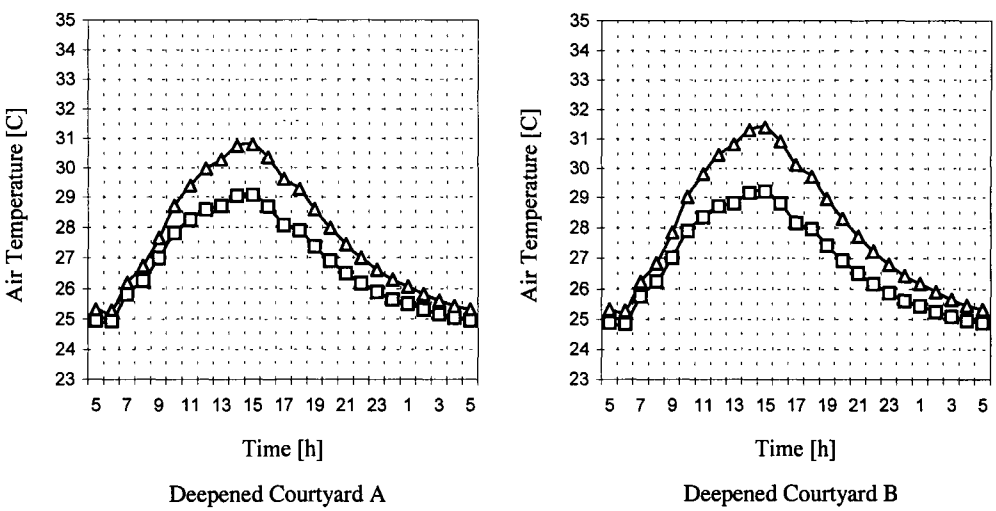

Figure 3 : Simulated patterns of diurnal air temperature in the two deepened courtyards A (H / W = 1.0) and B (H / W = 0.8)
Δ Deepened courtyard without trees ◘ Deepened courtyard with trees

The curves of the deepened two courtyards in Figure 3 show lower temperatures than the corresponding ones in Figure 2. The difference between the levels of the respective curves (actual 12 m height vs 20 m height) gives the cooling effect of deepening the courtyard. Table 5 summarizes these effects at 15:00 h.

The simulated effects in table 4 show that the air temperature lowering due to deepening is stronger in canyon-type courtyards without trees (about 2.6 K) than with trees (about 1.7 K). The effect of trees is also reduced by deepening. The reason is that the cooling effect of vegetation is used to cool a larger volume of air in the deep courtyard than in a shallow one.

TABLE 4

DEEPENING EFFECT [K] IN THE STUDIED COURTYARDS WITH AND WITHOUT TREES . 15:00 h

Site	Courtyard A	Courtyard B
Simulated cooling effect of Deepening		
In courtyard without trees (from H = 12 m to H = 20 m)	-2.51	-2.69
In courtyard with trees (from H = 12 m to H = 20 m)	-1.73	-1.74
Simulated Cooling effect of trees		
In courtyard with actual height (H = 12 m)	-2.50	-3.12
In deepened courtyard with raised height (H = 20 m)	-1.72	-2.18
Total Cooling effect of trees and deepening	-4.23	-4.87

The maximum combined cooling effect at 15:00 h due to trees and deepening in the two types of courtyard is estimated to be about 4.5 K (4.23 K and 4.87 K in courtyards A and B). This level of cooling is impressive considering the fact that the average rise in air temperature, from sunrise to noon, is about 9 K in August, in the hot-humid region of Tel-Aviv. The effect on indoor Air Conditioning (AC) energy saving following 4.5 K lowering of the surrounding air temperature is expected to be significant. Simulations run by Rosenfeld et. al (op. cit. [Rosenfeld et al. (1995)]) on sustainability design of building geometry, widespread use of cool surfaces and vegetation in cities indicate saving of up to 20% of cooling energy.

4. SUMMARY AND CONCLUSIONS

The Green CTTC analytical model, developed recently by the authors is applied to simulate diurnal air temperature patterns in canyon-type courtyards. The design control elements studied are the cooling effect of planted trees and thermal effects of deepening the cluster.
The main findings are:

1. The Green CTTC model is found to be suitable for predicting the air temperature inside an open outdoor canyon-type courtyard. Comparison with daily measurements in situ shows deviations less than 0.5 K.
2. The cooling effect of shade trees in such a courtyard in Tel-Aviv was found to be 3 K at noon, with shade tree coverage (PSA) of 75%. This level of cooling is significant considering the fact that the average rise in air temperature is about 9 K in August in the studied region.
3. Deepening the courtyard by raising the cluster's height lowers its air temperature as expected. The simulated effect of changing the height from 12 m (4 floors) to 20 m (6 floors) produces a cooling effect of about 2.5 K in a courtyard of 20-25 m wide. This effect is significant and even exceeds the cooling effect of trees.

4. The cooling effect of trees depends on the shade coverage (PSA level) as well as on the cluster's geometry. This effect is reduced by deepening the cluster, as the tree cooling energy serves a larger volume of air in a deep cluster than in a shallow one with an equal floor area.
5. The combined cooling effect in canyon-type courtyards due to trees and deepening is found to reach 4.5 K at noon in August. The implication on indoor AC energy savings from a 4.5 K cooling in the surrounding air temperature illustrates the benefits inherent in sustainability design.
6. The Green CTTC model applied to courtyards provide a practical tool for sustainability design in passive cooling through assessing the thermal impacts of various control elements defining the cluster's physical structure, properties of built-up forms and presence of shade trees. In this study, the model was applied, mainly, to assess the thermal impact of trees and of the cluster's deepening.

ABSTRACT

The performance of the built environment is behind schedule on the way to factor 20 environmental improvement by 2040. A case study with government office buildings, discussed in this paper, stresses the importance of improving more than just building materials and services. Substantial improvement can be achieved by focussing on all three dimensions of sustainability: technological efficiency, efficient use of space and a long functional life span.
Space efficiency can be improved by intensive use of space, like innovative work concepts, and multiple use of space, like stacking and combining functions. These avoid claims on rural areas and diminish the amount of building materials and energy needed.
The life span of buildings can be prolonged by a sustainable building structure that has possibilities of adaptability to unforeseen future functional changes of the building. Short term contracting in the real estate market requires functional adaptability of office buildings. This functional adaptability is enabled by technical flexibility.

KEYWORDS

Sustainability, sustainable building, environmental assessment, environmental performance, environmental impact, environmental index, factor 20, intensive use of space, multiple use of space, adaptability, flexibility, real estate market.

INTRODUCTION

In the year 2040 factor 20 environmental improvement is necessary if we allow the whole world population high welfare standards [Ehrlich & Ehrlich, 1990; Speth, 1990]. In order to see whether sustainable building policy is effective or needs to be changed the environmental performance of buildings can be determined and related to this factor 20 target. If the performance were to develop linearly (an assumption open to discussion) factor 4.8 improvement would have been necessary in the year 2000. The relation of a building to a 1990 reference building, the environmental index, can also measure the performance. Hence, this index should have been 480 in the year 2000.

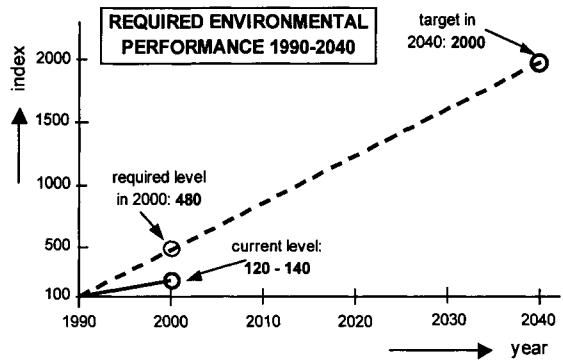

Figure 1: The factor 20 target line and recent performance of buildings.

Recent environmental assessments of sustainably built Dutch buildings show that, since the year 1990, the environmental quality of buildings has averagely improved factor 1.4 to 2.5 [Croes et al., 2001]. More specific conclusions can be drawn from an environmental assessment of 'normal' government office buildings [van den Dobbelsteen et al., 2002-2], in co-operation with the Dutch Government Buildings Agency (DGBA). The offices were compared to a well-defined 1990 reference office, based on the number of users (fte) of the studied office, the gross floor surface (gfs) or the office design itself. For more details about these references: see [van den Dobbelsteen et al., 2002-3].

Technical causes of the arrears

There are various causes for the environmental arrears of individual buildings. Sustainable building as a policy is focussed on small adaptations of traditional solutions. Technically, an environmental index of 800 is already possible, but the combination of measures necessary is expensive and complex.
Another reason for not meeting requirements, even in well-intented projects, might be caused by the approach on the building scale and by disregarding urban solutions. With a wider urban approach of sustainable building greater environmental profits can be achieved than just of an individual building.

Three dimensions of sustainability

The mentioned possible causes of insufficient environmental improvement are of a technological kind. Solutions tend to be automatically sought in that direction. The limited progress of environmental performance, however, shows that a focus solely on technological efficiency is not enough. Sustainability has more than one dimension. The factors space and time, largely independent from technology but important for the eventual environmental load, are often forgotten.
Improvement of the use of building space and prolonging the life span of buildings can be additional factors to technological efficiency, which together might enable factor 20 improvement of the built environment (the whole volume in Figure 3).

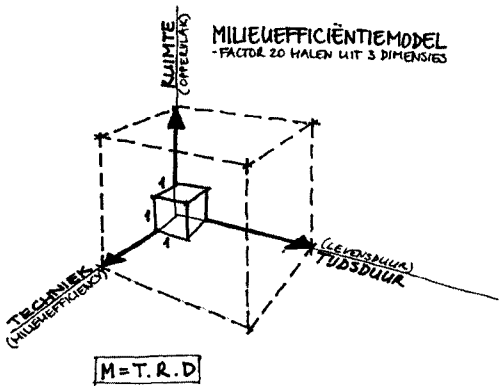

Figure 2 (in Dutch): Achieving factor 20 improvement by three dimensions of sustainability: technology (efficiency), space (surface) and time (life span).

In this paper solutions in all three dimensions will be elaborated. The case study of government office buildings will be used as illustration project for the different solution directions for sustainability: technology, space use and life span.

TECHNOLOGICAL EFFICIENCY

Results of the assessment of government office buildings [van den Dobbelsteen et al., 2002-2], all of them designed without special attention for sustainability, can be found in Table 1.

TABLE 1:
GOVERNMENT OFFICES ASSESSMENT RESULTS [AFTER: VAN DEN DOBBELSTEEN ET AL., 2002-2].

TOTAL AVERAGE	1947	1986	815	24.250 m2	€ 18.666.037	€60.879	€2.014	108

Beside general information about the buildings in Table 1 the environmental cost, an indicator for the environmental impact (calculated with the computer model GreenCalc) and an environmental index can be found. The environmental index results from comparison with the environmental cost of a

fictitious reference building, with the same design, same shape, but with different building materials and services. Hence, it assesses the applied building technology, given a certain building design. It is visible that the average improvement of the office buildings with respect to 1990 is 8%. The average construction or renovation year is 1992, but there is no particular tendency of improvement towards the year 2001: the index of older buildings is not particularly worse.

Energy consumption

Considering a reference life span of 75 years, about 60% of the environmental load is caused by energy consumption (see Figure 3). Since 1990 much effort is put into improving the energy efficiency of government buildings. Progress by energy conservation measures like thermal insulation and more efficient heating services has often been suppressed by a growth in computer use and cooling [Parap werkgroep, 2001].

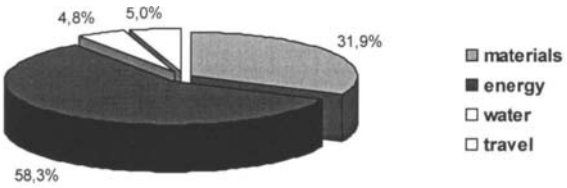

Figure 3: Environmental cost division of government offices [van den Dobbelsteen et al., 2002-2].

The environmental impact of energy consumption is dominated by energy for artificial lighting and heating, followed by apparatus like computers. Therefore, improvement should be focused on these aspects: more access of daylight, smart light switching and heat recovery systems. Further progress in the sustainability of technical services like energy, water and IT-supply can be made through collection of these functions, because of scale and efficiency advantages. One can think of cold and heat storage in the ground and a central heat pump, solar or power service.
Beside these short-term improvements a wide shift toward sustainable energy sources is necessary. Van der Linden & van den Dobbelsteen [2000] already highlighted this.

Building materials

Secondly important in the environmental load, growing of importance if the life span of the building is shortened and if the use of sustainable energy increases, is the use of building materials. The bearing structure is responsible for about 60% of the environmental load of building materials, dominated by the floor structure and beams.

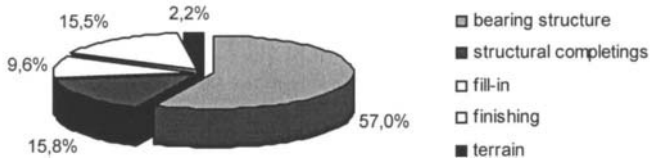

Figure 4: Environmental cost division of government offices [van den Dobbelsteen et al., 2002-2].

With this in mind, focussing on improvements in the building details is, however worthwhile, not effective. Putting effort in the improvement of the bearing structure will more effectively lead to better performance. For more information about the bearing structure: see [Arets et al., 2002].

IMPROVING THE USE OF SPACE

In Table 1 the design index only indicates the environmental impact of the applied materials and services. By using a different reference, 'constructing' a fictitious reference building based on the required gross floor surface (gfs index) or the number of users (fte index), the design efficiency and use of floor surface can be assessed (Table 2).

TABLE 2:
DIFFERENT ENVIRONMENTAL INDICES [AFTER: VAN DEN DOBBELSTEEN ET AL., 2002-2].

PROJECT name	INDEX des ind	gfs ind	fte ind
Food Inspection Department, Zutphen	110	121	181
Mixed Office Pels Rijckenstraat, Arnhem	109	118	109
Tax Office, Gorinchem	110	117	135
New Geometry Department, Delft	108	86	78
Ministry of Social Affairs and Employment, The Hague	116	119	105
Ministry of Housing, Spatial Planning and Environment, The Hague	91	102	102
Public Works Office (Johan de Witt monument house), The Hague	102	127	81
Traffic and Public Works Office ('The Artillery'), The Hague	119	139	120
TOTAL AVERAGE	108	109	103

Considering the design index as a measure for technical efficiency, the difference between the design index and gfs index tells something of the design efficiency (a space indicator). The difference between the fte index and gfs index gives an impression of the efficiency of floor surface use (a use indicator). If the fte index is less than the gfs index, too few people use the building. If it is greater, then there is efficient use of floor surface, compared to the 1990 reference. For instance, the building in the first row has an innovative office concept with shared and flexible desks. This turns out to be an important factor of improvement.

The FSI and surface indices

Another way of assessing space use is by indices for floor and ground surface use, again related to a reference building, or by the floor space index (FSI), the amount of floor area realised divided by the surface of the building area on which it is realised. In Table 3 these can be found for the assessed government buildings.
The index for floor use reflects the deviation from the 1990 average of 28 m^2 gfs per fte. The average shows the government uses more floor surface per employee, probably related to specific functions. Of the two positive exceptions the Food Inspection Department has an innovative office concept with shared and flexible workplaces.
In the indices for ground use there is a clear distinction between offices built in dense city areas and offices at the outskirts of town. Especially the ministries, located near nodes of public transport in the centre of The Hague, have a very efficient use of ground surface.

TABLE 3:

This example shows intensive use of space by efficient floor concepts (especially in offices), multi-functional use of buildings and multiple use of space in the third dimension reduce the urban space needed, and thus consumption of materials and energy. Furthermore, deterioration of nature through building extension outside the urban environment is prevented.

De Wilde [2002] introduced the following distinction between intensive and multiple use of space. Intensive use of space means intensifying use of surface for a certain function. Multiple use of space appears in three different forms with combinations being possible (see: figure 5). The first form is multiple use of space in the second dimension, the plain surface. Different functions are put next to each other, which is defined as *mixed use of space*. The second form is a differentiated form of mixed use of space, in which the different functions are put on top of each other: *multiple use of land*. The third form is *multiple use in time*, in which a set amount of floor area is used for different functions, one after the other.

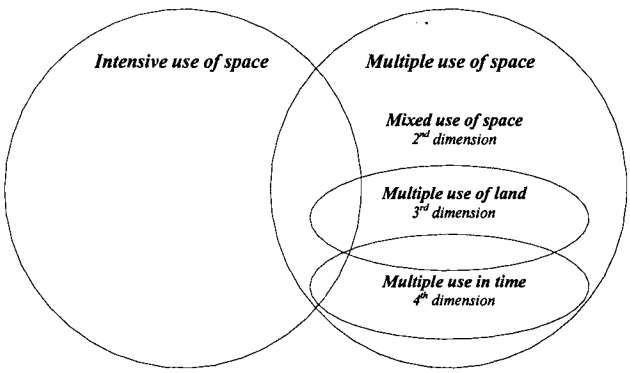

Figure 5: Different types of intensive space use [de Wilde, 2002]

PROLONGING THE LIFE SPAN

In the shown case study results life span consequences have not been taken into account; old buildings were considered as new buildings. With a limited look at sustainability a 'tight' building is the best solution for good environmental performance (a high environmental index): a smaller building envelope means less energy consumption and less building materials mean less environmental impact. However, with this approach future changes (new spatial requirements, different work forms etc.) are ignored, possibly shortening the eventual life span of the building.

Importance of the life span for sustainability

A part of the environmental load develops during the life span of a building (e.g. by energy and water consumption or travel); another part is mainly initial, imposed at the beginning of the life span of the building or urban area (e.g. use of building materials) or at the end of it (e.g. demolition waste). Because of the initial environmental load, in case of a short life span the environmental load per unit of time is bigger than with a long life span, taking a long lifetime as a reference.
Therefore, prolonging the life span of buildings and urban areas as a whole is an important means to diminish the environmental load. When buildings lose their function demolition is often the most feasible solution. Adaptability is a primal necessity, because functional changes can hardly be predicted.

Flexibility for adaptability

Sustainable buildings offer enough possibilities to undergo changes through times. In the real estate market adaptability starts with financial unboundness. The success and size of young companies is so fluctuating that they do not dare tie themselves to long-term contracts [van Eldonk et al., 2001]. This is also a tendency among bigger companies. For accommodation this means that the conditions might change completely within a few years. In that perspective it is dangerous to bet on a function that is boosting at the moment of decision. It is wiser to strive after multi-functionality, or functional flexibility. Technical flexibility forms the basis for functional flexibility. An overview of urban flexibility forms, the drive behind them and possible solutions can be seen in the table underneath.

TABLE 4
TYPES OF URBAN FLEXIBILITY [VAN DEN DOBBELSTEEN & KLAASE, 2002-1].

FLEXIBILITY TYPE and BACKGROUND	POSSIBLE SOLUTION
Financial flexibility	
Financial unboundness organisations are not tied to long financial obligations	• functional flexibility (see below) • short-term (hiring)contracts • buildings not tuned to current trends → sustainable quality
Functional flexibility	
Multi-functionality a building is adaptable to changing circumstances; it can accommodate different functions	• technical flexibility (see below) • reckon with growth • elaboration to the highest quality
Technical flexibility	
Oversizing/ overdimensioning the building structure has sufficient measurement for a dynamic and growing organisation	• high ceilings and large door openings • spacious floor plan, in which additions are possible • over-dimensioned floor structures for different functions
Extendibility parts can be added or removed on, under or next to the building	• reservation of space for later additions or adaptations • over-dimensioned bearing structure for additions • removable, dismantleable constructions
Re-arrangeability the building structure offers opportunities to vary the fill-in	• open bearing structure without obstacles • removable inner walls • comparting of technical functions and infrastructure • separability: additional entrances, stairs and elevator shafts

CONCLUSION AND DISCUSSION

Sustainable building should be focussed more on the intensification of space use and a longer useful life span of built areas, rather than solely improving technological efficiency. This paper gives an overview of conceptual solutions with which all factors can effectively add to a better environmental performance.

An important stimulance for solutions for efficient use of space and a long life span would be the assessibility of the environmental impact of these. At the moment only the use of building materials, energy and water, the technological efficiency, can be translated into environmental indicators. Space use can only be put into indices that visualise the difference with a reference, but comparison with the environmental impact of e.g. building materials is not possible yet. To estimate the eventual life span of a building, and thus the environmental impact of measures in that direction, is even more difficult. Therefore, development of assessment models for space use and life span are a necessity to make these factors of sustainability as important as the technological efficiency.

A final remark can be made about the relative importance of buildings within urban areas. Good buildings have no future in bad areas; a good urban plan however tolerates bad buildings. Therefore, it is important to have a good urban fabric as the foundation of sustainable building.

[2] Faculty of Architecture, P.O. Box 5043, 2600 GA Delft, Netherlands

ABSTRACT

In the year 2040 factor 20 improvement of environmental impact is necessary. Measuring the environmental impact of building provides insight into the progress or decrease with respect to the factor 20. One environmental assessment type is determining the environmental index, by relating the environmental load of the studied building to that of a certain reference. There are three ways of defining a reference:

1. basing it on the design of the studied building, but changing the building materials and services
2. basing it on the gross floor surface and 'constructing' a fictitious reference building around it
3. basing it on the number of people for whom the building is designed and relating that to a reference floor surface, followed by the 'construction' of a fictitious reference building.

A case study with 12 government office buildings shows that the definition of the reference is stipulating for the resulting index. This paper describes the different reference types and presents results and conclusions of the government office buildings assessment.

KEYWORDS

Sustainability, sustainable building, environmental assessment, environmental performance, environmental impact, environmental cost, environmental index, factor 20, reference, reference building.

INTRODUCTION

Sustainability has become an important new performance factor in the over-all quality of building design. Many models have been developed in order to assess the environmental impact of building designs. For a broad perspective the calculated impact has to be related to a target for the future. The World Commission on Environment and Development (1987) stressed that sustainable development has to be achieved in synchronic attention for welfare and environment. Ehrlich & Ehrlich (1990) and Speth (1990) made this quantifyable by relating the pressure on the environment (EP) to the world population (P), their welfare rate (W) and the environmental impact of goods, also called metabolism (E).

$$EP = P*W*E \tag{1a}$$

$$1/2 = 2*5*1/20 \quad (1b)$$

With the objective to weaken the pressure on the environment and a growing population, while giving the poorer part of the world a comparable welfare rate as the western population, requiring factor 5 improvement, 50 years later, by the year 2040, the environmental impact has to be reduced by 95%.

In order to estimate the progress in sustainability the environmental performance of buildings can be related to that of a 1990 reference. Thus an environmental index can be deducted, showing the achieved factor improvement. The difficulty is to define this reference in a specific design, exact measures, building materials and services.

CALCULATION TYPES

Buildings can be compared through the absolute environmental load or through relative scores or environmental indices. Environmental indices offer extra opportunities:

- simple scores, in contrast with different effect scores in many digits
- comparability of aspects of sustainability, of which scores are put in different units
- insight into progress or arrears of the environmental performance, with respect to a reference year
- environmental improvement of buildings, with respect to a reference building or the factor 20
- insight into environmental differences between functionally unequal buildings
- categorisation of buildings according to the environmental index (see Table 1)
- diminishment of absolute errors in environmental assessments.

If the calculated absolute values (basis for the index) stay reasonably valid, the comparison can also give information about differences and causes of the environmental load of buildings.

An environmental index can be obtained by relating the environmental load of a building to the environmental load of a reference (see Figure 1).

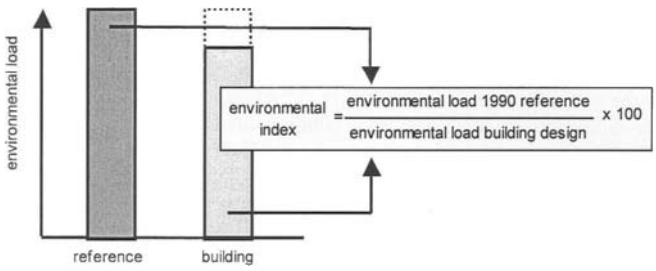

Figure 1: determination of the environmental index

In order to assess buildings in a correct way, comparisons based on the environmental index have to meet the following conditions.

1. Buildings should meet a *functional unity*, a collection of demands ensuring all assessed buildings have a comparable function and meet the same technical requirements.
2. An *input protocol* is necessary: the contemplated building elements or environmental aspects as well as the measure of input details should be equal for all studied buildings.
3. Different types of buildings can be compared. However, each building type demands its own reference and functional unity. A *functional conversion protocol* is necessary for slightly different buildings in a collection of buildings with one reference.

The most important part of a building comparison based on environmental indices is the definition of the reference, of which there are three different types.

REFERENCE TYPES

The design reference

In the design reference the design of the reference (shape, floor surface, façade fill-in, amount of building materials) is the same as the studied building. The design reference is based on a list of reference solutions for building materials, energy and water services. These reference data are pasted into the dimensions of the studied building design in the assessment model. The results of Table 1 were drawn in accordance with this approach. This reference type is appropriate for one specific building; every new building requires a new reference definition.

An index based on the design reference ('design index') only assesses the ecological quality of the applied building materials and services. The approach is quick and easy but in fact means working with a shifting reference, because the design, size, form, fill-in and building use change with each studied building. Hence, solely by the design index one building is not completely comparable with another.

The gfs reference

The floor surface reference is based on the *gross floor surface* (gfs) of the studied building or on spatial requirements in the original brief. The building geometry, façade and fill-in, however, are 'constructed' in accordance with a reference building design. The gfs reference is especially useful in case of design competitions, if different designs are made for the same building.

An index based on a gfs reference ('gfs index') assesses the environmental performance of the building design and the applied building materials and services. To get a picture of the building design alone, given certain material and service choices, the environmental index should be compared to an index based on the design reference.

The fte reference

In a fte reference the number of people (or *full time employment*, fte), for whom the building has been designed, forms the basis for comparison. With a fte reference the reference building is built from scrap, needing a definition of functions in a building, their reference floor surface and specific facilities, a standard fill-in, a standard bearing structure, façade design etc.

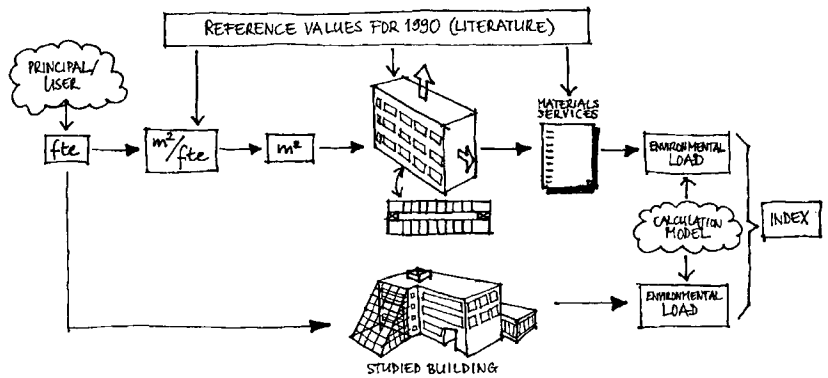

Figure 2: The determination of the fte reference, its environmental load and the environmental index.

With a fte reference more aspects of a building can be assessed than with a gfs reference, but the determination of it is more complex. The number of people using the studied building is not always known and can change during the lifetime of the building. Hence, the environmental performance will vary with different personnel data.
An index based on a fte reference ('fte index') assesses the complete environmental load of building use, building design and applied materials and services with respect to a fictitious building. To get an impression of the building use alone, given certain building design and materials and service, the fte index should be related to a floor surface index.

DEFINING DESIGN REFERENCES FOR OFFICES

Starting with the number of personnel using the studied building a next step is to determine the 1990 reference floor surface per fte, from which point the whole reference building can be defined.

Floor surface

There is no estimation of the floor surface use per employee explicitly for the year 1990. In the Netherlands in the year 1996 the average surface use was 27.9 m^2/employee, a value that dropped to 25.5 in 1999 and 23.8 in 2001 [van Eldonk et al., 2001]. If this trend already took place before 1996, in the year 1990 the average floor use must have been bigger than 27.9 m^2. However, in the Netherlands only around the year 1996 the first space-saving office innovation projects started [Rijksgebouwendienst, 1996]. Therefore, in 1990 the average gfs per employee can be assumed around 28 m^2.

Office concept

The fill-in of the required floor surface depends on the chosen office concept, which is a combination of organisational use and an architectural fill-in concept. In 1998 only 9% of the Dutch offices had an innovative concept [van Antwerpen & Hermans, 1998]; most had territorial workplaces. The largest

part of offices had a cell structured fill-in, of which 40% with 1 or 2 person rooms, 23% with 3 or 8 person rooms ('group offices') and 21% a combination of both. Therefore, it is reasonable to pick a territorial cell office as a reference for 1990.

Building depth and length

As many researchers found out, Dutch cell offices are mainly based on a floor module of 1.80 m x 5.40 m and a single middle corridor of 1.80 m. This means a common building depth for the 1990 reference building is 12.60 m.
Based on Dutch legislation rules for security exits a reference length of around 60 m can be chosen, or - with 32 bays of 1.80 m - rounded off to 57.60 m. Hence, the reference gfs per layer is 12.60 x 57.60 = 725.8 m^2. The exact building length can be tuned to an integer number of building layers. Reference offices with a gross floor surface of 725.8 m^2 and less have one building layer, the building length depending on the needed floor surface, rounded off upwards in order to fit the bay measure of 1.80 m.

Building height

In case of big floor surfaces a limited reference building length would lead to an unrealistic height, necessitating additional structural measures. Therefore, a maximum reference height has to be defined, based on a conventional concrete structure with a stiff core around the elevators. An assumed maximum height with this technique is 24 layers. A free floor height of 2.40 m is common [Boer et al., 1996], so with a construction and service height of 1.20 m the total reference floor height is 3.60 m. This means a maximum reference building height of 86.40 m. In case of a large reference office (20.000 m^2 and bigger, like a ministry) this maximum height is quickly attained, after which expansion of the reference floor surface can be found in an extension of the building length.

Calculation of the measurements for the reference building geometry

Following the definition of different reference measures the shape of the fictitious reference building for a studied office building can be determined from formulas (see Table 2).

TABLE 2:
REFERENCE LIST FOR ENVIRONMENTAL COMPARISONS [AFTER: VAN DEN DOBBELSTEEN ET AL., 2002].

number of fte (p)	p		
needed surface (A)	A=28*p		
total facade length (L_{tot})	L_{tot}=28*p/12,60=2,222*p		
	A<=725,8 →	A >725,8 →	
layers (y)		y=L_{tot}/57,60=0,0386*p	
		y<=24 →	y>24 →
number of layers (Y_{ref})	Y_{ref} = 1	Y_{ref}=A/57,60 round off upwards to integer	Y_{ref}=24
building height (H_{ref})	H_{ref}=3,60*Y_{ref}=3,60	H_{ref}=3,60*Y_{ref}	H_{ref}=3,60*Y_{ref}=86,40
needed surface per layer (a)		a=A/Y_{ref}	a=A/Y_{ref}
number of bays (t)	t=L/1,80 round off upwards to an integer	t=a/12,60/1,80=a/22,7 round off upwards to an integer	t=a/12,60/1,80=a/22,7 round off upwards to an integer
building length (L_{ref})	L_{ref}=1,80*t	L_{ref} = 1,80*t	L_{ref}=1,80*t
gross floor surface (A_{ref})	A_{ref}=12,60*L_{ref}	A_{ref}=12,60*Y_{ref}*L_{ref}	A_{ref}=12,60*Y_{ref}*L_{ref} =302,4*L_{ref}

This definition of reference design geometries looks complex but can be easily put in a spreadsheet model, as was done for the later presented case study of government offices.

Additional design references

For complete data input in an environmental assessment model the next additional features of the reference building were chosen, only presented briefly here.

- Having no statistical preference for the *orientation* of office buildings, the arbitrary choice the long elevations of the office were oriented on the west and east. The entry is at the eastern elevation.
- The east and west elevation are given a usual external *glass percentage* of 30%, the window-frame included. The short elevations on North and South are blind.
- A *cellar* is included, but it is not taken into account as functional space.
- The reference office has a flat roof without special facilities.
- The cell structured office floor has a modular fill-in based on a module of 1.80 m by 5.40 m. Based on databases of the Dutch Government Buildings Agency (DGBA) an average *internal wall surface* of 90% of the gross floor surface is chosen, of which 10 percent points internal doors.
- The *bearing structure* is a column structure with a stiff core of 3.60 m by 3.60 m.

References for building materials and services

Having the measures determined reference materials and building services can be defined (Table 3).

TABLE 3:
REFERENCE LIST FOR ENVIRONMENTAL COMPARISONS [AFTER: VAN DEN DOBBELSTEEN ET AL., 2002].

Building materials	
Bearing structure	foundation, columns, beams, floor structure, roof structure and bearing walls of concrete, cast on site, 40 mm EPS insulation of ground floor and roof
Facades	brick masonry - 50 mm rockwool - lime stone blocks, tropical timber windows with double panes, entrance of glass in tropical timber frames, security door of tropical plywood
Fill-in	25% massive lime sand block walls, 75% metalstud walls with 50 mm rockwool, honeycomb doors in tropical timber frames, concrete stairs
Finishing	cement decks, bituminous roofing with gravel ballast, gypsum ceiling panels, 90% lino and 10% ceramic tile floor covering, 10% ceramic tile wall covering and 90% lime plaster-work with acrylic paint
Terrain	50 mm asphalt pavement
Energy consumption	
Building use	opening times 8.00-20.00 h, 38 hours working week, 85% presence, 1 computer per person, no auto power-down,
Climatising	light walls, heavy facades and closed ceilings, conventional boiler, mechanic exhaust, 2.0 m^3/hm^3, no heat recovery, no ventilator control, no cooling
Warm tap water	conventional boiler with central heating, distribution by circulation
Lighting	conventional TL ceiling fittings, room switches, 40% of functional surface has daylight possibilities
Water consumption	
Facilities	restaurant, showers and greenery watering present, no air moistening
Sanitation	toilets with 9 liter reservoirs, standard taps and showers
Substitution	no substitution of tap water by rain water
Travel	
Site	town borders, 400-600 people/km^2, internal work (85% presence)
Public transport	railway station at 4 km, frequency 4 times per hour, bus abri at 500 m, frequency 4 times per hour
Private transport	motorway at 1 km, through traffic on service road, parking lots at 100 m, 0.6 lots per employee, pedestrian and bike paths separated from road by greenery

What does the fictitious reference building look like?

The reference office can be seen as a typical Dutch 'motorway office', located at the border of a town near a service road, with a rather large parking area and distant from public transport. The office design is rather traditional, with a concrete bearing structure and traditional brick masonry. It has a

cell-structured fill-in (every employee has his own desk). The building services and heat insulation are in accordance with 1990 legislation requirements.

THE CASE STUDY 'ENVIRONMENTAL LOAD OF GOVERNMENT OFFICES'

As part of the PhD research 'Effective sustainable accommodation of office work' government offices were assessed following the described methodology. With the computer model GreenCalc the environmental cost of the offices were determined and compared to those of a 1990 reference office. All three described reference types were applied so three different indices could be compared (Table 4).

TABLE 4:
ENVIRONMENTAL COST ASSESSMENT OF OFFICES [AFTER: VAN DEN DOBBELSTEEN ET AL., 2002].

PROJECT			ENVIRONMENTAL COST				INDICES

TOTAL AVERAGE	815	24.250 m2	€ 19.288.323	€ 20.286.352	€ 19.117.756	€ 18.666.037	103	109	108

The results show that environmental indices sometimes have a wide spread. Taking the first row of the Food Inspection Department in Zutphen as an example, interesting conclusions can be drawn.

- The design index mainly gives an impression of the environmental performance of the chosen building materials and services for energy and water. The design index shows 10% improvement with respect to the 1990 reference building. For a building realised 8 years after 1990 that's not a bad nor a good score. With the factor 20 target in mind it should have been better. Probably the zinc façade cladding is a cause of the limited improvement.
- The gfs index is better, meaning the building design efficiency improves the environmental performance by materials and services. To see the design efficiency alone, the gfs index has to be divided by the design index. Hence, a design efficiency improvement of 10% can be deducted, which can be explained by a relative compact geometry and sober fill-in.
- The fte index shows a large improvement with respect to the 1990 reference building. Related to the gfs index an extra improvement by factor 181/121=1.5 is achieved. This can be explained by the innovative office concept with shared and flexible working places; more people make use of the building than in the fictitious reference building. In case of a floor surface reference or - even worse - design reference, this measure would not have been taken into account.

Some of the office buildings show improvement in the gfs index, but worsening in the fte index. This means the building design is effective but, with respect to the standards in 1990, not enough people use it. In general, perhaps because of their specific function, in government offices more space is commonly used per employee than in commercial offices [van Eldonk et al., 2001].

CONCLUSIONS

The assessment of government offices also shows the environmental performance of common offices are far behind the target to achieve factor 20 environmental improvement in 2040.The case study also shows that the choice of a reference is stipulating for the results and their interpretation. Nevertheless, all index types retrieved from application of the different references are useful in environmental assessments of buildings, for every index unveals different aspects.
As a follow-up of the government office buildings assessment the average environmental load per m^2 or per fte can be deducted and applied as a reference performance demand in the nearby future. This performance per employee enables an easy fixation of the reference environmental load of a whole office organisation, apart from the chosen office concept, building design and applied technology. The principal and architect can use it improving the environmental quality of their project; society can deduct the achieved factor of improvement towards sustainability.

A consideration should be made about the factor time. Defining a reference building geometry and fill-in, a 'tight' building is the best solution for good performance (a high environmental index): a smaller building envelope means less energy consumption and less building materials mean less environmental impact. However, with this approach future changes (new spatial requirements, different work forms etc.) are ignored, possibly shortening the eventual functional life span of the building. In environmental assessment models the life span is usually fixed. Therefore, an extra factor should be taken into account, in which aspects like adaptability play a role. This factor could reflect the expectance of the functional life span of a building, with respect to reference life span. In the period of the case study such a time factor could not yet be enhanced.

CONSTRUCTING THE FUTURE

T. W. Broyd

Research & Innovation Director, WS Atkins plc, Epsom, KT18 5BU, England
Visiting Professor in Construction Management, University of Reading, RG6 2BU, England

ABSTRACT

Construction helps to shape the built environment and provides the infrastructure for society, yet despite the fact that it is an important industry in any country it is not good at planning for the future. In the UK the Government's Foresight programme has brought together business, government and science to identify the challenges and opportunities that face construction in the next twenty years. The Foresight report 'Constructing the Future' (2001) supports and extends other recent initiatives that are designed help improve and benefit the UK construction industry both now and in the future.

The Foresight study involved setting up a number of groups to examine the issues of housing; repair, refurbishment and re-use of facilities; sustainable materials; information and communication technology; business, globalisation and commerce; and safe construction. The final report was produced following extensive consultation and feedback. It indicated that the construction industry needs to embrace a wide range of new materials, technologies and innovative approaches in the future. These include: advances in components and materials (in particular nanotechnology), information and communications technology, and technologies that help to deal with the issues of sustainability. To ensure we fully benefit from these advances requires a shift in industry practices, attitudes and quality. The advantages include better housing and living conditions, environmental sustainability and lower construction costs. Action is needed urgently at every level of the sector because to meet the challenges most changes have to be substantially in place within 10 years .

The report made nine recommendations. To: promote 'smart' buildings and infrastructure; improve health and safety; enable supply chain integration; invest in people; improve existing built facilities; exploit global competitiveness; embrace sustainability; increase investment returns; and plan ahead.

Since publication, the UK's forward-thinking has continued, with a 'Blue skies', future scenario workshop and publication of a major review on Government construction R&D policies and practices.

KEY WORDS

Construction, research, foresight, future

INTRODUCTION

Construction is one of the most important industries in any developed country, not only in economic terms but also in the way it helps shape the built environment and provides the physical infrastructure for civilized society. Despite its sometimes tarnished image, the industry has always excelled at managing complex programmes, often involving groups of people necessarily brought together for one-off projects and working in hazardous or inhospitable places. As a result, the industry has developed both flexibility and good skills in problem solving. What it is not so good at, however, is planning for the future.

Until recently, this lack of forward thinking has been practically a virtue. With uncertain cycles of demand, the ability to respond quickly to changing economic drivers has perhaps rightly been seen as more important than scanning ahead. The signs are that that is now changing. With construction clients increasingly seeking 'lifetime' solutions provided by stable supply chains, and the growing importance of both sustainability and globalisation, there is now both the opportunity and the need for the industry to think ahead.

Within the United Kingdom, we are learning to use structured approaches within a national initiative known as 'Foresight'. It involves thinking intelligently about the issues that will affect the future - up to 20 years hence; not to predict what will happen, but rather to prepare for it and influence it as much as we can. In the past few years people from a broad spectrum of construction industry backgrounds have come together to develop sets of issues that will need to be addressed if the industry is to answer the needs of its customers, its users and its workers. The results are summarised in this paper

THE FORESIGHT PROGRAMME

Foresight (www.foresight.gov.uk) is not fanciful academic dreaming, but hard-nosed business reality. A Government programme, it brings together business, government, the science base and others to help identify the challenges and opportunities of the next twenty years. It includes a number of panels ranging from crime prevention and manufacturing, to financial services and healthcare. The Foresight study on construction, chaired by the author, also doubles as the futures theme group of CRISP, the UK Government supported Construction Research & Innovation Strategy Panel, through which it is linked to the entire construction industry. It is part of a number of initiatives – in particular, Latham (1994) and Egan (1998) - that have taken place in recent years to help assess and bring about substantial improvements to benefit the UK construction industry both now and in the future.

To determine the Foresight programme recommendations for the future of construction a number of issues groups were initially established to examine:

- Housing
- Repair, refurbishment and re-use of facilities
- Sustainable materials
- Information and communication technology
- Business, globalisation and commerce
- Safe construction

Working through a steering group, the feedback from these issues groups enabled the production of a consultation document which was made available to interested parties both from within and outside the construction sector. Their responses were taken into account in preparing the final report and recommendations published last year, Constructing the Future (2001).

CONSTRUCTION SCENARIO

As a sector of economic importance the UK construction sector business is worth £65 billion a year and employs over 1.4 million people. It comprises 186,000 SMEs and includes 165,000 private contracting firms. In the next ten to twenty years they will be faced with immense challenges as a result of new technologies and materials, different operational processes and intensifying cross border competition. The industry will also need to respond to a changing world, with climate change, traffic impact and a revolution in computers and information technologies, amongst other impacts, creating new and different demands, influencing demographic changes and altering life styles. The pace of change will be fast and all-embracing. It will create more business opportunities than ever before. It will also be highly dependent on information sharing, customer-centric thinking, electronic commerce and co-operation at every level throughout an integrated supply chain. It will embrace a changed cultural thinking that impacts on and benefits many aspects of the user environment.

Pointers to the future

There are numerous pointers to indicate that the construction sector is going to have to embrace a wide range of new materials, technologies and innovative approaches in the future. These include:

Advances in components and materials.

Amongst the many probable advances are: new composite materials such as fibre cement and light alloys; nanotechnology to impregnate building components with 'smart' solutions for identity, data collection and management; surface coatings that electronically change colour and warn of stress points; super-strong paint for crumbling concrete that cuts repair and maintenance costs; pre-wired looms which enable house wiring completion in one day.

Information and communications technology

Future construction teams will be process, not project-based, with integrated computer-aided design and data-sharing approaches linked by web-technology. Multi-dimensional modelling (x,y,z, time and cost) and visualisation will incorporate both design and client needs, whilst the Internet will enable fast 'intelligent' planning submission and approval. Remote data collection on the maintenance and operation of facilities will be the norm. The creation of supply-chain research partnerships between designers, constructors and component manufacturers are also very likely.

Methods and people

Amongst the changes that will impact on people within the industry will be the creation of innovation teams and technology clusters and extensive use of collaborative technology. Virtual reality and simulation will be used for safety purposes, whilst computers will provide on-site training and fitting guidance. Robots will increasingly become available, especially for hazardous or monotonous work. To protect workers intelligent clothing will help to communicate and react to changing conditions.

Sustainability

Advances will be made in many areas of sustainability. For example, a reduction in construction waste can be expected, with manufacturers required to collect and re-cycle materials. Efficient, low-cost micro power generators and fuel cells will provide local power networks. Embedded nanotechnology chips will monitor building conditions and contact repair and maintenance teams before breakdown, whilst 'smart' concrete will sense real-time vibration of structures and highlight early repair needs.

Gaining the advantages

To ensure we fully benefit from these advances requires a continuing shift in practices and attitudes within the construction sector and in the quality that the industry delivers. It also needs to overcome many existing problems with customer dissatisfaction and to improve the way its capability is perceived and understood by both public and private sectors.

The advantages of positive action are immense, delivering - amongst other things - better housing, improved living and working conditions, effective environmental sustainability, lower construction costs and a construction industry that is globally competitive and profitably sound. Yet, if the construction industry is to master this future, action needs to be taken now, for in construction planning terms twenty years is almost upon us. Consequently, if we are to see an improvement in the industry's value-added impact on the built environment in that time, then most of the influential changes required have to be in place within 10 years or less.

Furthermore, because the primary key to the future lies in achieving an integrated approach throughout the entire construction process, the changes that are needed cannot simply be each viewed in isolation. They require unified and collective responses, not piecemeal reaction, because the future of construction implies significant change at every level of the sector and not merely for the larger companies and the enlightened thinkers. This means that Government, professional and trade bodies, academia and financial institutions have to work closely with the industry to help deliver the changes that all of society can benefit from in the future.

RECOMMENDATIONS FOR ACTION

The Foresight report that resulted from our deliberations and the consultation exercise recommended nine areas where appropriate action was required. In priority order these are as follows:

Promote 'smart' buildings and infrastructure

Technology will enable almost anything, so deciding how best to apply it is the critical skill. Significant long-term advantages that benefit sustainability and improve design by feeding back information will be achieved by using intelligent, data gathering materials and components. Costs will be saved through use of standard components and factory-automated pre-assembled units. Innovation is the key to the future success of construction, using technology as the enabler. The industry therefore needs to embrace a complete technology and innovation culture change so that research and development is seen as the core value for the future and essential to business success.

Recommendation

Accelerate the introduction of new technologies, 'intelligent' products, standardised, pre-assembled components and advanced materials at all levels of the built environment. This will provide business opportunities, improve living/working environments and feedback to improve construction quality.

Improve health and safety

There are some 80 fatalities, 4,000 major injuries and 10,000 3-day injuries on UK construction sites every year, as well as an appreciable under-reporting of injuries and incidents of ill health.

Within 20 years it would be desirable to achieve zero deaths in construction and to reduce the number of serious injuries on site by at least 80%. For this to be feasible we need to undertake more research into the long-term health impacts of construction site working. Automation in the shape of pre-fabricated component manufacturing and on-site robotic assembly, together with site modelling and simulation, have a major role to play in improving construction safety. Nurturing the workforce and improving safety will enable better recruitment and retention of people. It is well known that a healthy workforce is a happy one. We also need to introduce a 'no blame / no fault' compensation system to encourage near-miss reporting and feedback on site-related health issues.

Recommendation

Improve the health and safety of people working on site. Enhance safety awareness and thinking throughout the construction process - design, manufacturing, build, operations and maintenance. Ensure better safety training, health monitoring and near-miss reporting, and introduce safety-driven construction automation. This will save lives, minimise health problems and improve productivity.

Enable supply chain integration

The integration of design into production and operation will join up areas such as quality of design, sustainability, standardisation, automated production and pre-assembly off-site, and lead to better supply chain management. Much of the industry currently deals with the construction project process as a series of sequential and largely separate operations undertaken by individual designers, constructors and suppliers who have no stake in the long-term success of the product and no commitment to its operating and maintenance costs. Supply chain improvements, enabled with new skills and talent will make a significant difference.

Individual supply chains within the construction industry need to seriously assess and understand their roles and responsibilities in being part of an integrated process. For example, information on all construction products and materials should be available over the Internet in the form of standard coded data (typically IFCs - Industry Foundation Classes) describing specifications, stock availability, prices etc. The skill in integration lies in how businesses manage and transform information, so that freedom of access and seamless interchange of shared information is an important issue. Standards for data exchange are crucial, in particular to enable communications between different IT platforms.

Recommendation

Advance technology-driven thinking and practice across design, production, build, operations and maintenance. Joining up web-enabled supply chain processes and communication standards will cut construction costs and promote seamless customer solutions throughout the construction lifecycle.

Invest in people

Construction firms need to become learning organisations, absorbing and using knowledge and providing for lifelong learning. Investing in human capital and knowledge awareness - a company's most important asset - will help to bridge the skills gap. Research and development will maintain competitiveness. The industry also needs to be responsible for assuring the health of its people, so that health monitoring / screening and better health and safety training are required.

In ten to twenty years the construction industry will require a complete range of different skills. To meet these needs a re-think is required in the way that construction education is organised. Computer integration of construction processes implies a need for cross-disciplinary education.

Recommendation

Re-think construction education. Define future people skills and integrate education, knowledge and learning across the entire construction process. Lifelong learning and knowledge management, will enhance industry standards, improve profitability and attract better people into the industry.

Improve existing built facilities

Half the UK's construction output consists of repairs and maintenance to existing facilities. New ways are needed to exploit alternative uses and innovative technology. The refurbishment 'process' needs clearer understanding and more efficient practices. Components need to be improved, with an emphasis on standardised, modular products. Much of the built environment was not designed for inclusivity, so there are few facilities easily accessible to the elderly and disabled. Obsolescence in existing facilities could be overcome by technical fixes or re-use. Data on operation and maintenance costs, and better asset management, will help to ensure the sustainability of existing facilities.

Recommendation

Improve renovation and repair methods and practices. Ensure research and development embraces technologies and components for repair and refurbishment. Better refurbishment 'processes' and standards for their supply will enhance living conditions and add value to existing built facilities.

Exploit global competitiveness

Global change needs to be faced and new strategies and alliances found to manage it. Opportunities exist for large and small firms to exploit global competitiveness through co-operation and information-sharing. UK component and construction suppliers don't understand their international competitiveness, and mid-size companies should dismantle their rigid structures and practices in favour of co-operative networks for greater flexibility. Today's technology can help achieve this.

Recommendation

Recognise the impact of globalisation and exploit flexible, collaborative, business frameworks and information sharing. Helping all construction businesses, from research and design to manufacturing and supply, to cope with globalisation and harness the technology required to manage it will improve business co-operation and create competitive advantage.

Embrace sustainability

Sustainability embraces long-term environmental viability as well as economic and social issues. Built environment design, construction and operation should be sustainable in use, re-use and recycling of materials and energy. Whole life thinking needs to prevail from design and manufacture, to build, operation, maintenance and disposal. Sustainability will increasingly be 'market-driven' and a concerted effort is required to change the embedded culture of construction industry thinking to embrace sustainability at every level. Sustainability needs to be clearly 'valued' and supported by the financial community, clients and public alike.

Recommendation

Sustainable construction and whole-life principles need to be client-driven. By shifting industry culture to embrace sustainable thinking at every level we can save energy, reduce waste and pollution and cut the lifetime costs of property ownership.

Increase investment returns

The perception of construction among financial institutions and the public needs to be changed to that of a high-tech industry delivering value through new methods of funding. To compete for funding the industry needs to be more innovative and show better assessment and understanding of risk. Increased risk sharing and greater profitability would make a notable difference to funders' attitudes. Investors need greater confidence in the ability of the construction sector to deliver results that reflect a sensible level of risk linked to reasonable returns. The existing image of construction as seen by institutional investors and the public is not good and there is a notable image problem.

Construction needs to change from being seen as a high-risk low-return sector to a low-risk high-profit industry. This will only come about through greater investment in innovation and in skilled people, higher standards, better quality and increased profitability. The move from public to private investment in infrastructure will continue but new ideas are needed to support and encourage this.

Recommendation

Seek innovative methods of demonstrating the value of built assets and lessening project risk. By better understanding 'risk and reward' principles the industry will increase profitability, improve the way it is perceived and valued and encourage new types of funding and investment.

Plan ahead

The industry needs to anticipate and plan for the future through long-term strategic thinking, better forecasting and investment, and new customer framework agreements. This requires the sector to change the business structure to reflect a longer term perspective. The industry needs to think about how buildings and facilities will be in twenty years, to consider future technology trends and impacts, and determine the future competition. These actions are needed so that construction companies can recognise and create new opportunities. The changing business structure should reflect local and global issues. It also needs to recognise the inherent lack of business skills within many smaller construction firms. Planning and preparing for the future will ensure it is always in the best possible position to manage economic downturns and remain globally competitive.

Recommendation

Anticipate and plan for change. Greater awareness of the cyclical nature of construction economics, long-term strategic thinking, future forecasting and co-ordinated planning will help the sector to better meet future customer needs, remain competitive and improve its contribution to the UK economy.

MAKING PROGRESS

Since publication of the Foresight report in Autumn 2001 we have continued to look ahead.

Future scenario

Earlier this year a joint workshop organised by Foresight, CRISP and the Foundation for the Built Environment, brought together 45 industry delegates representing a wide range of industry views, to consider how changes in a world in twenty years time might impact on the construction sector and what should be done to embrace the challenges and opportunities presented.

Participants first gave their views on possible and likely future trends in areas, such as lifestyles and attitudes, environmental issues, political and social issues, and scientific and technical developments. They were then asked to identify the top five aspects that they thought the construction industry should focus on. Their collective responses indicated that top priorities should be placed on:

- New technologies – especially nanotechnology, robotics and artificial intelligence
- Engagement and understanding with users and a better value proposition for society
- Addressing and mitigating environmental impact
- Building on the basis of whole-life performance
- Addressing human resource limitations, training and cross-profession fulfilment

Finally the participants were asked to determine the implications and indicate what needed to be done now to prepare for the future. Amongst the key suggested actions to emerge were the need for:

- A strategic forum to engage the financial institutions and government in developing an alternative value measurement system for construction
- A future 'blueprint' for construction, with consistent principles
- Political champions
- Best practice examples from other countries
- A single institution for construction
- A strategic forum to develop a future vision for the industry

Construction research

In support of the requirement to advance construction innovation and research and thereby improve the overall construction process, the UK Government earlier this year published a review of relevant Government R&D policies and practices, Fairclough (2002). This took into account many of the recommendations of the Foresight report and supported the views that both the Government and industry needed greater and more collaborative investment in construction research.

It proposed a new forum to play a pivotal role in strategic research thinking and called for a strategic vision for construction that acknowledged the construction sector's contribution to the 'quality of life' agenda. It also called for recognised centres of construction research excellence, longer-term and multi-disciplined university-industry research programmes for the built environment and greater support designed to encourage innovation throughout the industry.

IN CONCLUSION

Examining the future and determining what needs to be done now in order to prepare for it, is proving to be a catalyst for action. It remains for the construction sector in the UK to continue to adopt a proactive, rather than reactive approach to the constantly changing world that surrounds it and for which it has the responsibility for ensuring a sound and sustainable built environment for the future.

ENGINEERING PERFORMANCE IMPROVEMENT USING A HYBRID ARTIFICIAL INTELLIGENCE SYSTEM

Luh-Maan Chang and Lei Zhang

School of Civil Engineering, Purdue University,
West Lafayette, IN 47906, USA

ABSTRACT

Industrial construction projects have been experiencing serious problems such as cost overrun and schedule delay. While seeking for the causes of the problems, people have come to realize the impacts of engineering activities on a successful project implementation. Improving engineering performance can lead to better project outcomes. Former studies on engineering performance improvement have either focused on the promotion of certain techniques or products, or looked at specific engineering processes or areas. There is a lack of a systematic and analytical approach that improves engineering performance based on the understanding of the relationships between engineering inputs and project outcomes. The paper proposes a generic model, which integrates genetic algorithms with artificial neural networks, for modeling engineering performance measurement and improvement on industrial construction projects. Due to its robust and efficient search ability in complex situations, genetic algorithms are employed to search for solutions to improving engineering performance with the searching criteria, fitness function, being the neural networks that have been trained to predict performance for given engineering inputs. To make suggestions for possible engineering performance improvement, the research introduces the idea of self-comparison evaluation, which compares a project's actual engineering performance to its possible better performance searched by genetic algorithms.

KEYWORDS

Engineering Performance, Engineering Performance Improvement, Artificial Neural Networks, Genetic Algorithms

BACKGROUND

For a long time, industrial construction projects have been experiencing unsuccessful implementation of projects. An industry survey (Post 1998) reported that one-third of the projects surveyed was over budget and nearly half was delivered late.

The development of an industrial facility spans over five stages: pre-project planning, detailed design, procurement, construction, and start-up and commissioning (CII 1997). Early researches addressed the impact of engineering performance on the overall outputs of a project. For example, design errors, changes and omissions could constitute approximately 10% of the total installed costs of a project while construction mistakes account for only about 2% (Davis *et al* 1989). 25% of the

facility owners surveyed by Post (1998) ranked detailed design as the weak link in the process of facility development.

The Research Team 156 (RT-156) of Construction Industry Institute (CII) conducted a research project to measure engineering productivity and establish the cause-effect relationship between engineering inputs and project outputs. The team studied the industrial project data collected by CII Benchmarking and Metrics (BM&M) Committee. The study reported that the detailed design phase was a prime source of project schedule delays and that about half of the project scope and development changes were initiated during the detailed design phase. The report also pointed out that design errors were the utmost source of field rework and that design-related field rework surpassed that initiated by both owner and constructor (Georgy *et al* 2000).

PROBLEM STATEMENT AND RESEARCH OBJECTIVES

Since industrial projects involve huge amount of investment, even a small percentage of cost overrun or schedule delay will result in serious economic loss. Therefore, there is an urgent need to improve project outputs through improving engineering performance. This research aims at searching for approaches to improve engineering performance on industrial construction projects through integrating genetic algorithms with artificial neural networks. Engineering refers to the detailed design phase of an industrial project. The following objectives are to be achieved:

- To explore the power of genetic algorithms and artificial neural networks in improving engineering performance.
- To construct a plausible approach to evaluating engineering performance

PREVIOUS STUDIES ON ENGINEERING PERFORMANCE

Engineering Performance Measurement

Engineering is a systematic process with inputs and outputs. Engineering performance measurement deals with the output side. The ability to successfully perform the engineering and design activities on an industrial construction project depends on various project input variables (i.e., project attributes and conditions), which are essential in driving its engineering performance. There was a lack of analytical scheme that can approximate the cause-effect relationship between engineering inputs and outputs until the research work of CII RT-156.

CII RT-156 identified a total of 25 engineering input variables and ten engineering performance measures, as shown in Table 1 and Table 2 respectively. Figure 1 illustrates RT-156's framework. The first part is a framework for establishing the relationships between engineering inputs and engineering performance measures through neuro-fuzzy networks. The second part evaluates engineering performance via a composite index, which is the value of a multi-attribute utility function with the engineering performance measures being the variables (Chang *et al* 2001).

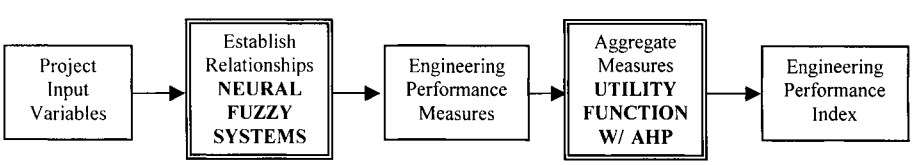

Figure 1: CII RT-156's Framework

TABLE 1
ENGINEERING INPUT VARIABLES

Category	Variables
General project attributes	Project size (total installation cost)
	Contract type
	Relative size of project compared to projects of the same industry type
	Relative level of complexity
	Site conditions
	Legal and environmental conditions
General owner attributes	Owner profile and participation
	Newness of process technology to owner
	Owner previous experience with designer
General designer attributes	Split engineering practices
	Designer qualifications and capacity
	Newness of process technology to designer
Project schedule	Design schedule
	Design-construction overlap
Project information inputs	Completeness of scope definition
	Completeness of objectives and priorities
	Completeness of basic design data
	Quality of constructor input and constructability
	Quality of vendor data
Level of automation	Use of 3D CAD modeling
	Use of Integrated Databases (IDB)
	Use of Electronic Data Interchange (EDI)
Project changes	Percent TIC scope changes
	Change management procedure
	Change communication system

TABLE 2
ENGINEERING OUTPUT VARIABLES (ENGINEERING MEASURES)

Category	Variables
Detailed design value	% design rework
	Design document release commitment
	% detailed design schedule delay
	% detailed design cost overrun
Fabrication and construction value	% fabrication and construction schedule delay due to design deficiencies
	% fabrication and construction cost overrun due to design deficiencies
	% construction hours for design problem solving and field design
	% estimated dollar savings due to constructability
Start-up and commissioning value	% start-up schedule delay due to design deficiencies
	% start-up cost overrun due to design deficiencies

Engineering Performance Improvement

Researchers in the past tried various approaches to improve engineering performance, but most of their approaches are qualitative in nature and have certain limitations. The limitations come from the fact that some approaches promote the use of a specific technique or product and some look at specific areas of engineering and design activities (Armentrout 1986, Atkin and Gill 1986, Breen and Kontny 1987, Choi and Ibbs 1990, Ginn and Barlog 1993, Teicholz 1996). There is a lack of a systematic and analytical approach that looks at improving engineering performance based on the understanding of the relationship between engineering performance and its driving factors (Tables 1 and 2).

THEORETICAL FOUNDATION

Artificial Neural Networks (ANNs)

ANNs emulate the behavior of human neurons as well as their learning ability. Their basic element is also called neuron (or node). All neurons are organized in layered structure and connected with weighted links. There is always an input layer where the initial stimulus happens, and an output layer where the final reaction of the system is shot out. There could be more than one hidden layer. ANNs' two major functions are learning and recall. Learning is the process of adapting the connection weights in an ANN to produce the desired outputs in response to inputs. Recall is the process of producing outputs in accordance to specific inputs using the knowledge obtained through learning (Tsoukalas and Uhrig, 1997).

Genetic Algorithms (GAs)

GAs are robust general-purpose search program based on the mechanism of natural selection and natural genetics (Holland 1972). Genes and chromosomes are the fundamental elements in GAs. A chromosome is a string of genes. In a real problem, genes are the variables that are considered influential in controlling the process being optimized, and a chromosome is a solution to the problem. GAs search for the optimal solution from populations of chromosomes. In this research, the genes will be the 25 input variables in Table 1. A chromosome is a set of the 25 input variables. There is an objective function (preferably called fitness function) in GAs. The search process seeks the maximum or minimum value of the fitness function. Crossover and mutation are two basic operations in GAs. Crossover is a process of producing new individuals by recombining the information contained in two parents. Mutation alters individuals randomly by changing the value of some of the variables.

MODELS

The fundamental approach of the research is to employ GAs to search for the engineering performance inputs that lead to optimal engineering performance. The neural network system shown in Figure 1 serves as a complicated fitness function. Three models were built.

- Engineering Performance Index Model (EPI Model).
- GA-ANN-Integrated Search Model (GA-ANN Model).
- Engineering Performance Evaluation Model (EPE Model).

EPI Model

EPI model is in essence the framework of CII RT-156. As illustrated in Figures 2a and 2b, EPI model is comprised of two parts. The first part is 10 neural networks that establish the relationships between the 25 engineering inputs and the 10 engineering performance measures respectively. The

second part is a multiple attribute utility function that takes the outputs from the 10 neural networks in the first part as its inputs and translates them into a composite utility score, called engineering performance index.

The 10 neural networks, after being trained, can predict performance measures for given engineering inputs. The 10 engineering performance measures depict, from different perspectives, the quality of outputs of engineering activities. However, if it is required to evaluate a project or to compare it with another one, it will be hard to make the judgment when 10 varying measures are presented. Therefore, there comes the need for a single composite measure that indicates the overall level of engineering performance and contains the information embedded in the 10 measures. Through multiple attribute utility function, an engineering performance index is defined on the scale of [0, 1] with 0 depicting the poorest engineering performance and 1 the best performance.

Thus, through the trained neural networks in EPI model, if given engineering inputs, EPI model can make prediction on engineering performance through both a group of 10 different measures and an overall engineering performance index. The set of 10 measures gives a comprehensive view of engineering performance. The engineering performance index will be used as fitness function value in the following GA-ANN model and EPE model.

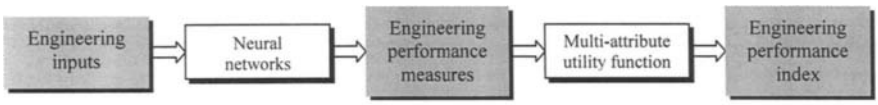

Figure 2a EPI Model -- General Idea

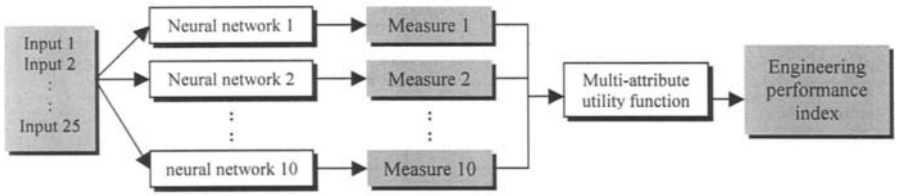

Figure 2b EPI Model -- Breakdown

GA-ANN Model

GA-ANN model, as shown in Figure 3 on the next page, depicts a typical genetic search process. The most distinguished feature of GA-ANN model is its fitness function, EPI model. This is where the GA-ANN integration happens.

The genetic search starts with an initial population. The initial population is comprised of a number of individuals. Each individual is a chromosome consisting of 25 genes, each of which corresponds to an engineering input. Then, all the individuals in the initial generation are evaluated through the fitness function, EPI model. Each individual, a set of 25 engineering inputs, is presented to the trained neural networks. The fitness function value will be the predicted engineering performance index. Then the initial generation goes through the genetic operations: selection, crossover and mutation, during which individuals with higher fitness values get selected, reproduced, crossed over and mutated. Thus, the second generation is formed, and the fitness values are assessed for its individuals, ... This process keeps going on until a certain termination criterion is met. Usually the termination criterion can be a desired fitness value, the maximum number of generations or

computation time. By the time the process stops, one or more sets of engineering inputs will be identified as the ones that can lead to an engineering performance levels close or equal to the desired one.

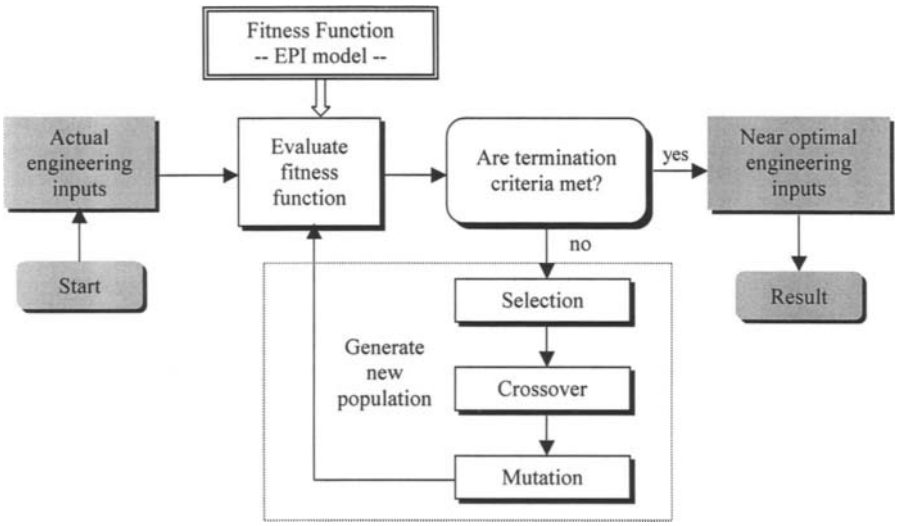

Figure 3 GA-ANN Model

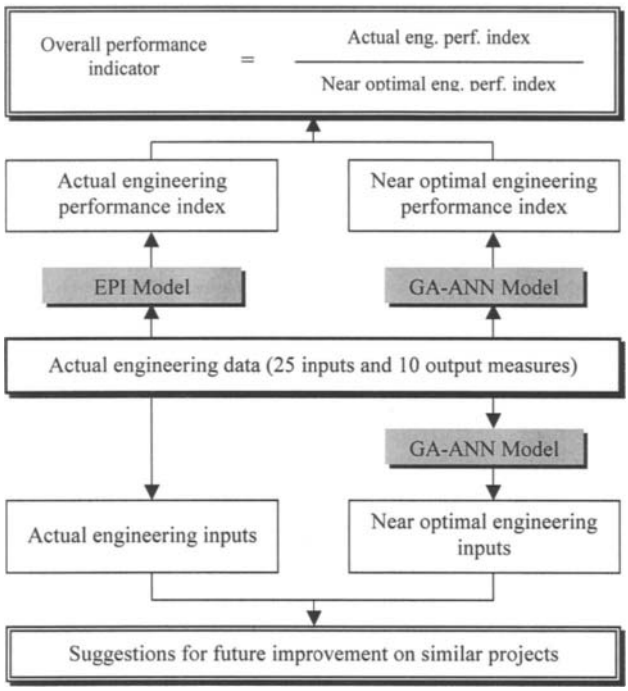

EPE Model

EPE model is the implementation of both EPI model and GA-ANN model, as shown in Figure 4. The fundamental idea of EPE model is a self-comparison concept. The following explains the idea.

As shown by the up-arrows in Figure 4, through EPI model, a project can get an engineering performance index that to some extent indicates its actual level of performance. The same project can also obtain a near optimal engineering performance index through GA-ANN model. The self-comparison compares the actual index with the near optimal one and uses the ratio as an overall performance indicator to indicate how much of the engineering performance potentiality has been realized on this project.

Thus, the evaluation is made by comparing what has been done to what could have been done on the project rather than by comparing the project to a common standard. Previous studies tried to find or create a common standard and made evaluations by comparing actual projects to the standard. However, industrial construction projects differ significantly from project to project, and clients and contractors keep a stable and long-term partnership that makes their projects highly customized. Therefore it is not appropriate to find a common standard for all projects even in the same category of heavy processing facility construction. This justifies the self-comparison idea.

EPE model does another self-comparison shown by the down-arrows in Figure 4. For a project, GA-ANN model can search for the near optimal engineering inputs. Comparing the actual engineering inputs and the near optimal ones may point out where improvements should be made on similar projects in future.

How the Models Work Together

EPI model, GA-ANN model and EPE model work together in a relationship shown in Figure 5. EPI model is the foundation that provides fitness function for GA-ANN model and serves as prediction model for both GA-ANN model and EPE model. GA-ANN model does near optimal search for EPE model. EPE model is the implementation of EPI model and GA-ANN model based on the self-comparison concept.

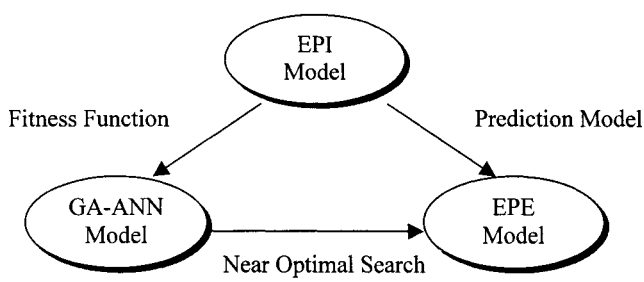

Figure 5 Relationships between Models

ANTICIPATED APPLICATIONS OF THE MODELS

For past projects, GA-ANN model and EPI model together search the near optimal engineering performance and the corresponding engineering inputs, and EPE model makes the overall engineering performance evaluation and points out what could have been done to achieve better engineering performance.

For future projects, GA-ANN model looks for the possible near optimal engineering inputs and outputs for the project. These anticipated project inputs and outputs might act as the guideline and goal at the actual implementation stage.

DATA ANALYSIS

The project data for validating the proposed models are being collected by the authors.

SUMMARY

This paper proposed a systematic approach to improving the practice of engineering performance. The fundamental idea is to find the possible best practice of engineering activities for a given project. To pursue this, artificial intelligence techniques are employed to build the models. Artificial neural networks provide the ability to establish the relationships between engineering activity inputs and engineering performance outputs, and genetic algorithms serve as a search engine to find the possible best engineering practice based on the relationships between engineering inputs and outputs identified through artificial neural networks.

LIFE-CYCLE INTEGRATED MANAGEMENT INFORMATION SYSTEM (LMIS) OF CONSTRUCTION PROJECT

HE QING-HUA

Research Institute of Project Administration and Management, Tongji University
Shanghai, 200092, P. R. China

ABSTRACT

Information systems, which are almost separately developed for Development Management in the decision phase, Project Management in the implementation phase and Facility Management in the operation phase, just serve their own separate management purposes and are established in different project languages and work platforms. Flexible, effective and efficient information communication is difficult to realize and this causes many potential disadvantages. The paper puts forward the concept of the Life-cycle Integrated Management Information System (LMIS); and focuses on the framework of the information model, and the level and method of system integration.

KEYWORDS

Life-cycle, Integrated management, LMIS, Information model, System integration

The Life-cycle period of a Construction Project is composed of a decisions phase, an implementation phase and an operations phase. Each phase has a corresponding management method, Development Management (DM), Project Management on behalf of the owner (OPM) and Fkacility Management (FM). The Development Management Information System (DMIS) used in the decision phase, the Project Management Information System (PMIS) used in the implementation phase and the Facility Management Information System (FMIS) used in the operation phase are almost independent and isolated, only serving their self-management and not able to share and integrate information and data. The main ineffectiveness are presented bellows:

(1) Because the owner's management in the decision phase, the implementation phase and the operation phase are almost separated, the information that should be inter-related is created by individual information system. The data just serves special phase and could not be applied in other phases directly.

(2) Information systems for the different phases have different data structures and platforms. The data created in different phases cannot be shared, which causes the same data to be input several times. Resource waste and a lot of unnecessary mistakes are caused.

(3) During the information communication in different phases, much valuable information is easily omitted. Because of the separation of the DMIS, PMIS and FMIS, many communication obstacles occur and effective information is attenuated. Information cannot meet the needs of the information receptors.

(4) Information communication in different phases easily distorts the information also. When information is transferred between different users, such as a development manager, the project manager and the facility manager, the original meaning will be altered in many cases.

(5) Information transferred through different phases is delayed or interrupted [2].

(6) The cost of information processing is increased.

(7) Information transparency is reduced [13].

(8) The Information system cannot assist in the realization of the planning and life-cycle control aims.

(9) It leads to information content overload in communication in the different phases, and also makes it difficult for management the documentation in different version [3,4].

1 DEVELOPMENT TREND OF MIS APPLIED IN CONSTRUCTION PROJECT

With the rapid development of communication technology and information technology, more and more attention is paid to the applications of Management Information Systems in the construction industry. In general, five key points are as follows:

(1) Among the different Management Information Systems (such as PMIS and FMIS), and the Management Information System subsystems (such as the finance management subsystem, cost control subsystem, contract management subsystem), research into systems integration has been paid more and more attention. Information sharing and data efficiency could be reached through using a uniform data structure and a more effective Documentation Management System [5,15].

(2) The integration of Management Information Systems applied in the construction industry and other computer-aided systems are being improved. Examples include the integration between FMIS and CAD system, and between cost control systems and CAD systems [6].

(3) With the adoption of a unified and open standard technology, such as TCP/IP protocol and java language platform, an openness is greatly improved. The reliability of the Management Information System on special software and hardware platforms will be reduced, its transplantable ability and inter-operation will continuously improve, making extension and application easier.

(4) A Management Information System attaches more emphasis to the integration of a computer network platform, so that different location projects can be managed conveniently, such as linear infrastructure projects [1,12,14].

(5) Management Information Systems are adopting more advanced systemic methods (such as the technology of Object-Oriented system analysis and design) and emphasizing users' participation which improve efficiency and agility in developing the systems [5.15].

2 THE CONCEPT OF LMIS

Based on the analysis of trends in development and the weakness in traditional Management Information Systems applied in the construction industry, the paper puts forward the concept of Life-cycle Integrated Management Information System (LMIS) for construction project. LMIS may be defined as an integrated human-computer interoperability system serving the investor, developer, operators, development managers, project managers, facility managers; it uses software, hardware, network communication equipment and other office equipment, and its aim is to realize the objective of the life-cycle management target (including cost objectives, schedule objectives, quality objectives, etc.) . It enables all the different participants to acquire and process life-cycle information accurately, on time, efficiently and effectively in supporting them to plan and control the project.

LMIS should possess the following characteristics.

(1) Integration
Interior and exterior integration are the two main aspects of the LMIS integration. Combined with Text data and Graphic data in the system, LMIS maintains the integration of the data by cooperative working with different function models in different phases of the life-cycle period. To reach this goal, the best method is to put all the data for the different phases of the life-cycle period into the same central database. LMIS should have an openness of input and output which can link to exterior systems so as to achieve integration with outside data.

(2) Openness
LMIS should have good compatibility with other systems and could examine the reliability of outside data to ensure safety. The GRANID system developed by GIB engineering consulting company in Germany has many merits to be referenced. The system is able to process data with different formats, such as inputting graphic data with DXF and DWG, inputting text data with PCX and ASC II , using SQL to exchange data with RDBMS, and receiving PDS, DXF, DWG, HPGL, HTML, ASC II .

(3) Better communication
In the decision making for, implementation and operation of modern construction projects, different involved participants provide service in different locations. To realize the life-cycle objective, LMIS should possess strong communication capability. Distributed database's Client-Server systems could be applied to organize information created in different phases during the life-cycle period. Users in different locations use the same central database independently and harmoniously as in a virtual LIMS' office. Consistency, continuity, integration, safety, reliability of data in a central database could be ensured through the definition of centralized and distributive working processes. By using data safety and security technology, data safety on a network platform could be achieved.

3 INFORMATION MODEL OF LMIS

A unique information model is necessary for information communication and processing among different phases and involved participants. But, LMIS should receive information such as CAD files, and other information and data from designers, contractors and suppliers. This could be realized through interface processing programs.

Using the unified information model to integrate information in different phases and between different participants has been paid more and more attention in recent years. The paper analyzes and compares the following information models focusing on the establishment of a unified information model: Building Construction Core Model (BCCM), Information Reference Model for AEC (IPMA), Building Project Model (BPM), information models in Information/Integration for Construction (ICON),

Unified Approach Model (UAM), General Construction Object Model (GenCOM), ATLAS LSE Project type Model (PtM), Generic Reference Model for life-cycle facility management 【2,3,9,10,11,16,17,18】.

The BCCM is suited for ISO STEP and has more advantages compared to other models. Figure 1 is the framework of BCCM information model 【9】.

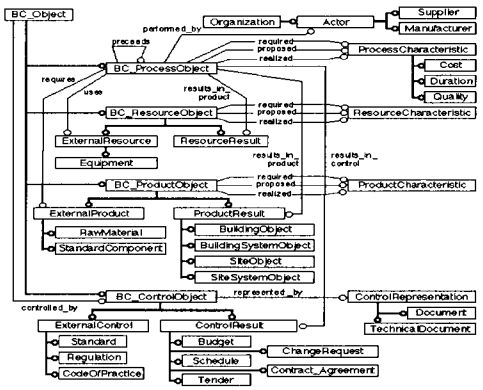

Figure 1: Framework of BCCM information Model

The BCCM information model reflects the relationships among the parts of a project. It could be used as a carrier for all the information in life-cycle management. Thus the central database can be defined and this database is surely well integrated. Meanwhile, the BCCM information model has good adaptability. It is suited for all different kinds of construction projects. It could be used as the basis of the LMIS information system design. To satisfy the character and requirement of LMIS, the BCCM information model should be adjusted in the following ways.

(1) The Product object is the description and definition of the construction project physically including the space usage. It will be adjusted until it is identical to the project, and used as the core of the LMIS information model. The Product object may be defined using a project breakdown structure and code system.

(2) Information objects for life-cycle integrated management is made from procedure objects, control objects and resources objects. Every information object is defined through several attributions.

(3) Building the relationship between project breakdown structure and all the information objects. Any node of the project breakdown structure may become a carrier of a certain information object and its attribution. So all the management functions can be linked through a project breakdown structure, and the data used for the same management function is integrated and the data from different management function is integrated too if necessary.

(4) The project breakdown structure based on product objects and information objects is a two dimensional information model of LMIS. Thus all the information in a construction project's life-cycle phase is integrated with the help of a project breakdown structure, and could be integrated in different ways for certain information objects such as contract, time, cost. etc..

According to the principles and methods just discussed, the system structure of an LMIS information model should be established as in Figure 2.

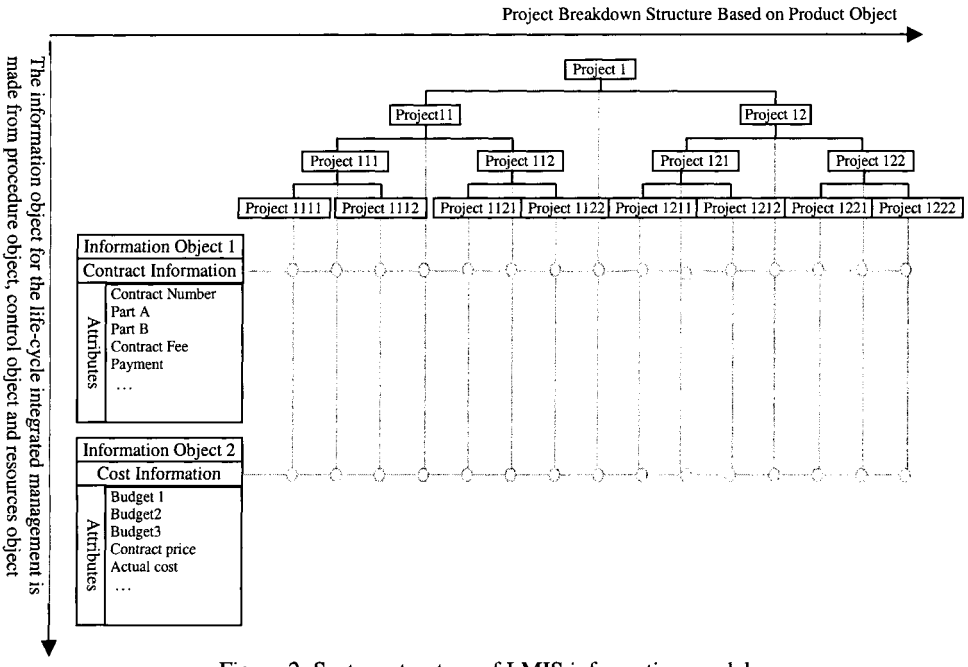

Figure 2: System structure of LMIS information model

4 INTEGRATION LEVEL AND METHODS OF LMIS DEVELOPMENT

Generally, the development of an LMIS follow two basic methods: integration based on a single project database and the integration based on an interfacing approach [15]. The integration level of the former is higher and the system has uniform information models and databases, and the integration level of the latter is lower. The latter comprises only communication between systems, and there is no uniform information model connecting different programs, databases, interfaces and project views. Normally the programs exchange data by links or an integrating environment [19]. After a comparison and analyses of many similar systems, the OPIS (Object-model based Project Information System) and GRANID system have significant advantages for studying the approaches and levels of LMIS.

Thomas Frose, who pursued his Ph.D. degree in Standford University, first declared the OPIS system in 1992. The main aim of OPIS is to realize computer-aided management integration through shared Object Oriented Models. Figure 3 shows the Integration levels and structure of the OPIS system [18].

OPIS system has four integration levels.

(1) System-level object. It includes system-level control and shared objects and allows users to switch between different applied models through an interface.

(2) Shared central database. It is shared by all applied models and is the core of the system. The system uses the database to store all information related to different applied models. The database has applied Objective-C for the writing of Shared Object Libraries for managing the system.

(3) Modules application. This has the ability to input and analyze the input data. The applied models defined in the OPIS system include libraries browsers, planning based on expert systems, cost-control, schedule-control and CAD links.

(4) Stand-alone Applications. This level introduces Stand-alone Applications, such as CAD to the OPIS system by the created linking models.

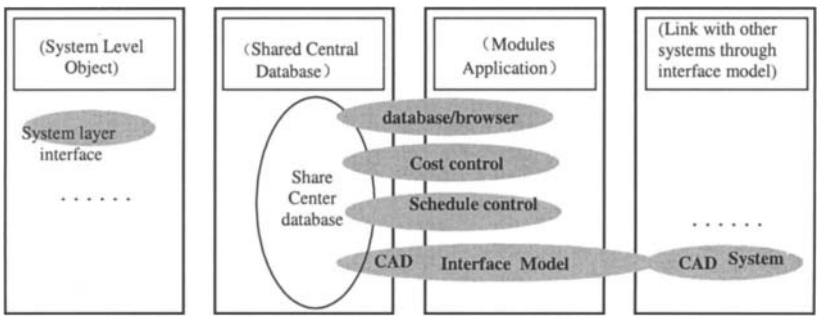

Figure 3: Integration levels and structure of the OPIS system

The GRANID system is developed by the GIB Engineering Consulting Company in Germany. It is integrated software approximately achieving the philosophy of a life-cycle integrated management information system. The application modules of the system include: strategic planning of project decision-making, project management and control, and facility management. [9]. Integration Levels and Methods of the GRANID system are shown in figure 4 [9].

Figure 4: Integration levels and method of GRANID system

The core functions of the GRANID system, such as cost-control, schedule control and strategic control, CAD management and housing handbooks, are based on a central database and ensure the consistency of the data for the Life-cycle period. The core functions include:

(1) Linking. In order to achieve flexible integration and process data with other applied systems.

(2) Reliability verification. In order to verify the data read by other applied systems and ensure the data input meet the applied requirement of the GRANID system.

(3) Report system. To provide different detailed-level reports to different users.

(4) Search system. To provide on-line search facilities and allow users to search by different combinations of methods.

(5) Management Information System. This is a user interface to the Report System and Search System, to provide a series of visualization express tools for such as figures, traffic lights [7].

The integration levels and method of LMIS are as follows based on the analysis of the OPIS system, GRANID system and other similar system.

(1) The life-cycle integrated management information system of a construction project should be based on a central database. Through the building of the central database, is achieved a management function including Development Management in the decision phase, Project Management in the implementation phase and Facility Management in the operation phase, which leads to efficient integration of data for different function models and ensures the consistency of data in different stages of the Life-cycle. The definition of the central database must use uniform information models.

(2) The data exchange between LMIS and other mature applied business software applied for designers, contractors and suppliers can be achieved by input-linked programs.

(3) LMIS will provide decision support information through data collection, transfer, processing, storage, updating and maintenance. According to the needs, a report system could output in terms of mature office software formats such as Microsoft Office format. The data exchange between mature office software and LMIS could be realized by an output-linked program.

Integration diagram of the LMIS system is shown in figure 5.

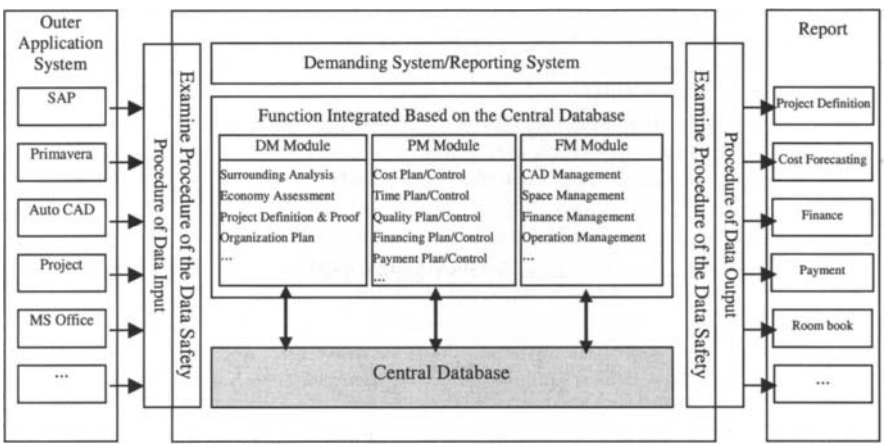

Figure 5: Integration chart of the LMIS system

5 SUMMARY

Recently, with the rapid development of management theories, information technology and communication technology, many researchers have tried to reform the traditional information management methods using different integration means, including product data integration, process integration, multi-disciplinary and supply-chain integration, tools integration and intra-business integration and so on. Compared with other industry, such as the mechanical manufacturing industry and motor industry, the application level of information technology in the construction industry is

much lower. The concept of LMIS uses a systematic view to integrate information in different stages. The aim is to overcome the weaknesses of the current isolated management information systems. The paper studies the key problem of LMIS system development, including the design of an information model, the integration levels and structure of LMIS.

Nagoya University, Japan

ABSTRACT

The mass information generated in the construction phase includes documents such as a bill of quantities and drawings, records of construction and so on. Since this set of information covers the whole construction process of the project and all parties related to the project, it is expected to be useful after the project is finished. A management information system named EPIMS has been developed to support the collaborative work and the sharing of project information through Internet among the multi-party in constructive phase. This paper focuses on the reuse of the project information from EPIMS. The information reuse mechanism is established, and then a system approach to the information reuse is proposed. Finally, a prototype system called EXPLYZER is analyzed and the relative important issues are clarified.

KEYWORDS

Construction Projects, Information Reuse, XML

INTRODUCTION

Computer systems are becoming indispensable tools in Architecture/Engineering/Construction (AEC) industry nowadays. Even in such a narrow field as construction projects, many kinds of software system have been developed and applied. For example, various software systems have been used for cost estimating, scheduling, construction planning, information management etc.

There are two aspects concerning the application of computer systems in construction projects according to the scope of users. One aspect is the application in each party, such as within a constructor company or within an engineer company, and the other aspect is the application among the concerned parties of the project. Although the former is advocated for many years, no single system covers the whole construction process up to now. As a result, the format of information set obtained in the construction process differs from project to project depending on what separate software systems

the party uses in the project, and few standards or regulations have been put forward for managing the format of the information set. On the other hand, as far as the latter is concerned, the use of Internet has made it possible for the multi-party in a construction project to share a software system as a platform of project management.

Two authors of the paper et al. have succeeded in developing such a system called EPIMS (Electronic Project Information Management System 2002). By using the system, the participants of a construction project from different party may submit and reply information through Internet and the information are stored in the database server. Thus the participants can collaborate and share the information according to his role in the whole construction process. As a result of using EPIMS for project management, a uniform set of information is expected to accumulate in the database server in the end of the project. Since this set of information covers the whole construction process of the project and all parties related to the project, it is expected to be useful after the project is finished.

Zantout & Marir (1999) analyzed electrical document management systems (EDMS) used in industry. Dany & Simaan (2000) conducted a study on integrating document management with project and company data based on EDMS. These studies dabbled into but did not solve this problem completely. Yunsik, Mark & Robert (2002) for the first time used the word "Building Documents" to regard the information that can be reused and clarified some basic issues.

This paper focuses on the reuse of the project information that is accumulated during the project by using EPIMS. EPIMS is reviewed with the emphasis on the structure of database. Then the mechanism of information reuse is analyzed. Finally, the system model is established for a prototype system called EXPLYZER and the prototype system is currently under development. Although the discussion in the paper is around EPIMS, the methodology is applicable for similar systems.

REVIEW OF EPIMS

Traditionally, some party needs to submit paper documents in the critical steps in the construction process according some regulations or in response to some request for some other parties to check. For example, when the contractor are prepared on the construction, he needs to submit a report using a specified form possibly with some appendix documents to the engineer in order to start the construction. As a reply, the engineer fills some comments in the report, and then returns it to the contractor.

EPIMS is devoted for the collaboration of multi-party in the management of construction projects through Internet. It provides the mechanism of workflow so that by using EPIMS in the management of construction, the above-mentioned information is submitted and processed through Internet in an efficient way. That is, if the information needs to go through several participants before the process is finished, then it is automated according to the system settings that reflect the regulations. It also provides the functions of browsing the information from several different views, such as by information type, submission date etc. so that the participants can easily look up the information according to his role. In addition, it contains functions of arbitrary querying and graphic representation of query results. If it is used with a spreadsheet software such as Microsoft Excel, the statistics of the query results can be obtained.

In EPIMS, three types of information are dealt with, i.e. report form, reference to report form and appendix documents. Among them, the report form corresponds to the traditional ones, while the reference to report form and appendix documents correspond to the traditional appendix documents, because a copy of the report form has to be appended when it is used as an appendix.

A hybrid scheme of database structure is used to store the three types of information in the system. Namely, XML files and relational database are used to store the first two types of information and normal files such as Microsoft Word files are used to store the last type of information, because the first two types of information are structured and the last one is not. The reason why XML is adopted in the storage of information is that it can better accommodate complex structured information and facilitate the change of report forms without changing the programming code of the system. The reason why relational database is used along with XML files is to raise the efficiency of the system, because XML is less efficient when dealing with simple structured information.

REUSE MECHANISM OF INFORMATION FROM EPIMS

The information accumulated in the construction phase normally includes documents summarized in Table 1. When a project is completed, participants need to extract relative information from the database that contains these documents and conserve it as construction archives for information reuse. This demand is driven mainly by two aspects. One is that companies want to preserve the relative documents for future reference, and the other is that the government forces the owner to submit construction comprehensive information in order to preserve construction evidence and use it in the urban management.

TABLE 1
INFORMATION IN ARCHIVES

Classification	Description	Examples
Project Information	Fundamental description of a construction project	Bidding Documents Drawings Contracts
Construction Information	Information to record various segments of construction activity	Construction Records Quality Control Records Test Records Job Cost Records
Management Information	Information of strategy, activity in management	Conference Records Supervisal Monthly Statements
Other Information	Other aid information	Specifications Licenses

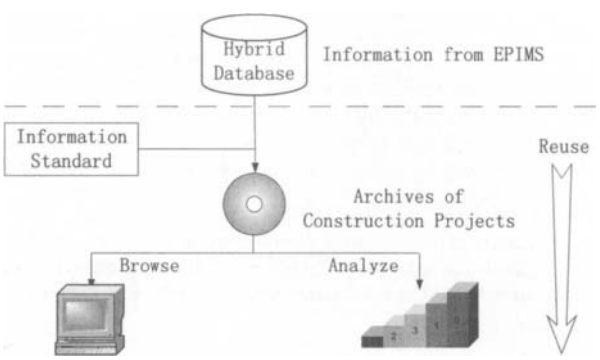

Figure 1: Information Reuse Mechanism in Construction Projects

Figure 1 illustrates the information reuse mechanism in construction projects, where the archives stand for the information in the construction phase that can be reused. To cope with different complete environments of participants, the archives should abide by information standard. Participants in construction projects obtain their archives from EPIMS based on their rights. Participants may reuse the information in their archives for different purposes. The comparison of information reuse among different participants is shown in Table 2.

TABLE 2
INFORMATION REUSE AMONG PARTICIPANTS

	Participant	Purpose	Reuse Method
Common	All	Archives to reconstruct various segments of a project's activity long after it has been completed	Browse Query
Special	Owner	Reference for operating the facility	Analyze
	Engineer Contractor	Consultant when similar jobs with similar problems are encountered in other projects	
	Government	Administration in construction industry	

The minimum objective of information reuse should be to ensure that archives are human-readable so that participants can reuse the information just as the archives in paper form. By using information technology, more efficient method for information reuse method is made possible. Two aspects can be expected. First of all, the function of query can be provided to help users find the desired information quickly. Secondly, the function of analysis can be provided to process the accumulated information to obtain information in the form of statistics, summary etc. to use them in decision-making. As a special case of analysis, artificial intelligence technology can be used to learn from the archives so that a system that can replace expert or at least can assist expert can be developed to cope with the requirements for experience from complex construction projects.

SYSTEM APPROCH ON REUSE OF INFORMATION FROM EPIMS

Conceptual Model of EXPLYZER

Based on the information reuse mechanism, we established the model of EXPLYZER, a prototype system that is named after Explorer and Analyzer, the two main components of the system. The conceptual model is illustrated in Figure 2. A component called Extractor will be developed and embedded in EPIMS to extract relative data from the system database according to the right of the participant. Explorer is the browser for the archives, by using which users can view or query information conveniently, and it can meet the common purpose of information reuse. On the other hand, Analyzer is the component by using which the information is analyzed to provide the users with information for the special purpose.

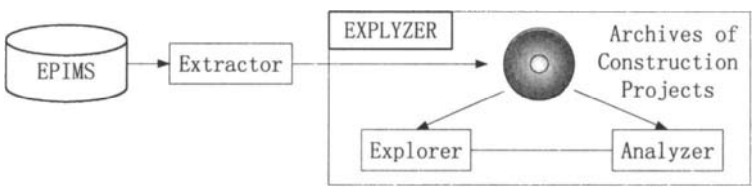

Figure 2: Conceptual Model of EXPLYZER

Structure of Archives

Archives should be a set of stored information. In order to make them be consistent with EPIMS and independent exclusively from a particular database management system, XML is adopted as the standard language in the archives. Namely, while EPIMS uses hybrid database to store the information in construction projects, the derived archives thus consists of mainly XML files without any relational database files.

The archives are formed in a hierarchical structure with 3-tire architecture shown as Figure 3. The core layer is the template layer that contains a set of schemata with corresponding XSL. Each schema can be viewed as the definition of a data container for a type of information, and the XSL file is the corresponding style format (Harold 2000). In this sense, the schema file and the style file together can be regarded as the template of information in construction projects. These templates can be derived based on that in EPIMS. The index tree of archives is described in the upper layer and data instances that conform to the schemata in the bottom layer. In addition, the normal files are connected with the data records through hyperlinks. In this way, any information entry can be retrieved from top to bottom.

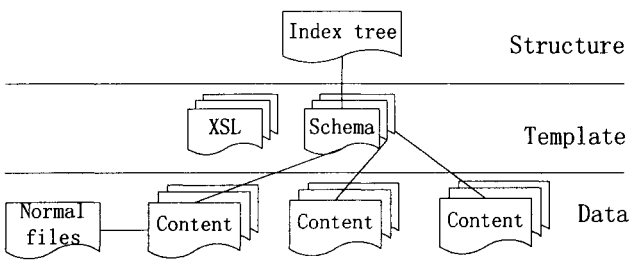

Figure 3: Hierarchical Structure of Archives

In order to efficiently and automatically retrieve the set of documents related to a given project, indexing data is included in the XML files. As shown in Figure 4, the indexing data in documents is directly derived from the reference to report form in relational database in EPIMS and contains references to project, participant, activity and other relative documents.

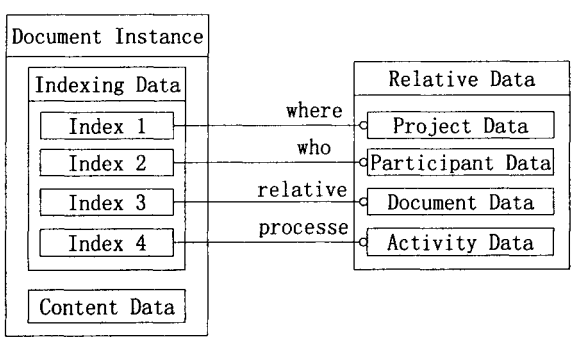

Figure 4: Document Indexing Structure

For example, an inspection record for a concrete beam takes the following form. In the part of indexing data, the information about this record such as the location, the constructor and supervisor of

the beam is described. The relationship between this document and others is represented by hyperlinks, which indicates the complementary information about the beam.

Information Query in Explorer

In EXPLYZER, three methods for information querying are available. They use hierarchical structure; document indexing data and document contents respectively to query. The corresponding algorithms are summarized in Figure 5.

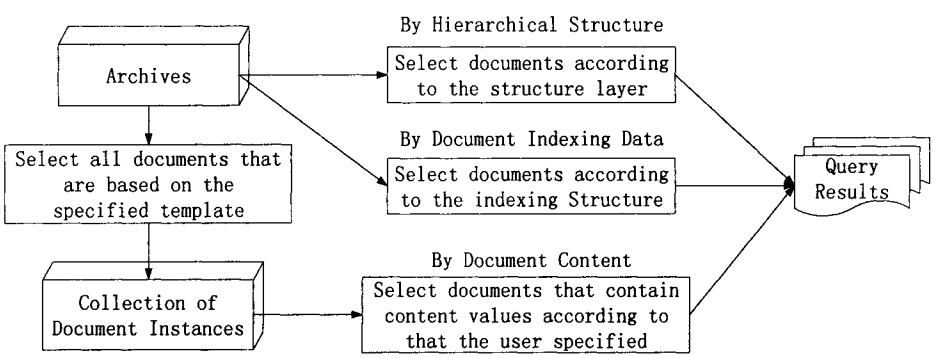

Figure 5: Query Algorithms for Three Supported Methods

The three methods of querying offer increasing detail of information query but with decreasing efficiency. Proper combination of these methods will achieve the balance between function and efficiency. For example, when structural cracks occur in several beams during the operation of the facility, the owner may need to inspect all beams constructed by the same contractor in the same period. He can do this in the following way. Firstly, he finds out the collection of document instances of inspection records in the project with the first method. Then he refines the collection according the contractor with the second method. Finally the required documents are selected by parsing the information item "ConstructDate" with the third method.

Case-Based Reasoning Model in Analyzer

In the experience-oriented construction industry, knowledge and judgments of past experience are critical to solving problems that may reoccur. Traditional mediums for transferring experience such as paper-based documents, photographs, and oral discussions have been found to be inadequate for transferring experience (Manavazhi, 1995). The shortcoming may be overcome by applying new technologies in the Artificial Intelligence domain, such as Case-Based Reasoning (CBR) and Data Mining (DM). Yang & You (1996) discussed the ability of CBR for providing suggestions for the current problem by remembering and learning from results of the past cases. DM is used in knowledge discovery to reveal new pieces of knowledge from large databases (Krzysztof 1998). Based on the CBR process, we establish the conceptual model of the Analyzer component shown as Figure 6.

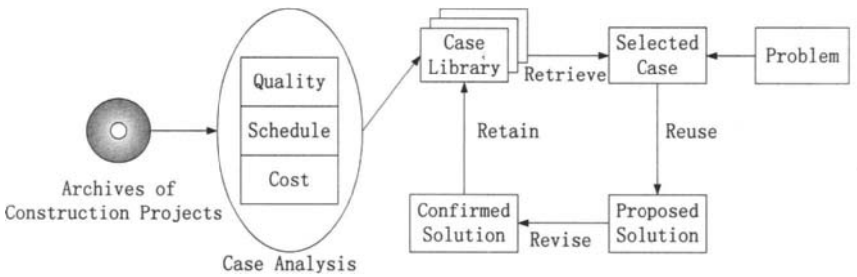

Figure 6: Conceptual Model of CBR in Analyzer

A case library is derived from the archives through case analysis at first. In this step, DM is used to mine the required information hiding in the mass data. Then a suitable case is retrieved from the case library by matching indexes established for the new case (or problem case). The information and knowledge in the selected case is then reused to provide an initial solution to the problem. When it does not fully satisfy the problem specification the proposed case is revised (or adapted) using domain rules and/or human intervention. The revised case is then evaluated and criticized to assess the suitability through the solution and is retained if suitable.

Quality assurance, schedule control and cost management are the major aspects of construction project management and the relative documents constitute the major body of facility archives of the project. So the function of Analyzer will to provide assistant information in these aspects of construction project management.

Now EXPLYZER is under development. The further work will be reported in future papers.

CONCLUSION

This paper focuses on the reuse of the information that is accumulated in construction projects by using EPIMS. The information reuse mechanism is established and then a system approach is proposed. In the approach, a prototype system named EXPLYZER is analyzed and the important reuse are clarified. EXPLYZER provides functions such as browse, query and analysis, which make it possible to reuse the information stored in the archives efficiently.

MOBILE COMMUNICATIONS – THE NEXT GREAT MODIFIER OF OUR HOMES, WORKPLACES AND CITIES

Bill Southwood

Arup Communications, Ove Arup & Partners Hong Kong Limited

ABSTRACT

There have been many technological advances that have modified our cities – the passenger lift, air conditioning and the motor car for example. The revolution in communications between people and machines on the move promises (or threatens) to be the next.

The time taken to travel between, for example, one's home and workplace depends on both distance and mode of travel used. Communications changes the access model radically by allowing work to be conducted at either place or in "third places" such as transport facilities and coffee shops.

Whilst it is too early to gauge fully the effect on the city and its buildings, there are some early conclusions to be drawn. There is the direct impact – antennas on roofs, space for IT equipment, demands for highly serviced work spaces. Secondly there is the effect on peoples' movement – mobile telephones have had a profound effect on peripatetic workers. Finally IT is making an impact on the design of the airports, railway stations, community areas in housing estates and shopping malls. The most advanced are now incorporating cabled and wire-less information access to allow visitors to be continually connected.

KEYWORDS

Information technology, mobile communications, intelligent building.

THE CITY – A COMMUNICATIONS PERSPECTIVE

The city has always been a powerful vehicle for communication. Lyon, at the confluence of the Rhone and Saone rivers, also became a hub for a network of Roman roads linking together parts of the greatest empire the world had known. The natural geography of Hong Kong's harbour, sheltered from typhoons and with entries to the east and west, made it an attractive place for the British Empire to trade in East Asia. Singapore, a trading city-state of great distinction, now seeks to replace trade in goods with trade in information – it sees many similarities.

Up to the end of the 18th century the dominant forms of communication involved sending a letter or emissary (or both) on horseback, coach or sailing ship. The 19th century brought steam to power rail and sea transport. These demanded faster communication, and the electric telegraph was developed. Suddenly it was possible to communicate to the other ends of the country and the planet instantaneously.

The 20th century added the automobile and aeroplane. These were mirrored by the rise of the telephone, firstly in the local environment but rapidly complemented at metropolitan, national and global levels. Telegraph evolved into the telex service which oiled business until the last decade of the century. The telephone dominated both as a means of voice communication and later as a bearer for data. The century also saw wireless communication thrive as a means of point to point communication, broadcast radio and television, and, most significantly in mobile communications.

Communications networks, by their very nature, are more valuable as more entities are connected to them. Your connection to the Internet increases the value of mine without costing me a cent, a true economic externality. Telecommunications networks therefore tend naturally to grow from the center and, as a result, have the potential to change the city's access model dramatically.

As well as allowing access the city also functions as a hub for social intercourse. Edward Lloyds 18th century coffee house allowed men of affairs to meet and found the insurance industry. The 20th century equivalent is the dealing room where men and women of affairs conduct business with their counterparts around the world. Another candidate for the title of heir to the coffee shop might be the internet café.

INFORMATION AND COMMUNICATIONS TECHNOLOGIES

The digital global economy was heralded by IBM's launch of the personal computer in 1980. But this is not necessarily the most important development. The 1970s had been long distance direct dialling become efficient and increasingly economical. People became accustomed to communicating casually over long distances. A relatively primitive and unsatisfactory technology, facsimile was the third major influence, with a boom in almost instantaneous written message transmission.

By the early 1990s fax had created a demand that brought email to the fore. With the growth of worldwide web the PC, previously a device for writing or calculating with, became a communications tool as important as the telephone. The final pieces of jigsaw came in the mid 1980s with the first generation of mobile phones. Although the early examples were heavy and coverage was patchy the industry responded to a demand for mobility in ways which could not have been anticipated.

The synthesis of these technologies is imminent and is about to make the greatest change to the way we live, work and play since the automobile. Third generation (3G) wireless communication promises to deliver all of our information, email, entertainment, multi-media to us "on the move". It will have three levels of mobile cells, the smallest being the pico cell which may cover an area as small as an office floor or a portion of a shopping mall. 3G users will thus be located to within a few meters. Apart from the concerns over civil liberties, the opportunities for providing useful location based information are tantalising. You need never again be lost in a city; you will always know where to obtain a decaffeinated latte; as you walk into the airport terminal your Personal Digital Assistant (PDA) which contains full details of your flight booking will tell the airline you are there, check you in and direct you to the appropriate lounge where your favourite drink will be waiting.

Two fundamental problems arise in the scenario: the first is the sheer volume of information with which people may be confronted. The second problem is security- are you happy to have the information on your Digital Assistant being constantly accessed by others?

The growth in power and speed

In the late 1960s Intel's chief scientist, Charles Moore, predicted that the growth in the power of a computer processor would double every 18 months[1]. This has proven remarkably robust and shows no sign of being invalidated in the next. This implies a 60% compound annual growth. Less well known is a "Law" published in 1998 by Jacob Nielsen[2] which states that bandwidth available for connection to the internet grows at 50% per annum. Thus computer power will continue to outstrip connection speeds. One can extrapolate both of these laws back by 150 years and see that bandwidth has been growing exponentially since the earliest days of the telegraph in the mid 19th century[3]. Figure 1 shows ICT analysed by its bandwidth and the distance over which it can operate. Distance can conveniently be divided into four zones:

- The personal area of a few metres supported by the personal area network (PAN)
- Local area covering an office or building (LAN), in a university or school this may be considered a teaching area network (TAN)
- Metropolitan area (MAN) and its variant for a campus (CAN)
- Wide area network connecting cities and countries (WAN)

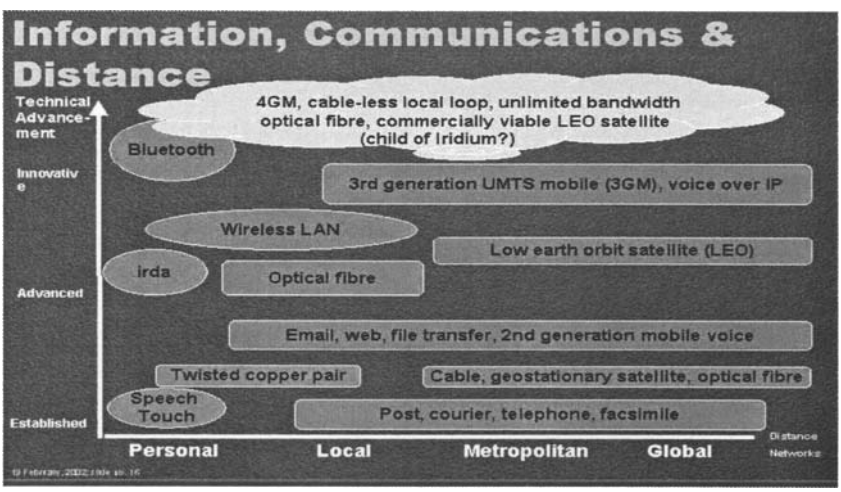

Figure 1: Bandwidth and distance for a range of technologies[4]

Copper cable

Copper has been written off as a transmission medium twice in the last forty years. The first time was in the 60s when the geo-stationary satellite first provided high quality affordable international communications. Submarine cable companies all but closed down in the face of this competition until demand for bandwidth brought cable back into the equation.

Copper survived a second attack from optical fibre a decade later and, once again, survived. For the final connection to the home or workplace, copper is affordable and, able to provide for all but the most bandwidth hungry applications.

Optical fibre cable

Optical fibre is a technologist's dream, having effectively unlimited bandwidth and very low loss making it ideal for long-haul routes between cities or for submarine cables. It is also almost impossible to tap into undetected, made from cheap materials, very strong if correctly installed and terminated and free from corrosion. Termination is complex and more expensive than copper, making it less suitable in the local area where copper is likely to continue to prevail in the foreseeable future.

Wireless communication

Line of sight microwave is a quick and convenient way of connecting over the wide area. It is a convenient way of covering the "last mile", and a number of companies are using it to deliver broadband connections to homes and businesses. For the reasons stated earlier, it is likely to be replaced by cable as the market matures and bandwidth demand increases. Radio and television broadcasting is a major user of the radio frequency spectrum. Not needing any physical connection to the receiver makes it an economical method of dissemination. However demands from competing businesses such as mobile communications operators means that more and more broadcast services are going to be provided over cable to free up spectrum. This reverses the pattern of the last sixty years where your phone was wired and your TV set had an antenna.

The ICT revolution is most evident in the growth in wireless mobile. Nonexistent as a commercial product twenty years ago the mobile handphone has surpassed and in many countries, the wired telephone as the preferred means of voice communication. The implications on our cities are many and various, and include:

- Sites for base stations, masts and antennas are increasingly in demand.
- The user becomes increasingly dependent on the service.
- Mobile communications has liberated people as diverse as plumbers, doctors and travelling sales executives from the tyranny of the fixed office phone.
- The technology is starting to encourage true m-businesses (e-business for mobiles), initially in low speed data applications such as share price information or sporting results.

The Internet and email

The explosive growth of the Internet in the last decade is well documented[5], the Internet and World Wide Web having become the information source of choice for increasing numbers of people. Email has similarly replaced paper and facsimile as the dominant medium of communication.

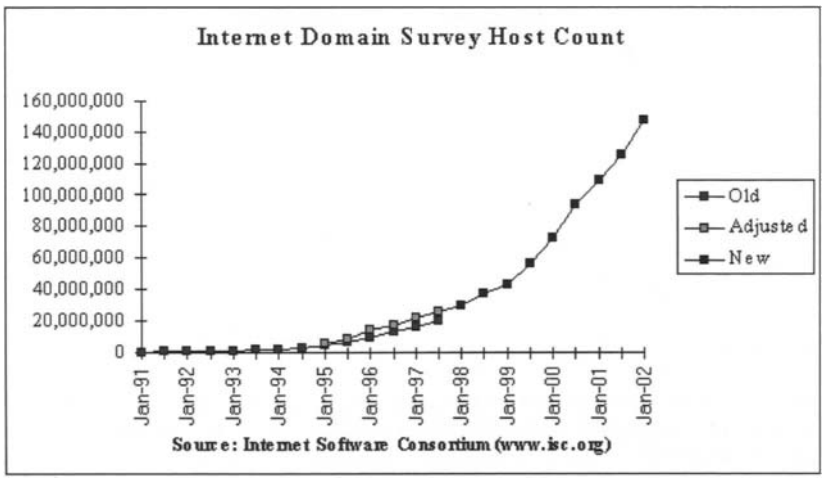

Figure 2: Internet growth

IT, THE URBAN LIFESTYLE AND CITY PLANNING

Good architecture can be said to display three fundamental characteristics: its function or commodity which makes a building or a city work; its firmness which makes it stand up; and delight, an almost impossible parameter to measure but one easily recognized, particularly when absent. In his two seminal books[6] on information and architecture, MIT's Bill Mitchell maps these onto the new age:

- Function is replaced by information, the *raison d'être* of more and more industry;
- Firmness is represented by the network that (more or less) reliably connects organizations in cyberspace (cyborgs) to one another;
- Delight Mitchell sees all around in the endless ways in which the cyborg can work or play in his or her garden.

This trend has both a baleful influence on the city and the potential to re-vitalise it. Technology alienates and fragments - it replaces banks with cash tills, post offices with email, shopping with web browsing, transport with video conferencing, the school with e-learning, the soccer pitch with electronic games and the theatre with a web-delivered video. But using the same technology we are free to re-define our boundaries and interact with a whole new community of people (and other entities). The unexpected success of the short message service over mobile phones is evidence of people subverting the technology in unexpected ways.

Faced with the need to be seen as thoroughly modern, city planners and commercial developers alike have sought to enter partnerships with ICT companies to give their patch a real (or at least perceived) competitive advantage. However even in the late 1990s, well before that decade's whirlwind romance with all things internet went sour, cautionary notes were being sounded. A paper in the British Town Planning Review [7] argued against seeing a technological "quick fix" to issues such as road pricing, access control and advanced commercial development. However others have continued to seize onto the opportunity. London's Chiswick Park has a web site which sums up a cyber-enabled philosophy - www.enjoy-work.com/chiswick-park/index.html.

The intelligently designed building and city

The term "Intelligent Building" tended to be technology focussed. But the building must meet the needs of its owners and occupants. Intelligent does not mean necessarily overwhelmed by technology. Competition for talented staff will be intense; digitally enhanced productivity will be the key to financial success; rapid and radical change organisations will require buildings to adapt and the ownership/rental models change.

The European Commission has funded a multi-disciplinary project SANE – Sustainable Accommodation for the New Economy[8] – to look into these issues and construction. SANE, with representation from organisations in Germany, Norway, Spain and the United Kingdom, will design and develop a work place model within which the different needs of business can be met. This will include the need for both "real" space but will also include "virtual" spaces – the work place I create when I spend time in an airport lounge communicating with my project team 10,000 kilometres away. The synthesis of these two ideas will bring together the thinking which Arup has been developing, often in conjunction with project leader DEGW, in projects such as The Intelligent Building in South East Asia (1995 to 1998)[9]

The Office

Today's office is broadband enabled. From any fixed point a worker can connect over copper or optical fibre cable with high speed data to allow access to multi-media information. The office will be able to change at will to re-locate people into project teams, work groups or individual study locations. The office will be linked to global broadband networks by a combination of optical fibre, line of sight microwave, infra red and satellite – the user will not know (and will not even care) which technology, telephone company or quantity of bandwidth is being used to connect to remote information bases.

Wireless local area networks will complement (but not replace) cabled solutions, providing similar communications to people working in offices, on conference tables or waiting in the lobby. Concern will be expressed over the increased radiation levels at the work place brought about by the systems. This will be particularly important in hospitals where sensitive and life critical processes are underway. The issue of security, both to protect personal information from intruders and to protect systems from damage by viruses, will become increasingly important.

Project teams will need to ensure that the right decisions are taking at the right time so that the building can adapt to this technology. The designs therefore must allow for cable, antennas and equipment – above all producing buildings which can adapt.

Transport nodes

The railway station and the airport terminal present two interesting communications challenges. Both have mission critical systems to enable them to carry out their primary function – to transfer people, goods and information between land and vehicle. In addition however they are places where people spend time and money and also where people will expect increasingly to be connected. The Cathay Pacific lounge at Chek Lap Kok in Hong Kong includes consoles where travellers may swipe their boarding pass through an elegant computer terminal, gain access to flight details, destination city, email or the web.

The back of house systems to support airport and rail terminals are both safety critical and vital to the terminal business. The opportunity to use mobile communications to speed the process of checking in a passenger whilst increasing the level of security can be achieved today – third generation mobile and other technologies will locate the passenger within a few metres.

Once on the aircraft or train the traveller is going to expect to work or play, constantly connected to the information used back at wherever "base" is today. They will also expect to have access to any other media – internet access in the aircraft seat or the rail carriage will become the norm.

Health Care institutions

Like the airport the hospital contains life critical systems which must be resilient, reliable and robust. At the same time they are places where people can spend considerable amount of time. The Hospital Authority of Hong Kong commissioned a study into all aspects of communications within and between their forty-three hospitals. They asked that maximum integration be achieved between, for example the nurse call buttons at the beds, the nurse stations the wards, the physician on the move between hospitals, the pathologist analysing data in a laboratory and the admissions staff. Wireless local area networks combined with the fixed links will allow a radical change to the way patient records are displayed to clinical staff in the laboratory or at the bed side.

Educational institutions

Universities around the world are delivering courses outside their own geographical patch. Almost every major institution in Europe, the United States, Asia and Australasia is linked in some way to provide technical and management courses. The Higher Education Funding Council of England is now implementing a e-University.

The Imperial College School of Medicine in London has used broadband communications, multi-media and audio-visual techniques to resolve the problem of how to teach trainee surgeons and have them available for work in hospital wards at the same time. Video cameras in operating theatres linked to video displays in lecture theatres link the lecturer, surgeon and students, giving unparalleled opportunity for many to participate in operations. There is nothing to prevent this information being transmitted to students anywhere in the world.

The shopping mall

The pico cell knows that you are within two minutes of a range of shops, food outlets and entertainment venues. Your PDA knows that you require a pair of shoes, a bowl of noodles and two tickets to a musical. It shows you which escalators to use to reach them, the options you have and the prices you will be charged. This is possible because the shopping mall has been "wired" with an internal radio network (IRN) which enables it to deliver all of the wireless information services to both the business and the customers within the shopping mall. The search engine will direct you to the commodities – the business will have better and quicker access to its customers.

The home

Research in Japan shows that people open their refrigerator door twenty-seven times more than their front door. The Japanese response has been to experiment with internet enabled refrigerators which tell you the content and age of the food, suggest recipes for your next meal and place orders with your local supermarket for delivery of your next order of vegetables.

People will expect the same high quality broadband connection to their homes as they enjoy in all other places where they live, work or are entertained. The home will be linked by broadband fibre, copper or microwave to a range of global networks. Landlords and local communities are providing portal services to give residents information about transport, security, forthcoming events and local news.

The design of the home, like the office before it, will need to accommodate these technologies efficiently and unobtrusively. The use of wireless will allow devices to communicate without cables, a huge advantage in the domestic environment. Public housing projects such as Shui Chuen O in Hong Kong are looking to adopt sensible levels of communication in both the developments' public spans and individual dwelling units.

The city

The city itself becomes part of this virtual living environment. Different users spend time in different parts of the city – the worker has communication needs while travelling between home and wherever the work place may be today. The home worker will venture out into the city with a different set of needs. Those caring for children, the elderly or the disabled will be more empowered by availability of information about services which are relevant to them. Those being cared for will be less discriminated against. The best modern cities are already universally wired and covered with wireless networks. The latter can cause aggravation as inconsiderate mobile phone users disrupt the tranquility of a park, restaurant or even a concert performance. Technological solutions to these fundamentally human and societal problems, such as jamming, are doomed to fail. Society will adopt a new set of norms, a new definition of "good manners" to define what behaviour is acceptable and what is not. In the meantime the city must ready to embrace the information which is travelling on optical fibres beneath its streets, within the pools of infra red and wireless connection within coffee shops and railway station waiting rooms.

CONCLUSION

Interaction between people, the built environment and the technologies is complex. The key is sustainability, the concept of using less of the earth's resources than we give back. Information technology, mobility and globalisation all have a part to play –a video conference can replace five long distance air journeys; a virtual team can work between a design office in London, a coffee shop in Manhattan and apartment in Hong Kong. Technology in the hands of imaginative people will allow us to work together developing our environment at internet speed without destroying the planet. This view of the future is not just promising, it is essential to the survival of our societies, businesses and life styles.

ONLINE REMOTE CONSTRUCTION MANAGEMENT (ORCM)

A. Weippert
Queensland University of Technology, Brisbane, Australia.

S.L. Kajewski
Queensland University of Technology, Brisbane, Australia.

P.A. Tilley
CSIRO Building, Construction and Engineering, Brisbane, Australia.

ABSTRACT

Unlike many other industries, construction is highly fragmented with numerous design firms, consultants, contractors, subcontractors and suppliers involved in almost any project. Due to the construction industry not having a coherent and integrated computer system that encompasses the whole of the construction process from design through construction to final account and facilities management, even though the today's technology can make this possible, data exchange between project participants is still largely undertaken on paper. In an attempt to bring the unique talents of various construction industry project participants together in a more productive and integrated manner, the Online Remote Construction Management (ORCM) project commenced in July 1999 proposing to test, field trial and/or evaluate online information and communication systems on up to 5 case study projects over a 2-year period. The ORCM research project aims to demonstrate leadership in facilitating the use of online technologies for the design, management and construction of building and civil construction projects, by identifying and implementing appropriate communication and information technology solutions that will ultimately improve resource management, support and integrate total project life cycle considerations, increase efficiencies on projects, reduce overall cost and improve project outcomes. This paper provides final results, findings and recommendations obtained through the implementation of two ORCM Surveys on one of five ORCM case study projects investigated.

KEY WORDS

Construction industry; information technology (IT); internet; communication systems; remote.

INTRODUCTION

The nature of building and civil construction projects requires team members to attend the construction site to resolve issues that arise during the design, documentation, and construction stages of a project. Australia, in particular, is a large country with dispersed projects and team members usually headquartered in the major cities and regional centres. Extensive travel is therefore necessary, with inefficiencies in time and delays in decision-making. Arguably one of the most significant problems presently facing the construction industry is communication. The industry is characterised by inaccurate and untimely communications that often results in costly delays to the progress of a construction project. If the current level of international research activities are any guide, Internet-based communication and information technology (IT) tools, systems and techniques is seen by many as a potential solution to the communication problems – i.e.: allowing seamless collaboration between project consortiums, promoting rapid resolution of ongoing project issues, and thereby reducing the need for unnecessary travel time and cost overruns. Yet, despite advances in computing and IT, the construction industry is making insufficient use of transferring project data and information electronically. McCaffer et al (1991) argue that data exchange between project participants is largely undertaken on paper. This 'traditional' paper-based form of project communication is still common today.

RESEARCH AIM AND OBJECTIVE

The Online Remote Construction Management (ORCM) project - a collaborative research project funded and supported by a number of Australian (Queensland) industry, government and university based project partners - commenced in July 1999 aiming, in general, to develop, trial and/or evaluate communications systems on up to five case study projects over a two-year period (1999 - 2001), allowing collaborative design and construction to be undertaken between members of a geographically dispersed construction project consortium. Thereby fostering the expansion of communication and information technologies in the building and civil construction sectors, and stimulating the use of such technologies in building and infrastructure projects, resulting in an increase in IT knowledge, awareness and skills of companies in both the public and private sector. Additionally, the project aimed to demonstrate leadership in facilitating the use of online technologies for the design, management and construction of building and civil construction projects, by identifying and implementing appropriate communication and information technology solutions that will ultimately: improve resource management, support and integrate total project life cycle considerations; increase efficiencies on projects; and reduce overall cost and improve project outcomes.

PROJECT SIGNIFICANCE

New South Wales Government (Australia) comments that a $10 million project with monthly cash-flows of $500,000 might have as many as 50 contracts, 5 different consultants, 200 tenders, 600 final drawings, 3,000 amended drawings, 150 contract variations, 600 site instructions, and 6 meetings per week. The use of appropriate IT would be invaluable in improving the efficiency and productivity of such projects. Further, the New South Wales Government indicates that even a 1% improvement in productivity on their annual expenditure of approximately $6 billion could fund the equivalent of 1 major hospital or 20 primary schools per annum. Nationally, the construction industry is valued at approximately $30 billion per annum and with preliminary studies indicating

that with appropriate utilisation of IT a 1% improvement in productivity may be conservative, the potential benefit for the construction industry is considerable (Fujitsu Centre, 1998).

CHALLENGES FACING THE CONSTRUCTION INDUSTRY

Love et al, (1996) comments that construction organizations are faced with many new challenges, including the need to: change current work practices; become more client orientated; more competitive as well as productive. These challenges are attributable to the many factors that effect the working environment, such as: globalisation of the economy; greater performance expectations from the clients; increased competition between local contractors; continued restructuring of work practices, and industrial relations. Better information sharing between disciplines and the automation tools used can ensure large improvements in the efficiency, productivity and quality of the building industry (Howell, 1996). It is proposed that more innovative IT (Internet-based) communication tools/systems could be used to help improve the flow of project communications to ensure that communications occur in a controlled, timely and less costly manner than would traditionally be the case, ensure that information leakage is kept to an absolute minimum, and thus ensuring that all members of the project consortia are in possession of the most up-to-date and accurate project information (Figure 1).

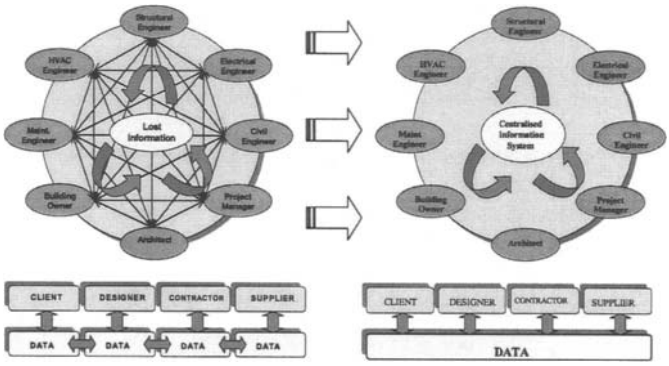

Figure 1: Traditional v Central Project Communication

ORCM CASE STUDY PROJECT (CSP1)

Queensland Department of Main Roads (QDMR) identified and provided access to a truly 'remote' ORCM case study project (referred to as CSP1). The project was completed with the full support of the client and contractor for the project's use as an ORCM case study project. A general description of CSP1 statistics is provided in TABLE 1:

TABLE 1

CSP1 PROJECT STATISTICS

Statistics	CSP1
Client	: QMDR
Project description	: Widening & overlay of Highway
Value at completion	: $ 4.1 million
Contract delivery system	: Traditional
Contract time	: 220 calendar days
Completion date	: March 2001
Primary Contractor	: PNC
Information Technology	: projectCentre

COMMUNICATION TOOL/SYSTEM USED AND INVESTIGATED

The implementation and use of projectCentre (http://www.projectcentre.net/) was examined as the Internet-based IT/communication medium for project communications and document control throughout the various phases of the CSP1 project. projectCentre is a "project web portal" or web-based project management system for construction industry projects. A web browser was all that was required by the project team to gain secure access with the use of a username and password, and/or transmit project documents from any location where Internet services are provided. Project team members sent, received and managed correspondence, requests for information, instructions, variations, drawings and many other documents involved in the construction process.

INFORMATION TECHNOLOGY (IT) ANALYSIS SURVEY

As a part of the ORCM project, research was required into the benefits of IT and (Internet-based) communication tool/system implementation into the construction industry. To ensure an 'Information Technology Analysis Survey' could be administered on the five ORCM case study projects without delay - i.e.: for the evaluation of IT implementation, as well as the benefits, advantages and barriers to that implementation - it was proposed that that the original 'Information Technology Analysis Framework' (Tucker et al, 2000) developed and implemented on the Acton Peninsular Project' be utilised (with publication authors' permission).

ORCM case study project participants, who made use of the various Internet-based IT tools and/or communication systems (including projectCentre), and who completed both sections of the 'ORCM IT Analysis Survey', included: Architects; Consultants; Contract Administrators; Contractors; Engineers; IT Implementation Managers; Managers/Directors; Project Managers; IT tool/system Representatives; Site Foremen; Superintendents; and Superintendent Representatives: In Section 1 ORCM researchers asked project participants, to provide a general background to their role in the project as well as provide a record of past and/or existing levels of IT 'exposure' and/or experience on projects. To determine project and organisational levels of IT implementation and application, as well as identify potential benefits, advantages and/or barriers experienced by that implementation, Section 2 of the ORCM IT Analysis Survey specifically examined IT implementation from 7 different but inter-connected perspectives (TABLE 2).

TABLE 2

SEVEN PERSPECTIVES DESCRIBED

#	Perspective	Description
1	Information Technology	*: Focusing on IT tools used and their technical aspects.*
2	User Utility	*: User satisfaction and perceived value of IT use - based on the extent to which it helps the user do the job more efficiently and effectively.*
3	Project Organisation	*: Role IT plays in facilitating integration of project participants.*
4	Project Management Functions	*: Impact of IT on project management functional goals - information needs, quality and timeliness, and construction.*
5	Benefits	*: Link between IT implementation and any project-related short-term benefits - both tangible and intangible benefits.*
6	Value-adding	*: Relationship between IT implementation and overall project delivery process - perceived value-added aspect of process in terms of generating business value to the client and project stakeholders.*
7	Strategic Positioning	*: Impact on the organisation at the strategic level. It is concerned with how lessons learned in this project are disseminated and hence contributed to the strategic positioning of the organisation.*

IT ANALYSIS SURVEY – RESULTS

In the first section of the ORCM IT Analysis Survey, ORCM researchers asked case study project participants and/or users of the various IT tools and/or Internet-based communication systems implemented on the five ORCM case study projects, to provide a general background to their individual roles/responsibilities in the project, as well as a record of past and/or present levels of IT 'exposure' and/or experience on projects. Results obtained from CSP1 project participants and/or users of the projectCentre system are summarised in Figure 2:

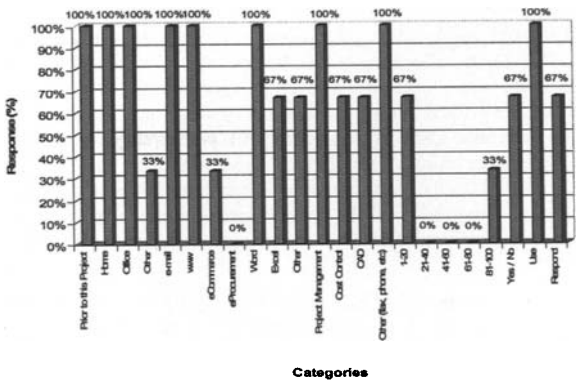

Figure 2: CSP1 Results - General Information

Similarly (for comparison purposes), Figure 3 summarises the combined/average result (%) calculated from responses provided by project participants and/or users of the same or similar IT tools and/or Internet-based communication systems implemented on the remaining four ORCM case study projects for the same 'General Information' criteria.

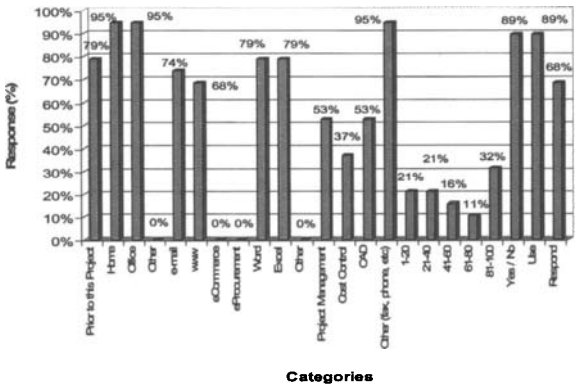

Figure 3: Combined Results of Remaining Four ORCM Case Study Projects - General Information

CSP1 results verify majority of percentages calculated for each criterion (Figure 2), exceed the combined/average percentage scores calculated from the remaining four ORCM case study project participant responses (Figure 3). This comparison provides a reasonable indication as to how CSP1 participants compared against the participants of the remaining four ORCM case study projects, i.e.: in relation to their individual IT strengths, weaknesses, levels of computer and software 'exposure', experience and/or usage, etc.

CSP1 project participants and/or users of projectCentre were also asked to score each of the 7 perspectives (TABLE 2), by allocating a number between 1 (lowest) and 5 (highest) to each (weighted) criteria listed within each of the seven perspectives. ORCM researchers then combined and 'manipulated' the individual scores to obtain an overall percentage (%) or rating for each perspective - i.e.: to determine CSP1 project participants perceived (overall) level of satisfaction for each perspective. Percentage ratings for each perspective were then 'ranked' to help illustrate CSP1 project participants' overall level of satisfaction and perceived influence the implementation and use of projectCentre had on the project (TABLE 3). Project participant responses, ratings, comments and/or suggestions were analysed and assessed in accordance with the framework proposed in Kajewski, et al (1999).

TABLE 3

CSP1 –RANKING OF SEVEN PERSPECTIVES

Rank	Perspective	Rate	User Satisfaction and Influence On Project
1st	Information Technology	68%	Highest

2nd	Project Management	62%	Above average
3rd	User Utility	58%	Average
4th	Strategic Positioning	56%	Low to average
5th	Value Adding	55%	Low
6th	Project Organisation	53%	Low
7th	Benefits	52%	Lowest

ORCM 2ND QUESTIONNAIRE

Additionally, research and analysis was required of a more 'qualitative' or 'descriptive' nature - i.e.: to help determine levels of personal 'impact' and/or influence each project participants perceived the implementation of an IT tool and/or Internet-based communication system (ICS) had on each of the five ORCM case study projects. This was achieved by implementing the 'ORCM 2nd Questionnaire', made up of fifteen questions, summarised in TABLE 4.

TABLE 4

ORCM 2ND QUESTIONNAIRE

#	Question
1	What has gone well with the use of [*ICS*] in this project?
2	What has not gone so well?
3	What problems have you had with implementing and using [*ICS*]?
4	How have the above problems been addressed?
5	Has the use of [*ICS*] improved communications in the contract?
6	How have you and/or your organisation overcome administrative and legal issues associated with using electronic as opposed to traditional methods of communication?
7	What types of communication are most suited to a [*ICS*] process?
8	What types of communication would you recommend that one should not use a [*ICS*] process for?
9	Has [*ICS*] improved efficiency on the project?
10	Has [*ICS*] assisted relationships on the project?
11	Would you recommend the use of [*ICS*] on future construction projects?
12	Would [*ICS*] be useful for pre-construction or maintenance activities?
13	If so, how?
14	What should one do to more effectively use [*ICS*]?
15	Kindly include any additional comments, recommendations, etc. that you may have regarding the implementation of [*ICS*].

CRITICAL SUCCESS FACTORS

In summary, based on the assessment by the researchers involved with the CSP1 project, combined with the comments provided during interviews and responses from project participants to the two ORCM questionnaires ('ORCM Information Technology (IT) Analysis Survey'; and the 'ORCM 2nd Questionnaire'), a list as a of critical success factors were made to help ensure successful implementation of IT tools and/or Internet-based communication systems (including projectCentre)

and/or processes for similar geographically dispersed (remote) civil and building projects, including:

- Main stakeholders need to strategically plan the implementation - creating a feeling of trust (reliability, relevance etc) to the potential user.
- Ease of use / compatibility- both client and contractor wants to learn only one system for ease of use - commonality of access, features and data entry is most important.
- Quality and accuracy of any project related communication or information (electronic or paper based) is still directly dependant on the user of the IT tool and creator of that piece of information or correspondence.
- Training and system support are a must, including on-demand onsite, or on-line demonstrations of the proposed IT tool or communication system.
- Trailing an incomplete system or one that has not had much exposure to users should be treated as a 'special case' and not left to the users to solve the problems. Best practice would be to adopt a 'proven' simple to use systems, or systems compatible with most other IT products and/or systems used in the industry which will not be unfamiliar to "new" users - potentially saving overall project time, cost, labour, errors, etc.
- Any implementation of a new system should be fully resourced to ensure that all aspects are covered during the early stages of development - reassuring users there is a corporate commitment (including hardware / communications provisions, and IT 'Help Desk' support).
- Reliability and adequacy (including sufficient speed) of the communications is essential to gain commitment from potential users. If it works well, new technology will be taken up so cutting costs on critical parts of a new system should not be considered.
- User is a key factor in gaining advantage from an IT system - taking only the type or potential advantages of a newly developed IT tool or communication system into consideration, is not enough during implementation on any remote project site; users needs must be a prime focus.
- Legal issues such as electronic signatures and requirements for hard copies need to be clarified.
- All project participants and stakeholders need to be fully committed to using the new IT tool or communication system, with "buy in" at the highest level within the participating companies. The project Superintendent (or equivalent) should be the driver of IT uptake for a project.

CONCLUSION

The Online Remote Construction Management (ORCM) findings help reinforce the need for further research and monitoring of IT tools and Internet-based communication systems development and level of adoption within the construction industry. Ensuring over time, all building and civil construction sectors project stakeholders realise the benefits of IT adoption thus overcoming barriers to changing existing organisational behaviours; people (culture); communication processes; structures and tasks. *"Without doubt the ability to bring people and technologies together in two-way communication will have major social impact and integrate the world in a way that we have never experienced before"* (Brandon, 2000).

ACKNOWLEDGEMENTS

The ORCM project was a major research project undertaken by the Queensland University of Technology (QUT) Commonwealth Scientific Industrial Research Organisation (CSIRO) Construction Research Alliance, based at the Queensland University of Technology, Brisbane, Queensland, Australia - jointly funded (July 1999 to December 2001) by the Queensland

Government Information Industries Bureau (IIB) Department of Communication and Information, Local Government, Planning and Sport; the Queensland Department of Main Roads (QDMR); the Queensland Department of Public Works (DPW); and the Queensland University of Technology.

ABSTRACT
This paper presents our experience gained from developing an industry-university collaboration through conducting research projects based on the use of computer-aided construction technologies. A research project, which is to develop the VHBuild (a Web-based project management system, is analyzed as a case study from the viewpoint of collaborative efforts of university researchers and industrial practitioners. The case study reveals many issues and discussions related to the current growing interest in developing IT applications to the construction industry.

KEYWORDS
Industry-University collaboration, innovation and development, construction IT.

INTRODUCTION

Yau Lee Construction Ltd (Yau Lee) is a medium-size contractor in Hong Kong. Because of its size and previous successes in investing in advanced construction technologies, the company was convinced, in early 1997, of the necessity to have sufficient in-house Construction IT expertise to be able to gain a competitive advantage in the Hong Kong construction market. Since then, Yau Lee actively pursued the adoption and development of advanced construction technologies and IT technologies. An early example is the design and implementation of a 4-day construction cycle which incorporates the use of prefabricated window facades, semi-prefabricated floors, prefabricated partition walls and staircases. Later on, this 4-day cycle was further improved by the introduction of fully prefabricated bathrooms which is the result of a collaboration with Yau Lee and the Hong Kong Polytechnic University.

At the same time, Yau Lee started several initiatives on the use of IT systems in its construction projects. From the very beginning, the company understands the IT research and development can not be as productive as it would need to be in the construction production business. Akin to any high-tech endeavor, the risk of failure is high, but even if there are only 3-5% of the projects are successful, the benefits and profit-returns can cover the entire investments.

Realising there wasn't sufficient expertise and technical strengths in the Company, the management of Yau Lee contacted Professor Heng Li (the academic partner) in the Department of Building and Real Estate at the Hong Kong Polytechnic University. The first collaborative project was the development of a computer system to integrate the preparation and visualization of interior designs, estimation of costs of interior designs, and virtual walk-through of the designs so that project participants can get a realistic appreciation of the project before the commencement of the construction. During this collaboration, the company provided the necessary funding support, users requirements, testbeds and feedbacks on the various developmental stages of the system. The academic partner was responsible for the system design and implementation of the system. As the academic partner is abreast with the most recent information and developments in the topical area, he can ensure that the technologies embedded in the system are the most suitable and updated.

The initial collaborations between Yau Lee and the academic partner enabled them to build a strong sense of trust and better understanding of the collaborative roles. This has proven to be crucially important for the continuing success of upcoming collaborations. Among other projects, the major collaboration has been the development of the VHBuild system which is a Web-based construction project management system.

VHBUILD: AN EXAMPLE OF INDUSTRY-UNIVERSITY COLLABORATION

VHBUILD can serve as a repository for project-specific information that can be accessed by all project participants. It can also acquire knowledge from previous cases of critical issues and experiences using data mining techniques. In order to clearly describe this system, it is necessary to firstly describe the computational model of VHBUILD, which is followed by the introduction of the knowledge management module embedded in the system.

Information Flow Model

An information flow model is developed for VHBUILD in order to define system components and their interactions within the overall information flow and sharing process. The model is based on a repository of all project information at different stages. The repository, or database, resides on a main server to ensure the security and integrity of data. The model is composed of four main components. The daily site report (DSR) component collects and stores information regarding daily site activities and produces schedule data. The schedule control (SC) component enables updating schedule and produces schedule reports. The document management (DM) component provides a convenient tool for users to manage different project files generated during the projects. The critical issues (CI) model keeps a track record of all important issues occurred or might occur during the projects. The model components and their interactions are illustrated in Figure 1.

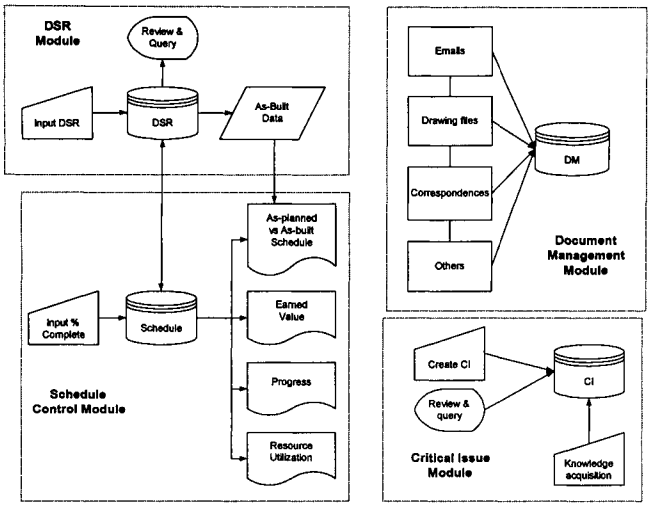

Figure 1: Components of VHBUILD (Modified after Abdelsayed and Navod 1999)

The four components are further described in the following sections.

Daily Site Report Module

Daily site report (DSR) provide project managers with a comprehensive record of site activities. The reports are prepared by creating and completing electronic forms. The format and content of the electronic forms are determined by users based on the level of details they required. The DSR allows users to register information regarding the types and descriptions of work done on a daily basis, and problems encountered. It can also keep track of periods of no work or inactivity. In addition, the DSR can keep records of types and quantities of resources allocated and used. Figure 2 shows an example of daily site report.

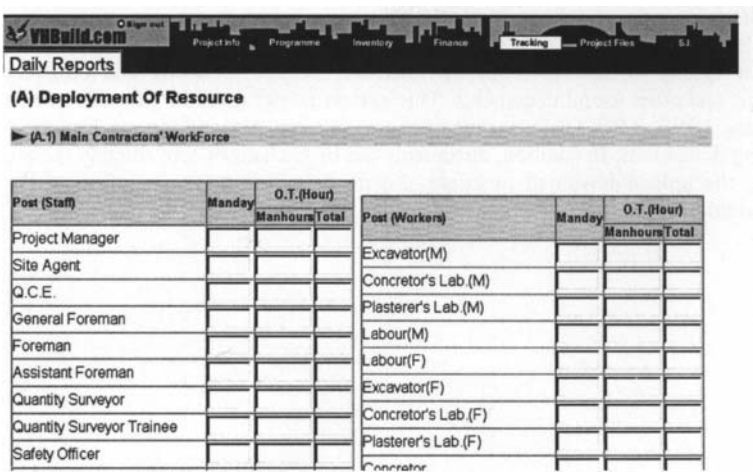

Figure 2: An example of DSR

Information collected from daily site reports can be used to generate as-built factual data. The availability of daily site reports allows project participants to review project information in real time, because these site reports are available at the end of a day rather then at the end of each month.

Schedule Control Module

The schedule control module provides access to "on-line" schedule information. Users have the option to select the level of details of the schedule to view. Typically, the schedule control module an present the percentage of an activity either in an-hours or dollars. The as-built schedule data, which is collected using daily site reports, an be summarized and incorporated into the schedule to form the realistic as-built representation of an activity's progress.

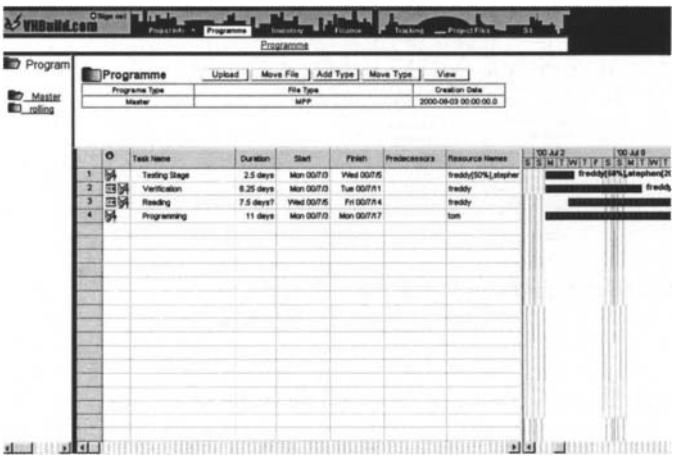

Figure 3: Schedule Control

Figure 3 is a screen dump of the schedule control module. From Figure 3, it can be seen that the comparison between the as-built and as-planned is presented graphically.

Document Management Module

A document management system is developed for the users to manage incoming and outgoing correspondences, drawings, and other useful documents. This system allows users to view documents in various formats including DWG, MSWORD, scanned images, and etc. A searching mechanism is also available for retrieving documents. In addition, documents can be exchanges conveniently among project participants using the upload/download functions. Figure 4 indicates the interface of the document management module.

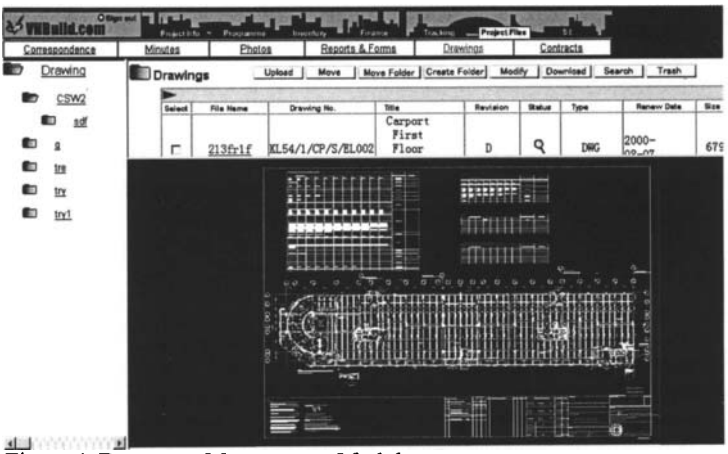

Figure 4: Document Management Module

The availability of the document management module maintains the integrity of project documents.

Critical Issue Module

The critical issue module enables project managers to record critical issues and/or events which have occurred or might occur during the project. By entering the nature of the critical issues which includes the consequences, reasons and related descriptions and files, the system can store the critical issues for further use. These critical issues can be important site instructions from architects, potential hazards and threats to the projects. The critical issue module has the following major functions:

- Store and retrieve critical issues
- Advise the project managers on how to handle the critical issues
- Automatically update its knowledge base on the arrival of new critical issues using data mining techniques.

When a new critical issue is prepared and entered into the system, it is stored as a case that can be retrieved and reasoned using case-based reasoning techniques (Li 1996).

Knowledge Management: Case-Based Reasoning Approach

Case-based reasoning (CBR) is a problem solving strategy which is based on re-use of past solutions to address a new problem. Instead of representing knowledge as rules in rule-based expert systems, a case-based reasoning system maintains a case base that stores cases previously solved. When a new problem is encountered, the system retrieves cases similar to the new problem from its case base, selects the most similar one, and then converts the old solution to a new one for the new problem (Kolodner 1988). This technique is appealing because humans often make decisions in similar ways, and many attempts have been made to address CBR as a scientific cognitive model (Kolodner 1988).

There are two important operators in a case-based reasoning system: select and adapt. Select is the means of retrieving the most similar case from the case base according to the features of the new problem. A weighted count of matching features provides one way to select the best case; however, this does not take into account the fact that the case itself may determine the importance of a feature. Some approaches to finding the best cases are: preference heuristics (Kolodner 1988), dimensional analysis (Rissland and Ashley 1988), and dynamically-changing weighted evaluation function

(Stanfill 1987). Once the best case has been selected, it is necessary to adapt the solution of the case to fit the new problem as closely as possible. In adaptation, decisions have to be made about what stays the same and what changes. The two alternatives for reusing a previous construction situation are to replay the operators that produced the solution and to reuse the construction situation itself. These are identified by Carbonell (1986) as derivational analogies and transformational analogies. The second transfer the solution of an old case directly to that it satisfies the criteria of a new problem; whereas a derivational analogy modifies the problem-solving processes or techniques of an old case to construct paths that result in solutions to the new problem.

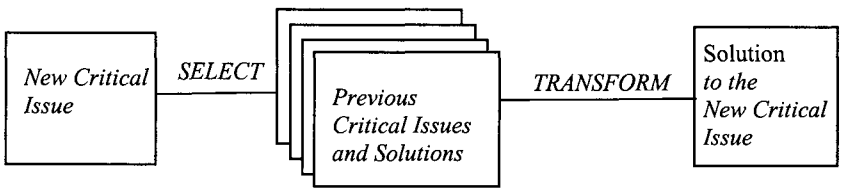

Figure 5: Case Based Reasoning Mechanism

A critical issue case is an abstract of information about a previous situation. The content of each case should include information that facilitates its reuse but not necessarily all the detail of the critical issue itself. Cases can be developed from a collection of previous critical issues. For our project, a critical issue case contained (1) case number and indexing keywords, (2) situational description addressing the background of the critical issue, (3) parties involved, (4) related documents, files and reasons for invoking the critical issue, (5) expected or actual results. A case has a root node indicating its indexing number and keywords representing important issues involved in the case. The retrieving process is based on searching for and matching keywords.

The retrieval and selection among cases entails the recognition of the relevance of each case to a new critical issue. The case base is indexed by the keywords of each case. When a new critical issue is defined as a set of issues and goals, the system traverses the cases according to the new definition of critical issue, and identifies the similarities between the cases and the new critical issue. The case with the highest similarity is then selected as a basis for generating a solution for the critical issue. To model this selection process, a weighted count of matching keywords can be applied. User interaction allows the set of matching keywords and their relative importance to be modified.

Case adaptation in VHBUILD forms the essence of solution generation. As a CBR model, the system assumes that case selection provides a specific case that is close to an acceptable solution and adapts those aspects of the case that are inconsistent. The selected case should contain most issues and goals that define the problem of a critical issue to be resolved. Knowledge used in case adaptation includes heuristics, common senses and issues, case base, and proportional relations. Modify reservation values, introduce new issues/goals, and select additional cases are three techniques of case adaptation.

Experience and lessons gained from the VHBILD collaboration

The VHBuild system has been in trial use for a number of housing projects commissioned by the Hong Kong Housing Authority. In the collaboration of VHBuild, the division of work between the academic partner and the industrial partner has been clear. The academic partner was responsible for the design of the information flow model and the module for knowledge management. Relying on his extensive contacts with international research communities and previous research experience, the academic partner has devised an information flow model which takes into considerations of the construction

practices in Hong Kong as well as the state-of-the-art research results. Because of this, the information flow model is perceived to be a useful one as it not only allows individual project participating companies to own and manage their information and data, but also maps out the flow of information in the same way as the conventional flow of information.

On the other hand, the industrial partner, Yau Lee Construction Ltd., has realized the full potential of Construction IT, and established a subsidiary company called VHSoft Technologies Ltd. (VHSoft). In order to ensure the strong support of the top management of its parent company, Yau Lee designated a senior manager to operate this new subsidiary. Since 1999, VHSoft has maintained an office of over 50 employees including programmers, sales consultants and administrative staff. In order to provide the first-hand experience and feedbacks on the use of Construction IT systems, the senior managers have led the trial use and implementations of the systems developed by the VHSoft. For example, the VHBuild was firstly used in one of the housing projects contracted to Yau Lee. The feedback information was crucial to the VHBuild development team in debugging, refining and gauging its usefulness.

Because both the academic partner and industrial partner understand clearly their relative strengths, the collaboration has been smooth and successful. In retrospect the following points emerge as being critical in maintaining an industry-university collaboration.

1. The academic partner should understand that not all of the collaborative projects are of high academic value. This also implies that not all of the collaborative projects can lead to high-level academic publications.
2. The management of intellectual property rights requires careful arrangement and consideration to avoid problems.
3. The industrial partner should understand that not all collaborative projects can have immediate and tangible benefits.
4. In order to achieve a successful collaboration, the industry and universities should better understand their relative strengths and work closely and productively together.

CONCLUDING REMARKS

Industry-university collaboration can allow both sides to share ideas, strengths and resources. Through the collaboration, the university researchers can find real-life research problems and additional resources to work with. The outcomes can not only bring about new discoveries and knowledge, but also enrich the contents of teaching materials. The industry, however, can obtain state-of-the-art technologies and solutions for their problems at hand, as well as trained personnel for future problem-solving. In the increasingly competitive operating environment in construction, the industry must try to obtain the best technologies, to educate and train the very best people, then make sure that they are employed effectively in the interests of the construction industry and of the society as a whole.

In order to sustain a longer term collaboration, the industry and universities should find answers to the problems emerging from the collaborative process, based on trusts and mutual benefits.

RAISED FLOOR SYSTEM: A PARADIGM OF FUTURE OFFICE BUILDING FITOUT?

G. Zhang, J. Yang and A. C. Sidwell

School of Construction Management and Property, Queensland University of Technology, Brisbane, QLD 4001, Australia

ABSTRACT

The ever-changing nature of the business environment requires office buildings to respond to organizational, technological and environmental changes. In addition to the latest technologies such as IT and telecommunication, interior configuration and reconfiguration of new office buildings will become a crux of the issue (Barber, 2001). However, conventional approaches to office building fitout, cannot always meet these diverse requirements on a cost-effective basis. Raised floor systems (RFS), also known as access floor systems and adopted in many intelligent buildings (IB) applications (Harrison et al., 1998), can satisfy these requirements because of its high flexibility, speedy installation process and wide adaptability with other building components. RFS technology is also capable of largely reducing fitout time and operation costs in retrofit projects, while allowing more ergonomic considerations for the workplace. This paper introduces current research on the RFS and relevant comparative studies of the conventional approaches to office fitout. The research includes product specification, life cycle costing, construction processes, system integration, and facility management during reconfiguration using the RFS systems. Attempts are also being made to identify appropriate RFS design, installation, implementation, monitoring and maintenance procedures. The paper aims to provide evidence that RFS will replace conventional approaches for office building fitout for many applications in the near future.

KEYWORDS

Raised floor system, office building, intelligent building, fitout, retrofit, comparative study, flexibility.

INTRODUCTION

Traditional office buildings were generally designed to satisfy the essential work requirements, such as provisions of desks, chairs and telephones. Today, new office buildings not only need to facilitate the basic functions, more importantly they must be able to cope with changing requirements of their owners and occupants. This can be reflected in three aspects.

- New and emerging IT and telecommunication technologies have caused a fundamental shift in business activities away from simple clerical processes and towards more communication-

based, managerial and creative work. As a result, new requirements of office buildings are emerging continuously, such as office automation, modularity, integration and ergonomics, to make office work more efficient for the organization and comfortable for the individuals.

- Organisational flexibility, perceived to be an important feature by many corporate owners and tenants of office buildings, demands an ability in these buildings to reconfigure quickly and economically. This flexibility can be evaluated by churn rate, the percentage of the organization that moves work location during a year, which directly reflects the volatility of the organization (Harrison et al., 1998).
- The role of facilities management is also changing today. It now must include distributed information systems and information exchange between systems to reach more effective management decisions, thus resulting in more savings in the optimised operations of the building components and systems (Flax, 1991).

Many existing office buildings in Australia, with fitout facilities and systems commissioned more than a decade ago, cannot meet these changing requirements. Fixed structures, rigid mechanical and HAVC systems, and quickly obsolete data connectivity are common problems (SRIA 1994). Alternative fitout methods, such as ones using raised floor systems (RFS), appear to be able to respond to these potential challenges. However, RFS is still in its infancy of development. Its advantages are yet to be realised by the vast majority of office building occupants and owners. How they compare to traditional fitout methods and what advantages they can bring about is the topic of a research project being undertaken in the Queensland University of Technology (QUT), Australia. This paper discusses the problems of conventional approaches to office building fitout before presenting the benefits of intelligent building systems and RFS. Based on these findings, this paper introduces the QUT research project, covering the initiation of research, research plans and methodology, main focuses, as well as on-going development processes.

CONVENTIONAL APPROACHES TO OFFICE BUILDINGS FITOUT

Offices were once designed to keep people apart, and space planning was based on the ruthless divisions of hierarchy and status (Myerson and Ross, 1999). In the conventional approach to office fitout, the aim is to provide staff with a place to work. According to their seniority and responsibility, the floor space is divided by dry walls into single rooms for managers and open place for junior staffs. Interior fitout is so simple that it may only include space dividers, desks, chairs, bookshelfs and telephones. When information technology is gradually adopted in the workplace, the office environment needs to accommodate desktop computers and peripherals, scanners and plotters, facsimiles and more recently, Internet based facilities. However the cumbersome wires and cables of these technologies, often requires additional work to office fitout when first installed, and can subsequently make relocation and reconfiguration costly and time consuming. Air conditioning, an important aspect of HVAC, presents another example. Its cooling units and fans are usually installed at the end of corridors, and the air from the central plant and cooling tower is delivered to rooms through inlets in the corridor walls or perforated ceilings. Very often the whole level of office space gets cold or heated air regardless whether they are required only for individual rooms or areas. Air is diffused with the same temperature, velocity and direction, without users' own control. Therefore it cannot provide a comfortable workspace.

Changing business requirements originating from innovations and advancement of IT and telecommunication, also demand more flexibility in office relocation and asset renewal or upgrades, as well as in facilities management. As we know, primary mechanical systems have a typical life span of 20-25 years, electrical systems 10-15 years, interior partition 5-10 years, telecommunications and IT technology 3-5 years (Yang, 2001). When the occupants upgrade the

systems with short life spans, the rigid partition, cables and wiring built in conduits cannot support the upgrade due to their fixed structure, limited capacity and quality. Shifts towards corporate downsizing and frequent physical relocation of employees to meet organizational uncertainty are reinforcing the trend towards the integration of building systems. The abilities to save energy costs and to reconfigure workspace on a cost-time effective basis are believed to be among the most critical issues of contemporary building design and construction. Furthermore, HVAC, especially air conditioning, are neither ergonomic nor healthy under the conventional installation. In the open office space, pollutants may be circulated continuously through the system. Air temperature, speed and direction cannot be adjusted to suit individual comfort levels. Staff may develop fatigue in such unhealthy environment. Lack of shared tenant services (STS), a problem common in conventional office buildings, will inevitably bring about the redundancy in facility acquisition and disorder in facility management processes. Finley et al. (1991) pointed out that the *raison d'etre* of STS is the economics of scale allowing many tenants access to services that they would not be able to afford on their own. All these problems will directly depreciate the functionality of the office building thus its marketability.

In summary, it is evident that conventional approaches to office building fitout are increasingly incapable of meeting the changing requirements of the occupants and owners in the era of rapidly advancing technologies. Intelligent buildings (IB) and new fitout approaches are now predicted to better serve the purpose of improving office productivity, comfort levels, and organisational flexibility.

INTELLIGENT BUILDINGS AND RFS APPLICATIONS

Intelligent Buildings and Their Development

An intelligent building is one that creates an environment that maximizes the efficiency of the occupants of the building, while at the same time allowing effective management of resources with minimum life cycle costs (Cho and Fellows, 2000). Intelligent buildings, also known as smart buildings, were originated in the early 1980s in the USA. Initially denoting buildings which incorporated sophisticated IT and telecommunications facilities, IB development was once closely linked to the growth of IT. However, the conception of intelligent building is far beyond the convergence of high technologies. In fact, a high-tech "intelligent building" cannot be regarded as intelligent unless these high technologies are integrated to foster creativity, productivity, dynamic intellectual stimulation, and information exchange as well as environment to promote mental and physical health. Intelligent buildings must also be able to respond to new changes, and learn and adapt to new operating patterns through usage. Therefore, "the intelligent buildings must be understood as a concept, not as a product. Needs are constantly evolving; Intelligent buildings is a direction, not a destination" (Moult, 1998). Another important feature of intelligent building is its cost-effectiveness, i.e., its lower installation cost of building control systems, reduced churn operational cost, lower renovation cost as well as reduced energy consumption costs, and most importantly, lower 'whole of life' cost. These advantages will undoubtedly add values to these office buildings.

Components of Intelligent Buildings

Intelligent buildings often integrate a wide range of services and systems into a unified whole. Table 1 lists the common components of intelligent buildings in the three categories of systems, structures and services.

Intelligent buildings can integrate advanced components to make office work more efficient and ergonomic, the occupants more comfortable and productive, the owners more cost-effective and

flexible, and the environment safer and healthier. These advantages can be achieved on the premise that the intelligent building's structure, skin, connectivity, service system and interior system work in orchestrated harmony as well as provide optimal performance for their functionality. Nowadays, the structure and skin may provide spatial adaptability with individual access to the natural environment, optimize design to reduce material use, and facilitate better constructability and no-waste construction processes. The connectivity systems can highlight the importance of just-in-time connectivity vs. redundancy; user-based reconfigurability of outlets, dynamically located shared services, flexible density of data, power and voice, and compatibility. The service systems can strengthen the applications of shared tenant services. The interior systems may provide a spatially flexible, individually conditioned, connected and healthy environment, and at the same time, ensure low energy use and other resource consumption (Loftness, et al., 1997). Within the office building's context, one aspect remains critical to realize these advantages, i.e., an infrastructure that integrates these components for the maximum benefits. To this end, interior fitout using raised floors has become a recent highlight.

Table 1 Common Component of Intelligent Buildings

Services and systems in intelligent buildings

Private automatic branch exchange 3. Public address system 4. Satellite services 5. Video conference 6. Office automation

Raised Floor Systems (RFS)

The origins of raised floor can be traced back to 1954, when Tom Tremer, an American inventor, designed a special floor to accommodate the weighty mainframe computers under development at IBM's test facility in Endicott, New York (Ellison and Ramsey, 1989). Tremer's floor offered a strong, level surface for the large computers and a way of storing the bulky cables. For this sole purpose however, the cost of raised floor was much higher than other methods. Therefore raised floors did not attract widespread attention until the last two decades when they were designed to integrate cable management, HVAC, plumbing and fire protection as a whole. This new approach not only reduced the initial cost largely compared to the other methods such as power pole (PP) or poke-through and cellular deck but also lowered the life cycle cost of office buildings. Figure 1 presents the life cycle cost (LCC) comparison for a building between the options of using RFS and PP systems with or without HVAC. This was a study done by Ellison and Ramsey (1989) on a 35,000 sq ft, open plan office building project based on the LCC of 65% computer usage and 20% relocation annually over 10 years life span. It indicates that RFS is has the cost advantage over PP without HVAC; however, it is much more much favourable than PP if the system included HVAC.

How RFS can respond to the emerging demands of office buildings can be illustrated through two examples:

- Flexibility: in most buildings the relocation of power and communication wiring is usually accomplished by cutting carpets, drilling holes on slabs, chasing walls and removing ceilings

panels. The ongoing maintenance and retrofit costs are high and can directly affect rental returns. RFS can simplify the relocation process and reduce expenses. The floor-mounted air diffusers and fan units require no ductwork and can be easily transferred to a new location. Conduit layouts and utilities can be accommodated within as little as 15cm of the underfloor plenum.

- Ergonomics: in the traditional HVAC system, the temperature in an open plan office environment remains constant to all occupants, who may have individual preference to air temperature, direction and strength of airflow. In the RFS environment, with task air from personal diffusers on the floor panel, each individual's preference can be met, thus maintaining a healthier work environment, reducing fatigue and uplifting productivity.

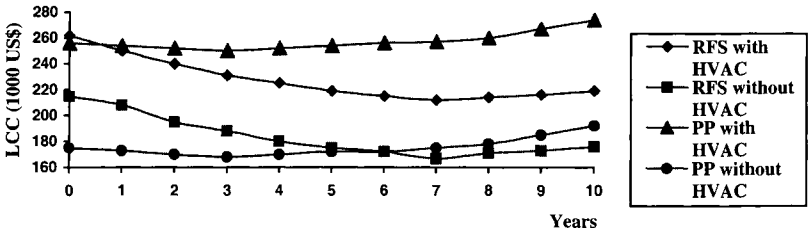

Figure 1. Life cycle cost comparison between RFS and PP
(based on data from Ellison and Ramsay research)

The effectiveness and economics of RFS are also due to its flexible design and construction process. Generally, RFS consists of structural components, panel support systems, finishes and accessories. Installations often include the following steps. First, the pedestals are laid on the floor surface, which can be either the rough slab of a new building or the original floor in a refurbishment project. The modular panels fixed by bolting, gravity, or corner lock and snap-on stingers, are then placed side by side on the top of pedestals forming a uniform smooth surface with the appearance of a solid floor. The stringers are optional in developing the panel strength while resisting horizontal loadings or seismic forces. Second, carpets, vinyl, cork and other surfacing materials are covered on the panels to protect their corrosion, avoid pedestrian slipping, reduce noise, as well as to meet aesthetic requirement. The resulting space between the RFS panels and the original surface can then be used to facilitate the layout of various cables, ducts, pipes and distribution box, with the added bonus of easy access for servicing and relocation. Finally, all other accessories including cable carriers, floor edging, ramps, diffusers, sockets, data and voice outlets, are installed to form the integrated RFS. Figure 2 illustrates the advantages of adopting RFS in office fitout and its association with other building components.

APPLICATION POTENTIAL OF RFS IN RETROFIT PROJECTS

RFS also has promising applications in retrofit projects in Australia. Many office buildings constructed during 1970s to 1980s in Australia adopted the conventional design for fitout and service utilities and had few considerations for office automation, connectivity and other induced innovations (SRIA 1994). These buildings will soon enter a stage of major upgrades of their service systems and subsystems and on a long-term basis, face substantial retrofit costs if using the conventional fitout method. RFS based applications, with reasons mentioned above, can play a major role in the upgrades of these office buildings if their advantages and benefits, and especially the LCC based cost savings, are commonly realised. Moreover, emerging new technologies,

changing requirements in the workplace and business routines and practice will lead to the retrofit of all office buildings on a more frequent basis. Trends in the US and Europe have already indicated resurgence of RFS applications. Given time and more exposure, RFS will prove to be a new and viable option for retrofitting Australian commercial buildings.

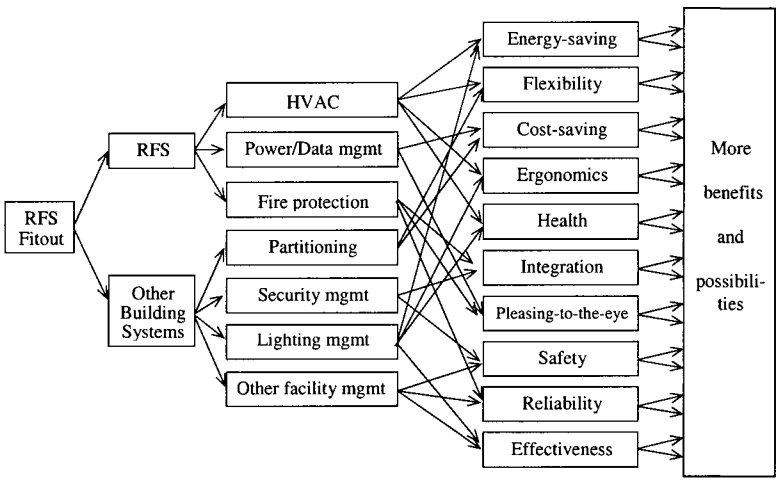

Figure 2. Advantages of RFS to office buildings fitout

A COMPARATIVE STUDY AT QUT

Research Initiation

The research originated from the authors field observation of the office fitout and retro-fit construction practice in Australia and was further inspired through their research work in the US and Europe between 1999 and 2001. A recent trend of practice of some of the largest corporate tenants of office buildings in the US and Europe is moving towards just-in-time office space provision, integrated services, organizational flexibility and maximized individual comfort levels (Barber, 2001). Pilot projects of new and retrofit office buildings in these regions have been equipped with IB technologies which incorporate RFS as a core component. While the initial response is encouraging, a question arises for many building professionals, especially owners and corporate tenants. That is, how does the RFS approach compare with the conventional suspended ceiling and floor furnishings, in terms of development and lifecycle costs, constructability, maintenance, and facility management? Given that Australia is often influenced by the economy and business trends in the US and Europe, it is vital to identify these issues before interests develop into urgent demands. The research project reported here aims to investigate and respond to these issues on a comparative study basis.

Research Focuses

Emphasis of this research is not on the actual development of RFS itself. Rather, it focuses on the integration of RFS with other building components to provide the RFS enabled environment to meet changing office building requirements. In particular, the research involves studies on RFS specification, constructability, system integration and procurement and other construction management issues associated with RFS implementation. Lifecycle costing analysis will be an

integral part of the study. A vital component of this research is a comparative study on some of the attributes mentioned above between RFS and the conventional fitout approaches. This will provide a much needed validation of the RFS potentials.

Research Plan and Methodology

The research will be carried out from both theoretical and practical respects. Literature reviews on previous RFS research, studies on RFS design and application specifications, and rationalization of RFS installation processes will form the basis of theoretical establishment in this research. The research will also be aided by a live experimental laboratory to provide first hand information on RFS installation and application issues. Field visits and observations will be conducted to verify and enrich findings. In the overall research process, comparative studies of RFS vs. conventional approach will be carried out in two stages: initial procedural study and comprehensive study on major cost and benefits issues. Figure 3 illustrates the overall research plan, which is scheduled for three years.

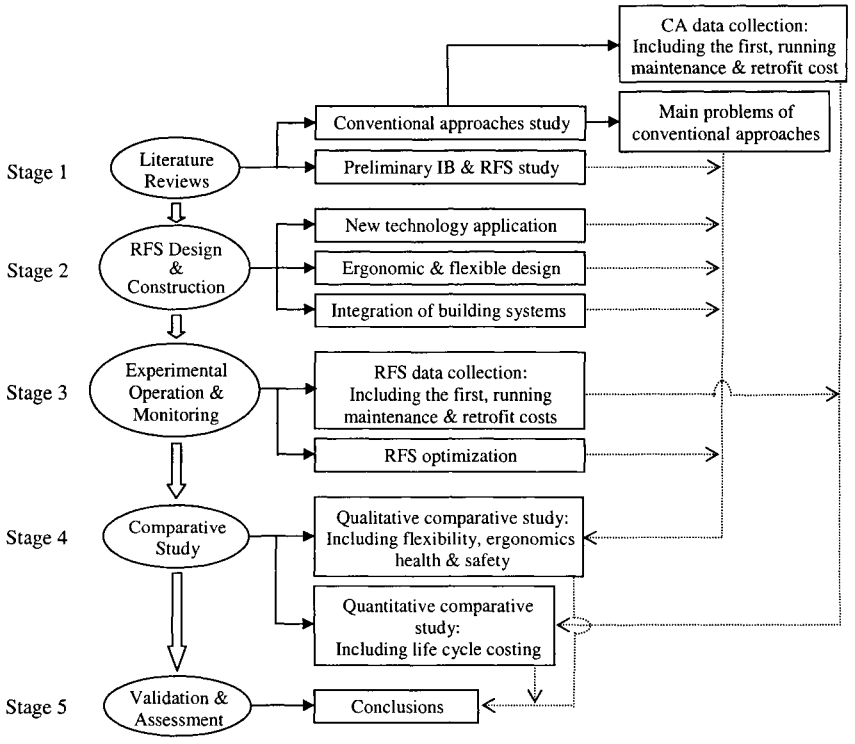

Figure 3. Research model of RFS study

Expected Outcome and Significance

The research will bridge a gap between emerging IB and RFS technologies and the relative lack of understanding thus implementation of these technologies and products. It will provide sufficient evidence and answers to lifecycle costing of RFS applications, their comparisons to conventional floor applications, and at the same time, identify a model of the optimal RFS practice for its

implementation and integration with other components. This will enable building professionals from clients to contractors to gain better understanding of the RFS application in order to identify the best options for commercial office fitout practice.

CONCLUSIONS

With the evolving requirements of the occupants and owners of office buildings, and with the emerging IT and telecommunication technologies, intelligent buildings will become increasingly popular for office buildings in the years to come. RFS, as a core component of intelligent building system and with its ability to integrate building control, wire and cable management, HVAC, power, connectivity, fire protection, security, asset management, etc. into a whole system, has the potential of meeting these evolving requirements. As RFS applications are becoming an integral module of intelligent building systems adopted in office buildings in the US and Europe, it is necessary to explore the potential and benefits of RFS under Australian conditions. A RFS research with Australian local characteristics is now being carried out at QUT, Brisbane, including product specification, whole of life cost-benefit analysis, constructability, utilities and system integration, and facility management during reconfiguration. Ongoing study may involve RFS installation, implementation, monitoring and maintenance procedures. It is expected that the outcomes of this research will justify the popularity of RFS applications and accelerate their implementation process in Australia.

A NEW 3D RECONSTRUCTION TECHNIQUE AND ITS APPLICATION IN MEASURING BUILDING QUANTITIES

Cao Yang[1] and Li Heng[2]

[1,2] Department of Building and Real Estate, The Hong Kong Polytechnic University
Hong Kong

ABSTRACT

3D reconstruction technique deals with developing 3D models from three 2D orthographic views. This paper reviews existing algorithms in terms of their relative advantages and weaknesses. Then, a new method developed to reconstruct 3D models from 2D construction drawings is presented. The method is unique in the sense that it combines knowledge based system with drawing interpretation so that engineering components can be recognized and reconstructed from simplified descriptions presented in the engineering drawings. The method is evaluated through the application of automatic measurement of quantities from drawings.

KEYWORDS

Feature recognition, 3-view drawing, 3D reconstruction, stretch object.

1 INTRODUCTION

In the construction industry, 2D drawings are used to describe the 3D construction components. Although there are CAD packages which allow users to draw 3D components, construction professionals are so accustomed to 2D drawings that it is very difficult, if not impossible, to persuade them to change from 2D to 3D drawings. Usually, if a 3D component is easy to describe and understand, then it is represented by a single 2D drawing, otherwise partial section drawings are added to assist the user to comprehend the details of the component. The process of reading and comprehending a drawing involves mentally reconstructing the 3D component from different 2D orthographic views. For example, the practice of quantity surveying requires the surveyor to be able to mentally reconstruct the 3D model so that relevant quantities can be measured. The process of taking off quantities from 2D drawings is very tedious and prone to errors. In order to develop a computer system to automatically measure quantities from 2D drawings, it is essential and important to be able to automatically reconstruct the 3D model from 2D orthographic views.

The first research of 3D reconstruction probably dates back in 1972, and from then onwards many studies have been carried out on this theme (Nagendra and Gujar 1988). Most of the algorithms developed are able to generate three dimensional objects only containing planar faces, as objects with curved faces are much more difficult to generate from 2D views (Aldefeld 1983, Sakurai and Gossard 1983). Although the developed algorithms are different in various aspects, the following major steps are generally adopted in the task of generating 3D models from 2D orthographic views:

Step 1: Transformation of 2D points to 3D vertices;
Step 2: Generation of 3D edges from 3D vertices;
Step 3: Construction of faces from 3D edges; and
Step 4: Formation of a 3D polyhedron from faces.

However, Step 3 creates a surface model which may include non-existent (false) vertices, edges and faces, how to efficiently detect and remove such elements from the intermediate model against the exponential increase of the number of the combination of candidate faces is a challenging issue in the development of algorithms for 3D reconstruction.

On the other hand, the characteristics of construction drawings also present difficulties in developing 3D reconstruction algorithms. Construction drawings have many components, such as reinforcement steel bars, that are very difficult and troublesome to draw in their true dimensions. Because of this, designers often use simplified ways to represent these components. For example, the reinforcement bars are represented by one line with attached text to indicate the numbers and sizes of the bars. These simplifications make it more difficult to recognize and reconstruct a 3D model from 2D orthographic views.

To solve the difficulties mentioned above, we developed a feature-based recognition method to recognize and interpret the symbols and elements in construction drawings (CDs). Then, based on the recognition and interpretation result, a 3D reconstruction method is presented. At last, its application in QS is implemented based on the reconstruction results.

2 CHARACTERISTICS OF CONSTRUCTION DRAWINGS

Construction drawings possess many characteristics which make the task of 3D reconstruction challenging and complex. For example, the 3D information of one construction component is often indicated by several 2D orthographic views and these orthographic views are often separated in several drawings. Information can be either described as graphics or texts in the drawings. If some components share the same features, then the shared features will only be represented once at a certain location of the drawings in the form of annotation.

Moreover, in the construction drawings, structurally connected components often have overlapped region in the graphic descriptions. This brings difficulties to the 3D reconstruction. Additional work is needed to correct this overlapped region. Sometimes, well-known information about standard components are omitted from drawings. This requires domain knowledge from experienced engineers so that the entire component can be reconstructed.

Because of these characteristics of construction drawings, existing systems or algorithms for 3D automatic reconstruction need excessive manual data input before they can generate a useful 3D models

from 2D orthographic views, not mentioning that these systems perform poorly in handling imprecise or error representations which are not uncommon in construction drawings. The feature-based recognition method developed by us

3 AUTOMATIC RECOGNITION OF CONSTRUCTION DRAWINGS

Before a 3D model of a construction component can be built, it is important that the 2D orthographic views are automatically recognized. This section presents how to automatically recognize construction drawings. Main components of a building include columns, beams, walls, slabs, and staircases. A construction drawing is used to describe the structural information of these components by the boundary projections of the components in the three orthogonal 2D views including the components' top view F(t), front view F(f), and section view F(s). In each of the 2D views, in addition to the boundary projection, information such as special symbols, descriptive texts are also attached. Thus, the task of recognizing a construction drawing must include recognizing both graphical and textual descriptions which will be elaborated below.

Before construction drawings can be automatically recognized, it is necessary to define some terminologies to be used in describing drawings. Graphic primitives (GPs) are basic graphic elements such as lines, circles, etc. A graphics primitive composition (GPC) refers to the combination of a GP and its relationships with other GPs. A GPC contains specific and sufficient information about a GP, such as the boundary of the GP, related symbols, annotations and so on. Analyzing each GPC can obtain useful features which are used to distinguish one particular GP from others.

In a CD, a construction component is composed of many GPs. It is therefore important to correctly identify all the GPs in the component as the recognition process is based on the recognition of GPs and their relationships in the component (Dori 1990). Specifically, the recognition process starts with recognizing the projection boundaries of the component that can be obtained by removing the GPCs representing the steel bars, the symbols, and descriptive texts. In Fig 1, the projection boundaries of a beam from its top view, front view and section views are presented.

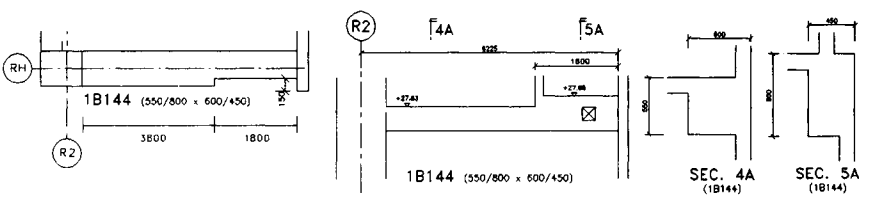

Figure 1: Projection boundaries of a beam from top, front and section views.

A single object's projection boundary in a 2D view is made of one or several closed polygons. Frequently, the projection of a component includes parts of other components' projections to show that it is connected with these parts. This results in unclosed polygons as redundant GPs are included. It is therefore necessary to remove the redundant GPs and enclose the polygons. For example, after removing the redundant GPs from the projection boundaries in Figure 1, the projection boundaries of the beam are as shown in Figure 2.

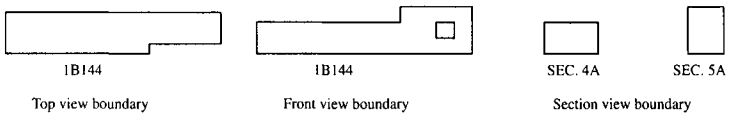

Figure 2: Projection boundaries after removing redundant CPs

A construction drawing contains many important symbols and texts. For example, the grid symbols are the reference for view matching; texts describing the sizes of components are indispensable. Thus, after the recognition of projection boundaries the associated information are extracted by analyzing the symbols, texts and boundaries of adjacent components.

The extracted data about the projection boundaries, as well as the associated information, are stored in a database structure indicated below.

The database structure of the projection boundaries:

```
{
    Component name;
    Size;
    Top view height (if it exists);
    Project view;
    Group of vertex G (v);
    Group of edge G (e);
    Group of Grid symbol G (g);
    Group of adjacent components G (E);
}
```

This database contains the essential information for drawing recognition. Once the projection boundaries of the 2D views are recognized, they form the basis of 3D reconstruction which is presented next.

4 3D RECONSTRUCTION OF OBJECTS

The availability of the recognized projection boundaries of the 2D orthographic views can be used to reconstruct a 3D object. Among all the reconstruction methods, the method for reconstructing stretch objects is the most commonly used one. A stretch object is defined as follows. Given the three orthographic views of an object, if there are at least two of the three views have rectangular projection boundaries, then the object is called a stretch object, or 2.5D object. The stretch object is regarded as an object that is created by stretching a plane along an appointed track. The plane to be stretched is called the stretch plane (Nezis and Vosniakos 1997).

In construction engineering, almost all the components/objects are designed as stretch objects or a composition of several stretch objects.

Because of this, the reconstruction method based on stretch of objects becomes very useful. This method requires to divide a composite object into a group of simple stretchable objects which can be reconstructed individually. The composition of the simple stretchable objects results in a complicated

object. The flow chart of the reconstruction method is shown in Figure 3.

In addition to the stretch objects, there are also other 3D objects that can be considered as special stretch objects. For example, prism and truncated cone are regarded as the special stretch objects, and can be reconstructed by the method. Although the sphere and objects with spherical surface cannot be reconstructed by the method, fortunately they appear only in the upholster, not in the structural components. Thus, the stretch method can cope with the reconstruction of most construction components and objects.

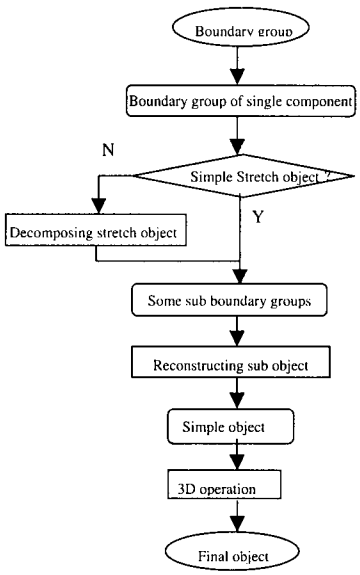

Figure 3 The 3D reconstruction method based on stretch of objects

4.1 Automatic regeneration of the absent projection

In construction drawings, some standard parts are often represented by their code names, with the graphical details omitted from the drawings. In order to obtain the complete 3D components, the absent parts have to be automatically regenerated after analyzing the existing projection boundaries and the code names (symbols and texts etc.). The regeneration process is controlled by the following two rules:

(1) If the missing part is a column or slab, and only the top projection exists, then draw the circumscribed rectangle R(out) of the top projection. The front projection is regenerated as a rectangle and the length of it is the length of the R(out), and the width of it is the height of the column (the data is obtained from the text information). The section projection is regenerated as another rectangle and the length of it is the width of the R(out), and the width is the height of the column.
(2) If the missing part is a beam or wall, and there exist two projections, then project the two projection boundaries to the third view, and the projections are two lines. The third projection is regenerated as a rectangle and the length of it is the length of one of the lines; the width is the length of the other line.

4.2 *Decomposition of complex projections*

If there are holes/voids in an object, the holes are shown as closed boundaries in the projections. The holes can be separated from the projections. For example, let us assume that there is a hole O(f) in object F(f), then the following procedure can separate the hole from the object.

(1) Project the O(f) into F(t), and the projection is a line L. From each end point draw a line that is orthogonal with F(f), then the two lines divide F(t) into three regions. The region that includes the line L is called the projection region (PR) of O(f) in F(t). The part of the boundary that in the PR is O(f)'s projection in F(t), called O(t).
(2) The O(f)'s projection in F(s) that called O(s) is obtained as in (1).
(3) {O(t), O(f), O(s)} is the projection group of the hole O. A hole flag is added to the projection group.
(4) Remove the O(f) from the F(t).

After identifying all holes' projection group from the main projection group, the projection group for the holes is removed from the object which can be reconstructed using the stretch method.

4.3 *Recomposition of simple stretch objects*

After the decomposition and reconstruction of individual stretchable objects, these objects have to be recomposed to form the actual construction component. This is achieved in a two-step process: aggregation of simple objects and removal of false objects.

For example, if a construction component is composed of three objects which include two true objects and one false object as shown in Figure 4.

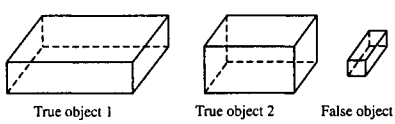

Figure 4: Decomposed and reconstructed 3D objects of a construction

Because all the objects are reconstructed by the stretch method in the same coordinate system, the objects are simply aggregated and 3D operations can be applied directly to obtain the actual construction component. Specifically, all the true objects are integrated by the 3D plus operation to obtain a temporary object. Then, using the 3D minus operation, the temporary object is reduced by the volumes of the false objects. The actual construction component is thus resulted as shown in Figure 5.

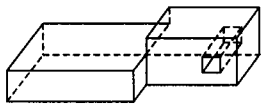

Figure 5: Actual construction component resulted from recomposition

5 REMOVAL OF EXCRESCENT PARTS

The reconstructed 3D objects of adjacent components based on the stretch method often have inter-penetrations at the joints. As a result, excrescent parts occur which should be removed.

A building is composed of many components that support each other. Different kinds of materials and joints are used according to the different mechanical relations. For the purpose of 3D reconstruction, the mechanical relations can be simplified into the following three cases.

- Non-mechanical connection (NMC) is that the two components are adjacent, but there is no mechanical relation between them.
- Horizontal traction connection (HTC) is that the two components are adjacent, and there is a horizontal pressure/tension through the surface.
- Vertical traction connection (VTC) is that the two components are adjacent, and there is a vertical pressure/tension through the surface.

The method to remove the excrescent parts is given as:

(1) If the mechanical relation of the components is NMC or HTC, then select a component arbitrarily, and remove the excrescent parts from it, keep the other component intact.

(2) If the mechanical relation of the components is VTC, then select the component which is relatively on the top or higher, and remove the intersectant parts from it, keep the lower one intact.

After this operation, the reconstruction of a construction component is completed and finalized.

6 CONCLUSIONS

This paper reviews existing algorithms in terms of their relative advantages and weaknesses. Then, a new method developed to reconstruct 3D models from 2D construction drawings is presented. The method is unique in the sense that it combines knowledge based system with drawing interpretation so that engineering components can be recognized and reconstructed from simplified descriptions presented in the engineering drawings.

The method is evaluated through the application of automatic measurement of quantities from drawings. As once the 3D models of construction components are resulted, measurement of quantities becomes a simple task, as the quantities are measured in volumes and/or surface areas of the components which are automatically obtained from any 3D software system.

Virtual Planning Environment Based on Internet

Chen Nengcheng [1], Gong Jianya[1] and Li Deren [1]

[1] National Laboratory for Information Engineering in Surveying, Mapping and Remote Sensing, Wuhan University, 129 Luoyu Road, Wuhan, China, 430079

ABSTRACT

"Virtual Reality Model Language (VRML)" combined with Java3D and XML is one of the key technologies which enable the new generation of Three Dimensional World Wide Web (Web-3D) to come true. With the supplement of three dimensional virtual scenery, the VRML can visualizes information in 3D means and carries them in Internet. And also, the development of VRML technology will become the noticeable focus to which urban planners will pay much attention. It will enables urban planning work a new look by helping to introduce planning information and display planning work in INTERNET and attracting more and more people to care for and join in urban planning job.Virtual Planning Environment(VPE) based on Internet is an interactive ,distributed and 3D Virtual Geographical Environment(VGE) which is a N-tiers complicated system running with multiple interfaces .In server side, The GIS business logical process constructed by J2EE is presented to provide spatial data and geo-processing services .In client side ,there are many approaches such as VRML,Java3D, Chromeffects to implement the visualization of spatial data ,The VRML method combined with Java3D is described in detail in this paper. The prototype of VPE in the virtual city zone under P2P network environment is studied. Moreover, how to organize distributed spatial data and process instant geo-spatial information is explained. In the end, some conclusions are drawn and some suggestions are proposed for later construction of VPE.

INTRODUCTION

The impact of the Internet, specifically the World Wide Web, on our future becomes more profound each day. The number of users and the amount of information increase at a phenomenal rate. The Web can now be found in our homes, in our children's schools and even in our places of employment. Many businesses are beginning to adopt Internet principles and apply them to their corporate Intranet. Those people proficient with Internet tools will be more valuable to their current or future employers.

With the popularity of new technology in virtual planning environment, it is a convenient way to publish the information of urban on Internet and universal accepted by people. However, there is existing some limitation in user interface because of its static and raster expression, that is to say, the user interface based on html is some collection of text, image and multimedia. For urban planning, the much more information is based on 3D besides law, principle and urban schema, which can't be represented by 2D static image. Therefore, it is difficult to make common people know these information .It is urgent to adopt new technology to render and transmit 3D information on Internet by WWW.

With the development of 3D technology, it is possible to solve the above problems. VRML is the combination of WWW, 3D computer graphics interface " Open Inventor " and enabled scenery description language. Java3D is another effective way provided by Sun and was designed with several goals in mind. Chief among them is high performance. Several design decisions were made so that Java 3D implementations can deliver the highest level of performance to application users.

Until now, we assumed that the GIS database server and its clients are connected by a fast local network and use the same operating system. Irrespective of whether the database is stored using a file system or a real database system, the communication between client and server is transparent and the only difference between working on the client and working on the server is a somewhat reduced performance due to networking overhead.

In fact, network is neither transparent nor changeless. With rapid scientific development and further exploration towards the network, the human kind gets to know that network is trustless, latency unequal to zero, bandwidth is limited, network is not security, topology is volatile, system is no only an administrator and transmission need cost.

Java, being robust, security, easy to use, easy to understand, and automatically downloadable on a network, is an excellent language basis for distributed applications. The Java 2 Platform, Enterprise Edition (J2EE) is a robust suite of middleware services that make life very easy for server-side application developers. For VGE, what's need is to develop a distributed application system in accordance with J2EE standard.

This paper provides the concept and features of VPE. Moreover, it explains architecture construction for VPE, accessing, displaying and analyzing planning data on Internet. It includes three portions: Presentation, Application server and Data server. Presentation tier finishes rendering different data source (vector, image, attribute, video) on universal information device (PC, PDA). Application server tier executes kinds of business logic (data access, extract data from spatial database, encode image data, encrypt data). Data server manages and stores planning data in file or database styles. And then, A case study on how to manage and render a small planning area is presented. Lastly, it comes to some conclusion about VPE.

VIRTUAL PLANNING ENVIRONMENT

Distributed virtual environments are the integrations of virtual environments and network. Distributed virtual geo-environments are virtual environments for studying geo-phenomena and geo-process. Virtual Planning Environment (VPE) based on Internet is an interactive, distributed and 3D Virtual Geographical Environment (VGE) which is a N-tiers complicated system running with multiple interfaces. VPE has the following features:

Distributed information system. One advantage of Internet is permitted to access distributed database and perform distributed operations. VPE based on Internet succeed to benefit of Internet, it may be a distributed system. In this system, the planning data may locate at different data server and planning operations consist in different application server. Consequently, data and analysis tool must be single component or module, Once user need any of them, it can be discovered and loaded on any node of Internet.

Universal device support. Both wire Internet users and wireless Internet users can access this system. Thus, It is available not only in different operation system (Microsoft, Unix, Solaris, Linux, POS) but also in different device (PC, PDA, MOBILE).

Real time system. Real time means the corresponding time. The System must reduce the round-trip time so that the remote operation reaction is same as local operation. For instance, If end user add a mark point, application must insert this information into database quickly and correctly and inform everyone on-line.

Interactive. The System must provide well user interface, which permit user who don't know GIS can perform operations in conformity to tips.

Multiple render styles. The information of urban planning must express in different style, which includes text, graphics, video, movie and so on. Just as figure 1 shows, Graphics can be rendered into image, vector, three dimension and VRML.

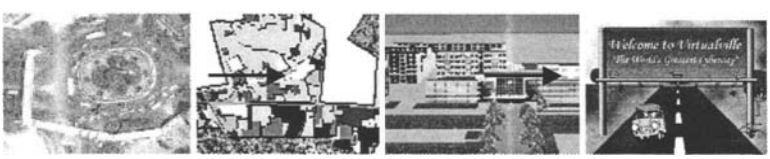

Figure 1:Four different rendering style of Graphics

ARCHITECTURE

In essential, VPE based on Internet is a web application service system, which includes URL, HTTP, HTML (XML), web server and web browser. In a sense, the internal meaning of web is a hypertext information system constructed on Internet and increasing extended information space is the external web resource mark mechanism, application protocol and data format.

The architecture of a web application service system is based on distributed N-tiers environment and includes client, web application server and data server. See figure 2, the architecture of VPE based on Internet includes client, web application server and data server. In this model, each application logic and business services are separated into different components, which communicates with each other by means of network. In general, it may be described as three-tiers computational model in logical.

Client tier: It is user interface that shows and operate planning data. It may run on PDA, information device based on J2ME, PC computer based on J2SE.It may be three kind of client just as table 1 shows. For thin client, in client side, Java Applet is loaded from Server, displays image, raster data and performs basic operation (zoom in, zoom out, pan and send request), Server side performs query

client side displays image, raster, vector and three dimension data and performs basic operations ir common or custom-built browser. For fat client, server side only execute spatial querying and send th prearranged spatial data selection to client, client receives the selection and analysis, renders and displays by means of Java Applet or Plug-ins in common or custom-built browser.

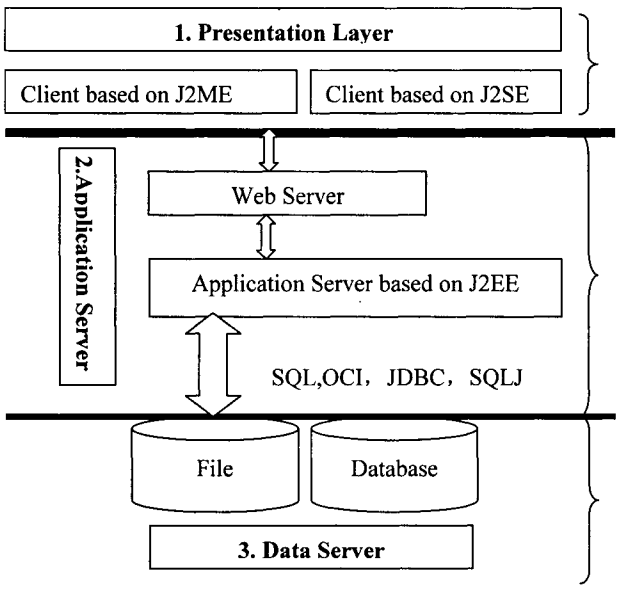

Figure 2: Architecture of VPE based on Internet

TABLE 1
COMPARISION AMONG THREE DIFFERENT CLIENTS

Client	Function	Protocol	Browser	Server	Running program
Thin	Display	HTTP	Common	Render, DEG, Filter	Applet, ASP+Applet, JSP+JavaBean
Medium	Display Render	HTTP RMI IIOP	Common custom-built	Render, DEG Filter	Applet,Application JavaBean
Fat	Display Render DEG	HTTP RMI IIOP	Common custom-built	Filter	Applet,Application JavaBean CORBA

Application server tier: Namely logical business tier, it executes critical business processing whic'. costs much more time. For example, coordinate transform service, geo-spatial encode, address matching and so on. As figure 3 shows, there is an instance of servlet engine which runs in web server, Meanwhile it is RMI client of application server. Applet in browser communicates with application server by means of servlet engine. The servlet engine accepts client's request and transmits it to application server, application server processes the request and return results to browser.

Data server tier: The planning data is stored in this tier, which includes file server ,database sever and existing information system. Application Server access data by means of JDBC, ODBC, SQLJ or SQL.

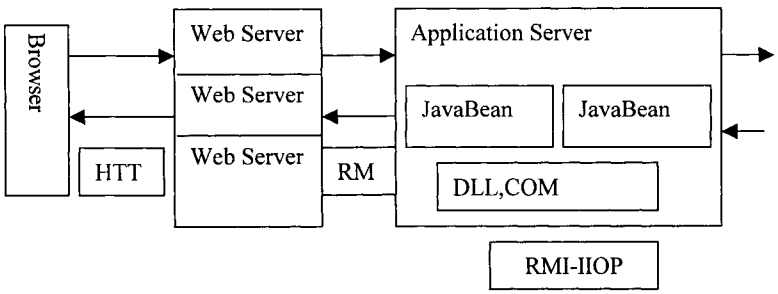

Figure 3: Application Server based on Servlet

CASE STUDY

In this section, a region is provided to explain how to create virtual planning environment based on Internet. It contains two phrases: design and implementation of entities, aviation implementation.

Design and implementation of entities: Abstraction of basic object is referenced to four domain guidelines of land use during the procedure of region design in the virtual planning scenery. As figure 4 shows, flat must be embodied into door, window, balcony and so on.

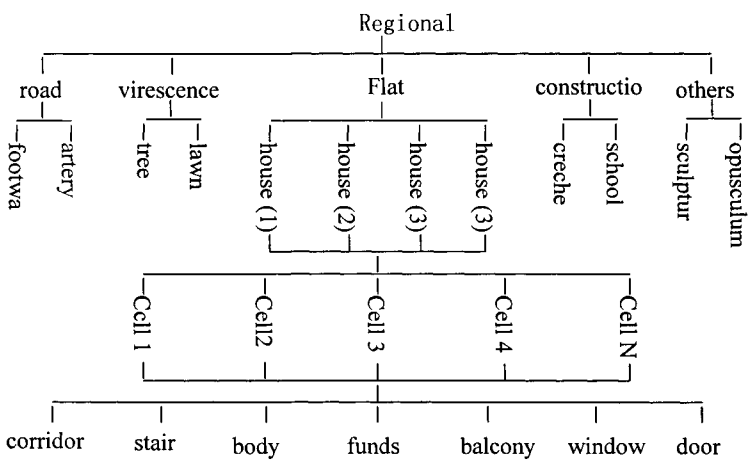

Figure 4: The Objects' Hierarchy Graphic In Regional Scenery

Aviation implementation: The navigation route was designed for purpose so that visitor can roam about in the virtual scenery. We think that footway and artery as the navigation route and viewpoint of visitor is consistent with that of "intelligent agent" (the representation of user in the scenery), visitor will feel scene changing by means of intelligent agent's moving on the route. The event during the procedure can be generalized into the following five phases: logical, engine, trigger, time and target phase. Trigger phase contains two portions: Global position variable is used to track and keep the current position (coordination, orientation) of viewpoint of intelligent agent in scenery. Road stop is used to store the beginning and end position information of road, answer the mouse event by means of touch sensor and realize intersection choose. Logical phase is composed of script nodes which can be used to accept data, send it to orientation interpolator and

position interpolator, startup time phase and bind viewpoint into scenery. In time phase, orientation and position interpolator in engine phase brings variety at specific time interval , sends and changes parameters of viewpoint in target phase, so that causes change of viewpoint of visitor. In target phase, parameters of current viewpoint is stored in global position variable pertain to trigger phase and used to the next interaction. Five phase revolves and aviation is in incessancy.

Example: Figure 5 expatiates the demonstration of scenery result.

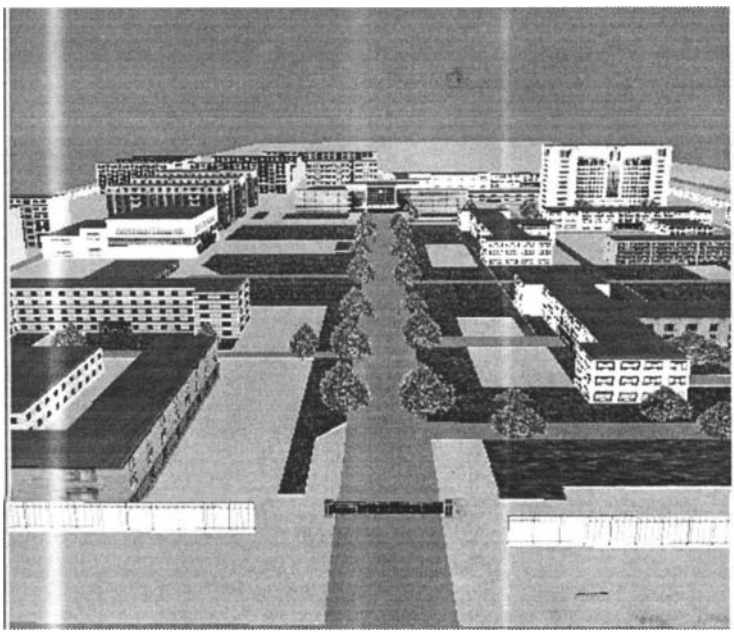

Figure 5 :the demonstration of scenery result

CONCLUSION

VPE is not only a distributed web application system but also virtual scenery based on three dimension technology. From the design and implementation of experimental regional scenery, it is proven that combination among J2EE, Java3D and VRML is an effective way to construct virtual planning environment.

ABSTRACT

Two-dimensional modeling has been employed in most currently available pre-processor for the structural analysis. It is not suitable for those complicated structures that are irregular in their shape, and the conflict parts of structural components cannot be easily discovered by manual examinations before construction. In this paper, a new method for the three-dimensional modeling of complicated structures in a virtual reality environment is presented. By employment of this method, users can specify beams, columns and other components in a three-dimensional space as if they are being constructed in the real world. Joints of components will be visible to users, and the clashed parts of components can be located in the virtual world. The solutions on modeling of complicated structures in a virtual reality environment are illustrated. Principles of computer-aided intersection testing of structural components in a virtual reality environment are also presented.

KEYWORDS

Structure modeling, Virtual Reality, Intersection Testing, AutoCAD, WTK, 3D modeling, ObjectARX.

INTRODUCTION

Two-dimensional (2D) modeling has been employed in most currently available pre-processor for the structural analysis. When the users work with those systems, they must draw the structural plans in a predefined 2D planar space first, specify the locations, sizes, and other relevant data of the cross sections of structural components, and then attach altitude parameters of each component to the corresponding

cross section, and finally all these information should be combined together to make the model of the structure applicable for analysis.

Such a modeling method is originally developed for the modeling of regular structures. It is still reasonable to use it when a structure is simple and regular in its shape. But structures have become more and more complicated, since many advanced technologies have been used in building industry. The 2D modeling method is then no longer suitable. For instance, it would be impractical to create a whole structure model of the steel-framed greenhouse of Beijing Arboretum to employ 2D modeling method, since the greenhouse is irregular and hard to represent in a planar space when it is seen from the plan view or the elevation view.

To construct models of complicated structure efficiently, three-dimensional (3D) modeling should be employed to handle all sorts of structures, especially irregular ones. Unfortunately, creating 3D models with existing CAD technologies is still unsatisfactory. For example, 3D models created by traditional CAD system are often unable to be manipulated in real-time, and attempts to use such models to explore different stages of construction process is also unfeasible. In order to solve these problems, a new method of 3D modeling based on the virtual reality (VR) and traditional CAD modeling technologies is presented in this paper.

Virtual Reality is a technology that generates simulative environment of real world by computers. In this environment, through different kinds of sensors, users are involved in such an artificial virtual environment and can interact with it directly and naturally. Virtual reality systems can be classified as three categories, that is, involved systems, non-involved systems and mixed systems. The equipments used in an involved VR system, including head-mounted displays, data gloves, and data dresses, would be so costly that the expense of equipments would be unacceptable to most users. Therefore, non-involved VR systems are employed to be integrated into 3D modeling systems to enhance their performance at reasonable costs.

The solutions on modeling of complicated structures in a virtual reality environment and the implementation details are presented in the following sections.

SYSTEM DESIGN

The so-called "complicated structures" in this paper refer to those structures with knightheads, oblique beams or columns, walls with holes, or arc-shape components. The structural system and the components in it are hard to be represented clearly on 2D CAD drawings. Therefore, the modeling process is carried out in a 3D space.

The functions of our system is designed as follows:

— Provide a real 3D design space, in which the locations and sizes of structural components can be described in the desired precision. Users are able to position the structure system with the most convenient coordinate system, observe the structure system from arbitrary view.

— The input of geometry of a component can be accompanied with assigning of attributes, which are

indispensable for further computation and design. During the modeling process, all these attributes can be queried, displayed and modified.

— In order to improve the efficiency of modeling, "group" input mode is provided. Components that meet the requirement of some specific rules will be viewed as a "group", and thus can be created or modified simultaneously. In this way, repetitive work is avoided and the tedious human effort of creating models can be reduced considerably.

— Intelligent processors to exam intersections by the computer are developed for the designers to find conflict parts.

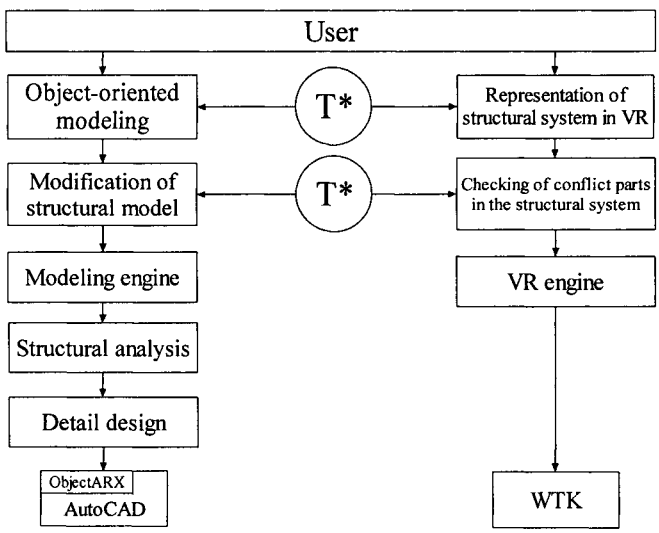

Figure1: System architecture
(*: T represents a "Transformer")

World Tool Kit (WTK) is selected as the platform for VR environment. WTK is an advanced cross-platform development environment for high-performance, real-time 3D graphics applications. With the high-level application programmer's interface (API), end-users of WTK can write codes to call the functions in WTK function library, and then create the virtual world. WTK also provides a 3D modeling tool, called World Up Modeler (WUM), which generates files known as NFF format. WUM is designed to create geometric models; consequently it is not inherently adapted to the modeling of structural components, because each of these components will contain not only geometric information, but also other attributes. All these attributes should be combined with the geometric model of the component, and be viewed as a single object. It is obvious that customized application should be developed to implement this idea. Unfortunately, WUM does not provide a powerful programming interface for developers to implement modeling with non-geometric attributes. Accordingly it is necessary for us to include another platform, AutoCAD, which can provide more convenient extension programming interface as well as stronger supports for 3D modeling. As one of the most popular CAD software, AutoCAD provides for its users the ObjectARX programming environment, an object-oriented C++ API, to use, customize, and extend AutoCAD. The ObjectARX libraries comprise a versatile set of

tools for application developers to take advantage of AutoCAD's open architecture. In an ObjectARX application, we can customize the graphics system, derive custom entities classes, and add extension data to the entities, and thus implement the modeling of building structures and the input of all other relevant data at the same time.

Employment of both AutoCAD and WTK may help us to build more powerful and efficient application of 3D modeling. Figure 1 shows the system architecture we discuss above.

To add and modify data of CAD models in a VR environment, a two-way data transformer between VR and CAD environment should be implemented. When the models are modified on AutoCAD, corresponding data in the VR environment should be automatically updated, and vice versa. Since the modeling functions of AutoCAD will be directly utilized, making changes to the structural models under AutoCAD will be convenient. Although data translation from CAD to VR will be done by WTK without much effort, the opposite directional data conversion, namely, modifying the structural models in VR environment and then updating the corresponding data in CAD, cannot be implemented simply by WTK. As a result, a VR engine should be developed.

IMPLEMENTATION OF OBJECT-ORIENTED MODELING IN AUTOCAD

Abstraction and Definition of Elementary-Component Classes

Object-oriented method has been employed when we try to define the types of elementary components. First of all, it can be easily noticed that different kinds of structural components usually share some attributes of the same types. Thus we may set up a base class to manage these attributes. In the class hierarchy of ObjectARX programming environment, AcDbEntity is the base class for all geometric entities, namely those database objects having a graphical representation. Accordingly, our base class for all structural components will also be derived from AcDbEntity. This class will be in charge of the material type of a component, the style, size and direction of its cross section, and other commonly shared properties.

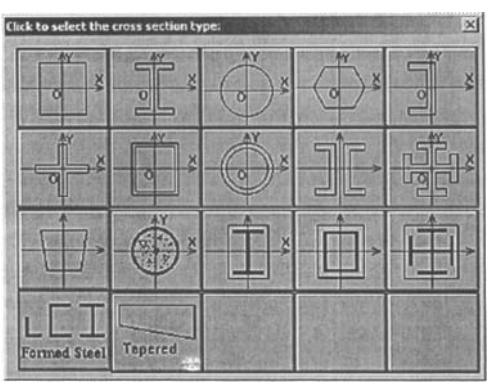

Figure2: Cross section types defined by the system

The system has predefined 9 sorts of material types, including brick, wood, concrete, and steel. And 17

cross section types, such as rectangular, circular, H-shaped, etc., are also predefined, as shown in Figure 2. In addition, user-defined section types are supported. Each type will have a corresponding code in the system, making the access to these types easier and faster.

The size and the normal vector of a cross section are also necessary for a complete description of the cross section. Hence they should be represented by member variables of the base class.

Any given kind of structural component can be defined as a component class, derived from the base class. Beams, columns and knightheads are examples of simple components that can be directly derived from the base class without making many changes. Given the axial line that passes through the central point of it cross section, any object of these three classes will be fully determined if the length or height is also specified. Walls, prefabricated slabs, stairs, and other structural components can be defined in a similar way except that their geometric parameters are more complicated.

The relationship of elementary-component classes is shown as Figure 3.

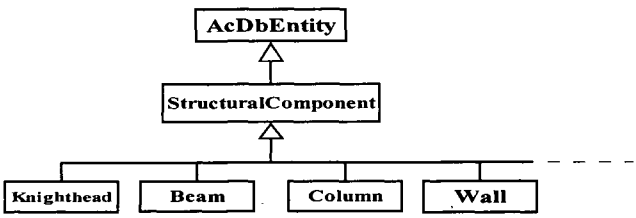

Figure 3: Relationship of elementary-component classes

Assembling of the Structural System from Elementary-Component Classes

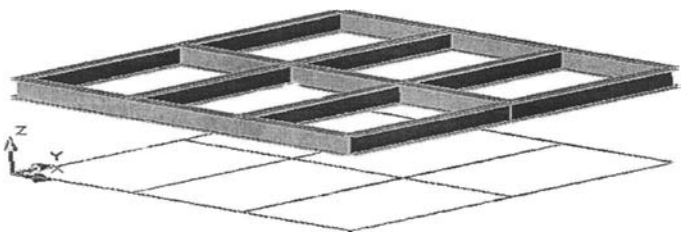
Once the elementary-component classes have been implemented, the users can construct the 3D models according to their designs. The modeling process is similar to those commonly used 3D CAD systems. Generally what a user should do is just to draw each part of the whole structural system through keyboard and mouse, by adding, modifying or deleting objects of those elementary-component classes.

Figure 4: The dialogue box of selecting a method to lay a group of beams.
(Other parameters of the beams may be also specified in this dialogue box.)

For the convenience of users, the system provides a fast approach, depending on the use of axes, to create structural models of the same kind. Here is an example of laying several beams in the system. Suppose two orthogonal groups of parallel axes lines have been drawn in advance and formed 6 rectangular reference grids. The first step is to pick up the desired cross section type, and then specify the length of each side of the cross section. A dialogue box is then shown (as in Figure 4), and one of the four available methods to add the beams can be selected:

— Grid Mode: to add a beam along one specified side of a certain reference grid;
— Axis Mode: to add beams along each segment of a specified axis;
— Window Mode: to add beams along all the reference grids inside a user-specified window;
— Two-point Mode: to add a beam, the two end-points of which should be specified by the user.

Figure 5 illustrates the results of using the "window mode" to lay beams on each segment of the six reference grids. There are altogether 17 beams, and each beam is corresponding to a segment of axis line. The cross sections of these beams are the same. We may notice that these beams are 3D entities, thus it is possible to observe them from any desired view if we properly make use of the system.



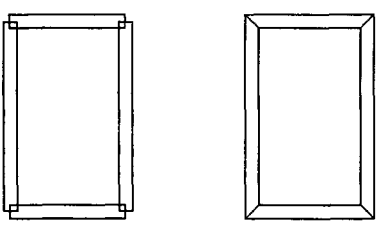


Figure 5: Results after "window mode" is used

The cross section of walls is simpler than those of beams and columns, but wherever a column or knighthead breaks the wall, special attention should be paid, since in a structure system a wall should be viewed as two independent parts once it is separated by another structural component. Consequently the system should recognize this situation and regenerate the wall. What's more, the connection point of several walls and the adjacent profiles should be recalculated to make display better, as shown in Figure 6.

(a) Before recalculation (b) After recalculation
Figure 6: recalculation of the profile of wall

DISPLAY OF THE MODEL IN A VIRTUAL REALITY ENVIRONMENT

In order to display the 3D models in a VR environment, data of models generated from AutoCAD must be translated into one of the formats that WTK can process. That is, after constructing the models under AutoCAD, users should save them in a DXF format file at first, and then use the WUM to open this DXF file, and make further conversion or map textures.

Since WUM does not support geometric entities other than polylines and 3D faces, we have to write extra codes to convert the original models to a set of polylines and 3D faces before they are exported as

a DXF file.

The geometric profile of a structural model is often complicated and sometimes even delicate, and the number of faces of a model is quite large. As a result, mapping texture will turn out to be rather time-consuming. Generally speaking, in most projects, engineers and their clients do not pay much attention to the texture of the surface of the structure. Then using proper colors to characterize the structural components, which can save a lot of time, will be a practical approach and be satisfactory enough.

When the NFF file is obtained, we may present the structural models in VR environment by applying WTK library.

Theoretically the detailed representation of sophisticated joints can be implemented in a similar way: The joint will be modeled under AutoCAD, and then converted to a NFF format file. After that, the detailed model will be viewed in WUM or our VR application. Because of the limitation of the length of this paper, further discussion will be carried on in another paper.

INTERSECTION TESTING IN A VIRTUAL REALITY ENVIRONMENT

Principle of Intersection Testing

Since the design for structure engineering projects is often accomplished by a number of engineers, design conflicts may be produced and would result in expensive construction mistakes if they were not discovered in advance. Traditionally, testing for design conflicts is done by experienced experts in every engineering profession who bring useful data together, check the plans and make oral discussions. Definitely much effort is required. In the modeling system discussed in this paper, users can not only examine the models intuitionally in the 3D VR environment, but leave this boring task to the system's automatic intersection testing utility as well.

The principle of computer-aided intersection testing is not too complex. Use computer programs to find out whether the structural components and pipes or other equipment in a structure have interfered with one another. If there is any undesired intersection, the model may have design errors and revision is needed.

Scheme for Implementation of Intersection Testing

The implementation of computer-aided intersection testing in our system includes the four steps: data digging, data analysis, data visualizations, errors feedback and modification.

Data digging means the collection of useful data related to the intersection testing. In the system discussed in this paper, data for intersection testing come from the models constructed under AutoCAD and their counterparts in VR environment. Structural components such as walls, beams and columns are geometrically made up of simple solids such as cubes, spheres, cylinders, etc. Since the CAD model of a structural component in our system contains all of its geometric data, we can calculate the size and position of each solid that constitutes the component.

In the data analysis step, the system will check the obtained simple solids for intersection in certain sequence. Mathematically speaking, to check whether two static solids intersect with each other or not is to find out whether the corresponding equations set has at least one reasonable solution. But solving these solutions is usually incredibly difficult. Fortunately we can take advantage of some powerful functions of intersection testing in the WTK library to simplify this problem.

The conflict parts of structure can be expressed in special color effects intuitionally in the VR environment. By real-time roaming, users will be able to discover these sites with ease.

By finding out the conflicts parts, designers may set out to make modifications. But the direct modifications of VR models are not currently practical because of two main reasons. On one hand, the technique of two-way data exchange between VR and CAD has yet to reach maturity and should make further optimization. On the other hand, nowadays most available personal computers still lack of the computation ability to achieve the data conversion from VR to CAD in an acceptable time limit. In this paper an indirect approach is contrived to replace the direct modification. Structural components that have conflict parts will be traced in the CAD platform and the original corresponding objects in the CAD models are obtained. Then the modifications will be applied to the CAD models, and finally new VR models will be regenerated using the revised data of CAD models. If the CAD and VR platforms had been integrated into one single software, and the computers were capable enough, then modifying VR models directly would become much easier.

CONCLUSION

Traditional 2D modeling method could hardly generate complicated 3D structural models immediately and check the consistency of input data intuitionally. By using ObjectARX to custom and extend AutoCAD, precise 3D models of various structures can be conveniently constructed. Making full use of WTK library allows us to view the 3D models in a VR environment and process the automatic intersection testing. Thus the complexity of modeling is largely reduced and the efficiency is greatly improved. Designers who take advantage of such a 3D modeling system will be able to fix their attention not on the modeling process itself but on their designs.

ABSTRACT

As an advanced navigation and measurement technology, GPS has been in the past two decades extensively applied to many fields and disciplines. One of the prominent applications of GPS is the precise monitoring of deformations of, e.g., engineering structures and the crust of the Earth. A limiting factor for large-scale use of GPS in such applications is however its high hardware cost. For continuous monitoring of deformations, each point to be monitored needs equipped with a set of geodetic quality GPS instruments. This makes many applications such as routine monitoring of landslides too expensive in most cases. A multi-antenna GPS system has been developed and tested by the research team aiming at significantly reducing the cost of GPS when used for monitoring deformations of objects such as slopes. The system uses special hardware and software components to allow one GPS receiver to be connected to a number of GPS antennas. One set of such equipment can therefore be used to monitor a number of points. The system reduces the cost of GPS hardware by many folds. This paper describes a new generation of the multi-antenna GPS system that has been developed by the research team. The system consists of integrated hardware and software components for data acquisition, transmission, processing, analysis and visualization. Integration of the GPS system with conventional slope monitoring systems will also be discussed in brief.

KEYWORDS

Slope deformation, GPS, multi-antenna GPS, landslides

INTRODUCTION

Many man-made and natural structures such as buildings and slopes undergo various forms of deformations. It is useful to study such deformations to understand the response of the structures to such factors as typhoons and groundwater level changes and to assess the safety and health conditions of the the structures.

As an example, Hong Kong has a large number of slopes. Some of the slopes may potentially fail and result in landslides. Since World War II, more than 470 people have lost their lives because of landslides. Monitoring of the progressive deformations of slopes and other parameters such as changes in groundwater levels, together with comprehensive analysis of the monitoring data, should help to prevent unexpected landslides.

GPS has been in the past two decades or so extensively applied to many fields and disciplines and proven to be a very useful tool for monitoring deformations of both man-made and natural structures. GPS offers many advantages over traditional surveying techniques that measure relatively geometric quantities (i.e., distance, angles and height differences) between selected points. In general, GPS is more accurate, efficient, highly automatic and low labor intensive. However, a limiting factor for large-scale use of GPS in such applications has been its high hardware cost. For continuous monitoring of deformations, each monitored point needs equipped with a set of geodetic quality GPS instruments. This makes many applications such as the routine monitoring of landslides too expensive in most cases.

In collaboration with researchers in Australia and China, we have developed in our past work a concept of using multiple GPS antennas with one GPS receiver to form the so-called multi-antenna GPS system, particularly for monitoring structural deformations (Tsakiri et al., 1998; Chen et al., 2000; Ding et al., 2000). The first system developed by the research team uses a standard commercial off-the-shelf GPS receiver together with a speically designed GPS multi-antenna switch (GMS) to enable multiple GPS antennas to be attached to the receiver so that all the points occupied by the antennas can be monitored with the system (Fig. 1). As a result of the devlopment, the cost of the GPS hardware per monitored point is grossly reduced, a multi-fold reduction in fact, making GPS a much more affordable technology for many applications.

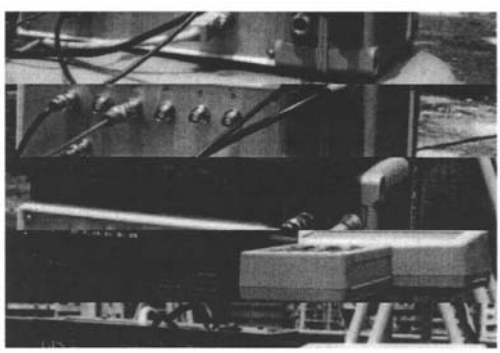

Figure 1: The first generation multi-antenna GPS system developed at the Hong Kong Polytechnic University

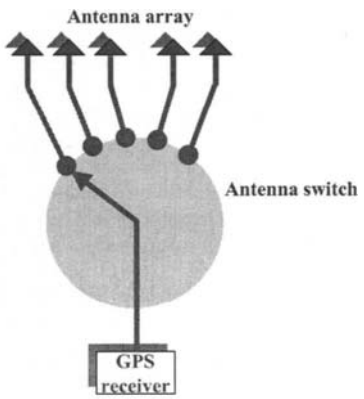

Figure 2: The design of the GPS multi-antenna switch (GSM)

To further reduce the cost of the system and to improve its performance, a second generation of the system has been developed. The new system includes tighter integration of the different hardware and softwre components and the employment of more advanced data processing and management algorithms. This paper first briefly reviews the design concept of the multi-antenna GPS system and then introduces the features of the hardware and software components of the new system.

THE CONCEPT OF MULTI-ANTENNA GPS SYSTEM

For standard GPS systems, one GPS receiver uses one antenna. Therefore, only one point as defined by the position of the antenna can be measured when using such a standard GPS system. Such GPS systems are widely used in navigation, surveying and many other applications. When using the standard GPS system to continuously monitor deformations, either the deformation of the Earth's crust or that of the various engineering structures such as slopes, each GPS system can only be used to monitor the movement of one point.

For the multi-antenna GPS system, on the other hand, a time-sharing concept is used to allow each of the antennas attached to the system to be connected to the receiver sequentially to collect GPS observations. The concept is realised by the use of a specially designed GPS multi-antenna switch (GMS) (Fig. 2). The data from each of the antennas can be used to compute the position, and therefore the movement of the corresponding antenna.

The configuration of a complete multi-antenna system when used in the differential mode is illustrated in Fig. 3 where a second receiver is used on a known station (reference station) to increase the positioning accuracy of the multi-antenna GPS system.

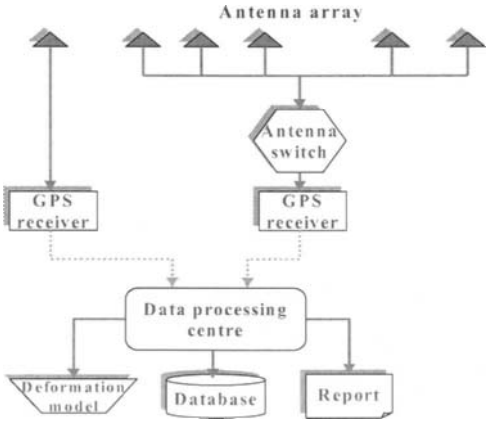

Figure 3: Configuration of a differential multi-antenna system

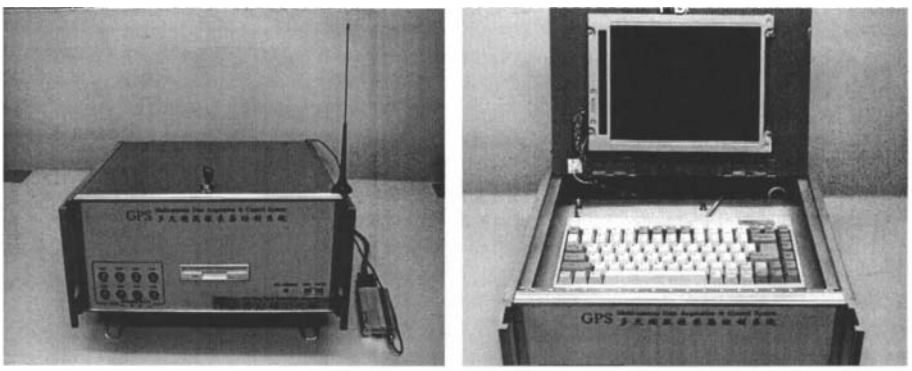
DESIGN OF THE NEW MULTI-ANTENNA GPS SYSTEM



In order to make the multi-antenna GPS system more robust, compact and cost-effective and easier to install, maintain and operate, impovement to the hardware, software and data processing algorithms of the earlier system has been made.

Hardware Components

The new system more tightly integrates the GPS receiver, the GMS and the data communication system through the use of a field industrial PC (Fig. 4). Instead of a standard geodetic quality GPS receiver, a GPS OEM board is used to ease the integration with other components and to further reduce

the cost of the system. There is a wide choice of GPS OEM boards available on the market that can be used with such a system. The main considerations for choosing a GPS board are the data sampling rate of the board and whether it is of single or dual frequency.

Either a fixed telephone line, a dedicated data line, a wireless GSM data line or radio transmitters can be used as the communication link between the office and the site GPS systems. The radio transmitters usually require direct line of sight between the site and the office or intermediate transmitting stations have to be used (e.g., Ding et el., 1996). Fiber optic cables are the best data links although the setting up cost is relatively high.

Figure 4: Integrated GPS receiver, GMS and data communication system. (a) shows the front side of the unit with eight-channel antenna connectors, a floppy disk driver and telephone line sockets. A GSM modem and antenna connected to the unit are also shown. (b) shows the screen and keyboard of the industrial PC.

Data Processing and Analysis Algorithms and Software

The software package developed for the new system is for remotely controlling the operation of the system, calculating the positions and movements of the GPS antennas attached to the multi-antenna GPS system and for assessing the risks of the monitored object. The main menu of the software is shown in Fig. 5.

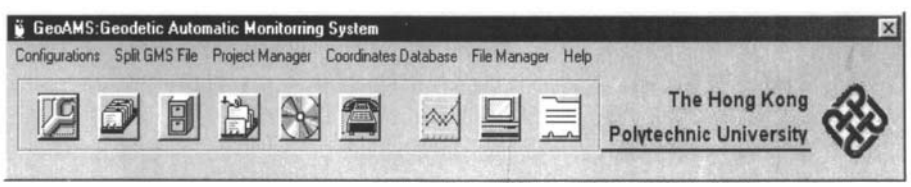

Fig.5: Main menu of the system software

The structure of the data processing and management software is shown in Fig. 6. Once the system is set up initially in the filed, its operation can be controlled remotely through the data communication system. The most important parameters that determine the operation of the system include the data

sampling rate of the system, the satellite cut-off angle, the time that the receiver connects to each of the antennas in each rotation loop, and how the data should be transmitted to the office, i.e., in real-time or at fixed time intervals.

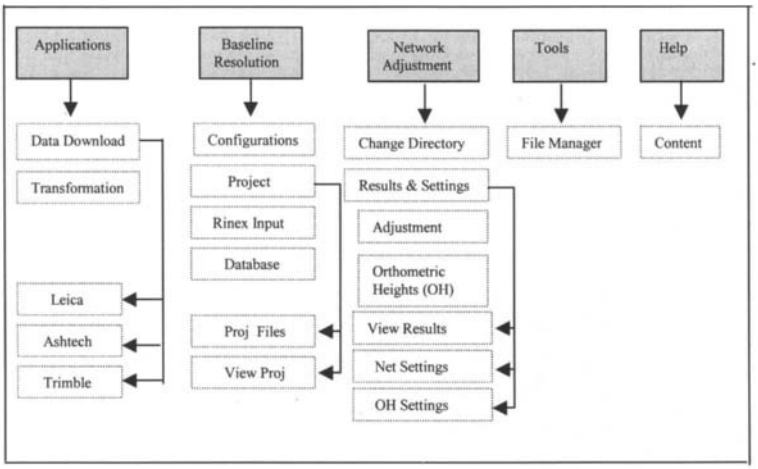

Figure 6: The structure of the data processing and management software

Fig. 7 shows the screen where the antenna channels to be used are selected, and the data sampling interval, satellite cut-off angle, time interval for each channel in a rotation loop and the form of data transmission are determined.

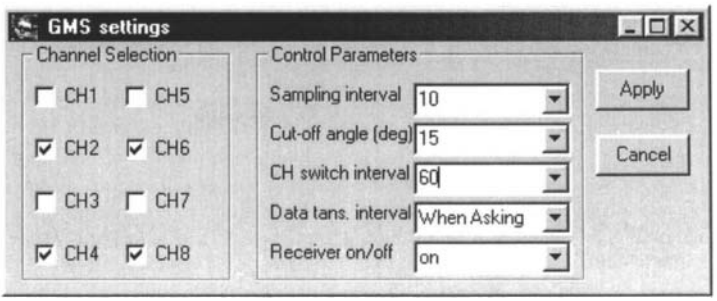

Figure 7: Setting up of some system parameters

Fig. 8 is a screen of the software that shows the system operation status, including the status of each channel, the number of the satellites that are currently being tracked, and the azimuth and elevation angle of the each of the satellites.

The software accepts the commonly used GPS data formats such as the RINEX, Leica, Ashtech and Trimble formats. The software can process GPS baselines, carry out GPS network adjustment and

transform ellipsoidal height into orthometric height. The system can work either in the static or the kinematic (RTK, real time kinematic) mode. The former offers milimeter positioning accuracy but requires a longer observation time period, from about 15 minutes to longer than half an hour depending on the site conditions and the length of the baseline, while the latter offers centimeter positioning accuracy and requires shorter observation time, i.e., near real-time to a few minutes.

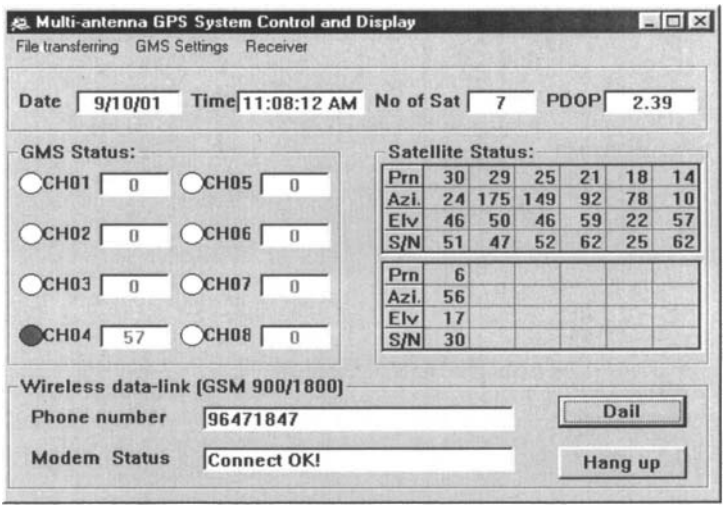

Figure 8: Screen showing system operation status

The well known LAMDA (Least squares Ambiguity Decorrelation Adjustment) method (Teunissen, 1995; Teunissen et al., 1997) method for the resolution of the carrier phase ambiguity is used in the software.

Fig. 9 shows a screen of the software that displays the movement of a monitored point in the forms of the 3D coordinate variations and of the plane view of the point positions.

INTEGRATION WITH TRADITIONAL MONITORING INSTRUMENTS

GPS has a number of advantages over traditional slope monitoring technologies. It provides accurate information on point positions and the changes in the point positions in a global reference frame that is not affected by local deformations. Besides, GPS works 24 hours and under any weather conditions. It is also highly automatic and cost-effective in the case of the multi-antenna system developed.

GPS however also has its shortcomings. The foremost is that it can only measure surface deformations. Besides, it is affected by the site conditions, e.g., the visibility to the sky.

GPS is therefore complementary in a number of aspects with the traditional landslide and structural monitoring techniques. It is advantageous to integrate GPS and other monitoring technologies in practical applications to utilise their respective advantages. Research is currently being carried out to optimally integrate the technologies (see Yin et al., 2002).

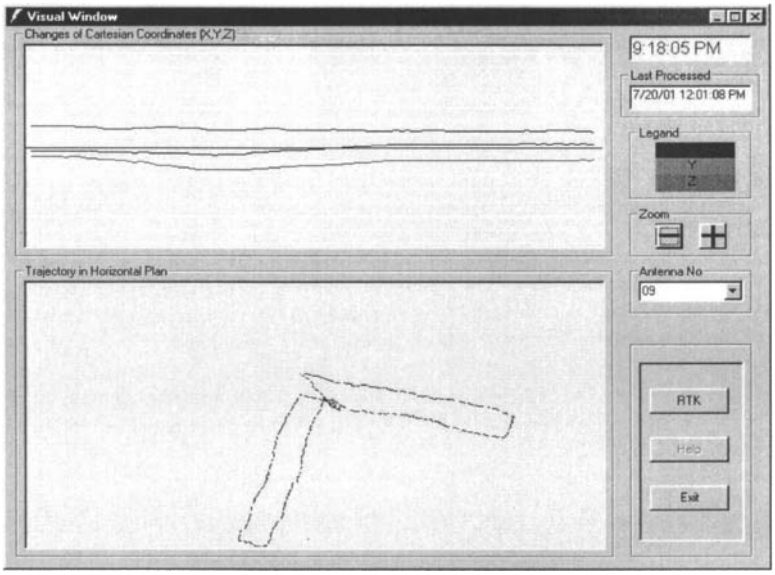

Figure 9: Visualisation of point movement

CONCLUSIONS

A multi-antenna GPS system developed for the monitoring of landslides and structural deformations has been introduced, including its conceptual design, and its hardware and software components. The multi-antenna design makes the cost of GPS hardware much lower than the standard GPS systems when used for monitoring landslides and structural deformations, and makes GPS a technology viable for many applications that have in the past been considered impossible. Besides the reduction in the cost of GPS equipment, the newly developed multi-antenna GPS system has also more tightly integrated the various components of the system and therefore much easier to install, operate and maintain.

ABSTRACT

This paper presents how ultra high resolution remote sensing data can be used within a GIS environment for the development of urban information systems and 3D city modeling. The paper concentrates on techniques to use digital surface models (DSM's) from remotely sensed data for the creation of highly accurate digital terrain models (DTM's). DSM's can be obtained from digital stereo scanner data or from laserscanning. It can be demonstrated that DSM'S from laserscanning are better suited for 3D city analysis. Using GIS techniques, however, also DSM's from stereo matching can be improved to produce highly accurate DTM's. Together with image and GIS (e.g. digital cadastral) data, these DTM's form a 3D urban information system which can be used for pollution modeling or telecommunication planning.

Ultra high resolution remote sensing, laserscanning, urban information systems, 3D city modeling, GIS, digital surface models, data fusion techniques

INTRODUCTION: GIS AND REMOTE SENSING FOR URBAN INFORMATION SYSTEMS

Geographic Information Systems (GIS) are more and more seen as an integral part of the modern information and communication society. Improved methods for data access and integration have accelerated this process. Consequently, GIS technology serves as the basis for the development of urban information systems (UIS). Remotely sensed image data can be used to generate the necessary current, accurate and synoptic information for the GIS databases. Due to the high spatial resolution requirements for UIS aerial photography has been used as standard imaging input. The advent of the new satellites with a resolution of better than 1m (e.g., IKONOS, Quickbird) and digital airborne scanner sensors with a high geometric fidelity and spatial resolutions (e.g., HRSC, ADS, DMC) in the cm range, however, challenges the analog airphoto techniques.

These airborne and spaceborne high resolution sensors offer an advanced potential for generating and updating GIS databases especially for urban areas. Moreover, digital airborne stereo sensors are capable of producing digital surface models (DSM) by automated techniques. Coupled with differential GPS and inertial navigation systems (INS), these sensors generate georeferenced ultra high resolution multispectral image data together with their accompanying DSM. Another way of creating this type of information is the use of laser scanning technology coupled with a multispectral imaging device. With these ultra high resolution sensors, however, the user community faces a new problem in the analysis of this type of image data. Standard techniques have to be augmented for an appropriate analysis because the necessary pixel homogeneity can no longer be achieved by the integration effect of large pixel sizes (e.g., 10 – 80 m). Due to their high spatial resolution the information content of the ultra high resolution data in such heterogeneous regions is very complex. Hence, the integration of the increasing amount of available GIS and/or elevation data (e.g., from stereo or laser scanners) as well as novel and efficient analysis techniques become a mandatory requirement for efficient processing and analysis.

We propose an integrated processing approach which fuses image analysis (e.g., segmentation or classification) and GIS (e.g., overlay or intersection) techniques. With that the heterogeneous properties of the objects of interest can actually be considered. The paper will present experimental results using high-resolution image and elevation data of two air-borne systems (HRSC-A, TopoSys II) which clearly demonstrate the benefits of introducing available GIS information for the classification and updating process for urban areas as well as the possibility of generating 3D city models for telecommunication industries or emission/immission modeling.

REMOTE SENSING PROGRAMS

There are many ways to distinguish between remote sensing systems. The most common one is probably the differentiation between space/satellite and airborne systems. Other possible taxonomies include spatial/spectral resolution, recording mode or spectral coverage (Table 1).

TABLE 1
TAXONOMY OF REMOTE SENSING SYSTEMS (FROM: EHLERS ET AL., 2002)

Taxonomy of Remote Sensing Systems						
Recording Platform	Satellite/Shuttle		Aircraft/Balloon		Stationary	
Recording Mode	Passive (Electrooptical, Thermal Infrared, Thermal Microwave)			Active (Laser, Radar)		
Recording Medium	Analog (Camera, Video)			Digital (Whiskbroom, Line Array, 2D CCD)		
Spectral Coverage	Visible/Ultraviolet	Reflected Infrared		Thermal Infrared	Microwave	
Spectral Resolution	Panchromatic 1 Band	Multispectral 2 – 20 Bands		Hyperspectral 20 – 250 Bands	Ultraspectral > 250 Bands	
Radiometr. Resolution	Very High (> 12 bit)	High (8-12 bit)		Medium (6 – 8 bit)	Low (< 6 bit)	
Spatial Ground Resolution	Ultra High < 1m	Very High 1 – 4 m	High 4 – 10 m	Medium 10 – 50 m	Low 50 – 250 m	Very Low > 250 m

Satellite Systems

Today, a wide variety of systems are used to detect energy patterns which provide information about the earth, its atmosphere, oceans, and land surfaces. The bulk of satellite remote sensing data is currently acquired by multispectral scanners such as Landsat TM and linear array devices such as SPOT HRV and IRS LISS sensors in the visible and near infrared positions of the electromagnetic spectrum.

With the advent of commercial high-resolution satellite programs from companies such as Space Imaging, Digital Globe or Orbview, new application fields have been opened for space based remote sensing. This includes – for the first time – operational applications for urban areas where the spatial resolution requirements are higher than for any other areas. Table 2 shows the characteristics of the two currently available commercial very high resolution sensors in space.

TABLE 2
SELECTED VERY HIGH RESOLUTION SATELLITE MISSIONS

Company	Digital Globe		Space Imaging	
System	QuickBird 2		Ikonos	
Mode	Pan 11 bit	Multispectral 4 bands 11 bit.	Pan 11 bit	Multispectral 4 bands 11 bit
Spatial Resolution	0.61 m	2.44 m	1 m	4 m
Spectr. Resolution (nm)	450-900	450 - 520 (b) 520 - 600 (g) 630 - 690 (r) 760 - 900 (nir)	450-900	450 - 520 (b) 520 - 600 (g) 630 - 690 (r) 760 - 900 (nir)
Suitable Scale for Applications	1:25,000 – 1:5,000			
Swath Width	16.5 km	16.5 km	11 km	11 km
Image Scene Size	16.5 x 16.5 km² Strip: 16.5 x 165 km²		11 x 11 km²	
Orbit Height	450 km		681 km	

Besides North America, Europe, India and Japan, other countries such as Israel, Brazil, China or Korea have been successful in launching their own national remote sensing satellites and challenge the established remote sensing nations.

Airborne Programs

Advanced technologies such as GPS coupled navigation systems and improved digital sensor technologies have the potential to overcome the strongest impediment of aircraft scanners: the lack of geometric stability. Public and private research concentrates on the development of digital line array or matrix scanners that will serve as successors to the 'classical' air cameras. Companies such as LH Systems or Zeiss Imaging are offering first commercial systems, research centers such as the German Space Establishment (DLR) fly their own prototypes. Such systems have to establish their market somewhere between the satellite image user seeking higher resolution and the airphoto user seeking digital input and GIS compatibility. Consequently, airborne scanner systems have to offer stereo capability and multispectral recording. The HRSC-A (High Resolution Stereo Camera - Airborne) is a narrow-angle digital multispectral stereo scanner for photogrammetric and remote sensing applications (Wewel and Scholten, 1999).

The camera was originally developed for the Russian Mars-96 space mission and later modified for airborne remote sensing applications. Especially the peripheral digital electronics were re-designed for use on aircraft. The system is mounted on a Zeiss T-AS stabilization platform. The HRSC uses the linear array imaging principle. Nine CCD line detectors are mounted in parallel at the focal plane behind one single optics and perpendicular to the flight direction. Nine images of the same strip are recorded almost simultaneously as a result of the forward motion of the aircraft. Five of the nine CCD lines of the HRSC-A are arranged at specific viewing angles (fore-aft-nadir) to provide stereo and photometric viewing capability; four of the nine CCD lines are covered with different filters for the acquisition of multispectral images (Tab. 3).

TABLE 3
SELECTED ULTRA HIGH RESOLUTION STEREO AIRCRAFT SCANNERS

	HSRC-A	HRSC-AX
Focal length	175 mm	151 mm
Total field of view	38° x 12°	41° x 29°
Number of CCD lines	9	9
Sensors per CCD line	5.272	12.172
Sensor size	7 µm x 7 µm	6.5 µm x 6.5 µm
Spatial resolution at 3000 m flying height	15 cm	20 cm
Radiometric resolution	8 bit	12 bit
Suitable application scale	1:500 (dep. on flying height)	1:500 (dep. on flying height)
Spectral resolution / band numbers	1 - Blue: 395- 485 nm 2 - Green: 485- 575 nm 3 - "Red": 730- 770 nm 4 - NIR: 920-1020 nm 5 - Nadir/stereo (Pan): 585- 765 nm	1 - Blue: 450 – 510 nm 2 - Green: 530 – 576 nm 3 - Red: 642 – 682 nm 4 - NIR: 770 – 814 nm 5 - Nadir/stereo (Pan): 520 – 760 nm
Read-out frequency	450 lines/sec	1640 lines/sec

A fully automatic photogrammetric and cartographic processing system was developed that allows that the system can work basically without ground control points (GCP's). This system makes use of DGPS and inertial navigation system technologies (Wewel and Scholten, 1999). For the generation of digital surface models (DSM's) a digital multiple correlation process is performed. The resulting identical image points are converted into object points by ray intersections. Finally, based on the DSM's digital orthoimages are generated and multispectral orthomosaics are produced. As a spin-off, an extended narrow-angle system (HRSC-AX) has been developed by the DLR providing higher radiometric resolution, larger swath width and re-designed multi-spectral bandwidths which are better suitable for terrestrial applications (see Tab. 3) (Neukum et al., 2001).

During the last couple of years, laserscanning systems have reached maturity due to the enhanced performance of GPS/IMU solutions for capturing orientation data of the associated moving platforms. Just recently the TopoSys company released their airborne TopoSys II system which simultaneously produces elevation data through laserscanning and multispectral imagery employing a line array scanner. The laser scanner operates with a glass fibre array producing a parallel acquisition pattern. First and last pulse elevation data with a height accuracy of about ± 0.2 m are delivered in a raster of 0.5 m x 0.5 m or 1 m^2, respectively. The imaging sensor produces four bands in the visible and near infrared spectrum with a ground pixel size of 0.5 m at a radiometric resolution of 8 bit (TopoSys, 2002).

SEGMENTATION APPROACH FOR THE ANALYSIS OF MULTI-SENSORAL DATA

As already pointed out, standard techniques have to be augmented for an appropriate analysis of the

available ultra-high resolution data for urban applications. In this context, we will firstly concentrate on the integration of the increasing amount of available multi-sensor data (multi-spectral imagery and elevation data, with the emphasis on the latter) as well as on the use of novel analysis approaches (in particular, segmentation methods). It should be noted that this rather data driven approach can be further extended to a hybrid procedure, i.e. it is able to integrate a priori knowledge from GIS databases and other sources.

Tasks

From an application point of view we will concentrate in the following on two key processing steps in the context of urban analyses which are the estimation of object and terrain surface heights and the separation of buildings from other objects. With respect to the first task, most elevation evaluation systems (like stereo matching or laserscanning) yield the respective largest values above a position, i.e. a *Digital Surface Model (DSM)*. However, for some applications (e.g., for hydrological modeling) those objects that stand clearly above the terrain surface (e.g., buildings, trees) are not of interest, i.e. the *Digital Terrain Model (DTM)* is required. Furthermore, for object extraction purposes and 3D city modeling the absolute height values of objects above the terrain surface (i.e., the difference between DSM and DTM) are required. Because in practice a DTM is not always available, not sufficiently accurate or reliable (or just too expensive) a substitute has to be estimated (*estimated DTM, eDTM*). The means, that a *normalization* has to take place. For this task, a couple of geometrically based algorithms have been developed (for an overview see Schiewe, 2001), but none of them have succeeded to an operational status so far. This is mainly due to the limited quality (especially for inclined terrain) and the missing grade of automatization (especially due to abstract thresholds). Thus, an application dependent combination of methods incorporating rather high interactive efforts for controlling and editing are presently applied in practice.

Also, the automated classification of topographical objects in urban scenes is still far from maturity. But for a couple of applications not a detailed but rather rough interpretation is sufficient. If, for example, the analysis of object heights has separated relatively high objects (i.e., building and trees) from lower ones, the recognition task might be reduced to the separation of the first mentioned classes.

Methodology overview

In the following we want to present a novel region-based, multi-scale approach for urban and landscape modeling purposes from multi-sensor data with the emphasis on elevation information. The procedure can be divided into two major parts: Firstly, the segmentation of multi-sensor data is performed which in analogy to a visual interpretation can be done at various scales. In order to attach semantical meanings to the obtained geometrical regions (e.g., terrain or non-terrain surfaces for the first task, or buildings or trees for the second), a classification using a fuzzy-logic approach takes place in a second next step.

Segmentation

Segmentation methods are well known from Computer Vision since the 1980's and have been applied in many disciplines. However, due to several reasons their use for the analysis of remotely sensed data has been rather limited (Schiewe et al., 2001). From the general strategies, we prefer a region-growing approach which from our experiences shows a good tolerance against noise and produces closed borders as well as sufficiently homogeneous segments with respect to relevant attributes. General goal of the segmentation step is an accurate delineation of the desired regions (terrain and non-terrain areas, buildings and trees, respectively). Obviously we also demand for the membership of one and only one class (which will be determined later on) to one segment. To achieve these goals, a proper choice of *homogeneity criteria* has to be applied. In the case of the DSM normalization we follow the hypothesis that regions which have to be reduced to the terrain surface are characterized by strong altitude gradients and curvatures (Schiewe, 2001). By extending the complexity presented so far by additionally introducing mul

tispectral or panchromatic image data, we have experienced worse segmentation results due to irregular and inaccurate border lines. This effect is mainly due to a strong affection of image data by noise and shadows. The region growing process is now controlled by a comparison of the obtained homogeneity measures of neighboring primitives with a user-defined threshold. Varying this threshold, one can influence the grade of generalization: The lower the value the less primitives are merged and the larger the total number of segments becomes.

Classification

For the interpretation of the obtained segments we apply a *fuzzy logic* classification approach. There are several reasons for introducing partial rather than crisp memberships in this context (see, for example, Cheng, 2002): On the one hand, the description of the real phenomenon is neither geometrically sharp nor certain. On the other hand, the limited spatial sampling rates and measurement errors (the latter being mostly unknown) also lead to indeterminate boundaries. As input for the classification we can use several application dependent features for every extracted segment. For each feature the membership function to a category is computed (fuzzification). Because a generic determination of these functions seems to be impossible we apply tolerance intervals from logical considerations and a linear function in order to describe the partial memberships. Finally, the assignment to one and only one class (de-fuzzification) is based on a comparison of the maximum of the obtained single membership values with a threshold. As *features* in the case of the normalization task the mean of altitude gradients (pointing to forest areas) and the 90% percentile of gradients (pointing to steep edges likes in buildings) can be taken into account. In order to handle the problem of flat roofs (i.e., segments with low gradients), we also consider the 90% percentile of gradients of all surrounding segments (referring to a building edge with high gradients). Finally, the mean difference between first and lust pulse laser scanning measurements, if available, can be considered for each segment (also pointing to wooded areas and building outlines). For the task of separating buildings from trees not only the object height but in particular the Normalized Difference Vegetation Index (NDVI) and the spectral texture (in panchromatic imagery) are meaningful features.

Examples

The multi-sensor data set which covers a settlement near the City of Ravensburg (Germany) consists of simultaneously acquired laserscanning and multispectral image data of the TopoSys II-sensor. Fig. 1 illustrates the processing results applying the described region based approach. As an example, the fuzzification result for the feature "mean gradient" demonstrates the desired high membership values of wooded areas to the class of non-terrain areas as well as the necessity of taking also the gradients of surrounding segments of roof regions into account. Comparing the achieved results for both tasks - normalization and separation of buildings and other objects - no omission errors were found. The number of commission errors is below 2% of the entire number of segments. Critical regions within the terrain surface estimation process are small clearings within wooded areas whose slope behavior in contrast to the surrounding trees could not be sufficiently separated. Applying the segmentation and the following classification not only at one, but at multiple scales, reduces the number of commission errors with decreasing generalization level. However, this scaling process must not be performed as far as possible because the number of omission errors would increase and in the extreme case one would end up with an undesired point-wise classification.

Significantly worse results have been obtained using elevation data derived from an automated matching using imagery of the HRSC-A sensor for the test site of the City of Osnabrück (Germany). Due to the stereo matching procedure that is used to create the elevation data, segments are produced that do not coincide well with actual borders. While the number of omission errors was quite low (about 2 %), the number of commission errors (ca. 40 %) was definitely too high. Also the integration of image data could not improve the resulting quality. It becomes obvious that without additional information (i.e., human or

GIS based knowledge) an *automated* procedure as presented here cannot compensate for the limited input data quality.

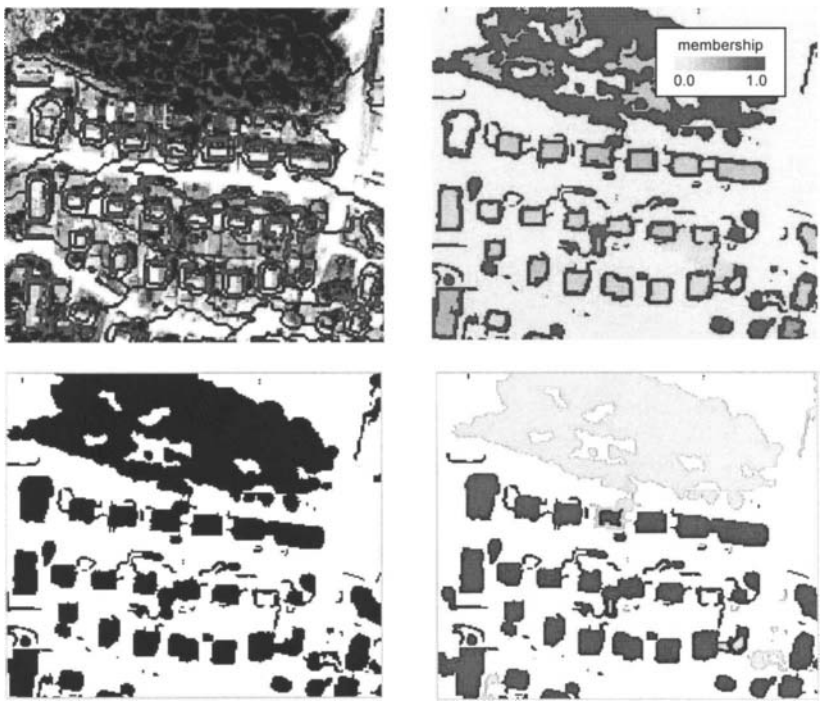

Figure 1: Results of multi-sensor data processing: segmentation (upper left), fuzzification based on feature "mean gradient" (upper right), classification of terrain surfaces (in gray; lower left), classification of buildings vs. wooded areas (in red and green, respectively, lower right)

URBAN ANALYSIS WITH DTM's FROM OPTICAL SCANNER DATA

DTM Generation

Despite the failure in the automated segmentation process, elevation data from stereo matching of digital image data can be improved by manual techniques if no laserscanning data are available. A number of automated (or semi-automated) methods have been developed for DTM extraction from laser DSM data. Unfortunately, they do not work well with HRSC-DSM-data (see above and also Baltsavias, 1999, von Hansen and Vögtle, 1999). This is caused by the representation of 3D objects in the HRSC DSMs. The edges of 3D objects do not appear as vertical lines but rather as slopes with a tent-like behavior (fig. 2). This effect is caused by the 18.9° fore and aft stereo bands and the employed stereo matching algorithm. In our test area, the city of Osnabrück (Germany), we obtained HRSC digital orthoimages with a ground resolution of 0.15 m data in addition to the DSM data. The imaging products had a geometric accuracy of $\pm$one pixel in x- and y-direction. They were directly integrated into a GIS environment. We used the orthophotos as GIS background information for on-screen digitizing of reference points (RP's). These RP's represented exact ground truth (e.g., streets, meadow, yards or parks). About 400 equally distributed

RP's per km² were found yielding a density of about one point per 2,500 m². This density is well suited for the representation of a terrain with a moderate morphology and without any steep slopes.

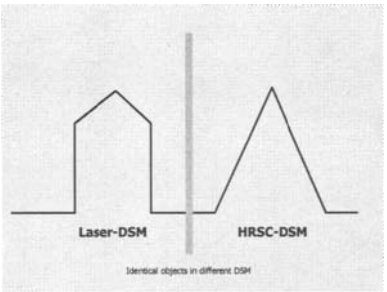

Figure 2: Object Representation in DSM's from laserscanning (left) and HRSC data (right)

In the next step, elevation values were assigned to the RP's from the underlying DSM using the GIS focal function operator. At last, the terrain surface can be interpolated from the RP elevation values using an inverse distance weighting (IDW) algorithm. For the calculation of each DTM point, the 12 next neighbor RP's were used. The accuracy of the interpolated DTM was checked from a total of 669 check points (CP's). These CP's were terrestrially measured with a very high accuracy. The average difference in height was about 1 m which represents an excellent accuracy. The maximum difference was 12.1 m which was caused by shadowed areas where no gray values can be used for the calculation of the HRSC DSM.

Assigning elevation to objects

Using the described techniques, it could be proved that both type of elevation measurements (i.e. DSM's by stereo matching and laserscanning) can be used as a basis for 3D urban information systems. Building heights are needed, for example, for the modeling of traffic noise and of the spreading of radio waves for mobile telecommunication purposes. For building height extraction, we combined a priori knowledge about house location and extension from the digital German cadastral database (ALK) with the HRSC DTM's in a GIS environment. The centroids of these building were extracted as GIS point layer and the DTM and DSM values were assigned to the points using the GIS overlay operator. The actual height of each building could then be calculated by subtracting the DSM value from the DTM value. The resulting elevation is the height at the centroid point of the building which can be linked directly to the respective building. The 3D data set can be exported from the GIS into a WWW compatible format using the VRML technology and can be visualized in every common internet browser.

This technique was used to demonstrate the effects of newly constructed buildings on the urban climate in Osnabrück. Fig. 3 shows that new large buildings (outlined in yellow) block the nightly cool air which comes from the outside of the city toward its center (indicated by blue arrows). This 3D view - if constructed in advance in an urban information system - allows planners and decision makers to visualize and simulate effects of city developments on its climate. With this, negative climatic and pollution effects in urban areas could be avoided or at least minimized.

CONCLUSIONS

Using advanced image processing, data fusion, and GIS techniques it could be demonstrated that ultra high

resolution image data from airborne scanners are an important information source for urban information systems. Accurate, current and high resolution DTM's can be generated from airborne scanners using direct laser techniques or indirect stereo matching algorithms of electro-optical image data. These DTM's can be used for 3D applications such as noise and pollution simulation or telecommunication planning.

Data Model and 3D Visualization of Underground Pipeline

Qingquan Li, Yong Yan, Bisheng Yang, Xianghong Hua
Wuhan University, Wuhan, Hubei
P.R.China, 430079

ABSTRACT

Pipelines are part of the infrastructure of any city and research about the 3D representation of pipelines is very important for integrating into 3D building models, road models and terrain models. These models are all indispensable components in a digital city. In this paper, the reality of managing pipelines is introduced first. Second, a Layer Model and data structure of a 3D pipeline object is proposed, which can meet the requirements of 3D spatial representation and interactive operation. Third, the paper illustrates how to build the 3D underground pipeline model and introduces the method of subsection calculation. Finally, an experimental system prototype is developed based on C++ and OpenGL, and several experimental results are illustrated.

KEYWORDS

3D pipeline model, visualization, interactive operation, layer model

1 INTRODUCTION

For a long time, the management and maintenance of pipelines has been performed manually and with low efficiency. Therefore much research about managing pipeline with computer assistance has been done. Now most systems of managing pipelines exploit programming language integrated with GIS software such as MAPINFO and ARC/INFO. Researchers and users trust them for they have strong basic function of GIS and have experienced the baptism of the market. Several systems of managing pipelines are based on GIS platforms developed independently such as GeoStar and MAPGIS. These systems include the professional function of managing a pipeline besides basal functions, but most of them are based on 2D or 2.5D and they cannot represent the spatial relation of complicated pipelines. Even some pipes vertical to the surface of the earth are difficult to handle. As a result, many approaches and systems for 3D pipeline models have been developed. Some famous GIS software such as MAPINFO and ARC/INFO can represent a simple 3D object, but they cannot depict and analyze 3D relations of the complex objects in detail. Furthermore, they cannot implement modeling of a 3D pipeline. In China, several corporations have been researching the 3D representation of pipelines such as ZONDY and LinTu. They have made achievements in virtual 3D image browsing and

roaming, and this is inadequate for managing a 3D pipeline. Based on close-range photogrammetry and CSG model, 3D pipeline model can be constructed(Bürger,2000, ERMES,2000). This method is useful for the representation of complicated objects aboveground, but cannot adapt to underground pipelines.

The increasing quantity of pipelines requires data management and storage to be powerful and efficient. At present, data models used in commercial GIS are mainly Topology-Relationship Model and Space-Entity Models. Topology-Relationship Models mostly adopt the POLYVRT structure, which can save memory because data does not overlap. But the structure is so complicated that data is difficult to edit and maintain. Though Space-Entity Models make data stored repeatedly, it enhances the maintenance of data. According to the types of pipeline data, the author combines the virtues of the two models and put forward a data structure named Layer Model, which not only saves memory but also is easy to edit and maintain the pipeline data.

The following sections are arranged as follows. First, the reality of pipeline management is introduced. Second, the Layer Model and data structure of the 3D pipeline object is proposed, which can meet the requirements of 3D spatial representation and interactive operation. Third, the paper illustrates how to build the 3D underground pipeline model and introduces the method of subsection calculation. Finally, an experimental system prototype is developed based on C++ and OpenGL, and several experimental results are illustrated.

2 ORGANIZATION OF PIPELINE DATA

Underground city pipelines can be sorted into seven classes such as pipelines for feed water and for drainage. Every class can be subdivided. For instance, pipelines of feed water include pipelines for industry, for homes and for fire protection.

2.1 Layer Model

The complexity and large amount of pipeline data requires an efficient management mechanism for spatial data. Therefore, a Layer Model of pipeline data is developed that can not only meet the requirements of 3D spatial representation, but can also meets the requirements of interactive operation with 3D objects. Figure 1 illustrates the Layer Model.

According to the different classes of pipeline, all data is organized and managed by different layers, which include layer of feed water, drainage, burning gas pipeline, and so on. The shapes of most pipelines are branching, orbital and radial, so a pipeline can be decomposed to several pipeline sections according to junctions or points of changing radius. At a joint, pipelines attachments such as T-junction and intersection junction are used to connect the pipeline sections. So we can consider that every pipeline is composed of pipeline sections and attachments, as figure 1 illustrates. And the most basic data about pipelines are points that marked the attachments and used to construct continuous pipeline sections. These basic data can be called "points on pipelines".

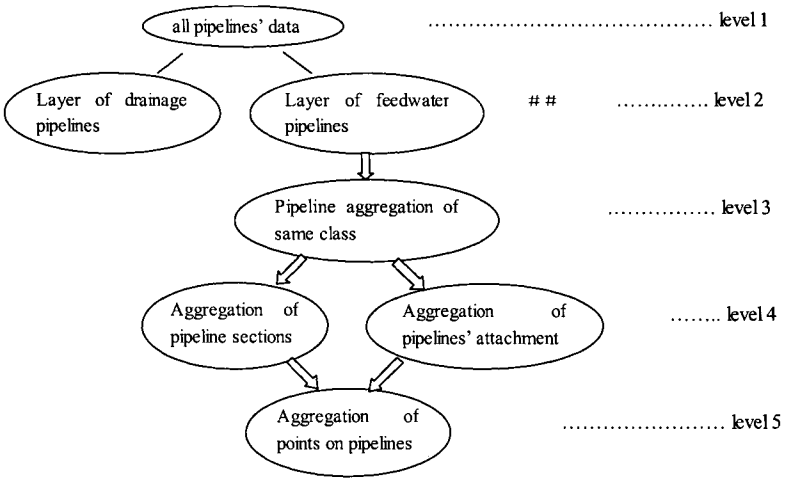

Figure 1: Layer Model of pipeline data

2.2 Data Structure

Based on the Layer Model, the structure of storing data is reticular that is close to a tree structure. The data type of every class has a little discrimination, but their structures are the same basically. Taking the data of feed water pipelines as an example, from figure 1, we can see these data comprise a reticular structure too. All nodes in the network denote the aggregation of some data, which is stored in the tables or files. The data in the same node is stored separately as spatial data and attributive data. Attributive data includes the material of the pipeline, time of burying, and so on. It is stored in the relative database and used to afford detailed information when inquiring or indexing. Coordinates, color and radius are spatial data, which are used for modeling and 3D visualization. It is stored in files with special format. Spatial data connects with Attributive data by the same identity.

This mode of storing data has several advantages:

- It can reduce overlapping data and save memory.
- It can be easy to edit and maintain.
- It makes quick data indexing, so the system can run fluently.

For the purpose of query and analysis, a pipeline index must be provided to speed up data retrieval. The R^+-tree index (Storcebraker, 1986) proves to be a useful index. When querying and analyzing, the identities of pipeline sections chosen are decided by the R^+-tree index first. Then the files of spatial data are indexed. It's a multilevel index, so depending on the identities of pipeline sections, we can decide which pipelines are chosen through indexing the files of pipelines, and which layers of pipelines can be decided subsequently.

3 3D PIPELINE MODELING

OpenGL is an excellent program interface for creating 3D Real-time graphics. With it, complicated objects are constituted by drawing basic figures such as dots, lines and polygons. The author uses numerous quadrangles to simulate the surface of pipeline object. Before modeling, enough data for calculation needs must be obtained. Through dealing with all the files of points on pipelines, we can obtain the 3D coordinates of all the nodes on the Centre Line Of Pipelines. Centre Line Of Pipeline means the conduit axes. These 3D coordinates, together with radius and color of pipeline, are initial

data ready for the 3D modeling and representation.

3.1 Surface Differential (Liu, 1999)

A pipeline is usually represented with a line on the plan. In 3D rendering, a pipe is represented with a column. The axis of column is the Centre Line Of Pipeline, and the radius of the column is the pipe's radius. The surface of column is divided into several quadrangles just as figure 2b illustrates. Some experiments indicate that the more quadrangles the more realistic is simulated pipe. At the same time, the speed of system running becomes slower. With a simulated pipe divided into coarser, the speed of system running is faster. When the surface of column is eight quadrangles, the speed of system running and the quality of display are in balance.

Figure 2a: 2D representation of pipe

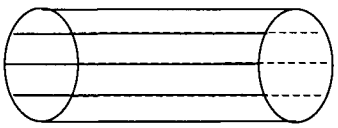

Figure 2b: 3D representation of pipe

3.2 Simulation of Pipeline Section

In plan, a pipeline section will be represented with a polyline which has no height (Fig.3a). In 3D rendering, we divide a pipeline section into several columns (figure 2b) and are simulated though connecting these columns. There are several problems to be noticed. If every column is composed by eight quadrangles and if columns are not connected well then gaps between columns will appear easily. The correctness of those quadrangles' coordinates is important too. The wrong coordinates may lead the vertexes of the quadrangles to be not coplanar and the simulated pipeline will look twisty. So the author has advanced an arithmetic named Subsection Calculation to solve the above problems. The arithmetic is first to calculate the coordinates of vertexes on the brim of node (node 1 or 15 in Fig 4), then to calculate the coordinates of vertexes on the brim of other node (node 2 to 14 in Fig 4) in turn. This is illustrated in detail below.

- Arcing the corner of Center Line Of Pipeline (Fig. 3b)

Centre Line Of Pipeline is a polyline that has height. It is ready to simulate the pipeline and it does not be shown eventually. At a corner, the value of radian changes with the angle. The radius of the circle including the radian equals to the radius of pipeline section.

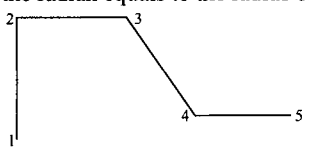

Figure 3a: polyline in the plan

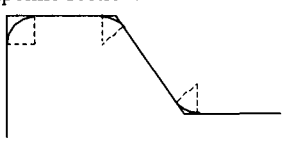

Figure 3b: Arcing Centre Line Of Pipeline

- Dividing the Center Line Of Pipeline into subsections (Fig. 4)

According to the value of radian, the number of subsections in the corner is decided. In figure 4, the node 1 to 15 serial numbers denotes the spots where the Center Line Of Pipeline is divided. The 3D coordinates of these spots will be calculated from the initial data.

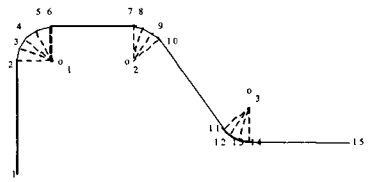

Figure 4 : dividing the Center Line Of Pipe

- Calculating the coordinates of vertexes on the brim of pipe (node 1 or 15) (Fig 5)

In figure 5, O-XYZ is a 3D Cartesian System. The reference frame (o-xyz) is defined below. Its origin superposes the first node (node 1) of the Center Line Of Pipeline. Its z-axis is parallel to the first line (node 1 to 2) of the Center Line Of Pipeline. Its x-axis is perpendicular to the Z-axes of Cartesian System.

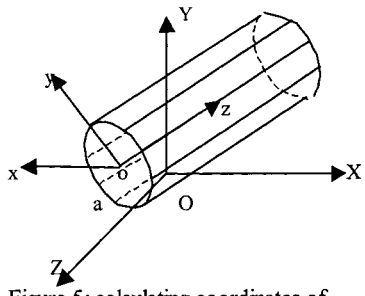

Figure 5: calculating coordinates of vertexes on the brim of port

Through rotation and translation, the reference frame can be change into the 3D Cartesian System. Known from the spatial analytic geometry, the arbitrary vertex "a" (Fig 5) at the brim of pipe has the relation in the reference frame and Cartesian System given formula (1). Its matrix form is given formula (2).

$$\begin{cases} X = a_1x + a_2y + a_3z + x_0 \\ Y = b_1x + b_2y + b_3z + y_0 \\ Z = c_1x + c_2y + c_3z + z_0 \end{cases} \quad \ldots(1) \qquad \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix} \quad \ldots(2)$$

In the two coordinate transforms, (x_0, y_0, z_0) is the coordinate of the origin of the reference frame located in the Cartesian System. Nine coefficients are the orientation cosines of two axes, i.e.

$$\begin{pmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{pmatrix} = \begin{pmatrix} \cos Xx & \cos Xy & \cos Xz \\ \cos Yx & \cos Yy & coxYz \\ \cos Zx & \cos Zy & \cos Zz \end{pmatrix} \quad \ldots(3)$$

The coordinates of the vertexes on the brim of pipe are easy to calculate in the reference frame. It, together with the nine coefficients and (x_0, y_0, z_0), are added to formula (2). Then the coordinates of vertexes on the brim of pipe in the Cartesian System, i.e. true 3D coordinates, are calculated.

- Calculating the coordinates of vertexes on the brim of other nodes

When calculating in turn, there are two possible circumstances met. One is "beeline" such as node 1-2 (Fig 6a). The other is "siphon" such as node 2-3, node 3-4 (Fig 6b).

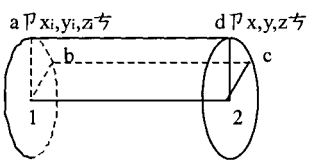

Figure 6a: calculation on the beeline

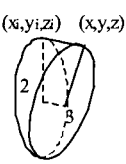

Figure 6b: calculation on the siphon

For the beeline (Fig 6a), the coordinates (x_i, y_i, z_i) of vertexes on the brim of port (node 1) have been obtained in the last step. The coordinates of node 1 to 15 also have been calculated in the before-mentioned step. So the coordinates (x,y,z) of vertexes on the brim of next node (node 2) can be

calculated as a rectangle. For the siphon (Fig 6b), the coordinates (x_i,y_i,z_i) of vertexes on the brim of node 2 have just been gained. The coordinates (x,y,z) of vertexes on the brim of next node (node 3) can be calculated as an isosceles trapezoid. By analogy in turn, the coordinates of all the vertexes on the brim can be obtained. Connecting them as rectangles 'abcd' in figure 6a, a pipeline section will be formed (Fig 7).

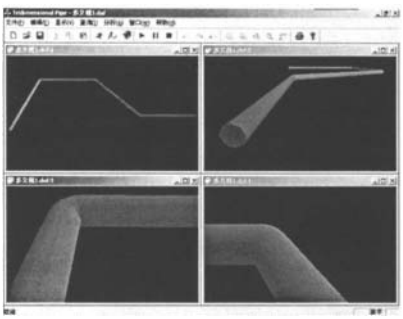

Figure 7: simulation of pipeline section

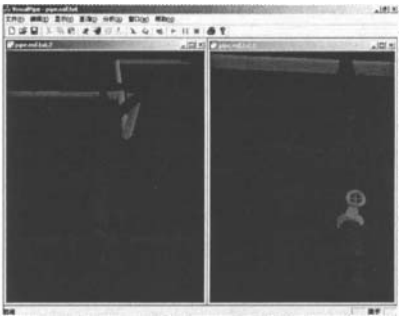

Figure 8: connection of pipeline sections

3.3 Connection of Pipeline Sections

In fact, there are attachments such as T-junctions, valves to connect pipeline sections. Therefore, the author abstracts them as 3D symbols and combines these simulated attachments with pipeline sections (Fig 8). Because there are so many attachments and varieties attachments, it's difficult to build all of them. If each attachment has only one uniform 3D symbol, it will affect the reality of pipeline. For improving the speed and quality of 3D visualization, what instrument of modeling for these attachments should be used? These problems await more research.

4 EXPERIMENT

Combined Layer Model of data and the method of modeling, a system has been developed using Visual C++ and OpenGL. The 3D system represents the underground pipeline mainly. The primary buildings are created with simple model and 3D character to mark it. The translucent allow the visibility of the underground pipeline. A existing pipeline model or a plan about burying pipeline, creating new pipeline model, analysis and query the attribute data of pipelines, walk through or fly through along a defined route or navigate by mouse and keyboard can all be visualized. Some experimental results are shown below in Fig 9.

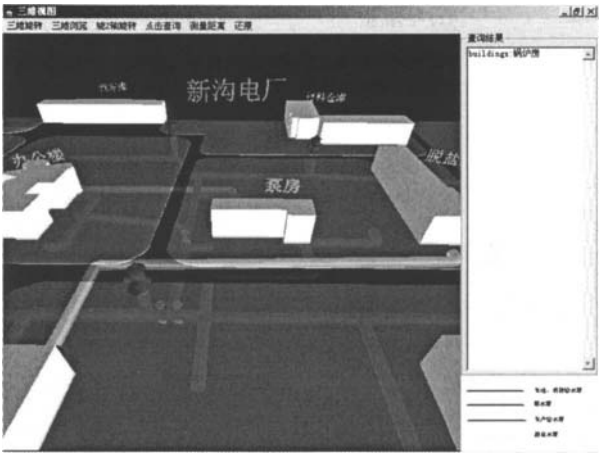

Figure 9: 3D pipeline model

5 CONCLUSION

Research on the 3D representation of pipelines is very important, for integrating into 3D building models, road models and terrain models. These models are all indispensable components in a digital city. The 3D pipeline model is very useful in many fields (management of plant, urban planning etc). This paper has introduced some researches about creating and storing 3D pipeline models. Many experiments are finished and several conclusions are drawn as follows:

- The Layer Model for pipeline data can not only decreases the volume of data storage but is also easy to edit and maintain the pipeline data.
- Subsection Calculation, not depending on the program language, makes the simulated pipeline fully connected with no gaps and with a realistic representation.
- Because a pipeline is modeled as several pipeline sections, spatial analysis can be used to define the topologic relation between pipeline sections.
- The method of data organization and pipeline modeling can be used for pipelines above the ground. But it isn't efficient enough to model most intricate pipelines in workshops.
- The problem of how to represent attachments more realistically needs more research.

A FAST GPS-BASED SYSTEM FOR SURVEY CHECK OF ROAD ALIGNMENTS

Esmond Mok

Department of Land Surveying and Geo-Informatics,
The Hong Kong Polytechnic University, Hunghom, Kowloon,
HONG KONG, SAR CHINA

ABSTRACT

Survey check of road alignments is an important quality assurance procedure in road construction. Before the kerb lines are actually laid, engineering surveyors have to set out road alignment reference marks and indicators. The positions of these indicators would be checked independently by consultant surveyors to ensure that they are set out according to design parameters. Many surveying methods can be adopted to set out and carry out survey check of road alignments. The most commonly used approach is by radiation with a total station [see e.g. Uren J. and Price W.F., (1978), Schofield W. (1993)]. This conventional surveying method has the disadvantage of requiring a sufficient number of intervisible control points near the survey area. To fulfill this requirement, sufficient control points have to be maintained inside the project area throughout the project period, which is a difficult task for surveyors in complicated construction site environments.

When consultant surveyors carry out the survey check of road alignments with the conventional method, they always encounter the same difficulty that request for survey check of setting out work is in a rather short notice, the results of which have to be reported as quickly as possible in order not to delay the progress, however, time is required to re-establish control points and to carry out data processing of survey check results. In order to alleviate this pressure imposed on consultant surveyors, a fast GPS-based system for survey check of road alignments is proposed. This system combines the GPS positioning techniques with an automatic database search and computational algorithm. With the high precision GPS Real-Time Kinematic (RTK) [see e.g. Hofmann W. (1992), Leick, A. (1995) and Misra P. et al. (2001)] positioning results fit into the processing engine, survey check results can be reported on-site.

KEYWORDS

GPS, Survey Check, Road Alignment.

INTRODUCTION

Setting out of design features and survey check of setting out work are essential roles of an engineering surveyor. As a quality assurance procedure, it is a common practice in Hong Kong that alignments set out by contracting companies are checked by a consulting company employed by the client. Therefore, in road construction projects, the contractor would, according to the design geometry, set out kerb line positions at regular chainage such as 100, 105, 110; and these positions will be checked by consulting company. To ensure independence, the consultant would survey positions as if the chainage information is not known. Although such information is normally shown, it is recorded for reference only. The actual chainage of the positions surveyed and their deviations from the design geometry are then determined. If any points are outside the acceptable tolerance, the contractor has to carry out necessary remedial work.

Many surveying methods can be adopted to set out and conduct survey check of road alignments. The most commonly used approach is by radiation with a total station [see e.g. Uren J. and Price W.F., (1978), Schofield W. (1993)]. This conventional approach has the disadvantage that control points are needed near the project area. Therefore, very often, additional field procedures have to be carried out to connect the distant controls to the project site. Consultant surveyors adopting this conventional surveying method would require additional efforts to re-establish the control points if they are destroyed or disturbed, or their visibility is obstructed. The situation may become worse if the request for survey check is in short notice and the survey check results have to be reported as quickly as possible in order not to delay the progress. In order to alleviate this pressure imposed on consultant surveyors, a fast GPS-based system for survey check of road alignments is proposed. This system combines the GPS positioning techniques with an automatic database search and computational algorithm. It is well-known that GPS positioning has the following advantages over classical surveying techniques:

1. Intervisibility between ground stations is not required. For GPS positioning, it is only necessary for the receivers to be able to track satellite signals in a fairly open area, which is normally the case in road construction sites.
2. GPS positioning can be carried out under all weather conditions.
3. Separation between stations within 10 km is considered as "short baseline" in GPS positioning. Therefore, establishment of one GPS reference station would well serve different survey activities inside the10km radius.

With the high precision GPS Real-Time Kinematic (RTK) [see e.g. Hofmann W. (1992), Leick, A. (1995) and Misra P. et al. (2001)] positioning results fit into the processing engine, survey check results can be reported immediately on-site. This paper discusses the configuration of the proposed system and the computational methods adopted for automatic processing of survey check results.

SYSTEM CONFIGURATION

Figure 1 below shows the configuration of the GPS-based road alignment survey check system. A GPS receiver with RTK capability is connected to a data storage and processing unit. This unit can either be a notebook or PDA type computer. RTK positioning results may either be referenced to the WGS84 coordinate system, or have been transformed to the grid coordinate system adopted for carrying out the project, depending on the settings of the GPS device and availability of transformation parameters. If the device output is in WGS84 coordinate system, they will be transformed to the relevant grid coordinate system before performing alignment check computation.

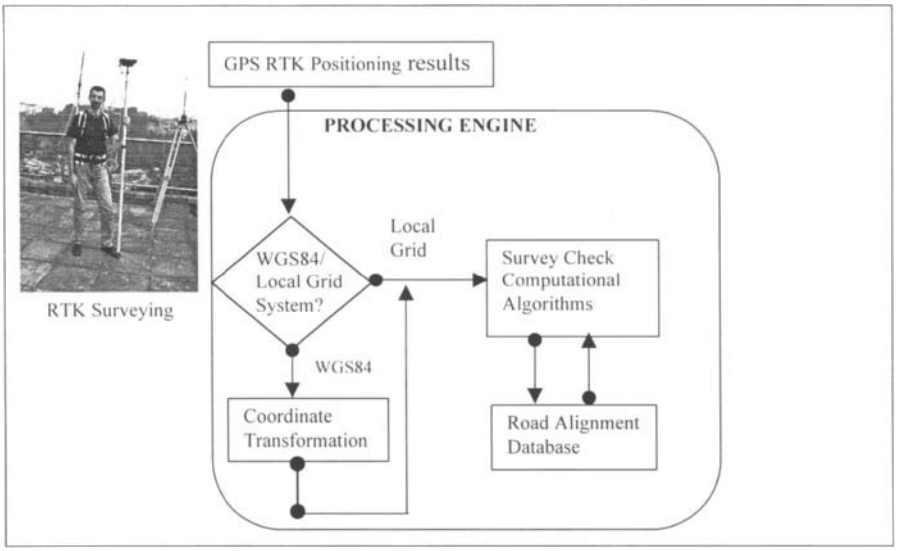

Figure 1: Configuration of the GPS-based Survey Check System

The database component of the processing engine contains information about type of alignment (straight, circular or transition), their start and end chainages, and geometrical parameters. With the GPS positioning result, an automatic search for the correct road section is performed and relevant road alignment parameters are extracted for alignment check computation. Details of the computational method is described below.

ALIGNMENT CHECK COMPUTATION

Straight Alignment

Computational check for straight and circular curve alignments are quite straight forward. For the case of straight alignment shown in Figure 2, P is the point requiring survey check. The bearing of the straight alignment; α_T, chainage at the tangent point T; CH(T), and the coordinates of T ; (N_T, E_T) are known design parameters extracted from the database.

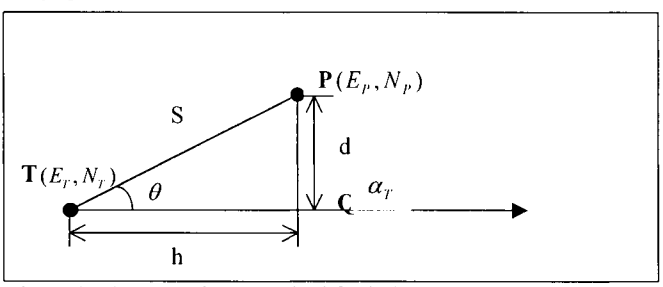

Figure 2: Computational method for independent check of straight alignments.

With the angle θ and distance S derived from coordinates of T and P, the chainage of point P and its perpendicular offset from the design alignment, denoted by CH(P) and OS(P) can be expressed as,

$$\begin{aligned} CH(P) &= CH(T) + h = CH(T) + S \cdot \cos\theta \\ OS(P) &= d = S \cdot \sin\theta \end{aligned} \qquad (1)$$

Circular Curve Alignment

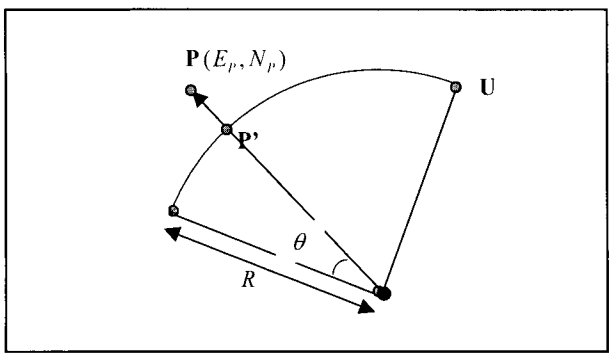

Figure 3: Computational method for independent check of Circular curve alignment.

Figure 3 shows a section of circular alignment TU. To determine the chainage of P' which is the projection of P on arc TU, the following simple mathematics are applied.

$$\begin{aligned} CH(P') &= CH(T) + arc\ TP' = CH(T) + R \cdot \theta \\ OS(P) &= CP - CP' = CP - R \end{aligned} \qquad (2)$$

where θ is obtained by subtracting bearings CP and CT, and the distance CP is determined from the known coordinates of C and P.

Transition Spiral

Survey check of transition spiral is not as straight forward as the above two cases. The computational approach suggested below requires iteration. Another approach based on the Method of Lagrange Multipliers was suggested in Mok, E. (1997).

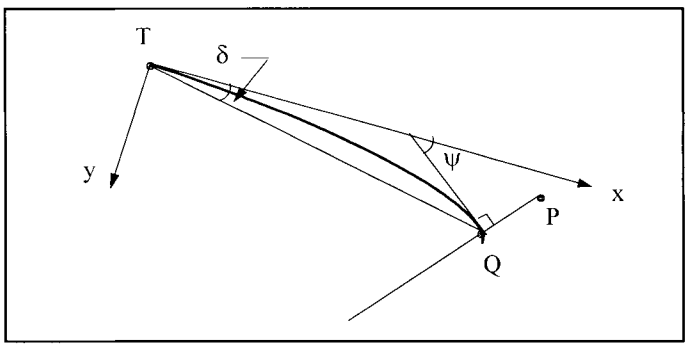

Figure 4 : Diagram showing a section of transition spiral. The chainage and offset of point P referring to the proposed alignment is to be determined.

A typical transition curve geometry is shown in Figure 4. Point P is the point surveyed whose chainage and offset with respect to the design alignment is to be determined. The tangent bearing; α_T, grid coordinates of T; (N_T, E_T), chainage of T; CH(T) and the transition spiral's RL value (R is the minimum radius of curvature and L is the total spiral length) are the four basic elements to define the geometry and orientation of a transition spiral. With this information, coordinates of P at any chainage can be deduced from the following well-known transition curve formulae.

$$\psi = \frac{s^2}{2RL} \qquad \text{(a)}$$

$$x = s - \frac{s^5}{40(RL)^2} + \frac{s^9}{3456(RL)^4} - \frac{s^{11}}{224640(RL)^6} + \cdots \qquad \text{(b)}$$

$$y = \frac{s^3}{6RL} - \frac{s^7}{336R(RL)^3} + \frac{s^{11}}{42240(RL)^5} - \cdots \qquad \text{(c)}$$

$$\tan\delta = \frac{y}{x} \qquad \text{(d)}$$

$$c = \sqrt{x^2 + y^2} \qquad \text{(d)} \qquad (3)$$

s is the spiral length from the tangent point T to the point of interest;
c is the chord length from T to the point of interest;
x, y are the x and y-coordinate of the point of interest referred to the spiral's coordinate system with the origin at T.

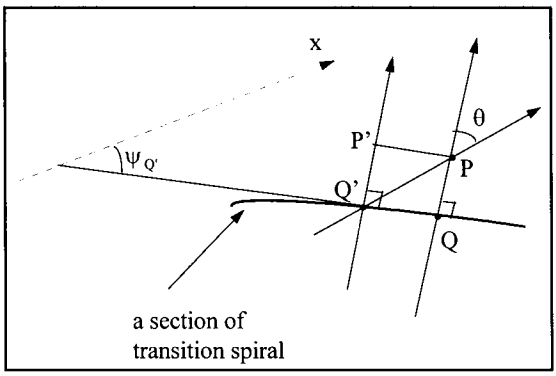

Figure 5 : Amplification of a section of transition spiral

As shown in Figure 5, the offset of P from Q and the chainage of Q are to be determined, with the spiral length of Q considered not exactly known initially. Therefore an estimation is needed to determine the initial position of Q and its normal bearing, denoted by Q' and bearing Q'P'. The estimated chainage of Q' can be readily obtained from the chainage information recorded on site, or by using the distance computed from the coordinates of T and P. Therefore

$$\alpha_{Q'P'} = \alpha_T + \psi_{Q'} - 90^\circ \tag{4}$$

$$\begin{aligned} N_{Q'} &= N_T + c_{TQ'} \cdot \sin(\alpha_T + \delta_{TQ'}) \\ E_{Q'} &= E_T + c_{TQ'} \cdot \cos(\alpha_T + \delta_{TQ'}) \end{aligned} \tag{5}$$

If the spiral length is correct, Q' would coincide with the correct position Q, then θ and distance PP' will be equal to zero. Based on this condition both θ and the distance PP' can be used as indicators to check if the iteration process has converged to the correct position Q. At the beginning of the iteration process, position of Q', the corresponding θ and distance PP' are computed. If PP' is outside the specified tolerance, say 1mm, the spiral length will be updated by adding or subtracting one-half of the distance PP', i.e.

$$s_{Q'}(i+1) = s_{Q'}(i) \pm \frac{1}{2} \cdot PP'(i) \tag{6}$$

and the new position of Q' is computed. This process continues until either PP' or angle θ is within the acceptable tolerance. It should be noted that the addition or subtraction of PP' to the spiral length depends on the position of Q' relative to Q as well as the increasing chainage direction. Suppose Q' is on the left of Q as shown in Figure 5, and the direction of increasing chainage is also from left to right, then the updated spiral length will be the previous length plus one-half of the length PP'. However if Q' is on the right of the Q with the same increasing chainage direction, one-half of PP' will be subtracted from the previous spiral length.

CONCLUDING REMARKS

Road alignment setting out provides important reference marks and indicators for workers to lay kerbs in accordance to design alignments, and any mistakes would significantly affect the road construction project. A GPS-based system suitable for survey check of road alignment in complex and rapidly changing construction sites has been proposed. The system helps consultant surveyors to obtain road alignment survey check results quickly on site. If there are any suspicions on the setting out work, a resurvey can be carried out for verification without delay.

The key factors that would affect the effectiveness of RTK positioning are the radio communication system used and its transmission power. The line of sight requirement for UHF and VHF radio links and the restricted use of high transmission power in some cities have limited the effective range of RTK positioning. As wireless communication through mobile phone's data link service has become increasingly popular, some GPS manufacturers have started integrating mobile communication with RTK to maximize the performance of RTK. Without doubt, such integration would enhance the effectiveness of the survey check system.

Finally, although the system proposed is for alignment check. With a little modification of the database design and processing software, the system can further be developed to become a system for checking structural and civil engineering works such as check for slope and pipe alignment, and pile location.

ABSTRACT

New applications for the use of GPS have emerged especially in construction industry in recent years. The applications are ranging from navigation of trucks in fleet management, the guidance of construction machines to precise surveying, setting out and monitoring of engineering structures. Thereby GPS can be employed in many different modes where the suitable method is selected depending on the accuracy requirements for position determination. Most of these applications require also the possibility for continuous position determination in real-time. If this is the case, nowadays modern real-time kinematic GPS (RTK-GPS) can be employed. The use of these modern surveying and positioning techniques facilitates also the development of new machinery and system processes in construction industry. Especially for the guidance of construction machines, systems have been developed to increase the productivity of construction works. Commercial systems are available nowadays from several companies, e.g. for the guidance of graders, dozers and caterpillars. In general, the systems use 3-D surveying systems for position determination mostly in combination with other sensors.

Following a brief description of satellite positioning modes, their major applications in construction industry will be highlighted and common features of modern 3-D machine guidance systems based on RTK-GPS will be outlined in this paper. Finally the 3-D machine guidance systems are compared with common conventional systems and their advantages summarized.

GPS, Satellite Positioning, Navigation, Fleet Management, Machine Guidance, Construction Machines, 3-D Machine Guidance Systems

1 INTRODUCTION

Whether the given application is in general construction, earthmoving or civil engineering, nowadays advanced surveying techniques using lasers, total stations and GPS positioning solutions and software are available that can provide more control over the job task and site. For site preparation, powerful software for design and estimating takeoff as well as a complete line of machine control systems for the smallest skid steer to the largest bulldozer can be employed. Thereby modern machine control systems use a variety of technologies, either in combination or alone, including laser, GPS systems, total station, sonic or laser tracers and software. Using advanced machine control systems operators have the information they need in the cab, allowing them to significantly increase productivity, reduce material overages and work with greater precision. Starting from a short description of the principle of operation of modern satellite positioning and navigation methods, the use of GPS in construction industry and machine guidance will be described more in detail in this paper.

2 GPS POSITIONING AND NAVIGATION

Satellite positioning systems have been developed to provide the possibility for continuous position determination worldwide. New systems are currently under development or at the stage of launching their satellites into orbit. All of them have in common, that they were developed following the concept of the successful U.S. NAVSTAR-GPS (**Na**vigation **S**ystem with **T**ime **a**nd **R**anging – **G**lobal **P**ositioning **S**ystem). The development of this system started already in the 1970's by the Department of Defence (DoD) of the U.S.A. Therefore the system was primarily installed for military navigation. Besides the U.S.A., also the former Soviet Union States developed a similar system, the so-called GLONASS (Russian's Global Navigation Satellite System). In the 90's, the integration of GPS and GLONASS was one step towards a future Global Navigation Satellite Systems (GNSS). Strategic goals of the GNSS were to create a system that is independent from any military or national control, to guarantee the continuity of service over a certain time period, and to offer an improved service compared to GPS which is affordable. Mainly because of military reasons and the disagreement of the U.S. government to allow international control for GPS, the European community also started to develop an own global satellite navigation system at the end of last century. This system is called GALILEO and should be fully operable at the end of 2008.

2.1 Basic Concept of Satellite Positioning

As the concept of satellite positioning systems is very similar it will be easy to understand the concept of others with the knowledge of the concept of one system. The design concept of a satellite positioning system has to fulfil the following requirements:

> The system must guarantee 3-D positioning determination anywhere in the world, at any time and during any weather condition with the specified positioning accuracy. In addition to position determination, for many applications also the determination of the velocity and acceleration of the moving receiver must be possible.

In general, the satellite positioning systems consists of three segments, i.e., the space segment (satellites in orbit), the ground control segment (monitoring stations and master control station) and the user segment (receiver and antenna). For identification and distance measurements, the satellites broadcast code sequences which are modulated on carrier phase signals. In the case of GPS, two

sinusoidal carrier phase signals, L1 and L2[1], and two PRN (pseudo-random noise) codes, the precise P-code and the C/A-code[2], are broadcasted. For the future generation of GPS satellites, it is planned to add a third civilian and another military frequency. The satellite orbits are determined by a network of monitor stations around the world. These so-called broadcast ephemeris are then transferred to the user from the satellites in the navigation message to obtain real-time position determination. The user segment can be broadly classified into users for military and civilian applications. There are various types of GPS receivers available on the market to suit different applications such as surveying and mapping, vehicle navigation and recreation. Further information about their principle can be found in books about satellite positioning, e.g. (Hofmann-Wellenhof et. al., 1992; Leick, 1995; Wells, 1986; Seeber, 1993; Mok & Retscher, 2000).

2.2 Observation Types and Positioning Modes

Position determination is done by distance or range measurements. Depending on the type of observation used, pseudorange measurements with the code phases (P-code or C/A-code) or carrier phase measurements (signal L1 or/and L2) can be carried out. Thereby positioning accuracies in the range of 0.3 to 40 m can be obtained using code observations. Higher accuracy position determination up to the centimetre level, however, can only be achieved using carrier phase measurements. The accuracy spectrum of different methods is compared graphically in Fig. 1. As can be seen, different satellite positioning techniques offer a wide range of positioning accuracies. After distinguishing between code and phase observations, the methods can be categorised into absolute and relative positioning techniques. The term absolute or single-point positioning is used to describe positioning techniques using only one receiver in stand-alone mode. This technique is usually applied for navigation. For relative positioning, however, at least two receivers are required. Due to the use of differencing techniques, the positioning accuracy can be increased for simultaneous observations of two receivers to at least four satellites. These techniques are usually applied in surveying, for mapping applications and also for precise navigation.

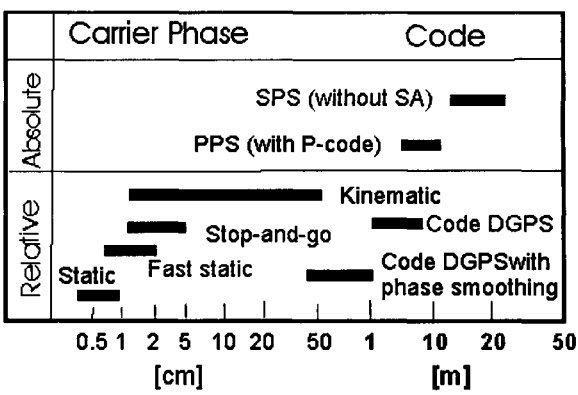

Figure 1: Accuracy spectrum and different modes of satellite positioning [3]

[1] The signals L1 and L2 are electromagnetic waves in the L-band with frequencies of 1575.42 MHz and 1227.60 MHz.

[2] P-code stands for Precise code and C/A-code for Coarse/Acquisition code. The PRN code is a random signal of '+1' and '-1' code sequences.

[3] SPS stands for Standard Positioning Service using the C/A Code and PPS for Precise Positioning Service with the P-code.

2.3 GPS Positioning Modes for Surveying

Positioning methods used in surveying are usually relative positioning techniques with carrier phase observations to achieve a high level of precision. In general, it can be distinguished between static positioning, rapid (or fast) static positioning, stop-and-go, reoccupation and kinematic positioning. The modes differ mainly in their observation time and whether the receivers are static or moving throughout the entire observation period. The highest positioning accuracy can be obtained using the static positioning technique. In this case, both receivers are stationary on their points over a certain period of time. The length of the observation period depends on the number of satellites, the precision requirements, the length of the line, the type of receiver (single L1 or dual frequency receiver L1 and L2), and the atmospheric conditions. Static observations are taken over a time span of 30 minutes up to several hours and rapid static observations within a few minutes up to 20 minutes. If more than two receivers are used, the static method can be employed for many survey applications, especially for the establishment of control networks very economically. Satellite positioning techniques have therefore nearly replaced conventional surveying techniques for this type of application. The survey work is very easy and the processing of the results is usually done in post mission. These technique is employed e.g. for the establishment of control points for engineering projects (construction of a tunnel or bridge). For the rapid static or stop-and-go observations, the limited factor is the short observation time of a few minutes or only seconds. Due to recent developments in satellite receiver technology, however, these methods can be replaced by modern real-time kinematic (RTK) positioning techniques. The above methods require that two receivers are stationary for a short time period. In the kinematic mode, the second or so-called rover receiver is moving and collects data continuously. Then position determination has to be done separately for each measurement epoch. Depending on the speed of the moving receiver, positioning accuracies on the few centimetre up to decimetre level can be achieved (see Fig. 1).

3 USE OF GPS IN CONSTRUCTION INDUSTRY

Satellite positioning and navigation can be employed in the construction industry for many different tasks. Especially in the navigation mode, nowadays GPS has become a standard tool to manage a large truck fleet or to perform vehicle navigation and guidance (see Fig. 2). These system have been developed due to the integration of GPS in common systems based on other sensors more than one decade ago and their application has become quite popular with professional and private users (see e.g. Krakiwsky, 1991). The combination with other sensors such as dead reckoning (DR) and map matching, however, is required as GPS for position determination in stand alone mode only works well for open areas. In the case of obstruction of the satellite-receiver visibility, either the position accuracy is bad or no position determination is possible. Especially in cities with high-rise buildings, the satellite visibility is a very critical issue for vehicle navigation systems (see Retscher and Mok, 2001).

Using precise methods with carrier phase measurements (see section 2.2) very high accuracies for continuous position determination can be achieved. Recent system developments include so-called attitude determination systems where also the orientation (or heading) and the current position of a truck or vehicle can be determined using one GPS system. In this case a L1/L2 RTK GPS receiver with dual-antenna is employed that provides precise position, heading and speed of a dynamic platform. The receiver achieves horizontal positioning accuracies of 20 mm and vertical accuracies of 30 mm up to 20 times per second as well as heading accuracies of 0.03° RMS (root mean square

error) at 10 times per second (Trimble 2002). Typical application areas are in the fields of construction, dredging, marine survey, commercial marine, and general machine guidance.

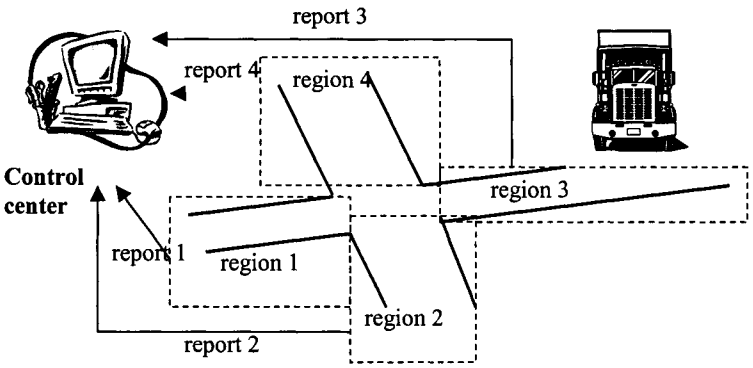

Figure 2: Operation principle of a fleet management service

4 MACHINE GUIDANCE AND CONTROL

Different types of construction machines are available that can be employed for different tasks. Dozers are usually employed for bulk earthworks and earthmoving, the construction of abutments and ramps, embankments, etc. For fine grading, course grading of materials, sub base formation or sideslope work usually motor graders are employed. The asphalt or concrete surface of a road can be built using paving equipment. The methods developed for the guidance of these machines can be distinguished depending on the level of automation they achieve. The highest level of automation is achieved with modern 3-D guidance systems and automatic blade control. In this case, the navigation parameters and deviations of the machine blades from the designed surface are obtained from a comparison with the given alignment of the road. The given alignment is usually based on a digital terrain model. If a correction is required, the parameters are automatically sent to the machine hydraulics to maintain the design elevation and cross slope. Visual control is provided for the machine operator using a navigational display. Some machinery employ also manual blade control where the guidance of the blades is controlled by the operator.

4.1 Components of Machine Guidance Systems

The main component of 3-D guidance system is a positioning unit which is able to track the machine movements continuously. Due to the availability of modern RTK GPS systems and total stations with automatic targeting and tracking such systems could be developed. They are able to determine the 3-D position of the machine continuously with a high frequency of up to 10 Hz, i.e., 10 times per second. The kinematic sequence of machine positions represents the trajectory of the machine. Fig. 3 shows the main components of a 3-D machine guidance system. Apart from the positioning unit, usually additional sensors are included into the system design, e.g. electronic inclinometer or tiltmeter to measure the pitch and roll of the machine or the blade. Inclinometers or tiltmeters are employed to measure the longitudinal and transversal tilt (i.e., pitch and roll) of the machine and/or its blade. The longitudinal sensor (so-called long slope sensor) measures the vehicle pitches in the direction of travel and hub for all system sensors. The transversal sensor is a highly

dynamic measuring unit that determines current lateral blade inclination for exact control of lateral inclination. In addition, a precise determination of blade rotation using a so-called rotation compensator provides for optimum lateral inclination compensation (see e.g. Moba, 2002). This sensor is in principle an electronic gyro compass or heading sensor. All the sensors are integrated with the positioning unit in the sense of a multi-sensor system (Retscher, 2002).

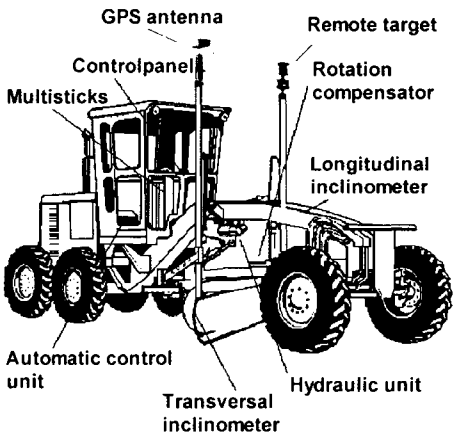

Figure 3: Main Components of 3-D Machine Guidance Systems

4.2 Comparison of 3-D Guidance with Conventional Systems

Table 1 compares the 3-D guidance systems using total stations and RTK GPS with traditional methods based on string lines and stakes or the use of rotating lasers. The conventional systems require surveyors to provide the interface between the engineering design and the machine operator on site. This can be achieved by using grade stakes that are placed at strategic locations around the site and indicate the level of cut and fill required at that point. Machine operators then have to use their experience to interpolate the grade between the stake locations. Grade stakes can be replaced by string lines (see Fig. 4) where the machine is guided along the line using detectors such as ultrasonic or laser tracers. Their main disadvantages, however, are that grade stakes or string lines are often knocked out by the machines during the course of the daily work and that they are very labour intensive in setting out and maintenance. On-site surveyors are required to stake and re-stake, to check the resulting surface, to calculate the volumes of earth moved and deviations from the desired design surface (see e.g. Carlson et al., 1999; Anderson 1999). The use of rotating laser systems shown in Fig. 5 has led to an increase in productivity and cost-savings. With the rotating laser beam a horizontal plane is defined and the deviations from the plane can be observed. The laser detectors are usually mounted on the blade of the machine. Using laser systems, height control can be performed with high precision. Their application, however, is limited for areas with small changes in gradient. Otherwise new setups of the laser instrument are required very frequently. Rotating laser systems are mainly employed for precise height control of graders.

The major applications for 3-D machine guidance systems can be found in construction industry and mining for the guidance of dozers, graders, excavators, scrapers as well as in agricultural applications for the guidance of tractors and harvesters (see Table 1). Depending on the accuracy

TABLE 1
COMPARISON OF MACHINE GUIDANCE SYSTEMS

	String lines or Stakes	Rotating Laser Systems	Robotic Total Station	GPS
Dimensions	3-D	1-D (height only)	3-D	3-D
Reference stations required per site	Many tachymeter stations required for setting out	One or more; site dependent	One per machine	One
Setups per construction site	Not applicable	Multiple times per site	Multiple times per site	One
No. of machines supported by reference station	Not applicable	Unlimited in one plane	One per total station	Unlimited
Maximum range	Sensors work in close-range	up to 300 m depending on line of site	up to 700 m depending on line of site	Several kilometres
Usability under bad visibility conditions	Not affected	Reduced	Reduced	Not affected
Accuracy	mm - level	mm - level	mm - level to cm - level	cm - level
Major applications	Guidance of road and slipform paving machines	Precise height control for graders; Guidance of road and slipform paving machines	Guidance of graders, excavators, scrapers or dozers	Guidance of dozers and scrapers, Precise Farming

Figure 4: Guidance of paving machines using string lines (after Anderson, 1999)

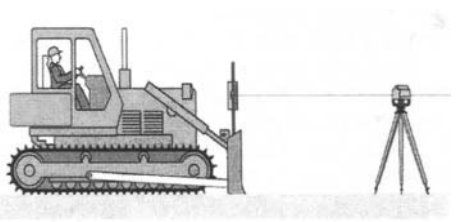

Figure 5: Operation principle of rotating laser systems

requirements, RTK GPS systems or robotic total stations are employed. Systems are available on the market from several companies (e.g. Leica, 2002; Gomaco, 2002; Trimble, 2002). The high precision requirements for the guidance of road and slipform paving machines, however, are still very challenging for 3-D guidance systems. In recent case studies 3-D systems using two robotic total stations (see Gomaco, 2002) or dual antenna GPS systems (see Trimble 2002) have been tested. The systems still need further improvements that conventional and labour intensive methods can be replaced totally. For the determination of the movements of the construction machine a new algorithm has been developed. For further information the reader is referred to (Retscher, 2001 and 2002).

5 CONCLUSIONS AND OUTLOOK

Due to the use of modern surveying techniques in combination with advanced software new application areas in construction industry have emerged. Nowadays construction machines can mainly be controlled and guided automatically. 3-D guidance systems will significantly reduce times for surveying and therefore achieve cost savings while increasing productivity of construction works. Thereby satellite positioning methods play an important role. To achieve very high precision requirements especially in the vertical in the course of fine grading and paving, however, a combination with other sensors and methods is still required. On the other hand, where precision requirements are low GPS systems are most commonly used in stand alone mode for navigation of machinery and truck fleets.

ABSTRACT
This paper introduces the concept of Geographical Information Systems (GIS) to the application of building design and management. In particular, it addresses the benefit of visualisation techniques to the better management of buildings in Hong Kong through a visual and animated building database of building components.

Keywords: Geographical Information Systems, GIS, Building Design, Building Management, Visualisation, Database.

INTRODUCTION

The use of GIS based tools to provide design and total database management for buildings is becoming more feasible. Simple information systems for buildings based upon GIS software are already being used in many areas including space management, human resource management and facility management. The concept of 3D GIS for buildings is in its infancy and as buildings become more complex the amount of data generated, analysed and stored will increase. Significantly GIS is able to aid visualisation of the data. It can be customised to meet specific building management and user requirements and can link with various databases of stored data.

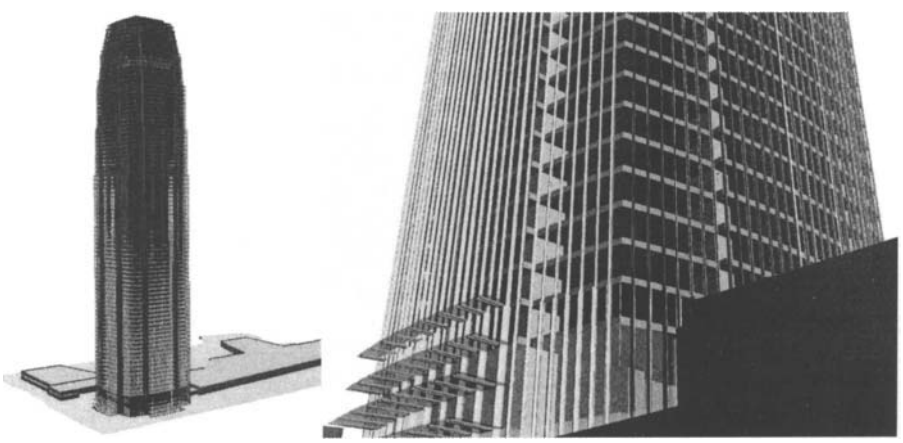

Figure 1: Tall Building 3D GIS Model

A conceptual 3D building GIS has been developed for a typical tall building, see Figure 1. This structure comprises over 100 storeys and will contain a large amount of systems and data. A 3D GIS could be developed for tall buildings or complex buildings such as combined office and retail and residential properties to store, monitor and provide a management system for the facility or a series of facilities. GIS technology provides a platform to manage spatial data and when linked to standard co-ordinate systems allows external data to be analysed and assessed within the same reference frame. GIS can be applied to various databases and information already gathered for various buildings and building design alternatively through the visualisation element of GIS it can be applied to simple display of spatial data to the complex analysis of relationships and responses to change within the system.

The future of GIS for buildings can be seen by looking at the images in Figures 1 and 2. Think of them as databases of building elements. Information can be embedded into each surface, cube, polygon, line etc and each can respond by varying its colour, transparency or texture to display current information about its condition. Obviously this requires feedback from data gathering within the building which could be carried out manually or from sensor arrays or monitoring equipment. This information could be selective depending on the tasks and analysis required or automated depending on the nature of the building.

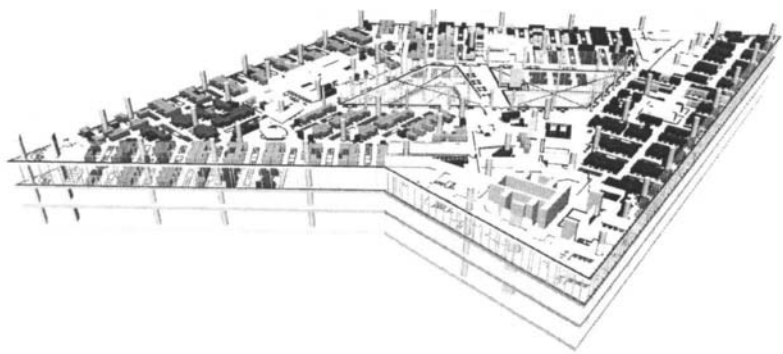

Figure 2: 3D Workstation Space Management System

The visualisation element of the technology allow data to be tagged to visible features within the virtual building. In Figure 3 the 3D building model shows how information has been extracted from selecting the desk to display the information stored on that individual workstation.

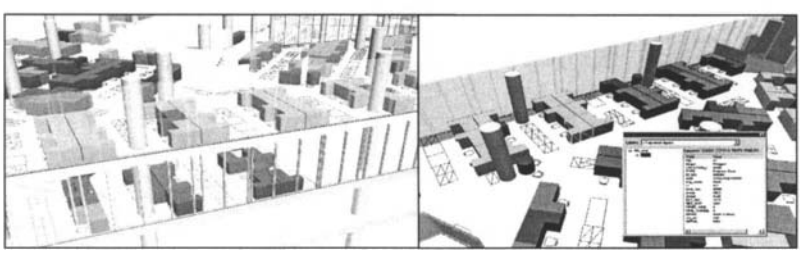

Figure 3: Data embedded within the 3D workstation

The 3D database system shown on Figures 2 & 3 can present various elements within a database to display information such as workstation user, their group affiliation and simple telephone directory information about that workstation. It can also display the current group layout of staff within the office by colour and identify any un-allocated desks to target efficient use of space within the office.

WHY GIS ?

The use of GIS within the building management field should increase due to the higher degree of flexibility of the software. The added value benefits of analysing and assessing various building performance attributes from database information is becoming more feasible. The spatial relationship of the building, its components and the interaction of the building with its surroundings can be modelled from the initial design process through to the entry of tenants and the human behaviour and activity within the building. It is most useful in the areas of building and facility management where managers have a large stock of property which require monitoring and control.

At present most large high rise buildings and other complex properties that combine office, retail and occasionally residential elements within the development have tailored building management systems (BMS). These BMS are usually built around the core building processes of electrical, environmental and mechanical systems such as heating, cooling, security, lighting, lift and escalator controls etc. Information from various sources are currently fed back into the system to provide information to make basic decisions, which are usually undertaken automatically such as for ventilation and air-conditioning when pre-set limits are exceeded. BMS are generally passive and are criteria driven in their logic.

GIS systems can be more easily developed to identify the cause and effect of changes within a building such as "increased air conditioning output" may be a result of open doors or windows. They can also determine more easily trends and change within a building and highlight this to the management. With an efficient inventory and reporting system, defects and poor quality systems or equipment within the building can be identified and quantified. This may be clear from increasing maintenance requirements or other cause and effect elements such as increased power consumption for example. If the data has been collected in a systematic and logical manner then the various forms of analysis can be undertaken to aid the decision process. GIS models can target the various office elements to visualise the layout and distribution of office information such as desk allocation and use of space as shown in Figure 2. They can also store as archival information all the associated building plans, reports, digital photographs and other details for easy retrieval through pop up displays and selective interrogation of the 3D virtual building.

As Information Technology advances, the use of local wireless network systems and controls will become cheaper, more accessible and more readily available. IT systems are already an essential element as well as an integral part of our buildings. The further development of local wireless networks and accurate positioning systems within buildings will allow information to be gathered more easily and efficiently from anywhere within a building. Security and reliability of these systems will be the key to integrating them into a GIS based building management system.

CAD systems are already available that incorporate 3D design elements within their systems to allow better visualisation of design as well as identification of conflicts between drawings

and designs within their 3D models. This is the future of better building design where computer simulation and drawing generation based upon these models can be issued directly to the contractor. Finishes as well as structural elements and interfaces for the various E&M and internal fixings can be seen within the model and rectified at an early stage of the design process. These systems are likely to realise substantial savings in time and cost on procurement of building projects. They can also be directly fed into a GIS system.

Where a building management system has been developed to gather and store data in connection with the building the real benefit of GIS is in the early development of the database structure and the linking of this with final required use and logic of the GIS. Development of the data structure and final output should be designed to allow sufficient query and interrogation of the GIS to aid the decision process.

Where several buildings contain the same database attribute information they can be compared to identify differences that may in part lead to cost savings due to early identification of efficiencies or deficiencies in each building. Procurement and maintenance costs could be reduced by combining resource for efficient ordering of supplies where building databases are linked together.

External influences on the building can also be more easily modelled such as sunlight and viewable area from office floors. This sort of information assists in the decision making on the suitability of the floor or aspect of the windows.

Other external influences can also be considered such as pedestrian and local traffic flow models in assessing various demands on the building for access and exits. A GIS based approach gives greater flexibility and ease of reference for the data stored for a building.

The GIS interface can be customised to present typical report generation and can be accessed through WEB servers or intranets to allow multi user query on the system. The benefits for this depend on how the data within the building needs to be displayed and presented and the user levels and requirements. Essentially this can be varied to suit particular objectives of the system.

TALL BUILDING 3D GIS MODEL

To test the potential for such a system a 3D GIS has been developed to model the building structure and the various elements and data layers likely to be required for a working and compatible system. The conceptual physical model for the structure was based upon the building plans and the architectural layout plans. Further detail was added for a few floors to determine the complexity and explore any limitations to the exercise.

Development Platform

The model was developed using ESRI ArcGIS 8.1 package with its extension 3D Analyst providing three-dimensional analysis and visualisation. The whole development process from data preparation, conversion and 3D model construction were carried out within this platform. Other GIS software are just as likely to be used to develop such a system. The hardware used to process and develop the system comprised a Pentium P4 1.5GHz PC with 512MB RAM incorporating an NVDIA Quadro 2 Pro 64MB display card.

Data Conversion and Preparation

Data preparation is always the most critical part of the model development. Usually the preparation of accurate and consistent data for a GIS model takes the majority of the development time. Appropriate data must be collected while irrelevant data must be excluded from the model. System structure is dependent on the overall objective of the system and the data to be embedded within it. The data conversion process and analysis is presented in Figure 4.

Data was collected from digital architectural and structural drawings in AutoCAD file format. The table below highlights the data development flow and details. This process was carried out for each of the individual layers within the model. The exterior and interior structural and

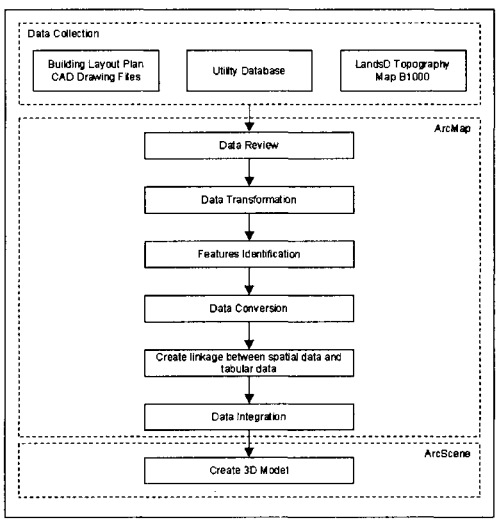

Figure 4: Data Model Development Flow

architectural layout as well as utilities plans, services function etc was assessed for each individual floor and podium. These were then converted into various GIS layers. Each layer contains a single element of the building data such as core wall, conduit, sprinkler layout etc and any surface, line, wall or element can have data embedded into the model. Figure 5 displays how the various complex floor layouts were developed for the building.

Complications with the model were mostly encountered with the merging of reference co-ordinate systems to local Hong Kong Grid as well as ensuring that the data was clean with connecting lines and points. The Hong Kong grid was used in preference to a local building grid to allow the data and model to be linked to external data if necessary.

The choice of data was also focussed at presenting visually acceptable and meaningful data for future development of the model. Identical floor layouts were linked together to minimise the size of the model. For visualisation duplicate floors shared the same data set and layout referencing to the database was linked to floor number to allow quicker interrogation of the various floor attributes. The lifts serving various floors and levels within the structure were also identified and the location and referencing system for these lifts were embedded into the

model so that lifts could be identified for each floor as through lifts or as lifts servicing that particular floor.

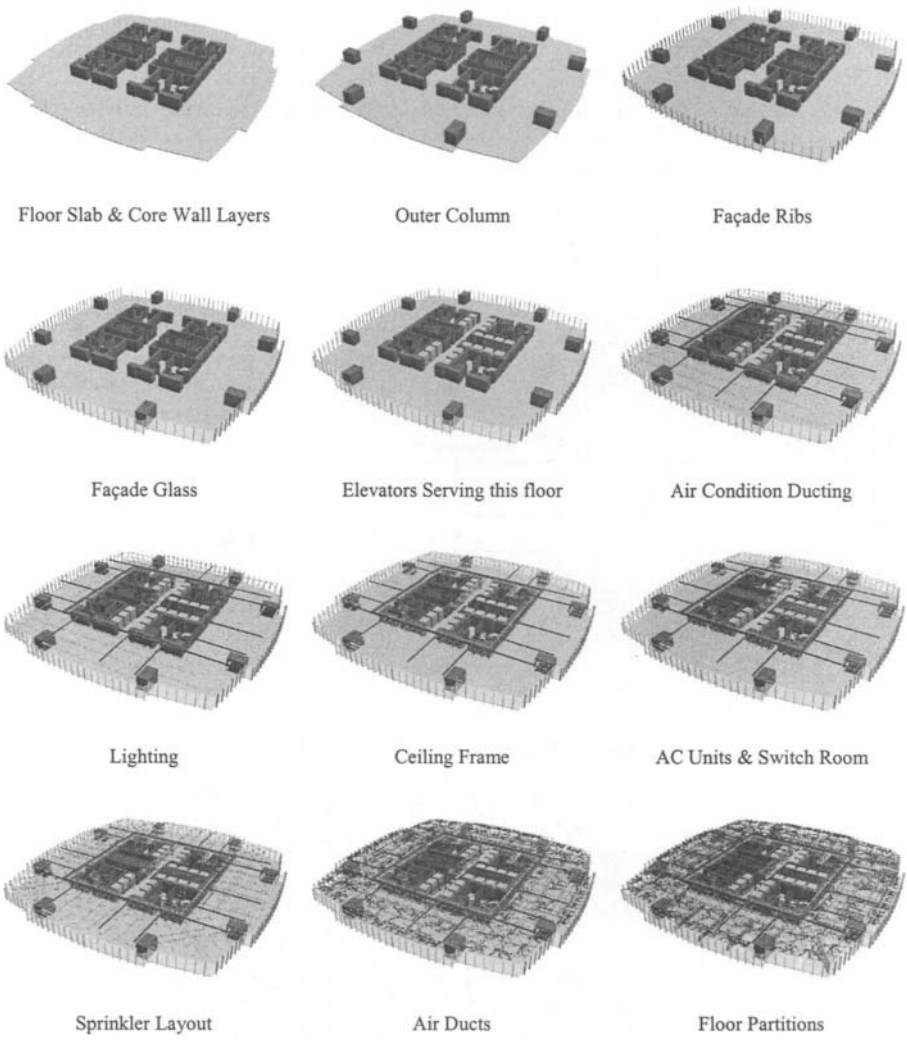

Figure 5: Complex Floor Data Layers

Features that had different functions and behaviour were separated into different layers for facility management and visualisation purpose. Individual structural features of the building were converted into the GIS as separate layers to allow each building element or layer to be switched off to display only that individual item requiring interrogation to be displayed for easier and quicker viewing of the information.

Additional data was added to the 3D model to simulate a working floor model to determine the benefit and capability of the GIS in displaying the floor plan layout. A seating plan comprising desk workstation polygons, partition walls and filing cabinets were included. Information can be tagged to any element within the 3D scenes by applying reference locations to the 3D model surfaces, polygons, lines and layout.

To link the building to its surroundings a digital terrain model (DTM) of the surrounding area was generated from local digital map data. This was incorporated to identify the surrounding aspect and position of the building to provide a reference to adjacent features. The model could be further expanded with the incorporation of external data such as surrounding infrastructure and associated facilities such as utility connections at pavement and road level.

3D Model Development

Layers are then added into the 3D GIS environment to build the 3D building model. The base height or floor number for each feature was assigned during data preparation. These layers were then offset or extruded vertically at their particular floor level. Appropriate colour and levels of transparency were set for each feature layer to present the best visual effect.

The speed of image rendering and display of information at the buildings simplest level comprising the structural frame and general layout of the building was smooth and acceptable. Zooming and display functions worked well. As further layers and seating plans were added to the model there was a marked decrease in speed of the system. This occurred when we developed a single complex floor plan.

Where only one or two elements of the system were needed to be displayed in the 3D environment the model appeared to perform well and as such further development could be targeted at processing and displaying only the data layers of interest.

As computer speed increases the capability of whole display of the building will improve and with better software development and storage of 3D data and rendering the future of this technology should be assured.

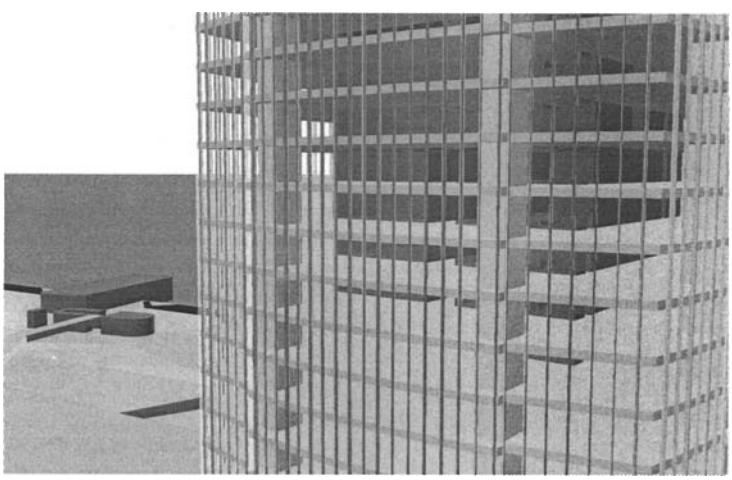

Figure 6: Close up of core wall, column and glass frame

One of the floors of the building was selected to display all the layers described in Figure 5. A full set of utility layers were added plus the building exterior and interior structure including core wall, void, glass frame, life shaft, life, washing closet, AC room as well as the seating plan for the floor. Various internal and external views of this floor level are shown on Figures 6 and 7.

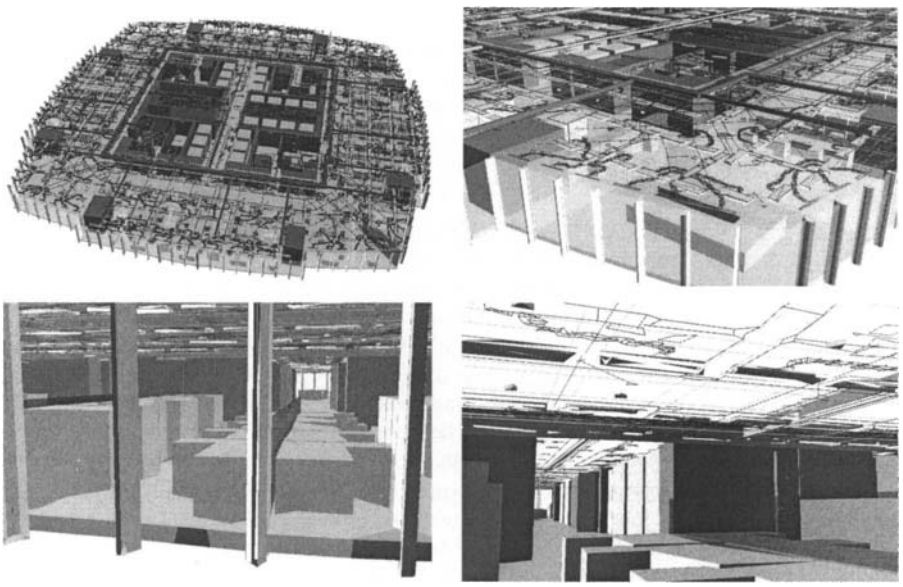

Figure 7: Images of Complex Floor

CONCLUSIONS

It has been demonstrated from the model that the use of 3D GIS for buildings is feasible and becoming more practicable. Improved speed and performance of the software and hardware will enhance the development of this tool in the future. The need to store ever increasing amounts of data and the trend to develop intelligence and data integration within buildings provides a sound basis for visual database as well as human interaction analysis within GIS.

The need for building GIS systems will be driven by developers and property management operators. The combined use of large building stock and facility management are inherent in the technology and with increased and cheaper sensor technology linked to wireless intranets, the feedback time and analysis of the system can be improved. Whether the system is used simply as a visual database or as a complex analysis tool depends on the user requirements. If data is generated, stored and presented with a view to presenting and easier understanding of the data then the potential uses and benefits of the system may be explored in ways not already realised.

ACKNOWLEDGEMENTS

The concepts and ideas included in this paper are based on a series of projects carried out by Ove Arup and Partners over recent years. The insight, contribution and constructive suggestions of all the team members involved have been greatly appreciated by the authors.

ABSTRACT

This paper presents an integrated system for monitoring and warning of landslides. The system consists of an automatic conventional slope monitoring package and a multi-antenna Global Positioning System (GPS) package. The automated slope monitoring package has (a) different types of sensors and (b) a remote data acquisition/control system connecting an office computer to datalogger for data communication and control with visual software. Sensors include (in-place inclinometers, (b) piezometers, (c) a rain gauge and (d) a Time Domain Reflectometer (TDR). The multi-antenna GPS is a special technology newly developed for monitoring surface movements of a slope. The two packages or sub-systems can work independently or jointly to monitor a slope. When working together, the two sub-systems can be set up at the same slope site. The conventional sub-system mainly measures the sub-surface ground movements and pore water pressures and the GPS sub-system mainly measures the surface ground movements. The data from the two sub-systems can be transferred to the same office computer, processed and analyzed together. The integrated data can be automatically retrieved, temporarily stored and transmitted from the two sub-systems. Software can perform data download, storage, analysis and real-time display. All data from in-place inclinometers, piezometers, a rain gauge, a TDR and the GPS are integrated in the process. A database has also been developed. Some preliminary monitoring data are also presented in the paper.

INTRODUCTION

Hong Kong is a hilly region with normally heavy rainfalls in the summer. Heavy rainfalls can easily induce slope failures or landslides. Other factors such as human activities, rock weathering and ground water rising may also contribute to the landslides. Landsides still impose a great

danger to human life and property, despite much efforts made, like the carrying out of slope maintenance and stabilization measures. In Hong Kong, many buildings, plants and important facilities are either very close to or even on the hillside. In a landslide, life and property may be at risk. Therefore, any pre-warning of slope failure will allow time for people to evacuate and take other preventive measures.

According to Malone (1998), many landslides in Hong Kong have a deep seated slip and noticeable displacement may occur prior to failure. Sometimes, the landslide is progressive in nature. It is possible to forewarn a landslide by monitoring any pre-failure displacement.

Therefore real-time slope monitoring may potentially play an important role in landslide warning and prevention. Parameters, such as slope displacement, pore water pressure and rainfall intensity that may be directly related to a landslide are particularly relevant. The data of these parameters once obtained needed to be interpreted and analysed in order to establish any trend that may be used as an indication of any potential slope failure. Before a slope failure takes place, people likely to be affected may be notified in advance and evacuated accordingly. Engineering stabilization measures may also be implemented in order to prevent or slow down the impending slope failure. In this paper, an integrated slope monitoring system is introduced. The system consists of an automatic conventional slope monitoring sub-system and a multi-antenna GPS sub-system. The method integrating the two sub-systems will be explained in the paper.

AUTOMATIC CONVENTIONAL SLOPE MONITORING PACKAGE

In Hong Kong, rainfalls induce most man-made or natural slope failures. The surface rainfall runoffs will cause the surface soil wash out and erosion. The rainfall infiltration will cause the reduction of suction (a stabilising stress) in the soil mass, ground water table rising, reduction of effectives stresses, all of which may cause a reduction in soil strength and slope movements. When the movements reach a certain limit, slope failure or collapse will occur. When a slope fails, very often a clearly defined slip surface in the soil mass is developed. To obtain data on the slope movements, it is necessary to monitor (a) rainfalls, (b) pore water pressures, (c) soil mass movements, especially down hill lateral movements, and (c) the location of the slip surface. Yin and Ding (1999) have proposed an integrated automatic system for monitoring all the four factors that may cause a slope to fail.

The automatic conventional slope monitoring system adopted in the project has the following features:

(a) Automatic data acquisition/control: remote data acquisition, storage data retrieval from a monitoring site to an office computer;
(b) Monitoring of slope movements, pore water pressure and rainfall intensity;
(c) Locating the slip surface in the slope mass by measuring relative displacements in the slipping zone;
(d) Detecting both small (a few mm) and large displacement (from 100 mm to more than one metre);
(e) High resolution or accuracy; and
(f) Reliable even under high temperature and high humidity weather conditions.

The conventional sub-system consists of (a) in-place inclinometers, (b) piezometers, (c) a rain gauge and (d) a Time Domain Reflectometer (TDR). The sub-system has a datalogger, a M20T modem, a power supply and software. Details of the instruments are presented in the following sections.

In-place Inclinometer

Figure 1. An in-place inclinometer

In-place inclinometers (model 906 'little dipper', biaxial and high-gain version) are adopted in this project (see Figure 1). Their specifications are: angular range ±12.5 degrees, response time of 0.15 second and operating temperature ranges from 10°C to 50C. The 'little dipper' inclinometer can also measure temperature with scale factor of 0.1°C/mV and an accuracy of ±0.75°C (User's Manual[1]).

In-place inclinometers are installed in boreholes, generally at depths less than 45m for purposes of monitoring ground movement. The inclinometers can be installed in a standard inclinometer access tube with an internal diameter of 2.75 inches. They can detect the rotation angles at different depths, which are used to obtain slope lateral movements and direction. After the inclinometers have been installed at a slope site, readings can be taken automatically by a data acquisition/ control system.

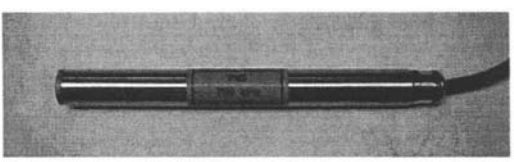

Figure 2. A piezometer

Piezometer

Vibrating wire (VW) piezometers made in Canada are selected in the project (see Figure 2). A VW piezometer can allow remote measurements of piezometric level and pore pressure over a long period of time. It also measures the temperature of the gauge and its surrounding soil. These piezometers have a measurement range of 750 kPa of pore water pressure at the maximum water depth of 76.53m. .

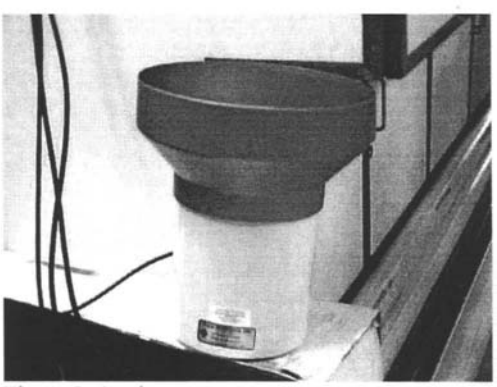

Figure 3. A rain gauge

Rainfall gauge

A rain gauge of type TE525 MM is selected to monitor rainfall intensity at a slope site (see Figure 3). It is a standard weather bureau tipping bucket rain gauge. Main specifications are: accuracy of ±1% (rainfall rate up to 1 inch/hour); infinite in increments of tip of rainfall; environmental limits from 0° to +50°C; humidity range from 0 to 100% (User's Manual[2]).

TDR 100 set

A Time Domain Reflectometer (TDR) is a new technology, which is very effective and accurate in locating a slip surface in the slope mass. Model TDR 100 is selected as a part of the automated integrated slope monitoring sub-system. The TDR consists of TDR 100 tester (see Figure 4), SDMX 50 multiplexer and one TDR cable. TDR 100 contains the pulse generator for the signal applied to TDR cable. The performance specifications of TDR 100 are: pulse generator output, 250 mV into 50 ohms; waveform sampling, 20 to 2048 waveform values over a chosen length;

range of up to 2100 metres, 0 to 7 microseconds; resolution of 1.8 millimetre and 6.1 picoseconds; operation temperature ranges from -20°C to 50°C. The SDMX 50 is a 50 ohms, eight-to-one, coaxial multiplexer to minimize signal attenuation. All channels have equal transmission line lengths (User's manual[3]).

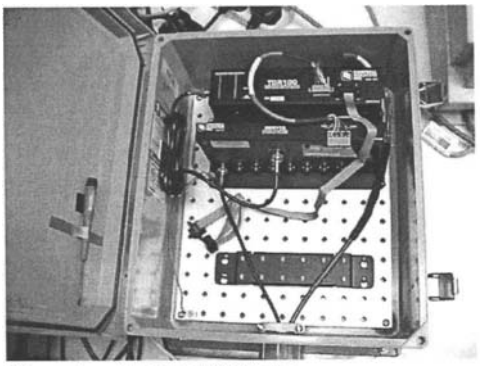

Figure 4. A TDR 100 Tester

The basic principle of TDR is similar to that of radar. TDR's original usage is to monitor breakage in communication or power lines. This technique has now been applied successfully in many applications in geotechnical engineering. One of the applications is to monitor the depth of a slipping surface.

The relative magnitude and location of the localised shear zone (or slip surface) can be detected immediately from the waveform when a TDR tester is connected to the TDR cable (see Figure 4). The size of the spike increase correlates roughly with the magnitude of movement in the slip surface.

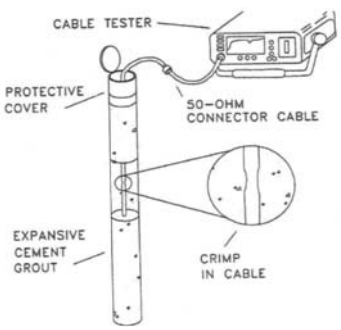

Figure 5. Coaxial cable installation and a TDR cable tester

Slope Sentry

A Model 798-B-TDR Slope Sentry (User's manual[4]) is a stand-alone datalogger for monitoring up to 10 inclinometers, up to 16 vibrating wire piezometers, a tipping bucket rain gage and up to 8 TDR cables (see Figure 6). Its main hardware consists of a CR10X datalogger, an M20 terminal modem, an AVW4 vibrating wire interface and a PS12 power supply. The Slope Sentry provides electric power to all instruments, manages measurement schedule, records the output readings from all instruments and transfers data from the monitoring site to a computer in the office.

Two external 12 volts batteries can be used to supply electric power to the Slope Sentry. In addition, two solar panels can be connected to perform automatic daily charging of both the external batteries and an internal battery in PS12, which is for emergency use only. An AVW4 interface is enclosed for signal transfer between a piezometer and a datalogger. A CR10 X datalogger performs data recording, sensing of alarm limits and control of an alarm system.

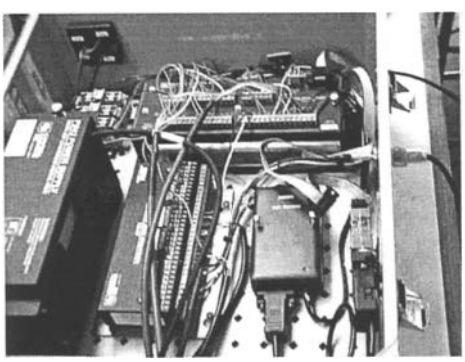

Figure 6. Slope Sentry

An M20 terminal modem is used to transmit data remotely. This modem allows transfer of data across a GSM900 digital cellular phone

network. The M20T is a GSM digital transceiver, which is considered to be a GSM mobile telephone without a handset. The M20T has an extra interface to allow a data device to be connected and can be used to collect data from a datalogger at a speed of a land-based 9600 baud modem, which closely emulates a standard "Hayes style" telephone modem. Through the M20T modem and the GSM communication technology, temporarily-stored data in the datalogger can be transferred to a computer in the office. Main specifications of the M20 Terminal modem are: standard RS 232 serial port; operating temperature ranges from -29°C to +55°C (User's manual [5]).

MULTI-ANTENNA GPS AND INTEGRATION WITH THE CONVENTIONAL SLOPE MONITORING PACAKGE

Among GPS instruments, the GPS receiver is the most expensive component. At present, one GPS receiver is used to monitor the movement of one point only. If there are ten points to monitor, ten GPS receivers are needed. This makes GPS monitoring more expensive than conventional geotechnical instruments. The one-receiver-to-one-point approach adopted in the standard GPS is the main reason of the high cost using GPS for monitoring.

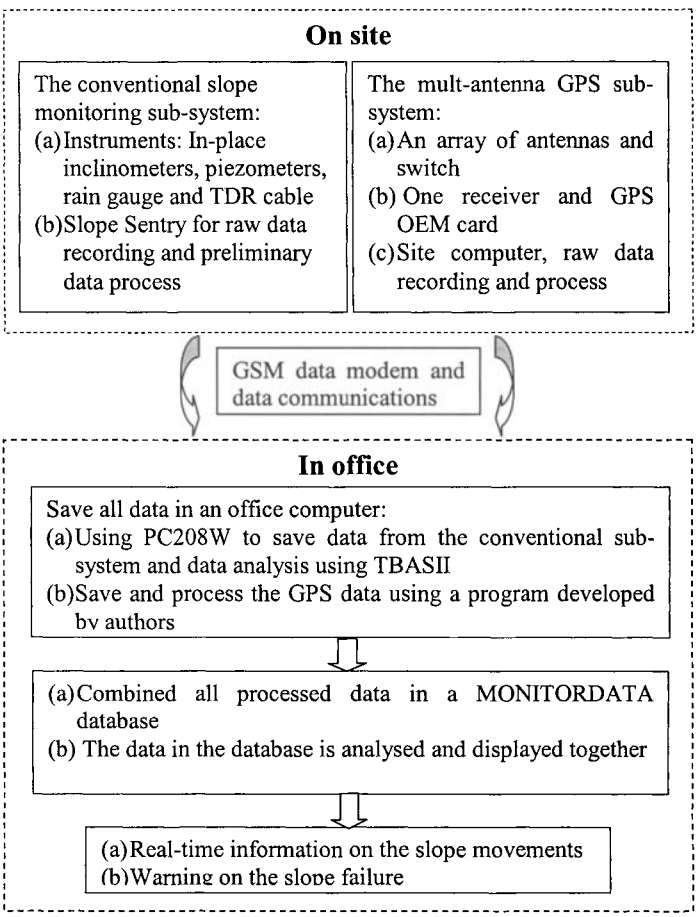

Figure 7. Illustration of the integration of the two sub-systems

In our newly developed GPS technology (Ding et al. 2002), a multi-antenna-switch is added to one GPS receiver to build up a multi-antenna GPS array, in which there are eight input ports (antenna) and one output port. After the receiver has got signal from one port, the receiver automatically switches to the next port until data from all ports are received. The one receiver in the multi-antenna GPS works in the same way as that of a standard GPS. Since only one receiver is used instead of 10 receivers, the multi-antenna GPS is much cheaper that the standard GPS with a resulting cost saving of about 80 %.

The authors have integrated the multi-antenna GPS with the conventional slope monitoring package as presented in the proceeding sections. The conventional package monitors mainly the sub-surface soil movements and pore water pressures while the multi-antenna GPS mainly

monitors the surface movements of a slope at an array of points. The integrated Slope Monitoring and Warning System (SMWS) combines and enhances the advantages of the conventional sub-system and the multi-antenna GPS. Data of the subsurface movements, pore water pressures and the slip location from the conventional sub-system plus rainfall measurements are combined with the data of the three-dimensional (3-D) movements of a large number of points on the slope surface to give a complete set of data, a whole picture, and better understanding of the slope movement. The integrated system can give a more comprehensive understanding of a slope and may give a more reliable warning before the slope starts to fail.

The method of integrating the multi-antenna GPS with the conventional sub-system is described here. In our design each sub-system can work separately and independently. The two sub-systems can also be integrated together and work jointly. When integrated, the two sub-systems are installed at the same slope site:

(a) The conventional sub-system is installed at a number of selected locations mainly sub-surface. The number of locations depends on the slope size and importance. The in-place inclinometers are placed in a vertical (or inclined) borehole with an access tube (a PVC pipe) at one-metre intervals, down through the potential slip surface. The TDR cable sensor is also installed through a vertical (or inclined) borehole through the potential slip surface at a location near to or away from the inclinometer borehole. A number of piezometers are installed at selected points in the soil mass. The rain gauge is normally placed on the ground surface at or near the slope site.

(b) An array of antennas are placed on poles (or small concrete blocks) on the slope surface. Special cables connect the antennas to one GPS receiver.

An illustration of the integration of the two sub- systems is shown in Figure 7.

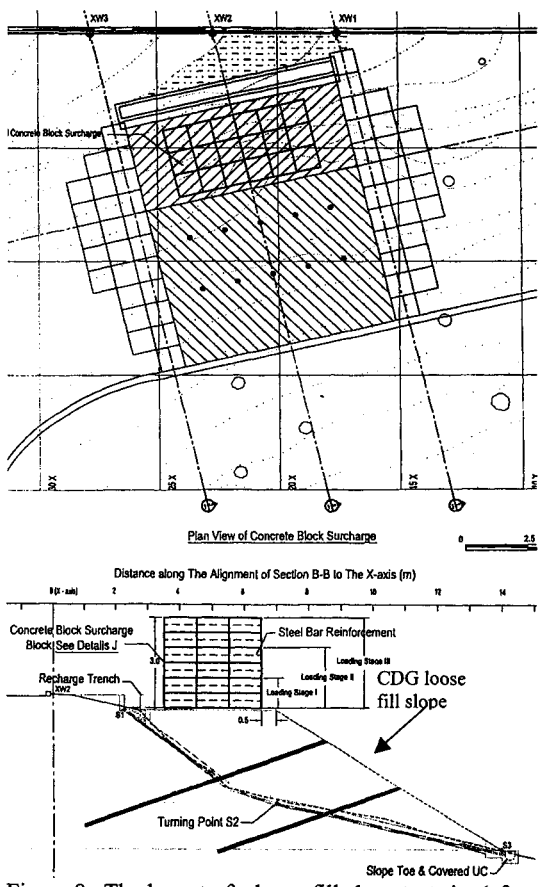

Figure 8. The layout of a loose fill slope test site (after Department of Civil Engineering of the University of Hong Kong (2002))

SITE TRIAL

The above integrated Slope Monitoring and Warning System (SMWS) has been installed at a loose fill slope test site in Hong Kong. The loose fill slope site is located in Kadoorie Agriculture Research Centre in Yuen Long of Hong Kong and constructed by the Department of Civil Engineering of the University of Hong Kong (2002) (see Figure 8). Completely Decomposed Granite (CDG) has been loosely placed to form the test slope. The natural ground below the test slope has a slope angle of 15°. The CDG loose fill slope has a slope angle of 33°. In plan view, the

slope area is 9.0m (width)×11.7m (length) with a maximum height of 4.5m. Two rows of soil nails are installed. There is a platform of 3m ×6.0m (see Figure 8) at the crest platform. Precast concrete blocks are to be used as surcharge acting on the crest platform. The concrete blocks will be placed gradually. Ground water table will also be raised. The idea is to cause the fill slope to fail under a control condition.

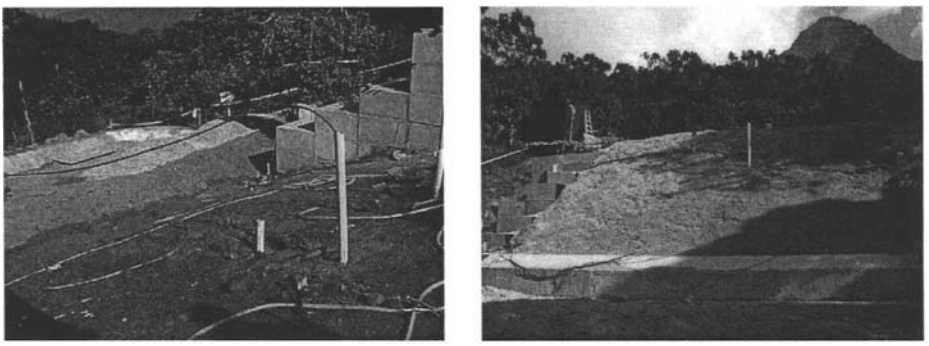

Figure 9. Installation of in-place inclinometers and TDR cable in two vertical boreholes – a down slope view (left) (partially built) and an upper slope view (right) (the final shape)

At the slope site, five in-place inclinometers have been installed in one vertical borehole of 6.3m in depth into the natural ground beneath the test slope (see Figure 9). One TDR cable is embedded in another near-by vertical borehople of 6.5m depths (see Figure 9). One piezometer is directly buried at the interface between the CDG fill and the natural ground next to the TDR and inclinometer boreholes. An array of five steel poles are installed on the sloping surface. The top of each pole supports one GPS antenna. Two further foundations on the stable ground support a portable station and a base reference station. The Slope Sentry, TDR tester, GPS receiver, switch box and other instruments are placed in a small shed close to the monitoring site. DC power battery supplies electric power to all instruments.

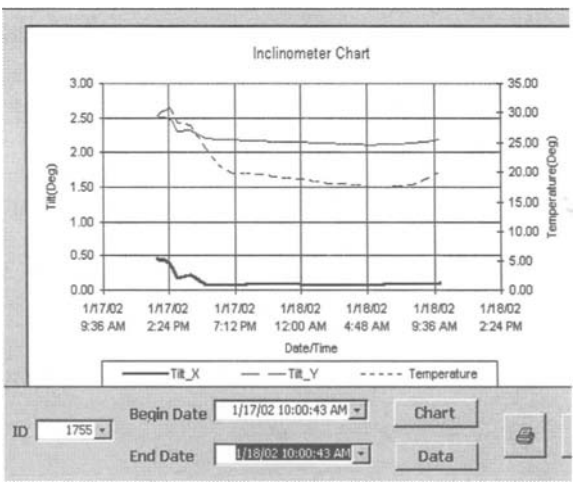

Figure 10. Graphical display of monitoring data in a database

A MONITORDATA database has been established for this particular site. Figure 10 shows the graphical display of data from Inclinometer No 1755 - relation of tilting angle and temperature with time on January 17, 2002 in the MONITORDATA database.

SUMMARY AND REMARKS

An integrated Slope Monitoring and Warning System (SMWS) is introduced in this paper. The method for integration of a conventional slope monitoring sub-system and a multi-antenna GPS

sub-system is described. The SMWS has been installed at a CDG loose fill slope test site in Hong Kong. Based on the work to date, the following main points can be summarised:

(a) The integrated SMWS can give a complete set of data on the slope under monitoring – subsurface and surface movements, pore water pressure, location of the slip surface and rainfall intensity. All these will provide more comprehensive information on the slope conditions and thus give a more reliable warning before the slope fails.
(b) The integrated system combines and enhances the advantages of the conventional sub-system and the GPS sub-system. Furthermore, the integrated system is more cost-effective for slope monitoring.
(c) The integration method is flexible. The two sub-systems can also work separately and independently if so required.

The functions, reliability, and accuracy of the integrated system need field verification. The field trial verification is currently still in progress and the findings will be reported in the near future.

ACKNOWLEDGEMENT

The research work in this paper is supported by grants (Project No. - CRC 4/99, A/C:3-ZB39 and Project No. - PolyU5090/98E) from the Research Grants Council of the Hong Kong SAR Government and The Hong Kong Polytechnic University. The project team is grateful to the Department of Civil Engineering of the University of Hong Kong for allowing us to use their loose fill test slope site for the field trial. Mr. Jeff N. Schuyler has provided valuable advice to us on the project. All the supports and advice given are gratefully acknowledged.

DECISION MODEL FOR THE SELECTION OF DEMOLITION TECHNIQUES

A. Abdullah and C. J. Anumba

Department of Civil and Building Engineering, Loughborough University, Loughborough, LE11 3TU, UK

ABSTRACT

The demolition of structures is governed by a number of criteria. The changing natures of demolition criterion from one demolition project to another makes the selection of demolition techniques very risky and time-consuming for the contractor. This paper describes the development of a multiple-criteria decision support system using Analytic Hierarchy Process (AHP) for the selection of the most appropriate demolition technique. The AHP comprises three parts: hierarchic structure, prioritization procedure, and calculation of results. A postal questionnaire and interview survey was conducted with demolition contractors in the United Kingdom to identify the criteria and the alternatives for the development of the hierarchic structure. There are six major influential criteria identified: Structure characteristics; Site conditions; Cost; Past experience; Reuse & recycling and Time. These criteria used to select three main alternatives: progressive demolition; deliberate collapses mechanism and deconstruction. An example is presented to illustrate the potential application of the proposed model using computerized decision support software, namely Expert Choice 2000.

KEYWORDS

Analytic hierarchy process (AHP), demolition technique selection model, multiple criteria, intelligent system and decision-making process.

INTRODUCTION

Selecting a demolition technique is one of the most important tasks faced by a demolition contractor at the tender stage. The changing nature of parameters from one structure to another makes the selection of demolition techniques difficult for the contractor. Before selecting any type of demolition technique, the demolition contractor needs to consider a set of criteria and assess their relevance to the demolition work to be undertaken in order to arrive at the most appropriate demolition technique. There are no sets of criteria, which uniquely and completely determine the appropriate demolition technique for a particular project (Fesseha, 1999). Furthermore, demolition techniques are continually evolving, becoming faster, safer and more cost effective (Atkinson &

Faulkner, 2000). The number of different demolition techniques in the demolition industry has increased over the last decade. In the past, the basic tools of demolition were wrecking ball, crane and front-end loader. Today, standard equipment used includes the hydraulic excavator with many attachments such as, hammers, shears, grapples, pulverisers and multi-purpose attachments. Implosion or using an explosive to demolish a structure is also an option. This has resulted in an increasing demand for systematic methods of selecting the most appropriate technique for a specific demolition project.

The nature of the problem involves a multicriteria decision-making ability. It requires an effective decision making technique to systematically evaluate demolition techniques against a number of criteria, which will help the individual or project team to select the most appropriate demolition technique from the alternatives available. The decision is based on experience, skill and knowledge and its varies from one to another decision-maker. Even with an experienced and knowledgeable decision-maker, their procedures are kept confidentially. From the literature search, there is still no systematic procedure by experts that can help in evaluating the selection of demolition technique.

With regards to the problem mentioned, the Analytical Hierarchy Process (AHP) was chosen for this study to gives the decision maker the framework needed to model a complex decision scenario, therefore allowing for a better understanding of the problem, its criteria and possible choice. Muralidhar, Santhnam, and Wilson (1990) support the belief that the AHP caters specifically for decision making with multicriteria attributes. This paper therefore presents the development of a theoretical framework using AHP for the selection of the most appropriate demolition technique.

RESEARCH METHODOLOGY

In this study, both questionnaires and interviews were used to elicit essential information from demolition contractors. The aim of the survey is to identify the criteria and alternatives used to select the demolition techniques.

Postal Questionnaires

The population for this research is the demolition contractors in United Kingdom (UK). National Federation of Demolition Contractors (NFDC) UK provides the sampling frame of this research. There were 157 demolition contractors as a corporate member registered with NFDC (Atkinson & Faulkner, 2000). All the contractors from the sampling frame were contacted by telephone to make sure the willingness and confirmation of address before the questionnaire were send by post. Finally, about 100 out of 157 demolition contractors were interested to be included in this research as a sample. The response rate for the survey was 37 per cent, out of 100 questionnaires delivered, of which 94.6 per cent of the represented usable replies and 5.4 per cent unusable replies. The experience and position of the respondents in the company stimulated confidence in the result of the survey. About 86 percent of the respondents has more than 10 years of experience and represents top-level management in the respondent's company.

The experts assessed each criterion in the questionnaire by ranking their relative importance to each other. Statistical analysis was carried out to refine these criteria with the purpose of identifying the relative degree of importance of each criterion. Table 1 shows the selection criteria for demolition techniques identified by the respondents.

TABLE 1
SELECTION CRITERIA FOR DEMOLITION TECHNIQUES (RANKING FOR RELATIVE IMPORTANCE)

Criteria	Ranking
Health and safety	1
Stability of the structure	2
Location and accessibility	3
Presence of hazardous material	4
Environmental consideration	5
Shape and size of the structure	6
Client specification	7
Structural engineer approval	8
Time constraint	9
Extent of demolition	10
Financial Constraint	11
Recycling consideration	12
Transportation consideration	13
Availability of plant or equipment	14

Structured Interview

Structured interviews (6 interviews) with key experts were conducted after the entire postal questionnaire returned. The refined criteria that resulted from the postal questionnaire were given to the key experts for reassessment and to ensure the relevance of the identified criteria. Statistical analysis was carried out to refine the criteria, which were used directly in the AHP method, to develop a proposed hierarchic structure.

THE DEMOLITION TECHNIQUES

The actual demolition starts when the structural elements demolished. There are three main types of demolition techniques, which are progressive demolition; deliberate collapse mechanisms and deconstruction. These are the alternative technique that can be selected by the contractor in the selection process conducted in the tendering stage.

Progressive demolition

The progressive demolition is the controlled removal of sections of the structure, at the same time retaining the stability of the remainder and avoiding collapse of the whole or part of the structure to be demolished. Progressive demolition is particularly practical in confined and restricted areas and may be considered for the majority of sites. The progressive demolition includes progressive demolition by machine i.e. Excavator attached with boom and hydraulic attachments such as pulverisers, crushers and shears; and Progressive demolition by balling which involves the progressive demolition of a structure by the use of a iron ball that is suspended from a lifting appliance and then released to impact the structure, repeatedly, in the same or different locations.

Deliberate collapse mechanisms

Demolition by deliberate collapse is the removal of key structural members to cause complete collapse of the whole or part of the building or structure. This method usually employed on detached, isolated, fairly level sites where the whole structure is to be demolished. A sufficient space must be allocated to enable removal of equipment and personnel to a safe distance. The demolition by deliberate collapse includes deliberate collapse by explosive and deliberate collapse by wire rope pulling.

Deconstruction

Deconstruction process reverses the sequence of construction, dismantling a structure that proceeds from roof to ground in a general trend. The structures are carefully dismantled in order to maximize the recovery of valuable building resources for reuse and recycling. This technique can be used, for example as part of renovation or modification work and prepare the way for deliberate collapse. The elements to be removed should be identified and the effects of removal on the remaining structure fully understood and included in the method statement, with the elements to be removed marked on site. If instability of any of the remainder might result in a possible risk to personnel on the site and to other people nearby, sections of the structure should not be removed. The deconstruction can be done by hand or machines.

MODEL DEVELOPMENT

Several methods are available to evaluate the multiple criteria decision-making problem i.e. ranking, weighting, rating, and paired comparison. Since the contractor bases judgement on experience and knowledge, the AHP method agree with the behavior of the decision process. The computerized decision support software (Expert Choice 2000) was used to structure the demolition technique selection model and will be discussed in the following section. One actual demolition project was used to illustrate the model development process (Table 2).

TABLE 2
THE PROJECT CHARACTERISTICS

Project Characteristics	Explanations
Type of structure	3-storey car park constructed from concrete beam, which are laid onto concrete supporting columns. The structure demolished because of the redevelopment project involved in the area.
Location	The car park located in the town centre where health and safety of the public is the main concern. The site can be easily access by road. The nearest adjacent structure is about 20 meter. There is a main road beside the car park, which have a high traffic volume during the peak hour.
Contractor background	Many years' experience demolished a concrete structure whether in urban or rural areas generally by using progressive and deliberate removal of element demolition techniques. Have several experiences demolish a structure by using explosive.
Reuse & Recycling	The only materials that can be recycled are rebar as a scrap iron and concrete debris as a fill material.
Time	Proposed project completion date is three months.

Analytic Hierarchy Process (AHP)

AHP has been applied to many types of decision problem, since its introduction by Thomas L. Saaty in the mid-1970s. Partovi (1994) described AHP as 'a decision-aiding tool for dealing with complex, unstructured and multi-attribute decision'. Fundamentally, the AHP works by developing priorities for alternatives and the criteria used to judge the alternatives (Saaty, 1994). Analytic hierarchy process takes into account judgements based on people's feeling and emotions as well as their thoughts (Saaty, 1994). Golden (1989) described AHP as *analytical* by using numbers, *hierarchical* by structuring the decision problem into levels, and *process*-oriented because its step-by step approach. Application can be found in such diverse fields as portfolio selection, transportation planning, manufacturing system design, and artificial intelligence (Saaty, 1994).

The number and diversity of AHP applications has grown rapidly with the introduction of its PC implementation, Expert Choice (Person, 2001). Expert Choice is intuitive, graphically based and

structured in a user-friendly way so as to be helpful for conceptual and analytical thinkers, novices and category experts. Because the criteria are presented in a hierarchical structure, decision-makers are able to practice their level of expertise, and apply judgments to the criteria consider important to their personal or organizational objectives. At the end of the process, decision-makers are fully aware of how and why the decision was made, with results that are meaningful and practical. Thousands of businesses and government agencies use Expert Choice to structure, justify and optimize critical group decisions (Person, 2001). The majority of these applications have introduced analytical solutions for the problems that involved both quantitative and qualitative criteria (Skibniewski & Chao, 1992), which is related to the selection process that is the objective of this study. There are three basic steps in using AHP: hierarchic structure, prioritization procedure, and calculation of results (Fong & Choi, 2000).

Hierarchic structure

A complex decision problem is expressed as a hierarchy structure (Saaty, 1994). Structure the hierarchy from the top (the overall objective or goal from a decision-maker's viewpoint), through the intermediate levels (the criteria or objectives affecting the decisions), to the lowest level (sub-criteria and decision alternatives are on each descending level of the hierarchy).

The selection of the most appropriate demolition techniques was the goal of the decision-makers and is located at level 0 of the model to serve as the goal node. The criteria which affecting the demolition technique selection was the result taken from the questionnaires survey and interview. These criteria had been classified into 6 categories, and inserted in level 1 of the model to serve as main criteria. The criteria for each category were inserted in level 2 of the model to serve as sub-criteria nodes. Statistically, level one; and two of the hierarchy consists of a total of 6, and 16 nodes respectively. Finally, the alternative solutions occupied the lowest levels to serve as the choice available for the decision-makers in the last screening stage. The hierarchy structure for the proposed model shows in Figure 1.

Prioritization procedure

The second step is to weight or to judge (define) the priority of each criterion. At each level pairwise comparisons are conducted for each category with the one in the adjacent upper level, and the weight are entered into a comparison matrix. The elements on the second level (Structure characteristics, site conditions, cost, past experience, reuse and recycling, and time) are arrange into matrix, and the decision makers make judgements about the relative importance of the elements with respect to the overall goal of selecting the most appropriate demolition technique. The judgements are entered using the fundamental scale for pairwise comparisons (see Table 3).

TABLE 3
SCALE OF RELATIVE IMPORTANCE USED BY (SAATY, 1994)

Intensity of Importance	Definition	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Weak importance of one over another	Experience and judgement slightly favor one activity over another
5	Essential or strong importance	Experience and judgement strongly favor one activity over another
7	Demonstrated importance	An activity is strongly favored and its dominance demonstrate in practice
9	Absolute importance	The evidence favoring one activity over another is of the highest possible order of affirmation
2,4,6,8	Intermediate values between the two adjacent judgements	When compromise is needed
Reciprocals of above nonzero	If activity i has one of the above nonzero numbers assign to it when compared with activity j, then activity j has the reciprocal value when compared with i.	

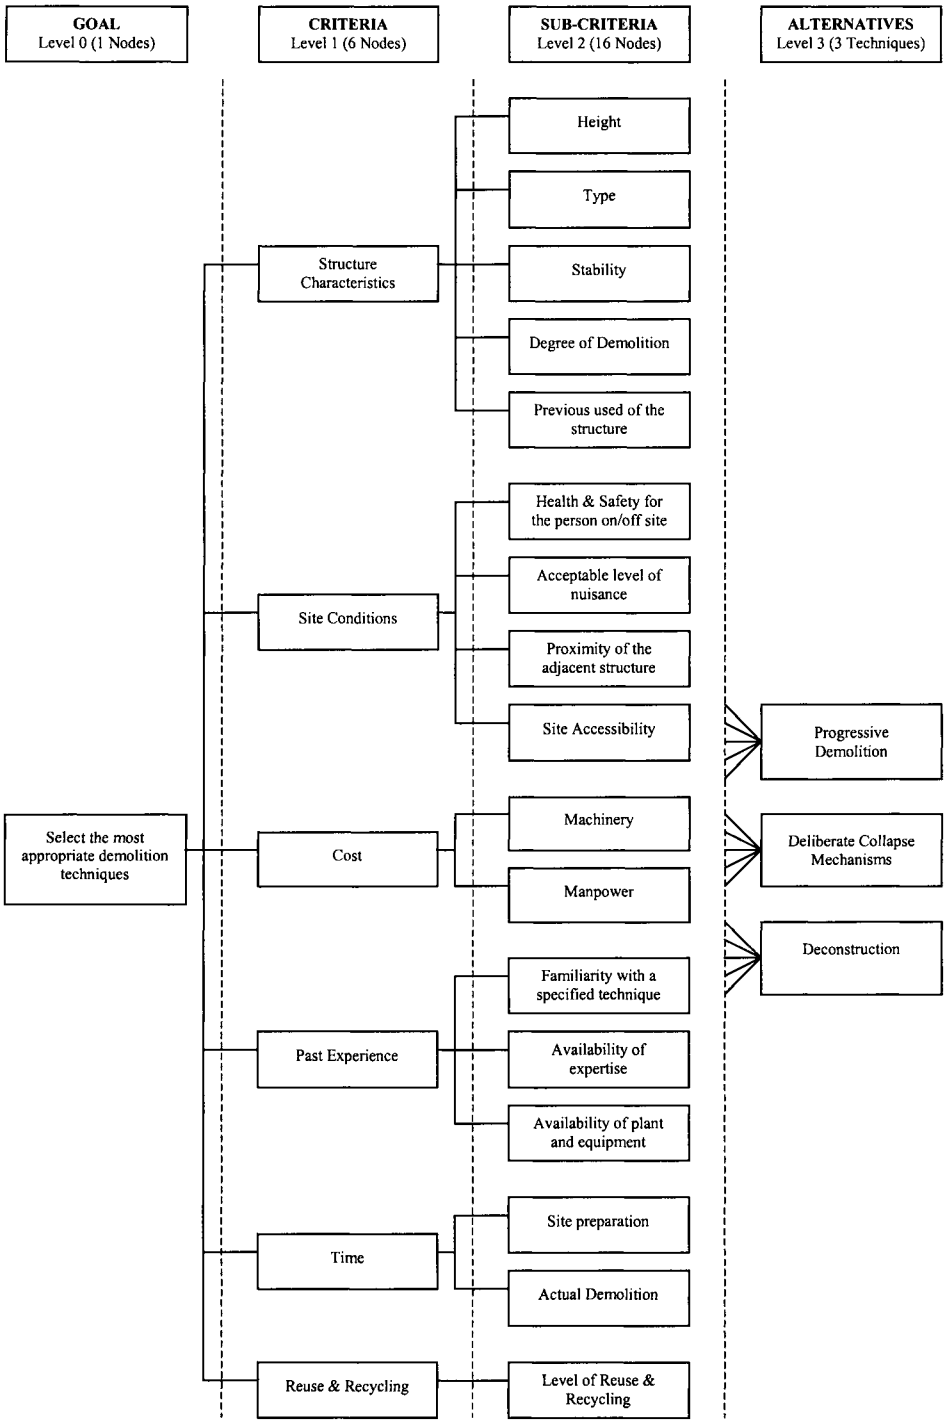

FIGURE 1: HIERARCHY STRUCTURE FOR THE SELECTION OF DEMOLITION TECHNIQUE

Saaty (1994) describes pairwise comparison as 'the element that appears in the left-hand column is always compared with the element appearing in the top row, and the value is given to the element in the column as it is compared with the element in the row. If it is regarded less favorably, the judgment is a fraction. The reciprocal value is entered in the position where the second element, when it appears in the column, is compared with the first element when it appears in the row'. For example, when judging the relative preference of factors located in level 1 with respect to the goal (level 0), a rating of 5 is assigned in the comparison with structure characteristics and site conditions. This indicates essential or strong importance or experience and judgment strongly favor structure characteristics over site conditions. In comparing cost with past experience with respect to the goal, the rating of 3 assigned. This means cost is weak importance of one over past experience. The same procedure repeated when the rating of 7 assigned in comparing site conditions with time with respect to goal. Intensity of importance (7) assigned for this matrix can be explains, as a site condition is strongly favored if compared with time. All the remaining pairwise comparison matrices among the nodes in the hierarchy can be established by following the same procedure. Table 4 presents the start of pairwise comparison of level 0 with level 1. Similar pairwise comparison tables exist for level 1 with level 2 and level 2 with level 3.

TABLE 4
START OF PAIRWISE COMPARISON OF LEVEL 0 WITH LEVEL 1

Demolition technique selection criteria (1)	Structure characteristics (2)	Site conditions (3)	Cost (4)	Past experience (5)	Reuse & recycling (6)	Time (7)
Structure characteristics	1	5	5	5	7	8
Site conditions	1/5	1	5	5	5	7
Cost	1/5	1/5	1	3	3	5
Past experience	1/5	1/5	1/3	1	1	3
Reuse & recycling	1/7	1/5	1/3	1	1	3
Time	1/8	1/7	1/5	1/3	1/3	1

Calculation of results

The next step is to perform synthesis process from the model global goal. This process converts all the local priorities into the global weights of alternatives. Saaty (1996) remarks that 'if there are more than two levels, the various priority vectors can be combined into priority matrices, which yield one final priority vector for the bottom level'. Local priority is the priority relative to its parent or upper level, while global priority, also called final priority, is the priority with respect to the goal. Table 5 shows the local and global priority of each criterion in the final selection of demolition technique. The table format was adapted from (Fong & Choi, 2000). As a result from the pairwise comparison matrices, the overall priorities of model's main criteria were determined (see Table 6). AHP provides a measure to test out the degree of inconsistency by the decision-makers called Consistency Index (CI). In general, a consistency index < 0.10 is acceptable. The CI can be calculated for each matrix as follows (Saaty, 1994):

The Consistency Index $CI = (\lambda\text{-}n) / (n\text{-}1)$; n = Matrix size, and λ = Eigenvalue

The contractors can select three alternatives for the demolition techniques (Progressive demolition, deliberate collapse mechanisms and deconstruction). These three techniques must be compared pairwise for each criterion. This process is similar to the procedures that used to develop the normalized eigenvector of criteria. Finally the synthesis with respect to goal, which is to select the most appropriate demolition technique, is presented in Table 7. The order of prioritization is progressive demolition, deliberate collapse mechanisms, and deconstruction (from the most to the least appropriate demolition techniques to be used in the project example).

TABLE 5
THE PRIORITY OF EACH CRITERION IN THE SELECTION OF DEMOLITION TECHNIQUE

Criterion	Local priority [a]	Global priority [b]	Subcriterion	Local priority [a]	Global priority [b]
Structure characteristic	0.491	0.491	Height	0.107	0.052[c]
			Type	0.054	0.027
			Stability	0.525	0.258
			Degree of demolition	0.281	0.138
			Use of structure	0.034	0.017
Site conditions	0.255	0.255	Health and safety for the person on and off site	0.057	0.148
			Acceptable level of nuisance	0.110	0.028
			Proximity of the adjacent structure	0.241	0.061
			Site accessibility	0.071	0.018
Cost	0.113	0.113	Machinery	0.750	0.085
			Manpower	0.250	0.028
Past experience	0.058	0.058	Familiarity with a specified techniques	0.268	0.016
			Availability of plant and equipment	0.117	0.007
			Availability of expertise	0.614	0.036
Time	0.028	0.028	Site Preparation	0.167	0.005
			Actual demolition	0.833	0.024
Reuse & recycling	0.054	0.054	Level of reuse and recycling	1.000	0.054

[a] Local priority is derived from judgement with respect to a single criterion
[b] Global priority is derived from multiplication by the priority of the criterion
[c] The result is obtained as follows: 0.491 X 0.107 = 0.052

TABLE 6
RELATIVE PRIORITY OF CRITERIA

Criterion	Relative priority
Structure characteristic	0.491
Site conditions	0.255
Cost	0.113
Past experience	0.058
Reuse & recycling	0.054
Time	0.028

Consistency index = 0.09

TABLE 7
OVERALL PRIORIZITATION OF THE THREE ALTERNATIVES

Criterion	Relative priority
Progressive demolition	0.534
Deconstruction	0.262
Deliberate collapse mechanisms	0.204

Consistency index = 0.07

CONCLUSION

The demolition contractor faces a problem in selecting the most appropriate demolition technique for a specified project because it involves a multicriteria decision-making ability. The characteristics of the problem require an effective decision making method to systematically evaluate the demolition techniques available against a number of influential criteria. With regard to this problem, computerised decision support software called Expert Choice 2000, which implements the AHP methodology was used to structure the demolition technique selection model.

A questionnaire survey and expert interview survey involving contractors and demolition experts in the UK were used to establish the influential criteria in selecting demolition techniques. The criteria

finally grouped into six main categories. The result shows that the structural characteristics followed closely by the site conditions are the main influential criteria to select a demolition technique. The most appropriate technique selected for the demolition project based on the weighting inserted during the pairwise comparison, is progressive demolition. The same technique also selected in the actual demolition project. Therefore the proposed model can be very helpful to assist the demolition contractor in selecting the most appropriate demolition technique in any given situation.

DEVELOPING AN EXPERT SYSTEM FOR PROJECT PROCUREMENT

Albert P.C. Chan[1]

Department of Building and Real Estate, Hong Kong Polytechnic University,
Hung Hom, Hong Kong, HKSAR, PRC

ABSTRACT

It is claimed that the correct choice of a building delivery method will lead to the success of a building project. Hence selecting an appropriate procurement system is an essential step in any construction project process. If a client makes a wrong choice, the penalty may be time and cost overrun and a general dissatisfaction. Despite considerable research into the choice of appropriate procurement systems for construction projects, no generally applicable solutions have been found. This paper reports a research study carried out in Hong Kong on procurement selection. The study aims to develop an expert system to aid the selection of the most appropriate procurement system. A procurement categorization is developed to reflect the current procurement practice in Hong Kong. The model is based on a set of criteria and utility factors derived from ten local experts through 4 rounds of Delphi survey. A statistically significant consensus on the weighting of the utility factors for each procurement system was obtained. The results vividly reveal that Delphi method is a powerful and appropriate technique in deriving objective opinions in a rather subjective area such as the multi-attribute model for the selection of procurement system.

KEYWORDS

Expert system, procurement selection, multi-attribute model.

INTRODUCTION

The construction industry in Hong Kong is rather conservative and not innovative. In contexts where there are no specific incentives or benefits for being innovative, most construction clients rely on traditional systems of design-bid-build to deliver their projects. This has been the case in Hong Kong for the last two to three decades, particularly for clients with mass building programs such as the Hong Kong Housing Authority (HKIA, 1998).

Many clients, however, are becoming increasingly dissatisfied with the traditional form's operational characteristics and seek other methods of procurement, organisation and management to meet their

more exacting needs (Griffith, 1989). Integrated procurement system and management-oriented system are approaches that can be used to help dealing with the problems associated with the traditional system (Masterman, 1992).

It is known that procurement methods play a major role in defining and shaping contractual and work relationships between parties involved in the construction process. It is also claimed that the correct choice of a building procurement method will lead to the success of a building project (Bennett & Grice, 1990). A project may be regarded as successful if the building is delivered at the right time, at the appropriate price and quality standards, and provides the client with a high level of satisfaction (Barclay, 1994). If the client makes an inappropriate choice, the penalty may be time and cost overrun and a general dissatisfaction.

Previous research (Chan & Fung, 1996) found that clients and their advisers often refer to past experience and personal preference in selecting procurement systems for their projects. Research regarding systematic procurement selection techniques and their application to the industry in Hong Kong is rather limited. Research by Skitmore & Marsden (1988), Bennett & Grice (1990), and Chan (1995) have developed similar procurement selection model. However, Tsoi (1997) has found that none of this model is applicable to the unique Hong Kong construction industry. Thus, in order to enhance the applicability of these models, future research should be directed to develop a Hong Kong based model by taking the local construction industry into account.

This paper, based on the earlier work by Chan et al (2001), reports the development of an expert system to guide the client in selecting an appropriate procurement method for a building project in Hong Kong. A multi-attribute model will be used to obtain the most appropriate choice of procurement system for a building project in Hong Kong. The model is based on a set of utility factors derived from a panel of local experts through the application of the Delphi methods.

DEFINING BUILDING PROCUREMENT

Franks (1998) described a "building procurement system" as "the amalgam of activities undertaken by a client to obtain a building". Masterman (1992) defined a "building procurement system" as "the organisational structure adopted by the client for the management of the design and construction of a building project."

Previous studies (Chan, 1994, 1995, 1996; Chan & Tam, 1994; Chan & Lam, 1995) suggest that alternative procurement systems can be used successfully on building projects and provide time and cost benefits to both clients and contractors. However, no one single system will suit every conceivable type of project (Chan & Tam, 1994). The selection of a system appropriate to the unique facets of a particular project is a critical determinant of the ultimate success of the project (Chan, 1996). Chan et al (2001) identify that the most popular procurement systems adopted in Hong Kong include sequential traditional, accelerated traditional, competitive design and build, enhanced design and build, novation, and management contracting.

Nahapiet (1985) found out that there is no one best contractual arrangement for building projects. The most appropriate choice of procurement system depends on the individuality of the particular project and its client. The key to successful procurement system is the identification of the clients' objectives and project characteristics and matching of these to the most appropriate procurement system.

One of the fundamental needs to ensure the successful delivery of a building project is the correct choice of method for managing the relationships between the different organisations and specialists that will form the project team (Masterman, 1994).

DEVELOPING A PROCUREMENT SELECTION MODEL BASED ON THE DELPHI TECHNIQUE

Delphi technique is being increasingly used in many complex areas in which a consensus is to be reached. Some of these areas included the development of residential areas (Anatharajan and Anataraman, 1982), theory and design application (Corotis and Harris, 1982), and bridge condition rating and effects of improvements (Saito and Sinha, 1991). Moreover, the Delphi method is a highly formalized method of communication that is designed to extract the maximum amount of unbiased information from a panel of experts. Therefore, it would be appropriate to adopt the Delphi technique for obtaining a set of universal utility factors for the selection model of procurement system.

Delphi Background

The Delphi concept was developed from the American defense industry. Project Delphi was the name of a study done by the Rand Corporation for the U.S. Air Force in the early 1950's concerning the use of expert opinion (Robinson, 1991). The objective of the study was to "obtain the most reliable consensus of opinion of a group of experts by a series of intensive questionnaires interspersed with controlled opinion feedback" (Linstone and Turoff, 1975). It was originally developed for market research and sales forecasting purposes (Goldfisher, 1992).

The Delphi method can be characterised as a method for structuring a group communication process so that the process is effective in allowing a group of individuals as a whole to deal with complex problems. Delphi is primarily a communication device, which is applied when the consensus of experts on an uncertain issue, often intangible is desired (Linstone and Turoff, 1975). It is conducted by rounds interspersed with group opinion and information feed back in the form of relevant statistical data. Delphi is an iterative forecasting procedure characterized by three features (Dickey and Watts 1978): 1) anonymity, 2) iteration with controlled feedback, and 3) statistical response.

Panel members remain unknown to one another and respond to a series of questionnaires. The iterative nature of the procedure generates new information for panelists in each round enabling them to modify their assessments and project them beyond their own subjective opinions. It can represent the best forecast available from a consensus of experts (Corotis, Fox, and Harris, 1981).

The Delphi approach offers an additional advantage in situations where it is important to define areas of uncertainty or disagreement among experts. In these instances, Delphi can highlight topics of concern and evaluate uncertainty in a quantitative manner. Group evaluation of belief statements made by panel members is an explicit part of Delphi (Robinson, 1991). Goldstein (1975) correctly points out that, while the group view has a higher probability of being correct than an individual, its success depends principally on the careful selection of the panel and formulation of questions. The major difficulties of Delphi, however, lie in maintaining the high level of response and in reaching and implementing a consensus (Robinson, 1991).

Format of Delphi Rounds

Ten experts were selected to provide opinions on the suitability of a certain procurement path for a given criterion. The ten members of the panel represent a wide distribution of professional, with four from the public client organisations; three from the private consultant groups and three are academics in the Universities in Hong Kong. The composition of this group of experts provides a balanced view for the Delphi survey. The Delphi method adopted in this research consisted of four rounds. In the first and second round of Delphi questionnaire, it was intended to gather a set of exclusive selection

criteria for the procurement system in the Hong Kong construction industry. The respondents were asked to provide a minimum of five criteria for the selection of the most appropriate procurement system in the first round Delphi. The second round of the questionnaire dealt with all the criteria provided in the first round and experts were asked to state the importance for each of the criterion. In the third round of questionnaire, a list of criteria with corresponding questions were presented and the respondents were requested to assess the suitability of each procurement system against each selection criterion.

While analysing the data, the focus should be on the opinion of the group rather than that of individuals. Therefore a Concordance analysis, which measures the consistency of the experts' responses over successive rounds of the Delphi, is adopted. In the fourth round of Delphi, respondents were provided with results in round three. They were asked to re-consider the scores of the utility factors and see whether they would adjust them. The consistency of the results improved significantly over the last two rounds. Full details of the Delphi survey are recorded in Chan et al's paper (2001).

THE MULTI-ATTRIBUTE MODEL

By the application of the Delphi method, a set of sufficiently consistent utility factors was obtained after the final round of Delphi questionnaire. The set of selection criteria and the corresponding utility factors are used to develop a procurement selection model. The multi-attribute model consists of the following set of client's criteria, which are re-phrased as priority questions.

1. *Price competition*: How important is it to choose your project team by price competition, so increasing the likelihood of a low price?
2. *Time available*: How important is early completion to the success of your project?
3. *Time predictability*: To what extent do you require a specific completion date at the start of the project?
4. *Availability of competent contractors*: How important is it to have a plentiful supply of competent contractors to work for the procurement system?
5. *Clear end user's requirements*: How capable is the client able to state his or her requirements clearly and precisely at the tender stage?
6. *Complexity*: Is the project highly specialized, technologically advanced or highly serviced?
7. *Certainty of cost without fluctuation*: How important is a firm price at the beginning of construction needed?
8. *Flexibility for changes*: To what extent do you expect the project to have frequent changes in the design and construction once the work has begun on site?
9. *Risk management*: To what extent do you need risk avoidance in the event of time, cost, design liability and quality slippage?
10. *Responsibility*: To what extent do you wish to have a single point of responsibility for the completion of the design and construction of the project?
11. *Familiarity*: How important is it for the client to choose a familiar system to deliver the project?

The priority questions will allow the users to prioritize the criteria according to a specific project and the user's specific requirements (Skitmore and Marsden, 1988; Bennett and Grice, 1990; Chan, 1995; Love et al., 1998). Figure 1 shows the multi-attribute model with the mean values of the utility factors for the each procurement system against each selection criterion.

The Use Of The Selection Model

The selection model can be applied by following the procedures laid down below (Chan and Yung, 2000; Skitmore and Marsden, 1988):

1) The user reads all the priority questions and enters the relative importance of each criterion in the table on a scale of 1 to 5, 1 being the least important, and 5 being the most important. The prioritisation exercise enables the users to specify their requirements according to the project needs and circumstantial factors.
2) Each priority rating is taken in turn and multiplied by each of the utility factors, the results being entered into the appropriate columns. This is compared for all the criteria.

The totals of each of the result columns, under each procurement path, are calculated, and ranked in descending order. The most appropriate procedure should have the highest total result.

Selection Criteria	Utility Factors													
	Traditional system					Integrated system						Management		
	Client's Priority Rating	Sequential		Accelerated		Competitive design & build		Enhanced design & build		Novation		Management contracting		
W significant at 0.05 level		U.F.	Score	U.F.	Score	U.F.	Score	U.F.	Score	U.F.	Score	U.F.	Score	
1. **Price Competition** • How important is it to choose your project team by price competition, so increasing the likelihood of a low price?		85.6		68.1		91.9		88.1		76.3		55		
2. **Time Available** • How important is early completion to the success of your project?		51.9		76.3		84.4		75.6		76.3		86.3		
3. **Time Predictability** • To what extent do you require a specified completion date at the start of the project?		77.5		70.6		93.8		86.9		87.5		71.3		
4. **Availability of Competent Contractors** • How important is it to have a plentiful of supply of competent contractors to work for the procurement system?		92.5		83.8		66.9		68.1		65.6		51.3		
5. **Ability to State Clear End user's requirements** • How capable is the client able to state the employer's requirements precisely at the tender stage?		93.8		75		87.5		95		95		56.3		
6. **Complexity** • Is the project highly specialized, technologically advanced or highly serviced?		70		55		73.1		85.6		85.6		83.1		
7. **Certainty of Cost without Fluctuation** • How important is a firm price at the beginning of construction is needed?		73.8		46.9		93.8		88.1		87.5		41.3		
8. **Flexibility for Changes** • To what extent do you expect frequent changes in design and construction once the work has begun on site?		66.3		65.6		50.6		55.6		55.6		88.1		
9. **Risk Management** • To what extent do you need risk avoidance in the event of time, cost, design liability, and quality slippage?		75.6		59.4		90		82.5		82.5		58.1		
10. **Responsibility** • To what extent do you wish a single point of responsibility for the completion of the programme, design and construction of the project?		66.9		57.5		100		93.8		89.4		58.1		
11. **Familiarity** • How important is it for the client to choose a familiar system to deliver a building project?		96.3		60.6		80.6		75.6		46.9		51.3

Order of preference														

Figure 1: Multi-attribute Procurement Selection Model (Chan et al, 2001).

CONCLUSION

Building projects in Hong Kong have been managed mainly in the traditional way. In the last two decades, alternative procurement systems have been mainly used in the public sector in Hong Kong, such as the Architectural Service Department (ASD) and the Hospital Authority. After a close investigation of the prevailing procurement system in Hong Kong, it was found that there is not a systematic and disciplined way to aid the client in selecting the most appropriate system. Clients in the public sector mainly based their choice on previous experience; the traditional system, being the most familiar, was usually chosen. These findings vividly support the aim of this research in which the development of a systematic procurement selection model for Hong Kong is essential in order to reduce the possibility of selecting the incorrect procurement system.

The application of the Delphi method in deriving a procurement selection model was shown to be an appropriate technique. It enables a sufficient consistency to be reached in a rather subjective area. With the aid of this model, construction clients can adopt a more reliable and objective approach to select an appropriate procurement system for a construction project.

SUPPORT SYSTEM FOR PROJECT MANAGEMENT AND PRODUCTION OF CONCRETE PRECAST ELEMENTS

E.Dassori[1] and M.Frasani[2]

[1]Department of structural and geotechnical engineering, University of Genoa
16145 Genoa, Italy
[2] CSG Information Technology
29017 Fiorenzuola d'Arda (PC), I

ABSTRACT

The paper presents the most important information system now used by Italian producers for project management and production of concrete precast elements. It is an information system developed for the automation and integration of activities affecting the duration of the order, for the co-ordination of the commercial office, technical office, production, transport and assembly, in order to optimise the use of resources and to increase the quality both of the services and the elements manufactured. The control of the order keeps all these phases under observation verifying the efficiency of the various areas and thereby reducing the time taken for the order.

KEYWORDS

Project management, production, concrete, precast, elements.

Introduction

The Italian market of precast elements in reinforced concrete (normal and pre-compressed) is characterised by strong demand and by the high quality of the components being produced, which are: plinths, mono and multi-level pillars, beams (9-40 m), floors (different typologies for lights between 3 and 10 m), joists (floors and coverings for lights from 10 to 25 m), non-load bearing wall elements (solid, lightened and sandwich).
Regarding demand, in Italy precast elements in concrete (non-load bearing external walls and structures) cover between 70% and 95% of the production of buildings for offices, commerce and industry. For housing there is a modest use only of linear structural elements (pillars and beams) in that, for this typology, on site solutions in concrete and load bearing walls in brick blocks are preferred.
The companies producing these components operate in a technically complex and highly competitive scenario and for this reason more and more they feel the need to use advanced management instruments that allow them to increase productivity and the quality level of their performance.
With this in mind the information system that we are dealing with here was designed and, at this moment in time, is the most widely used in Italy; it has also been chosen by firms operating in other countries of the European Community. The present version of the program offers an enormous range of performances that go from support to project management and control of production and that are the fruit of more than 20 years of research and applications.

Data flow

Figure 1 describes the flow of data within the information system, which as can be seen, covers all the areas concerned in the order: the commercial office, technical office, production structures, transport and assembly.

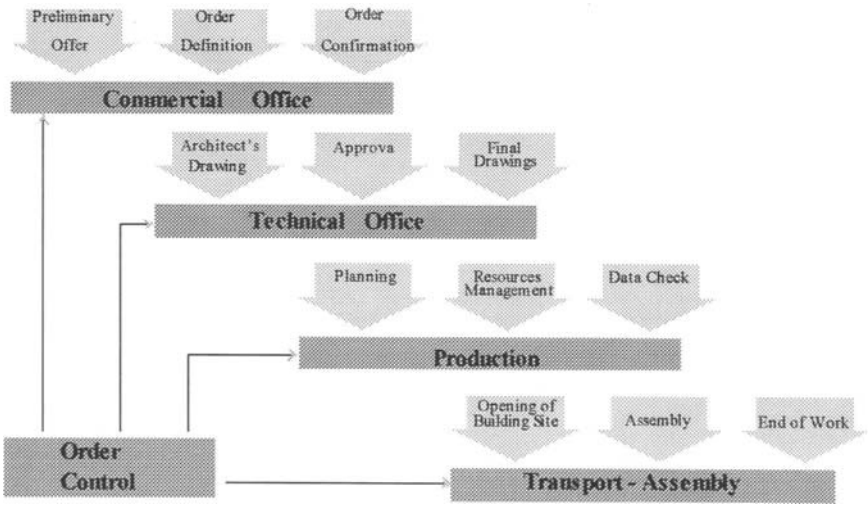

Figure 1:The flow of data in the information system

One of the most important characteristics of the system of management budgeting and control is that it does not use a price list but employs *"rules of cost"* that permit a better assessment of direct and indirect costs throughout the process. These also consider the quantity parameter, which, as a function of the repetitiveness of the same or similar items, allows optimisation of the administration of resources.
The information system sees departments as single entities structured like "small companies" that work together to reach the general objectives of the whole company. For each process planning (budget of costs and times) is therefore defined in such a way as to rapidly and globally check the expenses and the programmed/perceived deadlines.

The structure of the program

The system is based on two integrated software modules called LEGO-CAD and P2000, the first being destined to the technical functions and the second to management ones. Figure 2 shows the active functions in detail in the two programs and the way they interface.
Instead, the integrated flow of the system is shown in Figure 3, where the functions carried out by the modules are those listed in the following.

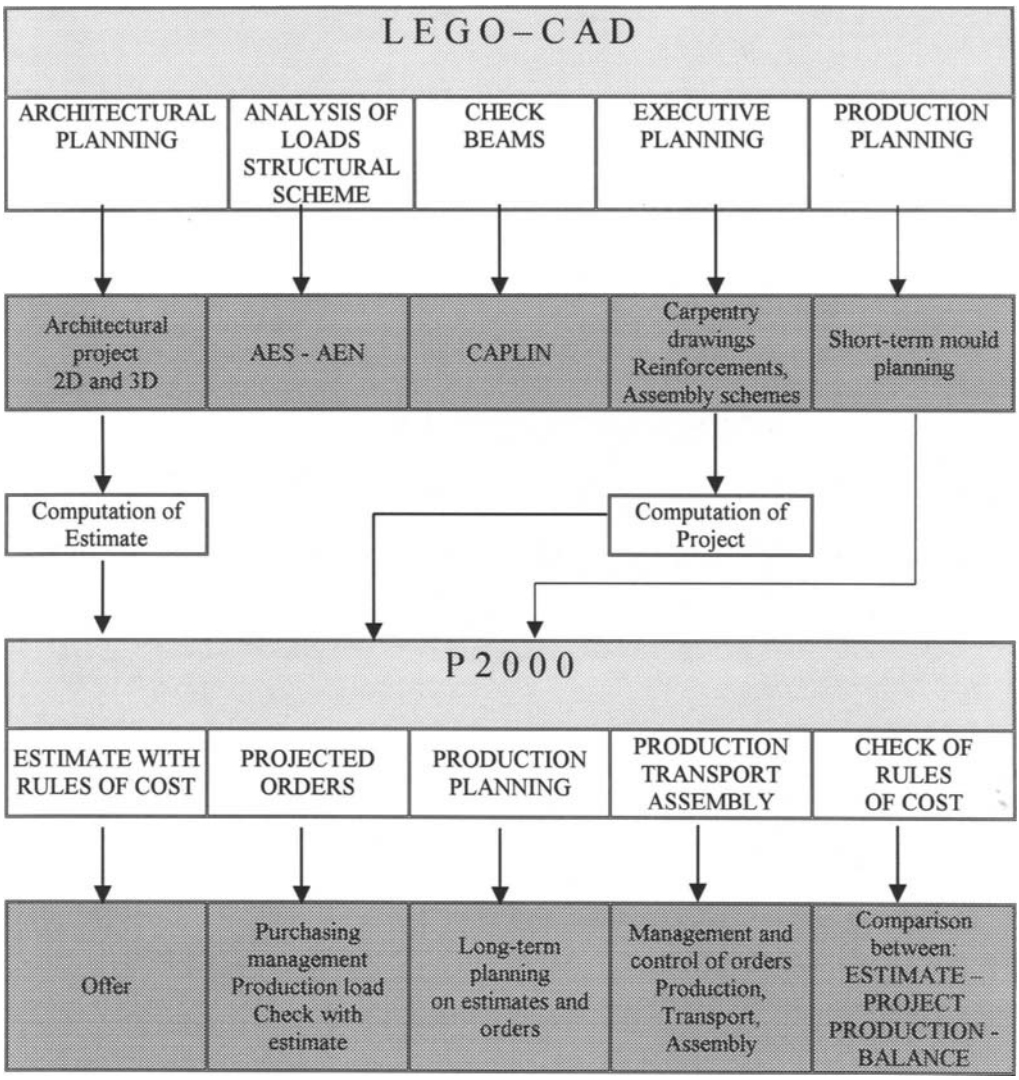

Figure 2: Integration and functions of the LEGO-CAD and P2000 modules

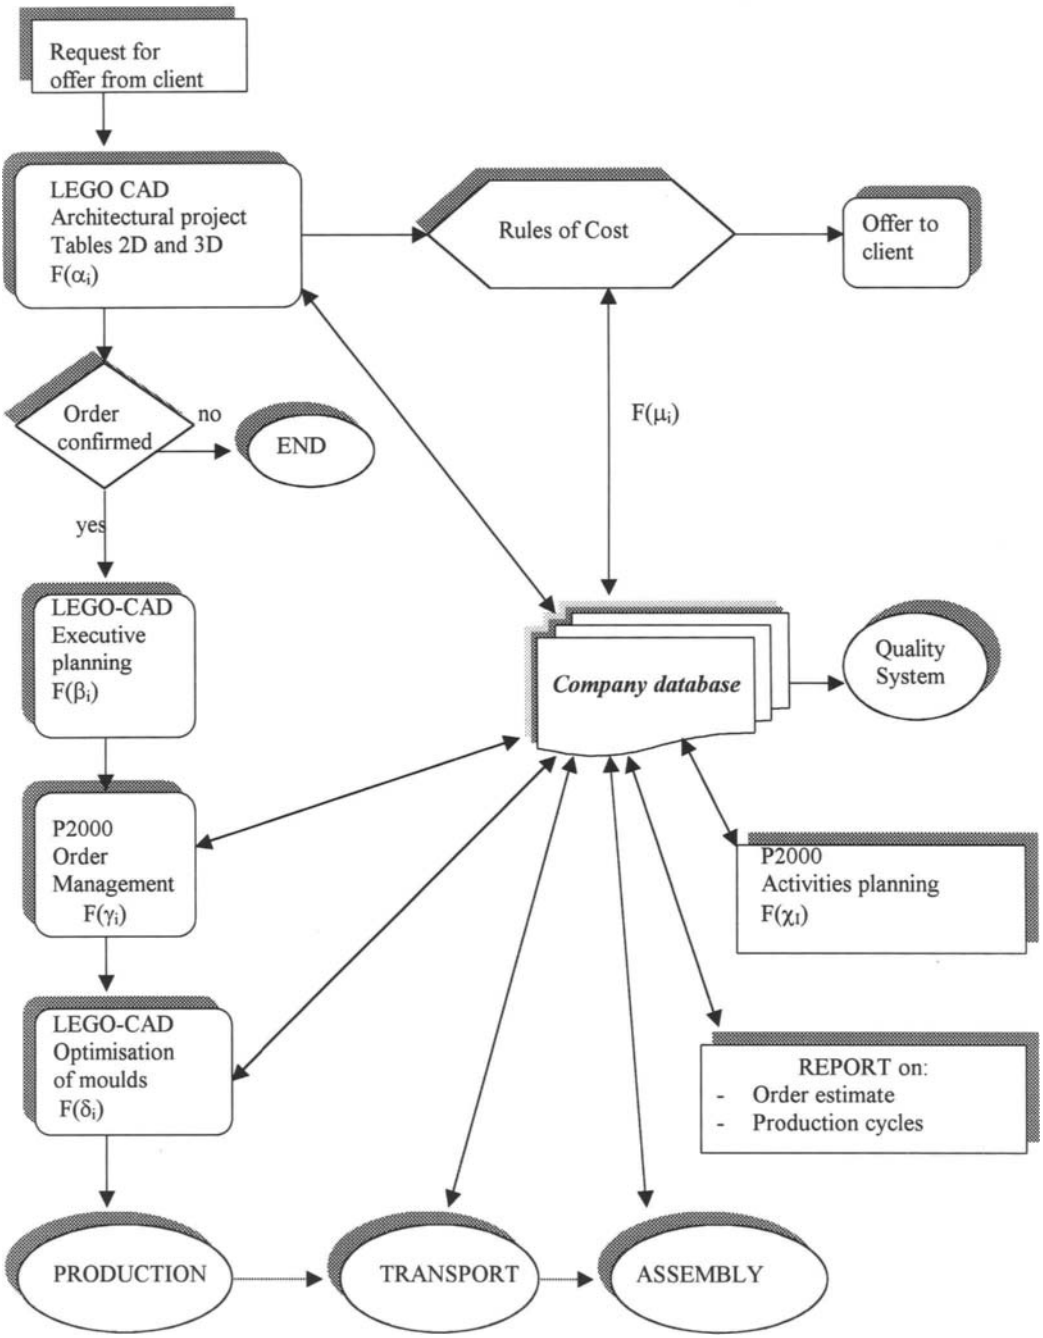

Figure 3: Integrated flow of the system

$F(\alpha_i)$ Architectural project for budget whose output is:

- Plant drawings, sections and complete prospects of automatic dimensioning
- Three-dimensional model of the structure
- Computation of the elements
- Cost analysis for each type of component
- Analysis of transport, assembly and complementary services
- Analysis of loads and static schematisation as output for generic structural solution finders (SAP,...)
- Printout of the offer

$F(\beta_i)$ Executive project whose output is:

- Definition of connections with metal inserts
- Production of the drawings for building of the moulds
- Production of the drawings for metal reinforcements
- Assembly schemes
- Summary of materials
- Computation of the designed products
- Data transfer to order management module
- Analysis of order costs and comparison with the approved estimate

$F(\gamma_i)$ Medium and long-term programming whose output is:

- General planning of production expressed in the form of a Gantt diagram.

The order is inserted in the general programming of medium and long-term production. This planning temporarily concerns the confirmed orders already designed, already confirmed orders but not yet designed and estimates in the acquisition phase.

To operate this programming and obtain the diagram, the necessary resources are defined and the order delivery priorities and those of the selected estimates are assigned.

$F(\delta_i)$ Short-term programming (10-15 working days) whose output is:

- Printout of the production plan with allocation of resources
- Visualisation of state through Gantt diagrams for every mould and for the group of orders. Graphically each order is identified with a colour, the alternation of colours shows the rhythm of work for each individual mould
- Order requests for the raw materials necessary for the production plan
- Printout of the cards for the automation of the production, transport and assembly phases
- Information for medium and long-term management control

The function aims at optimisation of the use of moulds. This phase is managed directly by the head of production. He operates virtually in a graphic environment using the executive project and the planimetrical scheme of the factory with the layout of the moulds. Simply by using the mouse, the person in charge takes the components from the executive drawings and drags them to the moulds. The program arranges to suggest the best position on the basis of the data concerning production in progress, the resources available and the general production deadlines.

$F(\chi_i)$ Activity programming whose output is:

- General programming of the activities shown by means of a Gantt diagram
- Programming and management of transport and assembly
- Information elements for the company database

The function is integrated with the optimisation module of the moulds and elaborates the data relative to daily production.

$F(\mu_i)$ Feedback

Through the structure of the company database a feedback function relative to validation of the rules of cost is active. The procedure detects real times and costs and compares them with the corresponding elements on which the rules of cost were set. Their congruence is thereby controlled in real time and

not at the end of the financial years. The comparison takes place on accurate values and not averages distributed over all the typologies in production that, in cases like these, would not be very significant. The company database supplies all the elements necessary for process controls that are guided by the company Quality System implemented according to ISO 9001/2000.
Figure 4 describes the structure of the only production, programming module:

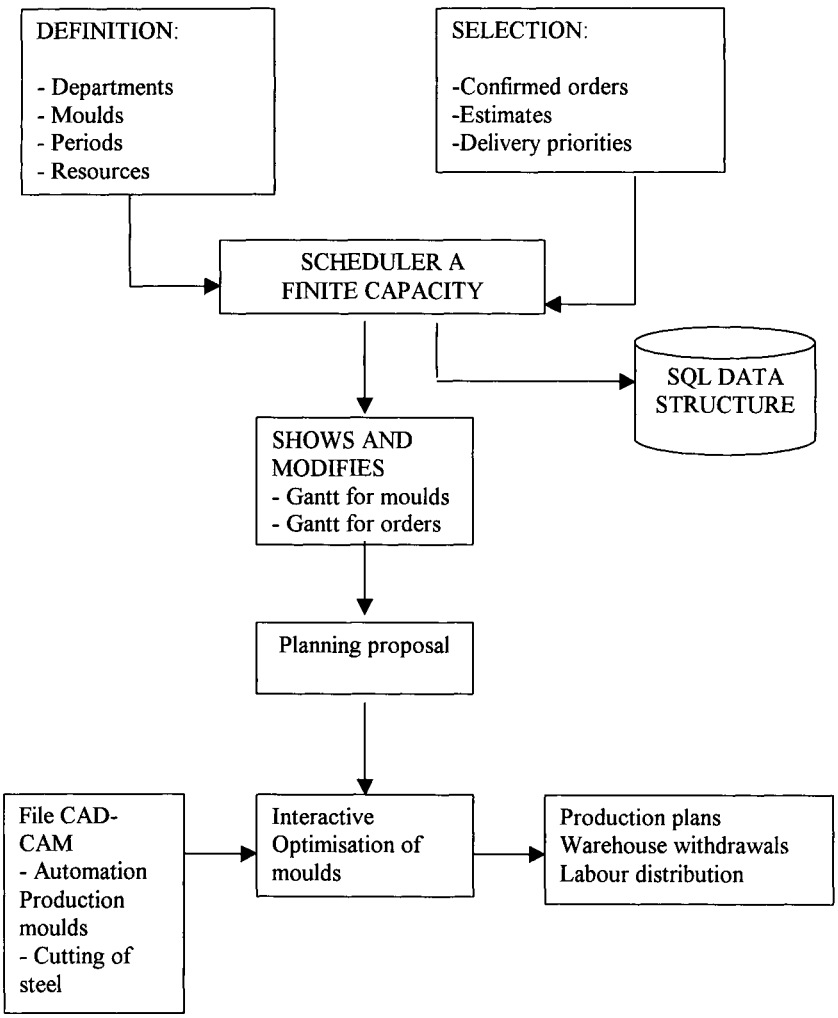

Figure 4: Structure of the production, programming module

The output of this phase is: printout of the general layout of production by date of pouring, printout of the executive forms of the products made in the same order as their positioning on the belt, printout of the summaries of concrete, inserts, polystyrene, lifting devices, printout of the reinforcement by profile and by diameter of each product in the mould, file CAD-CAM in UNITEC format to govern the robot

for the design of products and the positioning of the separators and sides, file CAD-CAM to cut the metal reinforcement bars, printout of the labels with barcode. The label with the barcode that is printed in the same order as the products are positioned on the belt. The label is in double format so that one part stays in the company while the other is automatically attached to the piece and goes with it the whole of its future life becoming the fundamental element for the traceability of the product (ISO 9001/2000).
Figures 6 and 7 show the Gantt diagram for the mould and the order Gantt.

The structure of the software

The analysis of the software starts from the complete knowledge of the problems of the sector. In practice the structure of the software envisages a database in which the different program modules are inserted. In this way the structure of the software offers total integration between the existing parts while maintaining a very high degree of elasticity compared to the needs of the users and the possibility of further developments.
Figure 4 shows the blocks that make up the structure of the software and that have the functions described in the following:

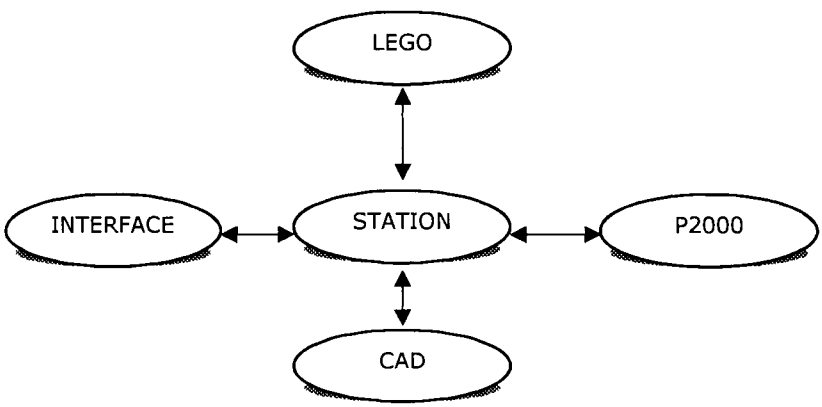

Figure 5: Structure of the software

STATION	Server of messages that makes the programs communicate with each other
LEGO	Design interface made up of different modules for architectural planning, executive planning and optimisation of moulds
INTERFACE	Manages the interface toward the user
CAD	Graphic motor
P2000	Management program

Development of these programs started with the Fortran language and HP computers. The modularity of the programs has allowed evolution over time of the different operating systems (RTE-A, DOS, UNIX, Windows from release 3.11 to present versions). The structure of the data is based on ASCII files for the graphic environment and on SQL relational database for management. These data structures envisage the archiving of any type of document produced even from other programs (Word, Excel,...).

A SURVEY MANAGEMENT SYSTEM FOR ADVANCED BUILDING CONSTRUCTION

Steve Y. W. Lam and Conrad H. W. Tang

Department of Land Surveying and Geo-Informatics,
The Hong Kong Polytechnic University,
Kowloon, Hong Kong SAR, China

ABSTRACT

This paper provides engineering surveyors with a practical and concise explanation of the concepts and techniques needed for managing the scope, project organization, quality, costs, time and risks in advanced building construction in Hong Kong and other parts of the world. It reviews briefly some of the key management concepts governing the survey operations, and describes how to apply the theory into practice in accordance with the ISO 9001:2000 standard.

KEYWORDS

Advanced building construction, engineering surveys, project-based survey management system, total quality management system, ISO 9001:2000.

INTRODUCTION

In the past decade, the authors observed four revolutionary changes in advanced building construction. Firstly, construction organizations manage construction teams on project basis as the more efficient way to accomplish their goals and strategies. Secondly, the adoption of total quality management (TQM) system under ISO 9001:2000 to deal with organizational and technical problems has been proved successful in managerial processes. Thirdly, the demand for high accuracy standards in engineering surveying is highlighted by the increasing adoption of precast and prefabricated components for modern building structures, and the setting-out of computerized construction machines being used in building projects. Fourthly, the integration of application software, 3D modeling and simulation, multimedia systems and robotics technologies are becoming technically and economically feasible in engineering survey operations and building construction.

Engineering survey operations required of building construction projects are given in Figure 1. In the projects, engineering surveyors are responsible for geodetic control surveys, detail mapping for alignment design and geometric modeling of building design, setting-out of the new structures, and deformation monitoring of buildings and ground displacements. They are the front line workers particularly in setting-out the precise geometric models of structures during construction. In fact, survey operations are required from start to finish in building projects.

To cope with rapid advancement of construction technology and managerial processes associated with the survey operations in advanced building construction, six functions of a project-based survey management system are briefly described in this paper. These management functions are managing the scope, project organization, quality, costs, time and risks (Turner 1999).

Early in Year 2001, ISO 9001:2000 officially replaced ISO 9001:1994, ISO 9002:1994 and ISO 9003:1994, and asserted the role of the well-known standard as a quality management model, in stead of, as a quality assurance model of the previous version. ISO 9001:2000 adopts the principles of TQM, and requires a construction organization to demonstrate ability in fulfilling four main aspects and eight principles of the quality management.

The four aspects of the TQM emphasized by ISO 9001:2000 are:
1. management commitment,
2. process-based approach,
3. customer service, and
4. continuous improvement.

The eight principles specified by ISO 9000:2000 are:
1. customer focus,
2. leadership,
3. involvement of people,
4. process approach,
5. system approach to management,
6. continual improvement,
7. factual approach to decision making, and
8. mutually beneficial supplier relationship.

Quality control elements of the TQM system under ISO 9001:2000 are given in Table 1. Details of implementing some of the quality control elements for managing engineering surveys in building construction are discussed in the following sections.

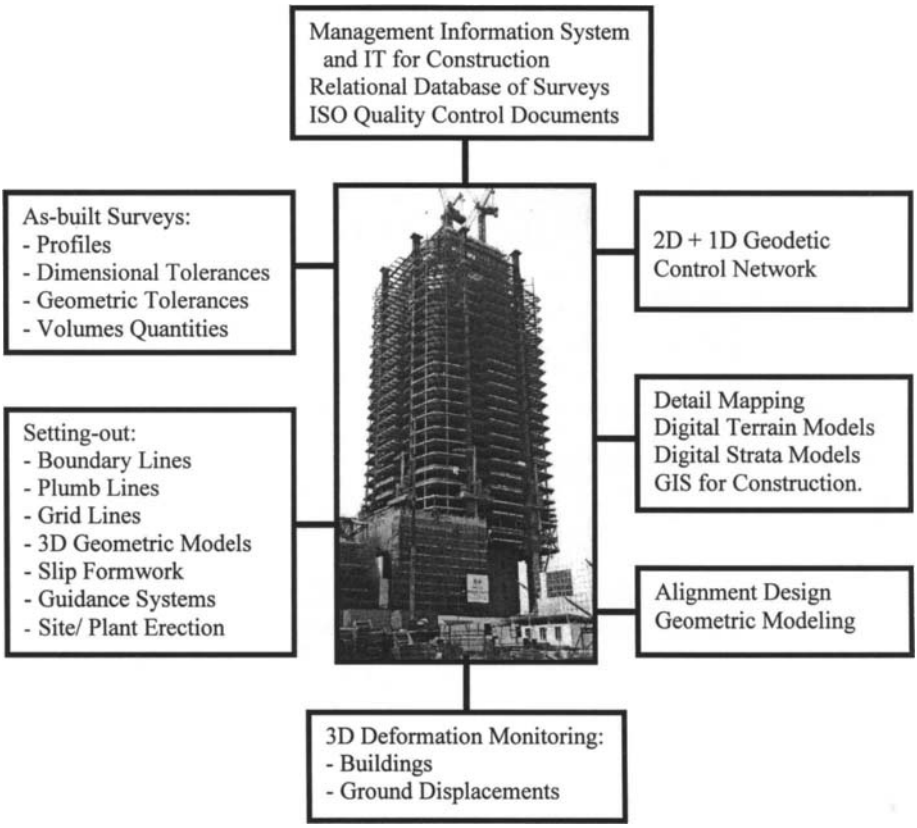

Figure 1: Engineering Survey Operations in Building Construction Projects

8	Measurement, analysis and improvement 8.1 General 8.2 Monitoring and measurement 8.3 Control of non-conforming product 8.4 Analysis of data 8.5 Improvement

MANAGING THE SCOPE AND PROJECT ORGANIZATION

Scope management is defined as the function of ensuring that enough, but only enough, work is undertaken to deliver the project's purpose successfully (Turner 1999). In the process of scope management, project requirements and organizational objectives are converted into statements of work to produce the expected benefits (ISO 9001:2000, Item 7.1). These scope statements must be published in the quality control documents of the organization (ISO 9001:2000, Item 4.2). The quality control documents include quality manuals, quality procedure manuals, department/section manuals, operation/work instruction manuals and quality control records (Lam and Tang 2000).

As different projects may have different contract requirements and customer expectation, project quality plans (PQP) and survey quality plans (SQP) are published to supplement the scope documents. In practice, a project engineering surveyor is responsible to design and establish SQP, and to integrate them into the overall milestone plan of the project. In building construction, a milestone is an event that marks the completion of a group of related tasks or the completion of a phase of the project. Three columns are usually found on a milestone plan form (MPF) having the planned dates on the first column, the milestone schedule and networks (e.g. flowcharts, bar charts, CPM charts and PERT charts) on the second column and the detailed description of the milestone on the third column. It is easy to create MPFs and modify a set of milestones for the survey tasks on personal computer systems by using Primavera Project Planner®, Microsoft Project® or other construction management software adopted by the project organization.

In managing a project survey team, an engineering surveyor has to control human, material and financial resources provided by the human resources department of the organization. Under ISO 9001:2000, it is the responsibility of an engineering surveyor to establish responsibility charts for each project to define:

1. the organizational structure of the survey team;
2. all necessary human resources policies and procedures to enable the survey organization to achieve its objectives; and
3. the job description and responsibilities of named survey workers and subcontractors to achieve a particular milestone.

Survey responsibility charts are then integrated into an overall responsibility chart of the project organization to expedite human resources management and achieve business objectives.

MANAGING THE QUALITY

To achieve high quality and profit on the survey operations, survey services must be completed on time, within budget, and meet the customer's requirements with satisfaction (ISO 9001:2000, Items 5, 7.1 and 7.2). All the positional, dimensional and geometric tolerances of survey measurements must be acceptable with respect to accuracy standards which are specified in the contract documents of the project. In building construction, contract

documents include government building standards and regulations, construction drawings and suppliers' specifications.

It is required that field notes and survey data of quality practices must be kept in traceable records. It is the responsibility of an engineering surveyor to ensure that all survey documents are properly labeled and addressed in files or computer systems so that the records are retrievable easily to meet particular demand or purpose, and that wrong use and loss of important data can be avoided. Use of relational database software, management information system for construction (MISC), E-commerce networks and computer systems are recommended for the document control process.

During the project period, survey staffs are responsible for ensuring that inspection work is carried out according to management procedures, approved method statements, inspection and testing plans, work instructions and other procedure manuals. All measuring and test equipment must be controlled, calibrated and well maintained (ISO 9001:2000, Item 7.6). This is to ensure that all survey measurements are consistent with the accuracy standards. It should be noted that test certificates and calibration of all survey instruments must be traceable to national or international standards, and in accordance with documented procedures.

In order to assure quality of survey services in the long run and to keep pace with rapid advancement of surveying technology we are experiencing in building construction, continuous improvement and life-long learning attitude of survey employees are needed. Therefore, training should be provided to ensure workers to capably accomplish the tasks correctly and productively. The survey of Dulaimi and Beckingsale (2001) on construction workers indicates that, under the Investors in People (IiP) Standard of the United Kingdom, employees are motivated by keeping their quality and skill level in line with the business objectives through long-term staff development. Under (ISO 9001:2000, Item 6.2), it is not enough for the company to provide training to its survey employees; the company has to evaluate whether the training produces competent people for the job.

A quality system for managing the survey operations should be reviewed at regular intervals by internal auditors of the project (ISO 9001:2000, Item 8). Any deficiency or non-conformance found in the audit should be recorded and brought to the person who is responsible for the problem to carry out corrective action with preventive measures for future operations (ISO 9001:2000, Item 8.3). Guidelines for performance improvements and establishing effective rewarding system are given in ISO 9004:2000.

MANAGING THE COSTS, TIME AND RISKS

During the life cycle of a building construction project, an engineering surveyor is often involved in cost planning and cost control processes. Cost planning is implemented during the feasibility study and design stage of a project, and it involves a breakdown of proposed total expenditure into allowances to be made for various cost targets of the project. Cost control is one of the most vital management functions that takes place throughout complete duration of a project. It is a systematic recording of costs incurred in the construction and their critical comparison among the planned cost of the scheduled work, the planned cost of the completed

work and the actual cost of the completed work by plotting them against duration on S-curves. A comparison of the planned cost of the completed work with the original estimates helps to control elapsed time (Turner 1999).

In a modern integrated cost-engineering system (e.g. Primavera Expedition®), standard cost codes and project cost codes are used to referencing and documenting items such as labor, materials, pants and equipment, subcontracts, procurement items, accounting items and human resources items to facilitate cost estimation, tendering and construction of the project. The database of the system enables surveyors and other members of the construction team to monitor project costs at any stage and time schedule of the project.

Turner (1999) lists the five steps of risk management as to:
1. identify the sources of risk;
2. determine impact of individual risks including its potential consequence or damage;
3. assess overall impact of risks;
4. determine how the risk can be reduced by avoidance, deflection and contingency plans; and
5. control the identified risk items by monitoring their potential consequence and risk resolution progress.

By experience, contingency approach to survey management is always emphasized in building projects because most of the projects have to be completed within tight budgets and short periods of time. Three types of contingency encountered are money (allowance in budget), time (allowance in schedule) and performance/ quality (allowable tolerances). Surveyors should develop a set of backup plans (contingency plans) which will be used when the original plan can not be implemented or when a crisis happens. Further management applications on identifying project risks, risk analysis techniques and overcome factors of risks in building construction are found in, for instances, (Salzmann and Mohamed 1999) and (Toakley 1995).

CONCLUSION

This paper describes briefly the methods and applications for managing the scope, project organization, quality, costs, time and risks associated with engineering survey operations under ISO 9000:2000 in building construction projects. Undoubtedly, the adoption of ISO 9000:2000 and the TQM system in surveying, construction and other industrial sectors will continue to grow. Whoever is able to supply better quality products at lower cost will capture more local and global market share. And TQM is a very necessary tool in pursuit such excellence and profitability in both the surveying and construction industry.

ABSTRACT

The in-situ concreting process involves both the site contractor and the readymixed concrete supplier. In practice, an inevitably imperfect concrete supply, causing interrupted site operations, often lowers the site productivity. Meanwhile, an oversupply of truckmixers by the concrete supplier to guarantee continuous site operations is not a solution since excessive queuing of concrete truckmixers on site not only results in underutilized resources but also increases the chances of concrete being unfresh. As found out from previous studies, the complexities and uncertainties involved in the concreting operations on site make it difficult for the site to accurately convey the temporal demand of concrete to the concrete supplier in advance, which, in turn, contributes to lack of coordination between the plant and the site.

The objective of this research is to characterize the concrete demand on a bored-pile construction site by simulating the entire concreting operations on an ongoing railway station project in Hong Kong. The well-known CYCLONE technology is used to illustrate the processes and the interaction of resources that define the method of concreting a bored pile. Further, the same bored-piling operations are modeled using a newly developed Simplified Discrete-Event Simulation Approach (SDESA) in order to precisely characterize the concrete demand. A comparison of the CYCLONE model and the SDESA model demonstrates the simplicity and effectiveness of SDESA in modeling complex construction systems. A comparison of the actual supply pattern, which is obtained from site QA records, against the SDESA-characterized demand pattern, has justified the frequent queuing of truckmixers as observed on the site. The outcome of the research will be of immediate help for local concrete plants to match the supply to bored-pile concreting sites and for local contractors to plan bored-pile construction activities.

Operations simulation, readymixed concrete, bored pile construction, CYCLONE, SDESA

INTRODUCTION

The heavy demand for ready mix concrete (RMC) in Hong Kong is among the most intensive in the world with an output of the order of 1.5 m3 per capita per annum for the existing population of 7 million when construction activity is at high levels. Thus, enhancing the operational efficiency, resource utilization and delivery service of Hong Kong's concreting industry is important to the improvement of productivity and competitiveness of the entire construction industry. Meanwhile, the in-situ concreting process involves both the site contractor and the readymixed concrete supplier. In practice, an inevitably imperfect concrete supply, causing interrupted site operations, often lowers the site productivity. On the other hand, an oversupply of truckmixers by the concrete supplier to guarantee continuous site operations is not a solution since excessive queuing of concrete truckmixers on site not only results in underutilized resources but also increases the chances of concrete being unfresh.

To provide local concrete producers with a simulation-based decision-support tool for the resource provision planning and the production planning of a RMC plant, so as to meet given demands at a number of sites for concrete over a working day, a computer platform for simulation modeling and analysis of Hong Kong's one-plant-multi-site RMC production system, called HKCONSIM, has been developed in-house based on the latest construction simulation research outcome, and validated by real-life operations data in Hong Kong (Lu et al, 2002). Demand at each site is expressed by quantity and timing. The emphasis of the simulation modeling is on the interactions of multiple sites with the plant, and the objective is to improve the supply service levels and the utilization of truckmixer resources. One significant improvement achieved via the research is that to simulate the RMC production operations with HKCONSIM does not require familiarity by the user with any software-specific terminology and modeling schematics, in contrast with existing commercial simulation packages. The process of constructing a simulation model is reduced to specifying the details for each pour and each site and allocating the plant and truckmixer resources available on self-explanatory on-screen forms. HKCONSIM produces quantitative performance measures of system operational efficiency and delivery service level as outputs for evaluating the simulated scenarios, and thereby, helping to optimize the simulated system in terms of pouring schedules on each site and resource provisions. Therefore, by experimenting on a HKCONSIM produced model the user, being a practitioner in the concreting industry, can readily study complicated relationships between the pattern of demand for concrete, the plant and truckmixer resources available to the system, and both the service levels achieved on sites and the utilization levels achieved for the resources involved.

By using HKCONSIM on an experimental, but realistic basis a local concrete producer helped validate the potential benefits that HKCONSIM can bring about to readymixed concrete producers in terms of enhancing efficiency, resource utilization, and the delivery service level. Nevertheless, one major barrier, which has been encountered in both the real system and the simulated one, has prevented the further optimization of the system performance: in general, the site could not clearly specify to the concrete supplier the temporal demand of concrete in terms of truckmixer arrival times due to the complexities and uncertainties involved in the concreting operations on site. For example, as normally practiced, on the day prior to the pour the site would only inform the plant on the first truckmixer arrival time (i.e. when the pour commences) and the average inter-arrival time of succeeding truckmixers (i.e. an approximate straight-line relationship between the time and the truckmixer arrivals). The temporal demand of concrete for keeping continuous site operations is actually highly non-linear depending on a number of uncertain or dynamic factors related to the concrete placing methods and site specific conditions, thus rendering it difficult to be predicted in

an accurate and quantitative way. Even the approximation of the linear relationship has so far relied on the knowledge, judgment, and intuition of experienced site personnel.

The objective of this research is to characterize the temporal demand of concrete on a bored-pile construction site by simulating the entire concreting operations on an ongoing railway station extension project in Hong Kong. The well-known CYCLONE technology is used to illustrate the construction processes and the interaction of various resources in concreting a bored pile. Further, a newly developed Simplified Discrete-Event Simulation Approach (SDESA) has been implemented to model the bored-pile processes aimed at predicting the arrival times of truckmixers to ensure continuous concrete supply and undisturbed site operations. The remaining sections first brief on the simulation methodology, followed by an elaboration on the variables of the simulation models including some physical properties of the pile and the technical specifications on the construction method. A comparison of the CYCLONE model and the SDESA model is made to demonstrate the simplicity and effectiveness of SDESA in modeling complex construction systems. A comparison of the actual supply pattern, which is obtained from site QA records, against the SDESA-characterized demand pattern, is also made to justify the frequent queuing of truckmixers as observed on the site. Finally, a conclusion is given for the research.

CONSTRUCTION OPERATIONS SIMULATION

Construction planning is the most crucial, knowledge-intensive, ill-structured, and challenging phase in the project development cycle due to the complicated, interactive, and dynamic nature of construction processes. The methodology of discrete-event simulation, which concerns "the modeling of a system as it evolves over time by a representation in which the state variables change only at a countable number of points in time" (Law and Kelton, 1982), provides a promising alternative solution to construction planning by predicting the future state of a real construction system following creation of a computer model of the real system based on real life statistics and operations. Ever since the inception of CYCLONE technology (Halpin, 1977), simulation models for typical construction systems have been delivered as electronic realistic prototypes for engineers to experiment on, eventually leading to productive, efficient and economical field operations. Nonetheless, operations simulation has lagged spreadsheets, databases, scheduling packages, and other types of software in acceptance and implementation in the construction industry because of the complexities and time requirements involved in constructing a model (Paulson, 1995).

The latest research endeavor on construction simulation has been driven to make simulation methods easier to users. Shi (1999) adapted the activity-based simulation approach to a construction simulation model with one single "activity" element. Hajjar and AbouRizk (2000) developed application frameworks that encapsulate reusable codes as well as common design patterns for a specific class of applications in order to expedite and simplify the development of special-purpose construction simulation tools. As a new attempt Lu (2001) proposed a simplified discrete-event simulation approach (SDESA). Compared with the existing event-based and activity-based approaches, SDESA has significantly streamlined the queuing structures and resources management in simulation by (1) reducing the queuing structures at individual activities into one single dynamic queue of flow entities for the whole simulation model; and (2) distinguishing disposable resource entities from reusable ones and managing all types of resources utilized in the simulation model with a dynamic queue of resource entities (Lu, 2001). A prototype of SDESA has been coded into a computer system using Microsoft Access, which is a relational database system with supporting VB macro programs. SDESA has been applied to model the one-plant-multi-site readymixed concrete supply system in Hong Kong (Lu et al, 2001), a granular base-course construction system featuring both cyclic and linear processes and an asphalt paving construction system with complicated technological/logical constraints (Lu, 2002). This paper reports a new case of applying SDESA to a

bore piling construction project in Hong Kong. In addition, the SDESA-based model is compared with the CYCLONE-based model for demonstrating the simplicity and usefulness of SDESA in complex construction planning.

BORED-PILE CONCRETING METHOD

Bored-pile construction using readymixed concrete supplied by a remote plant is the common piling construction practice in Hong Kong. The entire bored-pile construction method consists of (1) site formation (pre-drilling), (2) excavation (grabbing & chiseling), (3) Concreting, (4) testing and (5) finishing. The main contractor generally sublets the work packages to different specialty sub-contractors without overlapping them; hence, each may be treated as an independent process. The simulation of the complete bored-pile concreting process is based on the ongoing Sha Tin railway station extension project, as part of the Hong Kong's Kowloon-Cantoon Railway Corporation (KCRC) East Rail Extension Project, with over 200 piles to be constructed. Data for simulation modeling were collected through site investigation from September to November in 2001. Experienced site engineers were interviewed to elicit useful information on the construction method for building simulation models. The major variables for the bored-pile concreting simulation model are the length of the pile, which ranges from 30 to 60 meters dependent on the underground soil conditions and the diameter of the pile, which ranges from 1m to 3m depending on the loading capacity of the pile. In this paper, the simulation models are set up for concreting a pile of 50 meters long and 2 meters in diameter, which can be readily adapted to piles of any length and diameter in a more general sense. 7 m^3 truckmixers are used to carry concrete from the plant to the site, with each truckmixer delivery to raise the bottom level of the pile by about 2 m (i.e. $h = \frac{7}{\pi(1)^2}$) where 10% concrete loss is acceptable by the specification. Theoretically, the bottom level of the pile rises by 10 meters with the completion of placing five truckloads of concrete, at which time the temporary steel casing is lifted and truncated.

Each pile should be concreted as soon as practicable after obtaining the permission of the A/E engineer. By technical specifications, the entire process of concreting a pile should be conducted within a day and without interruptions. Resources utilized in concreting a bored pile include (1) truckmixers delivering concrete from the concrete plant to the site; (2) temporary steel casing bolted up with uniform sections, each being 2m in diameter and 6m in length; (3) one mobile crane controlled by one operative; (3) one hopper (7 m^3); (4) one oscillator to raise temporary casing; (5) termie pipe for directing concrete to the bottom of pile; (6) one Q/A inspector; (7) concreting crew of four to five workers; and (8) a general worker to help concreting.

The process starts once the first truckmixer arrives on the site. Following the concrete quality checking by the Q/A inspector, the truckmixer moves into the unloading position. When the hopper, the crane and a general worker are ready, the truckmixer unloads concrete into the hopper; the volume capacity of the truckmixer and the hopper is usually 7 m^3. After unloading concrete and washing out, the truckmixer leaves the site for the concrete plant. On the other hand, the crane lifts up the hopper and moves to the bored pile position for the working crew to pour concrete into the pile through the tremie pipe, which prevents the segregation of concrete due to the free fall effect. Next, the crane moves the empty hopper back to the truckmixer unloading position, and the above hopper-concreting cycle is repeated. In addition, one temporary casing section would be lifted up and truncated after five hopper-concreting cycles for constructing a 2m-diameter pile. When cutting the temporary steel casing, the crane is preempted from hooking up the hopper so as to hold straight the casing section being severed. The crew, usually made up of five skilled workers, unscrews the casing joints once the tremie pipe is temporarily removed and the casing has been withdrawn by the

oscillator. After releasing the casing section in a storage area, the crane hooks up the hopper again for a new hopper-concreting cycle. In constructing a 50m long bored pile, 5 cut-casing cycles and 25 hopper-concreting cycles are to be repeated.

CYCLONE MODEL VS SDESA MODEL

The CYCLONE model for the bored-pile concreting process as described is shown in Fig. 1. Note that the distributions of activities' duration as simulation input models are fitted using site-recorded data.

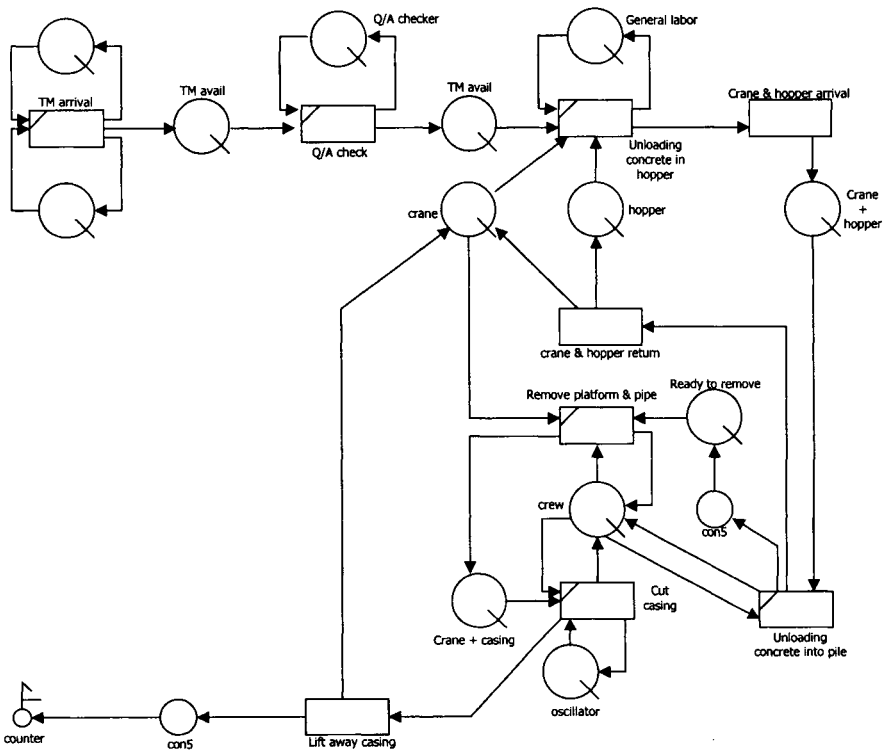

Figure 1. CYCLONE model for bored-pile concreting operations

In Figure 1, truckmixers are inserted into the system at the head of the model according to the supply pattern that is actually observed on site. The concrete supply was observed to be more than adequate in keeping continuous concreting operations on site, with truckmixers waiting to be unloaded most of the time. The mobile crane is used on three COMBI activities, i.e. "Remove platform & pipe" for cutting the steel casing, "Unloading concrete into hopper", and "Unloading concrete into pile". The crew resource (i.e. the "Crew" QUEUE) is shared by three COMBI activities, i.e. "Remove platform & pipe", "Unloading concrete into pile", and "Cut casing". One function node (CON5 after COMBI "Unloading concrete into pile") is used to control the initiation of withdrawing and cutting the casing, and another one (CON5 after NORMAL "Lift away casing") to control the completion of the bored-pile concreting.

For comparison, the counterpart SDESA model has also been constructed as illustrated in Fig. 2, which contains three production lines, the top line corresponding to the hopper-concreting cycle, the middle line for the cut-casing cycle, and the bottom line simply for controlling the completing of the whole process. In Fig. 2, the flow entities to be processed by each production line are marked with dashed diamonds, the resource entities requested by one activity are marked down at the left top corner of each activity block, with the resource entities released by one activity at the right top corner, and the disposable resource entities generated by one activity at the right bottom corner highlighted with quotation marks and dashed rectangles. Note that various production lines or cycles are logically connected with the disposable resources entities representing intermediate products or command units that are produced at the end of certain activities and can be used for once only.

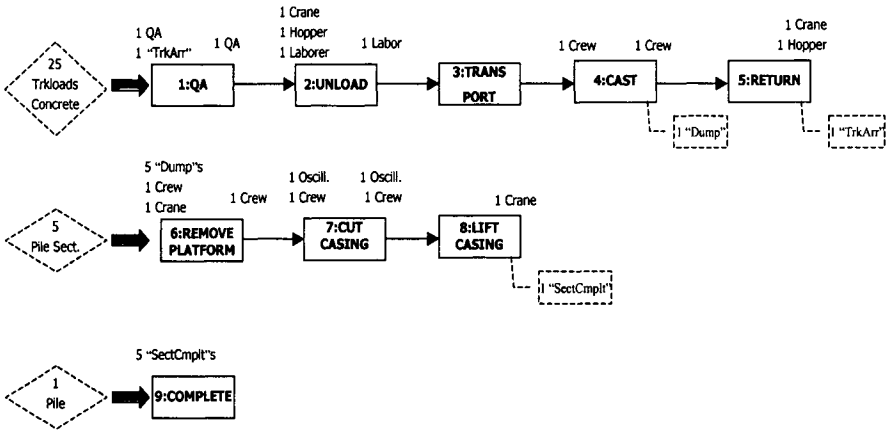

Figure 2. SDESA model for bored-pile concreting operations

The SDESA model is preferred over the CYCLONE model for two reasons: (1) simulating with SDESA does not require familiarity by the user with any software-specific terminology and modeling schematics as with CYCLONE; the process of building a SDESA model for complex construction operations is as simple as the CPM planning, thus allowing fast development of complicated models by common practitioners, which is in particular of significance to construction planning. (2) User outputs can be easily customized by running Access queries on simulation data, as the prototype of SDESA has been coded into a computer system using Microsoft Access, which is a relational database system with supporting VB macro programs. The finish times of the resources for concreting a 50-meter long bored pile are around 570 minutes after running the SDESA model on a PIII 850 PC, which takes only 15 seconds computer time. This fits closely with the 9-10 working hours for actual site operations. Next, the SDESA-characterized temporal demand of concrete are presented and discussed in detail.

SIMULATED DEMAND PATTERN VS ACTUAL SUPPLY PATTERN

Table 1 shows the temporal demand of concrete that has been characterized by running the SDESA model for three independent times. The start times of unloading concrete into the hopper for the 25 truckmixers are given under the "StartUnload" columns, i.e. minutes after the start of site operations. The interval of truckmixer arrivals based on the "StartUnload" times is calculated under the "InterArr" columns. The slight variability of outputs from run to run is caused by the

indeterministic activity duration. The cross-column average can be used for the plant to dispatch truckmixers to site to ensure uninterrupted site operations.

TABLE 1.
TEMPORAL DEMAND OF CONCRETE CHARACTERIZED THROUGH SDESA SIMULATION

Trkmixer	Run 1		Run 2		Run 3		Avg.	
ID	StartUnload	InterArr	StartUnload	InterArr	StartUnload	InterArr	StartUnload	InterArr
1	5.3		3.8		4.0		4.4	
2	20.2	14.9	19.7	15.8	18.7	14.8	19.5	15.2
3	33.6	13.4	32.7	13.0	36.0	17.3	34.1	14.6
4	46.7	13.1	47.5	14.9	51.2	15.2	48.5	14.4
5	63.7	17.0	63.4	15.9	66.8	15.6	64.7	16.2
6	118.5	54.8	117.5	54.1	116.7	49.8	117.6	52.9
7	136.7	18.2	133.3	15.7	132.3	15.7	134.1	16.6
8	148.7	12.0	148.3	15.0	149.6	17.2	148.9	14.8
9	163.2	14.5	163.6	15.3	166.3	16.7	164.4	15.5
10	178.5	15.3	178.0	14.4	181.3	15.0	179.3	14.9
11	226.6	48.1	228.4	50.3	231.9	50.6	229.0	49.7
12	243.1	16.5	243.1	14.8	248.2	16.3	244.8	15.8
13	258.1	15.1	259.7	16.6	264.7	16.5	260.8	16.0
14	275.2	17.0	275.6	15.9	278.6	13.9	276.5	15.6
15	290.0	14.9	289.6	14.0	296.1	17.5	291.9	15.5
16	340.8	50.7	341.8	52.3	344.6	48.6	342.4	50.5
17	355.9	15.1	356.8	15.0	359.4	14.8	357.4	15.0
18	371.7	15.8	370.8	13.9	374.2	14.7	372.2	14.8
19	388.0	16.3	386.4	15.6	389.8	15.6	388.0	15.8
20	406.4	18.4	400.5	14.1	404.8	15.0	403.9	15.8
21	458.4	52.0	448.9	48.4	459.0	54.2	455.4	51.5
22	472.3	13.8	462.7	13.8	475.1	16.1	470.0	14.6
23	486.1	13.8	476.8	14.2	488.7	13.6	483.9	13.9
24	499.7	13.6	492.1	15.2	505.9	17.2	499.2	15.3
25	514.7	15.0	505.2	13.1	520.8	14.9	513.5	14.3

It is noted that the inter-arrival time is about 50 minutes every five-truckmixer deliveries, because the hopper-concreting cycle is halted due to the crane being occupied in cutting the casing. Hence, SDESA simulation model is capable of handling the subtle and dynamic resource interactions in piling operations and accounting for such effects in the concrete demand characterized.

Fig. 3 shows the histogram of the actual truckmixer inter-arrival times, which are calculated from the arrival times on site for 125 truckmixer deliveries logged in the site Q/A records. The inter-arrival time ranges from 3 to 10 minutes with the mode around 7 minutes. Obviously, the concrete plant has treated the piling site being studied as a highly important customer by committing significant truckmixer resources to ensure undisturbed site operations. However, the plant must pay a high price to deliver such outstanding service in that truckmixers often queue up on site before unloading, which is deemed as waste of plant resources. In a one-plant-multi-site setting, the level of service to other site clients may be compromised because of truckmixers being held up on this site. In addition, excessive queuing may also end up with unfresh concrete that is not suitable for use. Therefore, the demand of readymixed concrete in concreting a bored pile characterized through simulation experiments will be immediately of help to local concrete plants for matching the supply to site requirements and optimizing resource utilization.

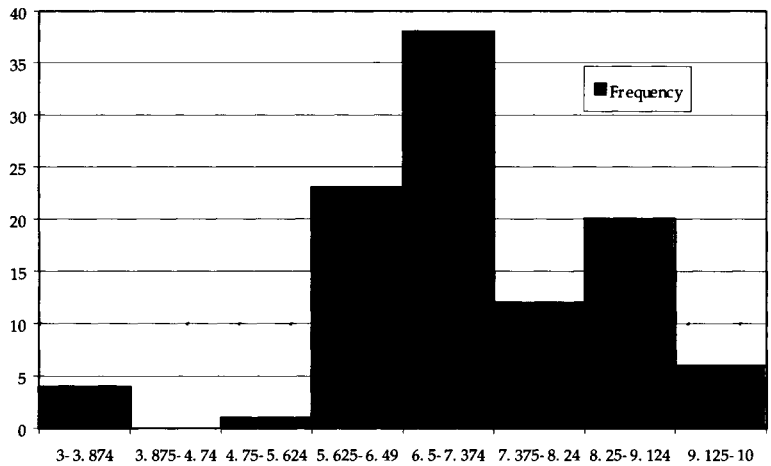

Figure 3: Histogram for actual supply pattern of concrete (inter-arrival times of truckmixers)

CONCLUSION

The concrete demand on a bored-pile construction site is characterized by simulating the entire concreting operations on an ongoing railway station project in Hong Kong with SDESA. A comparison of the CYCLONE model and the SDESA model demonstrates the simplicity and effectiveness of SDESA in modeling complex construction systems. A comparison of the actual supply pattern, which is obtained from site QA records, against the SDESA-characterized demand pattern, has justified the frequent queuing of truckmixers as observed on the site. The outcome of the research will be of immediate help for local concrete plants to match the supply to bored-pile concreting sites and for local contractors to plan bored-pile construction activities.

AGENT-BASED SPECIFICATION AND PROCUREMENT OF CONSTRUCTION PRODUCTS

E. A. Obonyo, C. J. Anumba and A. Thorpe
CICE, Department of Civil & Building Engineering Loughborough University,
Loughborough, Leicester, LE11 3TU, UK.

ABSTRACT

The specification and procurement of construction products is a key part of any construction project. Within an e-procurement environment, it is important that this function be automated to an appropriate degree. This paper is based on APRON, a project at Loughborough University focusing on agent-based specification and procurement of construction products. The paper starts with a brief introduction to specification and procurement of construction products, highlighting the main problems in these activities. It also introduces some key concepts in agent technology including a definition. The paper then gives an overview of other related projects. The main part of the paper uses six main themes to illustrate the need for agents in activities related to the specification and procurement of construction products. Each theme is discussed in terms of rationale and cues that may show that an application domain may benefit from an agent-based approach and these two concepts are extended into a case for agent-based specification and procurement of construction products. The paper ends with a brief discussion and concludes that the specification and procurement of construction products is an ideal application domain for the deployment of an agent-based solution.

KEYWORDS

Agent-based, specification, procurement, construction products.

INTRODUCTION

Specification of construction products involves defining constraints that have to be satisfied in a particular artefact. Procurement encompasses all activities involved in obtaining materials and services and managing their inflow into an organization towards the end user (Gebauer et al, 1998). When defined this way, there is a very thin line between specification and procurement. Obonyo et al (2001) point out that both activities rely heavily on retrieving information from sources have an open architecture with structures exhibiting dynamism.

Such problems can now be adequately addressed given that the latest developments in information technology model problems quite similar to fragmentation in the construction industry (Obonyo et al, 2001). Some emerging solutions are based on AI paradigms taking the form software agents.

DEFINING AGENTS

It is not easy to define the term 'agents.' Nwana et al (1996) advance a number of explanations for this difficulty: it is a common term in every day conversion; it encompasses a broad area: it is a meta-term and researchers in this area have come up with such synonyms as 'bots', 'spiders' and 'crawlers.' Various researchers have defined the term 'agent' in various ways (Brustolini, 1991, Jennings et al, 1998, Maes, 1994, Lieberman, 1997, Franklin and Graesser, 1996 & Ferber, 1999), but there is a general consensus that software agents exist in an environment and they have a perception of this environment. They can sense the conditions in the environment and such senses may affect how they act in future. Software agents are also perceived to be adaptive and capable of learning. They are also autonomous and proactive, exhibiting goal-directed behaviour. It, therefore, suffices to say that agents are systems capable of autonomous, purposeful action in the real world (Brustolini, 1991).

REVIEW OF RELATED WORK

Interest in Artificial Intelligence among people in the Construction Industry is nearly four decades old. As a matter of fact, the phrase 'Automated Design' preceded CAD (Howard, 1998). As early as the 1960s, various researchers in this industry had envisaged the use of Artificial Intelligence paradigms. Examples include such articles as 'On Evolution of Artificial Intelligence' presented at the 1964 IEEE Symposium on Human Factors and Benard Rudolfsky's 'Architecture without Architect' article published in the 1960s. Perhaps one of the greatest visionaries was Nicholas Negroponte of MIT who published an 'Architecture Machine' magazine in the 1970s documenting predictions on use of AI in construction. There are a number of recent related projects. ADLIB is a project at Loughborough University aimed at developing a multi-agent system framework for the representation of activities and processes involved in the collaborative design of light industrial buildings (Ugwu et al, 2000). A sister project at the same university focuses on the construction claims negotiation domain.

A CASE FOR AGENT-BASED SPECIFICATION AND PROCUREMENT OF CONSTRUCTION PRODUCTS

Various researchers have defined different matrices for determining when to use an agent-oriented software engineering paradigm (EURESCOM, 2000; O'Malley and DeLoach, 2001; Ferber, 1999; Wooldridge and Jennings, 1998; Paranuk, 1998; Heilmann, 1996 & Paranuk, 1996). The case presented in this paper is based on a review of such decision criteria.

Handling complex or diverse communication.

Rationale: Agent-based communication results in simpler interfaces, code reuse and analysis/ design reuse. This is beneficial in situations where complex or diverse type of communication is required.

Cues: The core activities in an ideal domain for an agent-based solution should be based on human-oriented communication. The problem should also require a solution that is more cognitive than computational by nature. Communication may be complicated by a need to integrate several heterogeneous, stand-alone applications and legacy systems. If the information required in the domain is only available as several, different limited portions, then there may be value in investing in agents.

Evaluating specification and procurement of construction products: Communication forms a vital part of this activity since it occurs in a naturally distributed and decentralised context. The problem is cognitive and involves a significant amount of intuition. Activities in this domain require tools that can

reason with uncertain or incomplete information because some information is only available during advanced stages of the project. Bielawski and Lewand (1991) point out that agents should solve problems that cannot be adequately solved by common sense reasoning. Many decisions made in the specification and procurement of construction products are based on the recommendation of an expert.

The disciplines involved in the specification of construction products use different programming languages, represent data with different representation languages and models, and operate on different computing platforms. In CICA's (Construction Industry Computing Association) 1996 Annual Report, there were 85 solutions specific to or customised for the construction industry listed under Software Directories. The use of heterogeneous tools makes communication a very complicated process.

The use of computing applications is further complicated by the fact that software development is very dynamic. Users need to make the existing applications future-proof, implying that when better tools become available, existing knowledge sources do not have to be redesigned. The legacy systems in the specification of construction products can benefit from being incorporated into a wider co-operating community using agent technology, allowing interoperability of all systems.

In addition, a construction product specifier needs to integrate information from various people. The tasks involved can thus be easily broken down into standalone processes and delegated to agents. It is evident from the above that the specification and procurement of construction products requires complex and diverse communication and will therefore benefit from the use of software agents.

A narrow, specific and restricted domain

Rationale: As explained in the previous sub-section, agents simplify communication. For this to be of any benefit to an organisation, this process of simplifying communication should be manageable. It should be possible to restrict the scope to agent tasks, which would not take an individual human being more than a few hours to solve otherwise writing rules for automation becomes a tedious and complicated task.

Cues: Greatest value from using software agents can be realised only when it is possible to precisely articulate the problem. The problem domain should be narrow and specific.

Evaluating specification and procurement of construction products: The best way to illustrate that the specification and procurement of construction products satisfies this requirement is to actually model an agent in this domain. A door specification agent is described below:

TABLE 1:
A Pseudocode for Door Specification

Scenario outline: Agent-based Door Specification
An APRON door specification agent is required to match Designer's requirements and the manufacturer's brochure. The building codes and the client's brief govern the choice, expense and type of product the Designer is allowed to use. Here we consider an agent, within a Designer's office, which the Designer can give product requirements to. The agent then explores the various product possibilities, within the scope of the Client's brief and the building codes. The agent asks the Designer to decide which options to pick generating a detailed specification for the product.

Door Specification Agent
Identity:
The agent is identified by the task of identifying door attributes and associating them with a Designer's requirement.

Roles:
Door requirements extraction and detailed door specification generation.

Interactions with environment:
Sensory input:
The Designer initiates the process by selecting a desired category of attributes, for example, fire rating, door style, surface performance and mode of operation. He then proceeds to specify a value for the selected attributes, for example 20 minutes fire rating.

Acquaintances:
In this scenario it has been assumed that the agent interacts with only one other agent, the Door Catalogue agent.

Resource ownership and access:
The Designer has read-only access to Manufacturer's Door brochures to enable the electronic viewing of product attributes.

Actions:
(Communicate) Get Door Attribute Category from the Designer (style, material, fire rating, mechanical strength, mode of operation etc).
(External) Gather information on options from Manufacturers' brochures.
(Internal) Evaluate the options and decide on the best selection based on the specified constraints.
(Communicate) Suggest options to the Designer.
(Communicate) Get choice from Designer.
(Communicate) Get a desired attribute value for the selected door attribute value (for example door fire rating could vary from 20 minutes to 30 minutes, 40 minutes, 60 minutes, 90 minutes etc).
(External) Gather information on various options from Manufacturer's brochures.
(Internal) Evaluate the options and decide on the best selection based on the specified constraints.
(Communicate) Suggest options to the Designer.
(Communicate) Get choice from Designer.
(Internal) Construct detailed specification for the product.

Mental state and behaviour:
Purpose:
The agent's goal is to extract door performance requirements from a Designer and to turn this into detailed product specification by suggesting alternatives to the user based on constraints imposed by the Designer and product availability as documented in the Manufacturers' door brochure. Once the Designer makes the choice, the agent generates a detailed product specification that can be used for bidding.

Behaviour:
The agent is not able to generate detailed door specifications without the Designer first confirming a choice.

Knowledge and beliefs:
How to generate specifications based on a Designer's requirements;
How to access and use information from a Manufacturer's product brochure.

From this example, it is evident that the specification and procurement of construction products as an application domain is narrow, specific and restricted enough to allow easy deployment of agents.

Worthiness of the Project

Rationale: The use of agents as opposed to other solutions should result in some identifiable value.

Cues: This criterion is very subjective because value means several things to different individuals and organisations. An organisation may invest in agent-based solution because it will result in a new and innovative way of handling problems and make a difference to the way the organisation operates. Agent-based solutions could also automate some functions thus freeing employees of performing routine tasks. This increases productivity and profits. Agents can also make the process of handling knowledge more efficient. They can be used to propagate and proliferate knowledge. When knowledge from previous projects is wrapped using an agent, it becomes easy to reuse them. Agents can therefore add value in a domain where it is necessary to preserve knowledge. Finally, domains that have multi-player or multi-criteria decision-making can ensure consistency through the use of software agents.

Evaluating specification and procurement of construction products: Construction project teams comprise a variety of disciplines with poorly integrated silos of knowledge. The 'dot-com' solutions solutions rapidly deliver more information through a bigger 'pipe' but there is a need to improve the quality of the information going through the pipe. Agent-based systems offer a means of using distributed artificial intelligence to model the distributed silos of knowledge and could improve the quality of information available for specification and procurement of construction products.

As pointed out earlier, the main problems in the specification of construction products emanate from the fragmentation in the industry. There is distribution of information across the disciplines; separation of the construction phases and spatial distribution on electronic networks as shown in Figure 1.

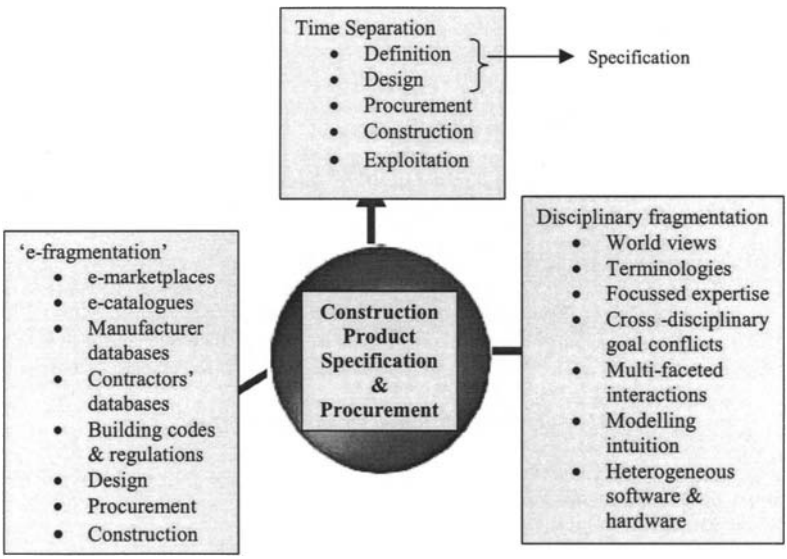

Figure 1: Dimensions of Fragmentation

Agents are capable of several things including making informed decisions; learning and adapting over time; communicating with other agents (including human agents) and integration with legacy systems. Agent services such as brokering, translation and coordination can be used to save time spent in gathering information. They can also handle the various dimensions of fragmentation and increase the knowledgebase. These can add value to the operations in the specification and procurement of construction products.

Impracticality or impossibility to specify system behaviour on a case-by-case basis.

Rationale: Agents have a goal-oriented behaviour and can therefore be used to develop a flexible system capable of adapting their behaviour patterns in a dynamic environment. Agent-based systems are highly modular. The agents can be 'easily' added or replaced and can therefore handle situations requiring systems that are likely to be expanded or modified or ones whose purpose may change.

Cues: An ideal domain for an agent-based solution should ideally require a system that will exist in an unknown environment in which it is impossible to foresee all future situations. Agent-based solutions also adequately model systems whose performances gracefully degrade as uncertainty increases.

Another identifying mark for an ideal application domain for agents is the existence of numerous ideal solutions to satisfy a goal depending on the prevailing circumstances. There should also be a need for systems that require dynamism.

Evaluating specification and procurement of construction products: The systems supporting the specification of construction products are ill-structured. There has been a significant shift to executing construction-related tasks on the Internet. The Internet is an open system whose structure dynamically changes. Therefore there is a need for open, distributed, heterogeneous and flexible architectures. Agents shift focus from systems with a particular configuration to the use of flexible agents 'that can be swapped in and out as the entities they represent are shuffled around' (Paranuk, 1996) enabling systems to adapt to changes in the context of operations and changes in needs. As the agent architecture permits re-use of existing code and self-configuration of the system, the cost and time for setting up a new unit in the electronic marketplace is reduced substantially.

In a construction project it is not possible to have a perfect view of what lies ahead. Agents address the problem of unavailability of all the necessary information at the initial design stage. The level of detail in a contract document depends on the amount of information available during design. The performance of the whole process therefore 'gracefully degrades with increase in uncertainty' and variations in product specifications are inevitable.

Every designer is faced with numerous options and each of them may be appropriate depending on the usage scenario. The use of agents can present designers with an intelligent way to query manufacturer databases on the properties of their products. Agent-based solutions can therefore enable systems in the specification and procurement of construction products to adapt their behaviour depending on the prevailing circumstances.

Handling negotiation, co-operation and competition among different entities.

Rationale: Agents in a multi-agent community communicate and collaborate. Their activities can be modelled into a grid of interdependencies.

Cues: Problems that require solutions that can handle concurrent execution of multiple tasks with conflicting goals are ideal for agent-based systems. Other qualifying features include the existence of multiple stakeholders with different interests and the existence of problems that are both too complex for a monolithic solution and too difficult to decompose into independent sub-problems.

Evaluating specification and procurement of construction products: Specification of construction products is executed as a multi-disciplinary operation meaning that in any project, there are different points of view. The various disciplines involved have compartmentalised themselves over time. Each of them has evolved a unique view of the world and developed special terminologies. Each discipline pursues built-in goals, which may conflict with the global goals of the design. Due to focussed expertise, certain solutions are only true *ceteris paribus* (all things held constant).

There are a number of stakeholders, the client wants a habitable space, the regulatory bodies demand compliance with stipulated codes and by-laws and the contracted companies seek to maximise their profits. In extreme situations parties quite remote to the contract may feature; For example, environmentalists and people concerned with maintaining a certain look and feel for heritage or cultural reasons.

Disciplinary design is presented in big chunks hiding details that may be necessary for integration (Shakeri, 1998). Further complexities arise from multifaceted interactions: multiple disciplines may focus on one parameter simultaneously. Also the designers have counter-intuitive behaviour. But modelling intuition is ineffective or adverse when constraints become active. Through modularity and abstraction, agents offer a means of dealing with such complexities.

Need for autonomous execution

Rationale: A core characteristic for agent-based systems is goal-directed, autonomous behaviour and negotiation. An ideal application domain must demonstrate a need for this advanced level of autonomy.

Cues: The deployment of agents in a given domain makes sense only when there is a need for a system that is capable of acting on behalf of a user.

Evaluating specification and procurement of construction products: The publicly indexable Web contained an estimated 800 million pages as of February 1999, encompassing about 15 terabytes of information or about 6 terabytes of text after removing HTML tags, comments, and extra whitespace (Lawrence and Giles, 1999). Specification of construction products requires searching, querying and filtering out 'noise' from this magnanimous library. Even within construction industry-specific Web sites there are numerous portals. By early 1999 there were 150 to 200 such companies (Valued Gateway Customer, 1999). (This number has subsequently shrunk). However, overwhelmed by 'information overload' (Maes, 1994), specifiers require agents to automate search processes.

DISCUSSION AND CONCLUSION

This paper has made a case for agent-based specification and procurement of construction products by pointing out the benefits that can be derived from the agents' ability to plan, set goals, reason about actions, and improve knowledge and performance through learning. The specification and procurement of construction products occurs in a collaborative environment and this fragments activities. The use of agents is justified by the existence of distributed teams. Information, which is very critical to the success of the project, is multi-dimensional by nature. The key questions in identifying the different dimensions of information are: who needs what information and in which format; who possess the information, where and in what format; when, where and how will the exchange occur? Existing technologies such as object-oriented techniques provide partial solutions that address distribution and dynamism. But as these solutions are becoming sufficiently developed, collaboration needs are advancing to a higher level and a potential 'killer-application' will have to model solutions that address all the possible dimensions of information. It has been demonstrated in this paper that the domain of construction product specification and procurement meets the six main criteria for potential agent-based applications.

IVMS - AN INTERACTIVE SYSTEM FOR IMPROVING VALUE MANAGEMENT STUDIES IN CONSTRUCTION

Qiping Shen and Jacky K.H. Chung

Department of Building and Real Estate, The Hong Kong Polytechnic University
Hung Hom, Kowloon, Hong Kong Special Administrative Region, China

ABSTRACT

Value Management (VM) is an organised function-oriented systematic team approach directed at analysing the functions and costs of a system, supply, equipment, service or facility, for the purpose of enhancing its value, through achieving the required functions specified by the customers at the lowest possible overall cost, consistent with requirements for performance. Because of its strong potential in improving value for money for construction projects, client organisations in both the public and private sectors are using VM increasingly in their projects. However, a recent study has suggested that the special characteristics of using VM in Hong Kong, such as the large number of participants and short duration, have presented some unique difficulties in implementing VM studies. These difficulties also prohibit further applications of VM in the territory. One way to overcome these identified difficulties is to develop an interactive group decision support system that can facilitate the decision-making process in VM studies. This paper introduces such a system, entitled the Interactive Value Management System (IVMS), which is designed to improve the implementation of VM studies. It gives a detailed description of the structure and characteristics of the system and the support that it can provide, including information, communication and analysis. This is followed by the functionalities of the modules inside the system. Finally, the potential benefits and limitations of the system are discussed. It is concluded that IVMS is a very useful tool for improving VM studies in construction.

Value Management, Group Decision Support Systems, Interactive Value Management Systems, Construction

INTRODUCTION

Value Management (VM) has been receiving increasing attention in Hong Kong, especially since the Asian financial crisis in 1997 (Shen and Kwok, 1999). There is a surge of interest in VM applications in the construction industry. Both the public and private sectors in Hong Kong have been using VM to ensure value for money for their projects during the preliminary project feasibility study stage. However, a recent survey suggested that VM users had encountered problems such as lack of active participation

and insufficient time/information in the decision analysis (Shen and Chung, 2000). There is a strong demand for improvements to the practice in order to maximise the benefits of using VM studies. One possible way to overcome the above difficulties is to apply information technology to facilitate VM studies. As a branch of information technology, GDSS has the potential to promote active participation, encourage interaction, and facilitate decision analysis in VM studies. To verify this hypothesis, a special GDSS prototype named the Interactive Value Management System (IVMS) is being developed at the Hong Kong Polytechnic University (Chung and Shen, 2001). This paper aims to introduce the conceptual framework of the IVMS and demonstrate how it can be applied to VM studies. It begins with an introduction of GDSS, including the definition, development and application, followed by a description of the system structure, its functionality, and the potential benefits of the IVMS.

GDSS, also known as Group Support Systems or Computer Support Cooperative Work Systems, is a computer technology which combines communication, computing, and decision support technologies to facilitate the formulation and solution of unstructured problems by a group of people (DeSanctis and Galluple, 1987). In short, GDSS is a computer-based system designed to support groups of people and to engage them in a common task through the interface of a shared environment (Aiken et al., 1995). It consists of hardware, software, people, and procedures. In the mid 1980s, GDSS research was mainly centralised in university research laboratories. The results, however, were inconsistent because of the different experimental settings and subjects adopted in studies. Nevertheless, the true effectiveness of GDSS in improving the group decision-making process has been assured by field studies. GDSS field studies have consistently shown positive results, and nearly all "real-world" users are extremely satisfied with the application of GDSS in meetings (Dennis et al., 1988). It is concluded that GDSS is highly useful in improving the group decision-making process (Dennis et al., 1988; Chun and Park, 1998). Today, the success of GDSS is gaining acceptance and it has been widely applied in many famous organisations, including the University of Arizona (GroupSystems), IBM (Team Focus), and Xerox (the Colab System).

THE INTERACTIVE VALUE MANAGEMENT SYSTEM

The IVMS is a specific GDSS system designed to enable team members to exchange information, make presentations, brainstorm and prioritise ideas in VM studies. It aims to:

- Improve collaboration between members
- Facilitate information management
- Promote exchange of ideas, opinions and preferences
- Improve the productivity and accuracy of data analysis

The IVMS is a web-based application in which software is essentially installed and operated on a server. It supports multi-platforms, including Windows 98, Windows 2000 and Mac OS, and allows users to access the system at any machine, anytime, and anywhere. The web interface is also user-friendly and assists users with varying levels of knowledge regarding computing and decision support.

In addition, the system is designed as a set of toolboxes, including a virtual team unit, an information unit, a communication unit, and an analysis unit, and a summary is given in Figure 3. This enables facilitators to decide what GDSS functions to use, and when and how to use them, so as to accommodate the various requirements in VM studies.

System Architecture

The design of the IVMS is based on the GDSS model proposed by DeSanctis and Galluple (1987). It is composed of users (members and facilitators), a user interface (web browser), software (IVMS toolbox), and hardware (input and output devices, databases, servers). A pictorial representation of the system architecture and a summary of the system components are given in Figure 1 and Table 1 respectively.

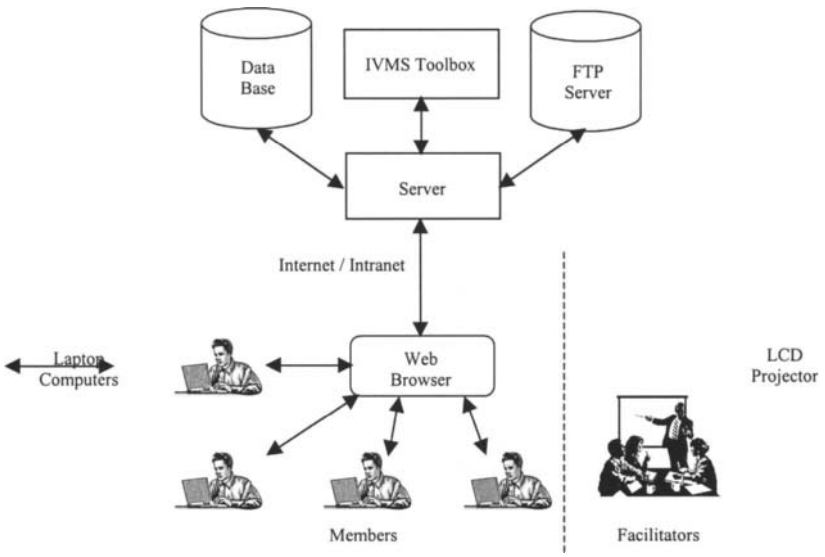

Figure 1: System Architecture of the IVMS

TABLE 1
COMPONENTS OF THE IVMS

Components	Description
Members and facilitators	Users
Laptop computer	An input and output device for users
Internet/Intranet	A connection link for laptop computers and the server
Web browser	An interface for users to operate the system
IVMS Toolbox	A set of GDSS tools
LCD projector	A public screen for information display
Server	A processor for data calculation and coordination
FTP server	A storage device for project information
Database	A storage device for data produced in meetings

The IVMS is designed to improve VM studies and its users include both members and facilitators of VM study teams. In a GDSS-supported VM study, the facilitator is responsible for the smooth operation of the IVMS and he/ she has to decide what GDSS functions to use, and when and how to use them in accordance with VM job plans. In order to share the additional workload, an assistant helps him/her to operate the system by starting and stopping the software, and provides technical support to members.

Figure 2 shows that members and facilitators are provided with laptop computers, which are used as input and output devices in workshops. The computers are connected to a server through the Internet or Intranet, and they allow members to operate the IVMS or carry out private work, such as text editing,

formatting, data file creation and modification. In addition, an LCD projector is provided so that facilitators and members can present the results of idea generation, voting, analysis, and private work on a public screen. A server, a database, and an FTP server are also included in the IVMS. The server is a computer processor which links up the workstations to the database and the FTP server. These storage devices are designed to manage all project information uploaded in the pre-study phase, and to record the generated ideas, collected comments, and voting results in meetings. For security reasons, the databases and servers can be placed in either the office of the client or that of the service provider, and maintained by assistants.

Figure 2: A Typical Setting of the IVMS in a Workshop Environment

The IVMS Toolbox

The IVMS is designed as a set of toolboxes comprised of four boxes, including a virtual team unit, an information unit, a communication unit, and an analysis unit. A detailed discussion of these toolboxes is given in Figure 3.

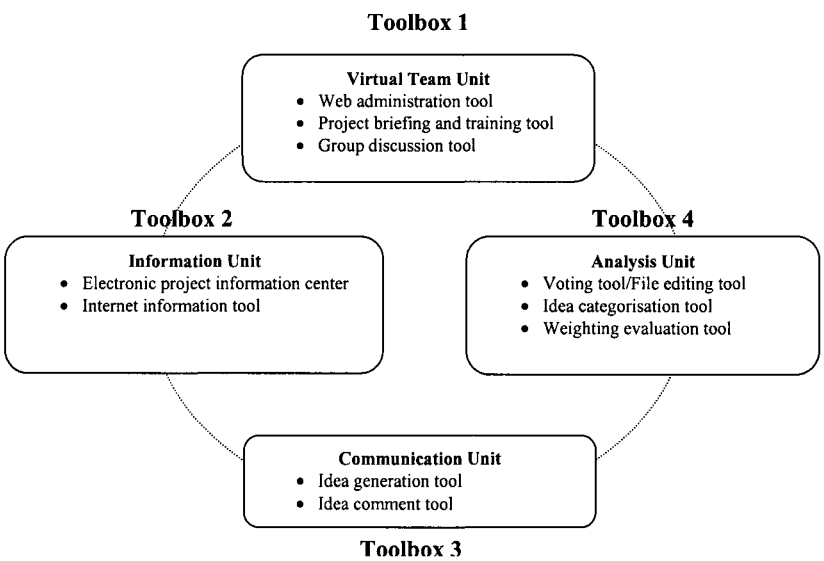

Figure 3: Toolbox of the IVMS

The toolboxes are designed to support a group of specific tasks: therefore, different toolboxes are applied to different phases of VM studies. As shown in Figure 4, Toolbox 1 (the virtual team) aims to improve the collaboration between team members, and mainly applies to the pre- and post-study phases. Toolbox 2 (information) aims to facilitate information management throughout the studies. Toolbox 3 (communication) aims to promote the exchange of ideas, opinions and preferences within groups and is mainly applied to the creativity and evaluation phases. Toolbox 4 (analysis) aims to improve the productivity and accuracy of data analysis and is mainly applied to the analysis, evaluation and development phases. These toolboxes are integrated into two modules, the Pre-meeting Module and the Meeting Room Module, in accordance with the SAVE 40-hour job plan. The following sections introduce these modules and illustrate how they can be applied to improve VM studies:

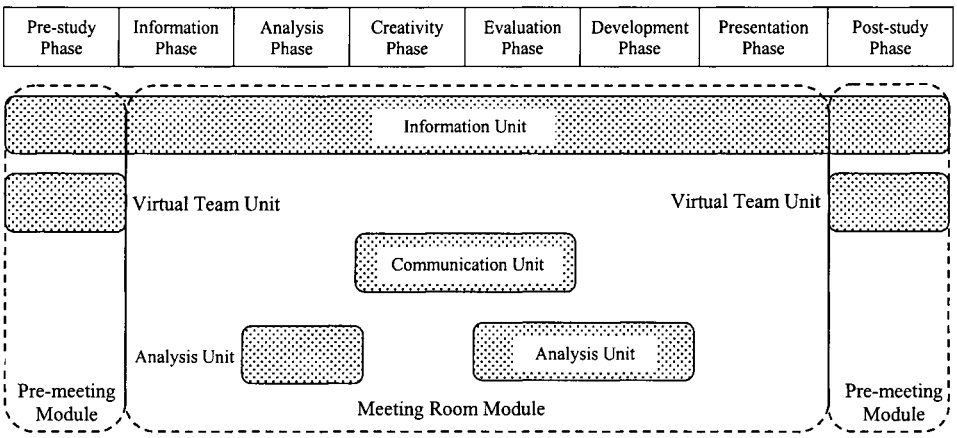

Figure 4: Toolboxes of the IVMS

Pre-Meeting Module

Virtual Team Unit

The virtual team unit aims to improve collaboration between team members in the pre- and post-study phases. It enables members to work together as a team at anytime and anyplace through the Internet, thus better coordination and preparation work can be achieved. It comprises three tools: a web administration tool, a group discussion tool, and a project briefing and training tool.

The group discussion tool is an electronic forum that allows members to enjoy group discussions before meetings. They can raise new topics or comment on other people's topics by posting messages on a newsgroup; the messages are then emailed to all the other members automatically. The project briefing and training tool assist clients or facilitators in conducting pre-meeting briefings. Besides the online PowerPoint presentation, the tool also provides a virtual site visit tour by the use of photos and online videos, in order to ensure that members have a better understanding before coming to meetings. Figure 5 illustrates this feature inside the virtual team unit of the IVMS.

Information Unit

The information unit aims to facilitate information management and improve the availability of information in VM studies. It includes an electronic project information centre and a set of Internet

information tools. Figure 6 illustrates the information tools that allow members to access to external information during the workshop. The electronic project information centre is a file exchange system which allows members to store and share project information on the Internet. Members are provided with web folders in an FTP server and they can simply use Internet browsers to upload or download the files, including correspondence, cost data and drawings, before meetings. If there is new information, a notice will be automatically sent to members so that they can download it through the system.

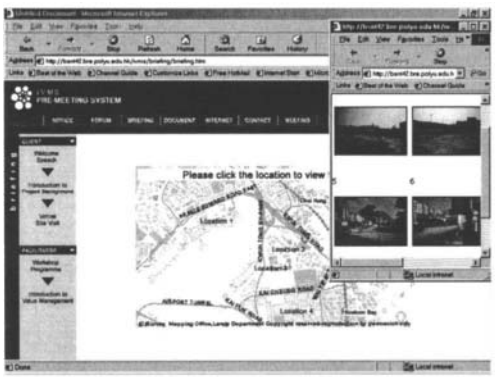

Figure 5: Virtual Site Visit Tour

Figure 6: A Set of Internet Information Tools

Meeting Room Module

Communication Unit

The communication unit aims to promote the exchange of ideas, opinions and preferences within groups. Research findings show that people feel freer to exchange ideas, comments and preferences in an anonymous environment. The communication unit makes use of this technique to promote participation and encourage interaction in VM studies; it is comprised of an idea generation tool and a comment tool.

Analysis Unit

The analysis unit is designed to improve the productivity and accuracy of data analysis in the analysis and evaluation phases. It is comprised of a set of analysis tools, including an electronic FAST diagram and voting tool, an idea categorisation tool, and an electronic weighting evaluation tool.

THE BENEFITS OF THE IVMS

(1) Facilitate Information Management in VM Studies

Previous survey findings suggest that lack of information is the most frequently encountered difficulty in VM studies (Shen and Chung, 2000). The project information centre can improve the quantity of information and make it available to other members through the Internet. It has simplified and centralised the information distribution process so that information can be easily shared among members to provide a common understanding of the project. The centre also facilitates the formation of a database of VM studies. As shown in Figure 7, the uploaded project information and meeting records can be combined to produce a completed record at the end of a VM study. The accumulated information becomes a good and reliable information source to support future studies.

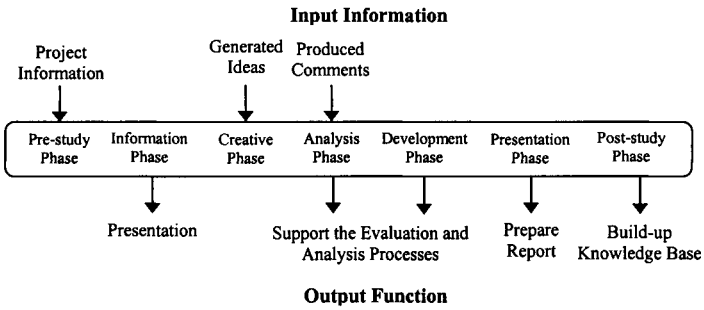

Figure 7: Input and Output of Electronic Information Centre

In order to further improve the availability of information, the centre provides an Internet connection during the workshops. Members can retrieve information such as government indexes and annual reports through the Internet, or directly connect to the desktop computers in their offices through the dial-up facilities, which overcome the constraints of the physical location.

(2) Improve the collaboration between team members

A VM team is normally comprised of people from different organisations. However, it is difficult to arrange an introductory meeting before the workshops because many clients are trying to shorten the duration of VM studies. The IVMS can improve collaboration among team members by enabling them to work together at anytime and anywhere through the Internet in the pre-meeting phase. In the virtual conference room, the Briefing Tools provide background information on the project. Members can gain a better understanding of the project objectives and limitations before attending the workshops. The Electronic Notice Board and Electronic Forum facilitate good communication between members and enable them to prepare better for VM workshops.

(3) Promote active participation and encourage interaction

Lack of participation and involvement of members is a typical problem in VM studies. Research findings show that people become free to exchange ideas, comments and preferences in an anonymous environment. The cyber forum creates such an environment to promote participation and encourage interaction in VM studies. It is especially useful in motivating those members who are afraid of speaking in public or worry about sounding stupid in front of a group of people. It is believed that members' active participation will lead to more ideas and comments in VM studies. The cyber forum reduces the conformance pressure on members (the fear of challenging a powerful player's bad idea), so that members can judge people's ideas solely based on their merits rather than other social factors.

The creative use of the cyber forum can assist facilitators to introduce new "group structuring techniques" into VM studies. For example, anonymous individual brainstorming can be integrated with face-to-face group brainstorming to form a new brainstorming technique. Ideas can be collected anonymously from individuals and then presented to the group to stimulate additional ideas. This approach can empower the process by utilising the strengths of both brainstorming methods. In short, the promoted active participation and enhanced interaction enable the group discussion to become more creative and vigorous, hence more good ideas and feasible solutions can emerge from the VM study.

(4) Assist the decision analysis in workshops

IVMS provides various computer tools to improve the productivity and accuracy of data analysis during workshops. The use of modelling tools can eliminate human errors and shorten the data processing time. The links to commonly used software packages enable members to use their familiarised tools to analyse different scenarios. These tools can assist members in responding to "what-if" questions quickly, by varying the data input and observing the impacts of different solutions.

CONCLUSION

This paper has demonstrated that the Interactive Value Management System can improve VM studies. A detailed description of the characteristics and structure of the system have been given, and the support that can be provided by the system has also been elaborated. The functionalities of the modules inside the system and the potential benefits of the system have been discussed. It is concluded that IVMS is a very useful tool for improving VM studies in construction.

ACKNOWLEDGEMENT

The authors wish to express their sincere gratitude to The Hong Kong Polytechnic University for financial support for the research project described in this paper.

PRODUCTIVITY EXCELLENCE THROUGH AN INTEGRATED CONSTRUCTION MANAGEMENT SYSTEM FOR THE BUILDING AND CONSTRUCTION INDUSTRIES

Peter Yan, Chief Executive Officer

Global e-Business Services Limited
30/F., MLC Millennia Plaza, 663 King's Road, North Point, HONG KONG

ABSTRACT

This paper describes the actual case of how an Integrated Construction Management application designed specifically for the construction industry can enhance productivity, efficiency and competitive advantage.

The application is an advanced web-based system covering construction tendering, procurement, workflow management, document management and project management functions. It is a full Internet based system with advanced PKI-based (public key infrastructure based) security features to ensure data confidentiality, data integrity and authenticity.

Among the users of various components and/or modules of the Integrated Construction Management system are the Hong Kong Government and various commercial enterprises.

In the paper, we will illustrate through describing one of our success cases, how various functions of the application have brought about the said improvements and elaborate on the quantitative achievement of such improvements. We will also illustrate the benefits of the application not only to the construction companies themselves but also how the implementation of such applications has improved the business partners of the construction companies, such as their subcontractors or suppliers.

In addition, we will also share with the audience the experiences we have in implementing such applications for various organisations. These include our assessment of the critical success factors, the challenges normally faced, the considerations of different stakeholders in the implementation process and the justifications for implementing such applications.

KEYWORDS

Integrated Construction Management System, Electronic Tendering, Bill of Quantity, Document Management, e-Procurement, Workflow, Project Management, Productivity

INTRODUCTION

In April 2000, the Chief Executive of the Hong Kong Special Administrative Region formed the Construction Industry Review Committee (CIRC) to review the current state of the industry and recommend improvement measures. The Committee has proposed items of improvement measures aiming for better performance of the industry. There were recommendations on certain areas which comprised of improvement on the existing tendering process and procurement logistics. This paper illustrates how information technology can be applied in real life situation through an Integrated Construction Management System (ICMS) to implement the recommendations of the CIRC review report and to improve companies in the construction industry in their productivity, efficiency and competitive advantage.

The paper starts by providing the background and characteristics of the construction industry, reinforcing the challenges faced by its practitioners and how ICMS applications could overcome such challenges. The paper concludes by illustrating a real case in Hong Kong – the Shui On Construction and Materials Limited, on how ICMS can achieve significant result in productivity and efficiency gain.

CHARACTERISTICS OF THE LOCAL CONSTRUCTION COMPANIES

The local construction industry is characterized by a high level of subcontracting. There are a small number of large local contractors while most local construction companies are usually small in size. More than 90% of the local construction companies had less than HK$10 million gross value of construction work performed in 1999. Many of them act as subcontractors to the large companies, that is, the main contractors. (Source: [July 2001] Profiles of Hong Kong Major Service Industries – Building and Construction, Hong Kong Trade Development Council). The industry is labour-intensive, traditional and old-fashioned. The result of such a manual characteristics is lengthy process and procedures in project administration, leading to loose control, increase cost and low productivity. Occurrence of several non-compliant construction incidents occurred in 2001 have increased much awareness and concern to improve existing practices in project management.

Since most of the companies are low in profitability, industry participants usually adopt a short-term vision. Many of them are resisting to invest in advanced construction technologies and more efficient work processes, it will ultimately decrease the industry's competitiveness in the long-term.

WHY IS A COMPREHENSIVE CONSTRUCTION MANAGEMENT SYSTEM REQUIRED FOR THE INDUSTRY?

According to the CIRC report, it is not uncommon that construction projects experience delays and exceed budget. In such cases, penalty would be incurred and results in financial loss and poor professional image. The reason behind as suggested by the report is due to a lack of accountability through the prevalence of many non-value adding multi-layered subcontractors with lax supervision (Source: [Jan 2001] Construct for Excellence, Report of the Construction Industry Review Committee).

When too many parties are involved in a construction project with the existence of a large amount of subcontractors in different stages, it is always be difficult to control the project progress since delivery of the construction products would be pieces by pieces. It is therefore recommended in the CIRC report that a structured site supervision system should be set up to safeguard the built quality. It allows the factors of consideration to be planned and designed at the very beginning

stage to facilitate downstream activities such that all processes and practices should be rationalized as far as possible to shorten the learning curve and to provide greater predictability over outcomes. To achieve this, IT solution will be required to improve the information flow among all project participants and to enhance project logistics management. For example, an on-line project management system would allow each construction sites situated in different locations to report project progress to head office. In this way, the most up-to-date project status can be readily compiled at the head office and travelling between the head office and the project sites will be greatly reduced.

Another highlight in the report is relating to the existing procurement and logistics practices. It points out that the method of procurement will directly affect the construction work quality and outcome. Focus has been imposed on two particular areas: pre-qualification of subcontractors and assessment of bids and contract award with a scoring system. However, the existing tendering system is much paper-based and traditional. There is low transparency and lack of openness to both tenderers (here refer to subcontractors) and the general public. The CIRC report suggested the use of prequalified tendering to identify the past performance and quality attributes of tenderers and use of a marking scheme to select the quality subcontractors.

To ensure that developers and contractors comply with the mechanism and to create an open and fair environment for industry players, the use of IT through a web-based electronic tendering solution is recommended. The CIRC report encourages the adoption of electronic tendering in the construction industry by endorsing the Works Bureau's initiatives in electronic tendering.

The CIRC report also advocates on the extensive use of information technology in other specific areas like document management system and workflow improvement processes. It concludes that an integrated system combining the above applications serving as a one-stop solution specifically designed for the industry is much desired in achieving significant productivity gain.

WHAT IS INTEGRATED CONSTRUCTION MANAGEMENT SYSTEM (ICMS)?

ICMS is a web-based application and is construction industry oriented. Users of the system require no proprietary software/hardware installation and the set up cost is minimal. It deploys strong encryption technology through PKI-based security framework to ensure extremely high level of data confidentiality, data integrity and authenticity.

The ICMS components include construction electronic tendering, procurement, workflow management, project management and document management functions. The characteristics of each component and their benefits to industry users are discussed below.

Electronic Tendering System

In the CIRC report, it stresses the importance of pre-qualification and bid assessment. To achieve this, an open and transparent tendering and procurement process is inevitable. The Electronic Tendering function, equipped with subcontractor pre-qualification exercise and on-line purchasing features, is able to improve industry users in daily tendering process. The suppliers and contractors registration management supports pre-qualification procedure by enabling the developers or main contractors to approve those qualified subcontractors with proven track records. Contracts could then be awarded to those industry participants with consistently good performance.

Features of Electronic Tendering System at a glance:

Suppliers and contractors Registration Management

- Online vetting for new and approved registration
- Pre-qualification of registered subcontractors
- Updates supplier's information for developer / main contractor's future assessments

Project based Tender Management

- Creation of project reference for new project
- Tender documents defined in individual project reference for easy identification

Refine project by Trade Management

- Categorizes project items in different trade, expandable sub-level and secondary sub-level
- Divides suppliers and contractors role according to their engaged business

Easy Site Purchase Management

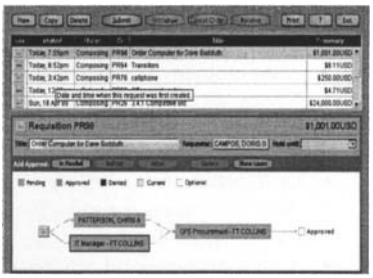
- Direct site purchase requests from site office
- Simple and user-friendly instant online request for quotation

Other Features

- Supports open and registered tender posting
- Supports electronic security keys certified by Hong Kong Post
- Supports tender clarification, postponement, suspension and addendum posting
- Online Q&A enquiry box
- Real time service by synchronizing with the Hong Kong Observatory
- Consolidated tender submission by highly secured tender box program

Based on the experience in developing the ETS system (www.ets.com.hk) for the Government Supplies Department (GSD), the Electronic Tendering System offers the most secured platform to industry users in disseminating tender notice and documents arising from works projects. Contractors could, through a simple web-browser, instantly download and submit their tender offer to a highly secured tender box.

Bill of Quantity (BQ) System

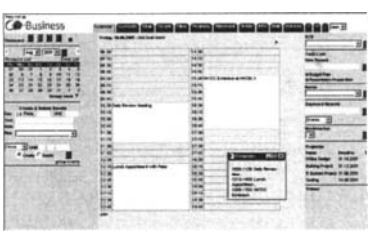


Integrated with the Construction Tendering System, the BQ (Bill of Quantity) Management System facilitates tender evaluation. The BQ summary report enables users to access all tender offers at a glance with automatic comparison process to facilitate bid evaluation.

Features of Tender BQ Management System

- Facilitates tender preparation and evaluation
- Displays in excel format
- Intelligent "waterloo" comparison of returned BQ Excel file to track unauthorized changes
- Discrepancy Report Generation to highlights only insertions / deletions / modifications
- Allows the import of returned BQ files from diskettes or CD-ROM with BQ summary report

Procurement and Workflow Management (e-Procurement)



Traditional procurement involves manual paper-flow processes which are time consuming, difficult to control, non-productive and inefficient. e-Procurement can streamline those tedious processes, resulting in procurement cost reduction. It could significantly reduce purchasing cycle time and increase operation efficiency accordingly.

Workflow management also applies in various project stages, ranging from project initiating, suppliers record vetting, tender posting, document and suppliers' bid sharing. Information could be exchanged between headquarters and site offices without boundary. Site offices could perform approval requests directly and send them to Headquarters for approval.

Features of e-Procurement

- Electronic catalogues for product / site materials selection
- Pre-customized electronic forms for on-site procurement request
- Establishes dynamic sequence workflows for request, review and approval according to company structure
- Real-time status tracking and control of entire process
- Advanced reporting tools for data analysis and supplier evaluation in business negotiations and strategic planning

e-Project Management System (e-PMS)

e-PMS is a real-time management tool for multi-construction projects. It is proficient in categorizing projects with status highlighted as well as to allocate relevant parties and timeline. The features of e-PMS are described:

Group Calendar

- Organization of related activities and perform group schedules
- Update meeting status among group members
- Resources and time allocation for projects
- Alert box to remind upcoming event

Project Administration

- Role-based control for member's identity
- Allows administrator to manage resources, groups and users
- Assigns and shares events of current projects to group members

Group Communication

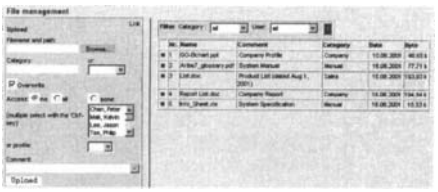
- Supports e-mail or fax sending with file attachments to select group members
- Contact Manager Tool to import directories from other formats
- Chat Forum for users to conduct on-line discussion
- Dialogues and data are displayed and stored as documentation for future retrieval

Request Tracker System

- Products and services support management
- Categorizes incoming request and automatically assign respective user
- Acknowledge request and online status checking for customers

- Views pending requests and assigns work time for billing calculation
- Forms a knowledge base for public searching or restricted for authorized access

Time Card System



- Administrates working hours and assigns working days to several projects
- Actual measurement of working hour by out and back on duty
- Calculation of working hours for progress tracking and cost estimation

Other Benefits

- Multi-languages support – English, Chinese and up to 15 languages
- WAP and PDA access
- Online Help Support, FAQ and tips

e-Document Management System (e-DMS)

Traditional filing system results in numerous loose-leaf papers difficult for searching and sharing. The construction industry produces tones of documents, maps and diagrams everyday which makes filing more complex and time-consuming. DMS can improve the existing situation through the following features.

Features of DMS:

- Central repository for users to share files and documents
- Uploads files / intranet links and directories
- Assigns access right for relevant parties
- Adds remarks and comments on each document
- File sorting and searching by categories

The e-Project Management System (e-PMS) together with e-Document Management System (e-DMS) served as a real-time management tools for multi-location construction projects. This function facilitates the coordination of construction activities and enables the multi-location construction sites to report the project progress to its head office. All paper documents including sizable maps and diagrams can be uploaded from all locations to the system which serve as a central repository for authorized users to share. The e-PMS is also equipped with time card system for recording of "in" and "out" time for duty or work which assist in working hours calculation for progress tracking and cost estimation.

Through these features, industry users can be benefited by monitoring the cost and time spent by group members against budget and schedule in a real-time basis. Project manager can modify the project plan and reassign resources immediately with quick response to unexpected circumstances. It also facilitates the circulation and access of confidential documents and drawings.

ICMS provides audit trail for all actions taken and which parties have been involved. It increases control and accountability of personnel involved and reduces improper access and approval within the process. ICMS aims at reducing the project cycle time, increasing contractors relationship management, achieving operation efficiency and ultimately, increasing project compliance and control.

CASE STUDY: SHUI ON CONSTRUCTION AND MATERIALS LIMITED

Company Background

SOCAM.com Ltd. is a wholly owned subsidiary of the Hong Kong construction giant –Shui On Construction Materials Ltd. (HKSE: 983) of the Shui On Group. It is a leading Hong Kong company engaged in construction, construction materials and property development in Hong Kong and the mainland China.

Applied Applications:

SOCAM.com is developed by SOCAM.com Limited for providing total solutions in tendering and procurement logistics. Selected modules in the ICMS are applied. One of the key functions is the electronic tendering (e-Tendering) system, a web-based tool to conduct the entire tendering process based on a secured system. For those low value purchasing items where tender document is not necessary, ec-Purchasing function is available for instant quotation. The whole implementation and operation, including supplier enablement, training and hotline, of this platform is outsourced to an application service provider.

Useful Statistics:

The system has been in operation since September 2000. As of March 2001, the total number of registered suppliers in the system has already exceeded 500 which accounts for more than 60% of the active supplier base of Shui On Construction and Materials Limited. More than 18,000 visitors have been attracted to the site with more than 3,800 tender documents downloaded. It generated more than HK$380 million tender value through its electronic tendering and procurement portal. In November 2001, SOCAM.com has been enhanced to include the Shui On Plant and Equipment Services Ltd. (SOPESL) and the MIS department as system users.

Benefits to SOCAM:

- Achieved 1 per cent cost savings in production within 3 months after implementation
- Productivity gain with 10-30 per cent improvement
- Streamlining existing tendering process, increase communication between SOCAM and existing/potential partners e.g. clients, subcontractors and suppliers
- Prompt delivery: implementation timeframe within 3 months through a ready-to-market application
- Enabled internal staff from different sites and offices to access updated project information remotely which expedite for tracking and information/data retrieval
- Outsourcing non-core operations to outside party, such as application hosting; telemarketing; help desk; supplier vetting/recruitment and user/supplier training, allows the company to focus on its core business

Key Issues Encountered and How They Are Resolved:

Issue: The implementation of SOCAM.com requires re-engineering of existing procurement and tendering process.

Actions taken to resolve the issue:

- A dedicated business unit was set up to oversee the electronic tendering system and capitalize on the business opportunity of this system.
- Strong management support and commitment were demonstrated and communicated to the working level at various levels of management.
- The benefits of process re-engineering were communicated to all internally

- Mass internal training on IT usage to all employees were conducted prior to the rollout of the electronic tendering system
- Advises were solicited from the expert opinion of the application service provider that has numerous experiences in building electronic tendering systems.

Issue: SOCAM has faced resistance to change from its subcontractors and suppliers.
Actions taken to resolve the issue:

- Special offers were given to award first movers.
- The message that electronic tendering will replace traditional process in the long term was repeatedly communicated to the contractors and suppliers.
- A step-by-step implementation plan was devised, starting with the more ready and capable contractors/suppliers, then extending gradually to those less ready companies
- A comprehensive suite of supplier enablement services, including training and help desk, was solicited from the application service provider.
- A Pilot Run was conducted to ensure the full consideration of the supplier/subcontractors' requirements before implementation

Issue: Concerns from internal users and external suppliers regarding security.
Actions taken to resolve the issue:

- Strong encryption technology based on PKI-based security framework was deployed to ensure high level of data security, integrity and identity authentication.
- A reputable application service provider with track records of implementation experiences of similar platforms was selected for the development of the system.
- An independent third party (i.e. the Hong Kong Productivity Council) was employed to conduct comprehensive audit review on the provider's technical infrastructure.

CONCLUSION

Despite of the recent economic downturn in Hong Kong, there is still a lot of infrastructure and construction works ahead. The government has proposed to award construction and consultancy contracts worth about HK$280.8 billion by the end of 2002, subject to funding approval of the Legislative Council Finance Committee. Sizable projects are underway which include the redevelopment work for old Kai Tak Airport and adjacent areas, works arising from railway development, public and private sector housing construction, etc. As recommended in the CIRC report, the construction industry must improve its long-term competitiveness through the use of innovative technologies and more efficient work processes. The government has already taken the lead in encouraging the use of I.T. in various industries.

The China's accession to World Trade Organization (WTO) enabled local construction industry to capture the opportunities in the mainland real estate development and construction market. However, the local industry players must maintain its competitive edge against local and overseas competition. The ICMS provides a mean for local industry practitioners to achieve significant productivity gain through the application of information technology.

ABSTRACT

With the development of computer network technology, research in Computer Supported Cooperative Work (CSCW) systems is becoming popular. CSCW has the potential of providing the environment needed for groups of diverse users to cooperate in order to achieve their common goals. Our current research has mainly focused on those extensions to a 4DSMM (4D Site Management Model) concept necessary to provide a wider scope that also allows cooperative work and information sharing by Internet for different project teams, and the development of a new experimental system. This paper presents a new 4D-CSCW model for construction management through integrating CSCW technology with the existing 4DSMM, and discusses the features of this newly extended model based on studying the cooperative work and communication methods of construction management and the regulation of data flow in construction process. The techniques for applying the model in construction management practice are then described.

KEYWORDS

Construction management, 4D-CAD, CSCW, Cooperative Work

INTRODUCTION

Today, computer technology has achieved rapid development and is being widely used. However, most of the users work in an individual mode. Though these users can communicate

*This research is supported by Natural Science Foundation of China

with each other by local network or Internet and share some of the information, for data access, information processing and programming, all these works are separated and independent. In the modern information society, people's living style and working modes have the features of grouping, interaction, distribution and cooperation. There is an urgent need for a new computer system, which can support group activities and enable the group members to coordinate and cooperate with each other. This has lead to a new technical field: Computer Supported Cooperative Work (CSCW), which can be defined as group cooperative work to accomplish a common task in a computer-supported environment (CS).

The earliest CSCW research started in the 1960s, D.Eaglebart[1] first developed an experimental system called NLS/AUGEMENT, and implemented the concept of hypertext, which is an information network composed of information nodes and links between nodes. Since the 1980s, with the development of the related technologies such as computer networks, multimedia technology, data compression and storage, CSCW has become the focus of much work by many researchers. In 1984, Iren Grief of MIT and Paul Cashma[2] of Digital Equipment Corporation organized a workshop to explore technology's role in the work environment and coined the term "computer-supported cooperative work" to describe it. In the construction field, CIFE (Center for Integrated Facility Engineering) [3] of Stanford University has undertaken a series of research projects on Internet collaboration in construction management since 1999. But still, there is no practical CSCW system that can completely meet the requirements of project management, because of the wide dispersals of the many parties and the complexity of construction management.

As we all know, during the construction phases of a project, many different developer, designer, contractor project teams work together and various specialist sub-contractors. These teams usually work in different places and need to frequently exchange information. However, these are always obstructions in information exchange between working teams and personnel. As modern construction projects are getting larger in scale, and the regulations, limitations and complexity for construction organizing increase, these obstructions and the influence then exert have become serious. The requirement for more effective communication and real time sharing of information between distributed teams has become even greater. In project implementation, it is necessary to achieve united management, leading into CSCW and developing an effective computer information management system. The generation of a new cooperative management environment can reduce and even eliminate the communicate obstructions caused by space and time isolation, so as to fulfill the purpose of information sharing, improving the working environment, reducing working intensity, saving time and cost, and raising the efficiency and technical level of the construction engineering management.

During this research, a 4D site management model (4DSMM) has been generated, which links a 3D model of a construction project with a project activity schedule, each activity suitably annotated with its resource requirements including material, plant, cost and work space [4]. A computer system for the 4D Management of Construction Planning and Resource Utilization (4D-MCPRU) based on the 4DSMM has been also developed. This system achieves dynamic

construction planning and resource management including site space utilization at the project level and 4D visualization and decision-making support within the construction process, so that an environment for exchanging and sharing information can be provided among the various management departments of a construction contractor [5]. Our current research work has mainly focused on those extensions to the 4DSMM concept necessary to generate a new 4D-CSCW model for construction management through integrating the CSCW technology, which allows cooperative working and decision making, and communicating and sharing information by computer network for different project teams, and the development a new experimental system.

4D-CSCW MODEL

Concept of 4DSMM

4DSMM[4] consists of the 3D model of the project coupled with a construction schedule, and allows incorporation of the 4D model into the whole site management information system and for dynamic resource management at project level, through the provision of decision-making support. 4DSMM has construction progress information features added and performs a number of site management functions over space and time. 4DSMM provides an information platform that allows dynamic site planning through the 3D model and the schedule to implement construction planning, analysis of resource requirements for each construction activity, assignment of construction resources and displays of site utilization. Extra to the traditional 4D simulation, a most notable feature of 4DSMM is the mechanism of two-way data exchange between the 4D model and scheduling information, which enables dynamic resource management, including material, equipment and labor usage and cost control at project level. This means that project managers can adjust resources plans according to changes of schedule in a timely manner. Figure 1 describes the organization of the 4DSMM model.

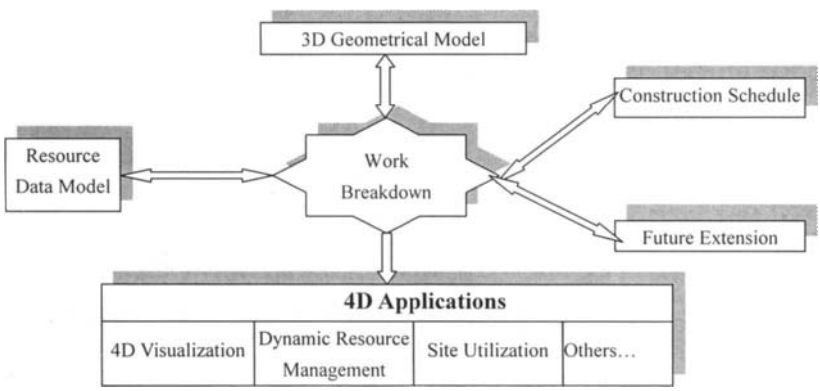

Figure 1: The 4DSMM Model

Architecture of 4D-CSCW

According to the architectures of popular CSCW systems, and considering the actual requirement and work flow in construction project management, the 4D-CSCW model adopts a centralized structure based on Client/Server mode. The 4D-CSCW involves a 4D application module, cooperation agent module, communication management module and a cooperative management module. The logical relationship between them is shown in figure 2.

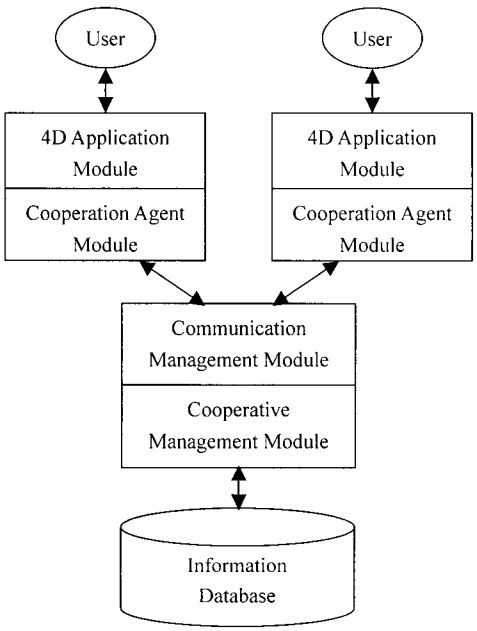

Figure 2: Architecture of 4D-CSCW

1. ***The 4D application module*** is user-oriented and concerned with how persons interact with the computer system in carrying out the overall function for inputting, modifying and browsing all project information including the generation of the 3D model of the project and the additional properties for any 3D object, manipulation of the Work Breakdown Structure (WBS) data, the access construction schedule information, the inquiry of various management data and so on. In this module, a 4D management engine is developed to link the 3D model with a project construction schedule automatically and describe the state of a site at any stage. It is pivotal for 4D simulation of the construction process, material quantities calculation, workspace analysis, and costs estimation. A graphical cooperation demonstration is also provided to complete real-time cooperative management based on sharing the application program and information.

2. ***Cooperation agent module*** is the core of the client in this system which can catch users'

operation commands with the event-driven program, transform them into a series of messages in a certain format and send them to the server of the system. The server can then transmit the messages to other cooperating parties. This module can also receive and process the operation messages from the server.

3. ***The communication management module*** is a message transmitter and manager on the server of the system. It mainly provided the functions for connecting and disconnecting users, responding to requests, and receiving, analyzing, processing and sending all messages.

4. ***The cooperative management module*** is the kernel of the whole cooperation system that resides on the server and completes the tasks of identifying the users, assigning responsibilities, controlling of user authorities and managing data.

Working Mode of 4D-CSCW

According to the spatiotemporal concept, group cooperation work can be classified into 4 work modes: (1) Synchronous mode cooperation work for common tasks at the same time and one place, such as mutual decision making, document compiling, computer aided design and indoor conferencing; (2) Distributed synchronous mode cooperation work for common tasks at the same time but different places, like co-design, co-editing, group decision making and video conferencing; (3) Asynchronous mode cooperation work for a common tasks at one place but not the same time, such as rotational working; (4) Distributed asynchronous mode cooperation work for the same task at different times and places, e.g. the development of a large-scale project.

Based on the characteristics of the construction industry with its usual requirements for project management and the need for maintenance of the system and reliability, 4D-CSCW uses two different working modes within a group and between various groups. The group members conduct real-time cooperative management with the synchronous mode within a group (i.e. design team, project management department), so as to exchange and share real-time information. Cooperative working between groups uses the distributed asynchronous mode, such as E-mail, WWW pages or Bulletin Board Systems for information release.

Database for Supporting Cooperative Work

Since the CSCW system possesses features for grouping, cooperation, distribution, and are dynamic, it is difficult to meet systems demands with a traditional relational database. A new database system that can support CSCW has been created to solve the problem on how to store, share and exchange data among systems for different purposes. The database contains a great deal of graphic data to represent the 3D geometrical model, non-graphic schedule data and all resource information, such as the WBS system, cost accounting, and material, equipment and labor management etc. Except for data storing and managing as above, this

database also has the following features for supporting CSCW:

1. **Man-man interaction** A predefined access interface is provided so that different modules will utilize the data for different purposes, and support the interaction between the group members. Each member can not only view, access and use the shared data, but also can be aware of any data operation by other members, and receive notification on data alterations.

2. **Management of nonstructural data** One significant enhancement of the database is the ability to organize, manage and access the nonstructural data by use of an index mechanism. This is to enable the effective storing and managing of complex information, such as multimedia data, special data, temporal data, complex objects, images, knowledge, ultra text.

3. **Synchronous and asynchronous working mode** The database can support the two working synchronous and asynchronous modes. A key objective is to provide real-time operation data for different purposes of the cooperative working.

4. **Cooperation work** Since the CSCW system involves the cooperation among several members, it is necessary to reserve past records for every member. The rollback ability of the cooperative working procedure is also needed in asynchronous mode.

Parametric 4D Construction Feature Model

In the 4DSMM model, the construction properties attached to the 3D solid model are used to provide the information about the structure components. They accurately and actually describe the shape and size of a structure component and finished state of the permanent work of a construction project. However this model, with its large amounts of stored information, is not suitable for network transmission. A new model description method is therefore needed to decrease the volume of data transmission.

A feature-based components model has been studied to establish a parametric construction features model. This model contains the geometry information for all structural components, CAD topology information, and components engineering information etc., and has the ability to greatly reduce the storage space needed by the model, and speed up network transmission. It can also be transformed into typical engineering drawings through a features database of the structure model, so as to achieve a graphical display of the features model.

In the features model, the following information must be included:

Global Information	—	Component Type
		WBS Code
		Component Shape and Size
		Component Position
Material Information	—	Material Type

		Material Specification
Construction Information	—	Working Flow Working Status Starting Time Finishing Time
Resource Requirement	—	Labor Material Equipment Site Space

Using a parametric features model also makes it possible to completely solve the problem of data exchange and sharing during construction progress including the construction schedule, quality control and resource management data, and to meet the requirements of 4D-CSCW for data sharing and transmission by computer network, so as to assure the consistency between geometric drawing and features data in the system. The object-oriented method also makes it possible to easily add new feature properties to the model, and is beneficial to the system extension.

KEY TECHNIQUES

System User's Role Control

Under the cooperative working environment, every one who enters the 4D-CSCW will act a certain role, and has different levels of authority to access different resources. How to control the user's authority limits is a very important problem. In the system, the controlling role-accessing right could solve this problem. First of all, the people who work for the same goal will be organized into a group, e.g. developer, contractor or specialized department, and sub-contractor, etc. In a working group, all the members are organized together with a certain type of relationship, e.g. equality relationship, master-slave relationship and client/server relationship. The different users act different roles with certain rights, which can be entrusted by data access authorities and cooperative operation authorities. There are several kinds of user role authority, such as accessing right, browsing right, modifying right, copying right or voting right, which determines whether the user can view the actual fact of the cooperation procedure, or whether the user can browse, modify related contents, can privately keep a copy of a common document, or whether the user has a voting right through cooperative discussion. With this role control measure, we can conveniently accept the dynamic change of a user's role and position, beneficial to both security and confidentiality in cooperation.

System Concurrent Control

In 4D-CSCW, one major feature is cooperative work among multi-users. Every user needs to

immediately perceive another user's operation for sharing data at the same time. To avoid the inconsistency of the sharing of objects, which occurs under multi-user concurrent operations, the system must provide concurrency control to solve conflicts caused by simultaneous operation.

The methods of achieving system concurrency control mainly are locking, centralized control, transaction mechanism, dependent test, reversible execution and operation conversion, etc. Two methods are designed and implemented in the 4D-CSCW for achieving system concurrent control. The locking and unlocking of the shared data is implemented and the concurrent operation of user by a locking mechanism control. However, this would affect rapid feedback to the user, but this locking control of shared data is effective and easy to operate and implement. The centralized control method is used to manage all the sharing objects operations to ensure consistency of the data, and to receive the users' data operation requests and broadcasts to all the users, so that orderly operations are enabled.

CONCLUSION

In view of the complexity of construction management with its many parties on different place and the requirement for more effective communication and real time sharing of information between distributed teams, a new 4D-CSCW model for construction management has been generated by integrating CSCW technology with the existing 4DSMM model developed by the authors. This model provides a cooperative working environment for cooperative working and decision-making, and for communicating and sharing information by computer network between different project teams and between managers. The application of the new model would reduce delays in the project schedule and losses caused by inefficient information transmission, and further improve information management in the construction domain.

THE IMPLEMENTATION OF KNOWLEDGE MANAGEMENT AND ORGANISATIONAL LEARNING IN CONSTRUCTION COMPANY

Dr Patrick X.W. Zou and Chie-Ann Lim

Faculty of the Built Environment, The University of New South Wales,
UNSW Sydney 2052, Australia; email: p.zou@unsw.edu.au

ABSTRACT

While organisational learning (OL) has been implemented in many companies, knowledge management (KM) has also become a new buzzword in the managerial world. Many commercial sectors have effectively adopted the concepts of KM and OL into their management system to improve their competency in the competitive business environment. However, construction company has not yet shown significant application of these concepts, despite it is also a competitive industry. This paper aims to encourage the implementation of KM and OL in construction company by providing an overview of the principles, along with a proposal of KM--OL model that is designed to best-fit the construction business environment.

KEYWORDS

Knowledge management, organisational learning, construction management, knowledge planning, knowledge organising, knowledge implementing, knowledge controlling, knowledge evaluating

INTRODUCTION

From the revolution of information technology, the technical capabilities that are available for storing, analysing, and transmitting information have been greatly increased. New information technology capabilities enable a company to improve its effectiveness in gaining, using or communicating knowledge from one person to another (Bernbom, 2001).

Knowledge is about understanding the meaning of information (Benson and Standing, 2002). As the 'knowledge era' grows and becomes more important, construction company needs to shift their focus from information management to KM. This paper focuses on the implementation of KM in construction company and discusses it in the context of encouraging OL culture. The paper also provides an overview of KM and OL principles, along with the proposal of a KM--OL model that fits construction business environment.

KNOWLEDGE MANAGEMENT

At present, there are no universally accepted definitions of KM. The intention of this section is to draw a definition for KM from a construction contractor's perspective. Numerous definitions of KM are collected from literature and these are summarised in Table 1.

TABLE 1 DEFINITIONS OF KNOWLEDGE MANAGEMENT

Authors	Definition
Spek and Spijkervet (1997)	'is the explicit control and management of knowledge within an organisation aimed at achieving the company's objectives.'
Webb (1998)	'the identification, optimisation and active management of intellectual assets to create value, increase productivity, and gain and sustain competitive advantage.'
Borghoff and Pareschi (1998)	'the management of the environment that makes knowledge flow through all different phase of organisational process life-cycle.'
Laudon and Laudon (1999)	'a process of systematically and actively managing the stores of knowledge in an organisation.'
Wiig (1999)	'the systematic and explicit management of knowledge-related activities, practices, programs, and policies within the enterprise.'
Beckman (1999)	'is the formalisation of and access to experience, knowledge, and expertise that create new capabilities, enable superior performance, encourage innovation, and enhance customer value.'
Rosenberg (2001)	'a system that supports the creation, archiving, and sharing of valued information, expertise, and insight within and across communities of people and organisations with similar interests and needs.'
Bernbom (2001)	'the fundamental about the discovery and capture of organisational knowledge, the filtering and arrangement of this knowledge throughout the organisation.'
Benson and Standing (2002)	'is concerned with automating and externalising explicit knowledge and devising support mechanisms to facilitate tacit knowledge transfer, including creation of knowledge.'

In fact, KM practices reach beyond the boundaries of computers and networks and it includes non-technical activities such as training and development, human resource management, intellectual property management (Bernbom, 2001), and organisational learning (Nonaka et al, 2001). In this paper, from the construction contractor's perspective, KM is described as:

'the management processes (including planning, organising, implementing, controlling and evaluating) of creating, capturing, transferring, sharing, retrieving, and storing of data, information, knowledge experiences, and skills by using appropriate information and network technology, with the endorsement of total involvement in organisational learning to enable knowledge acquisition throughout the processes.'

This concept addresses the viewpoint of 'it is the KM that facilitates and enables OL in a company', and this will be discussed in detail later.

ORGANISATIONAL LEARNING

There are articles suggest that not only KM itself is critical; OL is another issue that should also be addressed. Dixon (1999) states that 'knowledge is the result of learning and does ephemeral, constantly need to be revised and updated'. The author also claims that 'learning is the process that leads to knowledge'. In addition, Malhotra (2000) claims that '...information archived in a database doesn't ensure that people will necessarily see or use the information'. No matter how perfect a KM system being set up, it will just exist in name only if the organisation does not have a culture of 'willing to learn' and 'willing to share what's being learnt'. Thus, the concept of OL is recommended to balance any inadequate of KM implementation.

Organisation composes of intelligent adaptive agents and knowledge. Consequently, organisations themselves are synthetic agents in which knowledge and learning reside in the minds of the participant agents and in the connections among them (Carley and Hill, 2001). Nonaka et al. (2001) view an organisation as an entity that creates and utilises knowledge continuously and dynamically. They define OL as 'the interaction among individual learning which create knowledge in an organisation'. Further to this, Duncan and Weiss (1979) define OL as 'the process by which organisation members develop knowledge about action outcome relationships and the effect of the environment on these relationships, which leads to growth and change of organisational knowledge'. Other authors, such as Bennis and Nanus (1985) view OL as a set of processes used to obtain and apply new knowledge, behaviour, tools and values.

THE NEED OF KNOWLEDGE MANAGEMENT AND ORGANISATIONAL LEARNING IN CONSTRUCTION COMPANY

As the strategic management of intellectual assets (knowledge) is becoming major policy area for modern corporations (Neef, 1998), KM and OL are, therefore, not only key functions of the commercial world, they are also relevant and applicable to construction companies. In construction company, KM and OL are required to provide sustainable continuous improvement in its competitive and fragmented environment. If knowledge is the key of an organisation's long-term competitive advantage, it is incumbent upon organisations to help their employees to apply their knowledge and skills to the best.

Maxwell-Hart and Marsh (2001) have classified the modern construction management into 12 key roles. These include (1) corporate management, (2) business management, (3) financial and management system, (4) project management, (5) promotion and business development, (6) information and communication technology, (7) commercial and contractual practice, (8) communications and presentations, (9) health, safety and welfare, quality and environment, (10) respect for people, (11) client relationships, and (12) the construction profession in society. It is inevitable that every role requires the utilisation and application of skills, understanding, knowledge and experience in particular aspects. Maxwell-Hart and Marsh (2001) have then suggested four levels of competence for continuous improvement in management roles. These levels including:

- Appreciation – know what a term means and what its purpose and objective is.
- Knowledge – understand in detail the principles of the topic and how and where they applied to.
- Experience – have acquired working knowledge and skill.
- Ability – be able to fully apply skill with desired results.

It is clear that KM and OL has become an important issue in model construction management. KM and OL should be considered in each of these 12 key management roles, in order to achieve a higher level of competence and continuous improvement in a construction company.

A PROPOSED KM--OL MODEL FOR CONSTRUCTION COMPANY

In order to keep the business continuous growth, construction company is now required a specific tailored yet comprehensive KM and OL model. Thus, a KM--OL model is proposed to fit and fulfil these needs and this is shown in Figure 1 below:

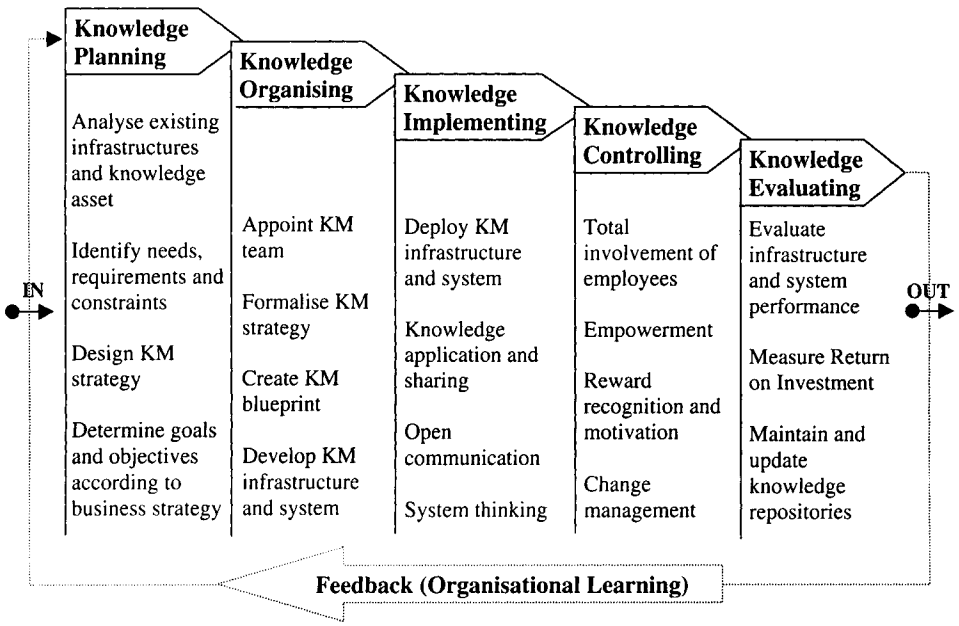

Figure 1: Proposed KM--OL Model for Construction Company

Knowledge Planning

The first stage for the application of KM and OL in construction company is the knowledge planning stage. How could knowledge be planned? This is just a concept. In the planning stage, the company management should analyse the existing infrastructures and knowledge assets they have, followed by identify the needs, requirements and constraints. Then, a primary KM strategy can be designed in accordance with the goals and objectives of business strategy determined. The knowledge infrastructures are the technologies used to facilitate KM in capturing, sharing, storing, retrieving and distributing knowledge throughout the company. They can be company existing intranet, data warehouse or project management tools. The analysis can be done by listing all existing infrastructures and systems in a checklist, including detail explanations of each infrastructure to be used in supporting KM. Besides, the existing knowledge asset, such as codified information, previous projects and historical records, should be identified in another checklist. This is to determine which type of knowledge is useful and can be reused in the company KM system. The understanding of these existing infrastructures and assets can assist in determine the needs of KM support as to identify the requirement for KM implementation. More crucially, it provides the ground for construction company to analyse its strength, weakness, opportunities and threats (SWOT) in application of KM and OL.

The design of KM strategy must be properly aligned with company business strategy so that both are able to drive each other toward the company goal and vision. Before that, a clear company vision is

essentially required. The company's vision can be effectively expressed to employees by using cryptic slogans. According to Nonaka (1998), cryptic slogans are highly effective tools for knowledge-creating companies in Japan. The key principle of this tool is the personal commitment which creates employees' sense of identity with the company and its mission. With the clear company vision, KM system can be designed in conjunction of both KM and business strategies. A well-designed KM system should include the following characteristics:

- Easy to use, easy to access at anytime and from anywhere,
- Flexible and scalable,
- Interoperatable,
- May be informal,
- Able to support collaborative works, and
- Support organisational learning.

Knowledge Organising

A cross-functional KM team, comprising senior management personnel and various representatives from company internal departments, should be established to analyse and integrate the knowledge asset within the company operations. The KM team has responsible to adapt the KM system in their departments so that knowledge can be fully utilised and best fit into the management systems. The development of KM infrastructure and system requires best practice knowledge repository which must include an appropriate knowledge resource navigator in the system to guide users in searching knowledge. Besides, the system must be able to support collaborative work by allowing e-conference and net meeting. The knowledge infrastructure can be organised by combination of different technologies. For instance, knowledge repositories, communication networks and collaborative platform (Tiwana, 2000) are suitable infrastructures to support KM. Knowledge repositories should contains both employees' knowledge and company's knowledge. Employees' knowledge, including their basic directories, skills, experiences, and expertises can be converted into company's knowledge, which comprise of company background information, operation experiences, and corporate visions. Thus, the knowledge that, perhaps, permanently stored in the repositories will become the company's valuable asset to enhance decision support system and case-based reasoning approach. The communication network should go beyond the company intranet system. The network system should be able to facilitate collaborative synergy, decision support, team learning and even informal conversation among users. In addition, knowledge servers should be used to provide the collaborative platform. This collaborative platform must include a comprehensive search engine that provides easy access to knowledge when acquired. Moreover, it should facilitate virtual meeting and conferencing on net so that tacit knowledge is able to communicate among users. In developing the KM infrastructures and systems, it is advisable to fully utilise the existing infrastructures and extend the facilities if necessary. Certainly, appropriate cost planning is required to keep the whole process in budget.

Knowledge Implementing

Once the KM infrastructures being set up, the capturing, transferring, sharing, storing and retrieving of knowledge can be deployed even if the systems have not yet been completed. Testing of the KM system can be carried out by studying on a pilot case or project to identify any pitfalls of the systems. From the testing process, KM system can be modified and upgraded to the preferences of the company. Knowledge application and sharing from the employees must be encouraged. Training is required for the employees to get familiar with the new systems. Employees should be familiar with the search engine and make use of it to search for knowledge they need while contributing their experiences and knowledge to the systems. Open communication must be encouraged in a successful KM system. Shared knowledge requires the creation of shared context (Tiwana, 2000). Every one in the company should be allowed to contribute and access to knowledge at anytime and from anywhere. Any new

knowledge updates should be immediately available to all users. However, confidential and private records must be protected. In addition, system thinking should be promoted among the employees for a complete implementation of KM system. System thinking is frequently used in problem solving, which emphasise on the aspects of the entire system surrounding a problem are taken into account and dealt with to satisfy all needs and constraints (Modarres and Bahrami, 1997). By applying system thinking, employees are able to consider and appreciate the full range of issues in establishing the KM system and generate innovative solutions to meet the new KM system.

Knowledge Controlling

Total involvement of all employees is essential to ensure the KM is deployed effectively. Ranging from office employees to construction site staffs, the understanding, participation and contribution to the vision of KM system should be thoroughly spread. If the member of company does not clearly understand the goals of the process, then commitment to a complete examination of the KM operations, processes, and future cannot be guaranteed (Chinowsky and Meredith, 2000). To a certain extent, employees should be empowered to participate in creating and modifying of company's decision support system through proposed KM system. The culture of knowledge sharing among employees should be encouraged. Thus, a strong reward recognition structure must be introduced in company to integrate the KM system into employees' learning culture. The employees who contribute to the KM system can be rewarded by financial incentive, evaluation, and promotion system. In addition to the reward recognition, appropriate motivation approaches should be used to enhance the employees' commitment to the new KM system. Organising knowledge campaigns, providing equal opportunities, allowing freedom of activity, upgrading working and learning environment, financial assistants, and medical allowances are some good approaches to motivate employees. After the KM system is built, the challenge is now shift to the management of cultural changes in the company's operations. Basically, managing change falls into three categories: structure, technology and people. This involves making an alteration in authority relations, coordination mechanisms, job redesign, changes in employee attitudes, skills, expectations, perceptions, and/or behaviour. To manage these changes, construction company should have change-development program interventions built on humanistic-democratic values that seek to improve the KM system's effectiveness and employee well-being. The program should include valuation of human and company growth, collaborative and participative processes, and a spirit of knowledge inquiry. Moreover, it should include sensitivity training, survey feedback, process consultation, team building, and intergroup development.

Knowledge Evaluating

The evaluation of KM performance can be conducted based on the measure of client's satisfaction levels, operational efficiency, staff motivation and competency, quality and improvement programs, employee turnover, and time taken in training (Edvinsson and Malone, 1997; Sveiby, 1997). The evaluation for Return on Investment (ROI) should be carried out in the way of expressing profit margin that comparing profits to value-added created, rather than to revenues. The measures should focus on resources such as the intellectual assets, which should consist of the following components (Sveiby, 1997):

- Growth/renewal – duration of experience, level of education, training costs, professional grading, and number of contracts secured from clients.
- Efficiency – ratio of professionals and value-added per professional.
- Stability – employee age, seniority ratio, and employee turnover rate.

A successful KM system must have the perspective on the past, present and future. Therefore, on-going management support and maintenance is needed for knowledge strategy and KM system in construction company.

Feedback (Organisational Learning)

The entire system learns as it interprets signals from the feedback of KM processes and enables planning for the future change. The feedback from KM system provides systematic and structured knowledge as the ground for OL. Therefore, construction company has the obligation to provide employees the opportunity to learn via shared knowledge, task assignments, and job rotation in the KM system. There is no generic solution in OL. However an approach can be modified from Kolb's Learning Cycle (cited by Bessant, 2000), as shown in Figure 2. This approach includes four phases – experiment, experience, reflection and conceptualisation.

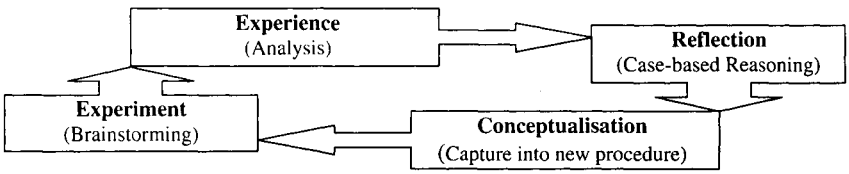

Figure 2: Modified Kolb's Learning Cycle

A good learning culture is vital for the establishment and development of a good KM system in construction company. The organisational cultural factors can eventually shape, underpin and support the overall effectiveness of the KM and OL model. The cultural factors to be taken into consideration include:

- Willing to share,
- High trust and mutual respect,
- Cooperation and collaboration, and
- Team learning – 'win-win' learning relationships.

KM--OL Model as Total Approach

As a whole, the KM--OL model described can be viewed as a total flexible approach that is suitable for construction company to implement KM in enhancing the ability to adequately respond to clients' requirements and its fragmented business environment. The model provides a mutually exclusive approach that is appropriate to use within the 12 roles of modern construction management described by Maxwell-Hart and Marsh (2001). This involves the creating, capturing, transferring, sharing, retrieving, and storing of knowledge, as well as learning, across different management roles in construction company and harnessing per capital knowledge from each construction project.

CONCLUSIONS

The paper has proposed a KM definition from construction contractor's perspective and a KM--OL model for construction company. The strategies and approaches that underpin the model have also been described. As the model indicates, OL can only be achieved when knowledge is captured and transferred. Therefore, it is the KM implementation that enables and improves the process of OL in construction company. The implementation of KM and OL should be focused mainly on the processes rather than solely on technology. Thus, the culture, behaviour and perspective towards the implementation of KM and OL should be placed at the first place. Although the KM--OL model is proposed, the viability is still inconclusive. Further research should focus on identifying and evaluating the real practical strategies of KM and OL application in construction company.

ABSTRACT

With a broad literature review, this paper highlighted the need of high level decision support systems for the industry and the possibilities of developing such system that is provided by the current information technologies. It was revealed that a range of cost-control and cost estimating softwares are available in the market. However, these softwares are mainly low-level computer-based systems for data storage/retrieval and cost calculation, high-end softwares with ability of data analysis and managerial decision support are rare. The paper hypothesises that in the future software for cost management in construction should focus on the implementation of expert knowledge, *i.e.*, the ability and expertise to apply the cost rate and other data in cost control, along with construction experience and make correct decisions in the competitive market. The design of a prototype of such decision support system is presented in this paper. This system is web-based and is an integrated suite of tools employing four software sub-products, which link to a comprehensive knowledge database. This knowledge base is the backbone of the system, and is accessible from any level within the system to provide support for better decision-making in cost management.

KEYWORDS

Decision support system, construction cost management, knowledge base, statistical analysis, what-if analysis, system functions

INTRODUCTION

Construction managers make many of small or big decisions during the management of a construction project. Their decision making is based on information in a wide area, including legal requirements, building codes and standards, manufacturer's specifications, material costs, site-specific data, and experience gained from past projects, *etc.* As building construction is such an information intensive industry, it is necessary to develop computerised decision support tools/systems to improve their effectiveness in the planning stage of construction projects.

Due to the recent availability of highly sophisticated software development tools, more accurate process models and more effective decision support systems can now be developed much more quickly with reduced cost. The opportunity now exists to quickly identify the systems most needed and to develop the tools that will enable the participants in the construction industry to plan and function more effectively and efficiently.

In this paper, a broad literature review was conducted in the area of building construction for decision support systems and cost management systems. Based on the findings from the literature review, a design of the prototype of a knowledge-based decision support system for cost management is presented.

LITERATURE REVIEW

Decision Support System

The research on decision support system in construction industry only started recently. Applications on various areas in construction industry have been identified in the literature.

Couzen *et al.* (1993) presented an executive information system for construction contract bidding decisions. Brightman *et al.* (1999) have been working with managers from a number of construction firms in order to develop a decision support tool to inform and support strategic thinking. Their work led to the creation of a Construction Alternative Futures Explorer (CAFE) - a computer based package which provides a means of structuring and analysing soft data, about possible future business environments.

Leu *et al.* (2000) developed a prototype of a decision support system for construction resource levelling. Construction planners can interact with the system to carry out *ad hoc* analysis through "what-if" queries. Hegazy *et al.* (2000) developed a simulation model of the operations for an actual design firm, which enables the analysis of resource optimisation needs.

The Construction Primer is a computer-aided design decision support system which was used as a learning-aid for students of architecture and building in New Zealand and Australia. Burry *et al.* (2001) described it as a database-drivable interactive multimedia environment that provides readily updated access to many levels of information.

Rule-based expert systems and artificial neural networks are two major systems for developing intelligent decision support systems. Li and Love (1999) presented a computer based mark-up decision support system called InMES (integrated mark-up estimation system) that integrates both rule-based expert system and neural networks.

Rule-based systems can be applied to a number of problems. The primary strength of these systems lies in their capacity to provide explicit explanations to their output. The explanation capacity enables users to understand the logic reference of why and how the output is reached, and increased the user acceptance of the output. However, directly implanting knowledge into rule-based expert systems is a tedious and labour intensive task, recent studies have focused on the automatic acquisition of knowledge for developing knowledge bases (Quinlan, 1986 and Li, 1994).

In summary, there have been efforts in developing decision support systems in contract bidding, resource levelling, mark-up estimation, evaluating business environment and construction related teaching and learning, *etc.* The continual advances in computer technology have created a potential for further improvement of these systems and expand its usage to other areas in the construction industry. These areas include networking multidiscipline teams, planning construction activities, project cost management, project status-report, and assisting project transaction and communication processes, *etc.* The following sections will focus on construction project cost management systems.

Cost Related Computer Systems

An investigation of software usage in cost estimation and management has been conducted. The literature search reveals an enormous number of cost-related softwares available in the market (Web Ref. 1-18). Most of them are targeted for specific industries such as building construction (Web Ref. 2, 4, 7, 10,14, 15, 17), social service and telecommunications (Web Ref. 3), manufacturing (Web Ref. 6, 8, 13), airspace industry (Ref. 12), while some of them (Web Ref. 1, 5, 11, 18) are general-purpose software packages. Cost optimisation of construction projects reported in the literature is limited to critical path method (CPM) or CPM-like models of the project (Liu *et al.* 1995, and Feng *et al.* 1997).

The main functions included in these estimating packages can be summarised as follows:

1. Importing quantity data.
2. Assemblies.
3. Calculation sheets.
4. Subcontractor bid analysis.
5. Calculating costs.
6. Export to scheduling and cost management software.
7. Overheads and profits.
8. Presenting the data in various formats.

There are also some other softwares evolved from the traditional accounting and cost management software packages (*e.g.*, Web Ref. 7). They often have all the normal accounting facilities as well as the estimating functions mentioned above.

It is found that most of the cost-related softwares in construction industry are estimating softwares connected with a database (Web Ref. 2, 10, 13, 14, 15). They represent low-level software systems for data storage, data retrieval, and calculating processes. These softwares are very mature in terms of technologies and functionalities. However, in construction industry, it is not enough for project managers and cost engineers to merely have project data, the more important thing is to analyse the data and make use of it. In order to do this, knowledge on the data and its interpretation is essential. These findings indicate that the future software for cost management in building construction should focus on the implementation of expert knowledge, which is the ability and expertise to apply the cost rate and other data in cost control and make correct decision in the competitive market.

The scale and complexity of a decision support system is governed by the scale and complexity of the data and expert knowledge involved in the decision making. A common theme amongst designers and developers is that prototype models are essential to building a successful decision support system. Prototyping can help users who often find it hard to state their information needs. Analysts and software developers learn immense amounts from building prototypes and from the users' reaction to them. This paper aims at providing the design guidelines of a prototype of a knowledge-based decision support system for cost management in construction industry, which can be used for evaluation and refinement.

A PROTOTYPE OF KNOWLEDGE-BASED DECISION SUPPORT SYSTEM FOR CONSTRUCTION COST MANAGEMENT

Types of Knowledge and Knowledge-Based System

There are different classifications of knowledge proposed by different researchers (*e.g.*, Machlup, 1980 and Holsapple, 1995, *etc.*). In this paper, the knowledge types initially proposed by Holsapple (1995) is adopted. Six knowledge types are included in this classification and they are: descriptive, procedural, reasoning, linguistic, assimilative, and presentation knowledge.

Knowledge about the state of some world is called descriptive knowledge. It is more commonly referred to as data, or information. The historical bidding records, material price, labour costs, *etc.* are descriptive knowledge.

The procedural knowledge is concerned with a step-by-step procedure for accomplishing some tasks. The steps used to compute cost estimation, a procedure for calculating an expected demand for some product are examples of procedural knowledge.

A third major type of knowledge is reasoning knowledge. A piece of reasoning knowledge specifies the conclusion that can be drawn when a specified situation exists. A set of company regulations, rules that prescribe forecasting approaches are reasoning knowledge.

Linguistic knowledge is the basis for acquiring every other type of knowledge as well as for acquiring greater linguistic knowledge. It enables the decision maker to make sense out of what is observed. A vocabulary, grammar, knowledge of the meaning of special terminologies, and an understanding of graphing conventions are all examples of linguistic knowledge.

Assimilative knowledge is the basis for controlling the changes permitted to a knowledge storehouse. It is housekeeping knowledge governing the permissible contents, orderliness, and efficiency of a knowledge storehouse. Examples include knowledge about how long to retain the historical records or derived data, what to regard as irrelevant or not valid, and the impact of new additions on existing pieces of knowledge.

Presentation knowledge is the inverse of linguistic knowledge. It is the basis for packaging outgoing messages or reports. Customised and standard forms, templates, vocabularies, grammars, and knowledge about preparing graphs and reports are all presentation knowledge.

In the proposed knowledge-based decision support system, the relationships between different types of knowledge mentioned above are illustrated in Figure 1. The descriptive, procedural and reasoning knowledge form the core of the knowledge base. The other three types of knowledge form the interface between the system and the user.

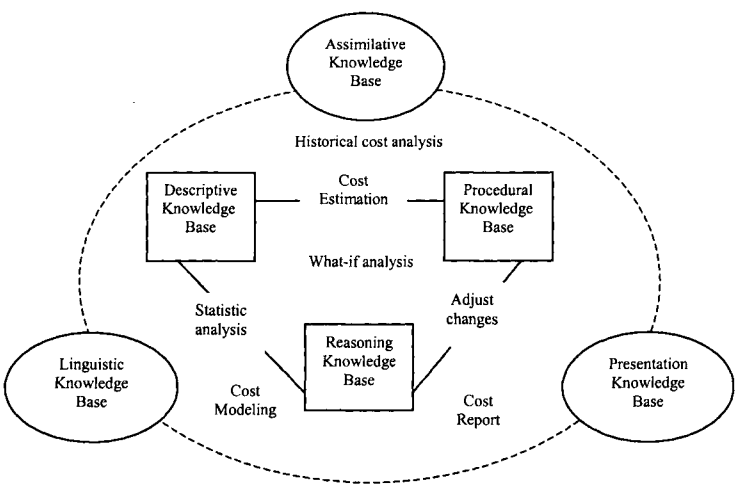

Figure 1 Structure of the knowledge base in decision support system

Functions of Proposed Knowledge-Based System

The proposed knowledge-base system is to support cost engineer and project managers in construction cost management. It is designed for two purposes: one is to offer estimating functionality and reliable cost

data while the other is to provide extensive knowledge base for cost control. The prototype of the system is expected to have basic estimating functions and advanced decision support functions, as discussed in the following sections.

For the basic functions, the system is supposed to assist the user to accurately calculate the cost of a construction project. It takes into account the bids and quotes from subcontractors, material suppliers, price mark-ups, taxation and cost analysis. These functions can be summarised as follows:

1. Estimation takeoff:
   (1) Lookup building items from the database, in categories;
   (2) Select items or add items if not available from database;
   (3) Assign quantities to items;
   (4) Assign notes to items;
   (5) Perform assembly (related items).
2. Estimation process:
   (1) Cost information displayed in categories;
   (2) Modify the material information;
   (3) Perform the estimate;
   (4) The above procedure can be repeated.
3. Report:
   (1) Dollar amount and percentage summary of the categories of work are given;
   (2) Apply percentage, lump sum and step mark-ups and other costs (tax, *etc.*);
   (3) Present the total net costs, mark-ups, and total costs for the job.

For the advanced decision-support functions, the proposed software system can access multiple knowledge rules base, prompting the user for necessary information, then optimising the cost modelling method based on the users' criteria. The optimising engine can generate the complete cost report.

The knowledge rules define the best possible, and other alternative ways, of making decision by asking a series of questions that an experienced cost engineer would normally consider. It also contains the engineer's expertise to convert the static data and the rates into useful information.

The advanced functions of the system include:

1.Present the database contents (can connected to multiple existing database);
2. Import/input quantity data from design drawing packages;
3. Use for variations and change control;
4. Use for interim payments to assess work in progress;
5. Analyse the priced tenders and use for future cost planning;
6. Obtain the material information from suppliers' web site;
7. Issue purchase orders and contracts (connect to the supplier through internet);
8. Monitoring cost and progress;
9. Provide appropriate levels of cost details for management reporting;
10. Support decision making (through knowledge rule-based system);
11. Compare predicted costs with real costs (graphs, curves);
12. Experiment with the workflow (in combination with a scheduling system);
13. Cost analysis (introducing statistic functions and cost modelling);
14. Automated cost estimating, cash flow model and documentation;
15. Automated cost and knowledge database development, search, and retrieval.

Structure and Implementation tool of the System

The structure of the system is designed based on the cost control cycle and can be clearly illustrated by Figure 2. The system is to be built as an integrated tool suite of some software sub-products which are specifically designed for the cost estimating, control and management in construction industry. The

software package is proposed to include four main sub-systems (details are given as follows), and each sub-system can be developed separately and linked to each other at the final stage.

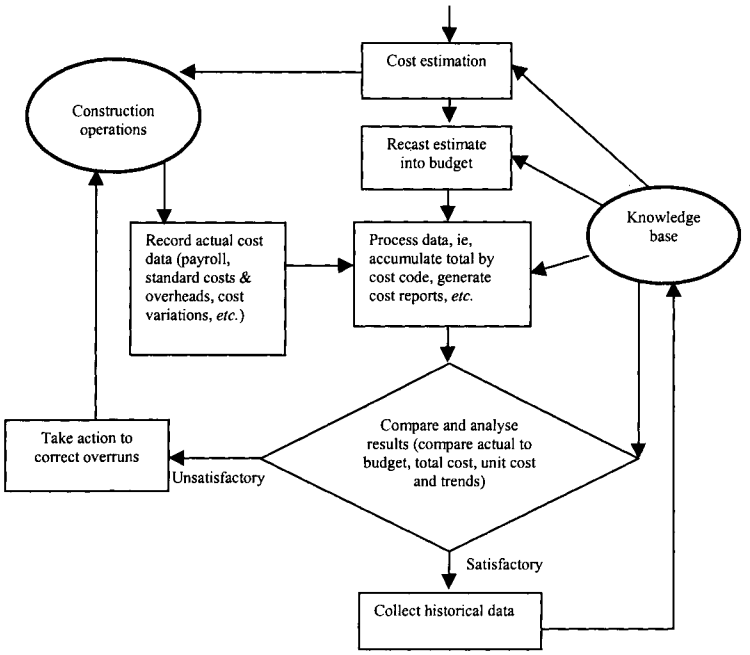

Figure 2 Structure of the proposed system

1. A sub-system for basic estimate functionalities, which integrates all the necessary cost estimating functions and allows the user to enter the process at any level. To save development time and costs, this sub-system can be introduced from existing estimating software packages.
2. Multiple databases to store the six types of knowledge as described earlier. This is the essential part of the system. The user can search the knowledge base for estimating methodologies. The knowledge base can also be built and/or customised by the user.
3. Statistical package to facilitate cost estimating relationship development and a uniquely designed spreadsheet that promotes structured, systematic model development. This system will be linked to the database to obtain maximum capabilities.

   The cost analysis statistical package will include most of the features contained in major statistics programs plus many tailored functions for the cost estimator. Within the system, the user can edit data obtained from other sources; review histograms and scatter plots; perform basic statistical analysis including linear, log-linear, and non-linear regression; fit beta curves; and fit learning curves both with and without rate effects.
4. A sub-system which has built-in inflation, time phasing, documentation, sensitivity/what-if, risk and other analysis capabilities. The results of the above analysis can be immediately integrated with the estimation and be automatically included in the estimate documentation. The results can also be used to populate custom knowledge database.

The prototype of the proposed decision support system are to be constructed with the latest computer technologies including Oracle database system, Enterprise JavaBean, JSP, XML, *etc.* Java is selected as the main programming language in building up the prototype, due to Java's full capability in working with the internet and Oracle database.

The software system is internet/web based. Internet technologies, including the web, web browsers, and search engines, have provided unprecedented opportunities for conducting business online. Together, these technologies enable the creation of web-based information systems. The web-based decision support system can overcome geographic and cost barriers to new markets, have access to worldwide communications and a global presence. It can also replicate and share scarce information by linking to data warehouses, and structure or restructure relationships both internally and externally.

A web-based system can provide latest information for material cost, labour cost, inflation data, foreign currency exchanging rates, *etc.* This is especially useful and efficient for large scale project. In another aspect, unlike many current software packages which must be used within the company's Intra-net, it is accessible from anywhere with Internet access.

CONCLUSIONS

This paper has focused on the use and development of decision support systems of cost management in construction industry. It is found that most of the cost-related softwares available in the market are estimating softwares, and usually they are connected with a database. They represented low-level computer-based systems for data storage and retrieval, with functions of calculating and estimation. High-level softwares with ability of data analysing and decision support are rare in building construction industry. It is predicted that next generation software for construction cost management will focus on the implementation of expert knowledge and supporting capabilities of managerial decision making.

The design of the prototype of knowledge-based decision support system for construction cost management is presented in the paper. The proposed knowledge-based decision support system is web-based, which provides global access and other service excellence. It is an integrated tool suite of several software sub-products, which is linked to the knowledge base which contains the six types of knowledge. The knowledge base is the backbone of the system. The structure of the knowledge base and the logistical design of the system are illustrated in the paper. The implemented system will help project managers to acquire timely and accurate information, carry out statistic analysis and what-if analysis, as well as access expert knowledge base, and this will lead to an improved decision making in construction cost management.

KEYWORD INDEX

Volumes I and II

Abrupt change, 297
ACBM, 239
Acceptable level for earthquake human mortality, 75
Active friction dampers, 465
Active variable stiffness system, 1009
Adaptability, 1501
Adaptive models, 1375
Added air mass, 1147
Adjacent buildings, 985
ADLINE, 1265
Advanced building construction, 1697
Advanced cementitious composites, 945
Agent-based, 1713
Air, 113
Air-conditioner performance, 1331
Air conditioning, 165, 1273, 1367, 1485
Air-conditioning load, 1199
Air-conditioning systems, 157
Air-cooled chiller, 1157
Airflow, 1173, 1225
Airflow modelling, 1165
Air pollutants, 1345
All-air system, 1383
Altitude, 1359
Anaerobic and aerobic treatment, 1423
Analytic hierarchy process (AHP), 405, 1671
Annual cooling load, 1289
Anti-earthquake optimum design, 555
Approach flow, 1131
Arch dam, 563, 571
Architecture, 1059, 1209
Artificial neural networks, 1527
Artificial simulated wind load, 1123
Asian climate, 1199
Assessment, 1209
ASTM E119, 105
Asymmetric, 281
Asymmetric beam, 1321
Atomic force microscope, 3
Augmented reality, 351
AutoCAD, 1601
Autoclaved aerated concrete, 865
Automated commissioning, 157
Automatic wheel washing machine, 1423
Axial compressive behavior, 289

Balance theory, 1431
Bamboo, 653
Bamboo columns, 661
Bamboo scaffolds, 629, 661
Barrier, 113
Based-isolated structure, 529
Base isolation, 473, 513
Base isolation principles, 961
Basement construction, 713
Basic mechanical properties, 637
Bay, 263
Bayesian inference, 457
Beams, 811, 819, 873
Bearing capacity, 603
Bearing structure, 1449
BEM system, 1297
Bending, 811
Bias errors, 157
Biaxial confinement, 873
Bill of quantity, 1729
Biocomposites, 225
Biological treatment, 1423
Biotechnology, 3
BNDWF, 771
Boiler, 1249
Bolted steel shells, 1091
Bond property, 811
Bond strength, 865
Bonded tendons, 1051
Borate, 129, 137
Bored pile construction, 1705
Boundary Layer Wind Tunnel (BLWT), 1131
Brick rubble, 1439
Bridge, 1001
Briefing, 1467
Buckling, 835, 1091
Buckling capacity, 215
Building demolition debris, 1415
Building design, 47, 1653
Building HVAC systems, 1265
Building integrating PV, 1313
Building management, 1653
Building management system, 173
Building materials, 121, 1257, 1449
Building processes, 343
Buildings, 113, 1059, 1281, 1457
Building systems, 343
Building thermal performance, 1375
Bump cutters, 679
Burnish finish, 679

CAD, 47
Calorimetry, 881

Case analysis, 611
Cement, 233, 1457
Cement Admixture, 853
Central heating systems, 1249
CFD, 1173, 1331
Check-list, 1339
Chemical composition, 897, 1439
Chilled surface cooling, 1165
Chilling system, 173
China, 375, 391
Chongqing, 391, 405
Circular concrete member, 889
Circular steel tube, 889
Civil infrastructure system, 555
Clay-bricks, 1415
Clay solution cementing, 723
Cleaning Robot, 339
Client, 1467
Closely spaced modal frequencies, 1107
Coagulation, 1423
Cold-formed steel frame, 375
Collection, 1281
Column buckling, 621
Column element, 273
Columns, 835
Comfort, 1233
Commissioning, 173
Common construction problems and solutions, 713
Communication systems, 1559
Community, 1081, 1475
Comparative study, 1577
Comparison, 993, 1115
Competitive advantage, 39
Complete quadratic combination rule, 763
Complete stress-strain curve equation, 289
Composite, 233, 781
Composite beam, 183, 207
Composite connection, 183, 199
Composite construction, 439, 703, 1091
Composite material, 255
Composite slab, 191
Composite structures, 835
Compressing consolidation, 723
Compression, 431
Compressive strength, 921
Computational agents, 47
Computer modeling, 637
Concrete, 233, 383, 423, 431, 789, 803, 1407, 1457, 1689
Concrete filled, 215
Concrete filled steel tubular column, 439
Concrete jacket, 827
Concrete mixing, 671
Concrete rubble, 1439
Concrete shells, 1091
Concrete structures, 297, 811, 835
Concrete uniformity, 671
Condensing temperature, 1157
Confined concrete, 889
Confined masonry, 247
Confinement, 431, 789
Confinement design, 889
Confinement effect, 889
Confocal microscopy, 3
Connection stiffness, 297
Connection system, 367
Connector, 367
Conservation, 1281
Construction, 367, 375, 1457, 1519, 1721
Construction and demolition waste, 1431, 1439
Construction cost management, 1755
Construction industry, 391, 1559
Construction IT, 55, 1569
Construction labour supply, 399
Construction-led design, 703
Construction machines, 1645
Construction management, 1737, 1745
Construction process improvement, 55
Construction process re-engineering, 687
Construction products, 1713
Construction projects, 1543
Construction sector, 39
Construction technologies, 687, 1081
Construction wastewater, 1423
Contaminant, 113
Continuity plates, 415
Continuous composite beam, 183
Contraction joint, 563
Control, 1249
Control algorithm, 993
Control strategy, 969
Conversion method, 695
Cool climate, 1359
Cooling, 1367
Cooling storage, 1273
Cooperative work, 1737
Copper gangue, 853
Copper Indium Diselenide (CIS), 1217
Cost, 361
Coulomb dampers, 465
Coupling beams, 755
Creep, 129
CSCW, 1737
c-shape, 1035
Cumulative damage, 913
Cyclic wall response, 247
CYCLONE, 1705
Cylinder splitting strength, 921

Damage assessment, 481
Damage detection, 1017
Damage free, 945
Damage index, 521
Damage reduction, 945
Damage tolerance, 781
Damper, 521
Damping device, 969
Data analysis techniques, 1017
Data fusion techniques, 1619
Data transfer and XML, 1209
Database, 1653
Decision-making method, 75
Decision support system, 1755
Deck-shading system, 1217
Deformability, 311
Deformation compatibility, 781
Degradation, 1399
Demolition technique selection model, 1671
Derivitized soybean oil, 225
Desiccant cooling, 1383
Design, 191, 263, 375, 431, 1091, 1457
Design agents, 47
Design criteria, 1035
Design development, 629, 637
Designer materials, 3
Design flexibility, 343
Design formulae, 921
Design innovations, 687
Design method, 611
Design of experiment, 121
Design process, 1209
Different elements, 361
Difficult construction environment, 713
Diffusion, 113
Digital map, 303
Digital surface models, 1619
Discontinuities, 579
Displacement, 747
Di Wang Building, 1115
Document management, 1729
Domestic hot water, 1189
Doppler sodar, 65
Double skin façades, 1233
Drift, 747
Drift-based design, 311
Drift decomposition, 311
Driving communications, 335
